Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Foreword

Since the publication of the last edition of this textbook, we lost our mentor and dear friend John F. Garde. Without his encouragement and guidance, our anesthesia career paths would have been much different and no doubt much less rewarding. John encouraged the publication of the first edition of this text, two decades ago, as an important milestone in the evolution of the specialty of nurse anesthesia. He felt it showcased the breadth and depth of nurse anesthetists' contributions to research and clinical care. John transmitted his enthusiasm for the unique role of nurse anesthetists to everyone he encountered. He believed that anesthesia excellence was manifest when a clinician made a difference in the everyday lives of patients. He was without question the most consequential nurse anesthesia leader of his time. We reprint the foreword he wrote for the first edition of this textbook in his honor.

John J. Nagelhout
Karen L. Plaus

FOREWORD FOR *NURSE ANESTHESIA*, FIRST EDITION

As a new century dawns, nurse anesthetists continue to provide the highest quality anesthesia services to their patients. To put this into perspective, consider that nurse anesthetists safely and compassionately administered anesthesia throughout the entire last century and even prior to that. The writings of Alice Magaw, published between 1899 and 1906, provide a noteworthy benchmark. Magaw detailed the use of chloroform and other anesthesia with the open-drop technique in more than 14,000 surgical cases without a single fatality attributable to anesthesia. She was the first nurse anesthetist to publish articles on the practice of anesthesia and was considered "the mother of anesthesia" during a time when surgeons selected nurses to specialize in anesthesia to provide greater safety for patients requiring anesthesia.

Many pharmacologic and technologic changes in anesthesia have occurred, however, since those noble beginnings. The chapter titles of this textbook serve as an atlas to this expanded knowledge base: "Clinical Monitoring in Anesthesia," "Anesthesia Equipment," "Pharmacokinetics," "Inhalation Anesthetics," "Intravenous Induction Agents," "Local Anesthetics," "Opioid Agonists and Antagonists," and "Neuromuscular Blocking Agents, Reversal Agents, and Their Monitoring," to name a few. Look at the specialty components of anesthesia contained in this book: Cardiac Anesthesia; Respiratory Anesthesia; Thermal Injury and Anesthesia; Trauma Anesthesia; Outpatient Anesthesia; Regional Anesthesia; Anesthesia for Ophthalmic Procedures; Anesthesia and Orthopedics; Anesthesia for Ear, Nose, Throat, and Maxillofacial Surgery; Anesthesia and Laser Surgery; and the list goes on. The continuum for practice in the twenty-first century is that of professionals learning anew how to ensure the best possible care for their patients.

When Agatha Hodgins and other nurse anesthetist pioneers gathered in a classroom in the anesthesia department of the University Hospital of Cleveland on June 17, 1931, they established what was to become the American Association of Nurse Anesthetists (AANA). This group sought to place better qualified people in the field, to keep those already in nurse anesthesia abreast of modern developments, and to give protection and recognition to this group of professionals.

When the AANA values statement was adopted in 1995, it was not surprising that it reflected this earlier philosophy. The AANA values the following:

- Its members and the advancement of the profession of nurse anesthesia
- Quality service to the public through diverse practice settings based on collaboration and personal choice
- Integrity, accountability, competence, and professional commitment
- Scientific inquiry and contributions to the fields of anesthesiology, nursing, and related disciplines
- Participation in the formation of healthcare policy.

These value statements are supported by knowledgeable practitioners ever in pursuit of their craft

Nurse Anesthesia is a textbook that builds on a formidable knowledge base and draws on the expertise of CRNAs and other professionals practicing in today's fast-paced, ever-changing environment. I look upon this volume as a means to demonstrate the profession's growth and encourage CRNAs and student nurse anesthetists to read it and reflect upon the dynamic field they have chosen.

I would like to close with one of my favorite quotations from Ralph Waldo Emerson, which I believe reflects all professionals on their prospective journeys:

To laugh often and much; to win the respect of intelligent people . . . ;
to earn the appreciation of honest critics . . . ; to find the best in others . . . ; to leave the world a bit better. . . .
Bon voyage.

John F. Garde, CRNA, MS, FAAN

Preface

This is a time of extraordinary advances in the accumulation, integration, and dissemination of medical knowledge. Technologic innovations that allow this textbook to be used in traditional as well as various electronic formats are now commonplace. We approach the 5th edition of *Nurse Anesthesia* with a clear intent to bridge these platforms while remaining true to our educational objectives. The volume of new information available to the clinician can be overwhelming, and keeping up-to-date in daily practice is an ongoing challenge. Since the conception of the first edition of this text over two decades ago, we continue to be guided by our original vision to fill the need for a scientifically based, clinically oriented work on which anesthesia practitioners and learners can rely to deliver excellent patient care. The need to integrate new concepts and findings into every patient encounter necessitates that we all commit to lifelong learning as one of the most basic tenets of our practice.

Our intent is to harness the vast knowledge that nurse anesthetists bring to clinical practice and provide a comprehensive, evidence-based resource for continuous learning. We are tremendously gratified that this textbook has become the seminal work of our specialty. This book is included in the Library of Congress's essential nursing textbooks for medical libraries throughout the United States and in national digital resource databases such as Mosby's Nursing Consult. We reach an international audience of nurses and nurse anesthetists and are always pleased when we hear of the positive impact we are having on anesthesia practice worldwide.

We are especially grateful to all of our new and returning authors who bring a wealth of expertise and experience to their respective areas. The majority of clinical anesthesia continues to be provided by nurse anesthetists, and this textbook is a testament to the leadership we bring to academic and clinical nursing. Each chapter has been extensively reviewed and revised to contain the most salient information available. The newest concepts, techniques, and areas of controversy in anesthesia are discussed in detail. This edition contains hundreds of new tables, figures, and boxes that add to the written materials. Effective anesthesia must be viewed as part of a therapeutic continuum of care. For this reason, we have been especially sensitive to include the latest medical and surgical information available from the specialties that impact our practice. Integrating new technology and knowledge in the basic sciences into clinical practice has allowed nurse anesthetists to continue to evolve as leaders in providing safe and comprehensive care.

As in past editions, we have completely revised our companion handbook that accompanies this text. It provides essential information regarding pathophysiology, surgical procedures, and drugs that can be easily accessed in both print and digital formats in the clinical setting.

Producing an educational resource of this size and complexity would not be possible without the tireless efforts of our authors and a broad array of experts. We would like to express our sincere gratitude to Retta Smith, who assisted in the production and editing of this textbook; our medical illustrator, Steve Beebe, Director of Multimedia Communications at Kaiser Permanente, who added dozens of new illustrations that greatly clarify the information presented; and Bryan Chen, computer graphics illustrator, Kaiser Permanente, who conceived numerous figures to illustrate the new material. We proudly carry over from the previous editions hundreds of anatomic figures that were specially hand drawn for this text by the renowned medical illustrator William E. Loechel. Special gratitude is expressed to the staff at Elsevier: Teri Hines Burnham, Executive Editor; Laura Selkirk, Senior Content Development Specialist; and John Gabbert, Project Manager.

CHAPTER 1

Nurse Anesthesia

A History of Challenge

◆ *Bruce Evan Koch*

It is fitting to open a text on nurse anesthesia with a history chapter. Nurses were the first professional anesthetists in the United States; the vast majority of anesthetics provided in this country are administered by nurses. And nurses have contributed to progress in clinical anesthesia, patient safety, and the science, education, and public policies supporting anesthesia. By teaching what nurse anesthetists in the past have accomplished, oftentimes against great odds and with few or none of the resources available to us today, we fix in the pupil's mind the fact that anesthesia is a practice of nursing.

FIGURE **1-1** **A**, John F. Garde (1935-2009) and **B**, Ira Gunn (1927-2011).

People have known since the late eighteenth century that inhaling nitrous oxide or diethyl ether could produce euphoria. The English scientists Joseph Priestley and Humphrey Davy experimented on themselves and even partied with these substances. Davy famously speculated that nitrous oxide "may probably be used with advantage during surgical operations."[1]

At the same time, American medical students used ether and nitrous oxide recreationally. But almost 40 years would pass before they attempted to use these agents as adjuncts to surgery. Crawford Long, a Georgia physician, used diethyl ether for the removal of a small cyst in 1842. Unfortunately, he did not report his findings. At least two other men, the Massachusetts physician Charles Jackson and the Connecticut dentist Horace Wells, experimented with ether or nitrous oxide. Finally, on October 16, 1846, the Boston area dentist William T.G. Morton conclusively demonstrated the use of ether for surgical anesthesia in an operating room (now memorialized as the "Ether Dome") at Massachusetts General Hospital. So important was the event that the surgeon John Collins Warren, who had witnessed many prior failed attempts, reportedly exclaimed, "Gentlemen, this is no humbug." Another eminent surgeon who had been in attendance stated, "I have seen something today that will go around the world."[2] From their vantage point, optimism seemed justified; however, another half century would pass before the promise of painless surgery would be substantially fulfilled.

From the outset, Morton's discovery caused problems. People realized its value, and some wanted a piece of the action. Morton attempted to disguise ether so he could profit from it. He named the substance Letheon and applied for a patent. Long, Jackson, and Wells all claimed credit for Morton's discovery. The four men battled for years. The physician and writer Oliver Wendell Holmes, Sr. (father of the Supreme Court Justice) wrote to Morton, "Everybody wants to have a hand in a great discovery… All I want to do is give you a hint or two as to names." Rather than Letheon, Holmes suggested "anaesthesia from the Greek for insensible." But it seems Holmes too wanted something for himself. The term *anaesthesia*, according to historian Julie Fenster, "had been in use before to denote parts of the body benumbed but not paralyzed." She added that, "Holmes only borrowed the word for the new state of being, though he has received credit

for coining it."[3] As Robert Dripps dryly noted, "anesthesia was placed under a cloud."[4]

Nineteenth century anesthesia was problematic in other more important ways. Related infections and the careless administration of anesthesia vexed surgeons, plagued patients, and delayed progress in the field of anesthesia for decades. They led the historian Ira Gunn to term this era "the period of the failed promise."[5]

THE PROBLEM OF THE OCCASIONAL ANESTHETISTS

In the nineteenth century, physicians expanded surgery as a medical specialty, but not anesthesia, although there were calls for them to do so.[6] James Gather, the pioneer physician anesthetist, gave one explanation for this medical disinterest: "So intense had been the interest in surgery that anesthetics had been used only as a means to an end, and this fully explained the attitude of the profession on this subject in America at the present time." But money was also an issue. One physician commentator S. Simon doubted whether a physician "taking the work up as a specialty could make a living at it alone; and especially is this true in the smaller cities."[7] Indeed, the historian Marianne Bankert agreed: "Apart from the few physicians who had a genuine intellectual interest in anesthesia, it would also take years for the economics of anesthesia to make it an attractive area for their colleagues—if at first, only as a supplemental source of income."[8] The Philadelphia surgeon J.M. Baldy thought anesthesia unworthy of a physician's intellect: "Every physician obtains his medical education with the idea of practicing medicine, and it is only dire necessity which will compel him to give up such a future for the narrow one of anesthesia. Every physician who for a few years of his early and least busy life devotes a part of his time to anesthesia does so with the distinct idea of observing and learning surgery, with the result that he is shortly paying more attention to the technic [*sic*] of the operation than he is to the anesthetic, and within a year or so he is demanding an assistantship from the surgeon as a reward for his faithful service in what he considers a subordinate position and which he has all along filled under mental protest and only as a means to an end."[9] As a result, anesthesia remained a medical stepsister to surgery until well into the twentieth century.

The work of anesthesia was relegated to others. "Students, nurses, newly graduated physicians, specialists in other fields, and even custodians were called upon to be *etherizers*."[10] "Anesthesia could be anybody's business," wrote Virginia Thatcher.[11]

Lack of attention led to a degradation of knowledge and technique. "Within a few months (of the discovery) at the Massachusetts General Hospital, Morton's inhaling apparatus (which had worked well) was abandoned in favor of a small bell-shaped sponge, which was saturated with ether and applied directly over the nose and the mouth of the patient."[12] Not surprisingly, ether pneumonia resulted. Some surgeons therefore turned to chloroform, which had been discovered by James Simpson in England to have anesthetic properties. "But, very soon, a death occurred from chloroform, then another and another in quick succession. This led to its more careful and restricted use by some surgeons, to its total abandonment by others, but in 1855, the general mass of surgeons and physicians still continued its use…"[13] Thatcher cited one physician who, in 1859, wrote, "In some cases Dr. M. had seen chloroform administered by young gentlemen rather in a careless manner…In fact, he believed that most of the fatal cases can be traced to a careless administration of the remedy."[14]

Careless anesthesia persisted for decades. A cogent example was recorded in 1894 by Harvey Cushing, the founder of neurosurgery.* Almost fifty years after the discovery of anesthesia Cushing was a student at Harvard Medical School:

> *My first giving of an anaesthetic was when, a third-year student, I was called down from the seats and sent in a little side room with a patient and an orderly and told to put the patient to sleep. I knew nothing about the patient whatsoever, merely that a nurse came in and gave the patient a hypodermic injection. I proceeded as best I could under the orderly's directions, and in view of the repeated urgent calls for the patient from the amphitheatre it seemed to be an interminable time for the old man, who kept gagging, to go to sleep. We finally wheeled him in. I can vividly recall just how he looked and the feel of his bedraggled whiskers. The operation was started and at this juncture there was a sudden great gush of fluid from the patient's mouth, most of which was inhaled, and he died. I stood aside, burning with chagrin and remorse. No one paid the slightest attention to me, although I supposed I had killed the patient. To my perfect amazement, I was told it was nothing at all, that I had nothing to do with the man's death, that he had a strangulated hernia and had been vomiting all night anyway, and that sort of thing happened frequently and I had better forget about and go on with the medical school. I went on with the medical school, but I have never forgotten about it.*[i]

Surgeons began to appreciate the need for professional anesthetists. The need as Thatcher defined it was for anesthetists who would "(1) be satisfied with the subordinate role that the work required, (2) make anesthesia their one absorbing interest, (3) not look on the situation of anesthetist as one that put them in a position to watch and learn from the surgeon's technic [*sic*], (4) accept the comparatively low pay, and (5) have the natural aptitude and intelligence to develop a high level of skill in providing the smooth anesthesia and relaxation that the surgeon demanded." Some surgeons, particularly in the Midwest, "accepted in this capacity a class of persons for whom they had learned to have deserved respect and from whom they had obtained commendable assistance and service—the Catholic hospital Sister."[15] And so as a result of medical disinterest, poor delivery of anesthesia in general, and an overwhelming need, nurses were asked to give anesthesia.

HISTORICAL ANTECEDENTS OF THE NURSE AS ANESTHETIST

The Civil War provided the first opportunity for nurses to assume the duties of anesthetist. Evidence is found in three different accounts. Mrs. Harris from Baltimore, Maryland, took chloroform and stimulants to the Battle of Gettysburg. Harris "penetrated as near as possible to the scene of the conflict, ministering as much as in her power to the stream of wounded that filled the cars…"[16] It is not known whether Mrs. Harris was a nurse. A second report connects a nurse with administering chloroform. "Private Budlinger of the 76th Ohio Unit, after breathing it for a few minutes without any apparent effect, more chloroform was added and reapplied by a nurse in attendance."[17]

But the most convincing example was written *by* a nurse. Catherine S. Lawrence, a native of Skaneateles, New York, wrote a 175-page autobiography in which she recorded administering

*I am grateful to EI Eger, MD for this citation.

[i]Cushing HW, Letter to FA Washburn, Anaesthesia Charts of 1895, Treadwell Library, Massachusetts General Hospital, Boston MA, cited. In: Shephard DAE, *Harvey Cushing and Anaesthesia*, Canadian Anaesthetists Society Journal. Vol 12, no 5, September, 1965.

anesthesia as a Union Army nurse. Lawrence described her duties at a hospital outside Washington, D.C., during and after the Second Battle of Bull Run (1863). She administered medications, resuscitated with restoratives like ginger, tied sutures around arteries, and administered chloroform. "I rejoice that the time has arrived that our American nurses are being trained for positions so important. A skillful nurse is as important as a skillful physician."[18-21]

The early use of nurses as anesthetists was mostly an American phenomenon. However, a 1911 article revealed that "(In) the European hospitals female as well as male nurses…were taught how to give anaesthetics [*sic*] in the …(Franco-Prussian War of 1870-1871). Only the nurses gave anaesthesia in the ambulatory hospitals on the field."[22]

The First Civilian Nurses to Practice Anesthesia

Civilian nurses began to practice anesthesia during the 1870s in the Midwest. Sister Mary Bernard founded the Sisters of St. Joseph of Wichita, Kansas, and in 1877 entered St. Vincent's Hospital in Erie, Pennsylvania, to train as a nurse. A year later, she took over the anesthesia duties of the hospital. This practice was repeated throughout the Midwest. The Franciscan Sisters, who were active in the building and staffing of St. John's Hospital in Springfield, Illinois, were particularly successful in preparing hospital Sisters as nurse anesthetists and sending them out to other Midwestern hospitals. Having been prepared by another community of the Sisters of St. Francis (Syracuse, New York), Sister Mary Erhard went to Hawaii in 1886, where she administered anesthesia and performed other nursing duties on the island of Maui for approximately 42 years.

The St. Mary's Experience

In the summer of 1883, a very destructive tornado swept through Rochester, Minnesota. In its wake, wrote Helen Clapsattle, the tornado "left an idea in the mind of the mother superior of the Sisters of St. Francis." During rescue efforts, Mother Alfred paid a visit to Dr. W.W. Mayo. "Did he not think it would be well to build a hospital in Rochester?" Dr. Mayo thought the town too small to support a hospital, but "Mother Alfred had made up her mind. Quietly she overruled the Old Doctor's objections and said that if he would promise to take charge of a hospital, the sisters would finance it." St. Mary's Hospital was built and opened and although hospitals ranked low in the public's mind, their venture was a huge success. By 1904 it had expanded twice in order to keep up with demand and has endured until today as the Mayo Clinic. The Mayos (William Sr., William Jr., and Charles) won international acclaim for their surgery.

But how did the Mayos handle the administration of anesthesia? Like many surgeons, they were aware of its dangers, but unlike their colleagues on the East Coast they were quick to embrace the open drop method of ether when it was brought to the United States from Germany. They also differed from East Coast physicians in one other respect. "In employing a permanent full-time anesthetist, and that a nurse, the Mayos were unusual if not unique. In other hospitals anesthetizing was one of the duties of the interns."

Why would they give the job to nurses? "The Mayos had given the job to a nurse "in the first place through necessity; they had no interns. And when the interns came, the brothers decided that a nurse was better suited to the task because she was more likely to keep her mind on it, whereas the intern was naturally more interested in what the surgeon was doing."[23]

Nurses won the Mayo's admiration by improving anesthesia care. Alice Magaw could discuss "a hundred and one details as to signs of sufficient anesthesia and ways of recognizing and preventing impending disaster." Magaw, along with her pupil Florence Henderson, refined and advocated the dripping of ether. Ether anesthesia required vigilance and careful attention to detail and to the psychological care of patients to minimize the agitation that often led to disasters like the one described by Harvey Cushing earlier.

Florence Henderson described how this was done. "A modified Esmarch inhaler, which is covered with two layers of stockinet, is used…With the mask held about an inch from the face the ether is dropped upon it, slowly at first, and the patient is asked to breathe naturally through the nose. Then the mask is gradually lowered, and the rapidity of the dropping increased, care being taken not to give the ether fast enough to cause a sensation of smothering or suffocation. As soon as the jaw relaxes the head is turned to one side, because the patient usually breathes more easily with the head in this position." This was quite a contrast to the "crude" methods of most early anesthetizers.

And it was successful. Nancy Harris and Joan Hunziker-Dean, who investigated Florence Henderson's life, concluded that "through a delicate balance of interpersonal skills and technical expertise, (Henderson) was able to essentially eliminate the excitement phase of ether anesthesia and consistently used a fraction of the usual ether dose. She demonstrated to all who observed that the administration of ether anesthesia could be elevated to an art form."[24]

Magaw and Henderson made anesthesia safe. Magaw accounted delivery of over 14,000 anesthetics "without an accident, the need for artificial respiration or the occurrence of pneumonia or any serious results."[25] Included were anesthetics for abdominal, intraperitoneal gynecologic, urologic, orthopedic, ophthalmic, head and neck, and integument operations. Some were even conducted in the prone position.[26]

Thatcher wrote that it was Alice Magaw who "brought to the profession of nurse anesthetist as well as to the Mayo Clinic no little fame at a time when poor anesthesia was the major worry of most surgeons." Charles Mayo was so impressed by Magaw that he named her "The Mother of Anesthesia."[27] Surgeons who visited from Minneapolis, Iowa, Baltimore, Chicago, and England "sent selected nurses to Rochester to observe Alice Magaw and other nurse anesthetists at St. Mary's Hospital at their work."[27]

Magaw and Henderson introduced better teaching methods too. Early anesthesia education has been described by A.J. Wright as "on the spot training of any person available…" At Mayo sometimes the "nurses stayed for 2 or 3 months and learned to give ether under supervision."[27]

The Lakeside Experience

A second "Mecca" of nurse anesthesia developed in Cleveland, Ohio. In 1900 Agatha Hodgins, a Canadian nurse, went to Cleveland to work at Lakeside Hospital. Dr. George Crile chose her to become his anesthetist in 1908, and as such she became perhaps even more renowned than Alice Magaw. Together with Crile, Hodgins pioneered the use of nitrous oxide/oxygen anesthesia and introduced it in World War I, opened and led a prominent school for nurse anesthetists that endured the first major challenge from physician anesthetists, and in 1931 Hodgins alone founded the American Association of Nurse Anesthetists (AANA).

Hodgins' primary interest was in education. Like St. Mary's Hospital, Lakeside Hospital was the recipient of many requests for anesthetist training from both physicians and nurses. According to Thatcher, "Visiting surgeons eager to emulate

the Lakeside methods, customarily bought a gas machine (the Ohio Monovalve) and then sent a nurse to Cleveland to find out how it worked."[28] Hodgins recalled, "The number of applicants increased so rapidly that we felt some stabilizing of work necessary and the matter of a postgraduate school in anesthesia presented itself." In 1915, Hodgins opened a school at Lakeside Hospital. The Lake School was not the first formal postgraduate anesthesia educational program. That honor belongs to St. Vincent's Hospital in Portland, Oregon. But the Lakeside School is the only program for which original records still exist. There were admission requirements, the course included both clinical and didactic components, tuition was charged, and a diploma was granted. "The department of anesthesia encompassed the school, both being under the charge of Agatha Hodgins as chief anesthetist. She, in turn, worked under the jurisdiction of the superintendent of the hospital and the chief surgeon. For the supervision of the students she had 1 or 2 assistants until 1922 when the number was increased to 3."[29] The evolution of nurse anesthesia education into a more formalized, scientifically based discipline can thus be seen.

Although records do not exist, 54 similar programs were said have to existed at major hospitals in Chicago, Illinois; Worcester, Massachusetts; Milwaukee, Wisconsin; New Orleans, Louisiana; Baltimore, Maryland; Ann Arbor, Michigan; St. Louis, Missouri; Detroit, Michigan; Poughkeepsie, New York; Tacoma, Washington; and Minneapolis, Minnesota.[30]

The Proliferation of Nurse Anesthetists

Prior to World War I, anesthesia grew more sophisticated. Nitrous oxide was reintroduced, and with it came the first anesthesia machines. Surgeons and hospitals sought nurse anesthetists who were capable of using the machines. The first recognition of the value of formalized education also occurred at this time. Four postgraduate programs were developed: at St. Vincent's Hospital in Portland, Oregon (1909);[31] at St. John's Hospital in Springfield, Illinois (1912); at New York Postgraduate Hospital in New York City (1912); and at Long Island College Hospital, Brooklyn, New York (1914).[32] Other nurse anesthesia programs were developed as a part of the undergraduate nursing curriculum as a specialty option. Isabel Adams Hampton Robb, a pioneer nursing leader and the first superintendent of the Johns Hopkins School of Nursing, which had opened in 1889, had in 1893 published a nursing textbook titled *Nursing: Its Principles and Practices for Hospital and Private Use*; this textbook included a chapter titled "The Administration of Anaesthetics." By 1917, as a result of the "superior quality of anesthesia performed by nurse anesthetists,[33] they were given the responsibility for surgical anesthesia at Johns Hopkins Hospital in Baltimore, where a training program was established under the direction of Ms. Olive Berger.

But success bred resistance. Thatcher wrote that, "The rapid growth of postgraduate schools of anesthesia in which nurses were trained, as well as the increasing enthusiasm for the trained nurse anesthetists during World War I, did not escape the attention of physician specialists in anesthesia, and during the 1920s resentment against the nurse anesthetist culminated in attempts to legislate her out of existence."[34]

The Great War, a Small Battlefield

Nurse anesthetists played a very large role during World War I. Their involvement began in 1913, 4 years before the United States became involved militarily, and lasted until the armistice in 1918.

When America entered the war, the Army Nurse Corps numbered 233 regular nurses; it would grow to 3524 nurses by 1918. The number of nurse anesthetists is unknown because at the time nurse anesthetists formed part of the general nursing staff.[35] However, nurse anesthetists were credited with introducing nitrous oxide/oxygen, and teaching its administration to the English and French.[36] As a result of the superior performance of nurse anesthetists, both the Army and the Navy sent nurses for anesthesia training for the first time.

Several outstanding World War I–era nurse anesthetists have been remembered because they wrote of their work. Nurse anesthetists spent countless hours etherizing wounded soldiers as they arrived in "ceaseless streams for days at a time after battles," wrote Mary J. Roche-Stevenson. "Work at a casualty clearing station came in great waves after major battles, with intervals between of very little to do.…Barrages of gun fire would rock the sector for days, then convoys of wounded would begin to arrive by ambulance. Night and day this ceaseless stream kept coming on.… The seriously wounded, especially the ones in severe shock, were taken to a special ward, given blood transfusions and other treatments in preparation for surgery later. From the receiving tent, the wounded were brought to the surgery, put on the operating tables stretcher and all given an anesthetic, operated upon, picked up on their stretcher, and loaded on hospital trains for evacuation to base hospitals."[37] Terri Harsch,[38] who described the works of Roche-Stevenson and others such as Sophie Gran Winton, reported that 272 nurses were killed during the war.

In a paper about Miss Nell Bryant, who was the sole nurse anesthetist for Base Hospital Number 26 from the Mayo Clinic[39] we learn that chloroform and ether were in use, the physiology of shock was poorly understood, oxygen and nitrous oxide were given without controlled ventilation, and venipuncture involved a surgical cutdown.

Anne Penland was a nurse anesthetist with the Presbyterian Hospital of New York unit, Base Hospital Number 2. She had the honor of being the first U.S. nurse anesthetist to go officially to the British front, where she so won the confidence of British medical officers that the British decided to train their own nurses in anesthesia, ultimately relieving more than 100 physicians for medical and surgical work. Several hospitals were selected for this training of British nurses, including the American Base Hospital Number 2, with Penland as the instructor.[40]

Commenting in the *Bulletin of the American College of Surgeons*, Frank Bunts wrote, "The (First) World War demonstrated beyond any question the value of the nurse anesthetist."[41] George Crile speculated that "if the Great War had gone on another year, the British army would have adopted the nurse anesthetists right in the middle of the war."[42] Looking back after World War II, Lt. Colonel Katherine Balz, Deputy Chief of the Army Nurse Corps, credited nurse anesthetists for the fact that 92% of "battle wounded who reached Army hospitals alive were saved."[43]

ANESTHESIA: MEDICINE, NURSING, DENTISTRY, OR WHAT?

Although few physicians chose to specialize in anesthesia before World War II, one who did, Francis Hoeffer McMechan—a Cincinnati native—began a crusade to claim the field solely for physicians around 1911. McMechan had become disabled shortly after entering the field of medicine and did not practice. He and his wife undertook his mission through writing, publishing, and speaking. McMechan's first target was the high profile Lakeside School and its famous surgeon George Crile. He alleged that anesthesia was the practice of medicine, and he petitioned the Ohio Medical Board to take action. McMechan considered Ohio a "pivotal state in the national fight for the preservation of the status of the anesthetist as a medical specialist."[44]

The board acted. In a letter to Crile in 1916, the board claimed that no one other than a registered physician was permitted to administer anesthesia. Essentially, the board ordered Lakeside Hospital's School of Nursing to cease its anesthesia program or lose its accreditation. Not wanting to be responsible for the loss of the school's accreditation, Crile obeyed the order, pending the outcome of a hearing conducted in 1917. At the hearing, Crile took the position that Lakeside Hospital was only following the lead of many of the major clinics in the country. Crile managed to persuade the board of medicine to lift its order, and he was able to reinstitute his nurse anesthesia educational program and his use of nurse anesthetists.

But to protect nurse anesthetists, Crile took an additional step. In 1919, together with supporting physicians, he "introduced a bill into the (Ohio) legislature to legalize the administration of anesthetics by nurses."[45] An amendment to the legislation stated that nothing in the bill "shall be construed to apply to or prohibit in any way the administration of an anesthetic by a registered nurse *under the direction of and in the immediate presence of* (emphasis added) a licensed physician," provided that such a nurse had taken a prescribed course in anesthesia at a hospital in good standing.[46] Physician supervision, first mentioned here, would recur many times over.

A second attempt to legislate nurse anesthesia out of existence occurred in 1916. The Louisville (Kentucky) Society of Anesthetists passed a resolution proclaiming that only physicians should administer anesthesia. The attorney general concurred, and the Kentucky State Medical Association followed with a resolution stating that it was unethical for a physician to use a nonphysician anesthetist or to use a hospital that permitted nurses to administer anesthesia. These events prompted the surgeon Louis Frank and his nurse anesthetist, Margaret Hatfield, to ask the state board of health to join them in a suit against the Kentucky State Medical Association. In the lower court, they lost.

But on appeal, they won. In 1917 Judge Hurt of the Kentucky Court of Appeals not only confirmed the right of nurses to administer anesthesia, he also enunciated clearly that state licensure was meant to protect consumers, not professionals.

These two cases showed physicians they could not rely on the courts to end nurse anesthesia. But still they were not deterred. A California case (1933 through 1936) in which Dagmar Nelson, a nurse anesthetist, was charged with the practice of medicine has been considered as the defining test case of whether nurse anesthetists are practicing medicine or nursing when they administer anesthesia. This case was decided in favor of Dagmar Nelson at each level of the California civil court system. The California Supreme Court ruled again that the functioning of the nurse anesthetist under the supervision and in the direct presence of the surgeon or the surgeon's assistants was the common practice in operating rooms; therefore the nurse anesthetist was not diagnosing and treating within the meaning of the medical practice act.[47,48]

At the time, nurse anesthetists welcomed and embraced supervision. Gene Blumenreich, who has written extensively on the legal history of anesthesia, noted that "A number of states adopted statutes recognizing the practice of nurse anesthetists. Typically, these statutes followed the formulation in *Frank v. South* and provided that nurse anesthetists were to work under the 'supervision' or 'direction' of a physician." But, the statutes did not define supervision. "It is clear that the legislation was not attempting to create new duties and responsibilities but merely to describe what was already going on in practice…to explain why nurse anesthetists were not practicing medicine."[49] Decades later, however, supervision would become a battleground.

ORGANIZATION: "WE WHO ARE MOST INTERESTED"

In 1926 Agatha Hodgins called together a small group of Lakeside Hospital alumnae to form a national organization. Hodgins had been an educator since World War I, and she must have sought strength in numbers to address problems related to education. One hundred thirty-three names were submitted and tentative bylaws were drawn up. But, as Ruth Satterfield recalled, "much of what she (Hodgins) said fell on deaf ears."[50] The association failed to thrive. As Thatcher has noted, "It is only when common problems become too big for individual solutions that the average professional person becomes conscious of the protection that can be found in organization." The national organization of nurse anesthetists would only come to life after several problems coalesced in 1931.

Physician opposition to nurse anesthetists was one factor in this development. For example, California nurse anesthetists organized in 1929 after the Board of Medical Examiners alleged that Adeline Curtis was practicing medicine illegally. Curtis, a natural public speaker, went on the road with this refrain: "…we can get nowhere without an organization. We're in the minority of course but we must organize."[51] California held its first meeting February 3, 1930.[52] Other states followed suit, and by the end of the 1930s, 23 had established organizations.

Hodgins in 1935 noted that "the strongest objection of physicians during this period was against those nurse anesthetists who were working on a fee for service basis."[53] Hanchett,[54] who examined the *Chalmers-Francis v. Nelson* case (1933), concluded that plaintiff California physicians were motivated by economic factors. And Thatcher observed that "Miss Hodgins' concept (of an organization) might never have been sparked into action, and organizations of nurse anesthetists might have stayed at the local level if the collapse of the nation's economy had not revived the physician anesthetist's interest in protecting his income by eliminating competition from nurses…"[55]

But it was the poor state of anesthesia education that most motivated Agatha Hodgins. In 1931 she wrote to Adeline Curtis who was embroiled in the California dispute: "My chief interest is in education."[56] And with the previous factors compounding each other, Agatha tried again.

The National Association of Nurse Anesthetists (NANA) was born on June 17, 1931. Its name would be changed to the American Association of Nurse Anesthetists in 1933. The first meeting was held in a classroom at Lakeside Hospital and was attended by 40 anesthetists from 12 states.[57]

Right away, the new association set its sights on improving the quality of anesthesia by raising educational standards. The new president, in a letter to Marie Louis at the American Nurses Association wrote, "It is because of the increasing number of nurses interested in the particular work and growing realization of difficulties existing because of insufficient knowledge of, and proper emphasis on, the importance of education, that we who are most interested are taking the steps to insure our ability to define and help maintain the status of the educated nurse anesthetist."[58]An education committee was formed. Chaired by Helen Lamb, the committee crafted "recommended" curriculum standards for schools and ratcheted them up in 1935 and again in 1936.

But the fledgling association was weak. With few members and little money, it could not hold its first national meeting for 3 years, much less advance an agenda of education reform. In that period, Agatha Hodgins sustained a heart attack and "for all practical purposes bowed out as administrative leader." Gertrude Fife took over the day-to-day affairs. There grew the realization, attributed by Bankert to Helen Lamb and her Education Committee, that the problems were of such magnitude that an

alliance with a more influential professional association would be required. But which one?

Forming an alliance with a major professional organization would likely prove problematic, as divergent interests collide and trust is tested to its limit. The small young NANA would have to fight to maintain independence, while at the same time obtain much needed support. According to historian Rosemary Stevens, the AANA "made overtures to the American Board of Anesthesiology (ABA) in 1938 which might have enabled the two movements to combine and the anesthesiologists to take on the responsibility of the nurses' training." But at the time, the ABA was struggling to emerge from under the wing of surgery, and "the nurses were summarily rejected."[59]

So, instead, with the guidance and support of the American Hospital Association, Gertrude Fife and Helen Lamb planned the first meeting, which was held in Milwaukee in 1933. They also crafted a highly centralized organization to efficiently address the association's concerns. Thatcher listed those concerns: "(1) building up the membership so that there would be a creditable showing at the Milwaukee meeting; (2) arranging a program; (3) getting a constitution and the bylaws revised; and (4) launching the association's educational program."

Membership was to be a privilege, a mark of distinction. The bylaws required that an active member have graduated from an accredited school of nursing, have passed the required state board examination, and maintained an active license. Importantly, an applicant must "have engaged for not less than three years in the practice of the administration of anesthetic drugs prior to 1934, and must be so engaged at the time of making application for membership."[60] The founders meant business.

These accomplishments are all the more remarkable in light of the "most important event" of the year, the existential threat posed by the Dagmar Nelson trial in California.

But there were other strides made during this era. As membership surpassed 2500, a survey of schools using on-site surveyors evaluated courses being taught. An Anesthesia Records Committee was formed to create a standardized anesthetic record. And the credential "Member of the American Association of Nurse Anesthetists" was implemented. These strides served to show that the profession was coming of age. Then World War II erupted and stalled further progress.

WORLD WAR II AND NURSE ANESTHETISTS

When World War II began, nurse anesthetists once again distinguished themselves. They served at home and in all theaters of operations. Nurse anesthetists were serving in Hawaii when Pearl Harbor was attacked. Mildred Irene Clark, who was originally from North Carolina, joined the Army in 1938. Under Army auspices, she graduated from Jewish Hospital in Philadelphia, where Hilda Salomon was program director. Clark also received training from John Lundy and Florence McQuillen at the Mayo Clinic (Woodson MIC: personal oral communication to Ira Gunn, October 1994).

Clark was on assignment as a nurse anesthetist at the Schofield Barracks Hospital in Hawaii when Pearl Harbor was struck. Clark was among other nurse anesthetists on active duty who set up educational programs for preparing additional nurse anesthetists. Clark completed her career in 1967 as the Chief of the Army Nurse Corps, the first nurse anesthetist to hold this position.

Annie Mealer, another notable Army nurse anesthetist, was sent from Walter Reed Army Medical Center to the Philippines in 1941. She served as chief nurse and chief nurse anesthetist of the hospital on Corregidor.

For 3 years Mealor was held as a prisoner of war. Among the nurse anesthetists imprisoned with her were Denny Williams, Doris Keho, and Phyllis Arnold Iacobucci. They and 62 other Army nurses were imprisoned until February 3, 1945.

Marianne Bankert quotes at length a letter Annie Mealor later wrote in which she described her experiences. Mealer recalled housing President Quezon and his family, dodging "Jap bombs," and "giving anesthetics to one casualty after another" who "all needed help that only a nurse could give them." In Japanese custody aboard a troop ship, and sick with dengue fever, Mealer wrote, "I threw my cape down on the deck to lie on it and prayed that the wind would blow the fumes of the stale fish in another direction. I looked around at the nurses in the various uniforms of coveralls and skirts. They had grown slender as reeds, but were smiling over some secret rumor about liberation—not realizing they had nearly three more years of hard work and starvation."[61]

Wartime greatly expanded the need for anesthetists in both military and civilian hospitals. Lt. Col. Katherine Balz, the Education Consultant to the Army, estimated that "approximately 15,000,000 patients were admitted to Army hospitals during the war, and something had to be done to provide the anesthesia services needed for these patients' care." Rosemary Stevens reported that in 1942, nurse anesthetists outnumbered anesthesiologists by 17 to 1.[62] By the end of World War II, the Army Nurse Corps had educated more than 2000 nurse anesthetists, most (though not all) of whom were given an abbreviated 4- to 6-month curriculum patterned after that required by the AANA.[63] Lt. Col. Balz recalled a situation in which some volunteer nurses were placed into anesthesia service after only 90 days training! "At the end of that time, these volunteers were thrown into a situation in which 100 operations were being performed every 24 hours….there were not enough hours in the day to care for the patients and at the same time provide for formal instruction. In this hospital, over 5,000 anesthetics were given during a six months' period, and not one death or complication occurred as a result of anesthesia."[64]

The increased needs and the shortened training period posed "extraordinary complications" for the AANA. The quality of newly minted graduates had to somehow be addressed. To maintain standards, the AANA implemented a temporary "program of certification by exam and certification by waiver."[65] Accreditation of programs was postponed entirely. In 1943 the Annual Meeting was reduced to just 1 day; a quorum could not be met, so already elected officers remained on the board.

From her sick bed, Agatha Hodgins sent these words of encouragement: "The immense and vital part all branches of medical service will play in this continuing task can—because of its greatness—be now only dimly conceived. They will in very truth be a 'green island' in 'the wide deep sea of misery' now encompassing the earth." These were among her last words. Hodgins passed away in 1945. Her gravesite is located on Martha's Vineyard.[66]

As World War II drew to a close, the AANA's plans for instituting a certification examination for civilian membership were at last realized. The first examination was given in June 1945. It was completed by "90 women in 39 hospitals in 28 states, plus one in the Territory of Hawaii."[67] It would be hard to conclude that their "high type of service" during the two world wars did not account for this accomplishment.

Nationally, World War II was also associated with bringing about certain human rights advances. President Truman integrated the armed forces in 1948. And the first male nurse was commissioned in 1955, a step attributed to nurse anesthesia. The AANA admitted its first African-American member in 1944 and its first male member in 1947. The first two male nurses commissioned

in the Army Nurse Corps were nurse anesthetists, Edward L.T. Lyon of New York and Frank Maziarski of Washington, who later became the sixtieth president of the AANA.[68,69]

A SHORT-LIVED PEACE FOR NURSE ANESTHETISTS AND THE NATION

After the war the number of physicians in anesthesia greatly increased. In 1940 there were only 285 full-time anesthesiologists, 30.2% of whom were certified; in 1949 there were 1231, 38.3% of whom were certified.[70] Ira Gunn attributed the increase to wartime medical experiences "alerting physicians to the potential of anesthesia as a specialty.[71] Bankert listed as causes "the increased complexity of anesthetics, but also…a military structure that encouraged medical specialization and a GI Bill that supported medical residencies."[72] The country produced more physicians, and many were drawn into anesthesiology.

An "old problem" reappeared. For upon returning from military service, "medical (physician) anesthetists—*many of them trained in the Armed Services*—(in an effort) to establish themselves in a civilian economy, brought about a resurgence of activity against the nurse anesthetist."[73] One activity was to render "historically invisible" the contributions of nurses. For example, the centennial celebration of ether at the Massachusetts General Hospital made no mention of nurse anesthetists. (It would, in fact, be the impetus for Virginia Thatcher's seminal history book.) Bankert listed other similar efforts: "a myth is launched of the early superiority of British anesthetists—a land, so the story goes, which was never so foolish as to allow nurses to administer anesthetics; the national association of physician-anesthetists backdates its founding (from 1936) to 1905; a new word (*anesthesiologist*) is coined in the 1930s to distinguish the work of physician-anesthetists from nurse-anesthetists; 'historical' studies are published with titles such as *The Genesis of Contemporary Anesthesiology*, as though nothing of significance occurred in the field until the 1920s, when physician-anesthesia began to be effectively organized…"[74]

Then anesthesiologists launched a public relations effort to denigrate nurse anesthetists. Bankert reported that in 1947, several "major articles" appeared in *Look Magazine, Hospital Management, Reader's Scope,* and *This Week*. One excerpt railed, "Bad anesthesia causes more operating-room deaths than surgery. Now many hospitals have physician-anesthetists to protect you." And fear was a part of this campaign: "Until the operating rooms of our hospitals are brought into line with the clear requirements of modern anesthesiology, hundreds of Americans will continue to die needlessly on operating tables, sacrificed to ignorance and incompetence."[75] It is not known what if any evidence was offered to support this opinion.

These efforts did not accomplish their goal. Surgeons, the public. and "often the anesthesiologist himself" were not dissuaded from trusting nurse anesthetists. However, they did "discourage many capable nurses from entering the field," prompting the AANA to promote the profession and recruit nurses who had been frightened away.[76] And soon thereafter, the first quality of care study in anesthesia took place. The results according to Gunn "shocked and dismayed many anesthesiologists."

In 1954 Beecher and Todd published a prospective analysis of anesthesia outcomes collected between 1948 and 1952. Ten university hospitals contributed data for approximately 600,000 anesthetics. The nurse anesthetists' death rate was one half that of anesthesiologists. Furthermore, there was no difference in physical status between groups of providers. However, that did not stop the authors from surmising (without evidence) that anesthesiologists were anesthetizing more complex surgical cases.[77] Not surprisingly, more quality comparisons would be conducted in the coming decades.

In fact, as Gunn pointed out, nurse anesthetists at that time were second to no one. In 1948, for example, Olive Berger at Johns Hopkins reported 480 anesthetics for repair of cyanotic congenital heart disease, including tetralogy of Fallot.[78] Betty Lank at Boston Children's Hospital, pioneered the use of cyclopropane in pediatric anesthesia.[79]After the United States committed troops to South Korea, the National Women's Press Club named the Army nurse as its Woman of the Year (1953). An Army nurse anesthetist, Lieutenant Mildred Rush from Massachusetts, was designated to accept the award on behalf of all Army nurses.

And it was the Korean War that ultimately led to the accreditation of all nurse anesthesia education programs. During the war itself, the AANA had begun accrediting programs, but it had little clout, and within each state the Veteran's Administration had its own standards concerning 'so-called' accredited schools. To enforce proper standards, the AANA successfully appealed to the Department of Health, Education, and Welfare for recognition as the sole accrediting agency.[80] Within a few years, civilian schools either brought themselves into compliance with AANA standards, or quietly closed.

SETTING EDUCATION STANDARDS AND DEVELOPING AN APPROVAL PROCESS

The foundation for the formal education of nurse anesthetists was embedded in the 1933 bylaws of the NANA (later renamed the American Association of Nurse Anesthetists [AANA]). The newly formed association was directed "to develop educational standards and technique(s) in the administration of anesthetic drugs," as specified in Article II, Objectives.[81] This objective revealed the vision of early nurse anesthesia leaders for a formal educational process that has grown and matured throughout the twentieth and early twenty-first centuries.

By 1934 the NANA's Educational Committee had studied curricular outlines submitted to them by several schools of anesthesia as the basis for creating a standard curriculum that should be offered to all students. In addition to the detailed standard curricular outline, other guidelines for operating a school of anesthesia were developed, including the type of conducting institution, instructors, recordkeeping, and other activities.[82] During the first decade of its existence, the Educational Committee worked on developing a list of schools of anesthesia and establishing an inspection process to evaluate whether the schools were offering the recommended standard curriculum. By 1939 a national survey of 106 hospitals and institutions had been completed that identified 39 courses of instruction located in 18 states of the United States. There was also a plan to have a representative of the NANA visit all schools for the purpose of collecting information, coordinating training methods, and promoting quality education. Helen Lamb's work on developing the initial method for approving schools led to a formal accreditation process.[82]

Lamb, a former student of Agatha Hodgins, frequently addressed the value of a university education for nurse anesthetists. She was founder, then director, of the Barnes School of Anesthesia in St. Louis, Missouri, from 1929 to 1954.[53] In 1989 the AANA established an annual award in Lamb's name to honor outstanding educators.

With the advent of World War II, a shortage of anesthesia personnel became evident, and many hospitals began training anesthetists to meet their own needs. During the critical period, the professional organization encouraged the use of established schools of anesthesia that followed the association's standard curriculum

to train anesthetists, rather than the development of new schools that might use substandard methods of training.[82]

The publication of the 1945 *Essentials of an Acceptable School of Anesthesiology for Graduate Registered Nurses* containing information on the proper training of nurses was partially in response to the establishment of new schools with questionable quality during the manpower shortage in World War II. A standard curriculum was finally submitted to members of the board of trustees by the Educational Committee on July 11, 1945, for approval as part of the *Essentials*.[82]

The formal accreditation process for schools of nurse anesthesia was approved unanimously during the 17th Annual Meeting of the AANA in September 1950. Membership dues were also increased at that meeting to $20, with $5 of the assessment allocated for the accreditation program. The formal motion to approve the accreditation program included the rationale that the competency of past, present, and future graduate nurse anesthetists could be emphasized by having the schools of anesthesia inspected by qualified consultants, approved, and publicly endorsed. According to Helen Lamb, serving as chair of AANA's Advisory to the Approval Committee, "Such accreditation would vouch for the fact that graduate nurse anesthetists, who now occupy or who in the future enter our field from our standard courses of training, are irreproachably equipped, educationally and clinically, to meet the professional requirements and responsibilities that are inherent in the practice of our specialty."[82]

In 1975 the Council on Accreditation of Nurse Anesthesia Educational Programs (COA) was established as an outgrowth of the AANA's Approval of Schools Committee Recognition. The COA was established in response to major revisions of the United States Office of Education (USOE) recognition requirements. The revised USOE criteria mandated a structural change in the AANA that resulted in the formation of three semiautonomous councils—accreditation, certification, and practice. The formation of the original council structure with three separate councils was a major change in the operation of the AANA. The COA has been continuously recognized by the U.S. Department of Education (USDE). In addition, the COA has been recognized by the Council on Higher Education Accreditation (CHEA) or its successors since 1985.

THE NEW AGE OF NURSE ANESTHESIA: THE 1960s

When the 1960s began, the AANA had evolved into a more fully fledged professional organization. It was under the influential leadership of its first full-time executive director, Florence McQuillen, who was hired in 1948. John Lundy, the chairman of anesthesiology at the Mayo Clinic, worked with McQuillen and referred to her as "the best-read person on the literature of anesthesia." McQuillen exerted such a powerful influence at the AANA[83] that in 1965 she was named association executive of the year by the journal *Hospital Management*.

During McQuillen's tenure, other certification of graduates and accreditation of programs placed the association firmly within the regulatory and educational spheres of American health care. Membership grew considerably, and exceeded 10,000. All 50 states had associations affiliated with the AANA. And the members had approved the beginnings of continuing education.[84]

But the decade of the 1960s was a transitional period for everyone in health care, including nurse anesthetists. The United States, which had relied increasingly on employer-based health insurance since WWII, extended coverage to elderly and poor people through Medicare and Medicaid in 1965. These programs led to a greater need for health providers. Educational programs for all health professionals, including nurse anesthetists, increased accordingly.

Growth was embraced by anesthesiologists in ways that were not entirely welcomed by Certified Registered Nurse Anesthetists (CRNAs). Gunn recounted that "Anesthesiologists held meetings to define the future." Some sought an all-physician specialty. Others knew such a goal was unattainable because nurse anesthetists were "providing the majority of anesthesia care in the United States."[85] To resolve the manpower issue, two ideas gained prominence. Adherents of the first idea advocated support of nurse anesthesia educational programs.[86] Adherents of the second idea proposed another type of anesthesia practitioner based on a physician assistant model that the anesthesiologist could control.[87,88] Either option would be problematic.

Clearly there would be value in communication between the two groups. But since 1947, the American Society of Anesthesiologist's (ASA's) "Anti-Adriani Bylaw" had precluded communication with the AANA. According to Marianne Bankert, ASA President Albert Betcher (1963) initiated efforts to establish relations with nurse anesthetists, in light of the reality presented by "present and projected personnel needs."[89]

In 1964 the ASA and AANA established a liaison committee that met twice a year. Florence McQuillen articulated the Association's goals. Through dialogue, the AANA sought "no interference with the progress of educational programs of the Association, and a curbing of anti-nurse anesthetist activity and publicity."[90] After 3 years of meetings, the *AANA News Bulletin* and the *ASA Newsletter* published a joint statement that read in part, "It is, therefore, highly desirable that continued close liaisons be developed between these organizations for enhancing the quality and quantity of available personnel, for advancing educational opportunities, for determining ethical relationships and for the overall improvement of patient care." C.R. Stephens, a noted anesthesiologist who had worked with nurse anesthetists for many years, wrote in a 1969 report to the ASA, "Progress has not been rapid, but the dialogue has enhanced understanding."[91] That progress and understanding would be tested severely during the next decade.

THE 1970s: A TURBULENT DECADE

Long-term American involvements, such as the Vietnam War, and the era of progressive reforms became part of this country's history during the 1970s. As federal expenditures for health care rose, the government exerted greater scrutiny of health services. In 1974 the U.S. Commissioner of Education revised the criteria governing nationally recognized accrediting agencies, of which the AANA was one. The new criteria were intended to protect the public's interest by completely separating the professional obligations of an association from its proprietary concerns. The AANA would have to give up its roles in accrediting programs and certifying graduates, roles it had nourished and cherished since 1931. To divest itself of these operations, AANA undertook a wholesale reorganization. In 1975, largely through the work of Ira Gunn, assisted by Ruth Satterfield, Mary Cavagnaro, and Ed Kaleita, autonomous councils were established and granted accrediting and certifying functions.[92]

The process of governmental review and revision provided an opportunity for physicians to attempt to take control over CRNA education. The ASA proposed a competing accrediting organization, the Faculty of Nurse Anesthesia Schools, and it misused both the Joint Statement issued by the AANA/ASA Liaison Committee (1972) and a manpower study to justify their activities. After many tense months of strategizing, however, the Councils on Accreditation and Certification ultimately won the government's approval.

The struggle over accreditation and certification had several important outcomes. By separating out the accrediting and certifying functions, the AANA was free to pursue laws and policies that would protect CRNAs, without fear of creating a conflict between its private interests and its public duties. Secondarily, it revived the AANA's relationship with the American Nurses Association, but it "increasingly strained relations between the AANA and ASA."[93]

Ira Gunn recalled that some nurse anesthetists saw this episode as an opportunity to upgrade educational programs and move into universities and colleges. John Garde, Ira Gunn, Joyce Kelly, and Sister Mary Arthur Schramm were the CRNAs who pioneered programs in the baccalaureate and then graduate frameworks in the early 1970s.[94]

In another outgrowth of this era, state nurse anesthetist organizations sought explicit legal recognition, either within the state nurse practice act or as a separate law. Gunn traced this phase of licensure to a Department of Health, Education, and Welfare committee report of 1971 that "supported an extended scope of function for registered nurses." Other factors influencing its development included higher educational standards, increased complexity of practice, the women's movement, and the increased presence of men in nursing.[95]

Nurse anesthetists were soon addressed in one or more places within state statutes or regulations in all 50 states. However, according to Mitchell Tobin, the former Director of State Government Affairs for AANA, "Although it is clear that legitimacy of nurse anesthesia as a profession is widely accepted, the manner, type, and frequency of statutory and regulatory recognition of CRNA practice varies considerably."[96] In the following decade, the AANA would have to issue position statements to influence the ways in which CRNAs were treated under state nurse practice acts and boards of nursing rules.

And last, the AANA, in a rare offensive legal maneuver, sought direct reimbursement for CRNA services within the Medicare program (1976). President John Garde spoke of the rationale in his 1973 report to the members. "If a physician is paid for a procedure or care, and that same procedure or care is provided by the CRNA, why should it not be reimbursed through health insurance programs?"[97] The effort failed. However, coupled with the other challenges of the 1970s, this attempt alerted CRNAs to the need for an increased presence in Washington, D.C.

FEDERAL LEGISLATIVE INITIATIVES IN THE 1980s

By the end of the 1970s, American medicine had "suffered a stunning loss of confidence." So wrote Paul Starr in "The Transformation of American Medicine." "Slower economic growth and persistent inflation in the seventies undoubtedly lay behind the shift from a redistributive to a regulatory politics in health care." But, although the economy declined, medicine "seemed to pass from stubborn shortages to irrepressible excess." From 1970 to 1980, healthcare expenditures had grown from $69 billion to $230 billion. And "the reimbursement practices for hospitals and doctors were peculiarly designed to encourage higher costs.[98] Conservatives and some liberals in Congress aimed to cut that back.

Gunn described how this played out within anesthesia: "Anesthesiologists billed for services when they were not present in the hospital or even in town. Some chose not to come out at night or on weekends to supervise care provided in emergencies, yet they billed as if they had been present. Anesthesiologist supervision or billing capability for concurrent cases was not limited to any specific fixed numbers, permitting abuse. During this time, some surgeons were openly critical of the number of fees being paid to anesthesiologists for concurrent services, particularly when the anesthesiologists were not available. A number of these surgeons and other providers complained to both private insurers and Medicare. As a result, some private payers began limiting reimbursement to not more than two concurrent procedures, and Medicare's Inspector General focused on anesthesia reimbursement in the search for potential fraud. Around this time, Richard Verville, the AANA's Washington counsel, stated that a source in the Inspector General's office of what was then the U.S. Department of Health, Education, and Welfare had told him that approximately 25% of Medicare fraud and abuse investigations concerned anesthesia services."[99] Two federal efforts to control anesthesia costs and accountability had their genesis in these peculiar reimbursement practices.

TEFRA

The first federal effort to control anesthesia costs and accountability was the Tax Equity and Fiscal Responsibility Act (TEFRA), enacted in 1982. TEFRA was designed to control costs, and "ensure that an anesthesiologist demonstrated that he or she provided certain services as part of a given anesthetic to qualify for payment. Among other things, TEFRA limited payment to anesthesiologists for no more than four concurrent cases, and stipulated seven conditions that anesthesiologists must fulfill as part of a given anesthetic procedure to qualify for payment."[100]

However ,TEFRA had some adverse implications for CRNAs. The seven conditions were misconstrued by the ASA as standards of practice. Its *Guidelines to the Ethical Practice of Anesthesiology* (adopted October 25, 1978; effective February 12, 1979), made this clear.[101]

They separated reimbursement for anesthesiologists based on supervision or medical direction and specified payments on the basis of direction to be limited to not more than two concurrent procedures. Payment took two forms. When the CRNAs were employed by the anesthesiologist, each service was billed as though the anesthesiologist had administered each case. When the CRNAs were hospital employees, the time units for the anesthesiologist were cut in half. When the anesthesiologist's service was supervision and not direction (i.e., supervising three or more CRNAs), the payment was to be made under Part A of Medicare on the basis of a "reasonable charge." The hospital could still bill for the CRNA services of their own employees under Part A if the services were provided within the hospital and under Part B of Medicare if the services were provided in a surgical center.

An Existential Threat Leads to Direct Reimbursement

In early 1983, while the AANA was still dealing with TEFRA, without much fanfare and with less media exposure than usually accompanies such legislation, Congress passed a second cost control bill, the prospective payment system (PPS). The PPS revised the means of calculating Medicare payment from a cost-plus fee for service basis to prospective pricing based on diagnosis-related groups. This measure posed a much greater threat to CRNAs than TEFRA.

The PPS legislation was a powerful disincentive to the hiring of nurse anesthetists: (1) it would be impossible for the anesthesia component of payment to cover the full cost of hospital-employed CRNAs; (2) unbundling of services and payment was prohibited; and (3) anesthesiologists who had been billing for CRNA services under Medicare Part B could no longer do so. Taken together these caveats meant "CRNA services were, for all practical purposes,

nonreimbursable."[102] Hospitals would terminate CRNAs and rely entirely on anesthesiologists.

The very real threat posed by PPS mandated action. Either the reimbursement for both anesthesiologists and CRNAs would need to be placed under the same source, Medicare Part A, or AANA would have to seek direct reimbursement rights for CRNAs under Medicare Part B.

In the 1980s CRNAs were heavily recruited healthcare professionals. The majority were employed by hospitals or anesthesiologists, but a growing number of CRNAs practiced privately. Private practice CRNAs were unable to obtain reimbursement directly from Medicare, Medicaid, and many private insurance companies.

After a 3-year-long effort that Bankert described as "one of the greatest lobbying achievements not only of the AANA, but of the whole of nursing," President Reagan signed into law the Omnibus Budget Reconciliation Act of 1986. Since then Medicare and Medicaid have paid directly for all CRNA services, making nurse anesthetists the first nursing specialty to be so accorded. Of its importance, Dr. Judith Ryan, the executive director of the American Nurses Association, said that "The American Association of Nurse Anesthetists' achievement to secure direct reimbursement for CRNAs is a singular, notable contribution to identification and payment of the nurse as a provider of care, and nursing services as covered health benefits."[103]

Non-Legislative Legal Problems Arise

In the same decade, events of no less significance took place in civil law pertaining to anesthesia. The courts tested whether a surgeon is liable for the actions of a nurse anesthetist. Traditionally, surgeons have been considered "Captains of the Ship" and were therefore thought responsible for everything that occurred inside an operating room. Logically this theory was extended to mean that "nurses (and nurse anesthetists) become the temporary servants or agents of the attending surgeon during the course of an operation, and liability for their negligent acts may thus be imposed upon the surgeon under the doctrine of *respondeat superior*."[104] Blumenreich explained the danger to CRNAs of this theory: "When surgeons work with nurse anesthetists, the surgeons become liable for their mistakes—but when surgeons work with anesthesiologists, the surgeons do not have to worry about what happens at the head of the table." But, in fact, the theory is fallacious. Blumenreich went on to say, "First, surgeons are not always liable for the negligence of nurse anesthetists. Second, surgeons may also be liable for the negligence of anesthesiologists. Third, because a surgeon's liability, whether working with nurse anesthetists or anesthesiologists, depends on the particular facts of the situation, as a practical matter, the surgeon is likely to be included in the suit whether the surgeon is working with a nurse anesthetist or an anesthesiologist." In fact, no surgeon has been held liable in a court of law for the negligence of a nurse anesthetist. Courts have apportioned liability according to specifics facts of a case.[105,106]

A second area of civil law that effected anesthesia in the 1980s was antitrust. Nurse anesthetists, like other professionals, are subject to antitrust laws. However, they also can use those laws when they allege others have conspired to restrict CRNA practice. Two cases filed by CRNAs, Vinod Bhan (*Bhan v. NME Hospitals, Inc.*, 84-2256, DC No. CV-S-83-295 LKK [October 2, 1985]) and Tafford Oltz (*Oltz v. St. Peters Community Hospital*, 861 F2d 1440, 1450 [9th Cir 1988]), illustrated these points.

Oltz had held clinical privileges and had worked as a private practitioner at St. Peters Community Hospital in Helena, Montana. His privileges were terminated when the hospital gave an exclusive contract to a group of anesthesiologists. Oltz alleged, and the court agreed, that the hospital and the anesthesiologists had conspired to terminate his privileges so that the anesthesiologists would have access to his cases. The verdict turned on the fact that St. Peters Community Hospital had significant enough market shares within its service area to exert a monopoly, and that by awarding the exclusive contract to the anesthesiologists, the hospital damaged competition. By August 1994, more than 12 years and numerous appeals later, Oltz prevailed. Although nondisclosure was a condition of the final settlement of monetary damages in this case, the court awarded Oltz (the plaintiff) $1.6 million in attorney fees.[107]

A second antitrust case involved Vinod (Vinnie) Bhan, who practiced anesthesia in California. When his hospital terminated his privileges and replaced him with anesthesiologists, Vinnie sued. The defendants (both the hospital and the anesthesiologists) challenged Bhan's standing—that is, his legal right to file suit. They asserted that Bhan, as a nurse and nurse anesthetist, did not, in the eyes of the law, compete with physicians because of their different licensure.

Bhan lost the case because the hospital that terminated his privileges did not have sufficient market share in the community to restrain competition. One essential element of antitrust laws is that they exist to protect competition, not competitors. Bhan's ability to compete was not adversely effected, because there were plenty of other local hospitals where he could seek to practice.

However, the appellate court ruling that gave Bhan and CRNAs standing to sue anesthesiologists as competitors set a significant legal precedent for the profession. The Circuit Court concluded, *"No doubt the legal restrictions upon nurse anesthetists create a functional distinction between nurses and MD anesthesiologists. They do not, however, necessarily preclude the existence of a reasonable interchangeability of use or cross-elasticity of demand sufficient to constrain the market power of MD anesthesiologists and thereby to affect competition"* [emphasis added]. The court continued, stating that "as a matter of law, Bhan's allegations are sufficient to establish that he is a proper party to bring this antitrust action."[108,109]

And Blumenreich said, "The Bhan case was important because it gave to some extent the protections of the antitrust laws to nurse anesthetists. Hospitals could not boycott nurse anesthetists." Its results would be more "long-lasting."

Hyde v. Jefferson Parish Hospital District No. 2

A third antitrust case, *Hyde v. Jefferson Parish Hospital District No. 2* (1983; New Orleans, Louisiana) centered on whether an exclusive contract by a group of anesthesiologists was by itself (per se) a violation of the antitrust laws. At East Jefferson Parish Hospital, a group of anesthesiologists held an exclusive contract with the hospital and worked with hospital-employed CRNAs. Dr. Hyde was denied privileges solely on the basis of the exclusive contract. Hyde sued, claiming that a patient who was admitted for surgery in effect had no choice but to buy anesthesia from the hospital's exclusive group of anesthesiologists. He alleged that this situation represented a tying arrangement, which had previously been deemed in violation of the antitrust laws. (A tying arrangement would be similar to going to a store to buy bread but being unable to buy it by itself. Rather, one would be required to buy butter to get the bread, whether or not the purchaser used butter on bread.)

The Jefferson Parish Hospital District won the case at the lower court level. But Hyde appealed all the way to the U.S. Supreme Court.

The ASA also filed an amicus curiae brief, but in support of Dr. Hyde. The ASA opposed exclusive contracts, but attempted to link its opinion to the quality of care: "the elimination of competition through a classic tying arrangement is not simply a matter of dollars and cents. It can adversely affect the quality of medical care. ASA believes that in this setting, it is particularly important that competition be allowed to reward superior performance and innovation, while exposing the indifference to quality that may too often be the hallmark of a monopoly.[110]

The Supreme Court ruled unanimously in favor of the hospital's right to award an exclusive contract for anesthesia services. The ruling was favorable to CRNAs in what Blumenreich recalled was a "footnote in the court's opinion to the effect that 'there has been no showing that nurse anesthetists provide a lesser quality of care.' So we feel like we accomplished what we set out to do."[111] Shortly afterward, the AANA appointed Blumenreich General Counsel, a post he held until 2011. Gunn wrote that "the Hyde case alerted the AANA to the need to revitalize its public relations program, continue its watch for attempts to discredit CRNAs, and take action either to correct or to prevent further damage."

CRNA Achievements of the 1980s

Although much attention focused on events taking place on the legal front, other important areas of practice were advanced. For example, liability insurance coverage, first offered to CRNAs in 1974 by outside brokerages, was skillfully brought in house when the AANA bought the Glen Nyhan Agency. Renamed A+, and now called AANA Insurance, the agency has provided a steady stream of insurance to CRNAs since 1988.

The AANA Education and Research Foundation was established in 1981; it would be renamed the AANA Foundation in 1995. The Foundation has enjoyed enormous support. A 2011 report[112] listed scholarships, grants, and workshops in excess of $2.2 million given to 2275 individuals.

- 739 scholarships totaling more than $1 million to support nurse anesthesia
- 131 fellowships totaling $650,000 to assist CRNA students pursuing their PhD and DNP degrees
- 173 research grants to CRNAs totaling more than $531,000
- 39 student research grants totaling $31,000
- 1193 poster presentations at AANA annual meetings totaling more than $50,000

The Conductor

No review of the 1980s would be complete without mention of the ascendance of John Garde, who served the profession from 1957 through 2009.

Mr. Garde's career at the AANA stemmed from being an educator. From 1964 to 1975, John was Program Director, Associate Professor, and then Chairman of Anesthesia at Wayne State University. Mr. Garde went to work for the AANA in 1980 as the Education Director and then in 1983 was appointed Executive Director. This was his post until retiring for the first time in 2000, and from which he would become an "iconic figure in the healthcare community."[113]

Under Mr. Garde's executive leadership, the profession prospered. Evidence for this includes the previously described legal and regulatory victories and educational advancements. The AANA also expanded to include AANA Publishing, AANA Insurance Services, AANA Management Services, the AANA Foundation, a Government Relations Office in Washington, D.C., and (not least) the AANA Archives. (John was "steeped in history.")

Because John "knew everyone," relations between the AANA and outside organizations flourished. According to Rita Rupp, "John facilitated and led in the formation of the National Federation of Nursing Specialty Organizations and later a national nursing executive directors group."

Nurse anesthesia even globalized during this era: the International Federation of Nurse Anesthetists was formed, and the AANA supported volunteerism in developing nations through Health Volunteers Overseas.

Mr. Garde had attended the venerable Alexian Brothers Hospital School of Nursing in Chicago, and the St. Francis Hospital School of Nurse Anesthesia in La Crosse, Wisconsin. According to Patrick Downey who was a contemporary of John's, the program director at St. Francis, Sister Yvonne Jenn, became his "mentor for life." "John was the student she waited for; she selected him to administer anesthesia for the first pneumonectomy at St. Francis…Their mutual trust was so strong. She taught John never to act on an impulse. Think things over. They glowed when they were together." (Personal communication, 2011).

As Executive Director, John practiced the lessons he learned from Sister Yvonne. Rita Rupp, who was John's executive assistant, said, "John had been (AANA) president, so he knew how it felt. As executive director he had an unwritten rule, defer to the president, but act as a mentor. He got involved with each president, and created a sense of comfort" (Personal communication, 2011).

With characteristic modesty, John later recalled that he saw himself as "the conductor of a great orchestra." Past President Larry Hornsby elaborated: "The president was the soloist. John used the orchestra to make the soloist sound the very best…(as president) you could not fail…He catered to each president's needs and strengths to make you the leader that the organization needed at the time" (Personal communication, 2011).

THE CALL FOR HEALTHCARE REFORM IN THE 1990s

Cost Containment in Health Care

Bill Clinton was elected president in 1992 with a promise to reform health care. The president's healthcare reform package was aimed at universal coverage and reflected a major shift in healthcare delivery toward managed care.

Clinton brought hope to CRNAs, who took note of the fact that the President's mother was a retired CRNA.[114] A component of President Clinton's healthcare legislation would have removed legal barriers to practice for advance practice nurses, permitting them to more directly compete with physicians to reduce costs. This provision would also have provided the legal authority for APNs to render services without physician supervision (in some instances collaborating with or referring patients to physicians).

For a variety of reasons, Clinton's healthcare plan was defeated. In its place, the health insurance industry, in conjunction with the major businesses that provided health insurance to their employees, forced a form of "managed care" on a large portion of the insured population. Because of the cost savings projected for a managed care system, the U.S. government offered Medicare beneficiaries certain incentives to instead accept a managed care version of Medicare. And some states began to pattern their Medicaid programs after the managed care concept, permitting managed care groups to bid to cover Medicaid patients.

Managed care, in theory, was intended to (1) move the healthcare system from a disease treatment to a health-maintenance system; (2) do away with incentives found in the fee-for-service system—that is, the more services provided, the more money made—and thereby reduce unnecessary health services;[115,116]

(3) promote a cost-effective workforce by emphasizing primary care providers and nonphysician professionals; and (4) promote a shift from independent practice patterns to greater use of salaried personnel. Some anesthesiologist groups found that under managed care their workload declined by 40%.[117] Physicians thus scrambled to protect autonomy and income, while patients sought to preserve some choice of provider.

When CRNAs won direct reimbursement rights in 1986, they agreed to accept as payment in full for each anesthetic, no more than the amount Medicare assigned for the service. In other words, CRNAs do not "balance bill." Payment schedules were then devised for anesthesiologists working alone, CRNAs working alone, and anesthesiologists medically directing CRNAs in team practice settings. In the early 1990s, a Government Accounting Office (GAO) study[118] revealed that payments for anesthesia services under the medical direction arrangement were 120% to 140% greater than payments for CRNAs or anesthesiologists working alone. This payment scheme served as a strong incentive for anesthesiologists to employ CRNAs, but it was not budget neutral, which had been the intent of Congress. The GAO recommended payment of only one anesthesia fee, totaling no more than when an anesthesiologist performed the service alone. Furthermore, the study recommended that payment for anesthetic procedures under the medical direction model be split 50% for the CRNA service and 50% for the anesthesiologist service, a significantly reduced portion for both the anesthesiologists and the CRNAs. The AANA chose to support the single-payment plan. The ASA opposed it. The single-payment reimbursement plan was implemented, and tension between the two groups again was exacerbated.

Attempts to Measure Quality of Care

In the second half of the twentieth century, physicians first, and then nurses, attempted to evaluate the quality of anesthesia care by measuring death rates. The first attempt was published in 1954 by Beecher and Todd.[119] The Beecher and Todd study looked at nearly 600,000 cases gathered at university medical centers nationwide. It was notable for shedding light on the "not yet entirely clear, nor completely appreciated" cardiovascular dangers of curare, with which there was an associated "six-fold difference, unfavorable to curare" in the death rate.

As mentioned earlier, Beecher and Todd compared outcomes between physician specialists, residents in anesthesia, and nurse anesthetists. Although there was "comparability of good and poor risk cases in the three groups," and "although the physician specialist anesthetizes only half as many patients as the nurse, he is charged with an equal number of anesthesia deaths." In other words, they found a glaring difference.

Two decades later amid complaints about the Veterans Administration (VA) healthcare system, the U.S. House of Representatives mandated a study by the National Science Foundation regarding the care given to veterans. At the time, much of the anesthesia administered at VA facilities was provided by nurse anesthetists. The reviewers reported back to Congress in 1977 that there were no significant differences in the outcomes of anesthesia based on the providers of that care.[120]

In 1980 an anesthesiologist, W.H. Forrest, published a portion of an institutional differences study conducted by the Stanford Center for Health Care Research. Forrest divided the institutions between those predominantly served by nurse anesthetists and those predominantly served by anesthesiologists; he concluded—using conservative statistical methods—that there were no significant differences in anesthesia outcomes between the two anesthesia providers.[121] (Ira Gunn wrote that she "spoke with Dr. Forrest regarding his study, and he mentioned that he had been castigated by his colleagues for reporting these results.")

A North Carolina retrospective study of anesthesia-related mortality from 1969 to 1976 (performed by a committee from the North Carolina Society of Anesthesiologists) was published in 1981. The findings based on providers (e.g., CRNAs working alone, anesthesiologists working alone, and CRNAs and anesthesiologists working together as a team) were similar. But no test of significance was made in this study.[122]

Subsequent studies deserve attention because they were used to support the claim that CRNAs should be anesthesiologist supervised.

Between 1992 and 2003, studies by Abenstein and Warner; Silber et al; Wiklund and Rosenbaum; and Vila et al were published and promoted as evidence that the "the utilization of anesthesiologists improves anesthesia outcomes." These studies and their rebuttals were summarized in "Quality of Care in Anesthesia," a 2009 publication by AANA.[123] The article by Abenstein and Warner "purported to analyze the quality of care…but failed to mention the key conclusion." For example, the authors claimed that there were "differences in the outcomes of care based on type of provider, *not withstanding that the actual researchers came to the opposite conclusion*." (Emphasis original.) The Silbur study "examined the death rate, adverse occurrence rate, and failure rate of 5972 Medicare patients. One analyst concluded this data was, in fact, not "specific to anesthesia staffing," and "the type of anesthesia provider does not appear to be a significant factor in the occurrence of potentially lethal complications." Two studies attributed to Wiklund and Rosenbaum were also found to be irrelevant. The reviewer pointed out that Wiklund and Rosenbaum, by attributing safer anesthesia to a federal decision to "support training in clinical anesthesiology" had left "the path of unbiased review of the specialty to make unsubstantiated or misleading comments about the unilateral contributions of anesthesiologists to the advancements achieved."

The Silbur study stirred up "serious questions of objectivity." "Reportedly, both the *Journal of the American Medical Association* and the *New England Journal of Medicine* declined to publish" it. The timing of its publication led to questions about its motivation. "The abstract was published in the midst of the controversy between anesthesiologists and nurse anesthetists over HCFA's [Health Care Financing Administration] proposal to remove the physician supervision requirement for nurse anesthetists in Medicare cases." The AANA reviewer concluded, "The timing of the publication in the ASA's own journal was politically motivated" to influence the Health Care Financing Administration (now known as the Centers for Medicare and Medicaid Services [CMS]). However, CMS ultimately "dismissed all claims" made by the authors in this study.

The Vila study compared outcomes at ambulatory surgery centers (ASCs) with those in office operating rooms (a practice for many independent CRNAs). It claimed that "the risk of adverse incidents and deaths was approximately 10 times greater in the office setting than in an ASC, and that if all office procedures had been performed in ASCs, approximately 43 injuries and six deaths per year could have been prevented." It concluded with the hopeful remark that "the presence of anesthesiologists in ASCs 'may be a factor in more favorable outcomes.' "

But the AANA analyst pointed out flaws in both its methodology and conclusions. The study "does not specifically mention CRNAs," yet it "makes the unsupportable assertion that office surgery may not be as safe when an anesthesiologist is not present."

Misuse of outcomes research was extensive during this era. Gunn wrote that "in the medical literature in the 1990s, serious questions were raised regarding the quality and relevance of published research, the peer review system, and the selection of articles for publication."[124] A 1993 review concluded that 95% of the medical research being published in journals was either flawed or irrelevant.[125]

The Federal Supervision Regulation

Recall that in 1919 surgeon George Crile and some of his colleagues secured legislation in Ohio that for the first time codified the practice of nurse anesthesia.[126] An amendment to that legislation made mention of physician supervision: "the administration of an anesthetic by a registered nurse *under the direction of and in the immediate presence of* a licensed physician."[127] Nurse anesthetists welcomed this development and sought similar legislation in other states.[128]

In the 1980s, there emerged physician oversight regulations within the Medicare Rules for Participating Hospitals. The regulations stemmed from the aforementioned Tax Equitability and Federal Responsibility Act (TEFRA) of 1982. They pertained only to anesthesia. And because they were federal, they preempted any state laws that permitted CRNAs to practice without supervision.[129]

At the same time TEFRA took effect, the number of anesthesiologists tripled. Increased competition in the anesthesia marketplace prompted Blumenreich to write that supervision became

> *the springboard for yet new attacks. In 1985, H. Ketcham Morrell, president of the American Society of Anesthesiologists (ASA) wrote: "…the operating surgeon or obstetrician who purports to provide medical direction of the nurse, in the absence of an anesthesiologist, carries a high risk of exposure, on a variety of legal theories, for the acts of the nurse."*[ii]

An unknown number of surgeons opted for anesthesiologists as a result. Imagined liability among surgeons became such a crisis that Blumenreich wrote "no subject has received more of my attention…"[iii]

Removing supervision from the Medicare Rules was an obvious remedy, because it would impact practice across the country. From 1994 to 2001, HCFA and AANA attempted to do just that. The struggles that ensued were chronicled by Patrick Downey. Legislation was introduced in both houses of Congress that would remove the supervision requirement and address reimbursement issues. Both the AANA and ASA responded with grassroots public relations campaigns, and the legislation went nowhere. Then in December 1997, HCFA proposed a major change in its *Hospital Conditions of Participation*, and it included the elimination of physician supervision of CRNAs. Nursing organizations lined up in support of the change, but medical opposition was fierce. Nullifying legislation was proposed, as were safety studies to delay its consideration. More public relations were deployed, and the controversial claims of the Silbur study (that outcomes are better when CRNAs are supervised by anesthesiologists) were invoked. In March of 2000, HCFA ruled that CRNAs could practice without physician supervision, and in its ruling, HCFA deemed the Silbur study "irrelevant." But the new rule was not implemented until the final days of the Clinton administration. And the Bush administration, as all new administrations do, placed a moratorium on late-term regulations. In November 2001 the Bush administration restored the earlier rule containing supervision.

The "final" rule contained an escape clause, a proviso allowing state governors to opt out.[130] Between 20 and 31 states (opinions varied) had no laws specifying supervision of CRNAs, which meant governors might be inclined to provide an opt-out. Before long, some governors did. Iowa was the first. Then a number of rural Western states opted out. To date, governors in 17 states have done so. These include Iowa, Nebraska, Idaho, Minnesota, New Hampshire, New Mexico, Kansas, North Dakota, Washington, Alaska, Oregon, Montana, South Dakota, Wisconsin, California, Colorado, and Kentucky. Depending upon one's interpretation, that was at least 50% of eligible states.

Two prominent health economists, Brian Dulisse and Jerry Cromwell, studied Medicare data between 1999 and 2005.[131] They found "no evidence that opting out of the oversight requirement resulted in increased inpatient deaths or complications." This came as no surprise to the AANA and CRNAs. The authors concluded, "We recommend that CMS return to its original intention of allowing nurse anesthetists to work independently of surgeons or anesthesiologist supervision without requiring state governments to formally petition for an exemption."

Other contemporary studies supporting this assertion were collected in the publication *Quality of Care in Anesthesia*.[132] Simonson, Ahern, and Hendryx (2007), and Needleman and Minnick (2008) found no significant differences between CRNAs and anesthesiologists with respect to obstetric (OB) anesthesia outcomes. Pine, Holt, and Lou (2003) studied Medicare outcomes for patients in 22 states between 1995 and 1997. Their findings were mortality rates were similar for CRNAs and anesthesiologists working individually; no statistically significant difference in the mortality rate for team versus solo practice; and no statistically significant difference in mortality for hospitals without anesthesiologists versus hospitals where anesthesiologists provided or directed anesthesia care. However, the Institute of Medicine, the health arm of the National Academy of Sciences, weighed in with a report entitled "The Future of Nursing: Focus on Scope of Practice."[133] The report came as a powerful endorsement of nurses as high-quality clinicians. Its conclusion reads, in part: "Now is the time to eliminate the outdated regulations and organizational and cultural barriers that limit the ability of nurses to practice to the full extent of their education, training, and competence. The U.S. is transforming its healthcare system to provide quality care leading to improved health outcomes, and nurses can and should play a significant role. The current conflicts between what APRNs can do based on their education and training and what they may do according to state and federal regulations must be resolved so that they are better able to provide seamless, affordable, and quality care. Scope-of-practice regulations in all states should reflect the full extent not only of nurses but of each profession's education and training. Elimination of barriers for all professions with a focus on collaborative teamwork will maximize and improve care throughout the health care system."

Doctoral Preparation of Nurse Anesthetists Achieved

Upgrading Nurse Anesthesia Educational Requirements

The upgrading of academic credentials for CRNA educators and their graduates has always been closely tied to the goals of the professional association to advance the art and science of anesthesia.[82] Nurse anesthesia leaders have been responsible for increasing requirements for curricular content, faculty qualifications, and academic credentials for graduates since early in the twentieth century. Over time, schools of anesthesia have changed from

[ii]Blumenreich G: Supervision. *JAANA*, October 2000.
[iii]Blumenreich G: Another Article on the Surgeon's Liability for Anesethesia Negligence. *AANA Journal*, April 2007.

apprenticeships at hospitals into degree-granting institutions fulfilling the vision of early anesthesia leaders for a university education for nurse anesthetists. This movement into academia required identifying the location of schools of anesthesia in the nation, determining the essential characteristics of better schools, agreeing on curricular requirements, inspecting schools, and developing a school approval process.

Doctoral Degrees. Beginning in the mid-1980s, the AANA and the COA have continually assessed the need for and feasibility of practice-oriented doctoral degrees for nurse anesthetists. In June 2005 the AANA board of directors convened an invitational summit meeting to discuss interests and concerns surrounding doctoral preparation for nurse anesthetists. Following the summit, the Task Force on Doctoral Preparation of Nurse Anesthetists (DTF) was formed and charged with developing options relative to doctoral preparation of nurse anesthetists that the AANA board could consider.[134] The DTF's final report and options were presented to the AANA board of direction in April 2007, and in June 2007 the board unanimously adopted the position of supporting doctoral education for entry into nurse anesthesia practice by the year 2025. This decision was based on more than 2 years of investigation to thoroughly explore the interests and concerns surrounding doctoral preparation of nurse anesthetists.

Setting a requirement for doctoral education followed in October 2009 when the Council on Accreditation of Nurse Anesthesia Education Programs adopted a position that "The COA will not consider any new master's degree programs for accreditation beyond 2015: and that students accepted into an accredited program on January 1, 2022, and thereafter must graduate with doctoral degrees." The position became part of the Standard on Accreditation of Nurse Anesthesia Educational Programs and the basis for drafting new standards for practice doctorate programs.[134]

CRNA PRACTICE TODAY

Demographic information collected from CRNAs by AANA in 2010 indicated there were about 40,000 members of the AANA. CRNAs are 56% female and 44% male. Their average age was 49.8 years. Of currently practicing CRNAs, 42% planned to retire by 2022. Ninety-six percent of CRNAs reported they practice clinical anesthesia, whereas only 2% worked in either management/administration or education. Median annual total compensation for CRNAs, including salary and benefits, was $165,571. CRNAs worked in all states and in every clinical setting using every anesthetic modality (general, regional, sedation, pain management). The data point out that American CRNAs are very productive and make an enormous contribution to the care of patients under anesthesia. And CRNAs are fulfilled by their work; only 10% expressed job satisfaction of 3 or less on a scale of 1 to 5.

The United States is currently a country at war, and so CRNA contributions to military anesthesia are particularly significant. The U.S. Army, Navy, and Air Force commission approximately 1100 CRNAs serving on active duty. Others work within the Department of Health and Human Services for the U.S. Public Health Service and Veterans Administration. Increased deployments of active duty CRNAs have disrupted the lives of many.

CRNAs are proving to be very versatile, filling more than clinical duties in today's military. They are also leaders and in some cases soldiers on the line. CRNAs Major Steve McColley and Captain Mitchell Bailey earned Bronze Star Medal nominations for acts of courage in Iraq. Major Jeffrey Roos, a CRNA stationed at Fort Benning, Georgia, earned a Bronze Star from the Army for his lifesaving efforts during Operation Anaconda, the first major U.S. offensive launched in Afghanistan after the September 11, 2001, attacks on the World Trade Center. A CRNA was in the news for extricating Private Jessica Lynch from a hospital in Iraq.

Deployments of CRNAs to Afghanistan and Iraq have reduced anesthesia staffs at stateside hospitals. No figures exist to describe the overall impact of the latest escalation on anesthesia services in stateside hospitals. However, the impact of deployments has been mitigated somewhat following a recent policy change in the Navy. Navy CRNAs are now considered "licensed independent practitioners" (LIPs), a term coined by The Joint Commission (TJC). According to Captain Annette Hasselbeck, NC USN, LIP status has enabled the Navy's medical planners to use global sourcing of CRNAs. In other words, CRNAs are used interchangeably with anesthesiologists, based on skills, seniority, and availability. This had always been the practice pattern, but defining CRNAs as LIPs has kept practice in compliance with TJC policy. According to Captain Ron Van Nest, NC USN (retired), the policy was changed in 2000 to reflect the facts that CRNAs very often deploy alone and capably make independent clinical decisions that affect anesthetic management. Recognizing CRNAs as LIPs has also kept morale high; all billets are filled and retention of Navy CRNAs is at 100% as of this writing.

International Federation of Nurse Anesthetists

The International Federation of Nurse Anesthetists (IFNA) is a federation of national associations of nurse anesthetists. It is an affiliate member of the International Council of Nurses and a Nursing Partner of the World Health Organization. The IFNA represents more than 50,000 nurse anesthetists worldwide and is a growing organization with members in both developed and developing countries (S. Quellette and J. Rowles written communications, January 21, 2012). The first organizational meeting was held in September 1988, and 11 countries were admitted as charter members in 1989. A World Congress is held every 2 years and is hosted by a member country.

To date there are 36 members countries. The IFNA has developed international standards for education, standards of practice, standards for patient monitoring, and a code of ethics for nurse anesthtists.[135] An anesthesia approval process for entry level programs was launched in 2010 offering three levels of awards: Registration, Recognition, and Accreditation. The goal of the Anesthesia Program Approval Process is to encourage programs to comply with the IFNA's *Educational Standards for Preparing Nurse Anesthetists* through an approval process that takes cultural, national, or regional differences into consideration.[135]

Progress in Anesthesia

Progress in anesthesia has occurred in all areas of the discipline. The AANA Foundation lists and describes hundreds of recent and ongoing CRNA-led research projects.[136] These projects range from basic and applied sciences to clinical anesthesia, education, and economics.

A *Special Research Edition* of the *AANA Journal* published in August, 2011, featured a "select and eclectic" group of articles all based on applied and basic research. The *Special Edition*, and some of the research, was funded by the AANA Foundation, whose president, Louise Herschkowitz, CRNA MSHA, wrote, "As our profession evolves, and as more CRNAs grow through doctoral education, the quantity and quality of both clinical and basic science research is rapidly expanding."

The Editor-in-Chief of the *AANA Journal*, Chuck Biddle, CRNA PhD, in an editorial wrote, "Of great pride to me is the quality and diversity of work that I see emerging from colleagues

nationwide, research that is altering the landscape of anesthesia care. I believe that strongly held views based on belief rather than sound evidence still exert too much influence on healthcare decision making. The age of evidence-based practice is upon us, and we should actively embrace the opportunity that it provides to merge research, skill, intuition, and humanitarianism."

EMINENT NURSE ANESTHETISTS FROM HISTORY

Olive L. Berger (1898-1981)

Olive Berger made her mark in clinical anesthesia at Johns Hopkins in Baltimore, Maryland, where she received her anesthesia training and held the position of chief anesthetist from 1931 until her retirement in 1967. She administered the anesthesia for the first total pneumonectomy performed at Johns Hopkins, and Miss Berger was the first nurse anesthetist to administer anesthesia to infants for the repair of tetralogy of Fallot. Berger and Helen Lamb, of Barnes Hospital, St. Louis, Missouri, developed an endotracheal technique for intrathoracic surgery. She served as president of the American Association of Nurse Anesthetists (AANA) from 1958 to 1960, and was awarded the Agatha Hodgins Award for Outstanding Accomplishment in 1980.

Margaret G. Boise (1883-1972)

While employed at Presbyterian Hospital in New York City, Margaret Boise traveled to St. Mary's Hospital in Rochester, Minnesota, in 1910, to be trained in ether anesthesia by Florence Henderson. She then trained other nurses at Presbyterian Hospital, and later at Johns Hopkins. In 1913, Samuel J. Crowe, head of otolaryngology at Johns Hopkins, employed Boise to provide anesthesia to his patients. She soon was also employed by urologist Hugh H. Young, and they collaborated on a gas-ether machine known as the Boise-Young apparatus. She also created a simple anesthesia machine for tonsillectomies. Boise also gave anesthetics to most of chief surgeon William Stewart Halstead's patients and was appointed head anesthetist in the surgical department.

Catholic Sisters (late 1800s to early 1900s)

Catholic Sisters around the United States played a prominent role as early nurse anesthetists. Because healing of the sick was part of their religious vocation, they established hospitals and nursing schools across the county. Many of these early nurse anesthetists were discovered by Virginia S. Thatcher while doing research for a history of nurse anesthesia. In 1877 Sister Mary Bernard, a nurse at St. Vincent's Hospital in Erie, Pennsylvania, was the first nurse known to specialize in anesthesia. The Hospital Sisters of the Third Order of St. Francis at St. John's Hospital in Springfield, Illinois, gained prominence starting in 1880 when Sister Aldoza Eltrich and others were trained in open drop ether and chloroform. Their nursing school first began to teach anesthesia to Sisters in 1912, and in 1924 the nurse anesthesia school was open to lay nurses under the direction of Sister Rudolpha, a devoted educator until her death in 1969. The AANA presented the 1954 Award of Appreciation to the Order in 1954 for their longtime contribution to the education of nurse anesthetists. Other sisters of note include Sister Mary Cyrilla Erhard, who journeyed to Hawaii in 1886 and administered anesthesia at a Maui hospital for 42 years.

Col. Mildred Clark (1915-1994)

Mildred Clark had a long and distinguished career in the Army Nurse Corps (ANC). She took her anesthesia training at Jewish Hospital, Philadelphia, 6 months after joining the ANC in 1938. She was stationed at Schofield Barracks when Japan bombed Pearl Harbor in 1941, and later served in numerous leadership roles both in the United States and at the 382nd Station Hospital in Korea. In 1947 she became the Director of Nurses of the XXIV Corps in Korea and less than a year later, Chief Nurse of the Far East Command in Tokyo, Japan. Her assignment as Procurement Officer in the Surgeon General's Office tested her skills and creativity to recruit nurses during a nationwide nursing shortage. In 1963 she was the first nurse anesthetist to be appointed as Chief of the Army Nurse Corps, and she served in this position until her retirement in 1967.

Mary Alice Costello (1943-2001)

Mary Alice Costello, a nurse anesthesia educator, founded the Cincinnati General Hospital School of Nurse Anesthesia (later the University of Cincinnati School of Nurse Anesthesia) in 1945 and served as its director for 27 years. Costello was one of the first nurse anesthetists to become adept at the administration of regional anesthesia and instructed nurse anesthetists from around the country in regional techniques. She also dedicated a large part of her career to the AANA and the Ohio Association of Nurse Anesthetists, serving as president of both organizations as well as serving on numerous committees. She was awarded the AANA's Helen Lamb Outstanding Educator Award in 1987.

Adeline Curtis (1897-?)

Adeline Curtis was employed as staff anesthetist from 1921 to 1928 at the Johnston-Wickett Clinic in Anaheim, California, to give anesthetics to patients of three surgeons working in Orange County hospitals. She resigned in 1928, when the California Board of Medical Examiners published a resolution alleging that nurse anesthetists were not licensed to provide anesthesia. She believed that she was within her scope of practice and employed an attorney who received a statement by the state attorney general that there was no law in California prohibiting a nurse from giving anesthesia. She resumed giving anesthetics at the clinic, and her experience prompted the Los Angeles nurse anesthetists to band together and form the California Association of Nurse Anesthetists. This was the first attempt to limit anesthesia by nurses in the state, and Curtis would later provide financial support to Dagmar Nelson when she was taken to court over the same charge in 1933.

Gertrude L. Fife (1902-1980)

Gertrude Fife was a dedicated leader of the AANA whose work provided a foundation for subsequent growth of the organization. Upon graduating from Lakeside Hospital School of Anesthesia in Cleveland, Ohio, in 1925, she was immediately appointed a member of the staff. Fife was appointed director of the school in 1934 and she served in that position, and as director of University Hospitals' anesthesia department, until her retirement in 1946. Fife worked closely with cardiac surgeon Claude S. Beck, and the "mechanical control of respiration during intrathoracic operations originated with" Beck, Fife, and F.R. Mautz. Fife virtually took over the running of the newly formed AANA in 1933 when president Agatha Hodgins fell ill and planned the first annual meeting in less than 6 months. She was a farsighted educator who implemented and extended many of Hodgins' educational goals. She promoted the idea of accreditation of schools in her address at the first annual meeting, and advocated a national board examination for nurse anesthetists. Her dedication to the AANA was unwavering. She was a charter member of the AANA and served as AANA's second president, AANA's journal editor from 1933 to 1944, and treasurer from 1935 to 1950. She was the recipient of AANA's Award of Appreciation in 1950 and the Agatha Hodgins Award for Outstanding Accomplishment in 1978.

John F. Garde (1935-2009)

John Garde's career spanned 44 years, including serving as the director of the Wayne State University School of Anesthesia, Detroit, Michigan, and as AANA's education director (1980-1983) and executive director (1983-2001). Additionally, he served a term as AANA president (1972-1973), which made him the first male to hold that position. Among the most notable accomplishments during Garde's tenure at AANA were the advancement of nurse anesthesia education programs to a graduate framework; the development of AANA public policy and a federal government affairs office in Washington, D.C.; and attainment of Medicare direct reimbursement for CRNAs. He received AANA's Helen Lamb Outstanding Educator Award in 1981 and the Agatha Hodgins Award for Outstanding Accomplishment in 2000. In 1994 he was named a Fellow of the American Academy of Nursing (AAN) and was posthumously inducted into the AAN Hall of Fame in 2009, the first nurse anesthetist to receive that honor.

Ira Gunn (1927-2011)

Ira Gunn was a polymath who saved and advanced nurse anesthesia several times. As an educator, Gunn established anesthesia educational programs at Tripler and Walter Reed Army Medical Centers. In the mid-1970s, together with Ruth Satterfield and Mary Cavagnaro, Gunn developed the AANA councils that assured the autonomy of accreditation and certification processes. Gunn is credited with mending the rift between organized nurse anesthesia and other nursing associations. She also was vitally involved with federal government relations during the 1980s when AANA secured legislation to assure "pass through" payment for CRNA costs and direct reimbursement for CRNA services. Gunn had exceptional writing abilities. She published many articles and edited journals. She was a coauthor of the AANA amicus curiae brief to the U.S. Supreme Court in the case of *Jefferson Parish Hospital v. Hyde*. Her many accolades included Fellow of the American Academy of Nursing (1981), the Agatha Hodgins Award (1983), the Order of Military Medical Merit (2001), and the American Academy of Nursing Living Legend Award (2003).

Edith Graham (1871-1943)

Edith Graham was the first anesthetist at St. Mary's Hospital in Rochester, Minnesota. In fact, she was the first trained nurse in the community, having received her nursing instruction at Women's Hospital in Chicago; she also taught nursing to the Sisters of St. Francis who staffed the hospital. Graham provided safe anesthesia for patients of Dr. Charles M. Mayo and Dr. William J. Mayo from 1889 to 1893, her career ceasing with her marriage to Charles Mayo. She was the only anesthetist during those years; as testament to her skills, of the 655 patients who were operated upon, 98.3 percent left the hospital alive.

Margaret Hatfield (dates unknown)

Although little is known about Margaret Hatfield, it was her administration of anesthetics for patients of Louisville surgeon Louis Frank that was the center of the 1917 legal case, *Frank v. South*. After the Kentucky State Medical Association passed a resolution instructing its members not to employ nurse anesthetists because they deemed it was a violation of the practice of medicine, Frank decided to take the issue to the courts. On appeal, the case was decided in favor of the plaintiffs and confirmed that nurse anesthetists were not engaged in the practice of medicine.

Florence Henderson (1876-1956)

Florence Henderson was another prominent nurse anesthetist who was hired by the Mayo brothers at St Mary's Hospital in Rochester, Minnesota. She provided safe anesthesia to patients of Dr. Charles Mayo from 1904 to 1917 and was a specialist in the administration of ether. She disseminated her knowledge by speaking at medical societies and publishing articles. In 1913 she read her paper, "Ether Anaesthesia," before the Southern Minnesota Medical Association, where she was the only nurse to speak. Her paper was published the next year in the *St. Paul Medical Journal*. In 1917 she moved to California and provided anesthesia for patients of a group of surgeons until her retirement in the 1920s.

Agatha Hodgins (1877-1945)

In 1908 surgeon George Crile asked Agatha Hodgins to be his anesthetist at Lakeside Hospital, Cleveland, Ohio. Her skills as an educator emerged, and soon Hodgins began to instruct nurses in the administration of anesthesia. In 1914 she served with Crile and others from Lakeside Hospital in France during World War I; together they introduced nitrous oxide/oxygen anesthesia to those performing war surgery, and Hodgins trained many in its safe administration. Hodgins formalized the Lakeside Hospital School of Anesthesia in 1915 after her return from France, and served as director from 1915 to 1933. She saw the need for nurse anesthetists to band together, and in 1931 she founded the AANA and was elected the first president (1931-1933). She was committed to improving educational standards and helped lay the groundwork for the association's program to accredit schools of nurse anesthesia, implemented after her death. Among Hodgins' publications are a chapter on nitrous oxide/oxygen anesthesia in Crile's *Anoci-Association* and two articles in the *Archives of Surgery*.

Alice Hunt (1880-1956)

Surgeon Philemon Truesdale asked Alice Hunt to be his anesthetist in 1908, and she received training in open drop either and nitrous oxide/ether. In 1917 she went to Peter Bent Brigham Hospital in Boston, where she trained both nurses and medical interns in the administration of anesthesia and gained recognition for her skillful administration of nitrous oxide/oxygen anesthesia. In 1920 an article she co-authored with surgeon Elliot C. Culter on postoperative complications was published in the *Archives of Surgery*. After the war ended, she became the anesthetist to Samuel Harvey, professor of surgery at Yale. She also was appointed as instructor of anesthesia with university rank in 1922. Later she was promoted to assistant professor in 1930 and taught nurses and medical students for 26 years. In 1949 she became the first nurse anesthetist to author a book, *Anesthesia: Principles and Practice*.

Helen Lamb (1899-1979)

Helen Lamb is an example of the productive collaboration between nurse anesthetists and surgeons. She developed and administered the anesthetic for the world's first successful pneumonectomy in 1933, performed at Barnes Hospital in St. Louis, Missouri, by surgeon Evarts Graham and contributed a chapter on endotracheal anesthesia to Graham's *Thoracic Surgery*. She also collaborated with Richard van Foregger in the development of the van Foregger anesthesia machine used at Barnes. In addition to her clinical work, Lamb founded the school of anesthesia at Barnes Hospital, St. Louis, Missouri, in 1929, and served as director until 1951. She was a charter member of the AANA and served as the fifth president (1940-1942). She was chair of the AANA Education Committee for over 10 years and tirelessly worked to establish the curriculum and minimum standards for schools of nurse

anesthesia. Lamb also organized the Missouri Association of Nurse Anesthetists and was its first president.

Betty E. Lank (1904-2001)

Betty Lank was a nurse anesthetist at Children's Hospital in Boston, Massachusetts, for 34 years (1935-1969) and was an early specialist in pediatric anesthesia. She quickly adopted cyclopropane for pediatrics in 1938 and published an article on its benefits the next year. Lank worked closely with renowned surgeon Robert E. Gross and safely administered the anesthesia while Gross divided the first patent ductus arteriosis in 1938; she also administered the anesthetic for the first successful esophageal atresia repair performed by William Ladd in 1939. Lank advanced pediatric anesthesia through the development of pediatric-sized anesthesia mask and ventilation bags. She also assisted in the design and creation of the hospital's first postanesthesia recovery room.

Alice Magaw (1860-1928)

In 1893 Alice Magaw became the anesthetist for Drs. William J. and Charles H. Mayo at St. Mary's Hospital in Rochester, Minnesota, a position she held until 1908 when she married Dr. George Kessel. Charles Mayo bestowed upon her the name "Mother of Anesthesia" for her mastery of open drop ether. In 1899, Magaw became the first nurse anesthetist to be published when the *Northwestern Lancet* printed her article "Observations in Anesthesia." Five more articles would follow. She spoke before a number of medical societies, unusual for a nurse at that time, detailing her safe administration of anesthetics. Many surgeons around the country sent their nurses to Magaw for anesthesia training. She gained a reputation for quietly talking the patient to sleep, without the struggle seen so often elsewhere.

Agnes McGee (1885-?)

Agnes McGee established the first postgraduate course in anesthesia at St Vincent's Hospital in Portland, Oregon, in 1909. The training included instruction in anatomy, the physiology of the respiratory track, and the pharmacology of anesthetic agents. McGee also taught third-year students at the University of Oregon Medical School. For her work as an educator, the AANA bestowed upon her the 1953 Award of Appreciation.

Florence McQuillen (1903-1981)

In 1927 John S. Lundy invited Florence McQuillen to join his staff at the Mayo Clinic. She worked closely with Lundy as chief nurse anesthetist and as a clinical instructor, and collaborated with him in editing and abstracting articles for *Anesthesia Abstracts*. In 1948 she became the first AANA executive director, a position she held until her retirement in 1970. In her 22 years with the AANA, McQuillen was influential in virtually all areas of the AANA's growth and expansion. Under her guidance, the U.S. Department of Health, Education, and Welfare officially recognized the AANA's authority to grant accreditation for nurse anesthesia programs and to grant certification for nurse anesthetists. She also instituted the AANA's voluntary continuing education program, which made the AANA the first professional nursing organization to recognize the need for continuing professional education; this eventually led to the adoption of a mandatory continuing education (CE) program. She received the AANA Award of Appreciation in 1970.

Ruth M. Nash (1882-?)

Ruth Nash, a graduate of the New York Post-Graduate Hospital, one of the early postgraduate schools of anesthesia, which was established in 1912, took over the postgraduate school of anesthesia in 1917. She was also appointed special lecturer on anesthesia for the department of physiology and pharmacology of the Long Island College of Medicine in 1927.

Jack Neary (1945-2009)

Jack Neary was a pioneer in pain management education and practice. He practiced for 23 years at Cottage Hospital, Woodsville, New Hampshire, and served as the anesthesia department director beginning in 1985. He expanded the department, began offering epidurals for labor and delivery, and developed a postoperative pain service. He extensively lectured and taught pain management and regional anesthesia techniques throughout the country. He also was an adjunct clinical faculty member and associate professor at the University of New England School of Anesthesia where he inspired and mentored many students. A strong political advocate, Neary fought for nurse anesthetists' practice rights throughout his career and worked with the AANA on policy and regulatory issues surrounding pain management. He received the AANA's Alice Magaw Outstanding Clinical Practitioner Award in 1999 and the Agatha Hodgins Award for Outstanding Accomplishment in 2009 (posthumously), and the New Hampshire Nurse Practitioner of the Year Award in 2006.

Dagmar Nelson (1892-1958)

Dagmar Nelson received her anesthesia training at St. Mary's Hospital, Rochester, Minnesota, where she worked for a short time; she later went to Los Angeles at the request of surgeon Verne Hunt, who was working at St. Vincent's Hospital. Nelson was the hospital's sole anesthetist. In 1933 she became the defendant in a landmark legal case, *Chalmers-Francis v. Nelson*, which alleged she was violating the California Medical Practice Act by administering anesthesia, that is, practicing medicine without a license. A lower court found in her favor and upon the plaintiff's appeal, the case went to the California Supreme Court. The judgment rendered in 1934 again found in favor of Nelson and confirmed the legality of nurse anesthesia practice.

Anne Penland (1885-1976)

In 1912 Anne Penland was trained in anesthesia by Margaret Boise at Presbyterian Hospital in New York City. During World War I, Penland was the only nurse anesthetist with the New York Presbyterian Hospital Unit (Base Hospital No. 2) and was the first official nurse anesthetist on the British front. Penland's demonstration of her anesthesia skills contributed to the decision by the British to train their nurses in anesthesia; Base Hospital No. 2 was one of the training centers for the British nurses and Penland served there as instructor. After the war, Penland served as Presbyterian Hospital's chief anesthetist for 20 years.

Hilda Salomon (1895-1983)

Hilda Salomon's career as a nurse anesthetist educator took place at Jewish Hospital in Philadelphia. She was appointed chief of the anesthesia department in 1924, and she founded the Jewish Hospital School of Anesthesia in 1929 and served as its director until her retirement. While director, she instituted regular local meetings among the students and faculty of the many schools of anesthesia then functioning in Philadelphia. She was a charter member of the AANA and was its third president (1935-1937). During her AANA presidency, she promoted several ideas that were considered radical for the time. In particular, she called for a

proposal permitting the membership of male and African-American nurse anesthetists. She also helped organize the Pennsylvania Association of Nurse Anesthetists and also served as president. In recognition of her service, she received AANA's Award of Appreciation and the Agatha Hodgins Award for Outstanding Accomplishment.

Col. Ruth Satterfield (1913-2008)

Ruth Satterfield dedicated her life to the development and advancement of nurse anesthesia education. The majority of her career was spent in the Army Nurse Corps, which she joined in 1940. She served as education director of all army schools of nurse anesthesia and director of the Army Nurse Corps Anesthesia Course at Walter Reed General Hospital in Washington, D.C. She concluded her army career as consultant to the Army Surgeon General. She also continued her work as Education Consultant to the AANA (1968-1981). Her honors include the second Oak Leaf Cluster to the Army Commendation Medal for her work as Special Course Director, Anesthesia, William Beaumont General Hospital; the prestigious Order of Military Medical Merit for her "sustained contributions to the betterment of Army medicine;" and the first AANA Annual Agatha Hodgins Award for Outstanding Accomplishment.

Sister M. Yvonne Jenn (1910-2002)

Sister Yvonne was a dedicated educator. She founded the St. Francis School of Anesthesia in La Crosse, Wisconsin, in 1942 and served as its director until her retirement in 1981. She also served as the director of anesthesia for the hospital. Sister Yvonne worked to ensure her students learned about new and innovative techniques and anesthetic agents, and she included ethics in schools curriculum long before it was popular. She was a pioneer in the field of respiratory therapy and served 12 years as registrar for the American Association for Respiratory Care. She received the AANA's Agatha Hodgins Award for Outstanding Accomplishment in 1982 and the Helen Lamb Outstanding Educator Award in 1995.

Helen Vos (1914-2007)

Helen Vos's career was marked by her dedication to the education of nurse anesthetists both in the United States and abroad. After serving 4 years in the Army Nurse Corps in the 1940s, she became the first director of the anesthesia program at Hurley Hospital in Flint, Michigan, and discovered her passion for teaching. She taught anesthesia in Lahore, Pakistan, for 4 years, and also served as Educational Director at the anesthesia program at Barnes Hospital, St. Louis. Most notably, she was the second director (1963-1977) of the North Carolina Baptist Hospital School of Anesthesia, Winston-Salem, North Carolina, where she was also appointed Assistant Professor, Allied Health Programs, Bowman Gray School of Medicine. She also traveled throughout the country presenting continuing education lectures and taught countless numbers of CRNAs the meaning of the "three-lead EKG." She served as the 1966-1967 AANA president and was presented with the AANA's Agatha Hodgins Award for Outstanding Accomplishment in 1979 and the Helen Lamb Outstanding Educator Award in 1996.

Sophie Jevne Winton (1887-1989)

A practitioner in anesthesia for more than 50 years, Sophie Winton began her career at Swedish Hospital in Minneapolis where she was trained in anesthesia. In 1918 she joined the Nursing Corps, then part of the Red Cross, and was assigned to Mobile Hospital No. 1 in the Chateau-Thierry area, often giving as many as 25 to 30 anesthetics a day with open drop ether and chloroform. She received the Croix de Guerre and six overseas service bars for her service on the front lines. In 1933 she lent her financial support in a test case (*Dagmar Nelson v. Chalmers-Frances*) in California that was to have far-reaching effects on the practice of nurse anesthesia. Winton was an early independent practitioner and managed her own dental and plastic surgery clinic in California until 1960. She was awarded honors by the Mexican Dental Association in conjunction with the International Dental Association for her advancement in the delivery of dental anesthesia. In 1984 she was presented with the AANA's Agatha Hodgins Award for Outstanding Accomplishment.

SUMMARY

Nurses were recruited into the field of anesthesia by surgeons in the latter half of the nineteenth century because inexpert clinical anesthesia administration by others often resulted in morbidity and mortality. The Civil War was the earliest documented use of nurses as anesthetists, and it became a trend afterward. By the 1890s, nurse anesthesia was well established, having spread from Midwestern Catholic hospitals to cities on both coasts. Before the turn of the twentieth century, nurse anesthetists provided gratuitous training to others. The first hospital-based anesthesia educational program opened in 1909. During World War I, nurse anesthetists were widely credited with significantly reducing combat-related surgical morbidity and mortality. By 1920, nurse anesthesia had become well established and well accepted.

Nurse anesthetists formed a national organization in 1931. Dedicating themselves to advancing anesthesia education and patient safety, nurse anesthetists implemented a number of firsts: annual meetings, a monthly bulletin, and a journal. In 1945 the first certification examination for graduates was implemented. As a result of service in the mid-century wars, nurse anesthetists earned officer's status, and men gained the right to join the military's nurse corps. When the military demanded that its nurse anesthetists pass the AANA certification examination, civilian hospitals soon followed suit. By the 1950s, nurse anesthetists worked with surgeons and engineers to pioneer anesthesia machinery, ventilators, and anesthesia for pediatric cardiovascular surgery. During this era, accreditation of anesthesia training programs was achieved.

The second half of the twentieth century was marked by a closer involvement between the profession and government. As Medicare paid for a larger proportion of clinical anesthesia services, the government in turn exerted increasing control over how those services were rendered and at what cost to taxpayers. Because federal dollars also went for nursing education, government exerted a measure of control over accreditation. Independent councils on accreditation, certification, recertification, and public interest evolved from this.

In the 1960s and 1970s, state governments modernized nurse practice acts to account for new subspecialties in advanced practice nursing. CRNAs had to participate even though they had long predated other advanced practice nurses. The 1980s and 1990s brought about governmental efforts to "reform" health care by extending services and containing costs. Quality of care entered the debate, and CRNAs ultimately proved what had been shown 50 years earlier: anesthesia outcomes are no worse and perhaps better when a CRNA administers the anesthetic. For CRNAs, constant vigilance and a presence in federal and state government

centers were essential because each of the aforementioned policy changes presented organized anesthesiologists with an opportunity to threaten nurse anesthesia. As a result, state nurse anesthetist associations became stronger, and the AANA established an office in Washington, D.C.

Progress in nurse anesthesia has occurred over many decades and resulted in an extraordinary record of patient safety. CRNAs have undertaken hundreds of clinical, scientific, and policy research projects to further professional and public understanding of nurse anesthesia.

CHAPTER 2

Nurse Anesthesia Specialty Practice and Education in the United States

◆ *Francis Gerbasi, Betty Horton, Lisa J. Thiemann, and John C. Preston*

In existence for nearly 150 years, the specialty practice of nurse anesthesia has become one of the most challenging and rewarding areas of advanced nursing practice. Nurse anesthetists, together with their professional association, the American Association of Nurse Anesthetists (AANA), have been role models for members of other nursing groups and allied health organizations. This chapter describes current educational requirements to become a Certified Registered Nurse Anesthetist (CRNA), the roles of the CRNA, and the roles the councils and the AANA play for the profession.

NURSE ANESTHESIA EDUCATIONAL REQUIREMENTS

The upgrading of academic credentials for CRNA educators and their graduates has always been closely tied to the goals of the professional association— advancing the art and science of anesthesia.[1] Nurse anesthesia leaders have been responsible for increasing the requirements for curricular content, faculty qualifications, and academic credentials for graduates since early in the twentieth century. Over time, nurse anesthesia programs have moved from apprenticeships at hospitals into degree-granting institutions fulfilling the vision of early anesthesia leaders for a university education for nurse anesthetists. This movement into academia required identifying the locations of programs in the nation, determining the essential characteristics of programs, agreeing on curricular requirements, inspecting programs, and developing a program approval process.

Nurse Anesthesia Education Today

Nurse anesthesia programs are governed by the *Standards for Accreditation of Nurse Anesthesia Educational Programs*.[2] The processes used to accredit programs are focused on ensuring compliance with the *Standards* and the Council on Accreditation of Nurse Anesthesia Educational Programs' (COA) *Accreditation Policies and Procedures*.[3] Revisions to the *Standards* and the accreditation policies occur periodically to ensure they continue to reflect the current requirements to prepare graduates for entry into practice, meet U.S. Department of Education (USDE) and the Council for Higher Education Accreditation (CHEA) recognition requirements and promote improvement in nurse anesthesia education.[4] In 2011 the COA initiated a major revision of its standards with the purpose of establishing new practice doctorate standards. The new standards will be used by the COA to assess programs transitioning to award practice doctoral degrees. The COA requires all students accepted into an accredited nurse anesthesia program on January 1, 2022, and thereafter to graduate with doctoral degrees (refers to Standard III, Criterion C2).[2]

Nurse Anesthesia Program Requirements

Nurse anesthesia programs are required to demonstrate compliance with the *Standards* and the *Accreditation Policies and Procedures*. The requirements include the need for programs to assess their integrity and educational effectiveness through ongoing evaluation and assessment. Programs must continually monitor and evaluate their didactic and clinical curriculum, including, but not limited to, curricular content, admissions policies, faculty, and clinical sites used for student educational experiences. In addition to programs' internal assessment processes, programs must submit annual reports to the COA, complete self-studies and host onsite COA visits at a maximum of every 10 years. The COA monitors programs' indicators of success and the attainment of their stated outcomes. This includes programs' pass rates on the National Board of Certification and Recertification for Nurse Anesthetists' (NBCRNA) national certification examination (NCE). Programs must demonstrate graduates take the NCE examination and pass it in accordance with the COA's pass-rate requirement.[3] The COA also monitors programs' attrition and employment rates. Programs are required to post their first-time NCE pass rates, attrition rates, and the employment rates of its graduates on their websites and to link their websites to the COA's list of recognized programs.[5] These stringent requirements help ensure the effectiveness of nurse anesthesia clinical and didactic education and also that the public is being provided with accurate information related to student achievement.

The COA has requirements related to the administration of nurse anesthesia programs. The requirements include programs' management of faculty and students, fiscal management, maintenance of COA accreditation and other higher-education accreditation requirements of the universities, faculty continuing education, and program evaluations. The COA Standards require that nurse anesthesia programs employ Certified Registered Nurse Anesthetists (CRNAs) with graduate degrees in the roles of program administrator and assistant program administrator. In addition, programs must demonstrate they provide an extensive educationally sound curriculum combining both academic theory and clinical practice. Programs must develop and implement policies and procedures that use outcome criteria to promote student learning while simultaneously enhancing the programs' quality and integrity.

The COA Standards also identify the minimum admission requirements. Admission to nurse anesthesia programs requires graduation from a school of nursing, a baccalaureate degree, current licensure as a registered nurse, and at least 1 year of professional experience in a critical care setting. The critical care experience must provide experiences for the registered nurse to develop as an independent decision maker capable of using and interpreting advanced monitoring techniques based on knowledge of physiologic and pharmacologic principles. Programs determine what types of work experience are acceptable for admission. Typical critical care areas include surgical, cardiothoracic, coronary, medical, pediatric, neurologic, and neonatal intensive care units.

Nurse Anesthesia Program Curriculum

The didactic curricula of nurse anesthesia programs are governed by the COA Standards and help ensure students are provided with the scientific, clinical, and professional foundation upon which to build sound and safe clinical practice. Based on the 2011 COA Annual Report data from all nurse anesthesia programs, the number of graduate semester credits for nurse anesthesia programs are greater than other graduate degrees in health professions.[6] The curriculum of graduate nurse anesthesia programs includes courses in anatomy, advanced physiology/pathophysiology, advanced health assessment, advanced pharmacology, chemistry, biochemistry, physics, professional issues, equipment, technology, pain management, research, clinical conferences, chemical dependency, and wellness (refer to Standard III, Criterion C14 and C21).[2] Courses in nurse anesthesia practice provide content such as induction, maintenance, and emergence from anesthesia; airway management; anesthesia pharmacology; and anesthesia for special patient populations such as obstetrics, geriatrics, and pediatrics. In addition, students are instructed in the use of anesthesia machines and other related biomedical monitoring equipment. Programs must evaluate students' knowledge and skills to ensure they are meeting the programs' stated objectives as they progress in the program.

The methods used to deliver nurse anesthesia curricula are changing as new technologies are being applied in higher education. Based on COA 2011 Annual Report data, more than 60% of nurse anesthesia programs use some form of distance education in their provision of didactic instruction.[6] Programs' distance education offerings vary from several core courses to programs in which the majority of the didactic curriculum is provided using distance education. In addition, 98% of programs report having access to some form of simulation (e.g., simple models, computer, full-body patient simulation).[6] The involvement of individual programs ranges from the use of simulation to supplement traditional content delivery methods to the utilization of simulation to entirely deliver curricular content.

The clinical curriculum of nurse anesthesia education provides students with an opportunity to apply didactic knowledge in clinical practice. Programs prepare graduates with the knowledge and skills to administer all types of anesthesia, including general, regional, and selected local and moderate sedation to patients of all ages for all types of surgeries. Students use a variety of anesthesia drugs, manage fluid and blood replacement therapy, and interpret data from sophisticated monitoring devices. Additional clinical responsibilities include the insertion of invasive catheters, the recognition and correction of complications that occur during the course of an anesthetic, the provision of airway and ventilatory support during resuscitation, and pain management. To meet COA Standards and be eligible to take the NCE, a student must have performed a minimum of 550 anesthetics, which must include specialties such as pediatric, obstetric, cardiothoracic, and neurosurgical anesthesia.[2] The anesthesia experiences include the care of not only healthy but critically ill patients of all ages for elective and emergency procedures. In most programs, the minimum number of clinical experiences is surpassed early in the clinical practicum. Based on 2011 certification transcript data, nurse anesthesia programs provide an average of 846 cases, 1683 hours of anesthesia clinical experience, and 2519 total clinical hours for each student.[7]

During students' clinical experiences, they must be supervised by CRNAs or anesthesiologists who provide instruction in the administration and monitoring of various techniques, including both general and regional anesthesia. The clinical faculty evaluates the technical and critical thinking skills of students. The entry into practice competencies for the nurse anesthesia professional are those required at the time of graduation to provide safe, competent, and ethical anesthesia care to patients for diagnostic, therapeutic, and surgical procedures (refer to Standard III, Criterion C21).[2] The entry into practice competencies should be viewed as the structure upon which the nurse anesthetist continues to learn new facts, obtain and refine knowledge, and develop skills along the practice continuum that starts at graduation (competent), and continues throughout their entire professional career (expert).

Future Specialization

Although nurse anesthesia entry-level education prepares individuals for the full scope of nurse anesthesia practice, certain areas of specialized practice are currently available to promote interested CRNAs to further develop additional post-entry knowledge and skills related to their preparation in specific areas of nurse anesthesia practice. One example of this type of specialization preparation is a postmasters certificate in pediatric anesthesia available through Wayne State University in Detroit, Michigan. This program provides selected CRNAs and/or graduate nurse anesthesia students with the opportunity for continued focused preparation in the practice area of pediatrics through an arrangement with Children's Hospital of Michigan.[8]

Another area of specialization that has been developed for practicing certified registered nurse anesthetists is in the area of nonsurgical (chronic) pain management. In 2008 the AANA assembled a group of CRNA practitioners who were identified as devoting most or all of their clinical practice to this specialized area. Through the input and guidance of this group of leaders, a theoretical foundation for pain practice was operationalized, and subsequently work was initiated to formalize the continuing education content for nurse anesthetists expressing an interest in nonsurgical pain management. Although the short-term goal was to develop comprehensive continuing education in this content area, the longer-term goal was to develop the preparation of these practitioners into a more formalized educational framework. Hamline University in St. Paul, Minnesota, was identified as possessing the traits and resources necessary for an ideal academic partner to house and offer a formal higher education program in advanced pain management for the nurse anesthesia community. The final product of this partnership was a four-semester/15 month postmasters educational program in advanced pain management.[9] Although other specialty groups could eventually avail themselves of this education, the commitment was to first focus on the nurse anesthesia community and to expand enrollment to other practice disciplines over time, based on demand and the adequacy of educational resources. The first class of students enrolled in this landmark educational undertaking began their program of study on February 1, 2012.

Also, at the time of this chapter's publication, no post-National Certification Examination for Nurse Anesthetists had been developed for either of the two areas of educational specialization noted previously. However, the NBCRNA is committed to "…continue to explore strategies to meet its goals and the needs of the profession. The future requirements for recertification and the possibility of specialty credentialing for subspecialty areas (pain management, pediatric, cardiac, and other clinical specialties) are under consideration."[10] Essential to this consideration will be the preparation of adequate numbers of individuals who have successfully completed post-entry level educational programs. Until an acceptable number of individuals are prepared and in the workforce, it is unlikely that any certifying examination would be considered for development.

Equally important to the development of new and varied areas of specialized post-entry to professional nurse anesthesia education is the need to remain mindful of the APRN Consensus Model.[11] This model for education, accreditation, and certification for advanced practice nursing specifically identifies that areas of educational specialization within advanced practice nursing that occur beyond the levels of role and/or practice foci are not to be used as sources for regulation of practice, but rather to serve the individual nursing practitioners in their delivery of care and services.[11] Therefore, future examination for specialty areas of practice by the certified Registered Nurse Anesthetist, above the *role of nurse anesthetists* and the population foci of *across the lifespan* should not be used as a gate-keeping mechanism to prevent any CRNA from engaging in any subspecialty practice. As long as a CRNA can demonstrate he or she has obtained the knowledge, skills, and abilities necessary to engage in a specialized area, the individual practitioner should not undergo regulation via additional professional licensure.

THE CERTIFIED REGISTERED NURSE ANESTHETIST

CRNAs are anesthesia specialists who administer approximately 32 million anesthetics annually to patients in the United States.[12] As an advanced practice nurse, a CRNA can serve in a variety of capacities in daily practice, such as clinician, educator, administrator, manager, and researcher. CRNAs furnish anesthesia services to patients, using all anesthetic techniques, for all types of surgical, obstetric, diagnostic, and chronic pain management procedures. CRNAs practice in urban hospitals, critical access designated hospitals, ambulatory surgical centers, and U.S. military, public health services, and Veterans Administration healthcare facilities. CRNAs also practice in the offices of dentists, podiatrists, ophthalmologists, and plastic surgeons. In some states, they are the sole anesthesia providers in almost 100% of all rural hospitals, which enables these medical facilities to provide obstetric, surgical, diagnostic, and trauma stabilization services.[12]

CRNAs have a variety of employment possibilities available to them. The largest percentage of CRNAs are employed by hospital facilities; however, others are self-employed or are employees of anesthesiologists, academic institutions, military installations, or clinics. CRNAs provide anesthesia services in collaboration with other qualified practitioners, such as physicians (e.g., surgeons, obstetricians, or anesthesiologists), dentists, or podiatrists.[13] To become a CRNA, an individual must comply with the following requirements[11]:

- Hold a current and unrestricted state licensure as a registered professional nurse
- Graduate from a nurse anesthesia educational program accredited by the COA or its predecessor
- Successfully complete the NCE administered by NBCRNA or its predecessor

To maintain the CRNA credential, the individual must meet the requirements as set forth by the NBCRNA concerning continuing education, document substantial anesthesia practice, maintain current state licensure, and certify that he or she has no conditions that could adversely affect the ability to practice anesthesia.[14] More information regarding maintenance of certification may be found at the NBCRNA website: www.nbcrna.com.

CRNA Activities

Professional certification indicates that an individual has met predetermined criteria that measure the knowledge, skills, and abilities necessary for entry-level practice in a specialty area. Certification affords the public an awareness of the qualifications and capabilities of its healthcare providers. The credential CRNA indicates that the individual who holds it has fulfilled prescribed criteria and is qualified to provide the services described within a CRNA's scope of practice. The AANA publishes a scope of practice for CRNAs (Box 2-1).

BOX 2-1

Scope of Practice for Nurse Anesthesia Practice

CRNA scope of practice includes, but is not limited to, the following:

1. Performing and documenting a preanesthetic assessment and evaluation of the patient, including requesting consultations and diagnostic studies; selecting, obtaining, ordering, and administering preanesthetic medications and fluids; and obtaining informed consent for anesthesia
2. Developing and implementing an anesthetic plan
3. Initiating the anesthetic technique, which may include general, regional, and local anesthesia and sedation
4. Selecting, applying, and inserting appropriate noninvasive and invasive monitoring modalities for continuous evaluation of the patient's physical status
5. Selecting, obtaining, and administering the anesthetics, adjuvant and accessory drugs, and fluids necessary to manage the anesthetic
6. Managing a patient's airway and pulmonary status using current practice modalities
7. Facilitating emergence and recovery from anesthesia by selecting, obtaining, ordering, and administering medications, fluids, and ventilatory support
8. Discharging the patient from a postanesthesia care area and providing postanesthesia follow-up evaluation and care
9. Implementing acute and chronic pain management modalities
10. Responding to emergency situations by providing airway management, administration of emergency fluids and drugs, and using basic or advanced cardiac life-support techniques

From *American Association of Nurse Anesthetists* (AANA): *Scope and Standards for Nurse Anesthesia Practice*. Park Ridge, Ill: AANA, 2010. Accessed January 18, 2012 at http://www.aana.com/resources2/professionalpractice/Documents/PPM%20Scope%20and%20Standards.pdf.

Individual state or facility rules and regulations may influence CRNA scope of practice; therefore, it is the CRNA's responsibility to ensure that he or she is practicing within his or her scope of practice when providing anesthesia care. More information regarding CRNA scope of practice is available on the AANA website at www.aana.com.

In addition to defining CRNA scope of practice, the AANA also publishes expected standards for nurse anesthesia practice that describe CRNA behaviors concerning informed consent, monitoring, and documentation of care, to name a few. These standards apply to all anesthetizing locations and are intended to encourage high-quality care. The standards for nurse anesthesia practice are available at www.aana.com. CRNAs are consulted on a 24-hour basis and are an integral part of the healthcare team, lending their expertise in airway management, respiratory care, management of fluid and electrolyte problems, pain management, resuscitative efforts, and other related clinical activities.[12]

Apart from a clinical practice role, CRNAs often function in many other capacities. CRNAs hold administrative or other managerial positions; participate in quality improvement processes; lead research activities; collaborate in interdepartmental activities; and participate on various state and federal governmental agencies.

A large number of CRNAs are involved with the education of nurse anesthesia students and other healthcare professionals (e.g., flight nurses, medical students).

AANA ORGANIZATIONAL STRUCTURE AND FUNCTION

The American Association of Nurse Anesthetists (AANA) is a professional association that represents the majority of CRNAs and students nationwide. According to 2011 AANA data, more than 90% of CRNAs in the United States are members of the AANA.[11] The AANA was first incorporated in Ohio on March 12, 1932, as the National Association of Nurse Anesthetists (NANA). It was reincorporated in the state of Illinois on October 17, 1939, and was designated as a tax-exempt organization in accordance with subsection 501(c) of the Internal Revenue Code, and that same year the organization's name was changed to the American Association of Nurse Anesthetists.

Configurations and Relationships of Councils

In the 1970s, the AANA bylaws were revised to allow for the establishment of four separate autonomous councils under the corporate structure of the AANA: the Council on Accreditation of Nurse Anesthesia Educational Programs (COA), the Council on Certification of Nurse Anesthetists (CCNA), the Council on Recertification of Nurse Anesthetists (COR), and the Council for Public Interest in Anesthesia (CPIA). In recent years significant changes have occurred in the structure of the councils. In 2007 the CCNA and COR incorporated to form the National Board of Certification and Recertification for Nurse Anesthetists (NBCRNA). The COA separately incorporated in 2009, and in 2010 the AANA members voted on a bylaws change at the August 7, 2010, AANA annual business meeting to not continue to recognize the CPIA. Subsequent to that action the CPIA chose to not continue its activities and has since been dissolved. The COA and the NBCRNA are solely responsible for their own internal affairs, including the election of officers and the direction of financial activities. In accordance with their bylaws, membership on these councils includes CRNAs, students, hospital administrators, and members of the public.[15]

The councils have been established with the intention of informing and assuring the public that accreditation, certification, and recertification activities are within the discipline of nurse anesthesia and are separate from and not unduly influenced by the national professional association (i.e., AANA). Communication between the AANA, COA, and NBCRNA takes place through scheduled leadership meetings that facilitate discussion of issues of mutual concern. A CRNA executive director serves the COA, NBCRNA, and the AANA. More information on the COA and NBCRNA can be found at their websites: home.coa.us.com and www.nbcrna.com, respectively.

Today, AANA's bylaws, available at www.aana.com, are essentially the AANA's working constitution, which dictates how the association functions. The bylaws address the different classes of membership, decision-making procedures, responsibilities of the AANA's elected officials, the staff role and responsibilities of the Executive Director, the configuration of committees, functions of committee members, and the AANA's relationship with state nurse anesthesia associations.[15]

The AANA board of directors (BOD) is elected by voting-eligible members of the AANA and serves as the administrative authority for the AANA.[15] The BOD includes the president, president-elect, vice president, treasurer, and seven region directors. The BOD develops organizational policy; oversees the budget and related financial affairs; promulgates clinical standards and guidelines; participates in legislative activities; and serves as a liaison with external governmental and professional agencies. In addition, the BOD receives and considers the reports from the AANA staff, the various committees of the association, and the autonomous councils and makes recommendations as needed.

As of 2012, the AANA organization resides in three offices from Park Ridge, Illinois, to Washington, D.C., and employs over 128 people. The AANA Executive Director manages the daily activities of the Association with the assistance of the Deputy Executive Director and the senior directors of the various divisions. Collectively, the AANA staff carries out objectives as established by the elected AANA BOD and consistent with the AANA's mission statement to "advance patient safety, practice excellence, and its members' profession." With this in mind, the AANA supports advocacy activities at the local, state, and federal levels on behalf of its members and the public. The AANA's organizational structure and more information regarding the AANA divisions and its advocacy efforts are available at www.aana.com.

AANA Subsidiary

The AANA owns one subsidiary, the AANA Association Management Services (AAMS), which provides non–dues-related sources of revenue, as well as services for the general membership. There are currently two divisions within the AAMS. These divisions provide services related to insurance and housing (hotel rooms and lodging arrangements in association with meetings and events of the AANA) to both internal and external clients.[16]

SUMMARY

With the ongoing dedication of its members, volunteer leaders, and staff, the nurse anesthesia profession has been growing and evolving for well over a century. As they encounter the challenges resulting from healthcare growth and change, all CRNAs must take an active role in securing their future, because a profession is ultimately the sum of its members.

Legal Concepts in Nurse Anesthesia Practice

CHAPTER 3

◆ *Kenneth M. Kirsner*

Few issues in nurse anesthesia practice cause the type of consternation that legal issues do. Perhaps it is that they are not known to nurse anesthetists as well as the issues surrounding the actual administration of anesthesia. This chapter attempts to demystify some basic issues surrounding the interaction of the legal and anesthesia worlds. This chapter is not intended to give specific legal advice.

SOURCES OF LAW

The source for all American law is the Constitution of the United States.[1] All governmental power, state and federal, stems from that document. The Constitution cannot be changed by legislation nor can the President act in contravention of the Constitution. The Constitution can be changed only by amendment, a difficult process.[2] The final authority on the interpretation of the Constitution is the Supreme Court of the United States.[3]

The Supreme Court of the United States, however, makes rulings only on laws in reference to federal law. State laws are interpreted by their respective state courts, unless those laws violate the Constitution of the United States or other federal laws. If the state law violates the U.S. Constitution or other federal law, the federal law supersedes.[4]

Laws may come from any of the three branches of government set out in the Constitution, the legislative, the executive, or the judicial branch. The legislative branch, in the federal system also known as the Congress, creates laws that are known as *statutes*. These statutes must be passed by both houses of Congress, the Senate and the House of Representatives, after which they are presented to the President. If the President signs the bill, it becomes law. If the President vetoes the bill, Congress can override that veto by a vote of two thirds of both houses of Congress. States have similar procedures, but the exact process varies slightly between states.

Regulations are promulgated by administrative agencies. On the federal level these include agencies such as the Food and Drug Administration (FDA), the Occupational Safety and Health Administration (OSHA), and other agencies. On the state level, regulations are promulgated by agencies such as boards of nursing, medicine, and dentistry. Administrative agencies create regulations, and they also may have the function of determining whether regulations and statutes were violated. In this quasijudicial function, a license may be revoked or a person may be fined by the administrative agency. The actions of administrative agencies are reviewable by courts. Courts will review the process used and whether an agency's actions were within its statutory powers, but they generally do not review decisions based on their expertise in their respective fields.

Nurse anesthetists must maintain an awareness of what regulations apply to them. Failure to adhere to the board of nursing regulations and standards of care may result in actions against a nurse anesthetist's license, up to revocation of the license and fines. In 2003 a nursing board in Oklahoma revoked a nurse anesthetist's license and imposed a $99,000 fine for unsafe injection practices that resulted in 699 probable hepatitis C virus (HCV) infections and 31 probable hepatitis B virus (HBV) infections. The Board of Nursing's action occurred after the CRNA was reported by registered nurses working in his pain control clinic.[5] Other regulatory agencies such as the Centers for Disease Control and Prevention also make standards that courts may apply to nurse anesthetists.[6]

Courts also have a law-making function in their role of interpreting statutes and regulations. If there is any ambiguity in the way that a statute or regulation is worded, courts will interpret those laws according to the intention of the writers of the statute or regulation, as best as that can be determined. Courts will also interpret whether the statute or regulation in question violates the state or federal Constitutions. Thus, not only must statutes and regulations be viewed to determine what the laws are but also courts' interpretations of those regulations and statutes must be considered.

In the United States, court systems exist at both the state and federal levels. The state systems deal primarily with issues of state law. This includes most malpractice cases, licensure issues, and contracts. Federal courts deal primarily with federal law issues. However, overlap can occur in both areas. Sometimes federal issues are addressed by state courts that are in the process of dealing with a case concerning primarily state issues; the reverse also occurs. Further confusing the issue, many cases dealing with federal law may be brought in a state court. A federal court may hear a case that is solely a state law issue because the parties to the lawsuit are residents of different states and the amount under dispute meets the requirement for federal jurisdiction.

The federal court system and most state systems have three levels. The first level is the trial level. In the federal system, this is known as the district court. States refer to courts of this first level by many names, such as district courts, juvenile courts, small claims courts, and county courts. New York calls its trial level courts supreme courts. Once a case has been tried, the court's decision may be appealed to the intermediate appellate court. In the federal system this is the United States Court of Appeals. Parties to lawsuits usually have a right to appeal the case to the intermediate appeals court. Appellate courts consider only whether trial courts made mistakes of law. For example, an appellate court can overturn a trial court's decision because it improperly allowed evidenced to be entered that altered the outcome of the case. In this instance, the appellate court would remand the case to the trial court for retrial. An appellate court does not go over testimony or evidence in the case to determine whether it would have decided the case differently.

The highest level of court is the supreme appeals court. In the federal system, this is the United States Supreme Court. In some states, the name of the highest court is different. For example, in New York, the trial court is called the Supreme Court, the

intermediate appellate court is the supreme appellate court, and the supreme appellate court is the New York Court of Appeals. Some states also have two separate supreme courts, one for civil cases and one for criminal cases.

In the federal and in many state systems, parties in a lawsuit do not have a right to have a case heard by the supreme appellate court. For a case to be appealed to the United States Supreme Court, a petition called a *writ of certiorari* is sent to the Court requesting that it hear the case. The Court then decides whether the case deserves review. Many states use this method but also have additional mechanisms for obtaining state Supreme Court review. Some states allow a trial judge or intermediate appellate court to certify a question for state supreme court review.

CRIMINAL LAW

Law in the United States' legal system can be divided into two basic types: criminal law and civil law. Criminal law is the body of law established to protect society from harm, declaring what conduct is criminal and establishing punishment for violation of the law. Civil law is the body of law concerned with private rights and remedies. Civil law applies to torts (private wrongs other than a breach of contract) and breaches of contract.

Nurse anesthetists usually are more concerned with civil law issues than with criminal law issues. However, nurse anesthetists can violate criminal laws in several instances. Fraudulent filing of insurance or Medicare claims can violate federal and state laws. Nurse anesthetists who knowingly sign forms indicating that procedures were performed when they actually were not or stating that anesthesia providers were involved with a case when they were not can be subject to fines and imprisonment for Medicare or insurance fraud. A nurse anesthetist who is asked to sign or fill out false forms by an employer is not freed from criminal liability by virtue of the employment relationship. A nurse anesthetist who practices without appropriate licensure or who knowingly employs an unlicensed person to practice anesthesia can be criminally prosecuted. The misuse of controlled substances is another area of criminal law that concerns nurse anesthetists.

At the time of this chapter's writing, two nurse anesthetists are being prosecuted for racketeering, insurance fraud, and neglect of patients in the Las Vegas hepatitis cases.[7] Nurse anesthetists must be aware that billing one patient for a single-use vial of medication that is used on more than one person may constitute insurance fraud. Likewise, charging both patients for medication from a single-use vial may constitute insurance fraud.

CIVIL LAW

Malpractice (Torts)

Malpractice is part of a greater area of the law called *torts*. A tort is a civil wrong committed against a person or property independent of a contract. Torts include two types of civil wrongs: intentional torts and unintentional torts. Intentional torts are actions deemed to be violations of the civil law when they are performed intentionally. Intentional torts include assault, battery, and false imprisonment. The legal area of greatest concern for nurse anesthetists is malpractice, which is a form of negligence. The term *malpractice* refers to professional misconduct or the consequences of unreasonable lack of skill of nurses, doctors, lawyers, and accountants. Malpractice is an unintentional tort—that is, the person who commits malpractice did not intend to cause the harm that resulted from negligence. Although healthcare providers can also be sued for improper medical care in some states, according to a theory of breach of contract, many states disfavor or statutorily eliminate this option.

Four elements constitute every cause of action for malpractice. There must be (1) a legal duty that the practitioner owes the patient; (2) a breach of that duty by the practitioner; (3) a reasonably close causal connection between the breach of duty and the damages that result; and (4) actual damages to the persons owed the duty.

Duty

The anesthetist's duty begins when a provider-patient relationship is established. This relationship is considered a type of contract. The anesthetist agrees to care for the patient in return for a fee, and the patient agrees to pay a fee in order to receive the anesthetist's professional care. This contract does not have to be in writing—in fact, it does not even need to be spoken of by the two parties. The contract is formed when the patient allows the anesthetist's care and the anesthetist agrees to care for the patient. The law implies a contract for professional care in return for a reasonable fee by the actions of the two parties. The situation is analogous to the case of a homeowner calling a plumber to fix a clogged drain. The two parties have shown by their conduct that they intended to have services rendered for payment of a fee. The law assumes that a reasonable person does not expect an anesthetist (or a plumber) to perform services for free and implies a contract based on the conduct of the parties. The law terms this an *implied-in-fact contract*.

The anesthetist's duty can begin even though all of the preceding terms are not met. The beginning of the provider-patient relationship is not dependent on the payment of fees for the services. Even if both the anesthetist and the patient expect that no fee will be paid, the duty begins with the rendering of services. The patient's lack of mental or physical capacity to enter into the relationship does not prevent the creation of a provider-patient relationship. The anesthetist who cares for an unconscious patient has a duty to that patient even though the patient is unaware of the care being rendered. The law refers to this as in *implied-in-law contract*, because the law implies that a reasonable patient would have agreed to be cared for had he or she not been unconscious.

Standard of Care. The law presumes that people follow a minimum standard of conduct. The driver of a car is expected to stop at red lights and to drive on the right side of the road. The driver need not be the best driver on the road but must act in a manner in which a reasonable driver would act. Thus determining the minimum standard of conduct is objective. What is reasonable is not what the driver thinks is reasonable, but rather what an average reasonable driver believes to be reasonable. For the nurse anesthetist, failure to act according to the standard of care is one of the elements of negligence. The nurse anesthetist must act as a reasonable and prudent nurse anesthetist would act under similar circumstances. It should again be noted that determination of this standard is objective. It does not matter that one particular nurse anesthetist may have had less knowledge than most practitioners and thus acted in a reasonable and prudent manner for the amount of knowledge that he or she possessed. All nurse anesthetists are charged with the duty of acting as would average, reasonable, and prudent nurse anesthetists.

At one time, the standard of care was based on how other practitioners in the community where the alleged malpractice took place would have acted. Today, courts hold healthcare professionals to standards that are relevant for the entire country. Nevertheless, courts still allow for differences related to the size of the community and the equipment available to the anesthetist. For example, although a rural hospital with 25 beds might not be expected to have an anesthetist in-house 24 hours a day

or to have equipment available for extremely specialized tertiary care, a 1000-bed urban tertiary care medical center would. However, the nurse anesthetist in both situations is expected to work at the same level given the limitations of the available equipment. For example, a nurse anesthetist in a small rural hospital might not have the same equipment for the rapid transfusion of blood that a nurse anesthetist in a large urban trauma center had. If a patient were exsanguinating, however, the rural anesthetist would be expected to recognize this and transfuse as rapidly as possible with the equipment available to him or her.

The general rule is that the expert testimony must be used for determining the standard of care in a case of professional malpractice. An expert is a person who has a special skill and knowledge about a subject. An expert need not have the exact same training as the defendant in the case but may be a nurse anesthetist, medical doctor, pharmacologist, or other person with special knowledge. The requirement may be waived only under limited circumstances—for example, if the deviation from the standard is so obvious that it is easily understood by a lay person. Anesthesia textbooks may be used in court as a method of determining the standard of care.

Standards promulgated by professional organizations may be used as evidence of a standard of care. In some jurisdictions, courts view the standards as evidence of the standard of care. In other jurisdictions, they are considered as conclusive proof. Nurse anesthetists should be familiar with the *American Association of Nurse Anesthetists (AANA) Standards for Nurse Anesthesia Practice*. Nurse anesthetists must also adhere to published standards such as the *AANA Position Statement on Syringe Safety*.[8] Deviations for the patient care standards during an anesthetic procedure should be documented and the reason for the deviation explained. In addition, nurse anesthetists should be familiar with the policies of the institutions in which they work. Those policies also can be used as evidence of the standard of care. Deviations from institutional policies should be documented and explained.

Nurse anesthetists must stay abreast of new and emerging standards of care. One emerging area is the issue of distractions in the operating room, particularly reading, texting, and surfing the Internet during patient care. Some institutions have created policies forbidding the use of such devices in patient care areas. However, there is a general move in society against such distractions when driving, flying, and engaging in other important tasks. Train drivers and boat pilots have been held liable both criminally and civilly for injuries that were the result of these distractions.[9,10] Two Northwest Airlines pilots lost their licenses after flying past their scheduled airport while working on their laptop computers.[11] Even though there may not be published standards forbidding all texting and Internet surfing in the operating room, nurse anesthetists must be aware of how their behaviors would be viewed by regulatory agencies and juries. Even if it is common practice, it may be viewed as a deviation from the standard of care. As Judge Learned Hand said,

> *Indeed in most cases reasonable prudence is in fact common prudence; but strictly it is never its measure; a whole calling may have unduly lagged in the adoption of new and available devices. It never may set its own tests, however persuasive be its usages. Courts must in the end say what is required; there are precautions so imperative that even their universal disregard will not excuse their omission.*[12]

Informed Consent. Nurse anesthetists must obtain patients' consent before they can begin treatment. In a much quoted 1914 decision, Justice Cardozo stated, "[e]very human being of adult years and sound mind has a right to determine what shall be done with his own body."[13] Consent is the patient's agreement to undergo a specified treatment. A nurse anesthetist who treats a patient who has not agreed to treatment might be liable to that patient. For example, if a patient was undergoing an elective procedure under local anesthesia and the surgeon asked the nurse anesthetist to give the patient a general anesthetic, the nurse anesthetist and the surgeon might be liable for treatment without consent, even though general anesthesia had never been discussed with the patient. Informed consent, as opposed to consent, is the process in which the practitioner tells a patient not only about the diagnosis and the proposed procedure but also about the probability of the procedure's success and its associated risks, as well as about reasonable alternatives to the procedure. If more than one type of anesthesia is possible—for example, epidural versus general—nurse anesthetists have an affirmative duty to explain both to the patient. The nurse anesthetist may make recommendations on the basis of experience and the surgeon's and anesthetist's personal preferences. However, they should avoid making unsubstantiated statements—for example, that one type of anesthesia should be administered because it is not associated with complications, or that desired results are guaranteed with the use of a particular anesthetic or surgical procedure.

In addition to the ethical and moral desirability of informed consent, its importance to the practitioner lies in the fact that the failure to obtain informed consent can transform a faultless complication into a damage award against the practitioner. In one case, a patient was told by an anesthetist that the only potential problem that could happen from her upcoming spinal anesthesia for a hysterectomy was postdural puncture-related headache. The patient suffered some paralysis on the left side and problems with bowel and bladder control. The Supreme Court of Kansas stated that "While there does not necessarily have to be negligence in the administration of the spinal anesthetic for the resultant damage which [the patient] experienced, the risk was still present…. [W]e find [the anesthetist] failed to obtain the informed consent of [the patient] to the spinal anesthetic prior to its administration."[14] The case illustrates that merely telling the patient what type of anesthesia will be administered or obtaining a signature on a consent form does not constitute informed consent. Nurse anesthetists must understand that informed consent is a process that goes well beyond its objective manifestation (i.e., the patient's signature on a form).

Some risks, however, need not be disclosed. If a patient is aware of a risk or if a risk is common knowledge and the patient's awareness can be presumed, no disclosure is necessary. An anesthetist is not liable for failing to disclose risks that were not known in the anesthesia community at the time of the anesthetic procedure. Risks that are problems only if the anesthetic procedure is performed negligently need not be explained. If a patient specifically asks not to be informed of risks, they need not be disclosed. In this instance, however, the nurse anesthetist should note the request in the chart. A final instance in which an anesthetist may withhold information about risks is known as *therapeutic privilege*. If revealing the information about risks would jeopardize the outcome of the treatment or have an adverse effect on the patient's well-being, then the information can be withheld. The anesthetist must document the reasons for nondisclosure before the procedure. Although therapeutic privilege was used successfully as a defense in a 1955 anesthesia-related case, today it should be used with great caution.[15]

Actions alleging a lack of informed consent have been brought under either of two legal theories: negligence and battery. Battery is the unwanted touching of an individual, and assault is placing

someone in fear of an unwanted touching. Although assault and battery describe both a civil offense and a criminal offense, this section deals primarily with the civil offense of battery—that is, the unwanted touching of a patient. Criminal battery charges against a healthcare provider for failure to obtain informed consent are possible but unlikely.[16]

The pressing of battery charges was the traditional method for seeking a damage award for treatment without consent. However, battery is an intentional tort. The practitioner must have intentionally touched the patient without the patient's consent. The intent need not have been malicious or hostile; the fact that no consent was obtained for the intentional touching is the determining factor. Typically, the patient consents to a certain anesthetic or surgical procedure, but another is performed. Again, the fact that the surgeon and anesthetist acted to help the patient does not prevent the patient from being able to sue for battery. Battery may still be used in some jurisdictions; however, many jurisdictions have eliminated assault and battery actions in cases of lack of consent. These jurisdictions view the failure to obtain proper consent as a form of negligence, and an action as a form of malpractice.

The modern approach to failure to obtain informed consent is the seeking of damages under a malpractice (negligence) theory. A major distinction of the new approach is that the patient who is suing on the basis of battery does not have to prove damages because the unwanted touching is actionable even if it caused no harm. On the other hand, a patient suing under a negligence theory must prove damages. The extent of the duty to disclose varies from state to state. Some states have no requirements of an affirmative duty of the provider to disclose risks, whereas others have specific requirements detailing what must be disclosed. However, even in those states in which the nurse anesthetist does not have an affirmative duty to disclose risks, withholding or misrepresenting information when the patient asks can result in an action against the nurse anesthetist.

Just as the contract between the patient and provider can be implied, in many situations, informed consent also can be implied. If a nurse anesthetist is called to a patient care area to insert an intravenous catheter, the provider typically does not give the same depth of information that is given to a patient undergoing an anesthetic procedure. The anesthetist's purpose is stated, and the patient allows the procedure to continue. Consent is implied by the patient's failure to object to the care.[17] Although consent for a minor procedure on an awake patient may be implied without specific discussion about the procedure, it is unlikely that a court would use implied consent to find that an awake, competent patient had consented to anesthesia and surgery without specific discussion about the procedure.

The other situation in which consent is implied is a medical emergency in which the patient is unable to respond with regard to matters of consent. The person must be unable to respond because of injury, intoxication, or illness and the procedure to be performed must be life saving or health saving. If the procedure can be postponed until effective consent can be given by the patient or another appropriate person without the risk of additional injury, then consent must be obtained.

As alluded to earlier, there are times when persons other than those undergoing treatment can authorize consent. These persons can be (1) relatives of minors or incapacitated persons; (2) persons designated by the patient before being incapacitated; and (3) persons designated by a court as able to consent to treatment for the patient.

Traditionally, a minor cannot consent to medical treatment.[18] For nonemergency, elective treatment, this rule still applies. Consent by the parents or evidence of legal guardianship must be obtained, even if the child is brought for care by an adult relative.

In emergencies, consent of the parents to treatment is implied. The definition of emergency is broad. If the minor's health is in immediate danger (i.e., the minor has a fractured limb that must be set under anesthesia), then consent is implied. Nevertheless, anesthetists and surgeons should attempt to contact the parents or guardians to obtain consent. Even if the parents are not found, the attempt to contact them shows that the providers made a good faith effort to obtain informed consent. Although the emergency exception is broad, anesthetists must be sure that the situation is a bona fide emergency. If the parents were to question the existence of an emergency, the burden of proving that an emergency existed would rest with the providers.

In certain situations, a minor may consent to treatment. Some states have statutes or case law acknowledging the concept of the emancipated minor. An emancipated minor is one who, for the purposes of law, is not a minor despite his or her being younger than the usual age of majority. If a minor lives on his or her own, is married, or is the parent of a child, then the minor may consent to treatment. Some states have specific laws that allow a minor parent to consent to the care of his or her own child. Even in those states without a specific statute, a minor may consent to his or her child's medical treatment because a child's parent may consent to the child's treatment. States differ widely on whether a minor may consent to care for sexually transmitted diseases, contraception, and abortion. Practitioners are advised to determine what their particular laws allow with respect to these areas.

A problem can arise when a parent refuses to consent to medical care for a child. If a treatment would be considered life saving, the providers can petition the court for an order to allow treatment. A common example of this occurs when the parents of a child refuse to consent to a blood transfusion because of a religious belief. Normally, courts order such a treatment to be given if it is deemed life saving. It should be noted that the amount of time necessary to obtain such an order should not be long. Most cities and even many rural areas have a judge on call for emergency warrants or orders. Court orders can be obtained in as little 15 to 30 minutes. Hospital administrators and attorneys should be aware of the procedure for obtaining an emergency order.

As discussed earlier, consent for emergency treatment is implied if the patient is unable to give consent. In nonemergency situations, however, a person authorized by law must give consent for the patient. Who is authorized to give consent for an incapacitated person varies from state to state. Some states allow relatives to give consent for treatment to designated relatives. Other states require that a court order treatment or appoint a guardian who is empowered to give consent. There is, however, a good practical reason to obtain consent from the relative of an incapacitated person even in a state that does not specifically provide for consent by relatives. It serves as evidence of the providers' good faith in the performance of care and aids in the development of a relationship with the family that might lessen the likelihood of a lawsuit. Although this action would not prevent a suit by the incapacitated person for lack of informed consent, it would be difficult for the relative who gave consent to later file a suit for lack of consent on behalf of the patient.

The mere fact that a person is undergoing general anesthesia allows neither a relative to consent nor a surgeon to invoke implied consent to additional nonemergency surgical procedures on the patient. If a surgeon discovers a problem that necessitates subsequent surgery, or if the scheduled surgery cannot be performed without additional unplanned surgery, the unanticipated

procedure should be delayed until consent can be obtained. No matter how good the intention of the surgeon and how correct the diagnosis of the unanticipated problem, if the life or health of the patient is not at risk, the procedure should be delayed.

Persons may be designated by a living will or durable power of attorney as representatives of an incapacitated person before his or her incapacitation. A power of attorney is an instrument authorizing one person (not necessarily an attorney) to act as the legally authorized representative of another with regard to a designated matter. Traditionally, powers of attorney automatically became invalid upon the death or incapacity of the person delegating the power. A durable power of attorney, however, is made with the specific intent that it remains valid after the patient's incapacity. Durable powers of attorney were traditionally devices for controlling the use of property after incapacity; however, many states allow binding durable powers of attorney for healthcare decisions.

A person who lacks the capacity to make decisions about his or her own health care may have a guardian appointed by a court. A guardian is legally able to make decisions concerning the person's affairs. If the guardianship is extended to cover decisions concerning health care, the guardian may consent to the treatment of that person. The guardian may even consent to surgical treatment over the patient's objections, if the guardian clearly was given the power to make healthcare decisions by the court. It is up to the providers to ascertain the veracity of the representation that the guardianship extends to healthcare decisions. An inspection of the court order granting guardianship should be performed.

Breach of Duty

A breach of duty occurs when an anesthetist's practice does not meet the level required by law. The breach may be an error in the performance of an act during the administration of anesthesia care. Such an error is known as an *error of commission*. The error may also be an *error of omission*—that is, the failure to perform an act that should have been performed. This act is the standard of care discussed earlier.

The plaintiff in a malpractice suit has the burden of proving that a deviation from the standard of care occurred. Breach of duty and standard of care are usually proven simultaneously. Frequently, it is not whether the anesthetist acted in a particular manner that is in dispute, but rather whether the action deviated from the standard of care. For example, in one case, neither the plaintiff nor the defendant anesthetist disputed that 15 mg of tetracaine was administered intrathecally to a patient for a cesarean section. The only question was whether the administration of this amount constituted an overdose and deviated from the standard of care.

Causation

It is not enough to prove that a practitioner deviated from the standard of care. Even if the deviation from the standard of care and the presence of damages (see later in this chapter) are undisputed, the plaintiff must still prove that the damages were caused by the defendant anesthetist's negligent act. Two types of cause must be understood: *but for causation*, which is sometimes referred to as cause in fact; and *proximate cause*, which is also referred to as legal cause.

With but for causation, what is of importance is whether the damage would have occurred had the defendant not breached the duty—that is, "but for" the defendant's action the damage would not have occurred. This test eliminates negligent acts that did no harm to the plaintiff, even though some other damage occurred. Consider the example of an anesthetist who negligently failed to obtain a preoperative hemoglobin value or hematocrit for a patient whose hemoglobin and hematocrit results would have been within the normal range. The patient subsequently suffered laryngospasm and pulmonary edema. Although the failure to obtain the laboratory results was clearly negligent, it had no relationship to the subsequent problem. Had the negligence not occurred, the subsequent event would still have followed.

But for causation, however, is lacking in several respects. It is unfair to the plaintiff whose injury was caused by several factors. For example, consider the case of a patient who is negligently extubated by an anesthetist while still partially paralyzed because he or she had been administered nondepolarizing muscle relaxants; as a result, the patient subsequently decompensates. The postanesthesia recovery room nurse is unable to manage the patient and negligently fails to call soon enough for help. If only the but for causation test were used, the plaintiff could not prove malpractice because there is more than one cause. If the anesthetist had demonstrated greater skill in the recovery room, the mistake would not have caused harm.

Conversely, but for causation can be unfair to defendants because minor breaches of duty could lead them to be found liable for unrelated acts. For example, an anesthetist negligently pulls out a patient's intravenous catheter on the way to the operating room. Because of the negligence, the patient is in the operating room for 15 minutes longer than he or she would otherwise have been. During the additional quarter hour, a sudden earthquake destroys the part of the hospital housing the operating room but does not affect the postanesthesia recovery room. If only but for causation were used, the anesthetist (or the anesthetist's estate) could be held liable for the patient's earthquake injuries because, but for the anesthetist's negligence, the patient would have been safe in the recovery room.

Because of these problems, the *substantial factor test* is added to the but for causation test. With the new test, the defendant's negligence must be proved to be a substantial factor in the causation of the plaintiff's injuries. The substantial factor allows for a just result in both of the preceding cases. In the first case—that of the patient extubated negligently—both the anesthetist's and the postanesthesia nurse's actions can be found to have been substantial factors in the patient's death. In the second case, the negligent removal of the intravenous catheter was not a substantial factor in the patient's death during the earthquake, even though the but for causation requirement was satisfied.

Once the plaintiff in a case has proved that the defendant breached a duty and that the breach was the cause in fact of the plaintiff's damages, it must be proved that the defendant should be liable for the damages. This is referred to as *proximate* or *legal cause*. The issue of proximate cause is not a factual determination; rather, it is a question of policy. The law does not hold a person responsible for consequences that are considered remote and unforeseeable or for those that would not have caused damage without the presence of a remote, independent, intervening factor.

The differences between what constitutes sufficient foreseeability and what does not, what degree of remoteness precludes liability, and how independent a subsequent intervening cause must be in order for it to preclude liability fill many books. It is sufficient for the practitioner to remember that the issue of proximate cause does not arise until cause in fact is established.

Thus, in the examples described, neither the recovery room nurse's negligence nor the earthquake would be charged to the anesthetist if the anesthetist's negligence did not cause the patient to be in that situation in the first place. If the anesthetist was negligent in both situations, there would be no liability in the case of the earthquake injuries because it is not a foreseeable consequence

of pulling out an intravenous catheter. It is sufficiently remote from that action to remove the anesthetist from any legal responsibility. However, it is foreseeable that a patient who was negligently left in the recovery room with an inadequate airway might suffer from further negligence by subsequent caretakers.

Damages

The last element of a malpractice action involves damages. The plaintiff must prove that the negligent actions caused actual harm or damage, whether it be financial, physical, or emotional. Damages can be special, general, or punitive.

Special damages are those that are the actual result of an injury and which, in fact, follow it as a natural and proximate consequence. Special damages include past and future loss of income, medical expense, and funeral expenses. General damages are pain and suffering that are a direct result of the injury. The courts assign a cash value to special and general damages in an attempt to compensate a patient for the injuries. Some states have put a limit on the amount of pain and suffering compensation a plaintiff can receive in a medical malpractice suit.

Punitive damages are awarded by courts to punish defendants for outrageous conduct (e.g., violence, oppression, malice, fraud, or wanton and wicked conduct). The punitive damages awarded are in excess of the actual harm caused. States vary on what happens with the proceeds of punitive damages. In some states, part of the proceeds goes to the plaintiff and part goes to the state. Also, some states do not allow attorneys to collect their contingency fees from the punitive damage award. Punitive damage awards in medical malpractice suits are rare.

Burdens of Proof and Res Ipsa Loquitur. The plaintiff must prove all of the individual elements of negligence. Legal cases must be proved in accordance with several standards. The first is *beyond a reasonable doubt*. This is the standard that the state must meet if someone is to be found guilty in a criminal case. It is the most stringent standard of proof used. The second, intermediate level is *clear and convincing evidence*. The clear and convincing standard is occasionally used only in special civil cases, such as cases involving fraud, reformation of a contract, or civil commitments. The standard by which the plaintiff must prove the case in an action for malpractice (and most other civil actions) is the lowest of the three standards. This is the *more likely than not preponderance of evidence standard*. This standard requires that the evidence prove the case by more than 50%. Thus the plaintiff must prove that the damage was more likely than not caused by malpractice. It should be noted that a mere possibility that the defendant's action caused the injury is insufficient.

The importance of which party has the burden of proof should not be underestimated, because if the burden of proof is not met, then the party with the burden loses. If the plaintiff cannot find evidence of all the elements of malpractice, then the case fails. Because of the importance of the burden of proof and the potential harshness of the rule, there are exceptions to this requirement. One exception is the case of multiple negligent defendants. This situation arises if the plaintiff can prove that the damage was caused by the action of more than one negligent defendant—for example, the negligence of both an anesthetist and a recovery room nurse. The defendants then have the burden of proof and must determine the liability of each defendant.

A second instance of burden shifting is *res ipsa loquitur*. Res ipsa loquitur is a doctrine that allows the plaintiff to use circumstantial evidence to prove negligence. It also shifts the burden of proof of negligence from the plaintiff to the defendant. The reason for the doctrine of res ipsa loquitur (which is Latin for "the thing speaks for itself") is best explained with a description of the case from which it evolved. In 1863 a pedestrian in England was walking down the street in front of a warehouse. As he walked, a barrel of flour fell out of the warehouse window and struck him on the head causing him injuries. The plaintiff did not see what caused the barrel to fall; thus he could not prove negligence under the traditional rule that places the burden of proof of negligence on the plaintiff. The court determined that it was unlikely that the barrel would have fallen in the absence of negligence. In such a situation, the plaintiff should be allowed to recover damages unless the defendant can prove that no negligence occurred.

The res ipsa loquitur doctrine has evolved since that case. Now, three conditions must be satisfied before the plaintiff can use this doctrine. First, the event causing injury must be of a type that does not normally occur in the absence of negligence. Second, the damage must be caused by something which is in the complete control of the defendant. Third, the damage must not have been due in any part to negligence of the plaintiff. Some courts add a fourth condition: that the evidence of the event be in the hands of the defendant.

The first condition that implies more than a bad outcome must have occurred for the doctrine to be invoked. The plaintiff still has the burden of proving that the event does not normally occur in the absence of negligence. Events such as operation on the wrong patient or on the wrong extremity and burns from the use of an electrosurgical unit have usually been the events that allow the use of res ipsa loquitur. Showing that an event is unusual or unexpected is not sufficient. For example, an instance of malignant hyperpyrexia in a patient who gave no personal or family history of the condition is not enough to invoke re ipsa loquitur, because malignant hyperpyrexia is not an event that is normally the result of negligence. It should be noted that the patient can still attempt to prove that the anesthetist's response was negligent; however, the burden of proving negligence remains with the plaintiff.

After satisfying the requirement that the events do not normally happen in the absence of negligence, the plaintiff must prove that the instrumentality was within the exclusive control of the defendant. The term *control* refers to a right to control rather than an actual physical control. An unconscious anesthetized patient does not need to prove the identity of the person causing the injury. In a landmark case in this area, a patient undergoing an appendectomy sustained a traumatic injury to his shoulder. The court allowed the use of the doctrine of res ipsa loquitur against all of the operating room personnel even though it was obvious that not all could have been responsible. This is different from the case of multiple negligent defendants because, in this case, res ipsa loquitur was used against both negligent and non-negligent defendants' being liable for damages. The rule is a result of a policy determination that states that it is better to have operating room personnel be forced to prove their lack of negligence than to have anesthetized patients forced to prove negligence that occurred when they were unconscious, which is nearly impossible. The non-negligent defendant can attempt to prove that another defendant should be liable for the damages.

In order for res ipsa loquitur to be invoked, the injury must not have been the result of contributory negligence. A patient who failed to disclose a previous allergic reaction or case of malignant hyperpyrexia should not be allowed to use the doctrine to find the anesthetist negligent for administering the triggering agent. It has been suggested that it is unlikely that an anesthetist defendant would be successful in preventing the use of res ipsa loquitur on this basis.

The final requirement in some jurisdictions is that the evidence be more accessible to the defendant than to the plaintiff. This, however, is the least important of the elements of the doctrine. It has been suggested that it is not actually a requirement. Rather, it is another argument for justifying application of the doctrine.

Defenses to Negligence. When the plaintiff brings an action for medical malpractice, the defendant may defend in several ways. First, he or she offers evidence rebutting the plaintiff's evidence about the elements of the suit—namely, duty, standard of care, breach of duty, causation, and damages. Even if the plaintiff is to prove the elements of negligence, several defenses can prevent the placement of legal liability on the defendant. These include statutes of limitations, contributory or comparative negligence, and Good Samaritan statutes.

Virtually all civil lawsuits must be instituted within the specified time period after an incident or they will be barred in accordance with *statutes of limitations*. The policy behind the rule is that after a certain period it is difficult to gather the evidence to defend the lawsuit. For medical malpractice lawsuits, most states allow a period of 2 years; particular states may have statutes allowing more or less time.

Some states measure this period from the time of injury to the time that the lawsuit was instituted. Under these statutes, when the injury appears is not important; if the time period is 2 years and the plaintiff does not discover the injury until 3 years have passed, then the action is barred. Because the rule as applied is very restrictive, most states suspend the beginning of the statutory period until the time when the injury was discovered. Thus if malpractice caused an injury that was not discovered for 4 years, then the plaintiff would still have another 2 years to institute a lawsuit for medical malpractice. Some states use a hybrid statute that allows for a time period after the date of discovery but still places a cap on the total length of time from the date of injury. For example, a state may require that the suit be instituted within 2 years of the time of discovery but no later than 4 years from the date of injury.[19]

Two other situations may lengthen the statute of limitation. One is *fraud* or concealment of injury by the provider. If the reason for the plaintiff's failure to institute the action within the period specified is the provider's willful concealment of the event, the defense of statute of limitation may be disallowed because of the defendant's unclean hands.

Most states do not begin the time period if the patient is a minor. Thus infants or children who are injured as a result of medical malpractice have until the number of years allowed by the statute of limitations after their eighteenth birthday to initiate a lawsuit for recovery from any damages caused.

In the previous discussion of res ipsa loquitur, it is mentioned that the defense of res ipsa loquitur cannot be used if contributory negligence is involved. Traditionally, contributory negligence could be used as a complete bar to an action in negligence. If a plaintiff's negligence is responsible for 10% of the damages and the defendant's negligence for 90%, the plaintiff is prevented from collecting anything.

Because contributory negligence could produce very harsh results, most jurisdictions have adopted a doctrine of comparative negligence. In comparative negligence, the damage award is reduced by the amount of the plaintiff's negligence. Thus if the plaintiff was 10% at fault, the award would be reduced by 10%. Some states place a limit on the percentage of fault that the plaintiff is allowed before recovery is barred. If the plaintiff is either 50% or 51% at fault, depending on the state, recovery is barred. Thus if the plaintiff is 60% at fault and the defendant is 40% at fault, there is no recovery.

Another defense to malpractice is the use of a *Good Samaritan statute*. Most states protect providers who render emergency aid to sick or injured persons outside the hospital. If the provider cares for the patient in good faith, there is no liability unless gross, willful, or wanton negligence occurred. There is dispute among the states concerning whether emergency care rendered in the hospital is covered by the statute. In the absence of statutes limiting the liability of providers of emergency care in hospitals, the Good Samaritan acts normally do not apply to hospital care.

Vicarious Liability. Agency is the "relation in which one person acts for or represents another by the latter's authority."[20] The person who is represented is known as the principal and the person acting for the principal is the agent. Vicarious liability describes the legal theory that is used to hold the principal liable for the agent's action; it also is referred to by the Latin name *respondeat superior*. The principal need not have committed any negligent act to be liable for the agent. In the medical malpractice arena, the principal is held vicariously liable for the agent's negligent acts. It is important to understand that vicarious liability is a method of increasing the liability of principals and is not used for defending the agent. One who commits a negligent act is always responsible for the results. Thus a nurse anesthetist who is employed by a hospital or corporation that carries no malpractice insurance or has inadequate malpractice insurance can be held legally responsible for payment of damages. If both the employer and employee are named in the lawsuit, they are jointly liable for the amount of the judgment. Nurse anesthetists who depend on their employer's malpractice insurance should make themselves aware of the specifics of those policies and should be satisfied that the coverage limits are sufficient.

The most common and easiest relationship in which to find vicarious liability is the employer-employee relationship. An employer-employee relationship exists if the employee has been hired to perform services in the affairs of the employer and if he or she is controlled, or the subject of a right to be controlled by another. Normally, an employer is responsible for the negligent acts of its employees but not for their intentional acts. However, in certain cases employers may be held liable for intentional acts of employees if they knew or should have known of the employee's propensity toward those violent acts. That liability is not based on vicarious liability but on negligence in hiring or supervising the employee.

Generally, vicarious liability does not apply to the negligent acts of an independent contractor. An independent contractor is one who performs contracted work in his or her own way. The independent contractor is subject to the employer's control only in reference to the outcome, not to the methods used. However, the determination of whether someone is an independent contractor is a question of fact. It is determined not only by the characterization that the contractor and the employer give the relationship but also by all the facts and circumstances of the case. Hospitals can be held liable for the acts of independent contractors if the facts prove that the employer had control over the contractor. A nurse anesthetist may be an independent contractor for tax purposes but an employee under malpractice law if the facts prove that to be so.[21]

Even if a person is an independent contractor, liability remains with the employer for his or her own negligence. If a hospital or anesthesia group contracts with a nurse anesthetist but failed to have a proper credentialing procedure to assure that the nurse anesthetist was properly licensed and certified and if damage occurred due to the unlicensed person's practice as a result, the employer could be held liable for negligence.

The borrowed servant rule pertains to situations in which an employer "loans" an employee to another employer. An anesthesiologist who controls a nurse anesthetist is liable for the nurse anesthetist's negligence, even if the nurse anesthetist is an employee of the hospital. When applied to the operating room, however, vicarious liability has confused surgeons, anesthesiologists, nurse anesthetists, lawyers, and judges. Courts fashioned a species of vicarious liability referred to as the *Captain of the ship doctrine*.[22,23] The doctrine's premise is that the surgeon is ultimately responsible for all that occurs in an operating room. The doctrine has been used to hold surgeons responsible for the acts of nurse anesthetists and anesthesiologists.

A surgeon's liability for the case is related to his or her involvement in the decision-making process. If the surgeon makes independent decisions that affect the anesthesia, he or she is liable for those decisions. For example, an orthopedic surgeon insists that a patient scheduled for an emergency repair of a fractured ankle be given a general anesthetic. This is done despite the anesthetist's recommendation that a nerve block be performed because the patient has not been fasting long enough. If the anesthetist proceeds with the general anesthetic and aspiration pneumonitis results, then the anesthetist and the surgeon would share any liability that might result. This hypothetical case should not suggest that there is any liability; if loss of limb function is a possible outcome of the injury, it might be the correct decision to proceed and to use a general anesthetic because of the type of repair that must be accomplished. This only demonstrates that if the surgeon participates in the decision making for anesthesia, he or she may be liable for any injuries if that decision is proven negligent. The point to be taken is that the liability that might result would be there whether the anesthetist is an anesthesiologist or a nurse anesthetist. The doctrine of Captain of the ship has been eroding over the years and has been shown to be specifically so in several cases because it no longer represents an accurate portrayal of the relationships between professionals in the operating room, if it ever did.[24-26]

THE DOCTRINE

Organization of a Lawsuit

A lawsuit begins when the attorney for the complaining party, the plaintiff, files the complaint with the court. A copy of the complaint also is sent to the party being sued, the defendant, or to the party's attorney. Depending on the jurisdiction in which the lawsuit is filed, the complaint may be sent to the defendant by mail or be personally delivered. The defendant's attorney responds to the complaint by submitting an answer. A complaint, or any other type of legal summons, should never be ignored. Failure to answer a properly served complaint within the permitted time period can result in a default judgment against the defendant. That means that the plaintiff automatically wins the lawsuit and is granted the damages sought.

Discovery

After the complaint and answers are filed, the parties begin pretrial discovery. Pretrial discovery includes depositions and interrogatories. Depositions are question and answer sessions during which the lawyers for both sides question witnesses. Both parties and nonparties to the lawsuit can be deposed. The depositions are usually held in one of the attorneys' offices. This should not lead the person being deposed to believe that the depositions are informal or off the record. A court reporter is present and records everything that is said, except when the parties agree to go off the record. The deponents are under oath, and testimony given at deposition can be presented during the trial either as evidence of malpractice or to contradict the deponent's subsequent testimony in court. Interrogatories are written questions submitted to the parties to a lawsuit. They must be answered fully in writing and are also under oath. As with the complaint, a subpoena or notice of deposition should never be ignored. Failure to answer a subpoena or to appear after a notice of deposition can result in a fine of imprisonment for contempt of court. A party to a lawsuit also may be forced to pay the other party's expenses because of the failure to respond. Additionally, a party may have part of the pleadings struck from the case, may have the case dismissed, or in the most egregious instances, may have a default judgment entered.

The scope of discovery, which encompasses both depositions and interrogatories, is very broad. Questions may be asked that would be inadmissible in court because of irrelevance or other reasons. A nurse anesthetist involved in a lawsuit must attempt to put aside the emotional feelings associated with a lawsuit and answer questions in a truthful and professional manner. The attorney examining the witnesses can use the witnesses' anger to obtain additional information or to make the witness look bad before a jury, The nurse anesthetist's attorney should be relied on to make the appropriate objections. Again, at time of trial, the attorney can object to testimony taken in a deposition and subsequently prevent its presentation to the jury.

Trial

The trial is a difficult and stressful time for all involved in it. The nurse anesthetist should remain calm and professional and follow the advice of his or her attorney closely. The court's rules of decorum should be followed completely. The most important person in the courtroom is the judge, and any violation of the court's rules can be seen as a challenge to the judge's authority. Violations can not only anger the judge but also alienate the jury. The jury identifies more closely with the judge than with anyone else in the courtroom. Disagreements with testimony or with the court's rulings should be handled by the attorneys in the appropriate manner. Outbursts, groans, and other expressions of displeasure can only adversely affect the nurse anesthetist's case.

In addition to being truthful and professional, a nurse anesthetist who is a witness during discovery or trial should never hesitate to answer that he or she has no recollection of an event. Guessing about situations or giving answers that show uncertainty afford a skilled trial attorney opportunities to find inconsistencies. Few things appear worse to a jury than testimony that is inconsistent and appears to have been calculated to deceive the jury or to make the witness look better. A witness's credibility is his or her most valuable resource. Testimony during lawsuits is likely taken several years after the event, and it is understandable that a witness may not remember every precise detail.

SUMMARY

Fortunately, anesthesia is safer than ever, and the number of lawsuits involving anesthesia care has decreased in the past several decades. Improvements in monitoring technology, drugs, and diagnostic tests and the greater knowledge and skill of anesthesia providers all play a role. When an untoward incident does happen, however, the consequences can be devastating for the patient, their family, and the provider. Patient safety should be a primary factor on a daily basis in every decision made and technique performed. Processes that incorporate safety into the workflow of the modern anesthesia department must be constantly reassessed and updated. This chapter has explained some of the current legal concepts underlying anesthesia practice. It is important to remember

that ignorance of the law is no excuse for improper practice judgments. Know the laws and regulations that govern your practice. Know and follow your professional standards and guidelines. Document accurately and in a timely manner. Find a lawyer now that you can rely on; don't wait for a crisis to occur and then not have time to conduct a thorough search. It is better to have an attorney and not need one than to not have an attorney and need one. Seek attorney advice before a problem arises.

CHAPTER 4

Nurse Anesthesia Research

Science of an Orderly, Purposeful, and Systematic Nature

◆ *Chuck Biddle*

The certified registered nurse anesthetist (CRNA) brings a wealth of knowledge to the clinical arena. Although this knowledge comes from a variety of disciplines, including physiology, pharmacology, physics, nursing, medicine, and psychology, it should be appreciated that research and critical thinking first and foremost make this knowledge possible. Evidence-based practice greatly enhances credibility within the clinical setting.

Research represents a rational approach to the making of practice choices among initially plausible alternatives and provides direction and a means for validating these choices. Whether selecting one intravenous opioid over another or choosing one particular pediatric induction technique instead of another, CRNAs rely on research to provide a solid foundation for clinical decision making, thereby avoiding fads and inferior alternatives.

The impact of research on the day-to-day activities of the CRNA has become an especially relevant topic. Before the mid-1970s the vast majority of nurses functioned without much consideration of research or publication of their ideas. In the late 1970s we experienced a period of punctuated evolution. Major driving forces behind this evolution included movement into a graduate educational framework, a more sophisticated appreciation of the scientific underpinnings of our specialty, recognition of the importance of evidence-based practice (EBP; see the discussion of this topic later in this chapter), national attention to issues of patient outcome and patient safety, and a growing self-awareness of nurse anesthetists not only as providers of excellent clinical care but also as active participants as scholars in the field.

Because CRNAs primarily function with a practice-oriented perspective, the recommendations of Brown et al[1] seem especially relevant. These scholars suggested that four characteristics of research are essential for the development of a scientific knowledge base for a discipline such as nurse anesthesia. First, research should be actively conducted by the members of the discipline. Second, research should be focused on clinical problems encountered by members of the discipline. Third, the approach to these problems must be grounded in a conceptual framework—that is, it must be scientifically based, emphasizing selection, arrangement, and clarification of existing relationships. And finally, the methods used in studying the problems must be fundamentally sound.

WAYS OF KNOWING

The term *research* can be broadly defined as the application of a systematic approach to the study of a problem or question. However, we do not know all the things we claim to know on the basis of systematic inquiry. For example, tradition and custom are important sources of human knowledge. Those who live in the United States are raised in a democratic society and are taught that democracy is the best and most advanced form of government. This is a powerful and efficient route for communication of knowledge because it excuses individuals from initiating an independent effort to come to grips with the concept of democracy. In the absence of evaluation for validity, however, such a route may lead to blind acceptance.

Another source of our knowledge is authority. We know something to be true because an authoritative person such as a parent, educator, clergyman, physician, or teacher tells us it is true. Yet, despite the fact that authorities are fallible, the knowledge they pass on often remains unchallenged. Should we not ask the basis for what we are being told?

Personal experience (the trial-and-error method) represents a powerful source of knowledge. We make observations (e.g., that placing a hand on a hot stove causes a burn) and on their basis make predictions (e.g., that a stove may be hot) and future behavioral decisions (e.g., to avoid touching a stove). However, a risk remains: Not only are certain events perceived differently by different people, but one person's experience may be too narrow to serve as the basis for the development of a reasonable and unbiased understanding of a given phenomenon. Although this mechanism is a practical way of knowing, it is highly fallible and represents a coarse and inefficient way to gain knowledge.

Logical reasoning is yet another way of knowing. The reasoning method has two components: inductive reasoning and deductive reasoning. Inductive reasoning results in generalizations that are derived from specific observations. Consider the following line of reasoning using a character in many action and adventure movies, James Bond, for example. We observe that James Bond is mortal; we observe that a number of other people are mortal as well; on this basis, we conclude that all people are mortal. Deductive reasoning is the development of specific predictions from generalities. In this case, we see the following line of reasoning: we know that all men are mortal; we know that James Bond is a man; therefore we conclude that James Bond is mortal. Both methods are useful, but the former offers no mechanism for evaluation or self-correction, and the latter is not in itself a source of new information.

Perhaps the most advanced way of knowing is reflected in the scientific method. Although it too is fallible, the scientific method is more reliable and valid than other methods. It provides for self-evaluation with a system of checks and balances that minimizes bias and faulty reasoning. In essence, it is a systematic approach to solving problems and enhancing our understanding of phenomena. It has, at its foundation, the gathering and interpretation of information without prejudice.

THE NATURE OF RESEARCH

Research is by definition a dynamic phenomenon. Whether it is directed purely at the acquisition of knowledge for knowledge's

BOX **4-1**

Research Scenario: Internal Versus External Validity

Internal Validity

The extent to which results can be accurately interpreted and the degree to which the independent variable (that which is manipulated) is responsible for a change in the dependent variable (that which is measured).

For example, the patient's blood pressure is measured. A combination of propofol, midazolam, isoflurane, and a new muscle relaxant is used for induction of anesthesia. A postinduction blood pressure is recorded, and the researcher concludes that the new muscle relaxant lowers blood pressure.

Questions

Has the researcher isolated the effect of the muscle relaxant from those of the other agents?

Are there plausible or competing alternative explanations?

Analysis

Internal validity is low because the results cannot be interpreted with any degree of certainty.

External Validity

The extent to which the results can be generalized; this issue relates to the question "To whom can the results be applied?"

For example, 35 obese men who are nonsurgical volunteers are anesthetized with a standard dose of a new induction drug. The clinical half-life of the drug is determined with plasma drug sampling and brain wave activity monitoring. The researcher concludes that future patients receiving the standard dose of the new drug will experience a clinical half-life of 11 minutes.

Questions

Is it reasonable to assume that obese patients might respond differently than their nonobese counterparts?

Might women respond differently than men?

Could surgical manipulation or other drug therapy have an impact on the pharmacokinetics of the new drug?

Analysis

External validity is low because the results cannot be generalized to any other individuals except those similar to the subjects in the study.

sake (basic research) or at the specific solution of problems (applied research), it is a process that can be conceptualized in terms of at least four characteristics.

First, research can assume many different forms. Second, research must be valid, both internally and externally (Box 4-1). Internal validity is necessary but not sufficient for ensuring external validity. Third, research must be reliable. *Reliability* refers to the extent to which data collection, analysis, and interpretation are consistent and to which the research can be replicated. Fourth, research must be systematic. The elements of a systematic approach include the identification of the problem or problems, the gathering and critical review of relevant information, the collection of data in a highly orchestrated manner, an analysis of the data appropriate to the problem or problems faced, and the development of conclusions within the study's framework.

Science is not a routine, cut-and-dried process. Rather, scientific knowledge emerges from an enterprise that is intensely human; as a consequence, it is subject to the full spectrum of human strengths and limitations. The scientific discovery and understanding that attend participation in research and its results can be professionally exhilarating and satisfying.

THE EIGHT CRITICAL STAGES IN THE RESEARCH PROCESS

Research accords several personal freedoms to those who engage in it: the freedom to pursue those opportunities in which one is interested, the freedom to exchange ideas with other interested colleagues, and the freedom to be a *deconstructionist*—that is, one who challenges existing knowledge. Yet, despite these freedoms, research must be logical, must progress in an orderly manner, and ultimately must be grounded within the framework of the scientific method. If research is a way of searching for truths, uncovering solutions to problems, and generating principles that result in theories, we must come to understand the process of research.

The research process can be described in many different ways. For purposes of simplicity, this process is defined as consisting of the following eight distinct stages:

1. Identification of the problem
2. Review of the relevant knowledge and literature
3. Formulation of the hypothesis or research question
4. Development of an approach for testing the hypothesis
5. Execution of the research plan
6. Analysis and interpretation of the data
7. Dissemination of the findings to interested colleagues
8. Evaluation of the research report

Stage 1: Identification of the Problem

The selection and formulation of the problem constitute an essential first step in the research process. The researcher decides the general subject of the investigation, guided principally by personal experience and by inductions and deductions based on existing sources of knowledge. The researcher makes the general subject manageable by narrowing of the focus of the problem. The following criteria must be met at this phase of the research process:

- The problem area should be of sufficient importance to merit study.
- The problem must be one that is practical to investigate.
- The researcher should be knowledgeable and experienced in the area from which the problem has emerged.
- The researcher should be sincerely motivated and interested in studying the problem.

We constantly encounter problems and situations that can be studied. At clinical anesthesia conferences, one might hear remarks such as the following:

"It seems to me that a tiny dose of thiopental given just before propofol alleviates virtually any pain on injection."

"Do you think there is less nausea and vomiting in outpatients who are deliberately overhydrated?"

"I find that the use of the waveform generated by my pulse oximeter gives me valuable information about depth of anesthesia."

"I believe that the inspiratory pause mechanism on the Ohmeda 7810 ventilator significantly improves arterial oxygen tension in my patients with chronic obstructive pulmonary disease."

"I am convinced that sleepiness is a major cause of anesthesia accidents."

A study could emerge from each of these situations, built on ideas, hunches, or curiosity. A problem that lends itself to research often materializes from personal observations and in the sharing of ideas and experiences among those who are familiar with the phenomenon in question.

Once identified, the problem should be stated in terms that clarify the subject and restrict the scope of the study. Defining the terms involved in the problem statement also is critical, as demonstrated in Box 4-2.

BOX **4-2**

Research Scenario: Stating the Problem

Poor
I am unsure of the effectiveness of etomidate in patients.

Better
I am unsure at what dose etomidate induces unconsciousness in patients undergoing hysterectomy and what impact it has on heart rate, blood pressure, and vascular resistance.

Comments
- The problem should be focused.
- The terms should be clarified.
- The relationships should be understood.
- The problem should not be so narrow as to be trivial.

The wording of the problem statement sets the stage for the type of study design used. Each step in the research process subsequently influences later steps, and this should be kept in mind at all times. A mistake made early inevitably creates difficulties at some later stage in the process. The novice researcher may be surprised to find that this first stage in the research process often consumes a large portion of the total time invested in the research effort. Yet the time is well spent, because research should not commence until a problem has been identified and formulated in a thoughtful and useful manner.

Common Mistakes

At this stage of the process, pitfalls can include an overly ready acceptance of the first research idea that comes to mind and selection of a problem that is too broad or vague to allow effective study.

Stage 2: Review of the Relevant Knowledge and Literature

Once the problem has been identified, information is needed for putting the problem into proper context so that the research can proceed effectively. A well-conducted literature review provides the researcher with the following:

- An understanding of what has already been accomplished in the area of interest
- A theoretic framework within which the problem can be optimally stated, understood, and studied
- An appreciation for gaps in current understanding of the phenomenon
- Information for avoiding unanticipated difficulties
- Examples of potentially useful or poorly constructed research designs and procedures
- A background for interpreting the results of the proposed investigation

The knowledge that influences the problem originates from three general sources: personal files and experience, personal contacts with experts, and the library and Internet. Both manual indexes and computerized databases should provide the researcher with immediate and full access to the world's published literature. Additional literature searches may be required at different times throughout the research process.

Common Mistakes

At this stage in the research process, mistakes include hasty review of the literature, overly heavy reliance on secondary (book) rather than primary (journal) sources, lack of critical examination of the methods by which conclusions were reached, and incorrect copying of references, for example, mistakes in noting the volume number or misspelling an author's name, which makes it more difficult to locate them again with ease.

Stage 3: Formulation of the Hypothesis or Research Question

In its most elemental form, a hypothesis is either a proposition of the solution to a problem or a stated relationship among variables. It establishes and defines the independent variable (the variable that is to be manipulated or is presumed to influence the outcome) and the dependent variable (the outcome that is dependent on the independent variable). The hypothesis is declarative in nature and assumes one of the following three forms:

1. A *directional hypothesis:* Patients premedicated with midazolam have less anxiety on arrival in the operating room than do those who were not premedicated.
2. A *nondirectional hypothesis:* Patients premedicated with midazolam experience a difference in anxiety on arrival in the operating room when compared with those who were not premedicated.
3. A *null hypothesis:* Patients premedicated with midazolam experience no difference in anxiety on arrival in the operating room compared with those who were not premedicated.

Research questions are generally reserved for investigations that are descriptive or exploratory in nature or for when the relationships among the variables are unclear. A research question might be more appropriate than a hypothesis in a study that proposes to determine the beliefs of anesthesia providers who interact with patients under specific circumstances. For example, consider the following research question: What are the attitudes of CRNAs in the northeastern United States who care for patients with acquired immunodeficiency syndrome (AIDS)?

Common Mistakes

At this point in the process, mistakes include use of a vague or unmanageable hypothesis and development of a research question that cannot be answered reasonably.

Stage 4: Development of an Approach for Testing the Hypothesis

After the research idea has taken shape in the form of a formal hypothesis or research question, a plan of attack is developed. The research proposal represents the stage at which the ideas of the project crystallize into a substantive form. The proposal includes the following:

- A problem statement and clarification of the significance of the proposed study
- The hypothesis or research question
- A sufficient review of the literature for justification of the study
- A description of the research design
- A careful explanation of the sample to be studied
- The type of statistical analysis to be applied

A research proposal is a useful and efficient way for the researcher to determine the completeness of the plan and is usually required if the researcher is to obtain departmental or institutional approval or is applying for financial support.

Research Methods

The research method is the way the truth of a phenomenon is coaxed from the world in which it resides and is freed of the biases of the human condition. A variety of research methods are at our disposal,

and researchers are not inflexibly wedded to any particular approach. Researchers do not follow a single scientific method but rather use a body of methods that are amenable to their fields of study.

Some of the methods available are highly recognizable, permanent components of the researcher's armamentarium, whereas others have evolved not only with respect to time but also in response to the specific needs of a particular problem or discipline. The research method can be influenced by the way a researcher views a problem. For example, a researcher can test a hypothesis, search for a correlation, ask "why" or "how" questions, or probe a phenomenon on the basis of "what would happen if" suppositions.

The researcher can view the method on the basis of the fundamental task that it will accomplish. For example, two broad categories into which research efforts can be divided are basic research and applied research. Basic research adds to the existing body of knowledge and may not have immediate, practical use. Applied research is oriented toward solving an immediate, specific, and practical problem.

The research method can be characterized in terms of its temporal relationship to the problem. A retrospective study is the process of surveying the past; the thing in which we are interested has already occurred, and we are simply looking to see what did occur. In contrast, a prospective study looks forward to see what will happen in a given situation; here, the collection of data proceeds forward in time.

It is important to understand several terms fundamental to the research process. As mentioned previously, the dependent variable is the object of the study, or the variable that is being measured. The independent variable is the one that affects the dependent variable and is presumed to cause or influence it. Another way of looking at this relationship is that variables that are a consequence of or are dependent on antecedent variables are considered dependent variables.

Another set of variables consists of control variables, also known as *organismic*, *background*, or *attribute* variables. Control variables are not actively manipulated by the researcher, but because they might influence the relationships under study, they must be controlled, held constant, or randomized so that their effects are neutralized, canceled out, or at least considered by the researcher (Box 4-3).

The term *blinding* refers to the process of controlling for obvious and occult bias arising from subjects' or researchers' reactions to what is going on. In a single-blind design, the patients are unaware of which treatment or manipulation is actually being given to the subjects. In the double-blind design, neither the researcher nor the subject is aware of which treatment or manipulation the subject is receiving. Whereas randomization attempts to equalize the groups at the start of the study, blinding equalizes the groups by controlling for psychological biases that might arise apart from any effect of the treatment. Many factors influence the decision to use a single-blind or a double-blind design. For example, in some situations, it may not be feasible to disguise a particular treatment or intervention.

Operationalization is the process of making the characteristics inherent in a given variable, condition, or process familiar or clear to others. If researchers do not operationalize the terms, phrases, and manipulations in the study, the net effect could be an ambiguous study. For example, in a study examining the effects of epidural anesthesia in critically ill patients, it would be essential to operationalize the terms *effects* and *critically ill patients*. Similarly, in a study comparing the quality of inhalation induction with isoflurane and sevoflurane in pediatric patients, it is essential that the researcher operationalize the terms *inhalation induction* and *quality*. Operationalization of terms clearly designates performable and observable acts or procedures in such a way that they can be replicated immutably.

BOX 4-3

Research Scenario: Understanding the Types of Variables

Study Group

A new intravenous drug that may be associated with fewer cardiovascular effects than thiopental during induction in pediatric patients is being studied. Fifty children ages 3 to 6 years undergoing intravenous inductions for hernia repair or eye muscle surgery are randomized to either the thiopental group or the new drug group. Blood pressure, heart rate, and rhythm are measured by a dedicated observer who is unaware of which drug the patients are receiving.

Analysis

The dependent variables are blood pressure, heart rate, and heart rhythm. The independent variable is the drug the child receives—either the thiopental or the new drug. A number of control variables are present, including sex, fluid status, time of day, underlying medical history, and concurrent drug therapy. With randomization, such control variables should be equated or neutralized for the two groups, but even randomization is not an absolute guarantee.

Classifying Research on the Basis of Methodology

Although different authors use a variety of classification schemes, the following example provides a simple way for the researcher to select and classify a design. This scheme attends to the study's purpose and scope and to the nature of the problem at hand. Table 4-1 offers a simplified approach to classifying research design.

Quasi-experimental research differs from experimental research in that it is missing one or more of the key elements required for the experimental design. Either a control group or a randomization procedure may be absent from the design. For example, at an institution, outpatients may routinely receive ondansetron from a particular practitioner, whereas they routinely do not receive the drug from another practitioner. A prospective trial in which both practitioners use a standard anesthetic technique could be initiated. For example, isoflurane, an opioid, and cisatracurium could be administered; this would allow the two practitioners to use or not use ondansetron as they normally would. Outcome, measured in terms of the incidence of nausea and vomiting in the first 6 postoperative hours, is quantified, and the groups are compared. Although randomization is not achieved, a study that may not otherwise have been possible because of the inflexibility of the clinicians involved is successfully accomplished. Quasi-experiments, by yielding to one or more of the rigid criteria of the experimental design, offer an attractive alternative in certain circumstances.

Qualitative Research: An Alternative Paradigm

Up to this point, the traditional approach to a problem has been characterized by deductive reasoning, objectivity, manipulation, and control. An alternative approach involves a group of methods characterized by inductive reasoning, subjectivity, exploration, and process orientation. These methods fall under the rubric of qualitative research techniques.

Qualitative techniques include philosophic inquiry, historiography, phenomenology, grounded theory, and ethnography. Generally speaking, *qualitative research* refers to systematic modes of

TABLE 4-1 Classifying Research by Method

Type	Qualities and Purpose	Example
Experimental	At least one variable manipulated Random assignment to groups Dependent variable is measured Good for determining cause and effect Prospective in nature	Is there more or less pain on injection of one or the other drug? What did the manipulation do?
Ex post facto	Independent variable has already occurred Examines relationships by observing a consequence and looking back for associations Retrospective in nature (Latin for "from a thing done after")	Looking back over 5 years, did a relationship exist between the rate of myocardial infarction and the inhaled anesthetic that was administered?
Descriptive	Describes something as it occurred Incidence, relationships, and distributions are studied Deals more with "what-is?" than "why-is-it-so?" questions	What are the attitudes of CRNAs regarding the care of patients who have AIDS?
Historical	Describes "what was" rather than what effect variables had on others Events are described as accurately as possible through a process of critical inquiry	A test of the hypothesis is that Sister M. Bernard was the first nurse anesthetist
Qualitative Phenomenology Grounded theory Ethnography	Experiences lived by people Perception is viewed as our access to that experience Discovers and conceptualizes the essence of complex processes	What is the nature of the relationship of CRNAs and surgeons in private and in academic settings?

inquiry directed principally at observing, describing, analyzing, interpreting, and understanding the patterns, themes, qualities, and meanings of specific contextual phenomena. Qualitative research seeks to gain insight by discovering the meanings associated with a given phenomenon and exploring the depth, richness, and complexity inherent in it.

For example, exploring how male and female CRNAs differ in the manner in which they deal with parental and child separation when a child is readied for induction of anesthesia might best be achieved through the use of a qualitative design. The actual experiences might be observed or videotaped. Those involved—anesthetists, parents, and children—might be interviewed immediately and at some time after the procedure. This study would be artificially constrained and disjointed if it were conducted in any setting other than the original one or if too many controls were brought to bear on the experiment.

The qualitative paradigm seems especially appropriate when the researcher does not want to artificially distance a study from its contextual richness or when there is not enough information available on a particular subject for the adequate development of sound and testable hypotheses. The treatise on qualitative approaches by Marshall and Rossman[2] is recommended to interested readers.

Sampling

Under most circumstances, studying everyone who might be affected by a particular study is impractical, if not impossible. For example, if we want to know how effective intravenous nitroglycerin is in minimizing the rise in blood pressure associated with laryngoscopy in hypertensive patients, we cannot realistically study all hypertensive patients who undergo laryngoscopy. Rather, we would hope to find a smaller group of subjects who are representative of the relevant population at large. By accessing certain information in the sample, we can credibly make inferences or generalizations regarding the population at large.

Similarly, if we want to know how often anesthesia machines in small community hospitals receive preventive maintenance, we cannot visit all the community hospitals in the nation. Instead, we might randomly select a number of hospitals in a number of different states, visit those locations, and inspect the maintenance records. By studying this representative sample, we can make some reasonable and safe generalizations regarding the phenomenon of preventive maintenance at large.

Consider the anecdote about the four blind people who encountered an elephant during one of their daily walks. Each person felt a different part of the elephant. When asked to describe what they had encountered, the first person replied, "a tree trunk" (the elephant's leg). The second reported feeling "a large snake" (the elephant's trunk). The third reported that it was "most definitely a wall" (the elephant's torso). The last person reported that it was "a large, frayed rope" (the elephant's tail). This analogy illustrates that a few discrete sampling points may not be adequate for describing a complex phenomenon. Not only is a random sample best, it also should be large enough and sample a sufficient number of points in the population that a truly representative perspective is gained.

Different sampling techniques can be used, depending on the research design used. In a true random sample (also known as *probability sampling*), all members of the population at large have a similar chance of being included in the study. This is rarely the case in clinical research, in which we are confined to dealing with those individuals who present themselves. In this situation, the sample is called a *convenience sample*. When a convenience sample is used in an experimental study, it is important to ensure that the subjects selected for the study are at least randomized when assigned to treatments or groups. In the ideal situation, the researcher aims for both random selection (from the population at large) and random assignment (to the different groups in the study).

For example, in a study designed to quantify the rate of arterial desaturation in pediatric patients who are transported to the postanesthesia care unit with and without supplemental oxygen, the researcher is limited to those patients who are undergoing surgery. It is difficult to obtain a sample from the pediatric population at large and subject them to anesthesia and surgery. Rather, a convenience sample of patients who are having an operation is used. However, the researcher should randomly assign the study participants to one of the two treatment groups—those who receive supplemental oxygen or those who do not receive supplemental oxygen.

Obtaining a random sample, especially in clinical research, is often a complicated process. Most important is the realization that the concept of randomness is essential to minimizing human biases associated with both selection and assignment.

Instrumentation and Measurement

Two important concepts essential to measurement are validity and reliability. Instrument validity is the degree to which an instrument, such as a blood pressure cuff or a personality inventory, measures what one believes it is measuring. *Instrument reliability* refers to the degree of consistency with which an instrument measures whatever it is measuring—that is, whether the same result is obtained on repeated trials.

Validity and reliability are often easily established for measures of certain physiologic phenomena but may be troublesome in behavioral or psychological evaluations. Imagine trying to determine reliability and validity for a thermometer. Contrast this to trying to establish validity and reliability for a psychological tool that professes to measure a CRNA's attitude toward euthanasia; obviously, the latter is a much more difficult undertaking. Although a measure must be reliable to be valid, it can be reliable without being valid. For example, a skin temperature probe might reliably (consistently) measure temperature even in a variety of extreme settings, although it would not be viewed as a valid indicator of core temperature. Both reliability and validity are discussed in degrees rather than in "all-or-nothing" terms.

Many published instruments have reliability and validity testing reported. When choosing an instrument for a study, it is critical to consider whether the instrument's reliability and validity have been established. For example, if an instrument measures evoked responses in the esophagus as an indicator of depth of anesthesia, it must be determined whether the reliability and validity of the instrument have been established under the conditions of the anesthetic protocol being used in the proposed study. Coefficients of reliability and validity are presented on a scale of 0 to 1, with 1 being perfect.

Occasionally the researcher may encounter no reasonable measures to use for a study. For example, instruments for measuring such phenomena as arterial oxygen tension, end-tidal anesthetic concentration, and opioid metabolic by-products are well established. A researcher may need to develop a totally new instrument (questionnaire) to determine perceptions regarding the propriety of a given manufacturer's high-pressure promotional campaigns for newly released pharmaceutical products. In developing such a tool, it is helpful to have an expert in the discipline look over the instrument and provide feedback to ensure that the instrument is appropriate.

Researchers have a variety of instruments for measuring phenomena. These include the following:

- Written tests
- Rating scales
- Questionnaires
- Chemical tests
- Physical tests
- Electrical tests
- Visual observation
- Auditory observation
- Psychological inventories

Levels of Measurement. In designing a study, the researcher must decide how to measure a phenomenon such as anxiety level, blood pressure, attitude toward health care, or rate of complications. There are four levels or degrees of measurement: nominal, ordinal, interval, and ratio. The type of data measured determines the kind of statistical analysis that can be done. Table 4-2 characterizes the four levels of measurement.

TABLE 4-2 Characteristics of the Four Categories of Measurement

Category	Characteristics	Examples
Nominal	Identifies	Male or female Diagnosis
Ordinal	Identifies	American Society of Anesthesiologists (ASA) class
	Orders	Order of race finish
Interval	Identifies	Intelligence
	Orders	Calendar years
	Equal intervals	Degrees Fahrenheit or Celsius
Ratio	Identifies	Blood pressure
	Orders	Reaction time
	Equal intervals	Weight
	Has a true zero	Distance Degrees Kelvin

Nominal level measurement allows categorization of data, but the only numeric data obtained are frequencies. For example, in a study assessing the educational level of CRNAs in the profession, only the frequency of each category (certificates, bachelor's degrees, master's degrees, doctorates) can be reported. No statement can be made concerning the amount of the characteristic.

Ordinal level measurement allows for data to be ordered or ranked. In a sense, numbers are used to indicate the magnitude of the observations. For instance, the American Society of Anesthesiologists' Physical Status system provides for a relative ranking system for patients on the basis of their pathophysiologic status.

Interval level measurement uses numeric data that are ordered and spaced equally, such as temperature on the Fahrenheit or centigrade scale, calendar years, or intelligence quotients derived from an intelligence performance test. Here, the distance between adjacent scores is highly meaningful.

Ratio level measurement uses numeric data that can be ordered and equally spaced. It is based on a scale with an absolute zero point, such as temperature on the Kelvin scale, reaction time, height, and blood pressure. Both interval and ratio level measures can be referred to as *continuous* in nature.

Measurement can also be defined in terms of four broad categories: cognitive, affective, psychomotor, and physiologic. Each can manifest as one of the levels noted earlier. *Cognitive measurement* addresses the test subjects' knowledge or achievement. For example, what actions should be taken in the face of unexplained bradycardia? *Affective measurements* determine interests, values, and attitudes, thereby providing behavioral insights. For example, how do CRNAs in different locations feel about anesthetizing patients with AIDS? *Psychomotor measurements* test the subjects' ability or skill in performing specific tasks, such as evaluating performance with a new laryngoscopic design. *Physiologic measurements* look at the biologic functioning of the organism—for example, heart rate differences in men and women at basal conditions.

Although researchers sometimes develop unique instruments, which must be tested for reliability and validity, many published and acceptable instruments can be located in any number of sources.[3,4]

The Pilot Study

A pilot study is the implementation of a study on a small scale. It includes only a few subjects, who generally will not be included in the formal study. Its purpose is to troubleshoot the methodology for any anticipated design problems. The pilot study allows the researcher the opportunity to perform a dry run, ultimately facilitating the progression of the study.

Common Mistakes

At this point in the process, mistakes include failure to adequately operationalize definitions, failure to define the population or sample adequately, unrealistic expectations for subject recruitment and participation, underestimation of the difficulty of design execution, failure to establish instrument reliability and validity, and failure to appreciate the ethical dimensions of the investigation.

Stage 5: Execution of the Research Plan

Up to this point, the research process has involved the acquisition of knowledge regarding the subject, planning the project, and critical thinking about what is to occur. The next stage of the process involves actual data collection and the organization of the data into a format that allows data analysis.

The data collection must precisely follow the procedure the researcher specified previously. The real payoff in research comes with the drawing of useful and bona fide conclusions once the data have been collected and precisely analyzed within the framework of the research design. The goal of the previous step—namely, maximization of both internal and external validity—would not be achieved if the researcher were to deviate from the plan.

Maintaining careful records of what was done and what results were recorded is essential. The labeling and sorting of data into the respective categories or chronologies should be extremely precise. No data should be discarded until the researcher knows that they are absolutely unnecessary. Many researchers "stockpile" raw data and their notes, because additional uses for the information may not manifest for months or even years after the initial project's completion and publication.

Common Mistakes

The mistakes associated with this stage include drifting from the stated methodology for convenience or administrative purposes, placing excessive demands on subjects, allowing personal bias to creep into the research plan, using observers or research assistants who are improperly trained, failing to obtain a sufficient sample size, and improperly using measurement instruments.

Stage 6: Analysis and Interpretation of the Data

A few words on statistics are in order. Not only is proper analysis essential to the design, analysis, and interpretation of the investigation, it also is necessary for understanding and evaluating research studies conducted by other investigators. Analysis has three general phases: the initial mechanical manipulation of the data, the analysis itself, and the thoughtful formulation of conclusions on the basis of the analysis.

For the purposes of this discussion, the following two questions are posed:

1. What is the rationale for the use of statistical analysis in research?
2. What are the more common statistical procedures used, and under what circumstances are they appropriate?

Descriptive Statistical Techniques

Once the data on the phenomenon under study have been collected, they often are categorized and described. For example, if the goal of a study is the determination of the incidence of headache and the change noted in blood pressure in 50 patients undergoing spinal anesthesia, the researcher would describe the demographics of the sample of patients in terms of sex, height, weight, or any other relevant variable.

The group or set of all the observations of the variable is called a *distribution*. The distribution yields information about the overall dispersion of the phenomenon within the sample, as well as the exact location of a given measure relative to the group as a whole. In the case of an interval- or ratio-level measurement, such as blood pressure, the distribution of values is probably Gaussian or bell shaped in nature (i.e., some pressures are low, most are intermediate, and some are high). By studying the distribution, the researcher can compare a particular measured value with all the values obtained for the phenomenon.

TABLE 4-3 Frequency Distribution for Initial Systolic Blood Pressure

Interval (mmHg)*	Frequency†
0-60	1
60-90	8
91-120	15
121-150	15
151-180	8
>180	3

*Interval equals the range or band into which a given measure is placed.
†Frequency equals the number of observations falling into that interval.

Alternatively, the researcher might use a technique that clusters data into rational blocks or intervals. For example, in the spinal anesthesia study, instead of listing all 50 initial blood pressures individually, the researcher could tabulate them according to frequency relative to a given interval. In this case, each measured blood pressure falls within a range, and the frequency of presentation in the sample is tabulated as shown in Table 4-3. Instead of using the tabular form, the researcher could arrange the same data in graphic form, indicating the frequency of the phenomenon on the vertical (*y*) axis and the blood pressure values on the horizontal (*x*) axis. In histograms and bar graphs, the width of each bar corresponds to the limits of the interval, and the height of the bar corresponds to the frequency or percent of the cases occurring in a specific interval. A frequency polygram also is a commonly used tool for displaying data. Points are plotted directly over the midpoint of each of the intervals. The data given in Table 4-3 are presented in Figure 4-1 as a frequency polygram.

Other descriptive statistics include the *mean* (the arithmetic average of the sample); the *median* (the point below which one half of the measurements lie); and the *mode* (the value occurring most frequently). The range shows the dispersion data from the highest to the lowest value. *Variance* and *standard deviation* (SD) must be computed and are based on the concept of deviation (the difference between an observed score and the mean value in the distribution). Variance is the square of the sum of all of the deviations divided by the number of scores, and the SD is the positive square root of the variance. Because of variation, investigators describe the data not only in terms of the typical or average value but also the amount of variation that is present. With respect to quantitative data such as blood pressure, number of attempts at intubation, or amount of blood loss, this task is generally a matter of characterizing the distribution of the attribute in terms of its central tendency and dispersion. This is achieved by providing the mean and the SD. The SD is a tool for describing the variation of individual observations around the mean. *Standard error of the mean* (SEM) is linked to the SD by the following simple mathematical formula:

$$SEM = SD/\sqrt{n}$$

where $\sqrt{n}$ is the square root of the number of observations in the sample.

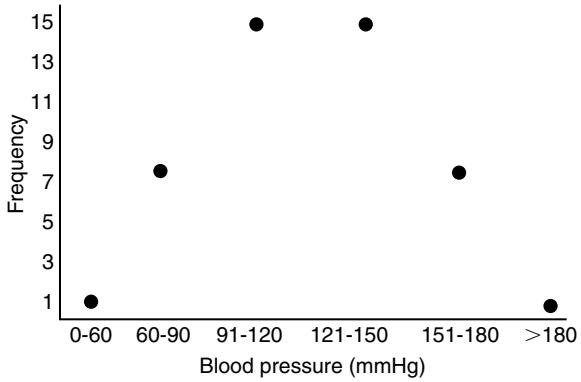

FIGURE **4-1** The frequency polygram. Note the bell-shaped configuration the plotted data have assumed; this typically is the "normal" distribution of biologic data (e.g., blood pressure, weight, heart rate, minimum alveolar concentration, intelligence).

The SEM describes the variation of the sample mean (that for the actual data collected) around the true, but unknown, population mean (that for all possible observations). The difficulty with using the SEM is that as the number of subjects or observations increases, the standard error of the mean decreases. In theoretic terms, as *n* approaches infinity, SEM approaches 0. Researchers are urged to consult with a biostatistician and to develop a rationale before deciding to use the SEM or SD.

In general, the higher the level of measurement used (i.e., ratio > interval > ordinal > nominal), the greater the flexibility in selecting a descriptive statistic. Using the data from the spinal anesthesia study noted earlier, it would be appropriate to compute the SD for initial systolic blood pressure (ratio-level data). However, such a computation would be meaningless for nominal-level information, such as whether subjects are male or female.

Correlational Statistical Techniques

The correlation coefficient is generally used for describing the extent to which two variables are related to each other or for quantifying the degree of that relationship. For example, it would be useful if one were studying the extent to which the level of carbon monoxide in the blood is related to cigarette smoking. Calculated correlations vary from +1.0 (a perfect direct correlation) to −1.0 (a perfect inverse correlation). A correlation of 0 indicates no relationship. Researchers often display the correlations visually in the form of a scattergram, which shows the shape of a relationship between two variables. There are many types of correlational techniques (Table 4-4).

In the hypothetic study of carbon monoxide level and cigarette smoking, a researcher might decide to use the product-moment correlation technique. The numeric value for carbon monoxide in the blood has a true 0 (ratio-level data) and a numeric value (ratio-level data) for daily cigarette smoking. The correlation between these variables would probably be positive and very high (e.g., 0.8 or even higher), which suggests that heavy use of cigarettes is associated with a high carbon monoxide level in the blood.

Conversely, assume a study examines the relationship between gender (a nominal-level variable) and anesthetic minimum alveolar concentration (a ratio-level variable). In this example, the researcher using the point biserial correlation technique would expect to see a very low correlation, because gender has been found to not be associated in any meaningful way with anesthetic requirements.

TABLE 4-4 Correlation Techniques Appropriate to Data Type

Correlation	Variable No. 1	Variable No. 2
Product-moment	Interval or ratio	Interval or ratio
Spearman's rank	Ordinal	Ordinal
Point biserial	Nominal or ordinal	Interval or ratio
Phi	Dichotomy	Dichotomy
Contingency	Nominal	Nominal

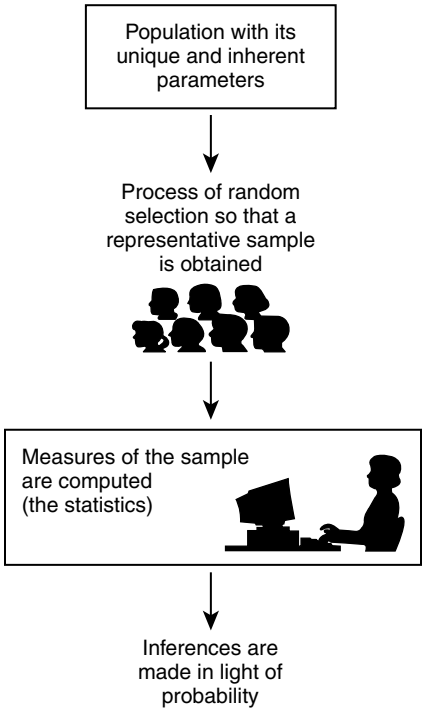

FIGURE **4-2** Conceptual model of inferential statistics.

Inferential Statistical Techniques

Inferential statistical procedures provide a set of techniques that allow the researcher to infer that the events observed in the sample will also occur in the larger unobserved population from which the sample was obtained. There are two basic reasons for using inferential techniques. First, they can assist the researcher who is testing a hypothesis and must decide whether to accept or reject it. For example, a researcher, having a particular value in mind, poses the question, "Is this value reasonable in light of the evidence from the sample?" Second, inferential techniques can be used for estimation. For example, a researcher may have no particular value in mind but wants to know what the population value is. The researcher draws a sample, studies it, and makes an inference about the population characteristic (Figure 4-2). These two classic situations as addressed by inferential techniques are as follows:

1. *Testing a hypothesis* (Table 4-5). Is there a significant difference in the incidence of nausea between those patients given thiopental and those who receive propofol?
2. *Making an estimation*. What percentage of CRNAs perform a thorough machine check at the start of each day?

Researchers are seemingly preoccupied with the concept of significance. The level of significance (also designated as *alpha level* or P *value*) is a criterion used in making decisions regarding a hypothesis. For example, if *P* is less than 0.05, the probability that the difference

TABLE 4-5 Statistical Methods Used for Testing Hypotheses

	TYPE OF EXPERIMENT				
Scale of Measurement	**Two Treatment Groups Consisting of Different Individuals**	**Three or More Treatment Groups Consisting of Different Individuals**	**Before and After a Single Treatment in the Same Individual**	**Multiple Treatments in the Same Individual**	**Association Between Two Variables**
Interval (and drawn from normally distributed populations)*	Unpaired *t*-test	Analysis of variance	Paired *t*-test	Repeated-measures analysis of variance	Linear regression and Pearson product-moment correlation
Nominal	Chi-squared analysis of contingency table	Chi-squared analysis of contingency table	McNemar test	Cochrane Q	Contingency coefficient
Ordinal	Mann-Whitney rank sum test	Kruskal-Wallis statistic	Wilcoxon signed rank test	Friedman's statistic	Spearman rank correlation

*If the assumption of normally distributed populations is not met, the observations should be ranked, and the methods for data measured on the ordinal scale should be used.

TABLE 4-6 Choice of Statistical Test Based on Assumptions

	Parametric Procedures	**Nonparametric Procedures**
Nature of the assumptions	Data are interval or ratio level	Data are nominal or ordinal level
	Each value is independent of the other values	Not necessarily distributed "normally" (i.e., data do not "fit" a bell-shaped curve)
	Value is normally distributed	
	Groups have similar variance	
	Usually work best with large population	
Examples of tests	*t*-Test for independent groups*	Chi-squared test
	t-Test for dependent samples†	Mann-Whitney test
	Analysis of variance	Kruskal-Wallis test

*For example, two totally unrelated groups are compared.
†For example, a pretest and posttest comparison on one group of people.

observed between the samples was the result of chance alone is less than 5%. Accordingly, if *P* is less than 0.05, the probability that the difference between the samples was real (i.e., it resulted from the treatment) and not just the result of chance is greater than 95%. It is conventional to establish the alpha level before the data analysis is begun; however, there seems to be an increasing trend toward reporting calculated *P* values after hypotheses have been tested. Commonly used levels in research are *P* is less than 0.05 and *P* is less than 0.01; *P* is less than 0.10 is sometimes used in preliminary or descriptive studies. There is also a trend to simply report the calculated *P* value and leave the interpretations up to the reader.

In recent years, there has been growing resistance to exclusive use of the *P* value in interpreting research findings, despite the still widespread use of the *P* value in interpreting hypotheses. *Effect size* is a measure of the magnitude of the observed relationship(s) under consideration. The *P* value is a dimensionless value that is, in the best case, only an indicator of the direction of the effect and in no way speaks to the clinical meaningfulness of the relationship.

A number of standardized effect-size measures are in use, and all have their unique place in the settings of reporting research findings. Although explanation and application illustrations are beyond the scope of this chapter, examples of these include but are not limited to Pearson's *r*, odds ratio, confidence intervals, and Cohen's *d*. The number needed to treat (NNT) is yet another example of a metric that provides clinically applicable "magnitude of effect" information. With these limitations involved, brief descriptions of some common statistical manipulations follow.

Selecting the Appropriate Statistical Procedure

There are two major categories of inferential procedures: parametric analyses and nonparametric analyses. The major factors that dictate which category should be selected involve the assumptions the investigator makes regarding the data. Tables 4-6 and 4-7 provide some guidelines for selecting a statistical procedure.

Power

The sensitivity of the planned experiment and analysis is known as its *power*. The concept of power is important to anyone planning a research project or evaluating a published paper. The estimate of an experiment's ability to accurately test the hypothesis under question should be computed before the research is begun. A researcher should ask the following two critical questions:

1. What is the chance I will incorrectly determine that my treatment had an effect when it really did not (type I error)?
2. What is the chance I will miss an effect that is actually present (type II error)?

Power estimates obtained during a study's design stage encourage investigators to thoughtfully enhance the study's sensitivity.

TABLE 4-7 Choice of Statistical Test Based on Purpose

Test	Goal
t-Test, independent groups	To test the difference between the means of two independent groups
t-Test, dependent samples	To test for the difference between dependent, paired samples (e.g., pretreatment and posttreatment) outcome
Analysis of variance	To test the difference among the means of more than two independent groups or more than one independent variable
Chi-squared	To evaluate the difference between observed and expected frequencies
Correlation coefficient	To test whether a relationship exists between two variables (e.g., product-moment)
Simple linear regression	Used when one independent variable *(x)* is used to predict a dependent variable *(y)*
Multiple linear regression	To understand the effects of two or more independent variables on a dependent measure
Analysis of covariance	To test for differences between group means after adjustment of the scores on the dependent variable to eliminate the effects of the covariate
Factor analysis	To reduce a large set of variables into a smaller, more manageable set of measures
Canonical correlation	To analyze the relationship between two or more independent variables and two or more dependent variables
Discriminant analysis	To make predictions regarding membership in categories or groups, in contrast to using interval- or ratio-level measures

Making such estimates forces the posing of questions regarding effect size (e.g., how potent is the effect of the independent variable on the dependent variable?) and sample size, both of which are essential in a study. Many adverse outcomes that occur as a result of anesthetic management are rare (e.g., death, postspinal hematoma, blindness, stroke), and studies proposing to measure such outcomes as a function of a particular interventional approach must be "powered" by a large sample size and other methodologic controls.

Established procedures and techniques can assist the researcher in determining what sample size must be used if a study is to have an acceptable chance of achieving its purpose (the testing of a given hypothesis). What is at stake is the issue of a trial's having sufficient rigor to detect whether a true difference between treatment groups exists. Other issues should be considered as well, and the reader is referred to the definitive text by Cohen[5] for further treatment of these issues. Careful attention to these issues may help prevent the commission of a type III error (conducting the wrong experiment). Most human subject committees and scientific journals require that study reports contain some discussion of power before they are seriously considered.

Data analysis allows the researcher to organize this information in a focused manner so the research question can be answered. Selecting the appropriate method of data analysis is essential to the proper execution of the research plan. Experienced and beginning researchers alike may need assistance when choosing an appropriate method for data analysis. Expert researchers, statisticians, and clinical nurse specialists may prove to be valuable resources for the beginning researcher.

Once the data collection and analysis have been completed, the researcher must interpret the results. These results are directly related to and should answer the research question or hypothesis. Researchers may find that the answers are different from those they were expecting. The answers, results, and outcomes should be interpreted and their implication for clinical practice described. The researcher also should discuss how the findings relate to other research studies and should present ideas for future practice.

Propensity Score

Mention should be made here of an increasingly common analysis, the *propensity score*. This is particularly important in observational studies where bias may be a powerful confounder. Many factors influence the decision of how to treat a patient. In the randomized control trial, the bias inherent in assigning a particular patient to a particular treatment arm in the study is minimized by the study design itself. However, in an observational study, it is important to know the conditional probability of a particular subject receiving the intervention (treatment), given observed or measured covariates. The propensity score affords us the opportunity to do just that. If there is no hidden bias and treatment assignment is thus "random," the propensity score should reveal that. There is some movement, using the propensity score, to elevate the "power" of observational studies to near that of the randomized trial. However, this is a somewhat contentious issue.

Nonetheless, propensity analysis has been used recently to illuminate clinical judgments associated with beta blockers, antifibrinolytics and other agents with important perioperative implications. Being an increasingly common methodologic and analytic approach to complex clinical questions, we are likely to see its use continue to grow.

Recursive Partitioning

A now commonly used tool that has both statistical and methodologic attributes and implications is recursive partitioning (RP). Its roots are in the word *recursive*, meaning to use a rule or procedure that can be applied repeatedly, and *partitioning*, indicating a division into or distribution into portions or shares. This type of approach creates a rule such as "if a patient has finding *a, b* or *c*……, then he or she likely has condition *x or* should be treated with *z*." Examples where this kind of rule application has been used include the Goldman Cardiac Risk Stratification, obstructive sleep apnea scales such as STOP-BANG, and the ASA (American Society of Anesthesiologists) Difficult Airway Algorithm.

RP tends to work best with dichotomous (e.g., 'yes/no') variables, and a "mistake" make early on is likely to have significant downstream consequences. Nonetheless, when applied appropriately, RP can provide clinical information and decision making that is grounded in supportive evidentiary decision making and can be used when there are multiple variables even in the presence of complex interactions—circumstances that are very often present in the real world of clinical anesthesia care.

Common Mistakes

At this step in the research process, mistakes include selecting an inappropriate statistical procedure, using only one statistical procedure when several should be used, overstating the importance of small differences that are statistically significant but of little clinical importance, interpreting correlational research as evidence of cause-and-effect relationships, and overgeneralizing the findings of the investigation. Some common errors in statistical usage are noted in Box 4-4.

BOX **4-4**

Top 10 Common Errors in Statistical Usage

1. No justification for reporting statistical results
   - No control group (when one is possible)
   - Random sampling or random group assignment not performed (or reported)
   - Statistical test not specified
   - Obvious biases or threats to validity
   - No documentation of consent or institutional review board approval
2. Errors in use of the *t*-test
   - Multiple application without correction
   - Use of independent groups form for paired data and vice versa
   - Use for ordinal data
3. Negative conclusions when statistical test results are not significant
4. Use of a test for independent samples for paired data or repeated measures
5. Inappropriate or no follow-up to analysis of variance
6. Hypotheses generated by the data
7. Use of one-sided tests without justification (or disclosure)
8. Inadequate number for chi-squared analysis
9. Standard error of the mean used for specifying variability
10. Misinterpretation or misrepresentation of *P* value
    - Small *P* value called "highly significant"
    - No confidence intervals stated
    - Different interpretation of $P = 0.04$ and $P = 0.06$

Stage 7: Dissemination of the Findings to Interested Colleagues

The research process is not complete until the results, conclusions, and implications have been adequately communicated to those likely to be interested in the study. Clearly, a study that has been completed but whose results have not been disseminated is of little value. Communication of the research findings can be done through a variety of routes, including publication in journals or newsletters, oral and poster presentations at formal symposia, or even simply discussion with others interested in the phenomenon.

Researchers fail to publish the results of their work for many reasons. These include such claims as "my findings were not significant," "my results were negative," and "the sample size was small." Negative or insignificant results can be as valuable as positive ones. For example, it has been found that in most circumstances, the by-product of atracurium breakdown, laudanosine, is unlikely to have significant clinical effects.[6] This is an important negative finding that has contributed substantively to clinical understanding.

Similarly, small sample sizes may provide an element of control over variables not present in larger studies or may indicate some preliminary direction as to how to approach a problem. An example is the finding that epidural anesthesia or analgesia in conjunction with light general anesthesia may be preferable to a purely general anesthesia technique and may be associated with lower mortality rates in critically ill patients.[7] Although the sample size in this particular investigation is relatively small, the overall design is acceptable and contributes to our understanding of the issue by stimulating other investigators to pursue answers to the questions raised.

Because the goal of nurse anesthesia research is the improvement of practice, the dissemination of research findings to clinicians is a major challenge faced by nurse anesthesia researchers. In a report directed at a highly research-oriented audience, the introduction is usually somewhat detailed, emphasizing the theoretic basis for the research. The introduction is followed by an extensive methodologic section that focuses on establishing the reliability and validity of the instruments used. The findings of the study are presented next, with emphasis on the statistical procedures employed. Finally, the conclusion focuses on the limitations and implications of the study's results.

Writing for a Clinically Oriented Audience

Generally, clinicians find research literature difficult to understand and its clinical application cumbersome. Both authors and journal editors can do much to make research more palatable to the clinical reader, thereby improving the chance that the research findings will be broadly disseminated and integrated into clinical situations. A recipe for successful clinical writing follows.

Clinical readers of research want to extract information applicable to clinical practice as quickly as possible. Therefore, the introduction of the research report should be brief, should establish the practical importance of the study, and should present a clear statement of the study's purpose. A deliberate effort should be made to connect the study with the realities of clinical practice.

With respect to the methods section, writing that "a quasi-experimental, Solomon three-group crossover design yielded data that were subjected to canonical and discriminant analysis" does little to satisfy the needs of the average clinical reader. Instead, stating how the subjects were obtained, what manipulations were made, how the measurements were taken, and how the statistical analysis was performed provides the reader with clear straightforward information, allowing him or her to put the study into a clinical context. The methods section should completely describe both the research design and the statistical procedures used, and it should indicate why this approach was selected.

The results of the study should focus on the relevant findings and describe them clearly and fully. Tables or figures, explicitly labeled and simple in design, should be used for representing the findings visually. Admittedly, the more complex the findings, the more difficult it is to avoid a statistical or technical focus.

In the discussion section, the implications of the investigation for theory and future research are somewhat less important to the clinical reader than are the implications for practice. For example, assume that a study demonstrates that the proposed intervention is not ready to be implemented in practice. In this situation, the discussion section should emphasize why this is so and what can be done about it. Encyclopedic comparisons of the results with those of other investigators at this point probably will not contribute materially to the report and may, paradoxically, deter the reader. Alternatively, if a researcher finds that a particular intervention, strategy, or assessment is ready to be introduced into clinical practice, the discussion section should emphasize how and for whom it should be used. It should include considerations such as efficiency and cost, as well as suggestions for clinical implementation.

This recipe for making research reports more palatable to primarily clinically oriented readers is not meant to diminish the importance of highly theoretic research-oriented writing. Many CRNAs continue to generate and publish valuable theoretic papers that contribute materially to a scientific basis for practice. Researchers and writers must keep the CRNA audience in mind as they develop and disseminate their findings.

All researchers must understand that the results of their studies, once published, become part of the general knowledge of the scientific community at large. However, the use of this knowledge requires acknowledgment of the original researchers; also, published results may be subject to copyright protection laws (i.e., their use may require permission from the publisher). It is not until

the information becomes common knowledge that others may use it freely without acknowledgment.

Common Mistakes

At this stage of the research process, common mistakes include not keeping the study focused on the original problem, overwriting, generalizing the findings too broadly, and failing to address the clinical significance of the study.

Stage 8: Evaluation of the Research Report

Both clinicians (in their reading for application) and researchers (in their writing and analysis) are called on to evaluate research reports, despite the fact that many may not have received formal training in reading and interpreting professional literature. Evaluation is the process of appraising the quality of a phenomenon—in this case, the findings of research as they bear on the art and science of nurse anesthesia. Outside of the practice settings, humans evaluate hundreds of things every day: Are the apples on the grocery shelves to our liking? Does the description of the program in the television guide entice us to tune in? Is the weather too warm to wear a jacket? Have we cooked the eggs sufficiently? These seem trivial and informal compared with the clinical evaluations the CRNA must perform daily: Is the patient's anesthesia too deep, too light, or about right? Should I administer more opioid? Is the patient dehydrated, or is the hematocrit level misleading me? Should I perform a rapid-sequence induction? What dose of which sleep agent do I use in this 80-year-old patient with a fractured hip? Both sets of questions, nonprofessional and professional, are highly evaluative and parallel the evaluative decision making that occurs when anesthesia research literature is read.

Systematic evaluation of the research, which influences the practice of nurse anesthesia, consists of a formal appraisal of the quality and value of the research. This essential step in the research process is multidimensional and can be approached in many ways. The approach outlined in the following subsections involves asking carefully orchestrated, critical questions. The answers to the suggested questions are not necessarily a dichotomous yes or no, but rather are qualitative in nature. An overview of this approach is detailed in Box 4-5.

Gaining Experience at Evaluation: the Journal Club

Most clinicians and researchers are familiar with the concept of the journal club, a common curricular component of many programs in the anesthesia community. A journal club offers a planned, periodic, and critical reading of anesthesia-oriented research and clinical articles pertaining directly to practice. Participants in a journal club are assigned to read selected articles; later, a discussion of the articles can proceed under the direction of an informed leader. Questions that should be asked during discussion and critique include the following:

- What are the purposes and the research questions or hypotheses, and how does the related literature review bear on the purpose or problem?
- What methods did the authors use to study or evaluate the problem?
- How are the data presented, and in what manner are they analyzed?
- What are the conclusions of the study, and what are the implications for practice?

Participation in a journal club can be a rewarding and intellectually stimulating activity that can be used for keeping one's knowledge of the field current and for gaining experience in evaluating the anesthesia-related literature.

BOX 4-5

Research Scenario: A Guide for Researchers* and Clinicians† in Evaluating Research for Completeness and Clinical Application

Problem
Is it lucid, researchable, justified, and practical?

Hypothesis
Is it clear, with the appropriate variables under consideration correctly identified?

Definitions
Are terms adequately defined and put into context?

Literature
Is it relevant, current, and organized?

Review
Is it logical, and does it justify the study?

Methods
Is the sample representative of the population being considered? Is the sample large enough? If human subjects were used, was institutional approval granted? Is the instrumentation described and valid? Is the design compatible with the problem and the hypothesis or research question? Is there any evidence of drift from established procedure? Are the data-gathering procedures defined? Is there enough information for replication of the study, if desired? Are the statistical procedures described, and are they appropriate?

Results
Are results presented clearly, concisely, and without bias? Are they organized and displayed logically in tables or figures? Are they relevant to the problem or hypothesis?

Discussion
Is the discussion logically based on the results? Is it intimately grounded in the original problem or hypothesis? Is there overgeneralization of the findings? Is the writing impartial and scientific? How can this study be used in the practice setting? How similar is the study's environment to the real world? What are the risks associated with implementation of the recommendations?

*Researchers should benefit from this by critically asking themselves whether they have included answers to these questions in their report.
†Clinicians should benefit from this by judging the report on the basis of completeness and utility and by finding out whether it contains answers to these questions.

Evaluating a Study: the Bottom Line

Ultimately, the nurse anesthetist evaluating a study is faced with the following three questions:

1. Do I disregard the study and its findings entirely, not applying them to either clinical practice or future analysis in any fashion?
2. Do I apply the study only in the sense of expanding my cognitive approach to anesthetic management? (In this scenario, although one may not materially or directly apply the study or its findings to practice, some intellectual growth or understanding is gained from the study, which subsequently is incorporated into one's repertoire.)
3. Do I make a direct application of the study to my practice?

Some questions to ask when one reads a study are listed in Box 4-6.

BOX **4-6**

Questions to Ask in the Reading of a Study

Object or Hypothesis

What are the objectives of the study or the questions to be answered?

What is the population to which the investigators intend to refer their findings?

Design of the Investigation

Was the study an experiment, planned observations, or an analysis of records?

How was the sample selected? Do possible sources of selection exist that would make the sample atypical or nonrepresentative? If so, what provision was made for dealing with this bias?

What is the nature of the control group or standard of comparison?

Observations

Are there clear definitions of the terms used, including diagnostic criteria, measurements made, and criteria of outcome?

Was the method of classification or of measurement consistent for all the subjects and relevant to the objectives of the investigation? Do possible biases in measurement exist, and, if so, what provisions were made to deal with them?

Are the observations reliable and reproducible?

Presentation of Findings

Are the findings presented clearly, objectively, and in sufficient detail to enable the reader to judge them for herself or himself?

Are the findings internally consistent? That is, do the numbers add up properly, can different tables be reconciled, and so on?

Analysis

Are the data worthy of statistical analysis? If so, are the methods of statistical analysis appropriate to the source and nature of the data, and is the analysis correctly performed and interpreted?

Is analysis sufficient for determining whether "significant difference" may be the result of lack of comparability of the group in gender or age distribution, in clinical characteristics, or in other relevant variables?

Conclusions

Which conclusions are justified by the findings? Which are not?

Are the conclusions relevant to the questions posed by the investigators?

Constructive Suggestions

Assume you are planning an investigation to answer the questions put forth in this study. If they have not been clearly asked by the authors, frame them in an appropriate manner. Suggest a practical design, criteria for observations, and type of analysis that would provide reliable and valid information relevant to the questions under study.

Adapted from Colton T: *Statistics in Medicine*. Boston: Little, Brown, 1974.

Common Mistakes

At this stage of the research process, mistakes include failing to adequately evaluate a study's methods and findings and in the process, uncritically accepting into practice information that may be misleading or incorrect. Although articles in professional journals should undergo critical review by peers who can detect mistakes, omissions, and alternative explanations, the ultimate responsibility for evaluating a study and determining the pros and cons of the implementation of its recommendations rests with the clinical reader.

FRAUD, DECEIT, AND HUMAN ERROR IN SCIENTIFIC RESEARCH

Scientists are human and suffer from the inherent frailties of the human condition. Even the most scrupulous and compulsive scientist can make an honest mistake, and such mistakes are tolerated by the community at large. Errors are costly in a variety of ways. Not only might an error result in months or years of wasted effort if it is not identified and rectified, but it also can mislead others who attempt to use or build on the original, flawed work.

Unfortunately, not all errors are honest. Scientific and academic misconduct occurs in a variety of forms. Although the motives of the involved parties are not always identifiable, some researchers feel pressure to publish, whereas others simply are intent on gaining attention by compiling a long list of publications or presentations. The bottom line is that scientific misconduct ultimately erodes the foundation on which science is built and may result in the administration of inappropriate therapy to those in need of treatment. Common examples of scientific and academic misconduct include the following:

- Plagiarism
- Alteration of data so they conform to expectations
- Outright fabrication of data
- Intentional sloppiness in scientific work
- Selective publication of data with intent to support one's beliefs
- Coercing subordinates to acknowledge oneself unreasonably
- Unapproved use or misuse of human or animal subjects
- Not giving appropriate credit in collaborative research

Recently there have been dramatic examples of research fraud and misconduct in the anesthesia literature by prominent (not so much as of this writing!) anesthesiologists in the domains of pain relief and perioperative fluid therapy. Drs. Scot Reuben and Joachim Boldt are dramatic recent examples of incredible misconduct leading to the retraction of dozens of papers by the authors and even the imprisonment of the former physician.

Guidelines for Dealing with Errors or Suspected Misconduct

The nurse anesthetist who is personally involved with or suspects scientific or academic misconduct on the part of a colleague is morally and professionally compelled to take action as soon as possible. Box 4-7 lists guidelines to adhere to if such a situation occurs.

STUDIES INVOLVING HUMAN SUBJECTS

The process of making a research project a reality involves coordination between patients' needs and rights and the study's parameters and goals. This process is controlled in some respects by criteria set up by various governing agencies. The 1947 Nuremberg Code, the 1964 Helsinki Declaration, and the 1971 guidelines of the U.S. Department of Health, Education, and Welfare were drafted to reflect the concern for individuals participating in research. In 1979 the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was established to continue work in this area. The culmination of that work, the Belmont report, defines the limits between research and practice and outlines the ethical guidelines to be considered for patient participation in research projects. According to the report,

BOX **4-7**

Dealing with Errors and Misconduct

If the Situation Has Resulted from Your Own Actions

Immediately acknowledge the error to your colleagues. If the error is in print, write to the journal editor or source in which the mistaken information was published.

If You Discover an Error in a Publication

Write a letter to the editor of the publication stating your case and supply any supportive materials you have.

If You Believe a Colleague Has Engaged in Misconduct

1. Discuss the situation with a trusted and experienced colleague, maintaining the anonymity of the accused. This will help you judge the motives of your own suspicions and establish the veracity of your charges.
2. Once the facts have been established, contact the colleague privately to determine whether the concern can be satisfactorily explained or rectified.
3. If resolution is not at hand, discuss the situation with the department director, chairperson, or dean, as indicated by the hierarchic administrative arrangement. Many institutions and universities have written procedures that carefully outline the process to be followed in such situations.
4. In situations in which resolution is still not achieved or if a definable administrative structure is not in place, consider contacting the National Academy of Sciences, Sigma Xi, the American Association for the Advancement of Science, the American Association of University Professors, or other scientific or professional organizations.

Adapted from Colton T: *Statistics in Medicine*. Boston: Little, Brown, 1974.

the difference between standard practice and research is defined in terms of design and outcomes. The phrase *medical practice* refers to diagnosis, treatment, and preventive health care whose purpose is the enhancement of the well-being of an individual. The term *research* refers to procedures whose purpose is the examination of a question or the testing of a hypothesis to expand the existing body of knowledge.

Institutional Review of Research That Involves Humans and Animals

All protocols involving the living must be submitted to a local institutional review board (IRB). The IRB is charged with the protection of each subject participating in the study. It is the responsibility of the IRB to ensure that informed consent is adequate, that no coercion is used in the recruitment of subjects, and that the risks to the subjects are minimal or no greater than necessary. To accomplish this, the IRB carefully reviews the study's protocol and consent forms, considering the study's design and patient selection.

A number of factors must be considered when a study calls for the involvement of human participants. The risk-benefit assessment compares the benefits of participating in a study with the potential risks generated by the study. Vulnerable populations (e.g., children, pregnant women) require special considerations. Risks can involve the patient, the family, or the community. The risk-benefit balance should be justified by an analysis of information to be gained from the research, a description of the available treatment alternatives, and the measures to be taken to minimize risks and discomfort.

Providing a patient with the information necessary for making an informed decision about participation is fundamental. Informed consent should be easy to understand and include a description of the research and plan of treatment, the risks and benefits, the alternatives to participation in the study, confidentiality, costs, and compensation. Informed consent also must include an assertion of the voluntary nature of the study, a statement that the patient may withdraw at any time without penalty, and a commitment that during the course of the study, the discovery of any new findings that may affect the subject's participation will be disclosed. In most instances, a signed consent form from a participant is necessary; ultimately, however, the IRB decides whether such a form is necessary.

Virtually all institutions and funding agencies have model consent forms whose format researchers must follow when developing a study. Consent forms (written in lay terminology) should include a brief description of the study, a summary of the anticipated risks and benefits of participation in the study, a statement regarding the maintenance of the participant's confidentiality, a disclaimer obviating the host institution of financial responsibility for damages that might occur, and the names and telephone numbers of the researchers. Under most circumstances, the individual who has agreed to participate in the study signs the consent form in the presence of the researcher and a witness who cosigns the consent. A copy of the consent form is given to the participant for his or her records.

CONTROVERSIES IN ANIMAL RESEARCH

Biomedical institutions now operate under guidelines that mandate the humane treatment of animals used in research. The use of animals for research is a subject of controversy fueled by disagreements between people who are highly supportive of the use of animals and those who strongly oppose it, such as supporters of the People for the Ethical Treatment of Animals (PETA) and the Animal Liberation Front (ALF). Researchers contemplating the use of animals in their research should carefully consult with their local IRB for guidance in this area.

EVIDENCE-BASED PRACTICE: EMPOWERING DECISION MAKING THROUGH RESEARCH

Evidence-based practice (EBP) is an approach to patient care founded on the belief that clinical decisions must be based on results obtained from rigorously controlled investigations. It cautions against using studies with low external validity (e.g., animal studies) or those based on uncontrolled observations (e.g., case reports, retrospective studies) in rendering decisions that influence or dictate patient care interventions.

Although many recipes for and approaches to EBP exist, the essential ingredients common to all include the following:

- Defining the patient's problem
- Proficiently searching the relevant literature
- Critically appraising the discovered literature
- Rationally applying the relevant literature in the context unique to the patient

At the core of EBP is the notion of critical thinking (appraisal) of the applicable literature. Here, intellectual rigor is balanced with clinical experience as the clinician determines whether the evidence is applicable to a particular patient's situation.

The dizzying array of studies in the anesthesiology field coupled with the complexities and vagaries of this patient population produce an informational tidal wave both frustrating and daunting to clinicians who endeavor to remain on the cutting edge with respect to patient care decisions. We all rely to one extent or another on

reviews of primary research to assist us in coming to understand and apply clinical research findings. Whenever possible, we should endeavor to use systematic reviews. Systematic reviews are those that incorporate (1) a comprehensive study retrieval process that minimizes publication bias, (2) selection criteria that identify only relevant studies, (3) a critical appraisal of the emergent literature accomplished by knowledgeable and sophisticated clinicians and researchers, and (4) reproducible decisions regarding the relevance and methodologic rigor of the selected primary research.

Recently the meta-analysis has begun to appear in the anesthesia literature. A meta-analysis is a systematic review that includes a quantitative statistical analysis of the findings that have emerged from several (or many) discrete studies examining a similar phenomenon. Examples of anesthesia-based meta-analyses include those by Tramer, who examined ondansetron as an antiemetic; Ballantyne et al., who studied pulmonary outcomes in patients who had epidural analgesia; Lee et al., who looked at acupuncture and acupressure as alternative approaches in the management of postoperative emetic symptoms; and Biddle, who evaluated the use of nonsteroidal anti-inflammatory drugs in the treatment of acute postoperative pain.[8-11]

When solid evidence evolves into sound clinical decision making, patients receive the best possible care; EBP helps us choose scientific evidence over confusing (or even unsound) opinion. In addition, EBP complements other foundational approaches to patient care and teaching. Some researchers argue that there is a crucial final step in the EBP model—namely, that clinicians self-evaluate their own EBP. In doing so, clinicians provide an ongoing process of evaluation and sensitivity testing for practice-based decisions.

Clinical research seeks to resolve, refine, and clarify the issues involved in the care and management of patients. Each day, we are faced with a host of common and uncommon patient scenarios that demand thoughtful, efficient decision making and resultant interventions. How we come to decide what course of action to take is in many cases as important as the action itself. Decisions involving the care of patients should be evidence based, a process of considerable complexity involving judging sources of information, evaluating the quality and relevance of information, recognizing the contextual elements that may alter the application of that information in a particular setting, and assessing its impact on the patient(s).

The Process of Evidence-Based Clinical Practice

What we do in a given circumstance is often more a matter of entrenched belief than a course of action firmly grounded in research. The published series *Clinical Evidence*, the international source of best available evidence related to common clinical interventions in various disease states, reveals that of 2500 treatments reviewed, 325 (13%) were rated "beneficial," 575 (23%) "likely to be beneficial," 200 (8%) as "a tradeoff between benefit and harm," 150 (6%) "unlikely to be beneficial," 100 (4%) "likely to be ineffective or harmful," and 1150 (46%) as having "unknown effectiveness." One might interpret this in many ways, but clearly it points to the theme that many treatment decisions are inadequately grounded in firm scientific rationale.[12]

The fundamentals of medicine and nursing have evolved from a time when the teaching and practice of authoritative figures (sages) were simply passed down and uncritically applied to patients. Advances came with clinical evolution, but primarily in the form of case reports, case series, editorials, and other publications that were too often based on preconceived notions, and deliberate or unintentional bias. The advent of the randomized controlled clinical trial (RCT) some six decades ago set the stage for a new era in patient care. In the RCT, patients are randomized to treatment strategies, the effect of outside influences on outcome are considered, and there is methodologic precision, not only with regard to the interventions applied to patients but also to how outcomes are measured. A brief overview/checklist is noted in Box 4-8 to help in judging the value of a particular RCT. Despite advances, practitioners, and nurses in particular, are often resistant in regard to bringing research advances to the bedside.

BOX 4-8

Checklist for Evaluation of the Randomized Controlled Trial

- Is a clear objective for the study stated?
- Is the sample size adequate?
- Is the study population well described?
- Are the interventions clearly described?
- Are randomization and blinding procedures adequate?
- Are valid and reliable outcome measures used?
- Is attrition (dropouts) considered in the analysis?
- Are the statistical methods appropriate?
- Are both clinical and statistical significance reported?
- Are the results generalizable to clinical practice?

Evidence-based practice (EBP) involves a series of consecutive, somewhat overlapping steps that follow.

Step 1: Asking a Question That Deserves an Answer

Should we anesthetize and perform elective surgery on a child who presents with an upper respiratory infection on the day of the scheduled procedure? What fluid and glucose management strategy should be used in the diabetic patient recovering from a major peripheral vascular procedure? Is it safe to use ketorolac in the patient just now recovering from tonsillectomy? What can be done to minimize the risk of ventilator-acquired pneumonia in the postoperative patient receiving mechanical ventilation? Should all patients recovering from general anesthesia receive supplemental oxygen in the PACU (postanesthesia care unit)? Should obstructive sleep apnea patients recovering from general anesthesia receive CPAP (continuous positive airway pressure) throughout their hospital stay if significant pulmonary hypertension is present? Such questions are common in practice and merit careful consideration in terms of intervention-related outcome, but relevant questions also apply to diagnosis, prognosis, and the potential for harm. It may seem like word play, but the answers to our questions are more likely to be important and valid if the questions posed are good. Questions should be focused to the extent that they are both applicable to the patients who are cared for and can be researched.

Steps 2 and 3: Searching for Relevant Evidence and Judging Its Worth

Once a question is at hand, the search for information begins, a process that can be both time consuming and challenging. Seeking evidence to address the question "What is the best antiemetic for the postoperative patient?" is much different than asking "Is isopropyl alcohol inhalation more effective than ondansetron in managing post–general-anesthesia nausea in the postpartum tubal ligation patient?"

Although providers usually have an opinion about care-related questions, EBP demands that we critically evaluate researchable and meaningful information sources to best address a particular

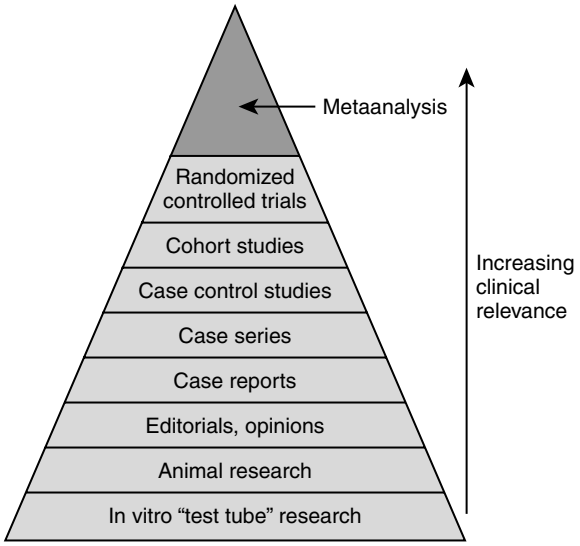

FIGURE **4-3** The pyramid of evidence.

patient's care. *Index Medicus* and *MEDLINE* are familiar and excellent sources but are not applicable in all circumstances, especially if time is of the essence. A particularly valuable database specifically related to EBP is the Cochrane Collaboration, a collection of well-conducted clinical trials organized into specific topics. Established websites, well-regarded (peer reviewed, authoritative) textbooks, or even colleagues with a more robust knowledge base than yours may suffice. But crucial to this is your level of confidence that your colleague, the database, or the book chapter is evidence based. The phrase "garbage in, garbage out" has particular application here.

A particularly powerful, and underused search tool that readers should investigate is CINAHL, the Cumulative Index of Nursing and Allied Health Literature. This tool has exceptional utility to the anesthesia domain and should be a part of any broad or focused research that one performs.

Definitions of EBP abound; for its practicality and relevance, consider the following description: EBP is the conscientious and critical use of quality published evidence in making decisions related to the care of a particular patient, considering the caregiver's unique expertise and the setting in which the patient presents. It is important to recognize that not all evidence that is retrieved or brought to bear on a question has the same value. Figure 4-3, the pyramid of evidence, demonstrates that the randomized, double-blind, controlled clinical trial has greater worth than the editorial or case report. This hierarchy of value is case and issue sensitive, because not all questions have relevant or applicable RCTs. On the other hand, when a number of RCTs are directed toward a similar issue, these can sometimes be combined, using rigorous methodology and a common set of statistical proceduring, to produce a meta-analysis (or quantitative systematic review).

Step 4: Determining Whether the Evidence Applies to Your Particular Patient

Translating knowledge into practice is the next critical step. If you have determined the evidence is valid and important, you must now decide whether you should apply it to the care of your patient. EBP then becomes an ongoing process of inquiry, asking "Why am I doing it this way?" and "Are there compelling reasons for me to do it differently to achieve a better outcome?" The factors influencing these decisions are complex. Ultimately the decision to implement an intervention is a blend of experience and science (evidence) as you carefully assess what value the evidence has in the context and setting of a particular patient. What is meant by *context?* Box 4-9 illustrates just a few of the contextual factors that we must consider in the process of EBP.

BOX 4-9

Some Contextual Considerations in the Process of Evidence-Based Clinical Practice*

Considerations in Weighing the Application of a Therapy in a Particular Patient

- Age and gender
- Hydration status
- Smoking history
- Current drug therapy
- Duration of illness
- Severity of symptoms
- Cost of therapy
- Side effects
- Inpatient or outpatient
- Coexisting conditions
- Physician and staff familiarity and experience with intervention
- The degree of technical mastery necessary to perform the intervention
- Staff makeup (specialists, generalists)
- Type of hospital (community, medical center, urban, rural)
- Support personnel
- Is reasonable follow-up available to assess the intervention's outcome?

*The list is partial and meant only to stimulate thinking regarding how factors may influence the application and outcome of a particular intervention.

Step 5: Evaluating the Effect (Outcome) of the Evidence-Based Intervention

Absolutely vital to the process of EBP is evaluation. Here one determines whether the evidence has altered the "usual" practice pattern. If so, has it been associated with improved efficiency and health outcome, and has it maintained the quality of care? Evaluation allows not only for deciding whether the intervention "works" but also for determining whether variations arise (e.g., dosing, timing, duration, complications, unexpected occurrences, etc.). In doing so, a kind of living, evolving document arises that can be used for purposes of assessing efficacy, quality assurance, and risk.

The "PICO" Approach

A common model used in developing an appropriate clinical question is the so-called *PICO* approach. PICO is a mnemonic that describes key components of good question construction, that is, **P**atient, **I**ntervention (or cause), **C**omparison (if appropriate), and **O**utcome. Because clinical circumstances, and their associated questions, vary considerably, not all questions will have a "comparison" group, although many will. Examples of PICO-derived questions follow:

Patient	Intervention	Comparison	Outcome
61-year-old male, infarction	Streptokinase	Plasminogen activator	Death
31-year-old female, laparoscopy	Ondansetron 4 mg	Droperidol 1.25 mg	Nausea
17-year-old male, arthroscopy	Spinal anesthesia	—	Time in PACU

Using the PICO approach, a clinically focused, relevant question emerges from each of the scenarios established earlier. For example, with respect to the second, a comparison scenario, the following question might emerge:

- In young women undergoing diagnostic laparoscopy for nonspecific pelvic pain and receiving anesthesia with sevoflurane, atracurium, and fentanyl, is there a difference in the rate of postoperative nausea when either ondansetron 4 mg or droperidol 1.25 mg is given 30 minutes prior to emergence?

With respect to the third, noncomparison question, the following question might emerge:

- In adolescents undergoing knee arthroscopy under spinal anesthesia with lidocaine 75 mg and sufentanil 10 mcg, what is the anticipated length of stay in the PACU before they are street fit?

SUMMARY

Although CRNAs are only now becoming prepared to assume the role of primary researchers, all CRNAs are in a position to read about the latest advances in nurse anesthesia practice and incorporate validated interventions into their clinical practice. Nurse anesthesia research is grounded fundamentally in solving patient-care problems during the preoperative, intraoperative, and postoperative periods. Although much behavioral, educational, and product evaluation–oriented research has been conducted by nurse anesthesia researchers, all nurse anesthesia research is wedded inextricably to patient care. Research is essential to the professional evolution of nurse anesthesia as CRNAs become increasingly accountable for their own independent basis for practice.

A number of antiscience movements are operative in the world today. At the heart of all of these movements is the sophisticated use of the concept of proof by proclamation rather than proof by experimentation. As active consumers and producers of scientific knowledge, nurse anesthetists can do their part by resisting the integration of aberrant and ill-founded thinking into their discipline. This can be achieved if each CRNA understands the need to maintain a critical dialogue regarding what can be incorporated into nurse anesthesia practice.

All CRNAs are mandated to understand and use research in their practices. The American Nurses Association strongly urges even undergraduate nursing students to learn how to read, interpret, and evaluate published research for applicability to nursing practice. Although the evolution of nursing research—and that of nurse anesthesia research in particular—has lagged behind that of many other disciplines, tremendous strides are being made as greater numbers of nurse anesthetists are prepared at both the master's and doctoral levels. It is essential that nurse anesthetists recognize the need to promote nurse anesthesia as a science-based profession. There is no better way to achieve this end than to continue emphasizing the importance of the research process.

General Principles, Pharmacodynamics, and Drug Receptor Concepts

CHAPTER 5

◆ *John J. Nagelhout*

The practice of anesthesia requires a full spectrum of drugs from which an anesthetic plan can be implemented to achieve the desired level of surgical anesthesia, analgesia, amnesia, and muscle relaxation. In addition to surgical anesthesia, pain medicine has evolved as a significant clinical practice component.[1,2] Now that the human genome has been mapped and the field of molecular and cellular proteomics is exploring new concepts, specific receptor-targeted drugs are envisioned, as is a revolution in the way health care is delivered. Likewise, the methods used to provide anesthesia care will undergo a profound change based on this new knowledge. Already, studies are challenging long-held concepts of pharmacodynamics and pharmacokinetics that guide the clinical use of anesthetic agents. Target-controlled drug administration that factors in clinical pharmacodynamic and pharmacokinetic information is already being applied.[3,4]

Although the mechanism of action of the general anesthetics remains unknown, the primary site of anesthetic action is now considered to be membrane receptors and not the lipid bilayer surrounding the nerve cells.[5-7] Spinal cord receptors are being differentiated from receptors in the brain and targeted with specific drugs. A more in-depth knowledge of the concept of minimum alveolar concentration, which is used to define inhalation anesthetic dosing, is now coming to light.[8,9] Receptor super families with definable amino acid subunits are the targets of new classes of anesthetic drugs such as α_2-agonists and analgesics.[10] The potentiation of the inhibitory γ-aminobutyric acid (GABA) receptors is considered a primary mechanism of action of inhalation and intravenous anesthetics.[11] The recovery from intravenous anesthesia is described in terms of context-sensitive half-time, which in addition to the usual concept of drug half-life takes into consideration the duration of anesthetic administration rather than just drug redistribution and elimination profiles.[12-14]

The importance of the individual, with his or her unique genetic profile, is surfacing as a major determinant of anesthesia outcome.[15,16] The number of patients who now make up the portion of the population classified as elderly—those age 60 years and above—is ever increasing. Clinical experience has shown that the response to anesthetic drugs in elderly patients differs from that in younger patients. Age-related changes in drug pharmacokinetics do not totally explain the differences in drug dosing necessary to achieve anesthetic end-points in elderly patients. Studies to date in elderly patients, although limited, demonstrate an age-related decline in most receptor populations and an overall decrease in pharmacodynamic responses.[17-20] Preoperative assessment may soon take on an entirely different meaning as patient information becomes more genetically oriented. The choice of anesthetic agents will be based on age-related receptor profiles and the patient's genetic ability to rapidly clear and recover from anesthetic drugs once their administration has been terminated.[21-24] Until that time, anesthetists will continue to administer anesthesia based on age-indexed population drug profiles adjusted for individual pathologies (i.e., general principles of pharmacology).

The current medical economic climate necessitates the optimum selection and use of anesthetic drugs based on their pharmacologic profiles. The term *pharmacology* refers to the study of processes by which a drug produces one or more measured physiologic responses. The concept of a drug-induced tissue response has changed little since Ehrlich first proposed it (circa 1905). What has changed, and continues to change, is our understanding of the processes involved in drug-receptor interactions.[25-27] Recent attention has focused on the biosphere, or the protein receptor site, as not only the locus of drug binding but also a primary regulator of the measured pharmacologic response. Secondary processes, including drug absorption, distribution, biotransformation, and excretion, also influence the pharmacologic response.[28]

RECEPTOR STRUCTURE

A *receptor* is a protein or other substance that binds to an endogenous chemical or a drug. This coupling causes a chain of events leading to an effect. Receptors have three common properties: sensitivity, selectivity, and specificity. These properties are characterized by the fact that a drug response occurs from a low concentration (sensitivity) produced by structurally similar chemicals (selectivity), and the response from a given set of receptors is always the same because the cells themselves determine the response (specificity). The bonds that form between drugs and receptors typically fall into these categories from weakest to strongest: van der Waals, hydrophobic, hydrogen, ionic, and covalent.

Drug Receptors

The historic concept of a drug receptor complex considered the receptor to be a single protein to which the drug aligned and attached itself. We now have identified multiple mechanisms by which an endogenous substance or drug may complex with a receptor and transmit a signal. There are seven classes of drug receptor proteins based on genetic characterization and similarity of structure and functions.[29] Some examples of different types of receptors are given in Box 5-1.

Drug receptor proteins may be located within the luminal membrane and at the surface of the ionic channel. They also occupy intracellular sites. The drug lidocaine and other amide and ester local anesthetics, for example, act at intracellular receptor sites near the sodium channel. Studies of acetylcholine and its receptor at the neuromuscular junction indicate that less than 1% of the cell surface binds drug to receptor protein to achieve the tissue response.[30] Complete saturation of available receptors with drug molecules is not necessary for a desired tissue response to be elicited. With recent advances in molecular biology, many receptors have been extensively characterized, amino acid sequenced,

BOX 5-1

Receptor Classification

- 7-Transmembrane receptors
- Ligand-gated ion channels
- Ion channels
- Catalytic receptors
- Nuclear receptors
- Transporters
- Enzymes

Data from: Guide to receptors and channels (GRAC), 4th ed. *Br J Pharmacol* 2009; 158(Suppl 1):S1-S254.

and cloned. This is leading to new and better understanding of receptor pharmacology and new approaches to drug discovery.[31-34]

For intravenously administered drugs, sufficient drug for a maximal tissue response is delivered to the receptor site within the time required for a single complete circulation (approximately 1 minute), provided an adequate drug dose was administered initially. Current understanding of molecular pharmacology suggests that the delay recorded from initial drug administration to the onset of the tissue response reflects the time required for molecular orientation and attachment to the receptor—that is, the time course of the receptor protein conformational change and the tissue response time.[35] As long as both the drug and the receptor are hydrophobic, bonding occurs.[36] Intravenous anesthetics act by binding to membrane receptor channel proteins. The $GABA_A$ (ionotropic receptor family A) inhibitory receptor has been implicated and suggested as a primary site of intravenous anesthetic action, except in the case of ketamine.[37-39] Inhalation anesthetics have long been thought to produce their anesthetic action by dissolving in the lipid bilayer surrounding membrane ion channels and interfering with their ability to open and close. Recent electrophysiologic evidence, however, indicates that inhalation anesthetics, like intravenous anesthetics, bind to $GABA_A$ receptor proteins and cause inhibition of signal transduction by increasing the influx of chloride ions through membrane channels.[11,37-39]

Individual agonist drugs have at least three configuration points for attachment to their receptors. With more points of attachment, a more perfect drug-receptor fit occurs. Agonist drugs can induce receptor proteins to alter their topography to achieve a more exacting fit with the drug. The alignment of a drug with its receptor is aided by various bonding forces, of which van der Waals forces and ionic bonding are prominent. Volatile anesthetics (e.g., desflurane, sevoflurane, isoflurane, and nitrous oxide) bond to cell receptors by means of a nonspecific hydrophobic bonding mechanism.

Some endogenous proteins provide alternative drug-binding sites. These sites are more correctly termed *acceptors;* the acceptor reduces the amount of unbound drug available for receptor complexing. Albumin contains numerous acceptor sites and generally binds to acidic drugs. $Alpha_1$ acid glycoprotein and β-globulin favor basic drugs. Drugs bound to these proteins are unavailable to interact with receptors, therefore reducing the available active drug concentration.

Types of Receptors

As noted earlier, a variety of receptor types have been isolated and investigated, including GABA, opioid, alpha, beta, acetylcholine, histamine subtypes, and the pain-related capsaicin receptor, as well as numerous others.[39-43] The nicotinic and muscarinic

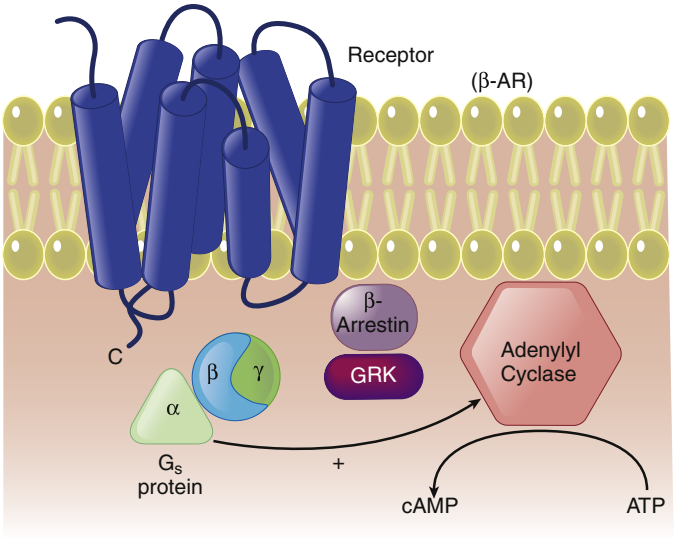

FIGURE **5-1** G Protein–coupled receptors. Upon ligand binding, β-adrenergic receptors (β-AR) bind to the heterotrimeric guanine nucleotide–binding protein Gs, inducing the exchange of GTP for GDP on the Gα subunit. Guanine nucleotide exchange induces dissociation of the α subunits from βγ subunits, the former of which activates adenylyl cyclase and the production of the second messenger cyclic AMP (cAMP). Signaling is terminated by GTP hydrolysis by the Gα subunit, resulting in its occupation by GDP, promoting reassociation of the heterotrimeric αβγ complex and inactivation of adenylyl cyclase. Moreover, receptors are inactivated by phosphorylation by G protein–coupled receptor kinase (GRK) resulting in the binding of β-arrestin, producing receptor desensitization by preventing productive interaction with G proteins and inducing internalization. (From: Waldman SA, Terzic A: *Pharmacology and Therapeutics: Principles to Practice*. Philadelphia: WB Saunders, 2009:55.)

cholinergic receptors that bind acetylcholine have been extensively studied.[44-46] The acetylcholine receptor protein is a pentamer of five peptide subunits conceptually forming a five-sided ring, with the central portion serving as the transduction ion channel. Only two of the five subunits are involved in acetylcholine binding. The remaining three peptide subunits participate in the signal transduction process that involves a protein conformational shift, allowing inward movement of sodium ions through the opened ion channel. It is interesting to note that the $GABA_A$ receptor also has been shown to be composed of five peptide subunits arranged to form a pentameric ring.[43,47-49]

Signal Transduction

In biology, *signal transduction* refers to processes by which a cell converts one kind of signal or stimulus into another. Most often, these involve ordered sequences or cascades of biochemical reactions inside the cell. They are commonly referred to as *second messenger pathways*. An example of a G protein–coupled receptor (GPCR) and its second messenger system is shown in Figure 5-1.

Many of the actions of the common anesthetic drugs are transduced through cell-surface receptors that are linked to GPCRs. Receptor signaling translates changes to G proteins that are then linked to a second messenger such as cyclic AMP (adenosine monophosphate) or cyclic GMP (guanosine monophosphate). These second messengers regulate enzymes such as protein kinases and phosphatases, which drive their ultimate intracellular actions.

Signal transduction for the $GABA_A$ receptor, for example, involves inward chloride ion movement through the opened central channel. The protein compositions of acetylcholine and GABA receptors are remarkably similar, despite their functional differences—specifically, acetylcholine and sodium ion transduce an excitatory signal, and GABA and chloride ion transduce an inhibitory signal.[50,51]

For many drugs, the composition of the receptor protein and the signal transduction process may be identical, even though the drug-induced tissue response is not. The primary difference among drug receptor proteins may be only the selective binding subunits and the ion species moving through the channel.[37,39,41,52,53] The specific peptide subunits are ultimately responsible for the pharmacologic properties of specificity, affinity, and potency.

In addition, specific isomers that have fewer side effects than the racemic mixture have been marketed. Drugs such as dexmedetomidine, ropivacaine, and cisatracurium are selective in their receptor binding and thus achieve a better clinical side effect profile.[54,55]

DRUG RESPONSE EQUATION

The drug response equation is fundamental to pharmacologic principles.[35] It is derived from the law of mass action and is shown in the following equation, where drug (D) combines with receptor (R) to form a drug receptor complex (DRC) that elicits a tissue response (TR).

$$D + R \rightleftharpoons (DRC) \rightleftharpoons TR$$

What remains unique about this equation is that in most cases, the drug receptor complex represents a highly selective process. Yet the resultant tissue response tends to vary from individual to individual, reflecting each individual's receptor and genetic profile and physiologic state. The basic drug response relationship conceptually depends on a common pharmacologic theory of drug action. This is the *occupancy theory*. Simply stated, the magnitude of a drug's effect is proportional to the number of receptors occupied. Although it is understood that drug receptor interactions have more complexity than this theory accounts for, it serves as a useful background for many pharmacologic concepts.

POPULATION VARIABILITY

Because the objective of pharmacologic intervention is to achieve a desired therapeutic response, anesthetists recognize that a range of responses to a given drug and dosage is possible within a patient population. Therapeutic drug doses reflect average doses of a "normal" population of individuals. Specific therapeutic doses for population subsets (e.g., pediatric, neonatal, geriatric, patients with cardiac or other chronic diseases) are available, thereby narrowing the degree of response variability for a given drug and clinical population. The age, sex, body weight, body surface area, basal metabolic rate, pathologic state, and genetic profile of an individual directly influence the pharmacologic response.

Given the increasing median age of the population in the United States, studies of the influence of age on the responses to anesthetic drugs have increased. Steady-state plasma concentrations of hypnotic drugs such as midazolam and propofol and minimum alveolar concentrations (MAC) for inhaled anesthetics (e.g., desflurane, isoflurane, or sevoflurane) required to achieve desired anesthetic end-points decrease as age increases, independent of any age effect on drug pharmacokinetics.[56,57-59] In addition, the effective plasma concentration 50 (median effective concentration [EC_{50}]) needed to achieve sedation with midazolam infusion is reported to be decreased by 50% in elderly volunteers.[57,60] Unfortunately, the specifics responsible for the observed age-related decrease in effective dose of anesthetic drugs is not presently known. Receptor changes associated with aging and kinetic differences in the elderly are in part responsible for the variation in response. Until a better understanding of the age-related changes exists, empirical dose reduction or the use of dosing algorithms for the elderly patient population is indicated.

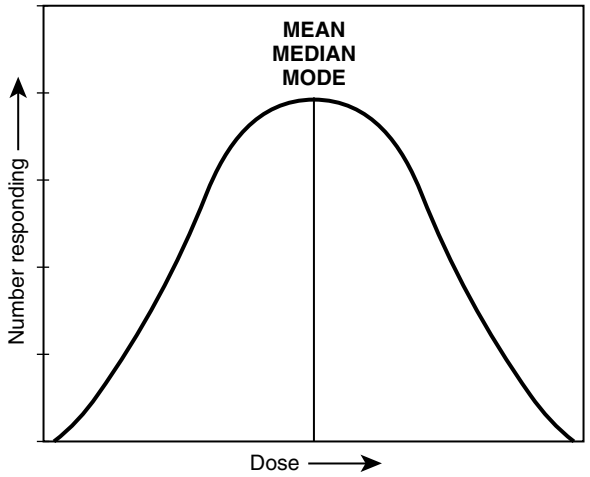

FIGURE **5-2** The theoretic normal frequency distribution of a drug response in a normal population.

Mean, Median, and Mode

A graphic description of the dose-response relationship is displayed in Figure 5-2. The theoretic normal distribution of quantal (desired) responses to increasing drug dose takes the shape of a Gaussian curve. Theoretically, the numbers of respondents on both sides of the mean (average dose) are equal, with the greatest percentage of individuals responding near the center of the curve. In a Gaussian distribution curve, the mean, median, and mode are equidistant from the two extremes.[61] Atypical responders fall at each end of the curve.

On the curve, the mean dose is the arithmetic average of the range of doses that produce a given response. The median dose is that dose on either side of which half of the responses occur. The mode dose is the dose representing the greatest percentage of responses. The mean, median, and mode doses are often close but are rarely the same in actual dose-response curves.

Standard Deviation

The terms *standard deviation* (SD) and *standard error of the mean* (SEM) describe population response variability.[62] The SD provides information regarding the actual responses measured and their difference from the calculated mean. In Figure 5-3, 1 SD makes up 68% of the responses (34% to the left and 34% to the right of the mean value); 2 and 3 SDs constitute 95% and 99.7% of the responses, respectively. The greater the SD, the less the mean reflects the central tendency of responses.

Standard Error of the Mean

The SEM describes the variance of the mean. It is equivalent to the SD of the mean. By repeating the dose-response measurements on different, normally distributed populations, a slightly different mean dose value is obtained each time because the mean value is only an arithmetic average of the responses obtained. In Figure 5-4, 1 SEM represents the range within which the mean value would occur on repeat testing 68% of the time, and 2 and 3 SEMs (not shown) represent the range within which the mean value

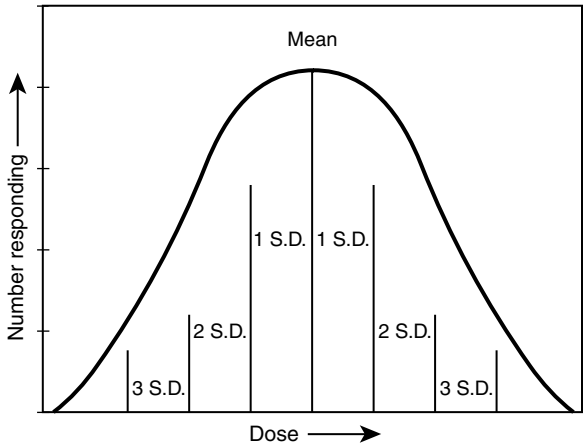

FIGURE **5-3** A normal distribution curve showing the standard deviation (SD) in relation to the mean (average) dose value.

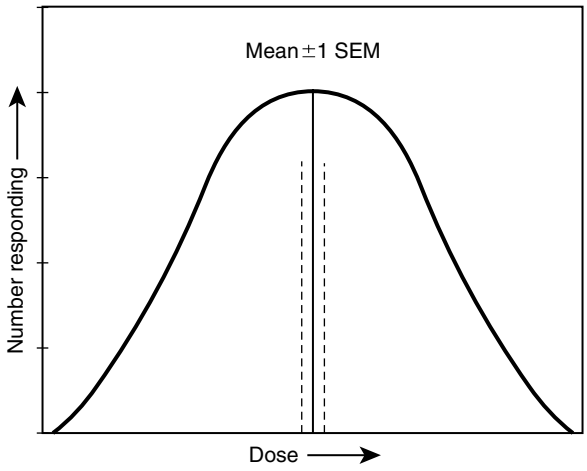

FIGURE **5-4** A normal distribution curve showing the relationship of the standard error of the mean (SEM) to the mean (average) value.

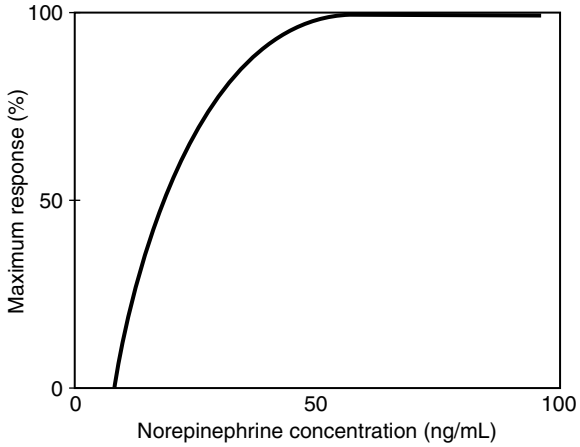

FIGURE **5-5** A linear arithmetic-graded response curve showing blood vessel constriction to increasing norepinephrine concentrations.

would occur 95% and 99.7% of the time, respectively. Both the SD and the SEM are important statistical descriptors of observed drug responses in patient care and in research and reflect pharmacologic principles of population variance.[62]

DRUG DOSE RESPONSE

The administration of drugs is largely determined by a mean therapeutic dose per kilogram of body weight or body surface area calculated from a previously determined average dose for the normal population. This approach may be responsible for underdosing and overdosing of patients, because population variability is not considered in the calculation. The individual therapeutic response to a fixed mean dose is frequently less than optimal.

Studies that used sensitive quantitative measurement techniques identified a response variability to given drug doses in the normal population that was far greater than previously demonstrated.[25] Clearly, the optimal dosing approach for patients when drugs are administered by the intravenous route is by titration until the desired therapeutic response is attained. This is particularly true in critical care and anesthesia patients, in whom drug onset and offset responses are relatively rapid.

Two types of dose-response curves—graded and quantal—describe average drug response and subject variability within a given population.

Graded Dose Response

The graded dose-response curve, which is plotted in linear fashion, characterizes the change in measured response as an administered dose is increased (Figure 5-5). The response curve has a hyperbolic shape, with the greatest change in response occurring to the left on a small portion of the x-axis. When plotted on a logarithmic scale, the graded dose-response curve takes an S shape; at the lowest dose, the measured response (e.g., vascular response to norepinephrine) is small or even nonexistent. At the highest doses, the response is maximal and approaches a plateau (Figure 5-6). Typically, at some point between 20% and 80% of the maximal response, the curve approaches a straight line because changes in dose and response reflect a proportional relationship.

Plotting on a semilogarithmic scale, with the dose in log units, provides a more detailed representation of the entire graded dose-response curve, especially at the two extremes.[25] From a semilogarithmic plot of graded dose responses, the potency of different agonist drugs with similar mechanisms of action (i.e., action through the same receptor) can be compared, or the ability of an antagonist drug to reduce the response to an agonist (e.g., in the alpha receptor blocker, phenoxybenzamine antagonism of norepinephrine-induced vasoconstriction) can be observed. It should be noted that "antagonist" drugs that do not bind to the agonist receptor are actually not antagonists. For example, neostigmine

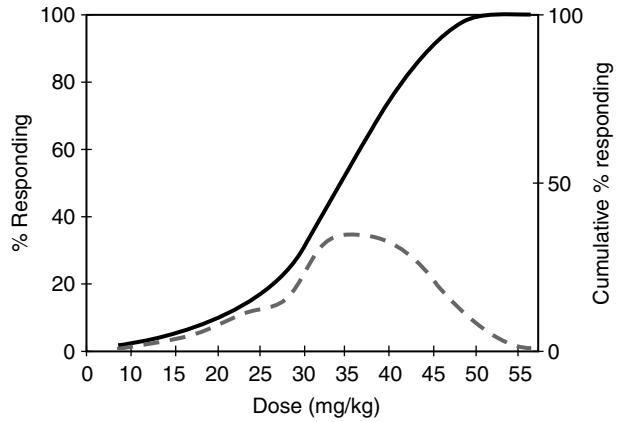

FIGURE **5-7** A quantal dose-response curve indicating the frequency of all-or-nothing dose responses. The *dashed line* represents a histogram of the number of responses measured at each dose. The *solid line* represents the cumulative response curve of the total number of responses up to and including each dose.

is not an antagonist of rocuronium, because it does not compete with rocuronium for the muscle end-plate receptor site. Neostigmine inhibits acetylcholinesterase, which allows acetylcholine to compete effectively with rocuronium and other nondepolarizing muscle relaxants for the receptor, leading to a recovery of muscle tone. Therefore, its effect is at least a partial form of indirect antagonism. Sugammadex is the first and so far only drug in a new class of muscle relaxant reversal drugs. Known as a *selective relaxant binding agent* (SRBA), sugammadex offers a unique mechanism in that it encapsulates the muscle-relaxant molecule, rendering it inactive. The complex formed is eliminated. This is a form of chemical antagonism, because no direct receptor action is evident.[63]

Quantal Dose Response

Clinically, a quantal dose-response curve provides information on the frequency with which a given drug dose produces a desired therapeutic response in a patient population. The response is measured in an all-or-nothing fashion. The quantal response curve describes the variation in response to the threshold dose within a population of seemingly similar individuals (Figure 5-7). For example, with propofol induction of anesthesia, a small number of patients become unconscious after administration of 0.5 mg/kg, more after administration of 1 mg/kg, and virtually all after administration of 2 to 3 mg/kg. Plotting the cumulative number of patients with all-or-nothing responses over a range of doses produces an S-shaped response curve. However, the quantal dose S-shaped curve differs from the graded dose-response S-shaped curve because it reflects population variation for the threshold dose needed to produce a given all-or-nothing desired response.

Descriptive information about population dose-response characteristics can be obtained from quantal dose-response curves.[25] Descriptors such as effective dose, toxic dose, and lethal dose can be identified. The effective dose 99% (ED_{99}) and lethal dose 1% (LD_1) identify the therapeutic safety margin of a drug, as shown in the following equation.

$$\text{Safety margin} = LD_1 - ED_{99} / ED_{99} \times 100$$

When the therapeutic safety margin is great, the risk of drug-induced death is small, and the margin of therapeutic safety is wide. The opposite is true when the therapeutic safety margin is small.

The term *therapeutic index* (LD_{50}/ED_{50}) describes a drug's median therapeutic safety margin for a particular therapeutic effect.[25] For example, chemotherapeutic drugs have a very narrow margin of safety. Drugs that produce surgical depths of anesthesia, such as sevoflurane and other halogenated anesthetics, also have a relatively narrow margin of safety. Sevoflurane is administered clinically in an amount that is 1.3- to 1.4-fold the MAC (minimum alveolar concentration), or the dose at which 50% of the patients do not move on surgical stimulation. The MAC can be lethal if the volume percentage delivered is increased to 1.7- to 2.0-fold and maintained for a prolonged period of time.

Another descriptor obtained from the quantal dose-response curve is the median effective dose (ED_{50})—the dose at which 50% of a population responds as desired. The ED_{50} is often used for comparing the potency of drugs within a class. Because the ED_{50} is derived from the linear portion of the quantal dose-response curve (20% to 80% of the responders), relatively accurate comparisons of drugs that cause similar responses can be made (see Figure 5-6). Important in each of these descriptions is the word *median*. Median ED_{50} dose values are derived average response doses from a population of patients.[25] Each individual within the population responds, more or less, to a median dose on the basis of his or her biologic variation or, specifically, genetic variations in drug-receptor protein. Confidence limits for a given median dose and its therapeutic response can be calculated. Typically, the proportion of subjects responding to an ED_{50} dose ranges from 45% to 55%. Derived median population dose values provide a point of reference for achieving an individual's optimum therapeutic dose.

For intravenously administered drugs used in anesthesia, the trend is toward drugs that have brief onset-offset times and can be administered by infusion, often with the use of a computer-controlled pump.[64,65] For example, the desired anesthetic response to propofol and remifentanil can be effectively titrated after an initial loading dose.

Future developments related to drugs will include the availability of indwelling drug-analyzing probes similar to the continuous mass spectrometers currently used for analysis of end-tidal anesthetic gas concentrations. Real-time analysis of drug concentration can incorporate feedback control to drug-infusion devices. These target-controlled infusions allow the dose to be set to patient response and automatically maintained with minimal fluctuations in blood and effect site drug concentrations and the tissue response.[66,67] Currently, computer-controlled infusion pumps use programs based on pharmacokinetic modeling studies in an attempt to approximate the required effect site drug concentration to achieve and maintain a desired level of anesthesia in patients. The continuing development of ultrafast onset-offset anesthetic drugs such as remifentanil and propofol will simplify titration of the anesthetic end-point by the anesthetist and minimize undesired effects.

DRUG RECEPTOR INTERACTIONS

Advances in molecular receptor pharmacology have provided a new understanding of patient drug responses.[26] The *drug receptor interaction* describes the formation of a single drug receptor complex, which leads to a fractional tissue response (FTR):

$$D + R \underset{k_2}{\overset{k_1}{\rightleftharpoons}} DR \overset{k_3}{\rightarrow} FT$$

The desired tissue response is observed when sufficient receptors have been occupied and activated by free drug. This process obeys the law of mass action: At steady state, equilibrium exists between bound and unbound drug receptors and the concentration of free unbound drug at the site. Specific characteristics of the drug and the receptor determine the association and dissociation of a drug with regard to its receptor and the kinetic, *k*, rates, which are constants.[35]

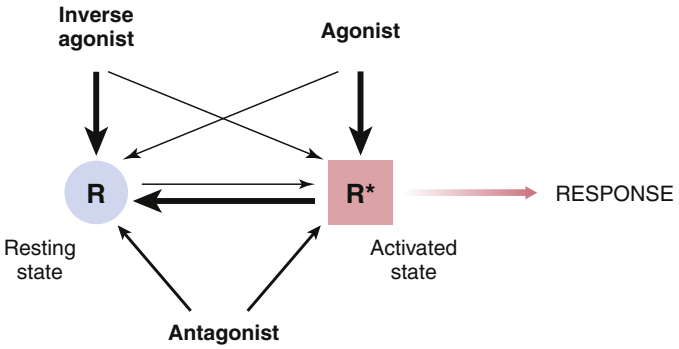

FIGURE **5-8** The two-state model. The receptor is shown in two conformational states, 'resting' (R) and 'activated' (R*), which exist in equilibrium. Normally, when no ligand is present, the equilibrium lies far to the left, and few receptors are found in the R* state. For constitutively active receptors, an appreciable proportion of receptors adopt the R* conformation in the absence of any ligand. Agonists have higher affinity for R* than for R, and so shift the equilibrium toward R*. The greater the relative affinity for R* with respect to R, the greater the efficacy of the agonist. An inverse agonist has higher affinity for R than for R*, and so shifts the equilibrium to the left. A 'neutral' antagonist has equal affinity for R and R*, and so does not by itself affect the conformational equilibrium but reduces by competition the binding of other ligands. (From Rang HP, et al. *Rang and Dale's pharmacology,* 7th ed. Edinburgh: Churchill Livingstone, 2012:14.)

Drug Affinity and Efficacy

The terms *affinity* and *efficacy* (intrinsic activity) describe the degree of drug receptor interaction for a given drug and receptor protein population (e.g., $GABA_A$ and propofol). The observed tissue response reflects the quantity of drug receptor complexes intact at any given moment. Each drug receptor interaction elicits a quantum of excitation, and the summation of many individual quanta produces the tissue response.[62]

The time constant that describes the fractional tissue response after the drug receptor complex formation typically has been considered to be near zero or instantaneous. Until recently, the primary time constant thought to influence the onset of tissue response was the duration of the delay in the delivery of drug to the receptor sites. The phrase *pharmacokinetic analysis* of drug absorption and distribution describes onset time and magnitude of drug response. *Drug elimination kinetic analysis* describes the duration of the tissue response.

Drug-Receptor-Response Triad

Current understanding of receptor dynamics has added an additional and possibly the most descriptive component of the drug-receptor-response triad. When a drug combines with its receptor, a conformational change occurs in the receptor protein itself. No tissue response can occur without the structural shift. Evidence does suggest that events within the biosphere after drug association with the receptor are the principal regulatory variables of the response onset-offset time course.[62] An additional theory of drug action is referred to as the *two-state model*. In this model, the receptor is thought to exist in equilibrium between either an activated or inactivated state. Constitutively active receptors can exist and are shifted toward the activated state, even though no agonist or ligand is present. Receptors for benzodiazepines, cannabinoids, and serotonin are examples. Agonists shift the equilibrium toward activation. Antagonists freeze the equilibrium, and inverse agonists shift the equilibrium toward inactivation.[68,69] The two-state model is shown in Figure 5-8.

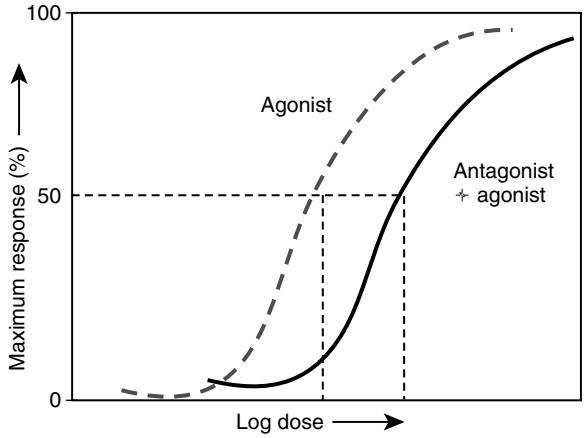

FIGURE **5-9** A logarithmic dose-response curve that shows an agonist drug response alone *(dashed line)* and in the presence of an antagonist drug *(solid line)*.

Until recently, the terms *drug absorption*, *distribution*, and *elimination* were used solely to describe the tissue-response time course.[70] However, the response may be more complex than was originally thought. It is now known that drug delivery sufficient to occupy 1% of the receptors is in many instances all that is required for a maximum tissue response to occur. Furthermore, the synthesis and destruction of receptor proteins occur at a much more rapid rate than was previously believed—within minutes rather than days. Receptor up-regulation and down-regulation can occur during drug infusion, with new receptor protein being synthesized in response to availability of free unbound drug.[25,26,71,72]

DRUG ANTAGONISM

Pure Antagonists

Pure pharmacologic antagonist drugs are similar in molecular structure to their corresponding agonist drugs. However, owing to the addition or subtraction of one or more chemical moieties, they are unable to initiate the receptor protein conformational shift necessary for eliciting a tissue response. Such antagonist drugs have receptor affinity but lack intrinsic activity or efficacy.

Antagonists that possess the property of weak affinity for the same receptor protein (e.g., atropine, esmolol) are competitive and may be displaced by an agonist. Noncompetitive antagonists, such as phenoxybenzamine and aspirin, have a strong affinity for the receptor protein, usually via covalent bonds, and cannot be displaced by the agonist.[73] New receptor protein must be synthesized if agonist receptor complexing is to occur.[72,73] As with agonist drugs, not all receptors are bound by antagonists. Antagonists cause a rightward shift in the drug dose-response curve. The extent of rightward shift reflects the number of available receptors occupied by the antagonist drug (Figure 5-9). Comparison of the ED_{50} in Figure 5-9 shows a reduced affinity of the agonist for its receptor when the antagonist is present.

Agonist-Antagonists

Agonist-antagonists are the second major type of antagonist drugs.[25] As the name implies, agonist-antagonist drugs have receptor protein affinity and intrinsic activity, but often only a fraction of the potency of the pure agonist. Narcotic antagonists often are of the nonpure, agonist-antagonist type, such as nalbuphine. The mechanism by which agonist-antagonist drugs elicit less of a tissue response is not fully understood. An incomplete receptor protein conformational shift has been suggested.

TABLE 5-1 Drug Interaction Terminology

Drug Interaction	Explanation	Viewed as an Equation
Addition	The combined effect of two drugs acting via the same mechanism is equal to that expected by simple addition of their individual actions.	1 + 1 = 2
Synergism	The combined effect of two drugs is greater than the algebraic sum of their individual effects.	1 + 1 = 3
Potentiation	The enhancement of the action of one drug by a second drug that has no detectable action of its own.	1 + 0 = 3
Antagonism	The action of one drug opposes the action of another.	1 + 1 = 0

Physiologic Antagonism

Physiologic antagonism, another form of antagonism, involves two agonist drugs that bind to different receptors.[25] For competitive antagonism, the agonist and antagonist have affinity for the same receptor protein; in contrast, in physiologic antagonism, both drugs bind to specific unrelated receptor proteins, initiate a protein conformational shift, and elicit individual tissue responses. The responses, however, generate opposing forces such as are observed with isoproterenol-induced vasodilation and norepinephrine-induced vasoconstriction. The net effect on blood pressure is less than it would be if either drug were used by itself. The drug response that predominates depends on the intrinsic activity of each and on the extent of the tissue response that can be elicited.

Chemical Antagonism

Chemical antagonism occurs when a drug's action is blocked and no receptor activity is involved. For example, protamine is a positively charged protein that forms an ionic bond with heparin, thus rendering it inactive. Sugammadex, mentioned previously, is another example.

Receptor Regulation and Adaptation

Receptors not only initiate regulation of physiologic and biochemical functions but also are themselves subject to many regulatory and homeostatic controls. These controls include regulation of the synthesis and degradation of the receptor by multiple mechanisms, covalent modification, association with other regulatory proteins, and/or relocation within the cell. Modulating inputs may come from other receptors, directly or indirectly, and receptors are almost always subject to feedback regulation by their own signaling outputs.

Continued stimulation of cells with agonists generally results in a state of desensitization, also referred to as *refractoriness* or *down-regulation*, such that the effect that follows continued or subsequent exposure to the same concentration of drug is diminished. This phenomenon is very important in therapeutic situations; an example is attenuated response to the repeated use of β-adrenergic agonists as bronchodilators for the treatment of asthma. Clinically the patient experiences tolerance; increasing doses are required to achieve the same effect.

Chronic administration of an antagonist results in up-regulation as the number and sensitivity of the receptors increase as a response to chronic blockade. Again the patient develops tolerance, requiring higher doses of the antagonist to counteract the increasing receptor number.

Drug Interaction Terminology

A drug interaction is an alteration in the therapeutic action of a drug by concurrent administration of other drugs or exogenous substances. The common classification is given in Table 5-1.

SUMMARY

The pharmacologic principles described in this chapter are essential to understanding drug responses in patients. The drug receptor subunit site is the primary regulator of onset-offset drug response. More and more evidence suggests that individual genetic variation in receptor proteins accounts for drug-response variation within seemingly normal populations. In clinical anesthesia, the range of patient responses to a given drug dose reflects this variation. The trend toward dosing by titration with rapid onset and offset anesthetic drugs minimizes the response variability factor by optimizing the use of available receptor proteins. The age-related decline in anesthetic drug dose needed to achieve a desired anesthetic end-point is related to a change in both pharmacodynamics and pharmacokinetics.

The anesthetist uses pharmacologic intervention to elicit a desired patient response. The site of the intervention is the biosphere, or the protein drug receptor, which is the primary regulator of the therapeutic response. Observed variation in patient drug response reflects the functionality of the biosphere and genetics, as well as physiologic variability.

The mean, median, and mode typically describe the dose-response relationship of a "normally distributed" population. In anesthesia, the patient population is rarely "normal." The drug response of population subsets can be expected to vary around the mean dosage. The trend toward dose titration by infusion allows individualization of the desired drug response, with fewer resultant overresponses and underresponses. The SD, SEM, and median effective dose provide a description of a population's response to a drug. Such descriptors provide only an approximate dosage; the anesthetist must adjust this dosage for each patient to achieve the desired physiologic response. Viewed at the molecular level, the observed response to a drug represents countless individual drug responses at the biosphere. Each drug-receptor interaction at the protein receptor elicits a fractional tissue response, and the sum of the fractional responses provides the observed response. In accordance with the law of mass action, when free drug binds to a receptor, a conformational shift occurs in the receptor protein. This shift causes a central space or channel to open, allowing specific ions to enter or leave the cell or a G protein to be activated, resulting in a biochemical cascade yielding pharmacologic effects. The resultant tissue response continues until the drug dissociates from the receptor. Antagonist drugs also bind to the receptor but lack the ability to initiate the required protein conformational shift. The sum of fractional tissue responses elicited when an antagonist is present is inadequate for maintaining the desired tissue response. Some common pharmacodynamic concepts are given in Box 5-2.

Molecular pharmacology is identifying site-specific and age-related causes for the observed variation in patient drug response. The fact that we can now sequence and clone many of the receptors and other proteins responsible for a drug's action is rapidly increasing our understanding of pharmacologic events.

BOX **5-2**

Pharmacodynamic Concepts

- **Agonist:** An agonist is a substance that binds to a specific receptor and triggers a response in the cell. It mimics the action of an endogenous ligand (such as hormone or neurotransmitter) that binds to the same receptor. In adequate concentrations, it can cause maximal activation of all receptors (a full agonist).
- **Antagonists:** An antagonist is a drug that has affinity for the receptor but no efficacy. It does not activate the receptor to produce a physiologic action. By occupying the receptor, it may block an endogenous chemical response, thereby producing a physiologic consequence. Antagonists commonly have a higher affinity for a given receptor than do agonists. Types of antagonism include pharmacologic, in which competitive is reversible and noncompetitive is irreversible, requiring syntheses of new receptors to reestablish homeostasis. Pharmacokinetic, chemical, and physiologic antagonism may also occur.
- **Affinity or potency:** When considering agonists, the term *potency* is used to differentiate between different agonists that activate the same receptor and can all produce the same maximal response (efficacy) but at differing concentrations. The most potent drug of a series requires the lowest dose.
- **Efficacy or intrinsic activity:** The efficacy of a drug is its ability to produce the desired response expected by stimulation of a given receptor population. It refers to the maximum possible effect that can be achieved with the drug. The term *intrinsic activity* is often used instead of efficacy, although this more accurately describes the relative maximum effect obtained when comparing compounds in a series.
- **Partial agonist:** A partial agonist activates a receptor but cannot produce a maximum response. It may also be able to partially block the effects of full agonists. It is postulated that partial agonists possess both agonist and antagonist properties, thus the term *agonist-antagonist* has been used. A partial agonist has a lower efficacy than a full agonist.
- **Inverse agonist:** A drug or endogenous chemical that binds to a receptor, resulting in the opposite action of an agonist. Using the two-state model, they appear to bind preferentially to the inactivated receptor. They may have a theoretic advantage over antagonists in situations in which a disease state is partly due to an up-regulation* of receptor activity.
- **Spare receptor concept:** The relationship between the number of receptors stimulated and the response is usually nonlinear. A maximal or almost maximal response can often be produced by activation of only a fraction of the receptors present. A good example can be found in the neuromuscular junction. Occupation of more than 70% of the nicotinic cholinergic muscle receptors by an antagonist is necessary before there is a reduction in response, implying that a maximal response is obtained by activation of only 30% of the total number of receptors.
- **Tolerance:** Individual variation can result in a situation in which an increasing concentration of drug is required to produce a given response. This usually results from its chronic exposure to the agonist. Very rapid development of tolerance, frequently with acute drug administration, is referred to as *tachyphylaxis.* The underlying mechanism may not be clear. Common causes include up- or down-regulation, enzyme induction, depleted neurotransmitter, protein conformational changes, and changes in gene expression.
- **Ligand:** In biochemistry, a ligand is a molecule that is able to bind and form a complex with a receptor to produce a biologic response. Ligands are endogenous chemicals such as neurotransmitters and hormones that are exogenously administered drugs.
- **Quantal drug response:** Using dose response curves, the actions of drug can be quantified and expressed as the effective dose ED_{50}, toxic dose TD_{50}, and lethal dose LD_{50}. The therapeutic index is the LD_{50}/ED_{50}.
- **Receptor adaptation or homeostasis:** The number and activity of a receptor population may increase or decrease in response to (usually) chronic drug administration.

**Up-regulation* is the process by which a cell increases the number of receptors to a given drug. *Down-regulation* is the process by which a cell decreases the number of receptors for a given drug in response to chronic stimulation. β-adrenergic receptors, for example, up-regulate in the presence of antagonists and down-regulate in the presence of agonists.

CHAPTER 6

Pharmacokinetics

◆ *Ladan Eshkevari and Donna Jasinski*

Pharmacokinetics is a term used to describe the study of the changes in the concentration of a drug during the processes of absorption, distribution, metabolism or biotransformation, and elimination from the body. Essentially, it is the study of what the body does to a drug once the agent has been introduced into the system. The knowledge of this discipline is important to understanding the time course and disposition of the anesthetic drugs and the variability of responses from patient to patient. Knowledge of pharmacokinetic concepts is vital for the delivery of serum concentrations that will result in desired effects while minimizing side effects.

Regardless of the route of administration, the vascular system delivers the drug to various tissues. Therefore most kinetic concepts revolve around assessment of blood level over time, even if the correlation with the amount of drug at the effector site is poor. Once in the blood, the drug can either remain within the vascular system and body water, bound to proteins, or cross membranes to enter tissues. The unbound drug enters organs, muscles, fat, and of greatest importance, the site of activity—the receptors. This transfer of drug to various sites depends on several intrinsic properties of the agent, such as molecular size, degree of ionization, lipid solubility, and protein binding. In addition to these drug properties, uptake also depends on the amount of blood flow to the tissue and the concentration gradient of the drug across membranes.

PROPERTIES THAT INFLUENCE PHARMACOKINETIC ACTIVITY

Molecular Size

The smaller the molecular size of an agent, the better it crosses the lipid barriers and membranes of tissues. When a drug is administered, it must be absorbed across biologic membranes that have very small openings or pores. Generally, molecules with molecular weights greater than 100 to 200 do not cross the cell membranes. Transport across the membranes can occur passively or actively. Passive transport does not require energy and involves transfer of a drug from an area of high concentration to an area of lower concentration. Active transport mechanisms are generally faster and require energy. This transport system uses carriers that form complexes with drug molecules on the membrane surface and can involve movement of the drug molecule against a concentration gradient from an area of low concentration to an area of high concentration.[1] Figure 6-1 depicts the movement of a drug across cell membranes.

Drug Transporters

Many cell membranes possess specialized transport mechanisms that control entry and exit molecules, such as sugars, amino acids, neurotransmitters, and metal ions. They are broadly divided into *solute carrier (SLC) transporters* and *adenosine triphosphate (ATP)–binding cassette (ABC) transporters*. The SLCs control passive movement of solutes down their electrochemical gradient. The ABCs are active pumps requiring energy derived from adenosine triphosphate. Over 300 human genes are believed to code these transporters, most of which act on endogenous substrates; however, some drugs are also transported. Other SLCs are coupled to ATP-dependent ion pumps and transport can occur against an electrochemical gradient. It may involve exchange of one molecule for another called *antiport* or transport of two molecules together in the same direction referred to as *symport*. The main sites where SLCs, including organic cation transporters (OCTs) and organic anion transporters (OATs), are important are the blood-brain barrier, gastrointestinal tract, renal tubule, biliary tract, and placenta. Drug transporters are recognized as key players in the pharmacokinetic processes. Transporter proteins have a unique gatekeeper function in controlling drug access to metabolizing enzymes and excretory pathways. This can affect bioavailability, clearance, volume of distribution, and half-life for orally dosed drugs. A classification model referred to as the Biopharmaceutics Drug Disposition Classification System (BDDCS) categorizes drug transporter effects.[2,3]

Degree of Ionization and Lipid Solubility

Most drugs are salts of either weak acids or weak bases. When introduced into the body, they behave as a chemical in solution. As acids or bases they exist in solutions in both ionized and nonionized forms. The charged (ionized) form is water soluble, and the uncharged (nonionized) form is lipophilic. Because the nonionized molecules are lipid soluble, they can diffuse across cell membranes such as the blood-brain, gastric, and placental barriers to reach the effect site. On the other hand, the ionized molecules are usually unable to penetrate lipid cell membranes easily because of their low lipid solubility. This results from the electric charges exerted by the ionized drug molecules. These charged drugs are repelled by those sections of the cell membranes with similar charges, preventing their diffusion across the membrane.[1] The higher the degree of ionization, the less access the drug has across tissues such as the gastrointestinal tract, the blood-brain and placental barriers, and liver hepatocytes. This is important in that ionized drugs are not absorbed well when taken orally and may not be metabolized by the liver to a significant extent. Instead, they commonly are excreted via the renal system.[4]

Whether acidic or basic, the degree of ionization of an agent at a particular site is determined by the dissociation constant (pK_a) of the agent and its pH gradient across the membrane. The pK_a is the negative log of the equilibrium constant for the dissociation of the acid or base. The relationship between the pK_a of the drug and the pH of the solution may be expressed by two equations. The first equation applies to drugs that are basic in nature:

$$pK_a = pH = \log \frac{(HA^+)}{(A^-)}$$

The second equation applies to acidic drugs:

$$pK_a = pH = \log \frac{(A^-)}{(HA^+)}$$

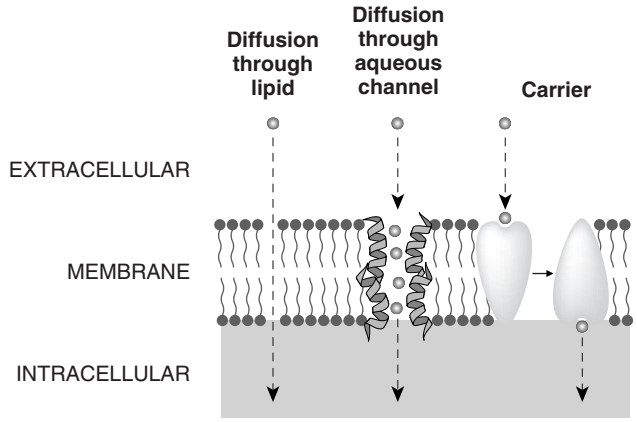

FIGURE **6-1** Routes by which solutes can traverse cell membranes. (From Rang HP, et al. *Rang and Dale's Pharmacology*. 7th ed. Edinburgh: Churchill Livingstone; 2012:100.)

From these equations an estimate of the degree of drug absorption can be developed.[4,5] Acids are usually defined as proton donors, whereas bases are made up of molecules that can accept a proton. When the pH is equal to the pK_a, the two species exist in equal amounts; for example, because phenobarbital has a pK_a of 7.4 and blood has a pH of 7.4, in the bloodstream the drug is present in equal proportions of charged and uncharged forms.

It is of importance to note that relatively modest changes in the pH of the environment, when it is close to the pK_a, are more significant in changing the ratio of charged to uncharged forms than the same change in pH at some value far removed from the pK_a. For example, phenobarbital, with a pK_a of 7.4, is for the most part nondissociated and therefore is nonionized at a pH of 1.4. This results from the fact that the pH is well below the pK_a, and when phenobarbital is in a relatively strongly acidic environment with an abundance of protons, it does not give up its protons readily. If a drug is a weak acid and if the pH of the fluid environment is below the pK_a, most of the drug's protons are associated with the drug molecule, and the predominant species is uncharged and therefore lipid soluble (Figure 6-2). Conversely, if the pH is below the pK_a for a drug that is a weak base, an abundance of protons exists, and most of the drug tends to ionize as the proton is donated by the drug molecule, which results in a species that is highly charged and therefore lipid insoluble[4] (Figure 6-3). The effects of pK_a and pH on ionization are summarized in Box 6-1.[6]

Ion Trapping

Ion trapping has several anesthesia-related applications. Influences on oral absorption of drugs, maternal-fetal transfer, and central nervous system toxicity of local anesthetics are commonly cited. The degree of ionization for a specific agent can vary across a membrane that separates fluids with different pH values. For example, morphine sulfate, a base with a pK_a of 7.9 when present in the blood (pH 7.4), exists in appreciable amounts in both ionized and nonionized forms. The uncharged drug fraction moves freely across tissue membranes, and the charged fraction does not. As the drug enters the stomach, a very acidic environment with a pH of 1.9, morphine accepts protons and becomes ionized, and ion trapping occurs[4] (Figure 6-4 illustrates this phenomenon using diazepam as an example). The drug, however, will be absorbed later, as stomach contents move farther down the gastrointestinal tract to the more basic and favorable environment of the small intestine.

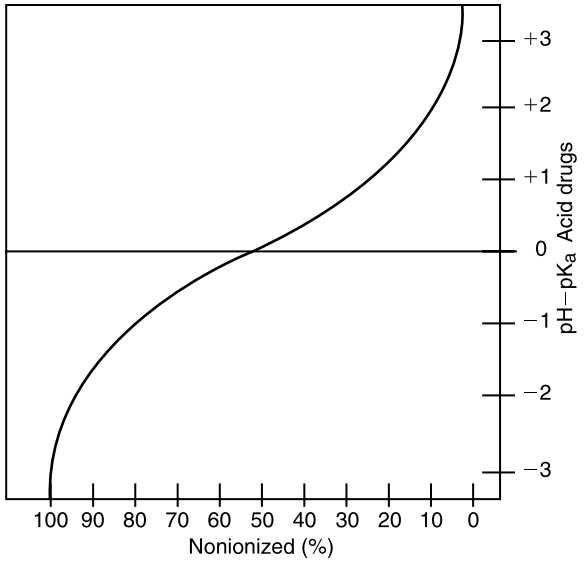

FIGURE **6-2** When acidic drugs are placed in physiologic solutions, the degree of nonionization is greater if the pH of the solution minus the pK_a of the drug (pH − pK_a) is less than zero. Conversely, when the pH − pK_a is greater than zero, more of the drug exists in an ionized, less absorbable form.

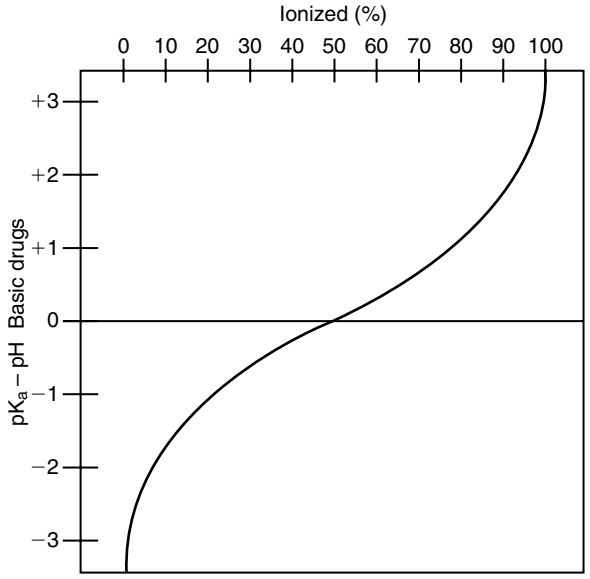

FIGURE **6-3** pK_a − pH versus the percent ionized. The degree to which a basic drug remains in its nonionized state depends on the medium in which it is placed. pK_a is the dissociation constant (see text for further explanation).

A similar scenario occurs when agents are transferred between a mother and a fetus, where the placenta is the membrane separating fluids with varying pH values—that of the fetus is more acidic than that of the mother. Again, the lipid-soluble fraction of basic agents such as lidocaine (pK_a 7.9) crosses to the placenta easily. However, once there, because of the lower pH of the fetus, the drug becomes more ionized and cannot easily cross the lipid bilayer of placenta, resulting in accumulation of drug in the fetus. Finally, ion trapping may occur in a local anesthetic overdose situation in which high concentrations of a basic local anesthetic agent have entered the central nervous system and caused toxicity. If the patient experiences respiratory arrest and hypoxia, the resulting

BOX 6-1

Relationship Between pH, pK_a, and Ionization for Weak Acids and Weak Bases*

Weak Acids

- If the pK_a – pH is 1 or higher and the pH is lower than the pK_a, then the drug is essentially 100% nonionized and in a lipid-soluble form. It will easily cross biologic membranes.
- If the pH – pK_a is 1 or higher and the pH is higher than the pK_a, then the drug is essentially 100% ionized and in a water-soluble form. It will not cross biologic membranes.

Weak Bases

- If the pK_a – pH is 1 or higher and the pH is lower than the pK_a, then the drug is essentially 100% ionized and in a water-soluble form. It will not cross biologic membranes.
- If the pH – pK_a is 1 or higher and the pH is higher than the pK_a, then the drug is essentially 100% nonionized and in a lipid-soluble form. It will easily cross biologic membranes.

For Both Weak Acids and Weak Bases

- If the pK_a – pH is less than 1 regardless of whether the pH is lower or higher than the pK_a, the drug will be partially ionized (water soluble) and partially nonionized (lipid soluble), and if the dose is adequate, the nonionized fraction can cross biologic membranes.

**Rule of thumb for determining ionization: Use absolute values for all calculations.*

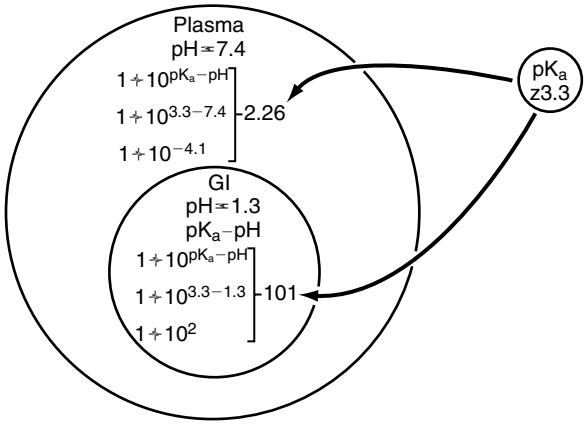

FIGURE **6-4** For both weak acids and weak bases, the total concentration of a drug is greater on the side of the membrane where it is more highly ionized. Diazepam, a basic drug with a pK_a of 3.3, is more ionized at gastric pH than it is in plasma. Consequently, it has a greater total concentration in the gastrointestinal compartment than it does in the plasma.

acidosis may trap the drug in the brain, resulting in prolonged and possibly more intense toxicity. Ion trapping also plays a role in the use of bicarbonate solutions and carbonated local anesthetics. A discussion of the effects of ion trapping on local anesthetics can be found in Chapter 10, Box 10-3.[7,8]

Protein Binding

Changes in protein binding have long been theorized to influence a drug's clinical effect. Two situations are commonly cited. The first involves a patient with a reduction in proteins, such as occurs with severe liver or kidney disease, with protein deficiencies caused by poor nutrition, and during the last trimester of pregnancy, when fluid shifts alter distribution volume. The second situation involves a drug interaction between two or more highly protein-bound drugs.

BOX 6-2

Binding of Drugs to Plasma Proteins

- Plasma albumin is most important; β-globulin and α_1-acid glycoprotein also bind some drugs.
- Plasma albumin binds, for the most part, acidic drugs (approximately two molecules per albumin molecule). Basic drugs may be bound by β-globulin and α_1-acid glycoprotein.
- Saturable binding sometimes leads to a nonlinear relationship between dose and free (active) drug concentration.
- Extensive protein binding slows drug elimination (metabolism and excretion by glomerular filtration).
- Competition between drugs for protein binding rarely leads to clinically important drug interactions.

Modified from Rang HP, et al. *Rang and Dale's Pharmacology.* 7th ed. Edinburgh: Churchill Livingstone; 2012:106.

Potential clinical changes are conceptualized by the following phenomena. Some drugs are bound extensively to proteins in the plasma because of their innate affinity for circulating and tissue proteins. The drug-protein molecule is too large to diffuse through blood vessel membranes and is therefore trapped within the circulatory system. Albumin is quantitatively the most abundant plasma protein, and although it is capable of binding basic, neutral, or acidic drugs, it favors acidic compounds. Two other proteins, α_1-acid glycoprotein (AAG) and β-globulin, favor binding to basic drugs.[9] Lipoproteins bind cyclosporine, and transcortin binds corticosteroids. Protein binding influences how a drug is distributed, because protein-bound drug is not free to act on receptors. High protein binding prevents the drug from leaving the blood to enter into tissue, which results in high plasma concentrations. The degree of protein binding for a drug is proportional to its lipid solubility such that the more lipid soluble an agent, the more highly protein bound it tends to be (Box 6-2).[10]

The number of potential binding sites on plasma proteins for drugs is finite; therefore the kinetics for binding behaves like any saturable process, in that protein binding can be overcome by adding more agent.[4] The bond between drug and protein is usually weak, and they can dissociate when the plasma concentration of the drug declines or a second drug that binds to the same protein is introduced. For example, when a drug has been in chronic use and is at steady state, an equilibrium will be reached between free and protein-bound drug. If a new drug with a high affinity for the same protein sites is introduced, the new drug competes with the chronic drug for binding sites. This leads to displacement of the first drug with an increase in free fraction of that agent. It is important to note that the displaced free drug does become available for biotransformation and elimination, so unless these clearance mechanisms are at capacity, a rise in free fraction will lead to a small change in free plasma concentrations.

Protein binding is expressed in terms of the percentage of total drug bound. Drugs with protein binding greater than 90%, such as warfarin, phenytoin, propranolol, propofol, fentanyl and its analogs, and diazepam, are conceptualized to have an unexpected intensification of their effect if they are displaced from plasma proteins.[11] Drugs that exhibit less than 90% binding have so little change in free active fractions that they are not a concern. The anticoagulant warfarin is commonly used as an example.

TABLE 6-1 Routes of Administration

Route	Bioavailability (%)	Comments
Intravenous	100 (by definition)	Most rapid onset; allows for titration of doses; suitable for large volumes
Intramuscular	75 to 100	Moderate volumes feasible; may be painful
Subcutaneous	75 to 100	Smaller volumes than intramuscular; may be painful; suitable for implantation of pellets
Oral	5 to 100	Most convenient and economical; first-pass effect may be significant; requires patient cooperation
Rectal	30 to 100	Less first-pass effect than oral; useful in pediatric patients
Inhalation	5 to 100	Common anesthetic use for inhalation drugs, steroids, bronchodilators, and occasionally resuscitative drugs; very rapid onset (parallels intravenous administration)
Sublingual	60 to 100	Lack of first-pass effect; absorbed directly into systemic circulation
Intrathecal	Low (intentionally)	Specialized application, as with local anesthetics and analgesics, chemotherapy, and antibiotic administration; circumvents blood-brain barrier
Topical	80 to 100	Includes skin, cornea, buccal, vaginal, and nasal mucosa; dermal application results in slow absorption; used for lack of first-pass effect; prolonged duration of action

Because warfarin is approximately 98% bound to plasma proteins, a reduction in bound fraction to 96% causes an increase in the free active fraction of the drug. Furthermore, when hypoalbuminemia exists, decreased albumin levels result in the availability of a greater amount of free drug. These theoretic concerns are rarely clinically relevant, as explained subsequently.

No clinically relevant examples of changes in drug disposition or effects can be clearly ascribed to changes in plasma protein binding. The idea that a drug displaced from plasma proteins increases the unbound drug concentration, increases the drug effect, and perhaps produces toxicity seems a simple and obvious mechanism. Unfortunately this simple theory, which is appropriate for a test tube, does not work in the body, which is an open system capable of eliminating unbound drug.[12]

First, a seemingly dramatic change in the unbound fraction from 1% to 10% releases less than 5% of the total amount of drug in the body into the unbound pool because less than one third of the drug in the body is bound to plasma proteins, even in the most extreme cases (e.g., when warfarin is used). Drug displaced from plasma protein, of course, distributes throughout the volume of distribution, so a 5% increase in the amount of unbound drug in the body produces at most a 5% increase in pharmacologically active unbound drug at the site of action.

Second, when the amount of unbound drug in plasma increases, the rate of elimination increases (if unbound clearance is unchanged), and after four half-lives, the unbound concentration returns to its previous steady-state value. When drug interactions associated with protein binding displacement and clinically important effects have been studied, it has been found that the displacing drug is also an inhibitor of clearance, and it is the change in *clearance* of the *unbound* drug that is the relevant mechanism explaining the interaction.

The clinical application of plasma protein binding is only to help interpretation of measured drug concentrations. When plasma proteins are lower than normal, total drug concentrations are lowered, but unbound concentrations are not affected.[1]

Absorption

Routes of Drug Administration

An important variable in the bioavailability of a drug at its effect site is the route by which the agent is administered. The route of administration determines how much of the drug is delivered to the systemic circulation. When the entire amount of drug given is delivered, the drug is said to have *100% bioavailability*. Many routes of drug administration are used; each has advantages and disadvantages (Table 6-1). The routes of drug administration are enteral (involves the gastrointestinal tract); parenteral (injected subcutaneously, intramuscularly, intravenously, intrathecally, or epidermally); pulmonary; and topical.[13] Absorption mechanisms of relevance to anesthesia are discussed in the following sections.

Enteral Administration. The oral route is the most common and convenient method for administration of drugs. It is relatively inexpensive, does not require sterile technique, and can be carried out with little skill. However, several disadvantages exist because many conditions—such as emotions, physical activity, and food intake—change the gastrointestinal environment. Therefore orally administered drugs tend to have a lower bioavailability. The stomach has a large surface area, and the length of time a drug remains there is a significant factor in absorption. Because of the low pH in the stomach (1.5 to 2.5), drugs that are highly acidic, such as barbiturates, tend to remain nonionized and are highly absorbed. Basic drugs that remain intact in the stomach acids can pass through and are more readily absorbed in the intestine. The small intestine is highly vascular and has an alkaline environment (pH 7 to 8).[13]

The enteral route often results in failure of the drug to be absorbed into the systemic circulation. Alternatively, chemical alteration may occur before entry into the intestines. *Presystemic elimination* refers to the elimination of drug by the gastrointestinal system before the drug reaches the systemic circulation. This occurs by means of three mechanisms: the stomach acids hydrolyze the drug (e.g., penicillin); enzymes in the gastrointestinal wall deactivate the drug; or the liver biotransforms ingested drug before it reaches the effect site.[4] This liver activity is called *first-pass* hepatic effect. Drugs absorbed from the gastrointestinal tract after oral ingestion enter the portal venous blood and pass through the liver first, with subsequent delivery to the tissue receptors. In the liver they may undergo extensive hepatic extraction and metabolism before they have a chance to enter the systemic circulation (Box 6-3). Agents such as these exhibit large differences between oral and intravenous dosages. To have the desired effect, oral dosages must be exaggerated to compensate for the initial metabolism that occurs before the drug reaches the effect site.

The role transporters play in drug absorption and distribution should be further clarified. P-glycoprotein transporter is part of a larger family of efflux transporters found in the intestine, liver cells, renal proximal tubular cells, and capillary endothelial cells comprising the blood-brain barrier. Using ATP as an energy

BOX **6-3**

Examples of Drugs That Undergo Substantial First-Pass Elimination

- Aspirin
- Glyceryl trinitrate
- Isosorbide dinitrate
- Levodopa
- Lidocaine
- Metoprolol
- Morphine
- Propranolol
- Salbutamol
- Verapamil

source, they transport substances against their concentration gradients. They appear to have developed as a mechanism to protect the body from harmful substances and can influence the ability of a drug to traverse barriers.

The sublingual and buccal routes of administration of drugs bypass the presystemic, portal system first-pass effect and are delivered rapidly to the superior vena cava for transport to the effect site.[1] Nitroglycerin is an example of a sublingual drug that is put under the tongue and absorbed by the rich blood supply there. If ingested, the drug would be hydrolyzed by the stomach; therefore sublingual administration is the ideal route for this agent. Protein hormones that would also be digested by the stomach are instead placed between the gum and cheek (buccal administration) and enter venous drainage without undergoing hepatic, presystemic elimination.[14,15]

Occasionally the rectal route of drug administration is the ideal route for prevention of emesis caused by irritation of the gastrointestinal mucosa by the drug. It is also a preferred method of drug delivery for patients in whom oral ingestion poses difficulty. For example, rectal acetaminophen is administered to infants and young children undergoing general anesthesia for postoperative pain control. Drugs placed in the proximal rectum are absorbed into the portal system via the superior hemorrhoidal vein. They will therefore undergo significant first-pass effect in the liver before entering the systemic circulation, leading to unpredictable responses.[1] Conversely, agents placed in the distal rectum do not undergo presystemic elimination and therefore have more predictable circulatory levels. The disadvantage historically associated with this route was the unpredictability of drug retention and absorption because of rectal contents. However, more recent studies have demonstrated that regardless of enema volume, agents are absorbed with consistent plasma concentrations within subjects.[16]

Parenteral Administration. *Parenteral administration* refers to administration by injection. The most rapid and predictable route to the systemic circulation is the parenteral route. With intramuscular injections, the drug is instilled deep into the muscle among the muscle fascicles.[4] Subcutaneous agents are placed under the skin. With both intramuscular and subcutaneous injections, the systemic absorption of the drug is dependent on the capillary blood flow to the area and the lipid solubility of the agent.[1] Conversely, intravenous injections allow for rapid and accurate delivery of drug into the systemic circulation. Parenteral administration is the route of choice for anesthetists, because it is an exact method of achieving the desired effect from agents delivered.

Pulmonary Administration. The lungs provide a large surface area for drugs administered by inhalation. Bronchodilators and antibiotics are administered via devices such as nebulizers, used to propel aerosols into the alveolar sacs.[16] Anesthetic gases are also effectively administered through the lungs, as described in detail in Chapter 7.

Transdermal (Topical) Administration. The transdermal route is usually chosen for administration of a sustained release agent, providing the patient with a steady therapeutic plasma concentration. Drugs that are administered via this route must possess several characteristics. They usually exist in a combined form—both water soluble and lipid soluble. The water solubility is necessary so the drug can penetrate the hair follicles and sweat ducts. Once in the system, the drug must be lipid soluble to traverse the skin and exert effect at the receptors. These agents must have a molecular weight of less than 1000, dose requirements less than 10 mg in a 24-hour period, and a pH of 5 to 9.[1] The area to which the drug is applied must have a relatively thin epidermis with a sufficient blood supply (Figure 6-5).

Bioavailability

Bioavailability is the extent to which a drug reaches its effect site after its introduction into the circulatory system. The rate at which systemic absorption occurs establishes a drug's duration of action and intensity. Many factors play a role in the bioavailability of agents, including lipid solubility, solubility in aqueous and organic solvents, molecular weight, pH, pK_a, and blood flow. For example, drugs given in aqueous solution are more rapidly absorbed than those given in oily solution or solid form because they mix more readily with the aqueous phase at the absorptive site.[17,18] A recent study demonstrated that propofol in the form of a water-soluble prodrug is metabolized to propofol with a longer half-life, increased volume of distribution, delayed onset, and greater potency.[19]

The environment into which the drug is introduced also has an impact on its bioavailability. The patient's age, sex, pathology, pH, blood flow, and temperature are all factors to consider. For example, pH plays a role when local anesthetic (a weak base) is injected into an infected wound (an acidic environment). In this instance, the local anesthetic is highly ionized (basic agent in acidic environment) and therefore cannot enter the lipid nerve membrane to reach the site of action. Some important concepts influencing absorption are listed in Box 6-4.

Distribution

Compartment Models

Compartment models depict the body as composed of distinct sections that represent theoretic spaces with calculated volumes and are used to describe the pharmacokinetics of agents. These models are useful for prediction of serum concentrations and changes in drug concentrations in other tissues. A single-compartment model represents the entire body, through which homogeneous distribution occurs (Figure 6-6, *A*). Although a one-compartment model is sufficient to describe the action of many drugs, it is generally insufficient to explain the kinetics of lipid-soluble anesthetic drugs. A two-compartment model is typically used to simplify and explain pharmacokinetic concepts that can be extrapolated to more complex models.[20]

In the two-compartment model, the first compartment is termed the *central compartment* and is composed of intravascular fluid and the highly perfused tissues such as the heart, lungs, brain, liver, and kidneys (see Figure 6-6, *B*). The central compartment represents only approximately 10% of body mass in an adult; however, it receives approximately 75% of the cardiac output and is also referred to as the *vessel-rich group*. The peripheral compartment (vessel-poor group) is composed of muscle, fat, and bone and

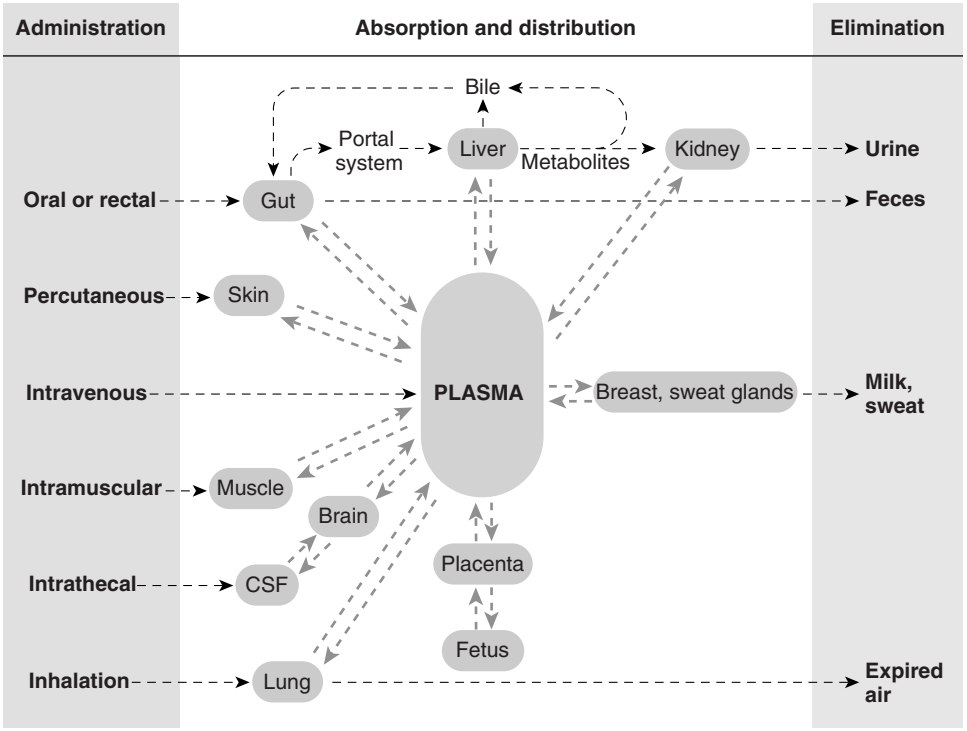

FIGURE **6-5** The main routes of drug administration and elimination. *(From Rang HP, et al:* Rang and Dale's Pharmacology, *7th ed. Edinburgh: Churchill Livingstone, 2012, p 107.)*

BOX **6-4**

Movement of Drugs Across Cellular Barriers

- To traverse cellular barriers (e.g., gastrointestinal mucosa, renal tubule, blood-brain barrier, placenta), drugs must cross lipid membranes.
- Drugs cross lipid membranes mainly by passive diffusional transfer or by carrier-mediated transfer.
- The main factors that determine the rate of passive diffusional transfer across membranes are a drug's lipid solubility and the concentration gradient. Molecular weight is a less important factor.
- Most drugs are weak acids or weak bases; their state of ionization varies with pH according to the Henderson-Hasselbalch equation.
- With weak acids or bases, only the uncharged species (the protonated form for a weak acid; the unprotonated form for a weak base) can diffuse across lipid membranes; this gives rise to pH partition or ion trapping.
- The term *pH partition* refers to the fact that weak acids tend to accumulate in compartments of relatively high pH, whereas weak bases tend to leave compartments of high pH.
- Carrier-mediated transport involves solute carriers (SLCs), including organic cation transporters (OCTs) and organic anion transporters (OATs), and P-glycoproteins or P-gp (P for permeability, also referred to as ABC [ATP-binding cassette] transporters) in the renal tubule, blood-brain barrier, and gastrointestinal epithelium, which are important for the distribution of some drugs. Many are chemically related to endogenous substances.
- Drugs of very low lipid solubility, including those that are strong acids or bases, are generally poorly absorbed from the gut.
- A few drugs (e.g., levodopa) are absorbed by carrier-mediated transfer.
- Absorption from the gut depends on many factors, including the following:
  - Gastrointestinal motility
  - Gastrointestinal pH
  - Particle size
  - Physicochemical interaction with gut contents (e.g., chemical interaction between calcium and tetracycline antibiotics)
- Bioavailability is the fraction of an ingested dose of a drug that gains access to the systemic circulation. It may be low because absorption is incomplete or because the drug is metabolized in the gut wall or liver before reaching the systemic circulation.
- Bioequivalence implies that if one formulation of a drug is substituted for another, no clinically untoward consequences will ensue.

Modified from Rang HP, et al. *Rang and Dale's Pharmacology.* 7th ed. Edinburgh: Churchill Livingstone; 2012:99-114.

represents 90% of body mass. This second compartment receives approximately 25% of the cardiac output.[20] The terms *central* and *peripheral compartments* refer to differences in the size of the compartments and the rate at which a drug is distributed to them. In reality, the compartments are not true anatomic areas but instead are conceptual representations of two separate volumes in which a quantitative change in drug concentration occurs.[21]

Drugs leave the central compartment in two phases. Drugs leave by distribution into the tissues or via metabolism and excretion. In the initial phase, after an intravenous bolus dose, those organs with the highest blood flow have the largest amount of drug delivered to them. These highly perfused tissues equilibrate with the initial high serum concentration and attain a high concentration of drug (Table 6-2). As blood flows through the less perfused organs, the

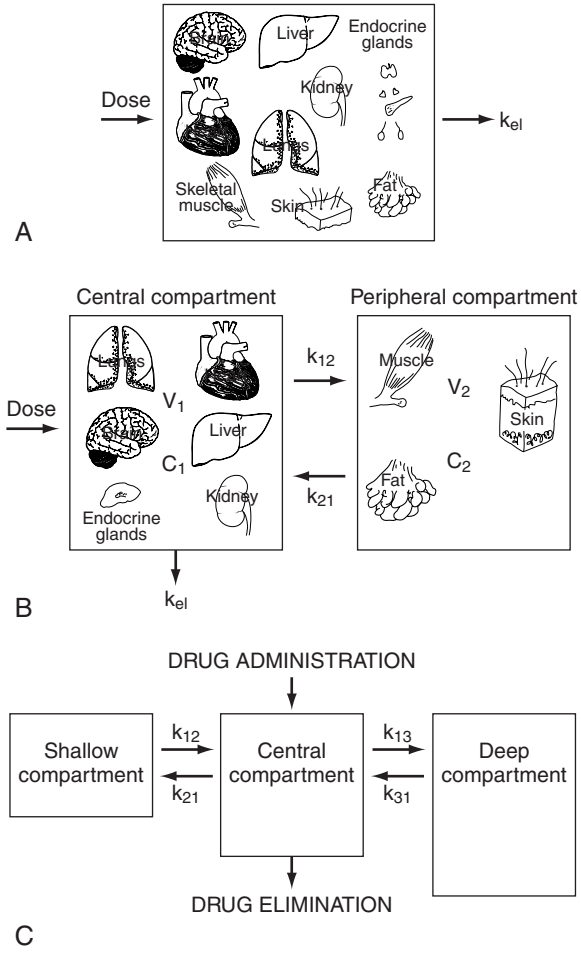

FIGURE **6-6** **A,** In the one-compartment model, a drug instantaneously and homogeneously is distributed throughout the fluids and tissues that constitute the compartment. When changes in drug concentration occur in any of these tissues, a corresponding quantitative change occurs in drug concentration in all the other tissues. **B,** In the two-compartment model, the body is assumed to be made up of two compartments: a central compartment (C_1) made up of a small apparent volume (V_1) and a peripheral compartment (C_2) made up of a larger apparent volume (V_2). **C,** The three-compartment model is depicted as having a central compartment into which the drug is administered and two peripheral compartments to which reversible drug distribution occurs. k_{12}, Rate of distribution of drugs to the peripheral compartment; k_{21}, rate of redistribution of drugs back to the central compartment; k_{el}, rate of drug removal or elimination from the body; k_{13}, rate of distribution of drugs from the central compartment to a shallow peripheral compartment; k_{31}, rate of distribution of drugs from the shallow peripheral compartment back to the central compartment (see text for further explanation).

drug begins to be deposited in those tissues as well.[17] However, the tissue levels rise more slowly and do not reach as high a concentration as in the vessel-rich group or central compartment, with extraction occurring to a lesser degree. As blood flows through the tissues, serum concentrations drop because of this distribution, and the fall in plasma concentration is described mathematically via the alpha half-life.[22] When the plasma concentration falls below the tissue concentration, the drug reemerges from the highly perfused tissue, enters the plasma serum, and is again redistributed. The drug enters the central compartment for clearance from the body. The degree to which drugs distribute and redistribute from the central compartment to the peripheral compartment, and the resultant concentration of the drug established before elimination occurs, allow for the calculation of the volume of distribution.

TABLE 6-2 Tissue Groups Based on Perfusion*

Characteristic	Vessel Rich	Muscle	Fat	Vessel Poor
Percentage of body weight	10	50	20	20
Percentage of cardiac output	75	19	6	0
Perfusion (mL/min/100 g)	75	3	3	0

*The vessel-rich group represents the central compartment, and the muscle, fat, and vessel-poor groups are peripheral compartments.

Volume of Distribution

The volume of distribution (Vd) is a proportional expression that relates the amount of drug in the body to the serum concentration. It is the apparent volume in which the drug is distributed after it has been introduced into the system.[1] Essentially it is calculated by dividing the dose of the drug administered intravenously by the plasma concentration before elimination occurs. The volume of distribution is used to calculate the loading dose of a drug that will achieve a steady-state concentration.[20] In practice, a patient's volume of distribution is unknown, and an average volume of distribution is assumed and used to calculate a loading dose that will attain a therapeutic concentration rather than a steady-state concentration.

$$\text{Volume of distribution} = \frac{\text{Dose of drug}}{\text{Plasma concentration of drug}}$$

The theoretical compartments and volumes are envisioned as follows. The plasma compartment contains 4 liters (L). The interstitial fluid (IF) volume contains 10 liters. The extracellular fluid (ECF) volume combines the plasma and IF and therefore contains (4+10) or 14 liters. The intracellular fluid (ICF) volume is 28 L. Total body water is equal to plasma (4L) + IF (10L) + ICF (28L) = 42 liters. The typical Vd, normalized for the body weight of a 70 KG adult, would be 42L/70KG or 0.6L/kg. The Vd gives one the sense of how extensively a drug distributes throughout the body. A drug with a large Vd (> 0.6L/KG) implies that it is widely distributed in the body and likely lipid soluble. A drug with a small Vd (< 0.4 L/ KG) is largely contained in the plasma and likely water soluble. Other factors such as size, carrier molecules, disease states, and fluid shifts associated with burn injuries or pregnancy may also alter expected distribution volumes.

The volume of distribution of a drug is affected by the physiochemical properties of that drug, such as lipid solubility, plasma protein binding, and molecular size.[4] Drugs that are free, unbound to plasma proteins, and lipid soluble easily cross membranes to tissues and therefore have large calculated volumes of distribution with low plasma concentrations. An example of a drug with a large volume of distribution is propofol.[1] On injection of an induction dose, this highly lipid-soluble drug is distributed quickly to peripheral tissue, thereby ending its action much more rapidly than its elimination half-life would predict. The patient wakes up in just a few minutes because of redistribution from the brain (central compartment) to the peripheral compartment; however, the patient may feel sleepy for hours because of the long elimination half-life of the drug from the whole body (11.6 hours).[4]

The volume of distribution of a drug administered by bolus is also calculated by dividing the total dose administered by the area under the plasma concentration curve. The greater the area under the curve, the longer the drug acts and the drug intensity increases.[4] However, if the drug is infused or given in multiple

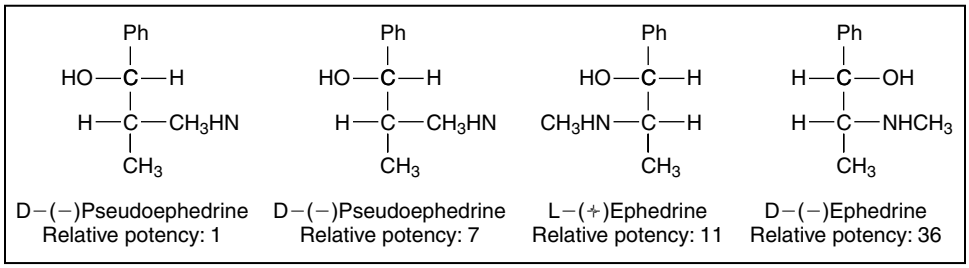

FIGURE **6-7** Ephedrine has two chiral centers and four isomers with varying potencies.

doses and the amount given equals the amount eliminated, the central and peripheral compartments are in equilibrium. Therefore the volume of distribution at this steady state would differ if the agent were given as a bolus injection.[5]

Structure-Activity Relationship

The affinity of a drug for a specific macromolecular component of the cell and its intrinsic activity are intimately related to its chemical structure.[23] The relationship is frequently quite a rigid one, in that relatively minor modifications in the drug structure may result in major changes in pharmacologic properties. In fact, manipulation of structure-activity relationships often leads to the synthesis of therapeutic agents quite varied in their therapeutic effects, as well as their side effects. Changes in molecular configuration must occur in a manner that leads to alterations of all actions and effects of a drug equally. Therefore it is sometimes possible to develop a congener with a more favorable ratio of therapeutic to toxic effects, enhanced selectivity among different cells or tissues, or more acceptable secondary characteristics than those of the parent drug.[23] Additionally, effective therapeutic agents have been developed by cultivating structurally related competitive antagonists of other drugs or of endogenous substances known to be important in biochemical or physiologic function. Minor modifications of structure can also have profound effects on the pharmacokinetic properties of drugs. The structure of a drug can therefore occasionally supersede all of the above properties discussed, and this structure is of great importance in how a drug behaves in vivo. Important considerations in structure-activity relationships are enantiomerism and isomerism.

Stereochemistry

A carbon-containing compound usually exists as stereoisomers-molecules with the same chemical bonds but different configurations in their fixed spatial arrangements. A specific configuration is achieved by either the presence of double bonds, where there is no freedom of rotation, or by chiral centers, around which varying groups are arranged in a specific sequence.[24] Chiral centers are therefore formed by a carbon atom with four different asymmetric substituents. A molecule with one chiral carbon can have two stereoisomers; however, as the number of carbons in a molecule increases, so does the number of its potential stereoisomers. Some stereoisomers are non-superimposable mirror images of each other called *enantiomers*. Free rotation about a chiral carbon is not possible, resulting in the existence of two stable forms of the molecule. These concepts become important in that interactions between biomolecules are stereospecific, and interface with biologic receptors can differ greatly between two enantiomers, even to the point of no binding. There are numerous examples among drug molecules in which only one isomer exhibits the desired pharmacology. Some isomers may even cause side effects or entirely different effects than their mirror image.[23] For instance, D(−) ephedrine, with a relative potency of 36, is used to a large extent as an antiasthmatic and, by an anesthesia professional, as a pressor amine to restore low blood pressure in the operating arena, whereas L(+) pseudoephedrine, with a relative potency of 7, is used primarily as a nasal decongestant (Figure 6-7). These drugs therefore have varying activities as well as potencies, rendering them ideal for varying situations. Cisatracurium, levobupivacaine, and ropivacaine are additional examples of select isomers with improved clinical properties.

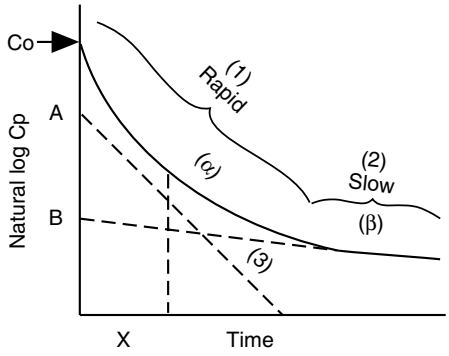

FIGURE **6-8** The plot of the natural log of drug concentration. For drugs that conform to the two-compartment model, the plot of the natural log of the drug concentration is not linear along its entire length. Rather, it is curvilinear. The initial segment *(1)*, which represents the decline in drug concentration, is parabolic, then linear *(2)*. This decline in the drug concentration is also described as *biphasic*—a rapid phase, representing distribution *(3)*, and a slow phase, representing elimination. The slope of the slow phase *(2)* is determined in a manner similar to that used for the elimination rate constant, k_{el}, in the one-compartment model.

Plasma Concentration Curve

A schematic depiction of the decline in plasma concentration of a drug with time after rapid intravenous injection into the central compartment is plotted on a logarithmic graph in Figure 6-8. The y-axis of the graph represents the plasma concentration, and the x-axis reflects the time after the dose is injected. The first phase of the curve is the α phase, or the distribution phase, which represents the initial dispersal of drug into the tissue compartments from the central compartment. This slope is usually steep with drugs that are highly lipid soluble, which demonstrates the ability of these agents to cross membrane lipid bilayers and be distributed to the peripheral compartment rapidly, leading to a rapid fall in plasma levels.[1]

The second phase of the curve is a logarithmic plot of the slower elimination, or β, phase of the plasma concentration curve. Once equilibrium has been reached, the concentration falls exponentially because of elimination. This portion of the graph is much less steep and has a plateau shape, illustrating the more gradual decline in the drug's plasma concentration. The slope is flatter because it reflects the elimination of the drug from

the circulation by the hepatic, renal, and other systems, which is a more gradual process. The plasma concentration curve is an example of a biexponential decay curve, because two distinct components of decay exist—a steep slope that describes distribution and a second, less steep slope that depicts the elimination phase.[4]

The elimination phase of the plot is used to determine the elimination half-life of drugs, which becomes important with regard to dosing intervals.

Steady State

Theoretically, a steady state occurs when a stable plasma concentration of a drug is achieved. In this instance, all body compartments will have had ample opportunity to equilibrate with the circulating agent, and although tissue concentrations of the drug vary from organ to organ, they are not changing. At this point, drug elimination is equal to the rate at which the drug is made available, so the amount being eliminated in a given time equals the amount being added to the system at the same time.[25] This state is typically reached with chronic administration of a drug or by continuous intravenous administration. Some important distribution concepts are listed in Box 6-5.

Metabolism

Drug *metabolism* is synonymous with drug *biotransformation*. Metabolism is an enzyme-catalyzed change in the chemical structure of agents, and it usually involves more than one pathway. The main organ for drug metabolism is the liver, although metabolism can occur in the plasma, lungs, gastrointestinal tract, kidneys, heart, brain, and skin. The goal of metabolism is to change lipid-soluble agents into more water-soluble forms so the kidneys can then eliminate them from the body. Metabolism usually leads to transformation of active drugs into inactive metabolites; however, numerous consequences can occur. For example, a drug can be metabolized to an active drug with the same or new activity, or an agent can be converted from an inactive prodrug to its active form, as occurs with the metabolism of inactive enalapril to active enalaprilat. A new formulation of propofol, fospropofol, (Lusedra), is a prodrug that is converted by hydrolysis in the plasma by alkaline phosphatases to free active propofol.[21]

For most drugs administered in therapeutic doses, metabolism occurs as a first-order process, in that the drug is cleared at a rate proportional to the amount of drug present in the plasma. Thus a constant fraction of total drug is metabolized in a set time period. The greatest amount of drug eliminated per unit time occurs when the concentration is highest.[26]

Drugs such as alcohol undergo zero-order kinetics at therapeutic doses. This means that even at therapeutic levels, they exceed the body's ability to excrete or metabolize them. In zero-order kinetics, the available enzyme systems for elimination of drugs are saturated. For these agents, a constant amount of drug is cleared regardless of the plasma concentration, as opposed to a constant percentage as occurs with first-order kinetics. The amount of agent cleared per unit time during zero-order kinetics is the same amount, independent of its plasma concentration.

Drug metabolism occurs in two phases. Phase I reactions are oxidation, reduction, and hydrolysis reactions and generally result in increased polarity of the molecule, transforming a lipid-soluble compound to a water-soluble one. Phase II reactions involve conjugation reactions, in which a drug or metabolite is conjugated with endogenous substrate such as glucuronic, sulfonic, or acetic acid.[27]

BOX 6-5

Drug Distribution

The major compartments are as follows:

- Plasma (5% of body weight)
- Interstitial fluid (16%)
- Intracellular fluid (35%)
- Transcellular fluid (2%)
- Fat (20%)
- Volume of distribution (V_d) is defined as the volume of plasma that would contain the total body content of the drug at a concentration equal to that in the plasma.
- Water-soluble drugs are mainly confined to plasma and interstitial fluids; most do not enter the brain after acute dosing.
- Lipid-soluble drugs reach all compartments and may accumulate in fat.
- For drugs that accumulate outside the plasma compartment (e.g., in fat, or by being bound to tissues), V_d may exceed total body volume.
- For many drugs, disappearance from the plasma follows an exponential time course characterized by the plasma half-life.
- Plasma half-life, in the simple case, is directly proportional to the volume of distribution and inversely proportional to the overall rate of clearance.
- With repeated dosage or sustained delivery of a drug, the plasma concentration approaches a steady value within 4 or 5 plasma half-lives. Elimination of a drug also takes 4 or 5 half-lives.
- A two-compartment model is often needed. In this case the kinetics are biexponential. The two components roughly represent the processes of transfer between plasma and tissues or distribution (α phase) and elimination from the plasma (β phase).
- Some drugs show nonexponental "saturation" kinetics, with important clinical consequences, especially a disproportionate increase in steady-state plasma concentration when the dose is increased.

Modified from Rang HP, et al. *Rang and Dale's Pharmacology.* 7th ed. Edinburgh: Churchill Livingstone; 2012:118.

Phase I Reactions

Oxidation reactions generally are reactions in which oxygen is introduced into the molecule or the oxidative state of a molecule is changed so that its relative oxygen content is increased. The molecule of oxygen is split; one atom oxidizes each molecule of drug, and the other is incorporated into a molecule of water. The loss of electrons results in oxidation. Oxidative metabolism reactions are catalyzed by the enzymes of the cytochrome P-450 system.[27] Reduction pathways of metabolism also use the cytochrome P-450 system. When insufficient amounts of oxygen are present to compete for electrons, these enzymes transfer electrons directly to a substrate rather than to oxygen. Reduction involves the gain of electrons.[28]

Hydrolysis is the addition of water to an ester or amide to break the bond and form two smaller molecules. Adding water to these compounds leads to an acid and alcohol, in the case of esters, and to an acid and an amine, in the case of amides. Amide drugs rarely undergo hydrolysis, even though they are formed by removing water. Steric hindrance limits the ability to add water to a drug (hydrolyze it) once the water has been removed. Examples of drugs that are hydrolyzed are listed in Box 6-6.

The end result of phase I reactions is typically a more polar compound that is easily excreted by the kidneys. It is also important to

BOX 6-6

Common Anesthesia-Related Drugs That Undergo Phase 1 Hydrolysis

Pseudocholinesterase Catalyzed
- Succinylcholine
- Cocaine
- Procaine
- Chloroprocaine
- Tetracaine
- Neostigmine (partial pathway)
- Edrophonium (partial pathway)

Nonspecific Esterase Dependent
- Remifentanil
- Atracurium (partial pathway)
- Cisatracurium (partial pathway)
- Esmolol (RBC esterase)
- Aspirin
- Clevidipine
- MOC-etomidate

Alkaline Phosphatase Hydrolysis
- Lusedra prodrug to active propofol base

BOX 6-7

Drug Metabolism

- Phase I reactions involve oxidation, reduction, and hydrolysis—usually form more chemically reactive products; sometimes pharmacologically active, toxic, or carcinogenic. Phase 1 reactions often involve a monooxygenase system in which cytochrome enzymes play a role.
- Phase II reactions are conjugation (e.g., glucuronidation) of a reactive group (often inserted during phase I reaction) and usually form inactive and polar products that are readily excretable.
- Some conjugated products are excreted via bile, are reactivated in the intestine, and then reabsorbed (e.g., enterohepatic circulation).
- Induction of enzymes by other drugs and chemicals can greatly accelerate hepatic drug metabolism. It can also increase the toxicity of drugs with toxic metabolites.
- Some drugs show rapid "first-pass" hepatic metabolism and therefore poor oral bioavailability due to presystemic metabolism in the liver or intestinal wall.

Modified from Rang HP, et al. *Rang and Dale's Pharmacology*. 7th ed. Edinburgh: Churchill Livingstone; 2012:119.

note that phase I reactions, by placing hydroxy or carboxy groups on drug molecules, enable phase II reactions to occur.[1]

Phase II Reactions

Phase II reactions are also referred to as *synthetic reactions* because the body actually synthesizes a new compound by donating a functional group usually derived from an endogenous acid. The new compound is the conjugate of the drug or the drug product of the phase I reaction with either glucuronic acid, sulfuric acid, glycine, acetic acid, or a methyl group.[25]

The products of phase II reactions almost always have little or no biologic activity. Conjugation always leads to a more polar compound that is more highly ionized at physiologic pH and therefore more easily extractable by the kidney via glomerular filtration. The conjugation proceeds by joining the body's donated group (during phase I reactions) with an OH, COOH, or NH group to form an ester or amide bond. However, many drugs already possess an appropriate functional group for conjugation and therefore do not need to be modified by a prior phase I reaction in order to be conjugated.

Many intracellular sites exist for drug metabolizing enzymes, such as the endoplasmic reticulum, mitochondria, cytosol, lysosomes, and plasma membrane. Hepatic microsomal enzymes, responsible for biotransformation of numerous agents, reside mainly in the smooth hepatic endoplasmic reticulum. They are termed *microsomal enzymes* because microsomes are fragments of the endoplasmic reticulum that are obtained in vitro by physical disruption of the tissue and differential centrifugation. This microsomal fraction includes proteins called *cytochrome* (iron-containing hemoprotein) *P-450*, indicating its peak absorption at 450 nm, when it reacts with carbon monoxide. The cytochrome P-450 is also called the *mixed-function oxidase system* because it includes both oxidation and reduction steps and has low substrate specificity.[4] Some extrahepatic sites of the P-450 system exist, such as the kidneys, lungs, skin, and intestinal mucosa.

Six well-characterized forms, or isozymes, of the cytochrome P-450 system are involved in drug metabolism in humans: CYP1A2, CYP2D6, CYP2C19, CYP2E1, CYP2C9, and CYP3A.[29] The letters *CYP* stand for cytochrome P-450; the first number denotes genetic family, the next letter describes the genetic subfamily, and the second number stands for the specific gene or isozyme.

It is important to note some characteristics of these isozymes. It should be appreciated that small differences in amino acid sequences of the different isozymes lead to differences in drug metabolism and account for genetic variability among individuals' abilities to metabolize agents.[29] Therefore hepatic enzyme activity varies among individuals and is determined genetically. Genetic variability exists in the expression of CYP2C19, CYP2C9, and CYP2D6 and other cytochromes. Genetic variation in CYP2D6 enzyme, for example, leads to changes in metabolism of β-blockers, which may produce toxicity or their ultrarapid degradation decreasing efficacy. These polymorphisms in the adrenergic signaling pathway and CYP2D6 gene may influence efficacy, safety, and toxicity of β-blocker therapy in prevention and treatment of perioperative myocardial infarction.[30,31]

It is possible to increase enzyme activity by stimulating the enzymes over a period of time. This is called *enzyme induction* and is usually produced by exposure to certain drug or chemical compounds. Alcohol is one such compound; when ingested chronically it induces enzymatic activity. The system can more quickly break down agents that use the same enzymatic system for biotransformation. Other drugs capable of enzyme induction include phenobarbital, phenytoin, rifampin, and carbamazepine. This increased capacity to clear drugs leads to reduction in half-lives of agents and is important with regard to dosing intervals.[32,33]

Microsomal enzymes also can be inhibited. This usually occurs through exposure to certain drugs and chemicals, leading to accumulation of the substrate agent, and can cause elevated plasma levels and potentially greater activity and toxicity. For example, erythromycin inhibits the metabolism of theophylline, and cimetidine inhibits metabolism of many drugs.[29] Box 6-7 contains a summary of important metabolic concepts. A list of cytochrome enzymes, metabolites, inducers, and inhibitors is given in Table 6-3.

TABLE 6-3 List of Cytochrome Enzymes, Metabolites, Inducers, and Inhibitors

Isozyme	Metabolic Substrates	Inducers	Inhibitors
CYP1A2	Theophylline—has a narrow therapeutic range, so inhibition of its metabolism can lead to toxic levels Imipramine Propranolol Clozapine	Tobacco smoke—smokers may require higher doses of these drugs because their metabolism is increased	Ciprofloxacin Erythromycin
CYP2C19—absent in 20%-30% of Asians, who therefore need a reduced dose when these drugs are administered	Diazepam Phenytoin Omeprazole (proton pump inhibitor for ulcers)		Omeprazole Ketoconazole (antifungal agent) Isoniazid
CYP2C9—absent in approximately 1% of Caucasians	NSAIDs COX II inhibitors Warfarin Phenytoin		Fluconazole
CYP2D6—absent in approximately 7% of Caucasians; hyperactive in approximately 30% of East Africans (Ethiopians) because they have multiple copies of the gene	Codeine → morphine Some β-blockers Some tricyclic antidepressants		Fluoxetine Haloperidol Paroxetine Quinidine
CYP2E1	Acetaminophen Ethanol Some halogenated hydrocarbons such as halothane	Chronic ethanol Isoniazid	Disulfiram
CYP3A—present in GI tract and liver; responsible for a large amount of first-pass metabolism	Calcium channel blockers Most benzodiazepines HIV protease inhibitors HMG-CoA reductase inhibitors (lipid-lowering agents) Cyclosporine (immunosuppressant) Most nonsedating antihistamines	Carbamazepine Rifampin Rifabutin (to treat TB) Ritonavir (to treat HIV) St. John's wort (herbal product used for depression and menopause)	Azole antifungal agents such as itraconazole Ketoconazole Fluconazole Cimetidine (broad range P-450 inhibitor) Macrolide Antibiotics (but *not* azithromycin) Grapefruit juice

COX, Cyclooxygenase; *GI*, gastrointestinal; *HIV*, human immunodeficiency virus; *HMG-CoA*, 3-hydroxy-3-methylglutaryl coenzyme A; *NSAIDs*, nonsteroidal antiinflammatory drugs; *TB*, tuberculosis.

Drug Elimination

Elimination Half-Life

The elimination half-life (t½) is the time necessary for the plasma content of a drug to drop to half of its prevailing concentration after a rapid bolus injection. It takes the same amount of time to reduce a drug's concentration from 100 to 50 mg/L as it does to decrease the concentration from 10 to 5 mg/L. The amount of drug remaining in the body is related to the number of elimination half-lives that have elapsed (Table 6-4). For practical purposes, a drug is regarded as being fully eliminated when approximately 95% has been eliminated from the body. This usually occurs when four or five half-lives have elapsed and is important with regard to dosing intervals because drug accumulation occurs if dosing intervals are shorter than this. The body has not been able to rid itself of the initial dose, and subsequent doses will lead to overdose and potential adverse effects. Instances can occur in which, although only 5% of the drug amount remains, it is still somewhat active; however, for the majority of agents, four half-lives is considered sufficient time for the drug's action to be terminated and the agent eliminated from the body. As noted earlier, most drugs leave the body at a constant rate or percentage over time. This is referred to as *first-order kinetics* or *dosage independence* and is the reason half-life is constant. Other elimination rate kinetic models include zero-order (e.g., alcohol) elimination, in which a constant amount (not a percentage) is eliminated over time, and Michaelis-Menton models (e.g., phenytoin), which are dose dependent and follow zero order at high doses and first order once drug levels have fallen.[4]

TABLE 6-4 Relationship Between Half-Life and Drug Remaining in the Body

Half-Life	Drug Eliminated (%)	Drug Remaining (%)
0	0	100
1	50	50
2	75	25
3	87.5	12.5
4	93.75	6.25
5	96.875	3.125

Context-Sensitive Half-Time

Deficiencies in the use of standard pharmacokinetic parameters such as half-life when describing anesthetic drug administration have led to a proposal for the introduction of a new model that accounts for continuous infusion or repeated dosing-induced changes in drug behavior.[3,4] *Context-sensitive half-time* was developed through use of computer simulations of typical anesthetic dosing practices to provide a more clinically relevant measure of

Table 6-5 Pharmacokinetic Metrics for Describing Drug Offset

Parameter	Definition	Advantages	Limitations
Terminal half-life	Time taken for drug concentration in the blood to fall by one half of the current value	Easily understood Simple to calculate Useful for describing drug disposition in a one-compartment model	One-compartment models rarely used for describing the kinetics of anesthetic drugs Not "context sensitive" with respect to infusion duration Not informative with respect to actual duration of action
Context-sensitive decrement times	Time required for drug concentration to decrease by a given percentage, after termination of an infusion of a given duration	Can be calculated for the central (plasma) or a peripheral effect compartment Context sensitivity allows rational drug selection based on anticipated infusion duration	Decrement curves are generated by kinetic-dynamic simulation using known models Impractical to attempt clinical validation due to vast numbers of patients required An arbitrary decrement time (particularly if relating to plasma concentration) may not relate to actual recovery time
Mean effect time	Calculation of the average recovery time, based on the probability of drug effect as a function of drug concentration and time	An extension of the context sensitive half-time. For example estimates of C90, the concentration at 90% recovery, which considers the probability of drug effect, in addition to pharmacokinetic parameters	Calculation requires knowledge of the concentration-effect relationship and the variance of drug concentration Useful for quantifying the duration of drug effect when dealing with "response or no response" binary data

Adapted from Rigby-Jones AE, Sneyd JR. Pharmacokinetics and pharmacodynamics—is there anything new? *Anaesth* 2012; 67(1):5-11; Minto CF, Schnider TW. Contributions of PK/PD modeling to intravenous anesthesia. *Clin Pharmacol Ther.* 2008; 84(1):27-38; Bailey JM: Context-sensitive half-times: what are they and how valuable are they in anaesthesiology? *Clin Pharmacokinet.* 2002;41(11):793-799.

drug concentrations, taking into consideration the method and duration of administration.[35] It is defined as the time to halving of the blood concentration after termination of drug administration by an infusion designed to maintain a constant concentration. It is believed that through incorporation of the effect compartment, the context-sensitive half-time of the pharmacodynamic effect can be modeled.[36] A flaw in the concept is that it describes only the time to a 50% decrease in central compartment concentration, which may not be the decrement in drug level required to achieve recovery.[37] Whether context-sensitive half-time is a useful secondary kinetic descriptor may await its more widespread application. Advantages and disadvantages of the various elimination models are summarized in Table 6-5.

Other parameters have been introduced including the *relative decrement times*. This is the time needed for 80% or 90% decreases in inhalation anesthetic concentration. The major differences in the rates at which desflurane, sevoflurane, and isoflurane are eliminated occur in the final 20% of the elimination process.[38,39]

Clearance

The clearance of a drug is an independent value and is governed by the properties of the drug and the body's capacity to eliminate it. It is defined as the volume of plasma completely cleared of drug by metabolism and excretion per unit of time. Clearance is directly proportional to the dose and inversely related to the agent's half-life as well as its concentration in the central compartment. Clearance is a very important pharmacokinetic concept, because it influences the steady-state concentration for a given drug administered at repeated intervals or by infusion.

The two main organs for clearance are the liver and kidneys. The rate of clearance is determined by the blood flow to these organs, as well as by their ability to extract the drug from the bloodstream. Mathematically, clearance is equal to the product of the blood flow (Q) and extraction ratio (E):

$$\text{Clearance} = Q \times E$$

Total clearance is the sum of all organs' clearance values. The changes in clearance occur when blood flow to the liver or kidney is altered or when their extraction ratios are changed.

Hepatic Clearance. Drugs typically go through perfusion-dependent elimination or capacity-dependent elimination in the liver. Drugs that have a high extraction ratio of 0.7 or greater rely heavily on the perfusion of the liver to be cleared. These drugs are referred to as *high-clearance drugs*. Examples of high-clearance drugs are verapamil, morphine, and lidocaine. Hepatic blood flow for these agents far outweighs enzymatic activity in clearing them from the body, so a decrease in hepatic blood flow decreases the rate of clearance, and a high perfusion state leads to faster clearance. This is termed *perfusion-dependent* elimination.[1]

Capacity-dependent elimination occurs with agents that possess a low extraction ratio of 0.3 or less. When a low extraction rate exists, only a small fraction of the agent is removed per unit time, and changes in hepatic perfusion do not have significant effect on hepatic clearance. Clearance of these drugs depends on hepatic enzymes and the degree of protein binding. Therefore alterations such as enzyme induction or suppression cause a change in the elimination of these drugs from the body. An increase in enzyme activity causes faster elimination from the body, and enzyme suppression has the opposite outcome. A decrease in protein binding (increase in availability of drug at hepatocytes) also leads to a greater rate of clearance. Examples of drugs with a low hepatic extraction ratio are diazepam and theophylline.[1]

Renal Clearance. The kidneys excrete water-soluble molecules with great ease. The excretion of drugs involves passive glomerular filtration, active tubular secretion, and some reabsorption. Selected substances that are actively secreted are noted in Box 6-8. The amount of drug made available to the renal tubule for elimination depends on the amount of free, unbound drug and the glomerular filtration rate. Water-soluble metabolites are filtered by the glomeruli and eliminated. The kidneys do not excrete lipid-soluble agents as efficiently as water-soluble compounds. For these agents, elimination depends on the liver for metabolism

BOX 6-8

Important Drugs and Related Substances Secreted into the Proximal Renal Tubule by OAT or OCT Transporters

OAT	OCT
p-Aminohippuric acid	Amiloride
Furosemide	Dopamine
Glucuronic acid conjugates	Histamine
Glycine conjugates	Mepacrine
Indomethacin	Morphine
Methotrexate	Meperidine
Penicillin	Quaternary ammonium compounds
Probenecid	
Sulfate conjugates	Quinine
Thiazide diuretics	5-Hydroxytryptamine (serotonin)
Uric acid	Triamterene

OAT, *Organic anion transporter;* OCT, *organic cation transporter.*

into water-soluble molecules. Indeed, increased water solubility reduces the volume of distribution of agents, leading to their excretion by the kidneys. Conversely, lipid-soluble molecules are reabsorbed from the renal tubules back into the systemic circulation. An example of a lipid-soluble drug that is almost completely reabsorbed (such that little or none of it is excreted unchanged) is propofol.

The pH of the urine can also affect the elimination of drugs. Weak acids are better excreted in alkaline urine; conversely, weak bases are readily excreted in acid urine. The kidneys can use glomerular filtration for elimination of drugs that are highly polar (e.g., aminoglycoside antibiotics). Certain agents (e.g., penicillin) are eliminated via secretion. Some important clearance concepts are noted in Box 6-9.

OTHER FACTORS THAT INFLUENCE PHARMACOKINETICS

Age

Age plays an important role in the manner in which drug disposition occurs. Elderly patients have a decrease in renal function, resulting in impaired excretion of agents that are eliminated in the urine.[6] Creatinine clearance, as an indicator of renal function, parallels the kidneys' ability to excrete drugs and is a useful test in predicting renal pharmacokinetics in the elderly.[4] Liver blood flow decreases with age as well, decreasing the metabolism of agents with moderate to high extraction ratios. The elderly also have an increase in the fat compartment, leading to an increased volume of distribution, which can lead to accumulation of lipid-soluble agents.[15] Liver and renal function are also important in neonates. Elimination of drugs via the kidneys is altered in neonates because of poor renal function in the first year of life. Neonates and premature infants lack the ability to metabolize certain agents because of immature liver enzyme systems.[4] It is therefore important to consider extremes of age when administering any agent that may be highly lipid soluble with a high hepatic extraction ratio or that relies primarily on the kidneys for elimination.

Gender

Gender differences account for some variability in the pharmacokinetics of many agents. In a recent review of the literature, it was found that female patients had a 20% to 30% greater sensitivity to the muscle relaxant effects of vecuronium, pancuronium, and rocuronium.[40,41] It was also found that male patients were more sensitive to propofol than female patients and that it may be necessary to reduce propofol doses in male patients.[42] Gan et al.[43] studied emergence from general anesthesia with propofol, alfentanil, and nitrous oxide. Female patients emerged significantly more quickly than male patients. In fact, female patients were three times more likely than male patients to experience recall under general anesthesia. Females are more sensitive than males to some of the effects of opioid receptor agonists while being more resistant to others.[40-42]

BOX 6-9

Elimination of Drugs by the Kidney

- Most drugs, unless highly bound to plasma protein, cross the glomerular filter freely.
- Many drugs, especially weak acids and weak bases, are actively secreted into the renal tubule and therefore are more rapidly excreted.
- Lipid-soluble drugs are passively reabsorbed by diffusion across the tubule and are not efficiently excreted in the urine.
- Because of pH partition, weak acids are more rapidly excreted in alkaline urine, and vice versa.
- Several important drugs are removed predominantly by renal excretion and are liable to cause toxicity in elderly persons and patients with renal disease.

Modified from Rang HP, et al. *Rang and Dale's Pharmacology.* 7th ed. Edinburgh: Churchill Livingstone; 2012:121.

Temperature

Because temperature affects tissue metabolism and blood flow, it follows that the pharmacokinetics of agents are also affected by varying temperatures. Knibbe et al.[44] examined the pharmacokinetics of long-term propofol sedation in critically ill patients. Temperature was a significant covariate for clearance of propofol. Warmer temperatures led to faster elimination of propofol, regardless of the concentration of the drug in solution.

Disease States

Comorbidities account for some of the variability observed in drug pharmacokinetics. The pharmacokinetics of ropivacaine in patients with and without uremia after axillary brachial plexus block was examined. An enhanced absorption and larger total plasma concentrations of ropivacaine and its main metabolite were noted in the patients with uremia.[45] Conversely, Goyal et al.[46] found a negative correlation of propofol dose with preoperative hemoglobin concentration in patients with renal failure. They concluded that the hyperdynamic state caused by anemia in these patients was responsible for their higher propofol dose requirement.

Other disease states can cause variability, as illustrated by a recent study that found an increase in the volume distribution of ketamine disproportional to increases in clearance in spinal cord injury inpatients in the intensive care unit, leading to a longer than expected half-life for the drug, again placing the patients at risk for overdose.[47] See Box 6-10 for a summary of some pharmacokinetic principles.

PHARMACOGENETICS AND PHARMACOGENOMICS

Definition

Pharmacogenetics is the study of variations in human genes that are responsible for different responses to drug therapy. These

BOX **6-10**

Summary of Pharmacokinetic Principles

- Clinical pharmacokinetics is the discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients who require drug therapy.
- Clearance is the most important pharmacokinetic parameter, because it determines the steady-state concentration for a given dosage rate. Physiologically, clearance is determined by blood flow to the organ that metabolizes or eliminates the drug and the efficiency of the organ in extracting the drug from the bloodstream.
- The dosage and clearance determine the steady-state concentration.
- The fraction of drug absorbed into the systemic circulation after extravascular administration is defined as its *bioavailability.*
- Pharmacokinetic models are useful for description of data sets, prediction of serum concentrations after several doses or different routes of administration, and calculation of pharmacokinetic constants such as clearance, volume of distribution, and half-life. The simplest case uses a single compartment to represent the entire body.
- The volume of distribution is a proportionality constant that relates the amount of drug in the body to the serum concentration. The volume of distribution is used to calculate the loading dose of a drug that will immediately achieve a desired steady-state concentration. The value of the volume of distribution is determined by the physiologic volume and how the drug binds in blood and tissues. The volume of distribution determines the loading dose.
- Half-life is the time required for serum concentration to decrease by one half after absorption and distribution are complete. Half-life is important because it determines the time required to reach steady state and the dosage interval. Half-life is a dependent kinetic variable because its value depends on the values of clearance and volume of distribution.
- The half-life determines the time to reach steady state and the time for "all" drug to be eliminated from the body.
- If a drug obeys first-order pharmacokinetics, a simple ratio of dosage to steady-state concentration can be used to estimate a new dosage, as long as the clearance has not changed.
- Phenytoin is an example of a drug that obeys the Michaelis-Menton model rather than first-order pharmacokinetics. In this case, as plasma concentration increases, the clearance decreases and the half-life becomes longer.
- *Cytochrome P-450* is a generic term for the group of enzymes responsible for most drug metabolism oxidation reactions. Several P-450 isozymes have been identified, including CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4.
- Factors to be taken into consideration when deciding on the best drug dose for a patient include age, gender, weight, ethnic background, other concurrent disease states, and other drug therapy.
- The importance of transport proteins in drug bioavailability and elimination is now better understood. The principal transport protein involved in the movement of drugs across biologic membranes is P-glycoprotein. P-glycoprotein is present in many organs, including the gastrointestinal tract, liver, and kidney.

differences are identified in the pharmacodynamic and pharmacokinetic processes.[48] Pharmacogenomics is an evolution of pharmacogenetics research and involves the identification of drug response markers at the level of disease, drug metabolism, or drug target.[49,50]

Pharmacogenetics and pharmacogenomics take into account the genetic basis for the variability in an individual's drug response. Pharmacogenetics studies variations in genes suspected of affecting drug response, whereas pharmacogenomics encompasses the genome (all genes). The discipline of pharmacogenetics integrates biochemical and pharmacologic concepts and seeks to correlate phenotypic biomarkers such as toxicity with genetics via twin studies. Pharmacogenomics involves DNA sequencing and gene mapping to identify the genetic basis for variations in drug efficacy, metabolism, and transport.[51]

History

The history of pharmacogenetics goes back to the days of Pythagoras (510 BC) when he recognized only some people had fatal responses to ingestion of fava beans, but not all.[52]

Archibald Garrod's 1902 study of alkaptonuria in humans constituted the first genetic link to disease in humans. He later advanced the hypothesis that genetically determined differences in biochemical processes may be the reason for adverse drug reactions.[53]

Familial clustering of toxic drug responses led to suspicion of a biochemical genetic basis for the toxicities.[48,51] In a seminal article published in 1957, Motulsky[54] outlined many genetic conditions associated with toxic reaction to a specific drug or chemical and proposed that inheritance of certain traits may explain individual variations in drug efficacy and toxic reactions.

Early advances in the field of pharmacogenetics came from research into the biochemical and genetic basis for idiosyncratic drug responses. Several independent observations were made. For example, in the 1950s following reports of prolonged muscle relaxation following administration of succinylcholine during anesthesia, the variation in serum cholinesterase levels was found to be an inherited trait.[55,56] Similarly, hemolytic anemia found in African-American male soldiers after administration of the antimalarial drug primaquine during World War II led to the discovery of a defect in the gene encoding glucose-6-phosphate dehydrogenase (G6PD).[51]

The term *pharmacogenetics* was coined by Vogel in 1959 and defined as "clinically important hereditary variation in response to drugs."[48] In 1962, Kalow wrote a text, *Pharmacogenetics: Heredity and the Response to Drugs*.[48,57]

In the 1960s, twin studies established the role of genetic factors in individual variations in rates of drug metabolism; however, they did not identify the specific genes involved. Gene identification emerged in the 1980s.[48] Now that the human and many animal genomes have been sequenced, huge strides in genomics and drug therapies are occurring. The development of genomics has led to the hope of individualized drug therapy with increased and targeted efficacy and fewer side effects. The characterization of single nucleotide polymorphisms (SNPs) and the effect on drug action has opened new areas of drug research. Recently, the emergence

of pharmacometabonomics assesses the influence of the metabolic factors and the environment on gene expression. The combination of these disciplines permits factors involving the genetic background of individual and exterior interventions to tailor individual therapies.[58,59]

Polymorphisms

Polymorphic genes relevant to pharmacokinetics (absorption, distribution, metabolism, and excretion) and pharmacodynamics (drug targets–receptors and enzymes) can have a significant impact on pharmacotherapy.[60] Pharmacotherapy may be affected by three types of genetic variation. These include variations in target proteins, enzyme metabolism, or idiosyncratic effects.[61]

Polymorphisms are defined as variations in the DNA sequences that occur in at least 1% of the population.[62-65] There are a number of different types of polymorphisms, but most attention has been focused on single nucleotide polymorphisms (SNPs—pronounced "snips") in which one nucleotide is exchanged for another in a given position.[52] Approximately 10 million SNPs exist, and they can occur anywhere on the genome, but only a fraction are likely to prove relevant to drug response. To matter from a pharmacologic standpoint, the differences generally affect either the function or amount of target proteins involved in the biochemical pathways of the disease processes the drugs are used to treat.[61]

The genomes of any two individuals are nearly 99.9% identical regardless of race.[61] Most variations in the human genome (polymorphisms) occur in drug-metabolizing enzyme genes. Others occur in the enzyme receptor genes and drug transporter genes.[45] Much of the observed variability in drug response has a basis in pharmacogenetic polymorphisms arising in genetically determined differences in drug absorption, disposition, metabolism, and excretion. The best-characterized pharmacogenetic polymorphisms are those in the cytochrome P-450 family of drug-metabolizing enzymes.[64]

Most drugs are lipophilic and must be metabolized to polar products for excretion. This involves hepatic enzymes and a sequence of steps dependent on the cytochrome P-450 system. Drugs are first metabolized by phase I enzymes (oxidation) and then phase II enzymes (conjugation that involves sulphation, glucuronidation, or acetylation). Although the effects of polymorphism in phase II enzymes are often less pronounced, the effects of inherited variations in both phase I and II metabolism can be synergistic.

Genetic polymorphisms occur in most if not all of the human cytochrome P-450 (CYP) isoenzymes, but functional polymorphisms reside in only four, which account for 40% of all drug metabolism (CYP2A6, CYP2C9, CYP2C19, and CYP2D6). Thus genetically controlled variations are common.[48] For example, CYP2D6 metabolizes up to 25% of all commonly prescribed drugs and is inactive in 6% of the Caucasian population. Similarly, the CYP2C19 poor metabolizer phenotype occurs in 2% to 5% of Caucasians and 3% to 23% of Asians and results in high sensitivity to diazepam, propranolol, amitriptyline, and hexobarbital.

Individuality in the expression in the P-450 isoenzymes may have a variety of consequences. These include toxic side effects due to impaired metabolism, no therapeutic effect due to ultrarapid metabolism, activation of toxic products, and failure of prodrug activation.

Individual Drug Response/Genetics

Many variations of pharmacogenetic interest have been elucidated, and with the deciphering of the human genome, many innovative opportunities exist. Genetic variations can modify responses to drugs. Variations in target pathways and metabolic enzymes may render a drug ineffective for some, yet effective for others.[62-65]

Recognition of genetic differences among patients has the potential to allow for individualized drug therapy. Further, with the recognition that certain genetic differences are associated with risk of disease, opportunities to identify these individuals and treat them early may improve efficacy and specificity of their treatment.[48]

There are marked ethnic differences that need to be taken into account when drugs subject to polymorphic metabolism are prescribed to patients from different ethnic backgrounds. The variation in CYP2C19 is reflected in a significant dosing reduction for diazepam in Asians, for example.

Genetic variation may also alter pharmacotherapy responses by creating idiosyncratic effects. These are not caused by alterations in target proteins, pathways, or metabolism, but rather result from chance interactions between the medication and the individual's physiology.[61]

The identification of specific polymorphisms and the ability to screen for them opens up the possibility of rational, individualized treatment with ideal dosing, as well as minimization of side effects based on genetic constitution. Recognition of differences may also facilitate identification of good responders versus poor responders to therapy.[51]

SUMMARY

Pharmacokinetics is an integral part of modern anesthesia clinical practice. Anesthesia providers balance the administration of a number of drugs simultaneously to achieve the necessary drug actions that constitute anesthesia. A thorough understanding of the processes that govern drug kinetics allows for safe and effective practice and facilitates operating room efficiency. This knowledge also allows the clinician to anticipate and avoid potential problems and tailor each anesthetic to particular patient characteristics. Recent advances in pharmacokinetics and pharmacogenomics will further impact anesthesia care in years to come. Pharmacogenomics has made a significant impact on the direction of drug research and drug therapy. Diseases and drug therapies are complex processes that may challenge the predictive powers of pharmacogenetics. A systems approach may be needed to integrate overall pharmacotherapeutic effects with polymorphisms in multiple genes.[62,63,65-67]

CHAPTER 7

Pharmacokinetics of Inhalation Anesthetics

◆ *John J. Nagelhout*

The basic action of an anesthetic in the body is largely a function of the drug's chemical structure and the resulting interaction with a cellular receptor complex (Figure 7-1). A number of heterogeneous compounds exhibit anesthetic properties. The inorganic molecule nitrous oxide and halogenated ethers (e.g., isoflurane, desflurane, and sevoflurane) are all capable of binding to central nervous system and spinal cord neuronal membranes to produce reversible depression. A single specific anesthetic receptor has yet to be found. In fact, multiple sites of action and protein targets probably exist; however, once a critical concentration of drug has entered the brain and spinal cord, loss of consciousness ensues.[1-3]

The administration of inhalation anesthetic gases plays a primary role in modern clinical anesthesia. In anesthesia's early years, administration of a gas such as diethyl ether constituted the entire anesthetic regimen. Now, one or two gas anesthetics are combined with a variety of intravenous drugs to produce an anesthetic state. These intravenous drugs include sedative induction agents, analgesics, neuromuscular blocking drugs, and local anesthetics. This combination allows the use of smaller and more easily manipulated doses of specific receptor agonists and antagonists. Used in the proper combination, the desired amount of anesthesia, analgesia, amnesia, and muscle relaxation can be achieved. Current practice dictates that the anesthetic technique allow for a quick and pleasant induction and recovery with maximum patient safety and efficient caseload management. A sound understanding of inhalation anesthetic pharmacokinetics is essential to safe practice.

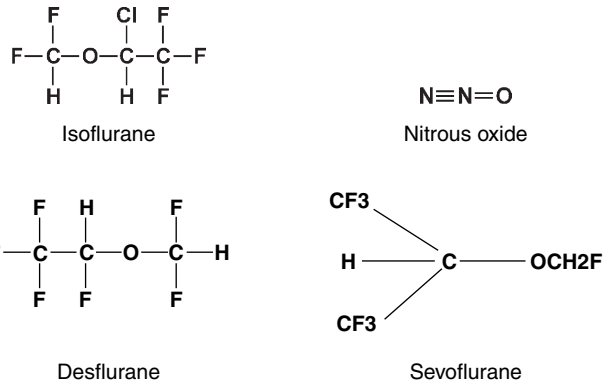

FIGURE **7-1** Chemical structure of anesthetic agents. Nitrous oxide is inorganic, and the rest are halogenated ethers.

PRIMARY FACTORS CONTROLLING UPTAKE, DISTRIBUTION, AND ELIMINATION OF ANESTHETICS

The basic task of anesthetic administration involves taking a drug supplied as a liquid, vaporizing it in an anesthesia machine, and delivering it to the patient's brain and other tissues via the lungs. Therefore the main factors that influence the ability to anesthetize a patient are technical or machine specific, drug related, respiratory, circulatory, and tissue related. The primary factors that influence absorption of the inhalation anesthetics are ventilation, uptake into the blood, cardiac output, the solubility of the anesthetic drug in the blood, and alveolar-to-venous blood partial-pressure difference. Other factors such as the concentration and second gas effects also play a role (Figure 7-2).[4]

A few assumptions are usually made. The level of anesthesia is related to the alveolar concentrations of anesthetic agents, which can be readily and continuously measured or inferred. The concentration or partial pressure of anesthetic in the lungs is assumed to be the same as in the brain, because the drugs are highly lipid soluble and diffusible, and they quickly and easily reach equilibrium among the highly perfused body compartments. For this reason, the dose of an individual drug is expressed in terms of the minimum alveolar concentration (MAC) necessary to produce anesthesia (lack of movement) upon surgical stimulation.[5-8] The faster the lung (and therefore brain) concentration rises, the faster anesthesia is achieved. Conversely, the faster the lung (brain) concentration falls after discontinuation of the drug, the more quickly the patient emerges.[9]

Machine-Related Factors

Concepts regarding the anesthesia machine and its function are described in detail in Chapter 15. Two factors that may affect uptake early in anesthetic administration are drug solubility in the rubber and plastic machine parts and total machine liter flow of the gases chosen.

The rubber and plastic components of the machine, as well as the ventilator and absorbent, can retain small quantities of anesthetic gases. Theoretically, this could slow administration to the patient at the start of anesthetic delivery. The effect on uptake is minimal in actual clinical practice and essentially ceases after approximately 15 minutes of administration.[10] Nonetheless, sequestration of small amounts of gas in the apparatus has other implications, such as when anesthetizing patients with malignant hyperthermia. All gases except nitrous oxide are potent triggering agents for a hyperthermic episode. To avoid exposure resulting from residual trace amounts of gases, a thorough flush of the anesthesia machine with 100% oxygen at 10 L/min for at least 20 minutes, replacement of breathing circuits and the carbon dioxide canister, and draining, inactivation, or removal of vaporizers are advised when preparing for a patient who is susceptible to malignant hyperthermia.[11] Proper preparation may vary with different machines and consultation with the machine manufacturer is advised.[12,13]

Low liter flows of oxygen and nitrous oxide carrier gas, although economical, deliver the anesthetic more slowly at the start of induction. Increasing liter flows for the first few minutes of the anesthetic minimizes this effect without unduly adding to cost.[14]

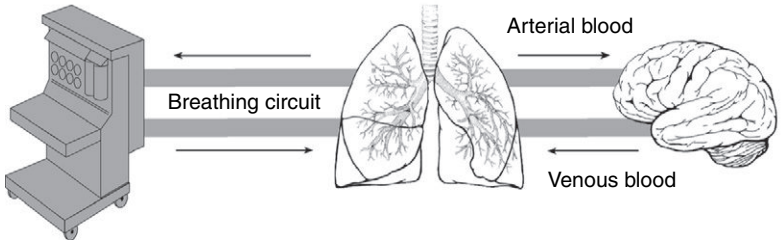

FIGURE **7-2** Transfer of an anesthetic gas from the machine through the lungs into the blood and tissues.

TABLE **7-1** General Anesthetic Properties of Inhalation Agents

Anesthetic	MAC (%)	Blood/Gas Partition Coefficient (at 37° C)	Oil/Gas Partition Coefficient (at 37° C)
Sevoflurane (Ultane)	2	0.6	50
Isoflurane (Forane)	1.15	1.4	99
Nitrous oxide	105	0.47	1.4
Desflurane (Suprane)	5.8	0.42	18.7

MAC, Minimum alveolar concentration.

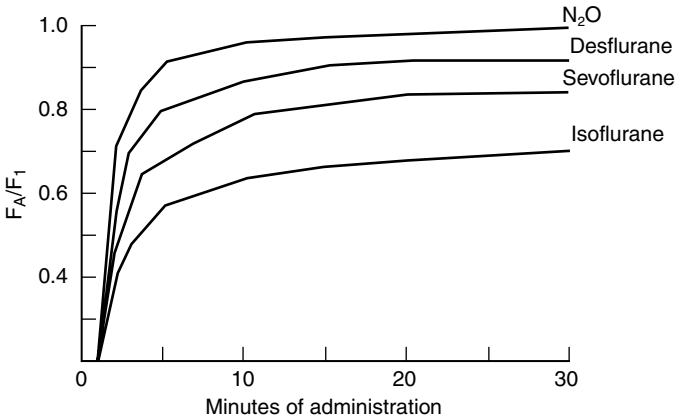

FIGURE **7-3** Rate of rise (F_A/F_1) of alveolar concentration of inhalation anesthetics over time. Low blood/gas anesthetics such as nitrous oxide and desflurane achieve a lung concentration much faster than moderate-solubility gases such as isoflurane. Note that nitrous oxide rises in the lungs more quickly than desflurane, in spite of a slightly higher blood/gas solubility. This is due to the concentration effect.

Drug-Related Factors

Blood/Gas Solubility

The blood/gas solubility coefficient of an anesthetic is an indicator of the speed of uptake and elimination.[15,16] It reflects the proportion of the anesthetic that will be soluble in the blood, "bind" to blood components, and not readily enter the tissues (blood phase) versus the fraction of the drug that will leave the blood and quickly diffuse into tissues (gas phase). The more soluble the drug (high blood/gas coefficient), the slower the brain and spinal cord uptake and therefore the slower the anesthesia achieved by the patient. Soluble drugs stay in the blood in greater proportion than less soluble agents; therefore, less of the drug is released to the tissues during the early, rapid-uptake phase of induction. For example, isoflurane has a blood/gas solubility coefficient of 1.4 or, expressed as a ratio, 1.4:1. Therefore 1.4 times as much stays in the blood as a nonreleasable fraction for every 1 molecule that enters the tissues and produces anesthesia. Conversely, agents with low solubility properties (low blood/gas coefficient) leave the blood quickly and enter the tissues, producing a rapid anesthetic state. Desflurane, for example, has a low blood/gas coefficient of 0.42 or, expressed as a ratio, 0.42:1. Only 0.42 of a molecule stays in the blood for every 1 (greater than twice as much) that enters the brain. Anesthesia is achieved quickly. Blood/gas solubility coefficients for the inhalation anesthetic agents are listed in Table 7-1.[17] The rate of rise of an anesthetic in the alveoli relative to the concentration administered is graphically depicted by plotting the fraction in the alveoli over the fraction inspired (Figure 7-3).

As noted previously, the lower the blood/gas solubility, the faster the rise in lung and brain concentrations. The rate of rise of low-solubility agents such as nitrous oxide and desflurane is greater than moderately soluble drugs such as isoflurane. Note in Figure 7-3 that nitrous oxide exhibits a slightly faster rate of rise compared with desflurane, despite a higher blood/gas coefficient. This variation in the usual trend is a result of the concentration effect—that is, nitrous oxide is given at much higher concentrations (50% to 70%) than desflurane (3% to 9%). Figure 7-4 depicts the effect of anesthetic blood solubility on uptake.

Ventilation Factors

As with all diffusible drugs, anesthetics move down a concentration gradient. Continuous inhalation administration of the agent into the lungs promotes subsequent diffusion into the blood and tissues as the anesthetic progresses. Anesthetic uptake slows throughout the surgical procedure as the tissue compartments become more saturated.[18] The anesthetic is delivered, along with the necessary amount of oxygen or an oxygen mix appropriate for the patient's condition. Supplemental nitrous oxide may also be used. Basically, the faster and more deeply a patient breathes or is ventilated, the faster the patient loses consciousness at the start of anesthesia and emerges at the end.[16,19,20] This is often referred to as the *ventilation effect*.

Ventilation-perfusion deficits or poor lung function hinders inhalation drug administration.[21,22] Rapid-acting (low blood/gas solubility) agents are affected by these deficits to a greater extent than are slower-acting (high blood/gas solubility) drugs.[23] These decreases in speed can be partially compensated for by increasing the concentration of insoluble (fast) agents or increasing ventilation with soluble (slow) drugs.

Concentration or Dose

During the first minutes of gas administration, a higher concentration of the drug than necessary for maintenance, or a loading dose, is delivered to speed initial uptake. This is commonly

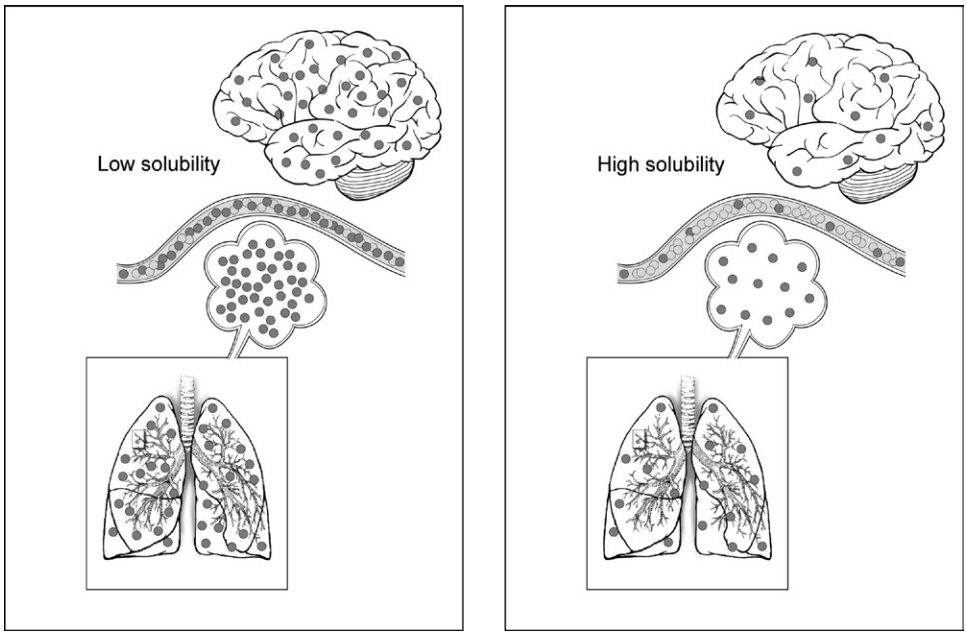

FIGURE **7-4** Effect of anesthetic blood/gas solubility on uptake. *Left*, an anesthetic gas with a low blood/gas solubility is not taken into the blood (*lightly shaded circles*); therefore, the alveolar (thus brain) concentration rises rapidly (*darkly shaded circles*), and the patient achieves anesthesia quickly. *Right*, an anesthetic gas with a high blood/gas solubility is taken up and held in the blood (*lightly shaded circles*), resulting in a slower rise in alveolar (thus brain) concentration (*darkly shaded circles*) and a slower onset of anesthesia.

TABLE **7-2** Inhalation Anesthetic Doses*

Anesthetic	Induction (%)	Maintenance (%)
Nitrous oxide	50-70	Same
Isoflurane (Forane)	1-4	0.5-2
Desflurane (Suprane)	3-9	2-6
Sevoflurane (Ultane)	4-8	1-4

*Doses vary according to patient status, procedure, and types of medications coadministered. Doses are given as vaporizer setting or partial pressures.

referred to as *overpressuring* or the *concentration effect*.[24] Overpressuring during initial administration is a common clinical practice and is more effective the more soluble the anesthetic. Overpressuring can speed the effect of slow agents but has less of an effect on relatively fast agents. This practice follows the kinetic standard of using a loading dose to speed onset. After the first few minutes, the dose is decreased to normal maintenance levels.[25]

As noted previously, the dose of an anesthetic is expressed in terms of MAC—the relative concentration when the anesthetic is combined with all the other gases in the lungs. Induction and maintenance doses are given as vaporizer settings of partial pressure in Table 7-2.

Second-Gas Effect

Simultaneous administration of a relatively slow agent such as isoflurane and a faster drug such as nitrous oxide (in high concentrations) can speed the onset of the slower agent. This is known as the *second-gas effect*.[26] The uptake of the slower agent in the alveoli and to even a greater proportion in the arterial blood, is increased by administering it with a high concentration of the faster anesthetic nitrous oxide.[27] The faster the inherent speed of the second gas on its own, however, the less prominent the augmentation when given with nitrous oxide. For example, sevoflurane, which has low blood solubility (blood/gas solubility coefficient 0.6) is rapidly taken up into tissues. Coadministration of sevoflurane with the slightly faster nitrous oxide produces a small but significant increase in uptake as compared with sevoflurane administration alone.[25,28-30] The mechanism for the second-gas effect is not definitive, but it has traditionally been explained as the large volume uptake of nitrous oxide concentrating the other alveolar gases. Recent data suggests an added effect of ventilation perfusion scatter on the distribution of blood flow and gas uptake in the lung.[27] The second-gas effect also occurs during emergence where the rapid elimination of nitrous oxide produces a clinically significant acceleration in the removal of the accompanying volatile agent.[31]

Tissue-Related Factors

Oil/Gas Solubility

The oil/gas solubility coefficient is an indicator of potency. The higher the solubility, the more potent the drug (see Table 7-1).[32,33] A high solubility coefficient reflects high lipid solubility. Because the anesthetic must traverse the blood-brain barrier and penetrate other lipid membranes to produce its action, highly lipid-soluble drugs tend to be the most potent. Of the current agents, isoflurane (oil/gas partition coefficient 99) is the most potent, and nitrous oxide (oil/gas partition coefficient 1.4) is the least potent. Remember that two factors are at play: how fast the drug is delivered to the tissues (blood/gas solubility) and how efficiently it can access and affect the sites of action (oil/gas solubility). Recent investigations suggest that polarity along with lipophilicity plays an important yet not fully understood role in the mechanism of inhalation anesthetics.[34-36]

Circulatory Factors

The cardiovascular system exerts two major influences on anesthetic uptake and distribution.[37] First, the majority of the blood leaving

TABLE 7-3 Tissue Compartments and Perfusion Comparisons

Characteristic	Vessel Rich	Muscle	Fat	Vessel Poor
Body weight	10%	50%	20%	20%
Cardiac output	75%	19%	6%	0%
Perfusion	75 mL/min/100 g	3 mL/min/100 g	3 mL/min/100 g	0 mL/min/100 g

TABLE 7-4 Anesthetic Metabolism

Agent	Average Metabolism (%)
Sevoflurane	3-6
Nitrous oxide	<1
Isoflurane	<1
Desflurane	<0.1

the lungs with anesthetic is normally distributed to the vital organs or high–blood-flow areas, commonly referred to as the *vessel-rich group* or *central compartment*. Organs such as the heart, liver, kidneys, and brain receive proportionately more anesthetic sooner than the muscle and fat areas (Table 7-3). The longer the anesthetic is given, the greater the saturation of all body compartments.

Second, during induction, increases in cardiac output slow onset. All anesthetics are affected; however, the more soluble the agent (higher blood/gas coefficient, and therefore slower), the greater the effect. An increased cardiac output removes more anesthetic from the lungs, which slows the rise in lung and brain concentration.[38-40] This effect dissipates as the anesthetic proceeds.

Metabolism

The modern anesthetics are minimally metabolized (Table 7-4).[41] Possible toxic metabolite formation is not currently a clinical issue.[42] Drug metabolism has historically been associated with various anesthetic-related toxicities. These include hepatotoxicity from halothane[43] and other agents and nephrotoxicity from methoxyflurane. Nitrous oxide, desflurane, and isoflurane are the least metabolized and do not result in metabolism-related toxicity. Although sevoflurane is metabolized approximately 5%, releasing free fluoride ions, no related clinically significant toxicity has been noted.[44-47]

Emergence

After surgery, when the anesthetic is discontinued, the same principles that influence onset apply. The anesthetic leaves the tissues via the blood and exits the lungs with ventilation. Routine practice is to administer 100% oxygen to assist recovery. If nitrous oxide was given, 100% oxygen prevents diffusion hypoxia. Anesthetics redistribute out of the tissues in a more uniform manner compared with the way they distribute during onset. An equilibrium is approached among tissues during the anesthetic period, so recovery tends to be smoother than induction with respect to the excitatory stage responses. In general, the longer an anesthetic is administered, the slower the patient emerges. This effect is greatest with the most soluble isoflurane and less with sevoflurane and desflurane, respectively. Differences among anesthetics are small but significant and are seen primarily during the final 10% of the elimination process.[48]As expected, the least soluble desflurane exhibits the fastest clinical recovery, with sevoflurane and isoflurane following in that order. Residual anesthetic has been shown to remain in the body for several days following a routine anesthetic.[49]

TABLE 7-5 Nitrous Oxide–Induced Space or Compartment Change*

Air Space	Nitrous Oxide–Induced Change
Pneumoencephalogram	CSF pressure increases to three times baseline in 5 minutes
Intraocular hexafluoride gas	2-18 mmHg increase in pressure in 20 minutes
Middle ear pressure	Increased 1-7 mmHg in 1 hour
Pneumothorax	2-3 times the volume in 5-20 minutes
Intestinal gas	Double in 150 minutes
Air bubble	Immediate increases in size occur

Data adapted from Evers AS, et al, eds. *Anesthetic Pharmacology*. 2nd ed. Cambridge: Cambridge University Press; 2011:393.
*The rate at which the pressure changes depends on the perfusion of surrounding tissue, compliance of the space, and the concentration of nitrous oxide.
CSF, Cerebrospinal fluid.

Diffusion Hypoxia

During emergence, when high concentrations of a rapid (insoluble) anesthetic such as nitrous oxide have been given, the drug exits the body quickly through the lungs and is replaced by less soluble nitrogen in air. This may result in a transient dilution of normal respiratory gases such as oxygen and carbon dioxide. This phenomenon is referred to as *diffusion hypoxia*. Administration of 100% oxygen for several minutes when anesthesia is terminated entirely avoids this potential problem.

Diffusion of Nitrous Oxide into Closed Spaces

Nitrous oxide diffuses into air-containing cavities in the body during an anesthetic procedure. These air-containing spaces are normally rich in nitrogen, which is 34 times less soluble than nitrous oxide. If the space is expandable, it increases in volume. Examples of expandable air cavities include air embolism, pneumothorax, acute intestinal obstruction, intraocular air bubbles produced by sulfur hexafluoride gas injection, and pneumoperitoneum. Rigid air-containing spaces will undergo an increase in pressure. This includes tympanic membrane grafting after tympanomastoid procedures and intracranial air during diagnostic or surgical intracranial procedures. Nitrous oxide should be avoided in these situations. The endotracheal tube cuff, laryngeal mask airway, and balloon-tipped pulmonary artery catheters may expand during nitrous oxide anesthesia, and appropriate precautions and adjustments should be considered.[50-52]

Some characteristics and time courses for air expansion are noted in Table 7-5.[53]

PEDIATRICS

The uptake of anesthetic drugs is faster in children than in adults.[54] In other words, a child goes to sleep faster than an adult patient.[55]

TABLE 7-6 Inhalational Anesthetic Pharmacokinetic Concepts

Concept	Comments
Minimum alveolar concentration (MAC)	The MAC required to achieve surgical anesthesia (immobility) in 50% of patients exposed to a noxious stimulus
Minimum alveolar concentration awake (MAC awake)	The MAC suppressing appropriate response to commands in 50% of patients; memory is usually lost at MAC-awake; approximately 0.3-0.5 MAC
Minimum alveolar concentration—block adrenergic responses (MAC-BAR)	The alveolar concentration of anesthetic that blunts the autonomic response to noxious stimuli; approximately 1.6-2.0 MAC
Ventilation effect	The greater the alveolar ventilation, the faster the patient achieves anesthesia
Concentration effect	The higher the concentration of anesthetic delivered, the faster anesthesia is achieved; this is also referred to as *overpressuring;* as with any drug, the larger the initial dose administered, the faster the onset of action
Blood/gas solubility coefficient	The blood/gas solubility coefficient is the indicator of an anesthetic's speed of onset and emergence: the higher the coefficient, the slower the anesthetic; conversely, the lower the coefficient, the faster the anesthetic
Oil/gas solubility coefficient	The oil/gas solubility coefficient is the indicator of an anesthetic's potency: the higher the coefficient, the more potent the agent
Second-gas effect	The second-gas effect is a phenomenon in which two anesthetics of varying onset speeds are administered together: a high concentration of a fast anesthetic such as nitrous oxide is administered with a slower second anesthetic gas; the slower gas achieves anesthetic levels more quickly than if it had been given alone
Diffusion hypoxia	Diffusion hypoxia occurs when high concentrations of nitrous oxide are administered; at the end of the procedure, when nitrous oxide is discontinued, it leaves the body very rapidly, causing a transient dilution of the oxygen and carbon dioxide in the lungs; hypocarbia and hypoxia may occur; administration of 100% oxygen for approximately 3-5 min when nitrous oxide is discontinued alleviates this problem
Cardiac output effect	Increases in cardiac output decrease the speed of onset of all anesthetics; the more soluble anesthetics are affected to a much greater extent than the insoluble anesthetics
Ventilation-perfusion abnormalities	Ventilation-perfusion abnormalities reduce the speed of onset of all anesthetics and affect the insoluble agents to a much greater degree than the soluble agents
Pediatrics	Children achieve anesthesia more rapidly than adults because of a higher ventilatory rate and vessel-rich-group blood flow; this occurs despite the fact that the required dose and cardiac output are higher in children
Obesity	Obesity has minimal clinical effects on anesthetic induction; however, emergence may be slower because of deposition of anesthetics in fat
Pregnancy	The kinetics of the inhalation anesthetics are similar in pregnant women and nonpregnant women; placental transfer is time dependent as expected

The child's higher alveolar ventilation per weight accounts for this effect.

Infants and children have a higher cardiac output per weight than adults. As noted previously, the higher the cardiac output, the slower the onset. This effect is minimized, however, by the increased cardiac output distributed to the vessel-rich group in children. The infant's lower muscle mass allows more of the agent to concentrate in the vital organs. This overall effect is to promote uptake to the brain.

Finally, anesthetics appear to be less blood soluble (i.e., they work faster) in children than in adults. This effect varies with age and the agent.[56-58] The MAC or required dose of anesthetics is higher in infants and children and decreases with increasing age. Infants aged 6 months have a MAC 1.5 to 1.8 times higher than a 40-year-old adult.[59]

Recent data suggest that during recovery from anesthesia with some inhalation agents, especially sevoflurane, emergence reactions and agitation may occur in infants, children, and young adults.[60-62] Evidence suggests that this phenomenon is not pharmacokinetic or related to rapidity of emergence.[63] Risk factors include preschool age 2 to 5 years, difficult parental separation behavior, and postoperative pain.[62,64] Administration of fentanyl, dexmedetomidine, propofol, or ketamine reduce the incidence of emergence agitation.[65,66] Midazolam or serotonin antagonists have no reducing effect.[62] A glossary of pharmacokinetic concepts is given in Table 7-6.

OTHER FACTORS

Obesity

Obesity has no clinically significant effect on the uptake of the inhalation anesthetics. Some clinicians prefer desflurane due to its low solubility and lipophilicity, which appears to promote a slightly faster recovery. Long procedures and morbid obesity allow for an increase in deposition of anesthetics into fat and may prolong recovery.[67-69]

Pregnancy

Pregnant women have a higher minute ventilation than nonpregnant women, which would predict a faster uptake. Conversely, they also have a higher cardiac output, which tends to slow uptake. Overall, these actions oppose each other so that the uptake of anesthetics in pregnant women will be similar to nonpregnant women.[70] Maternal to fetal transfer of the nitrous oxide has been studied and data suggests that placental transfer

during cesarean section is slower than maternal uptake and time dependent.[71]

SUMMARY

A thorough understanding of the basic pharmacokinetic principles involved in administering anesthetic gases and the development of clinical skills in their use are the cornerstones of modern anesthesia practice. Adults are generally induced with one of the several available intravenous agents and maintained with a combination of inhalation and intravenous drugs. Better anesthesia machines and more sophisticated monitoring have greatly facilitated the quantification of clinical anesthetic levels and depth, contributing to the remarkable safety of modern anesthesia practice.

Inhalation Anesthetics

◆ *Mark A. Kossick*

CHAPTER 8

In the span of almost two centuries major advances have been made in the development and clinical use of inhalation anesthetics (Table 8-1); this continuum includes the investigation of nitrous oxide (N_2O) in 1800 by Humphry Davy[1] following its preliminary discovery by Dr. Priestly in 1786[2] with what was termed "dephlogisticated air." Then 195 years later the most current inhaled anesthetic (sevoflurane) was approved by the Food and Drug Administration in 1995. Interestingly, each of these agents share a common characteristic that promotes their clinical use today—a low blood:gas solubility coefficient, which portends a favorable pharmacokinetic profile.

The present-day use of N_2O can be credited to Edmund Andrews, a professor of surgery in Chicago. In 1868 he declared that a safer anesthetic could result from combining oxygen (O_2) with N_2O.[3] Before that time N_2O was administered through a mouthpiece with a nose clamp to prevent the rebreathing of air.

One of the earliest "complete" anesthetic agents used was diethyl ether (C_2H_5–O–C_2H_5). The first ether anesthetic was administered in Georgia on March 30, 1842, when Crawford Long anesthetized a patient for a minor operation (excised a tumor).[4] However, the recognition of numerous unfavorable characteristics (excessive secretions with inhalation induction, laryngospasm, excessive depths of anesthesia) prompted its disappearance from clinical practice as newer agents were subsequently developed.

In the 1930s, research into potential anesthetic agents was based on the principle of a structure-activity relationship.[5] One of the earliest inhalation anesthetics developed in this manner was divinyl ether. Halothane was introduced into clinical practice in 1956 by Bryce-Smith and O'Brien in Oxford[6] and Johnstone in Manchester[7] and represented a significant advancement in inhalation anesthesia. Its sweet odor, nonflammability, and high potency offered clinical characteristics that were absent from the previously available inhaled anesthetics. The search for newer and improved inhalation anesthetics persisted as concerns with hepatotoxicity and arrhythmogenicity of this alkane derivative began to be documented.

The two most recently released inhalation agents, sevoflurane (synthesized by Regan in the late 1960s) and desflurane (the 653rd compound of more than 700 synthesized by Terrell and colleagues between 1959 and 1966), are commonly used today for a diverse surgical population, based on their pharmacokinetic and pharmacodynamics profile. Although desflurane and sevoflurane do not possess all of the properties of an ideal inhalation agent, the sufficient number of clinical benefits attributed to these agents has been instrumental in anesthesia providers routinely selecting one or the other for many surgical procedures.

TABLE 8-1 History of the Introduction of Inhalation Anesthetics

Anesthetic	Year(s) Anesthetic Properties Demonstrated/Introduced
Ether (Crawford Long)	1842
N_2O (Horace Wells)	1845
Chloroform (James Simpson)	1847
Cyclopropane (George Lucas, Velyien Henderson)	1934
Fluroxene	1951
Halothane	1956
Methoxyflurane	1960
Enflurane	1973
Isoflurane	1981
Desflurane	1993
Sevoflurane	1995

RELATIONSHIP OF CHEMICAL STRUCTURE AND AGENT CHARACTERISTICS

An understanding of the chemical structure of inhalation agents provides insight into their physical properties (e.g., flammability). However, the relationship between the pharmacologic characteristics (e.g., arrhythmogenic properties) and chemical structure of agents is not as predictable. This section reviews the structure-activity relationship of anesthetic vapors and their clinical relevance. Some selected nomenclature in regard to physical and chemical properties are listed in Table 8-2.

All commonly used inhalation agents are ethers (R–O–R) or aliphatic hydrocarbons (straight-chained or branched nonaromatic hydrocarbons) with no more than four carbon atoms (Figure 8-1). The length of the anesthetic molecule is significant in that immobility (anesthetic effect) is attenuated or lost if carbon atom chain length exceeds a distance of four or five carbon atoms (5 angstroms [Å]).[8] The molecular shape of the agents is spherical or cylindrical with a length less than 1.5 times the diameter.[9]

Of primary importance to the development of volatile agents was the discovery of the impact of halogenation of organic compounds. Halogenation of hydrocarbons and ethers (the addition of fluorine [F], chlorine [Cl], bromine [Br], or iodine [I]) influences anesthetic potency, arrhythmogenic properties, flammability, and chemical stability (e.g., oxidation during storage and reactions with bases).

Anesthetic potency has been shown to increase when a halogen with a lower atomic mass unit (amu) is replaced by a heavier halogen (e.g., bromine at 80 amu substituted for fluorine at 19 amu).[10-12] Nonetheless, a ceiling effect exists with halogenation of anesthetic compounds. For example, adding F atoms to ether results in a continuum in which the ether becomes more potent, then acts as a strong convulsant, and finally changes to an inert compound with full fluorination.[13]

TABLE 8-2 Select Characteristics of Inhalation Anesthetics

Characteristics	Nitrous Oxide	Isoflurane	Desflurane	Sevoflurane
Molecular formula	N_2O	$C_3H_2ClF_5O$	$C_3H_2F_6O$	$C_4H_3F_7O$
Ostwald blood/gas partition coefficient (37° C)	0.47	1.43	0.42	0.68
Oil/gas partition coefficient	1.4	99	18.7	50
Saturated vapor pressure (mmHg, at 20° C)	Gas	238	669	157
Molecular weight (g/mol)	44.01	184.49	168.04	200.05

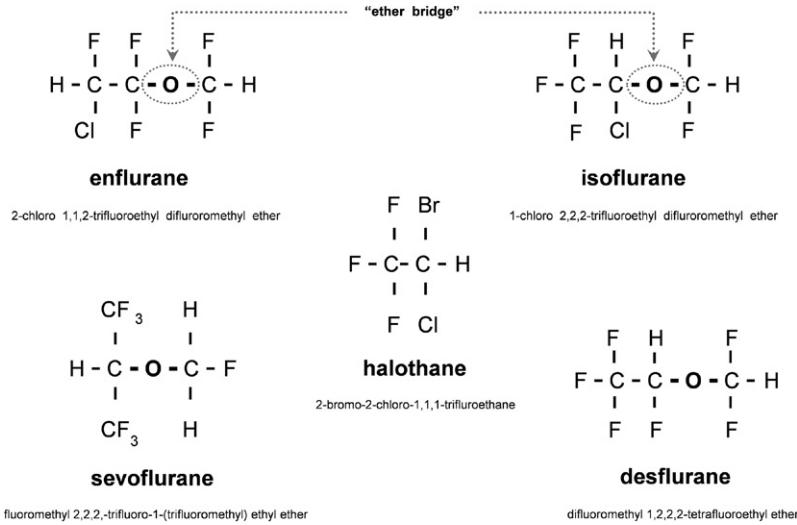

FIGURE **8-1** Chemical structure of volatile agents. The "ether bridges" (R–O–R) are seen with sevoflurane, desflurane, and isoflurane. *R* refers to alkyl group. Halothane (no longer used) is an example of a halogenated hydrocarbon. Enflurane and isoflurane are isomers (have the same molecular formula).

In general, the potency of volatile agents has also been found to correlate with the physical property of lipid solubility. A decline in potency (meaning an *increase* in the minimum alveolar concentration [MAC] of volatile agents) is associated with a proportional decrease in oil/gas partition coefficient values. Exceptions to this principle exist and demonstrate that the correlation between potency and lipid solubility is not perfect.

With regard to arrhythmogenic properties, increasing the number of halogen atoms within a volatile agent favors the genesis of cardiac dysrhythmias.[13] Nevertheless, alkanes that contain five halogens (e.g., halothane) are more prone to induce arrhythmias than ethers with six halogen atoms (e.g., isoflurane).[14]

Flammability is reduced and chemical stability enhanced by substituting hydrogen atoms with halogens. The epitome of this relationship is demonstrated with desflurane, a compound that contains fluorine as its only halogen and thus strongly resists biodegradation; desflurane is metabolized one tenth as much as isoflurane.[15,16]

METABOLISM

As stated previously, the chemical structure of each inhalation agent determines the extent to which it is metabolized. In general, increasing the number of fluorine atoms to a anesthetic molecule retards biodegradation (halothane has 3 and desflurane has 6). The current agents undergo metabolism at the following rates: sevoflurane 5% to 8% and isoflurane, desflurane, and nitrous oxide in trace amounts.[17-20] Desflurane has been shown to resist biodegradation, even after 7.35 MAC-hours, as determined by peak mean urinary excretion rate of trifluoroacetic acid (TFA). This metabolite (TFA) is recognized as being a sensitive marker of desflurane metabolism.[21]

The biodegradation of all currently used volatile anesthetics is predominantly accomplished by way of hepatic metabolism through oxidation (phase I). Sevoflurane has been used in the United States since 1995. Its biotransformation and lack of nephrotoxicity are reviewed later in this chapter.

PHARMACODYNAMICS

Mechanisms of Action

The following properties of anesthetics must be taken into account when developing a theory that attempts to explain their mechanism of action:

- Lipid solubility is directly proportional to potency (Meyer-Overton rule).[22,23]
- Reversal of anesthetic effect can be achieved with the application of pressure, with some exceptions (species variation).[24]
- No common chemical structure for the variety of compounds is capable of producing anesthesia.
- The molecular and structural changes responsible for producing anesthesia must occur within seconds and be reversible.
- A reduction in body temperature lowers anesthetic requirements.

The unitary hypothesis was previously offered as an attempt to meet these prerequisites. This theory proposed that all inhalation

anesthetics work via a similar (undefined) mechanism of action but not necessarily at the same site of action. One factor that supported this hypothesis was the Meyer-Overton correlation, which recognized the more lipid soluble the agent, the greater its potency (the lower its MAC value). This correlation suggested that anesthesia is produced by the volume of anesthetic molecules present (dissolved) at the site, not by the type of inhaled agent present. Nevertheless, continued research on the mechanism of action of inhalation anesthetics has mitigated the utility of this theory.[25]

For the current review on how inhaled anesthetics produce anesthesia, it is important to define "general anesthesia." This would include a drug's capacity to induce and sustain as needed, a state of unconsciousness, amnesia, analgesia, and immobility. Secondary effects of general anesthesia can be therapeutic or problematic (e.g., attenuate stress response to surgical stimuli, appearance of arrhythmias).

It should be understood that the limitations of this chapter do not permit a substantive review of the extensive research done in attempting to explain the mechanism of action of inhalation anesthetics. What investigators have accomplished is to illuminate how diverse and complex is the means by which anesthesia is produced. Grossly, anesthetic sites of action include supraspinal and spinal anatomic structures; and on the molecular level a myriad of protein structures (receptors, channels). For the reader interested in a more comprehensive review of this topic, the *Canadian Journal of Anesthesia* published in 2011 a special issue titled "Mechanisms of Anesthesia" (Vol. 58 [2]).

In vitro, in vivo, animal, and human subject research has permitted the description of the mechanism of action of inhaled anesthetics relative to distinct anatomic regions of the body (including the cellular level) and molecular changes. The spinal cord is known to mediate immobility to a painful stimulus via several mechanisms including (1) enhancing background potassium (K^+) currents in tandem-pore-domain, weak inward-rectifying K^+ channels (TWIK, TASK [TWIK-related acid-sensitive K^+ channel])[26-28] and (2) reducing spontaneous action potential firing of spinal neurons via glycine receptors and γ-aminobutyric acid type A [$GABA_A$]) receptors.[29] Investigators have also demonstrated that nonimmobilizers with lipophilic characteristics (e.g., perfluoropentane) are able to produce amnesia but not immobility to noxious stimuli, which suggests two separate sites and mechanisms of anesthetic action for some drugs.[30] In contrast with other research, spinal *and* cerebral $GABA_A$ receptors (same receptor-clinical effect) were shown to contribute to volatile anesthetic's ability to produce immobility; therefore the anesthetic effect of immobility is modulated at the spinal cord and supraspinal level.[31,32] In summary, research has validated the concept of a distinct anatomic division for the mechanism of action of volatile agents as being oversimplistic (and inaccurate); one example being the isolation of TWIK and TASK (members of the tandem-pore-domain K^+ channel subfamily) in both the spinal cord and brain.[27, 28] Clearly, supraspinal areas of the nervous system are recognized to mediate amnesia and immobility.[28,32-35]

Other specific anatomic sites where volatile anesthetics produce an effect include the reticular formation within the brainstem,[36] cerebral cortex,[37] and hippocampus.[38] Evidence of changes in cortical activity by volatile agents includes alterations in electroencephalogram (EEG) activity. All inhalation agents cause a dose-dependent change in the EEG—an initial increase in voltage (and decrease in frequency), then a peak, followed by a decline.[39,40] Deeper levels of anesthesia produce burst suppression and eventually a flat EEG.[41] Nonspecific generalized EEG changes may also persist for several days postoperatively.[42]

Increased or decreased neuronal excitability and enhanced or depressed inhibitory postsynaptic currents can occur, depending on which anesthetic agent or specific area within the central nervous system (CNS) is manipulated. In addition to supraspinal effects, depression of motor neurons within the spinal cord has also occurred with volatile anesthetics.[43,44]

On a molecular level, researchers have found that the most likely site of action for volatile anesthetics involves interactions with membrane proteins in specific receptors (stereoselective) and not perturbation of lipid bilayers.[45-48] The primary receptor within the CNS believed to modulate anesthetic effects is the GABA receptor, specifically the subtype A.[31,33,34,49] This receptor is located abundantly in the CNS and is a ligand-gated chloride (Cl^-) ion channel.[50] Agonism of this receptor by full anesthetics (volatile agents) results in enhanced Cl^- conductance,[51] which leads to *inhibitory* actions on local neurons.[50] Ultimately, what is expressed is an extension of the amount of time the Cl^- channel remains open. Neuronal nicotinic acetylcholine receptors (nAChRs) have also been shown to be highly sensitive to inhalational anesthetics and are believed to significantly influence several stages of anesthesia.[52]

An investigation by Kaech et al.[53] revealed a new anesthetic site of action within the CNS; chloroform, diethyl ether, methoxyflurane, halothane, enflurane, and isoflurane were each shown (in clinically relevant concentrations) to block the morphologic plasticity of dendritic spines. Prior research has demonstrated that dendritic spines can change shape in seconds.[54] This phenomenon occurs secondary to motile actin, which is abundant in the spines.[55] These volatile agents were found to strongly inhibit actin motility, which blocked changes in dendritic spine shape; the inhibition was fully reversed after removal of the agents. The dendritic spines serve as excitatory postsynaptic contact sites.[56] They are extremely abundant in the cerebral cortex (greater than 10^{13}) and are also located in large numbers in the cerebellum, basal ganglia, and olfactory bulb.[57] The details of how these rapid morphologic changes in dendritic spines contribute to an anesthetic state are unclear and merit further research.

The CNS effects of amnesia and loss of consciousness likely are produced separately from the immobility conceptualized in the theory of MAC. The concept of MAC refers to the concentration required to prevent movement in response to a surgical situation. This is probably the result of an effect at the spinal cord level via glycine, sodium, and *N*-methyl-D-aspartate receptor (NMDAR) action. Potassium, $GABA_A$, opioid, α_2−, $5HT_3$, and acetylcholine receptors are likely not involved in producing immobility.[58] They may be involved in varying degrees in the amnestic and anesthetic effects in the CNS. Lastly, researchers have found halogenated inhaled anesthetics inhibit voltage-gated sodium (Na^+) channels, which may represent a common means for producing an anesthetic effect.[59] A summary of reviewed mechanisms of action of inhalation anesthetics is provided in Box 8-1.

MINIMUM ALVEOLAR CONCENTRATION

A useful means of comparing the potencies of inhalation agents is to use the concept of MAC, defined as the minimum alveolar concentration at equilibrium (expressed as a percentage of 1 atmosphere) in which 50% of subjects will not respond to a painful stimulus (i.e., initial surgical skin incision).[60] The response is defined as gross, *purposeful* movement of the head or extremities. The MAC values for the modern inhalation agents are listed in Table 8-3.[61-64]

The MAC of volatile agents can be affected by numerous factors, surprisingly even hair color.[65,66] With increasing age,

BOX 8-1

Mechanisms of Action of Inhalation Anesthetics

Anatomical/Molecular Sites and Proposed Mechanisms

Brain (Supraspinal)

- Reticular formation, brainstem, cerebral cortex, hippocampus
- Enhanced Cl^- conductance via agonism of cerebral $GABA_A$ receptors (ligand-gated Cl^- channel), which produces an inhibitory effect on neurons
- Neuronal nicotinic acetylcholine receptors
- Abatement of the morphologic plasticity of dendritic spines (cerebral cortex, cerebellum, basal ganglia, olfactory bulb)
- Affecting K^+, opioid, α_2-, $5HT_3$, and acetylcholine receptors
- Modulating two-pore domain K^+ channels (K2P [TWIK, TASK])
- Inhibition voltage-gated Na^+ channels

Spinal Cord

- Immobility in response to painful stimuli via
  - Modulating two-pore domain K^+ channels (K2P [TWIK, TASK])
  - Reducing spontaneous action potential firing of spinal neurons via glycine receptors and $GABA_A$ receptors
  - Interaction with glycine, Na^+, and *N*-methyl-D-aspartate receptors
- Depression of motor neurons (perhaps via hyperpolarization)

$GABA_A$, γ-aminobutyric acid type A; *TWIK*, tandem-pore-domain, weak inward-rectifying K^+ channels and subfamily of K2P, *Cl–*, chloride; *Na+*, sodium; *TASK*, a subfamily of K2P channels.

TABLE 8-3 Potencies of Volatile Anesthetics in Humans with and without N_2O Expressed in MAC Values

Anesthetic	MAC* (expressed as a % of 1 atmosphere)	In 60%-70% N_2O MAC
Nitrous oxide	104	—
Isoflurane	1.17	0.56
Desflurane	6	2.38
Sevoflurane	2	0.66

*Age 30 to 60 years.
MAC, Minimum alveolar concentration; N_2O, nitrous oxide.
MAC-awake is the minimum alveolar concentration of anesthetic that inhibits responses to command in half the patients. It is approximately one-third MAC.
MAC-BAR is the minimum alveolar concentration of anesthetic that blunts the autonomic response to noxious stimuli. It is approximately 1.6 times higher than MAC.

BOX 8-2

Relationship of Physiologic and Pharmacologic Factors to the MAC of Inhaled Anesthetics

Factors That Reduce MAC

- Increase in age
- Hypothermia
- Administration of depressant medications (e.g., opioids, opioid agonist-antagonist analgesics, benzodiazepines, barbiturates, chlorpromazine, hydroxyzine)
- α_2 Agonists
- Acute ethanol consumption
- Hypoxemia
- Anemia (less than 4.3 mL O_2/dL blood)
- Hypotension (MAP less than 50 mmHg)
- Pregnancy
- N_2O, ketamine, lidocaine, clonidine, alpha-methyldopa, reserpine, chronic amphetamine use, lithium

Factors That Increase MAC

- Young age
- Hyperthermia
- Hyperthyroidism
- Chronic alcohol consumption
- Acute administration of amphetamine
- Red-headed females

Factors with No Effect on MAC

- Duration of anesthesia
- Gender
- Hypocapnia and hypercapnia
- Metabolic alkalosis
- Hypertension
- Administration of propranolol, isoproterenol, promethazine, naloxone, aminophylline, and neuromuscular blocking agents.

MAC, Minimum alveolar concentration; N_2O, nitrous oxide.

the MAC of all inhaled anesthetics is reduced; in humans with mean age 18 to 30 years, the MAC of desflurane is 7.25%, in contrast to 6% in humans 30 to 55 years of age.[63] Infants represent an exception to the MAC age concept in that their anesthetic requirements exceed those of neonates. In general, the duration of anesthesia is believed not to effect MAC; however, one group of investigators found the MAC of isoflurane was reduced over time during surgery.[67] Box 8-2 lists variables shown to reduce and increase MAC.

Two other areas related to MAC are MAC-awake and MAC-BAR (block adrenergic response). *MAC-awake* is defined as the minimum alveolar concentration at which 50% of subjects will respond to the command "open your eyes." It has also been described as the anesthetic concentration that is between the end-tidal values that allow and prevent response to a command.[68] This end-tidal concentration is usually associated with a loss of recall and encompasses approximately one third of MAC values. MAC-awake can also be used in combination with MAC values to evaluate the potency of each agent with regard to amnestic properties. This is done by dividing MAC-awake by MAC (MAC-awake/MAC ratio). This parameter indicates that agents with ratios between 0.3 and 0.4 (e.g., desflurane, sevoflurane, isoflurane) are considered potent anesthetics. In contrast, N_2O, which has a ratio of 0.64, is considered a weak amnestic agent.

The MAC-BAR parameter represents the MAC necessary to block the adrenergic response (e.g., changes in plasma norepinephrine concentration, heart rate [HR], rate-pressure product, and mean arterial pressure) to skin incision. It can be expressed as a $MAC\text{-}BAR_{50}$ or $MAC\text{-}BAR_{95}$. The former is similar to AD_{95} values, which represent the anesthetic dose that inhibits somatic evidence of light anesthesia in 95% of subjects in response to skin incision. Established $MAC\text{-}BAR_{50}$ values for volatile agents include (in 60% N_2O) 1.85 MAC for both isoflurane and desflurane. Desflurane's $MAC\text{-}BAR_{50}$ value has been shown to be reduced by 85% with the use of 1.5 mcg/kg of fentanyl given IV 5 minutes before skin incision.[69] When investigating desflurane in 60% N_2O combined with a remifentanil at a target plasma concentration of 1 ng/mL (via a computer-driven infusion device), the

$MAC\text{-}BAR_{50}$ is reduced by 60% and with a target concentration of 3 ng/mL further reduced by 30%.[70]

The $MAC\text{-}BAR_{50}$ for sevoflurane in 66% N_2O is 2.2.[71] In canine studies it has been shown to be reduced (but not in a dose-dependent manner) with intravenous ketamine.[72] It should be emphasized that MAC-BAR values exceed the requirements for ablation of skeletal muscle movement with surgical stimulation; therefore blocking an adrenergic response requires a greater depth of anesthesia than preventing skeletal muscle movement. From a clinical standpoint, patients usually require anesthetic concentrations that exceed MAC by 20% to 30% (1.2 to 1.3 times MAC). At this alveolar concentration, somatic evidence of light anesthesia will commonly be abated, and fewer patients will respond adrenergically to the stresses of surgery.[73]

The concept of MAC has limitations when applied clinically to determine adequacy of anesthesia. It should be viewed as a general guide to the overall depth of anesthesia. One variable that restricts its application is the frequency at which surgical patients receive muscle relaxants, which attenuates the recognition of skeletal muscle movement in response to light planes of anesthesia. This results in the dependence of anesthesia providers on other traditional signs of anesthetic depth, such as changes in heart rate (HR), blood pressure, pupillary size, and sweating. Unfortunately, a light plane of anesthesia can exist even with a decreased blood pressure and a normal heart rate (e.g., patients with limited cardiac reserve). Pupillary changes can also be affected by opioids (miosis) and volatile agents (mydriasis) over time, even in the absence of surgical stimuli.[74] Also, the usefulness of a traditional clinical end-point as a guide to depth of anesthesia can change over time. For example, one investigator found that decreases in blood pressure served as an estimate of anesthetic depth during the first hour of an anesthetic, but after 5 hours they were unreliable—further declines in blood pressure did not occur even with increasing concentrations of halothane.[75] The challenge to the anesthesia provider is to estimate anesthetic depth based on a collation of variables (HR, blood pressure, synergistic and additive effects of anesthetic adjuvants, volume status, physiologic reserve, MAC, MAC-BAR, and MAC intubation values). The last variable (MAC intubation) is similar to MAC-BAR in that its values exceed the anesthetic requirements for surgical skin incision. Clearly, different stimuli require different end-tidal concentrations (brain anesthetic partial pressures) of volatile anesthetics.[76]

INFLUENCE OF INHALATION AGENTS ON ORGANS AND SYSTEMS

Central Nervous System

The volatile agents can adversely affect the care provided to patients with CNS pathology. Such effects include areas related to intracranial compliance, autoregulation of cerebral blood flow (CBF; e.g., cerebrovascular reactivity to carbon dioxide [CO_2]), cerebral metabolic rate, cerebrospinal fluid pressure (CSFP), and neurologic assessment.

Cerebral Metabolic Rate and Cerebral Blood Flow

In general, volatile agents decrease cerebral metabolic rate of O_2 consumption ($CMRO_2$) in a dose-dependent manner, whereas their effect on cerebral blood flow is variable; the latter has been reported by various researchers to be unchanged,[77,78] increased (dose-dependent and time-dependent manner),[79-81] or decreased.[82] When vascular resistance is decreased, CBF, cerebral blood volume (CBV), and CSFP increase. The order of potency for increasing CBF varies; it is affected by the dose of volatile anesthetic,[81,83] the administration of other drugs (e.g., propofol, N_2O),[84] the rate of change in end-tidal concentration of agent,[79] and the animal model used.[85] In other cases, differences in research findings lack a plausible explanation. A distinct picture of a homogeneous versus heterogeneous change in CBF, $CMRO_2$, and other anesthetic effects of volatile agents has been noted.[86,87] For example, in rats halothane has been shown to globally increase CBF, whereas isoflurane's sphere of influence predominates in the subcortical regions and hindbrain structures.[88]

Uncoupling of Cerebral Blood Flow and Metabolism

When decreases in $CMRO_2$ are accompanied by increases in CBF, *uncoupling* is said to occur. As noted earlier, volatile anesthetics are capable of producing this effect. This paradoxic response (decreased $CMRO_2$ occurring in conjunction with increased CBF) seems not to occur with 1.0 MAC or less of halothane and isoflurane[89]; the magnitude of change is variable and dose dependent,[81] meaning some flow-metabolism coupling mechanism is preserved.[90, 91]

Nitrous oxide reduces cerebrovascular tone significantly. This effect is unmasked and enhanced when N_2O is combined with a volatile anesthetic (decreased autoregulation).[92] The mechanism for increased CBF may be related to a sympathoadrenal-stimulating effect of N_2O. The changes produced by N_2O in the $CMRO_2$ are the reverse of what takes place with volatile agents (i.e., increased $CMRO_2$).[93] Thus N_2O increases $CMRO_2$ and CBF. Nevertheless, the combination of elevated CBF and $CMRO_2$ still results in an uncoupling between flow and metabolism, because the increase in $CMRO_2$ exceeds, albeit slightly, the elevation in CBF.[94] In summary, N_2O use in neurosurgical procedures is acceptable, as long as the anesthesia provider recognizes that its vasodilatory effects might adversely affect surgical outcome in patients with reduced intracranial compliance. Mild hyperventilation to low normal ranges of carbon dioxide helps attenuate the increase in CBF that accompanies the use of N_2O.[95]

Cerebral Vasculature Responsiveness to CO_2

The normal physiologic response of the cerebral vasculature to CO_2 is to vasoconstrict in the presence of hypocapnia and vasodilate with hypercarbia. This reflex is effective in the acute setting when used during neurosurgical procedures to counteract drug-induced vasodilation and to reduce brain bulk within a closed compartment (cranial vault).[96] The usual goal for patients in which a reduction in intracranial volume is desired is a $P_{a}CO_2$ of 30 to 35 mmHg with a duration of effectiveness being perhaps no more than 4 to 6 hours.[97]

Differences exist among the volatile agents in their ability to interfere with the cerebral vasculature's responsiveness to CO_2. Variables that affect the reported differences include the type of surgical procedure the patient is undergoing, associated pathophysiology, and the presence of any coexisting disease(s). For example, patients with hypertension given 1 MAC isoflurane with 67% N_2O have better control of CBF via manipulation of arterial CO_2 than those receiving 1 MAC sevoflurane with 67% N_2O.[98] Similar results have been reported by other investigators.[99] In contrast, CO_2 reactivity in insulin-dependent patients is equally impaired by 1 MAC isoflurane and 1 MAC sevoflurane, each given with 67% nitrous oxide.[100]

On a side note, sevoflurane has been shown (in rodents) to impair glucose metabolism and produce hyperglycemia.[101] Other investigators have suggested that sevoflurane is less vasoactive than halothane, isoflurane, and desflurane and recommend it as a good alternative to propofol in patients with normal intracranial

pressure.[102] It has also been reported to better preserve dynamic cerebral autoregulation than isoflurane when both are given at 1.5 MAC in combination with 100% O_2.[103] Desflurane administered to patients undergoing craniotomy for tumor resection with an air-O_2 mixture at 1.0 to 1.5 MAC has been shown to act similarly to isoflurane and maintain cerebrovascular reactivity to CO_2 and cerebrospinal fluid pressure.[104-106] These research findings suggest that increases in CBF produced by isoflurane, desflurane,[106] and sevoflurane[107] can be effectively prevented by very mild hyperventilation and using concentrations less than 1.5 MAC. In addition, anesthesia consisting of sevoflurane and remifentanil appears to be similar to total intravenous anesthesia (TIVA [i.e., propofol combined with remifentanil]) during supratentorial craniotomy procedures in regard to emergence times, adverse effects, intraoperative hemodynamic events, and brain relaxation scores.[108]

Electroencephalogram and Evoked Potentials

The volatile agents produce a dose-related suppression of EEG activity (initial increase [later a decline] in amplitude and decreased frequency) and at high concentrations produce electrical quiescence.[109] At deeper levels of anesthesia, the EEG may temporarily stop recording; at such time, burst suppression is said to have occurred.

For those procedures requiring monitoring of the integrity of the spinal cord or mapping of cortical regions of the brain, the anesthetist should be aware that inhalation agents can skew cortical somatosensory, motor, brainstem, auditory, and visual evoked potentials. Isoflurane, desflurane, sevoflurane, and N_2O produce a dose-dependent reduction in these evoked potentials, with visual evoked potentials being most sensitive and brainstem-evoked potentials most resistant.[109,110] Two evoked-potential variables commonly assessed are latency and amplitude. An increase in latency or decrease in amplitude of evoked potentials can reflect ischemia or be secondary to the volatile agent. Latency is the time between the initiation of a peripheral stimulus (e.g., electrical stimulation of the median nerve at the wrist) and onset of the evoked potential (e.g., cortical) recorded by scalp electrodes.

Isoflurane has been shown to interfere with the recording of cortical somatosensory evoked potentials (cSSEP) at light planes of anesthesia (0.5 MAC with 60% N_2O)[111] and desflurane and sevoflurane have been found to produce fewer changes than isoflurane in amplitude reduction of cSSEP at 0.7, 1.0, and 1.3 MAC (without N_2O). In contrast, no difference exists among the volatile anesthetics' effect on latency.[112] The addition of N_2O to isoflurane, desflurane, and sevoflurane can also produce a significant reduction in the amplitude of cSSEPs.[113,114] It may be prudent to avoid the use of this agent in patients who have baseline low-amplitude evoked potentials.

Sevoflurane,[115,116] unlike desflurane[117] and isoflurane,[39] can predispose pediatric and adult[118] patients to epileptic activity, even though sevoflurane[119-121] can suppress drug-induced convulsive activity in a manner similar to desflurane[122] and isoflurane.[122] Sevoflurane combined with N_2O has produced epileptiform EEG activity during inhalation induction with adults in a single-breath technique. A hyperdynamic response can accompany the EEG changes if concurrent hyperventilation occurs. The incidence of epileptiform EEG changes has been shown to nearly double in the presence of hypocapnia (100% versus 47%).[123] Similar results have been observed in children aged 2 to 12 years.[116] In contrast, intravenous induction with thiopental followed by anesthetic maintenance with 2% end-tidal sevoflurane in air does not produce seizure-like changes in the EEG in children.[115] Epileptiform activity has also been reported to occur during emergence from sevoflurane.[124]

Emergence and Neurologic Assessment in Adults

Although the objective of a smooth and rapid emergence from a general anesthetic is desirable for all surgical patients, it is especially meaningful for neurosurgical candidates. Delayed emergence in this specialty of anesthesia can have devastating consequences. A slow return of consciousness makes it difficult to perform the initial postoperative neurologic examination. It can also add to unnecessary therapeutic or diagnostic intervention and predispose the patient to respiratory complications.[125]

Because of this, the bias of some anesthesia providers is to administer TIVA techniques such as propofol with remifentanil and/or dexmedetomidine for neurosurgical procedures involving supratentorial tumors. Some investigators report a more rapid awakening (after approximately 2 hours of anesthesia) from TIVA in non-neurosurgical patients compared with sevoflurane and desflurane combined with N_2O.[126] Recovery profiles for sevoflurane and desflurane indicate they are superior to isoflurane.[127,128] In side-by-side comparisons of desflurane and sevoflurane, desflurane permits for a more rapid awakening than sevoflurane in volunteers after 8 hours of exposure.[129] In contrast, sevoflurane allows for acute changes in vaporizer settings without evoking neurocirculatory excitation (i.e., significant increases in sympathetic nerve activity, norepinephrine concentrations, heart rate, and mean arterial blood pressure); of particular interest was the finding that desflurane's sympathomimetic response occurred in response to a controlled adjustment in vaporizer settings (i.e., changing from 6% to 9%)—that is, in the absence of overpressurization.[130] Sevoflurane may be preferred over desflurane if concentrations equal to or in excess of 1 MAC are used during neurologic surgery.[79] One study also found no difference in early postoperative recovery and cognitive function between a balanced sevoflurane-fentanyl technique versus propofol-remifentanil (TIVA) management in patients undergoing supratentorial intracranial surgery.[131] Similarly, a multicenter randomized controlled trial of patients scheduled for elective supratentorial craniotomy surgery found no significant difference between sevoflurane-remifentanil and propofol-remifentanil techniques.[108] Further research will help to illuminate whether any substantive differences exist in neurosurgery outcome secondary to the choice of inhaled anesthetic or primary TIVA techniques employed.

An area of ongoing research has been the application of volatile anesthetics via preconditioning and postconditioning techniques for neuroprotection following global and/or focal ischemia/hypoxia.[132] One of the etiologies of neurodeficits occurring in this setting is ischemia/reperfusion injury. In vitro and in vivo (animal) cerebral, spinal, and cardiac studies have demonstrated that isoflurane, and especially sevoflurane, can reduce cerebral infarct volume, improve learning and memory deficits, attenuate ischemia/reperfusion injury to the spinal cord, and lessen hypoxia-induced neuronal cell damage.[133-137] Problematic with transitioning from bench research to clinical practice is recognizing that the application of inhaled anesthetic preconditioning treatments would require a need to predict when a reperfusion insult would occur; in contrast, volatile anesthetic postconditioning interventions would ideally occur when the patient develops clinical symptoms.

Several foundational questions remain unanswered regarding anesthetic conditioning with humans: What is the ideal time and duration of anesthetic prior to postconditioning? Also, what is the optimal anesthetic dose for producing a neuroprotective effect? Current research suggests that a dose-response relationship and

ceiling effect do exist. For example, in one study it was demonstrated that 1.0 MAC sevoflurane reduced infarct size in the setting of reperfusion injury, whereas 0.75 MAC sevoflurane had no effect[138]; in a second study it was shown that 1.0 MAC and 1.5 MAC sevoflurane given at the start of reperfusion was neuroprotective (focal cerebral ischemia) and yet at 0.5 MAC, no protection was seen.[135] Current research suggests that anesthetics can provide long-term durable protection against ischemic injury that is mild to moderate in severity. Experimental data do not provide support for the premise that anesthetics reduce injury when the ischemic injury is severe.[139] Anesthetics consistently and meaningfully improve outcome from experimental cerebral ischemia, but only if present during the ischemic insult.[140] To summarize, although research continues to help define the future role of inhaled anesthetics in the context of reperfusion injury, currently there is insufficient evidence to definitively recommend the use of one agent over another in the operating room setting.[141]

Emergence Phenomenon in Children

Sevoflurane and desflurane are associated with emergence agitation or delirium in children.[142] The emergence phenomenon is short-lived but troublesome, and the etiology is uncertain. A variety of factors have been suggested to play a potential role in emergence delirium (ED). Restless behavior upon emergence causes discomfort to the child, postanesthesia recovery nurses, and parents. Some suggested factors related to transient emergence agitation are noted in Box 8-3. These children may require analgesics or sedatives, which can delay discharge. Emergence delirium is self-limiting and devoid of apparent sequelae, as long as the child is protected from self-injury. Preventive measures include reducing preoperative anxiety and postoperative pain and providing a quiet, stress-free environment for postanesthesia recovery. Treatment may include small doses of fentanyl, clonidine, or dexmedetomidine. Reuniting the child with the parents is also helpful.

BOX 8-3

Possible Etiologic Factors of Pediatric Emergence Agitation/Delirium

- Intrinsic characteristics of an anesthetic
- Postoperative pain
- Surgery type
- Age
- Preoperative anxiety
- Child temperament
- Adjunct medication
- Behaviors including nonpurposefulness; eyes averted, staring, or closed; and unresponsiveness during early emergence.

FIGURE **8-2** Mean arterial pressure response to the administration of isoflurane, sevoflurane, and desflurane in healthy volunteers. With increasing minimum alveolar anesthetic concentration, progressive decreases in blood pressure occurred with each of the volatile anesthetics. (Adapted from Ebert TJ, Muzi M: Sympathetic hyperactivity during desflurane anesthesia in healthy volunteers: a comparison with isoflurane. *Anesthesiology. 1993; 79*(3):444-453; Ebert TJ, Muzi M, Lopatka CW: Neurocirculatory responses to sevoflurane anesthesia in humans: a comparison to desflurane. *Anesthesiology.* 1995; 83(1):88-95.)

Cardiovascular System

All inhalation agents are capable of altering hemodynamics, the extent being related to various preoperative and intraoperative factors (e.g., American Society of Anesthesiologists physical status classification, coadministration of vasoactive drugs, opioids, benzodiazepines). This section reviews the influence of volatile agents on the cardiovascular system.

Systemic Hemodynamics

Isoflurane, desflurane, and sevoflurane all reduce mean arterial pressure (MAP) (Figure 8-2) and cardiac output (CO) and cardiac index (CI) in a dose-dependent fashion.[130,143-145] The mechanism by which each accomplishes this varies. For example, desflurane, sevoflurane, and isoflurane predominantly reduce MAP via a reduction in systemic vascular resistance (SVR), with the dose-response relationship being least with sevoflurane (Figure 8-3).[130,146] Halothane, by comparison, causes less disruption in inherent vascular tone and therefore predominantly reduces MAP by direct myocardial depression versus a reduction in preload.[147] Nitrous oxide activates the sympathetic nervous system and increases SVR,[148] which can also lead to an increase in central venous pressure (CVP) and arterial pressure. This sympathetic nervous system response appears to be intact during coadministration of volatile agents.[144]

In general, N_2O used in combination with inhalation agents increases SVR and helps support arterial blood pressure. In contrast, with opioids, the addition of N_2O augments cardiac depression instead of supporting it[149] because N_2O also produces a direct negative inotropic effect. This property can be unmasked in patients with decreased left ventricular function secondary to coronary artery disease or valvular heart defects.[150] Desflurane supports CI better than halothane at both low and high MAC levels (i.e., 1.66 MAC)[151] (Figure 8-4). With light levels of anesthesia, desflurane maintains the CI without an accompanying elevation in HR. For deeper levels of anesthesia, the CI is probably supported by the associated rise in HR. Some investigators believe the favorable circulatory profile of desflurane, isoflurane, and sevoflurane results from their ability to attenuate the body's circulatory compensatory mechanisms in a dose-related manner.[130,152] In summary, there is no appreciable difference in the ether anesthetics' ability to produce dose-dependent depression in arterial pressure and cardiac output.[143-145,151]

Regarding the impact of the duration of anesthesia on hemodynamics, isoflurane, sevoflurane, and desflurane produce a similar response—that being as MAC-hours of anesthesia increase, CI

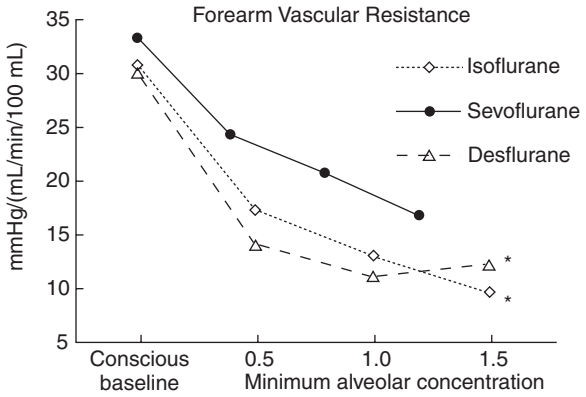

FIGURE **8-3** Forearm vascular resistance response to the administration of isoflurane, sevoflurane, and desflurane in healthy volunteers. In general, forearm vascular resistance was progressively decreased with increasing minimum alveolar anesthetic concentrations of each of the volatile anesthetics; however, this decline was less in the group receiving sevoflurane. (Adapted from Ebert TJ, Muzi M: Sympathetic hyperactivity during desflurane anesthesia in healthy volunteers: a comparison with isoflurane. *Anesthesiology*. 1993; 79(3):444-453; Ebert TJ, Muzi M, Lopatka CW: Neurocirculatory responses to sevoflurane anesthesia in humans: a comparison to desflurane. *Anesthesiology*. 1995; 83(1):88-95.)

MAC, Minimum alveolar concentration. (From Cahalan MK: *Hemodynamic Effects of Inhaled Anesthetics. Review Courses*. Cleveland: International Anesthesia Research Society, 1996, pp 14-18.)

and HR increase slightly.[144,151] The CI effect may be secondary to a continued reduction in SVR and increase in HR following prolonged exposure to each of the agents. Protracted anesthesia (8 hours) in healthy volunteers anesthetized with desflurane and sevoflurane leads to an increase in pupil size and HR independent of surgery.[74] These changes are not associated with increases in plasma catecholamines, blood pressure, or CO_2 production; therefore mydriasis and tachycardia as signs of anesthetic depth could be misleading at times.

Although anesthetic changes produced at the cellular level have already been discussed, it is sensible to briefly review the cellular effects of inhaled anesthetics on the aforementioned areas of the cardiovascular system. In vitro and in vivo studies have revealed that isoflurane, sevoflurane, and desflurane reduce intracellular free calcium (Ca^{2+}) concentrations in cardiac and vascular smooth muscle.[143,145] The mechanism for this is believed to be a reduction in Ca^{2+} influx through the sarcolemma and a depression of depolarization-activated Ca^{2+} release from the sarcoplasmic reticulum.[143,145,153] The end result is a depression in the contractile state of the myocardium, along with dilation of the peripheral vasculature. Other reported cellular effects of volatile agents include augmentation and attenuation of endothelium-derived relaxation factor, inhibition of acetylcholine-induced vascular relaxation,[154] and attenuation of sodium (Na^+)/Ca^{2+} exchange that leads to a reduction in the quantity of intracellular Ca^{2+}.[155] Future research is needed to clarify the effect of volatile agents in patients with cardiovascular dysfunction (hypertension, diabetes, geriatric patients) in which vascular responses can be altered. In these populations (compared to patients with normal physiology) the mechanisms for regulating vascular tone at the cellular level are altered.

Heart Rate

Volatile agents and N_2O induce changes in HR relative to the concentration of the anesthetic being used. Alterations in HR are a result of several variables: antagonism of SA node automaticity,[156] modulation of baroreceptor reflex activity,[157] and sympathetic nervous system activation via activation of tracheopulmonary and systemic receptors.[158]

Sevoflurane produces only minor alterations in HR, even when used in excess of 1 MAC,[159] although a rapid and large increase in the inspired concentration (i.e., from 0.5 MAC to 2.9 MAC) of sevoflurane (and isoflurane) may produce an increase in plasma epinephrine concentrations.[160] Isoflurane and desflurane can cause an increase in HR,[161] and when more than 1 MAC of desflurane is used (even without overpressurization), the dose-response relationship becomes more prominent, particularly when compared with sevoflurane (Figure 8-5).[130] Desflurane's steep dose-response to HR can potentially be problematic by diminishing the reliability of HR as a guide to anesthetic depth and by predisposing patients at risk for coronary artery disease to myocardial ischemia secondary to an increased myocardial oxygen demand.

Research has shown pretreatment with fentanyl (1.5 or 4.5 mcg/kg) 5 minutes before an increase in end-tidal desflurane concentration from 4% to 8% modulates (not abolishes) an increase in HR by 61% and 70%, respectively.[162] In this same study, increase in MAP was attenuated by 31% and 46%. Another group of investigators found 5 mcg/kg of fentanyl followed by a continuous infusion of 2 mcg/kg/hr initiated 12 minutes before induction significantly blunted the HR and MAP response to a rapid increase in end-tidal desflurane concentration (5.4% to 11%).[163] The acute change in desflurane concentration occurred 20 minutes after intubation. Fentanyl's efficacy was also assessed 2 minutes after induction when desflurane was given in three incremental 1-minute steps (3.6%, 7.2%, 11%). Of interest was the finding that fentanyl was ineffective in diminishing the desflurane stimulatory effect during this induction period. Therefore the optimal use of fentanyl may be during steady-state periods of anesthesia when acute adjustments of desflurane are desired.

Esmolol (0.75 mg/kg) has been shown to attenuate HR response but not MAP and therefore may be less desirable than

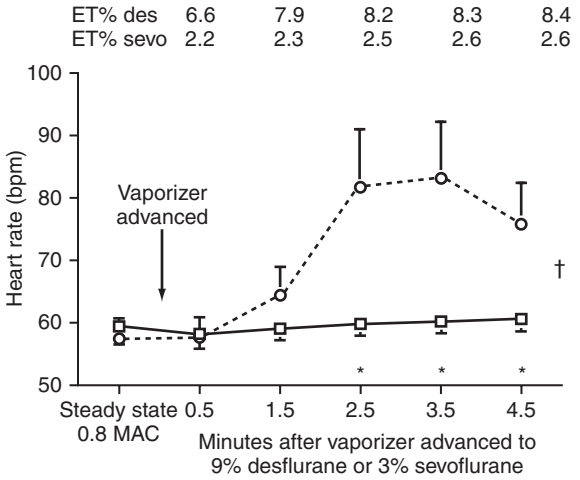

FIGURE **8-5** The effects of sevoflurane *(solid line with squares)* and desflurane *(dashed line with circles)* on heart rate in healthy young volunteers when the inspiratory concentration is rapidly increased from a steady-state value of 0.83 MAC to 1.25 MAC. MAC, Minimum alveolar concentration. *(Reprinted with permission from Ebert TJ, Muzi M, Lopatka DW: Neurocirculatory responses to sevoflurane in humans: a comparison to desflurane.* Anesthesiology *1995; 83(1):88-95.)*

fentanyl.[162] Prior administration of intravenous lidocaine (1.5 mg/kg) has not been shown to be effective in modulating the sympathetic response associated with an acute change in desflurane end-tidal MAC value of 0.7 to 1.5.[164]

Coronary Blood Flow

The term *coronary steal* is defined as a reduction in perfusion of ischemic myocardium with simultaneous improvement of blood flow to nonischemic tissue. Simply stated, blood has been taken from the "poor" and given to the "rich" (a "reverse–Robin Hood" syndrome). In addition, this phenomenon has been demonstrated to occur more easily with "coronary steal–prone anatomy" (i.e., multivessel disease models).[165] Several articles have suggested that isoflurane and perhaps desflurane are capable of producing a coronary steal with clinically relevant concentrations,[166,167] but other researchers have not found this to occur.[168,169] One investigator's results suggest that the use of 0.5% isoflurane in combination with 50% N_2O might be protective to the myocardium (i.e., improve the tolerance to pacing-induced myocardial ischemia).[170]

An important qualifier to isoflurane's ability to maldistribute coronary blood flow is the presence of hypotension; when normotension is maintained, a steal phenomenon is abated.[171] Reduced blood flow to ischemic myocardium can also be reversed if normotension is reestablished with phenylephrine administration.[172] To summarize the effects of isoflurane, desflurane, and sevoflurane on the coronary circulation, it can be stated that each produces vasodilation, with sevoflurane doing so the least.[167,173] In the presence of hypotension, a steal phenomenon can occur (as it can with inappropriate use of intravenous nitroglycerin or sodium nitroprusside), and this effect is reversible if normotension is reestablished. The magnitude of coronary vasodilation also is markedly less for isoflurane than that which occurs with dipyridamole[174] and the endogenous nucleoside, adenosine,[175] both of which produce coronary vasodilation even in the presence of normotension. Any of these three volatile anesthetics can be used in patients with a history of ischemic heart disease. If ECG monitoring demonstrates ST-segment or T-wave changes suggestive of myocardial ischemia (in the absence of abnormal hemodynamics), a change in primary anesthetic techniques may be warranted (e.g., substituting isoflurane for sevoflurane).[169]

As mentioned previously, volatile agents may produce a neuroprotective effect; similarly, the heart appears to benefit from isoflurane, sevoflurane, and desflurane inhaled anesthetics via initiating the phenomenon of preconditioning.[176-180] Anesthetic preconditioning (APC) results in a cascade of intracellular events that help protect the myocardium from ischemic and reperfusion insult, potentially limiting infarct size. The mechanism for this effect is multifactorial and includes such things as improving contractile function, preventing the down-regulation of major sarcoplasmic reticulum Ca^{2+} cycling proteins, thereby reducing calcium overload in the myocardial cells. The latter effect has been shown to be independent of potassium-sensitive adenosine triphosphate (K_{ATP}) channels[181] and confers 30% to 40% of the cardioprotective effect produced by inhalational anesthetics.[182]

On the molecular level, sevoflurane has been found to produce in healthy male volunteers late preconditioning (24 to 48 hours after sevoflurane administration), as evidenced by altering gene expression in white blood cells (e.g., reduced proinflammatory L-selectin [CD62L] expression on granulocytes).[183] A theoretic application of APC, along with other cardioprotective substances such as insulin and adenosine, is administering preconditioning drugs during early coronary artery reperfusion, as is currently done with antiplatelet and antithrombotic therapies. Research has shown the administration of volatile agents during myocardial reperfusion activates a group of prosurvival kinases called the *Reperfusion Injury Salvage Kinase* (RISK) pathway. These prosurvival kinases produce potent cardioprotective effects. The RISK pathway has also been found to be activated during ischemic preconditioning (a brief stimulus of myocardial ischemia/occlusion leading to cardioprotection).[184]

Other factors that have been identified with preconditioning include protein kinase C activation of K_{ATP} channel opening, adenosine receptors (α_1 and α_2 subtypes), and inhibitory G proteins.[185-187] The recent American College of Cardiology/American Heart Association Guidelines on perioperative cardiac evaluation and care note that it can be beneficial to use volatile anesthetic agents during noncardiac surgery for the maintenance of general anesthesia in hemodynamically stable patients at risk for myocardial ischemia.[188] This is due to a protective effect on the myocardium associated with preconditioning.

It has been advocated that sulfonylurea oral hyperglycemic drugs be discontinued 24 to 48 hours prior to elective surgery, owing to their ability to close K_{ATP} channels. Insulin is recommended as replacement therapy during this time period to abate the negative impact of hyperglycemia on preconditioning.[189] Finally, it should be recognized that not all research supports a positive correlation between inhaled anesthetics and cardioprotection.[190-192]

Arrhythmias

The arrhythmic potential of inhalation agents has long been recognized. All of the agents, with the exception of isoflurane and probably desflurane, are conducive to the development of bradycardia and disturbances in atrioventricular (AV) nodal conduction (excluding second- or third-degree AV block). The mechanism for this is their ability to depress slow-response (sinoatrial and atrioventricular nodal tissue) and fast-response (atrial or ventricular musculature, Purkinje fibers) action potentials. When fibers become ischemic or injured, the volatile agents are prone to produce reentrant excitation.[193] In addition, desflurane and sevoflurane[194] have been shown to prolong action potential duration (APD). This effect is consistent with the clinical finding of

a prolonged QTc interval in healthy adults[194,195] and in children receiving desflurane.[196] The mechanism by which desflurane prolongs the action potential is that of reducing the peak transient outward K^+ current in ventricular myocytes.[197]

The ability of the volatile agents to reduce the quantity of catecholamines necessary to evoke arrhythmias is commonly but inaccurately called "sensitization." It is more accurate to describe this phenomenon as an adverse drug interaction. Researchers have determined the nasal and oral submucosal ED_{50} dosage (median effective dose) of epinephrine for volatile agents to be 2.11 ± 0.15 mcg/kg for halothane and 6.72 ± 0.66 mcg/kg for isoflurane.[198] With these dosages, 50% of subjects developed three or more premature ventricular contractions or ventricular tachycardia during or immediately after a single injection of epinephrine (which required 3.5 to 11 minutes to complete). Variables that may influence epinephrine ED_{50} values are differences in systemic absorption, route of administration, animal model,[199] existing plasma catecholamine levels, and preexisting atrial or ventricular arrhythmias. The infusion of ketamine in a feline model has been shown to produce no appreciable change in the arrhythmogenic dose of adrenaline when administered during isoflurane or sevoflurane anesthesia.[200] When these variables are taken into consideration it is not surprising that data regarding volatile agent "sensitization" are conflicting. Regarding the two newest volatile agents, desflurane and sevoflurane, both appear to be similar to isoflurane in their epinephrine-arrhythmogenic potential.[201,202]

In general, it is reasonable to anticipate the fewest difficulties with arrhythmias in physical status I and II patients if the submucosal epinephrine dose remains 7.0 mcg/kg or less with 1.0 to 1.3 MAC desflurane,[201] or 5.0 mcg/kg or less with 1.0 to 1.3 MAC sevoflurane or isoflurane.[202] Additional protection may be achieved by combining 0.5% lidocaine with epinephrine, the net effect being an increase in the minimum threshold dose of epinephrine.[198]

One other point is worth mentioning in relation to rhythm disturbances and inhalation agents: patients who are given a general anesthetic (primary opioid supplemented with a volatile anesthetic) and who are on amiodarone can have significant arrhythmias intraoperatively or postoperatively (e.g., atropine-resistant bradycardia requiring isoproterenol infusions, atrioventricular sequential pacing). These significant rhythm disturbances can also result in death.[203] For clarification and emphasis, it should be understood that amiodarone and its major metabolite are detectable in plasma for up to 9 months after discontinuation of therapy.[204] Lastly, isoflurane and sevoflurane have been shown to be associated with an attenuation of arrhythmias associated with digitalis toxicity,[205] occlusion/reperfusion ischemia,[206] and postmyocardial infarction.[207] Isoflurane has also been demonstrated to increase the effective refractory period of the accessory pathway with preexcitement syndrome. It is possible these inhaled anesthetics may be preferred agents if a significant concern exists for the appearance of intraoperative arrhythmias related to the pathologic states described previously.

Pulmonary Circulation

Pulmonary vascular resistance (PVR) is also affected by the volatile agents and N_2O. The effects of N_2O on PVR vary with age and preexisting levels of PVR. In adults with normal PVR, the addition of N_2O results in a small increase in PVR,[208] presumably due to an increase in sympathetic nervous system tone.[148] If a subject has preexisting pulmonary hypertension, the addition of N_2O results in larger increases in PVR,[208] which may become clinically significant. Volatile agents (including 0.8 or 1.2 MAC desflurane) decrease pulmonary artery pressure[144,151]; the opposite effect occurs when desflurane is administered at 1.6 MAC.[151]

The pulmonary vasculature also minimizes changes in alveolar-arterial oxygen tension gradient via hypoxic pulmonary vasoconstriction (HPV). This normal physiologic response to atelectasis or hypoxia is attenuated in vivo by isoflurane and markedly by N_2O.[209] All of the currently used volatile agents only marginally affect HPV.[210-212] Consistent with this finding, one group of researchers noted only minimal impairment in oxygenation (approximately 20% reduction in HPV at 1 MAC) in patients having one-lung ventilation performed during thoracotomy procedures. Desflurane and sevoflurane delivered at 1 MAC without N_2O have also been shown to only slightly affect arterial oxygenation in patients placed in a lateral position while undergoing esophagogastrectomy.[211,212]

Respiratory System

As seen with other systems of the body, the volatile agents exert a dose-response effect on the respiratory system, primarily tidal volume (TV). Responsiveness to CO_2 is depressed and the TV reduces as concentrations of the agents are increased. The compensatory mechanism for the diminished TV with isoflurane, sevoflurane, desflurane, and N_2O is an increase in respiratory rate (RR).[213-215] However, the increase in RR is not sufficient to prevent elevations in arterial CO_2 tension. Nevertheless, surgical stimulation is a variable that helps to overcome the respiratory-depressant effects of volatile agents.[216]

Emergence from an anesthetic can be associated with hypercarbia if minute volume (MV) is not adequately supported, owing to a volatile agent's capacity to depress the ventilatory response to $PaCO_2$ and PaO_2.[215, 217-219] Hypercarbia also represents an increase in the apneic threshold (higher $PaCO_2$ values are required for spontaneous ventilation to occur). Patients should be closely monitored during emergence from an anesthetic and following adequate reversal of muscle relaxants to avoid acidemia or hypercarbia. During this phase of the anesthetic, significant end-tidal values of residual volatile anesthetic may persist, particularly if there was recent administration of an opioid (synergistic effect). It is important to recognize that impairment of the hypoxic ventilatory response by volatile agents is not abated with central nervous system arousal or acute pain[220]; even as little as 0.1 MAC of a volatile agent (excluding desflurane) can suppress ventilatory drive to hypoxia.[221] These research findings have implications for patients whose MVs are maintained via a hypoxic drive (e.g., emphysematous patients with depressed central chemoreceptors).

The smoothness of an inhalation induction is directly related to the ability of an inhalation agent to avoid provoking an irritant response. Nitrous oxide and sevoflurane are considered the standards by which other agents are measured because of the low incidence of breath holding, coughing, secretions, and laryngospasm encountered during inhalational induction.[222] In contrast, desflurane is considered a respiratory irritant when used for mask induction in concentrations greater than 6%[222, 223]; therefore it is generally not used to induce anesthesia in pediatric[224] and adult patients. One alternative method to incorporate desflurane in the pediatric population is to induce the child with sevoflurane, then change to desflurane for maintenance. Researchers have shown that reactive airway problems encountered during inhalational induction with desflurane are lost when this agent is used for anesthetic maintenance.[225] Lastly, the volatile agents have been

shown to relax airway smooth muscle and produce bronchodilation. They have also been used in the treatment of refractory status asthmaticus.[226]

Kidneys

In general, autoregulation of the renal circulation remains intact during the administration of inhalation agents. Reductions in systolic blood pressure are accompanied by decreases in renal vascular resistance.[227] Nevertheless, compensatory reductions in renal vascular resistance can still lead to a decline in the glomerular filtration rate. This may contribute to the commonly observed intraoperative reduction in urinary output.

The potential for a volatile agent to produce renal damage is commonly assessed by the extent to which it elevates creatinine, blood urea nitrogen (BUN), and serum inorganic fluoride (F^-) concentrations.[228] With the older volatile agent methoxyflurane, a "toxic threshold" for peak serum concentration of F^- was established (50 μmol/L)[229]; at this value, vasopressin-resistant polyuric renal insufficiency occurs.[230]

Of the currently used inhalation agents, desflurane has been shown in both healthy and chronic renal disease patients[231] to alter indices of renal integrity the least, including no change in the renal function tests of urinary retinol-binding protein and *N*-acetyl-β-glucosaminidase (NAG).[232] The significance of this is that NAG is considered a sensitive indicator of drug-induced proximal tubular necrosis,[233,234] and retinol-binding protein has been shown to be a specific marker for indicating the presence of tubular damage of any cause.[235] Recent advancements in clinical markers for renal integrity have shown two new, perhaps better, biomarkers of tubular injury. Isoforms of glutathione-*S*-transferase (GST) include alpha GST, which is located exclusively in the proximal tubules, and pi GST, found only in the distal tubules.[236] In humans the urinary levels of each of these enzymes have been shown to increase after acute tubular necrosis and renal infarction.[237]

In contrast to studies involving desflurane[238] (and isoflurane[239]), early research with sevoflurane generated concerns about compromised renal function. However, the current debate has settled on the degradation of sevoflurane by carbon dioxide absorbents. Most researchers now accept that serum inorganic fluoride (F^-) levels associated with sevoflurane administration do not represent a significant risk to patients, including those with compromised renal function.[240-244] Millions of sevoflurane anesthetics worldwide have failed to demonstrate any significant untoward renal outcomes in the general surgical population, including patients having coronary artery surgery.[245] Nevertheless, FDA (Food and Drug Administration) guidelines recommend sevoflurane be used with caution in patients with renal insufficiency (creatinine greater than 1.5 mg/dL). In morbidly obese patients, researchers have found no appreciable difference in sevoflurane's biotransformation and subsequent fluoride levels, compared to nonobese patients.[246]

A concern still exists regarding sevoflurane's degradation within anesthesia circuits by soda lime,[247, 248] with each having a chemical makeup of monovalent hydroxide bases (potassium hydroxide [KOH] and sodium hydroxide [NaOH]). These carbon dioxide absorbers break down all modern-day volatile agents.[249] The two by-products of sevoflurane's degradation that have been measured in a closed circuit are fluoromethyl-2,2-difluoro-1(trifluoromethyl)-vinyl ether (also known as *compound A*, an olefin) and fluoromethyl-2-methoxy-2,2-difluoro-1-(trifluoromethyl) ethyl ether (compound B).[250] The former is known to produce proximal corticomedullary tubular necrosis in rats.[251] Clinical studies involving low-flow (1 to 2 L/min) sevoflurane given over approximately 3 to 8 MAC-hours[240] in healthy patients[252] and in patients with stable renal insufficiency[240] were found to have no statistically significant changes in serum creatinine, blood urea nitrogen, urine protein, and glucose. It has also been reported that sevoflurane with desiccated soda lime can yield excessive temperatures that produce anesthesia machine fires and patient injuries,[253,254] the potential explanation being the by-product of hydrogen (3 moles) following the chemical reaction of sevoflurane with heated desiccated absorbent.[255]

In summary, it is widely recognized that the following variables do increase compound A content: low fresh gas flows, high concentrations of sevoflurane, and drying of soda lime CO_2 absorbant.[256,257] One way to eliminate compound A is to replace soda lime with a newly formulated absorbent such as Amsorb or DragerSorb Free.[258-260] These new CO_2 absorbents do not contain strong bases (NaOH or KOH), which are responsible for the degradation of sevoflurane to compound A, as well as the production of carbon monoxide from the breakdown of desflurane and isoflurane.[261,262] In the absence of Amsorb or DragerSorb Free carbon dioxide absorbents, current FDA dosing guidelines recommend sevoflurane exposure not exceed 2 MAC-hours at flow rates of 1 to less than 2 L/min.[263] Fresh gas flow rates less than 1 L/min are not recommended.

Liver

All of the volatile anesthetics have been shown to decrease total hepatic blood flow and increase or maintain hepatic artery blood flow, thereby limiting any accompanying attenuation in portal vein blood flow.[264-267] Hepatocyte hypoxia is of clinical concern, and its etiology can be multifactorial (e.g., volatile agents, surgical manipulation, enzyme induction). One significant outcome of liver hypoxia is increased reductive metabolism, which fortunately does not occur with ether-based anesthetics. The previously used halogenated hydrocarbon, halothane, has been investigated since 1963 regarding its potential to produce "halothane hepatitis."[268] A better understanding of the pathophysiology of this phenomenon has improved diagnostic capabilities for volatile-agent hepatitis.[269,270]

Isoflurane and desflurane are similar to halothane in that each possesses a common metabolic pathway via cytochrome P-450 that eventually yields TFA-protein molecules.[269,271] However, because of differences in the rate of biodegradation, these volatile agents are probably less likely to produce hepatic injury than halothane. For example, isoflurane is metabolized 100-fold less than halothane, and as such it is estimated that fulminant hepatic failure caused by isoflurane may occur in 1:3,500,000 anesthetics.[269]

Several case reports and clinical studies suggest that a potential immunologic mechanism (including cross-sensitization) may exist for the development of "isoflurane hepatitis,"[272] "sevoflurane hepatitis,"[273] and "desflurane hepatitis."[274] In one report, following isoflurane anesthesia the patient developed fulminant hepatic failure that led to death.[275]

Although desflurane is metabolized the least of all volatile anesthetics, it has also been associated with hepatotoxicity.[274] In one case report, a 65-year-old woman without a history of liver disease developed desflurane hepatitis 12 days postoperatively. The patient had a rash, nausea, polyarthralgias, marked elevations in liver transaminases, and jaundice. Serologic markers for hepatitis A, B, and C were negative. It was significant that the patient had undergone two prior halothane anesthetics lasting approximately 45 minutes each (death from a halothane anesthetic given 28 years after primary exposure has been documented[276]). The patient was discharged from the hospital 27 days after surgery, with continued improvement in liver function. This patient's exposure

to halothane decades earlier combined with the ether-based anesthetic produced hepatic damage, probably secondary to "immunologic memory" and possible cross-sensitization.[274]

Sevoflurane is unique among the volatile anesthetics in that it is the only one that appears not to be biodegraded to TFA-protein molecules.[277] This step is a prerequisite to the formation of TFA-protein antibodies, so it is unlikely that sevoflurane will produce fulminant hepatic failure via an immunoallergic mechanism.[278] Nonetheless, there have been several case reports of hepatic injury associated with sevoflurane use,[273,279,280] including one that involved a child.[281]

In spite of the case reports listed, it is extremely rare for isoflurane, sevoflurane,[245] and desflurane to produce clinically significant liver damage. Their molecular structure (increased fluorination) resists hepatic degradation, and their pharmacodynamic profile is associated with no changes or slight reductions in hepatic blood flow.[282-285]

In vitro research suggests that N_2O is metabolized minimally (0.004%) by intestinal microflora, yielding molecular nitrogen (N_2).[286] The limited metabolism does not necessarily mean that N_2O is an inert substance within the body. On the contrary, studies have demonstrated that chronic exposure to N_2O can lead to inactivation of the vitamin B_{12} component of methionine synthetase,[287] which can disrupt deoxyribonucleic acid (DNA) synthesis. For routine surgical cases this is generally not an issue, but caution should be exercised with patients who are pregnant, patients who receive a general anesthetic more than once a week, or patients who are debilitated and have problems with wound healing.[288]

In summary, the ether-based volatile agents have an extremely low risk for evoking hepatic injury. Future research will help to further clarify the incidence and cellular mechanism by which isoflurane, sevoflurane, and desflurane evoke hepatic pathophysiologic processes. Nonetheless, with the knowledge that cross-sensitization and immunologic memory are factors to be considered in any patient who has received a prior halothane anesthetic, even decades before, vigilance by anesthesia providers is still required.

Neuromuscular System

All volatile agents produce a dose-dependent relaxation of skeletal muscle, as well as potentiation of the effects of depolarizing and nondepolarizing muscle relaxants.[289] The mechanism by which this occurs is multifactorial, involving reduced neural activity within the CNS and a presynaptic or postsynaptic effect at the neuromuscular junction.[43, 290] Of the synaptic changes produced, the volatile agents predominantly affect the postjunctional membrane.[291]

With the exception of halothane, it is variable as to which volatile agent potentiates neuromuscular blocking agents the most.[292] Studies incorporating a broader methodology indicate that the greatest degree of potentiation of neuromuscular blockade occurs with sevoflurane, then isoflurane, and finally halothane.[293,294] Desflurane has been found by some investigators to potentiate the effects of neuromuscular blockers to the same extent as isoflurane[295] and sevoflurane. Similarly, other studies have shown that sevoflurane and isoflurane equally augment[296] and prolong[292] neuromuscular blockade produced by nondepolarizing muscle relaxants. In contrast, one investigation found that desflurane and sevoflurane enhanced the intensity of neuromuscular blockade with rocuronium, whereas isoflurane's effect was no different than that observed with a total intravenous anesthetic (TIVA).[289]

The discrepancies reported with interactions between volatile agents and muscle relaxants may be the result of differences in research methodology (e.g., type of muscle relaxant used in the study). For example, recovery of neuromuscular blockade after the use of cisatracurium and rocuronium is prolonged with sevoflurane but not isoflurane.[293,296] In contrast, the recovery profile for both volatile agents is the same after the use of vecuronium.[292]

Isoflurane[297] and N_2O[298] have been shown to potentiate the effects of succinylcholine. The former can accelerate the transition from a phase I to phase II block during an infusion of succinylcholine.[297] In general, nondepolarizing muscle relaxant dosages are decreased by approximately 25%[289,299] (sometimes as much as 50%)[293] of that required with TIVA when they are used in combination with a volatile agent. Of interest are two studies that found no difference in potentiation of nondepolarizing muscle relaxants and neuromuscular recovery profiles between an isoflurane/N_2O and TIVA technique.[293,296]

The volatile agents have also been shown to produce a time-dependent potentiation of nondepolarizing muscle relaxants (beginning in 5 to 10 minutes),[300] as well as a delayed recovery. For example, after 30 minutes of exposure to sevoflurane, recovery from vecuronium to 25% of baseline neuromuscular function is prolonged by 89%, and after 60 minutes, recovery exceeds 100%.[301] The inhalation agents have also been implicated in impairing reversal of nondepolarizing neuromuscular block.[302,303] For the reasons listed, anesthetists should carefully titrate muscle relaxants used in combination with inhalation anesthetics. Also, in select cases, a volatile anesthetic alone may produce adequate skeletal muscle relaxation without concurrent use of muscle relaxants.[304,305]

Malignant Hyperthermia

All of the volatile agents are capable of triggering malignant hyperthermia. These agents should not be used in malignant hyperthermia–susceptible patients. If a reaction occurs, it is treated instituting a hyperthermia protocol that includes intravenous dantrolene; the recommended dose is 1.0 to 2.5 mg/kg repeated every 5 minutes up to 10 mg/kg (although with some patients a larger dose may be necessary).[306] Of interest is the observation that a delayed response (e.g., 6 hours) to malignant hyperthermia provoked by inhalation agents has been reported to occur with the use of nondepolarizing muscle relaxants and with desflurane if it is administered in the absence of succinylcholine.[307]

Nitrous oxide is considered at most a weak trigger of malignant hyperthermia in susceptible patients.[308-310] Overall, the clinical use of N_2O, in combination with many other agents (e.g., barbiturates, propofol, ketamine, etomidate, opiates, and amide and ester anesthetics), is considered acceptable in patients susceptible to malignant hyperthermia.[311]

SUMMARY

Inhalation agents remain the most common class of drugs used to maintain a general anesthetic. The pharmacokinetic and pharmacodynamic profile of desflurane and sevoflurane facilitate meeting the anesthetic goals of an ever-increasing, same day–surgery population. The ease of administration of all ether-based volatile anesthetics, with or without N_2O, lends itself to common use among a diverse surgical population. Continued research will help guide anesthetists in the selection and application of a variety of inhalation anesthetic techniques. A summary of the systemic effects of the major inhalation anesthetics is given in Table 8-4. Some advantages and disadvantages of selected inhalation anesthetics are given in Table 8-5.

TABLE 8-4 Effects of the Inhalation Anesthetics

Variable	Isoflurane	Desflurane	Sevoflurane
Kinetics			
Alveolar equilibration	Moderate	Fast	Fast
Recovery	Moderate	Very fast	Fast
Liver			
Hepatotoxicity	No	No	No
Metabolism (%)	0.2	0.02	5-8
Musculoskeletal relaxation	Moderate	Moderate	Moderate
Cardiovascular System			
Heart rate	Mild increase	Moderate increase	Stable
Cardiac output	Slightly reduced	Slightly reduced	Slightly reduced
SVR	Reduced	Reduced	Reduced
MAP	Reduced	Reduced	Reduced
Respiratory System			
Respiratory irritation	Significant	Significant	No
Central Nervous System			
Seizure activity on EEG	No	No	Yes
Renal System			
Renal toxic metabolites	No	No	No

Modified from Aitkenhead AR, et al: *Textbook of Anaesthesia*, 5th ed. Edinburgh: Churchill Livingstone, 2007, pp 26-27.
EEG, Electroencephalogram; *SVR*, systemic vascular resistance; *MAP*, mean arterial pressure.

TABLE 8-5 Clinical Advantages and Disadvantages of Selected Inhalation Anesthetics

Anesthetic	Advantages	Disadvantages
Nitrous oxide	Analgesia Rapid uptake and elimination Little cardiac or respiratory depression Nonpungent Reduces MAC or the more potent agents	Expansion of closed air spaces Requires high concentrations Amount of oxygen delivered is reduced Diffusion hypoxia
Isoflurane	Moderate muscle relaxation Decreases cerebral metabolic rate Minimal biotransformation No significant systemic toxicity Inexpensive	Pungent odor Airway irritant Trigger for malignant hyperthermia
Desflurane	Rapid uptake and elimination Stable molecules Minimal biotransformation No significant systemic toxicity Decreases cerebral metabolic rate	Airway irritant Expensive compared to the other agents Needs special electrically heated vaporizer Rapid increases in inspired concentration can lead to reflex tachycardia and hypertension Trigger for malignant hyperthermia
Sevoflurane	Rapid uptake and elimination Nonpungent Excellent for inhalation induction Cardiovascular effects broadly comparable to those of isoflurane	Reacts with soda lime Trigger for malignant hyperthermia

MAC, minimum alveolar concentration.

CHAPTER 9

Intravenous Induction Agents

◆ *John J. Nagelhout*

An historic milestone in anesthesia was reached in 2011 with the decision to cease marketing sodium pentothal, a thiobarbiturate, in the United States and many other countries. Thiobarbiturates, when they were introduced in the 1930s, changed the way anesthesia was delivered. Although their use has declined dramatically in recent decades with the introduction of propofol, the practice of using intravenous push boluses of sedatives to initiate anesthesia remains the standard. Induction refers to the start of anesthesia when the patient is rendered unconscious. The intravenous induction agents allow the patient to experience a pleasant loss of consciousness while also rapidly achieving surgical levels of anesthesia.

A single ideal intravenous anesthesia induction drug has yet to be developed; however, the agents currently available can be exploited to select an appropriate drug for all surgical and anesthetic requirements. Desirable properties for an induction agent include rapid and smooth onset and recovery, analgesia, minimal cardiac and respiratory depression, antiemetic actions, bronchodilation, lack of toxicity or histamine release, and advantageous pharmacokinetics and pharmaceutics. Propofol is the current standard agent and is widely used for induction of general anesthesia and intravenous sedation. Etomidate and ketamine are valuable agents for select anesthetics when propofol use is undesirable. Dexmedetomidine is gaining popularity for niche uses as well. This chapter discusses the advantages and limitations of the currently used intravenous anesthesia induction agents.

NONBARBITURATE INTRAVENOUS ANESTHETICS

Propofol

Chemical Structure and Pharmaceutics

Propofol is a 2, 6-diisopropyl phenol (Figure 9-1). It is prepared as a 1% solution in a lipid emulsion of 10% soybean oil, 2.25% glycerol, and 1.2% purified egg lecithin. The pH of propofol (Diprivan) is 7 to 8.5, and the pK_a (negative logarithm of the acid ionization constant) is 11. The pH of the generic form of propofol is 4.5 to 6.4, and the pK_a is 11.[1] This unique vehicle is especially favorable to bacterial contamination. The original trade product, Diprivan, contains 0.005% disodium edetate (EDTA [ethylenediamine tetraacetic acid]) as a preservative to inhibit bacterial and fungal growth. Generic forms of propofol contain 0.025% sodium metabisulfite or benzyl alcohol depending on the manufacturer. Clusters of infections reported after mishandling of earlier preservative-free preparations prompted the addition of these preservatives.[2] Careful handling is still important. It is recommended that aseptic conditions be maintained and the drug be used immediately upon withdrawal from a vial for a single patient. Any remaining drug should be discarded. Syringes or vials should never be used for more than one patient. Opened vials or syringes should be discarded within 12 hours or 6 hours if propofol was transferred from the original container.

The pharmaceutical preparations are shown in Table 9-1.

Reformulations of Propofol

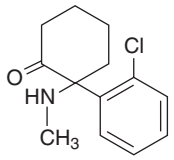
Newer formulations of propofol are being investigated that will have a more favorable vehicle than the lipid emulsion. These include other soybean and albumin emulsions, micelles and nanoemulsion cyclodextrins among others.[1,3]

A clear aqueous preparation of propofol as a phosphate prodrug is available for conscious sedation. A prodrug is a drug administered in an inactive or significantly less active form. Once administered, the prodrug is metabolized in the body into the active compound. Although propofol has many advantages such as rapid onset and offset when given for minor procedures such as colonoscopy or bronchoscopy, it can also present some challenges. It has a narrow therapeutic index, and hemodynamic and respiratory depression as well as general anesthesia can easily result from minor dose adjustments. Unlike the benzodiazepines, there is no pharmacologic antagonist. Fospropofol (Lusedra®) is being marketed as a safer formulation for mild to moderate sedation.[4] As a prodrug it requires metabolic conversion to active propofol. The resulting slow onset makes it unsuitable for general anesthetic induction. The aqueous preparation avoids the injection pain associated with lipid emulsions. Figure 9-2 depicts the conversion of the prodrug of propofol by plasma alkaline phosphatases to the active propofol molecule, releasing formaldehyde and phosphate. Formaldehyde is further metabolized to formate by formaldehyde dehydrogenase. Select pharmacokinetic and clinical properties of fospropofol are listed in Box 9-1.[4-6]

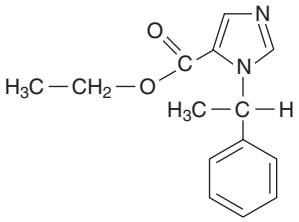
Pharmacokinetics

Propofol exhibits a generally favorable kinetic profile, which is one of its main clinical benefits in comparison with other induction drugs (Table 9-2).[7,8] Rapid distribution following an IV (intravenous) bolus dose into the brain and other highly perfused areas results in a fast onset of generally one circulation time. Rapid redistribution from the central to the peripheral compartments as the drug more evenly distributes to the entire body produces a quick initial decline in blood levels. As distribution continues, the drug is circulated to less well perfused tissues such as muscle, and the brain concentration falls. This effect leads to a rapid reawakening after sedative and anesthetic doses. The time to awakening is dose and patient dependent but is usually in the range of 5 to 15 minutes. The movement of propofol through various body compartments over time is depicted in Figure 9-3. A visual conceptualization of the redistribution of drugs given by rapid push bolus is shown in Figure 9-4.

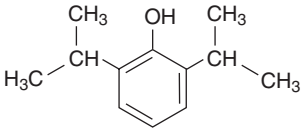
A complete discussion of the pharmacology of the barbiturates is available in the 4th edition of this textbook.



Ketamine

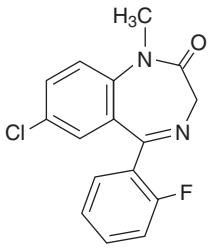


Etomidate

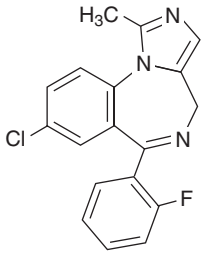


Propofol

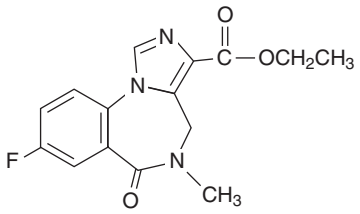
BENZODIAZEPINES



Diazepam



Midazolam



Flumazenil

FIGURE **9-1** Agents used for the induction of general anesthesia, sedation, and benzodiazepine reversal.

TABLE 9-1 Pharmaceutic Preparation of Intravenous Anesthetic Agents

Class	Drug Name	Available Solution	Pain on Injection*
Benzodiazepines	Diazepam (Valium)	0.5% in 40% propylene glycol and 10% alcohol	+++
	Lorazepam (Ativan)	0.4% in propylene glycol	+
	Midazolam (Versed)	0.5% buffered aqueous solution (pH 3.5)	0
Imidazoles	Etomidate (Amidate)	Water soluble at acidic pH, lipophilic at physiologic pH (pK_a 4.24); 0.2% solution in 30% propylene glycol (pH 5)	+++
	Dexmedetomidine (Precedex)	Dexmedetomidine HCl is freely soluble in water and has a pK_a of 7.1 with a pH of 4.5-7.0. The solution is preservative free. Prepare by adding 2 mL of dexmedetomidine (100 mcg/mL) to 48 mL of 0.9% sodium chloride injection for a total of 50 mL. The final concentration is 4 mcg/mL.	0
Alkylphenol	Propofol (Diprivan)	1% solution in an aqueous emulsion containing 10% soybean oil, 2.25% glycerol, and 1.2% egg phosphatide, EDTA (pK_a 11)	++
	Generic propofol	Generic formulations vary; may contain metabisulfite (use with caution in patients with allergies and asthma); formulations that contain benzyl alcohol pH 7-8.5 (benzyl alcohol should be avoided in infants)	++
	Lusedra (fospropofol)	Water-soluble prodrug of propofol that undergoes hydrolysis by alkaline phosphatases to propofol	0
Arylcyclohexylamines	Ketamine (Ketalar)	White crystalline salt 1% or 10% aqueous solution (pH 3.3-5.5; pK_a 7.5)	0

*0, None; +, mild; ++, moderate; +++, marked.

EDTA, Disodium ethylenediamine tetraacetic acid.

Metabolism plays little role in the initial awakening of the patient but is important in the eventual clearance of the drug. An interesting characteristic of propofol is its rapid metabolic clearance, which actually exceeds hepatic blood flow.[8] These extra hepatic sites of metabolism probably account for the lack of changes in elimination seen in patients with severe cirrhosis. [9] Less than 1% of propofol is excreted unchanged. It is rapidly metabolized in the liver by CYP2B6, UGTHP4, and CYP2C6.[10] The drug's kinetics are also influenced by age, with the elderly requiring lower doses.[11] Children require higher doses because they have an increased volume of distribution based on body weight. Their rate of clearance is also higher.[12] Some accumulation can occur with prolonged infusion secondary to tissue saturation.[13] The elimination half-life is 1 to 2 hours.

Concerns that the traditional concept of half-life is misleading when drugs are given for prolonged periods by infusion led to the introduction of context-sensitive half time. The context is the duration of the infusion.[14] It is the time required for a 50% decrease in plasma concentration after an infusion. Further refinements have described decrement times that include the 20% and 80% declines.[15] The decrement time is from the end of the infusion to 50% recovery and includes pharmacokinetic data related to concentration decrease and pharmacodynamic data correlating with recovery. These concepts are discussed in Chapter 6.

Propofol reversibly binds to erythrocytes (50%) and plasma proteins, most commonly to plasma albumin (48%). The free concentration is less than 2%.[16] Decreased plasma protein levels resulting from severe renal or hepatic disease and those patients in the third trimester of pregnancy may lower drug binding and increase the free active fraction. This may increase the effects of propofol. Clinically this may be a factor when prolonged infusions are used.[17] Factors that can alter protein binding are noted in Table 9-3. Drugs that are highly lipid soluble cross cell membranes rapidly, including the blood-brain and placental barriers. Propofol being highly soluble easily enters all body compartments.[18]

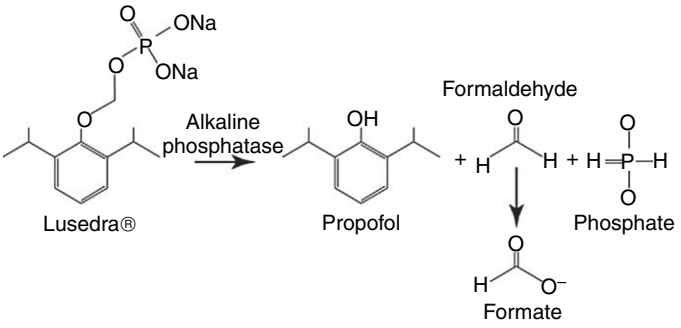


FIGURE **9-2** Conversion of the prodrug of propofol to the active propofol molecule by alkaline phosphatases.

Mechanism of Action

Like many other sedatives and anesthetics, propofol appears to exert its effect via an interaction with the inhibitory neurotransmitter γ-aminobutyric acid (GABA) and the $GABA_A$ glycoprotein receptor complex.[19] γ-Aminobutyric acid (GABA) is a major inhibitory transmitter in the central nervous system (CNS). The $GABA_A$ receptor, which is a ligand-gated ion channel receptor, is activated by the binding of the neurotransmitter GABA. This binding of

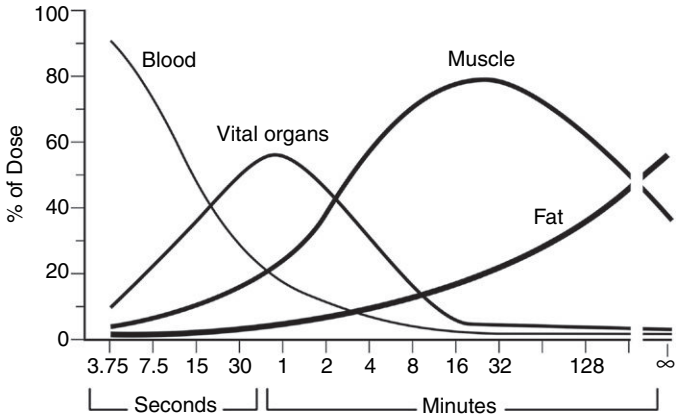

FIGURE **9-3** Propofol kinetics. Note that propofol rapidly enters the brain and other vital organs, with peak effects at 1 minute after bolus injection. The brain concentration then falls rapidly over the next 10 to 15 minutes as the drug redistributes more evenly throughout the body to muscle and fat.

BOX 9-1

Clinical Pharmacology for Fospropofol (Lusedra)

Indication

Intravenous sedation in adults undergoing diagnostic or therapeutic procedures

Dose and Administration

- Standard dose: Initial dose 6.5 mg/kg
- Supplemental dose: 1.6 mg/kg no more frequently than every 4 minutes
- For patients 65 years old or younger and without severe systemic disease: Standard doses apply
- For patients 65 or more years old or with severe systemic disease: Modified dose 75% of standard dose

Pharmacokinetic Profile Compared to Propofol

- Onset: 5-13 minutes
- Duration: 15-45 minutes (depending on dose)
- Volume of distribution (L/kg): Fospropofol: 0.3; propofol: 5.8
- Total body clearance (L/hr/kg): Fospropofol: 0.36; propofol: 3.2
- Terminal elimination half-life (hours): Fospropofol: 0.88; propofol: 1.13

Most Frequent Adverse Events (Incidence 5% or greater)

Perineal paresthesia, pruritus, hypoxemia, hypotension

TABLE 9-2 Select Pharmacokinetic Values for Intravenous Anesthetic Agents

Drug Name	Distribution Half-Life (min)	Elimination Half-Life (hr)	Clearance (mL/kg/min)	Volume of Distribution (L/kg)	Protein Binding (%)
Diazepam	10-15	20-50	0.3	0.8-1.3	98
Lorazepam	4-5	10-16	0.8-1.8	0.8-1.3	90
Midazolam	7-15	2-4	7-11	1-1.7	94
Etomidate	2-4	2-5	22.5	2.5-4.5	75
Propofol	2-4	1-5	25	2-8	98
Ketamine	11-17	2-3	14.5	2.5-3.5	12
Dexmedetomidine	6-8	2-2.6	8.9	1.54	94

GABA to the $GABA_A$ receptor initiates the movement of chloride (Cl^-) through ion channels into the cell. This results in hyperpolarization of postsynaptic cell membrane and the inhibition of neuronal cell excitation. A model has been developed that includes sites of action for GABA on the postsynaptic membrane, as well as sites for numerous other drugs. Propofol directly stimulates $GABA_A$ receptors and potentiates the actions of endogenous GABA. The GABA receptor and its function are described in Figure 9-5.

Pharmacodynamics

Central Nervous System Effects. Propofol produces a rapid and pleasant loss of consciousness and emergence from anesthesia. Low-dose infusions for conscious sedation result in dose-dependent anxiolysis, sedation, and amnesia.[20] There are dose-dependent reductions in cerebral blood flow (CBF), cerebral metabolic rate of oxygen consumption ($CMRO_2$), intracranial pressure (ICP), and cerebral perfusion pressure(CPP).[21] These effects result in part from the decreased mean arterial pressure, depressed metabolic rate, and cerebral vasoconstriction produced by standard doses in a manner comparable to the effects of barbiturates and etomidate.[22,23] Cerebral autoregulation and reactivity to changes in carbon dioxide (CO_2) are preserved with propofol. Hyperventilation should be applied cautiously in patients with an increase in ICP to avoid hypocarbia-induced cerebral circulatory compromise.[24]

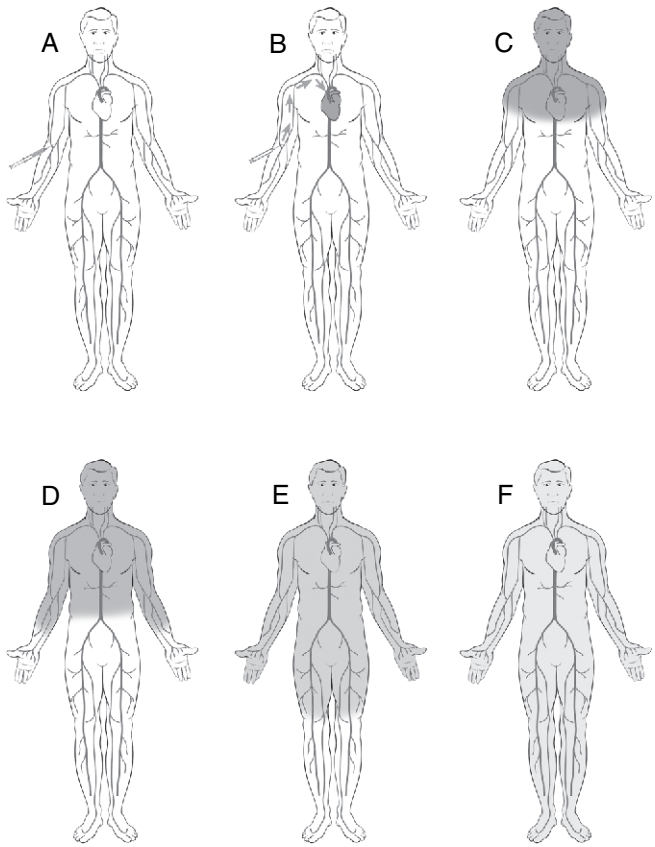

FIGURE **9-4** Redistribution of intravenous drugs is shown. **A** and **B,** A drug is administered in the arm and follows the venous circulation to the heart. **C,** The high cardiac output and circulatory flow initially distribute the drug to the brain and upper body, and rapid central nervous system effects begin. **D, E,** and **F,** As time passes, usually minutes, the drug more evenly distributes throughout the body, lowering the initial high brain concentration, and the patient awakens.

Electroencephalogram (EEG) data produced a delta rhythm without evidence of epileptiform activity and burst suppression with higher doses.[25] Even with these findings, controversy exists over the use of propofol in the patient with epilepsy.[26] Three epileptic patients were reported to experience increased epileptiform activity on EEG after the administration of propofol 2 mg/kg.[27] Studies in patients with epilepsy showed a different response in that the EEG showed no increase in epileptogenic activity at any of the sites monitored.[28] It was also found that activation or extension of EEG activity was greater with thiopental than with propofol (although not statistically significant).[29] Propofol has been used successfully to manage status epilepticus.[30] Myoclonia induced by propofol results in spontaneous excitatory movements secondary to selective disinhibition of subcortical centers. Adequate dosage may prevent the occurrence of these movements. Myoclonia may occur on induction, but the incidence appears to be lower than that with etomidate. Opisthotonos has also been associated with propofol. Intraocular pressure is decreased by propofol.[31] Evidence for a neuroprotective effect is controversial because studies in both animals and humans have not been consistent. Propofol cannot be indicated as a clinical neuroprotectant alone, but it might play an important role in multimodal neuroprotection. Beneficial effects include preservation of cerebral perfusion, temperature control, prevention of infections, and tight glycemic control.[32]

The use of propofol for electroconvulsive therapy (ECT) has been somewhat controversial as a result of the drug's effects on seizure duration. Several studies have shown that propofol reduces the duration of the ECT-induced seizure when compared with barbiturates. Evaluating the efficacy of ECT as an antidepressant was typically based on the duration of the seizure; a shortened seizure implied a less effective therapy. However, researchers have found that a reduction in seizure duration does not decrease the efficacy of the ECT, and that propofol is an appropriate agent for use in this procedure.[33-35]

CNS effects of the intravenous induction drugs are shown in Table 9-4.

Cardiovascular Effects. Propofol usually results in a mild to moderate transient decrease in blood pressure in healthy adults and children during anesthesia induction. The decrease in blood pressure is not usually clinically significant. The effects are more pronounced than those seen with equivalent doses of etomidate or midazolam. It can, however, result in significant hypotension in usual induction doses in select patients. Predictors of hypotension during induction are age greater than 50 years, ASA (American Society of Anesthesiologists) class 3 to 4, baseline mean arterial pressure less than 70 mmHg, and coadministration of high doses of fentanyl. Hypotension usually occurs within 10 minutes after induction and is more prevalent in the second half of the 0- to10-minute interval.[36] As with most cardiovascular-depressing sedatives, these effects result from varying degrees of a combination of CNS, cardiac

TABLE **9-3** Factors That Alter Protein Binding

Factors	Percent Bound
Decreased lipid solubility	Decreases binding
Increased pH (≤8.0)	Increases binding
Increased drug concentration	Decreases binding
Increased protein concentration	Increases binding
Increased competition for binding sites with other drugs	Decreases binding

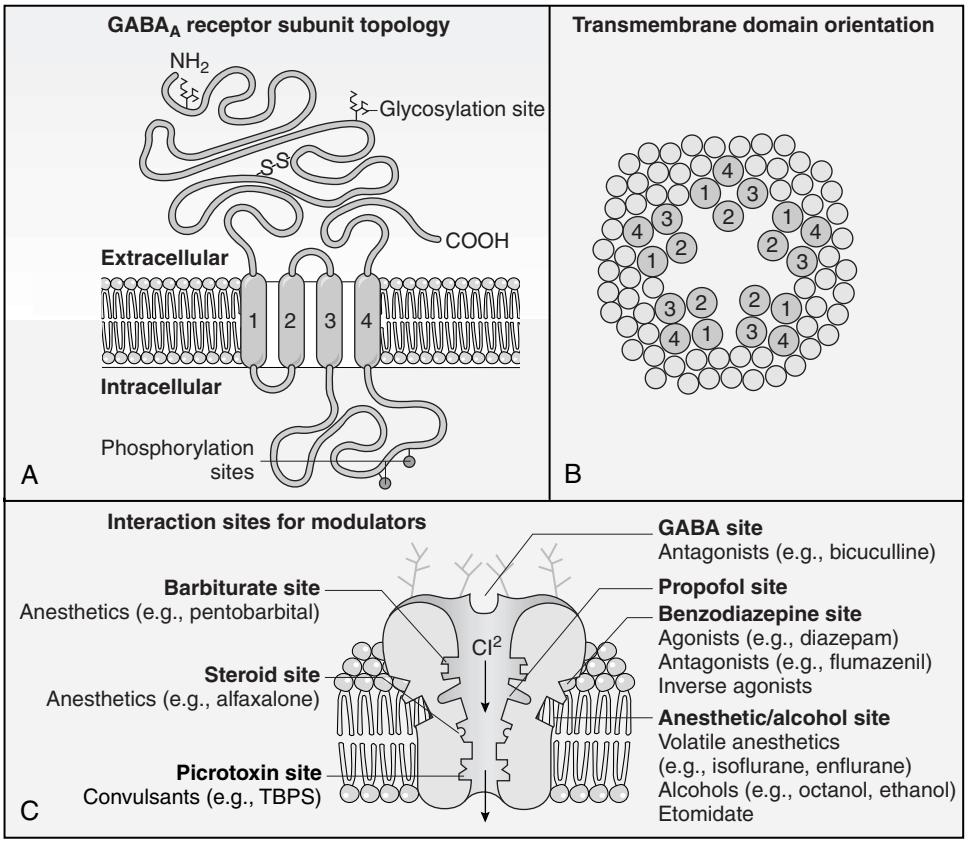

FIGURE **9-5** The GABA$_A$ receptor. **A,** The generic GABA$_A$ receptor subunit has four hydrophobic transmembrane segments that are thought to form amphipathic α-helices. The *N*-terminal domain contains *N*-glycosylation sites and a conserved cysteine bridge; it forms the agonist-binding site. The large intracellular loop undergoes phosphorylation in several isoforms. **B,** Plane view of the transmembrane hydrophobic segments showing interactions to form a central ion-conducting pore lined by the second transmembrane domains. The hetero-oligomeric structure consists of five subunits, with each subunit contributing to the ion channel pore. **C,** The GABA$_A$ receptor gates an anion channel permeable to Cl^- and HCO_3^-. The general anesthetics are distinguished from the benzodiazepines (which allosterically modulate GABA binding to potentiate GABA responses) by their ability to activate/gate the GABA$_A$ receptor channel directly. A separate site at the interface between the third and fourth transmembrane segments appears to interact with volatile anesthetics, alcohols, and etomidate, as demonstrated by site-directed mutagenesis studies. *(From Hemmings HC, Hopkins PM, (eds):* Foundations of Anesthesia Basic and Clinical Sciences, *2nd ed. St Louis: Mosby; 2006.)*

and baroreceptor depression, and decreases in sympathetic tone and systemic vasodilation. The primary reasons for propofol-induced hypotension are decreased sympathetic tone and vasodilation.[37] Central nervous system and direct cardiac depression play less of a role. A decrease in dose or alternative agents should be considered in the elderly or cardiac-compromised patients. Propofol has been used successfully for cardiac anesthesia when combined with fentanyl in low-dose or infusion regimens (Table 9-5).[38]

Respiratory Effects. Transient respiratory depression, more prominent than that seen with etomidate, is common with induction doses of propofol. Decreases in tidal volume are greater than decreases in respiratory rate, although apnea is common on initial administration of induction doses.[39] The frequency and duration of apnea are dependent on the dose, speed of injection, patient characteristics, and the presence of other respiratory depressant medications.[40] Dose-dependent respiratory depression is also common with maintenance infusions. This appears to result from a decreased sensitivity of the respiratory center to carbon dioxide.[41]

Propofol has a minimal bronchodilating effect in patients with or without asthma and in patients who smoke. It does not cause histamine release and has been used successfully for anesthesia induction in asthmatic patients. After tracheal intubation, respiratory resistance is lower, and the incidence of wheezing is decreased, compared with the effects of etomidate.[42,43] Propofol or ketamine are the preferred induction agents in patients with asthma.[44]

TABLE 9-5 Cardiac and Respiratory Effects of Intravenous Anesthetic Agents

Drug Name	Mean Arterial Pressure	Heart Rate	Cardiac Output	Venous Dilation	Systemic Vascular Resistance	Respiratory Depression	Bronchodilation
Etomidate	0	0	0	0	0	0/–	0

–, Mild decrease; – –, moderate decrease; +, mild increase; ++, moderate increase; 0, no effect.

Other Pharmacologic Actions. Propofol possesses mild antiemetic effects that are most prominent when given by continuous infusion.[45,46] The mechanism for the antiemetic effects is unclear. It also exhibits antipruritic effects against opioid-induced pruritus.[47,48]

Patients experience mild to moderate pain on injection with propofol. The incidence is approximately 60% and is most frequently related to the use of smaller veins for injection The two most effective interventions to reduce pain on injection are the use of the antecubital vein or pretreatment with lidocaine 20 to 40 mg in conjunction with venous occlusion when the hand vein was chosen. Other effective pretreatments are using a lidocaine-propofol admixture, opioids, ketamine, and nonsteroidal antiinflammatory drugs.[49] Intraarterial injection of propofol does not cause vascular injury.

Obstetric Use. As you would expect from a highly lipid soluble drug, propofol easily passes the placental barrier when administered to a pregnant woman. Sedative effects occur in the neonate when propofol is used for cesarean delivery. Lower 1- and 5-minute Apgar scores have been noted.[50]

The anti-emetic effects of propofol may be an advantage in these patients. It is also used for sedation and hypnosis in postpartum tubal ligations and assistive reproductive techniques.

Contraindications and Precautions

Few absolute contraindications exist for propofol other than cases in which a known hypersensitivity exists to propofol or its components or the patient has a disorder of lipid metabolism.[51,52] New generic formulations of propofol, which contain sodium metabisulfite, should not be used in sensitive patients. The sulfite may cause allergic-type reactions such as anaphylactic symptoms and life-threatening or less severe asthmatic episodes in certain susceptible people. Sulfite sensitivity is more common in patients with asthma than in patients without asthma.[53] As noted, caution is advised in elderly, debilitated, and cardiac-compromised patients.

Allergy

Propofol lipid emulsion formulations have been scrutinized because of their lecithin content. Lecithin (from the Greek *lekithos*, meaning "egg yolk") is a phospholipid compound composed of a range of phosphatidyl esters such as phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine. These are combined with varying amounts of triglycerides and fatty acids. Lecithin was originally obtained from eggs, although now soybeans and other vegetables with high lecithin content have also become useful sources. Apart from its use as an antioxidant synergist, lecithin has important surfactant properties and is used as an emulsifying agent.[54]

Controversy exists regarding whether propofol should be avoided in patients who are allergic to eggs, soy, or peanuts. Egg allergy is most common in children and usually outgrown by adulthood.[55] The 2009 guidelines published by the Association of Anesthetists of Great Britain and Ireland claim there is no evidence that propofol should be avoided in egg- or soy-allergic patients.[56,57] The warning labels differ among countries for the same formulation of propofol supplied by the same company. The product information for Diprivan 1% warns of its use in egg- or soy-allergic individuals in Australia, soy/peanut (but not egg) in the United Kingdom, and lists no food allergy warnings in the United States. This is despite all three formulations being supplied by the same company.[56]

A retrospective case review of 28 egg-allergic patients was recently reported. Two of the 28 patients had documented egg anaphylaxis. All but the two children with a history of egg anaphylaxis safely received propofol.[58] Data on the two children with documented egg anaphylaxis were not conclusive. The authors suggest propofol is likely to be safe in most egg-allergic children; however, propofol should not be administered to any child with a history of egg anaphylaxis until further evidence is available. Other authors note that there are no confirmed reports of propofol-induced anaphylaxis in egg-allergic patients. They generally demonstrate immediate hypersensitivity to proteins from egg whites. Lecithin is from egg yolks, so there is no reason to contraindicate propofol in egg-allergic patients.[59]

Soy allergy is a common early onset food allergy in children. Many children outgrow the allergy by age 7.[60] Refined soy oil of the types used in propofol have the allergenic proteins removed during refining; therefore it is safe in patients with soy allergy. The suggestion that peanut-allergic patients may exhibit propofol allergy is due to cross reactivity between these leguminous plants; therefore just as with soy allergy, there are also no data to support the avoidance of propofol in patients with peanut allergy.[59]

Propofol Infusion Syndrome

Propofol is frequently used in adult and pediatric intensive care units for prolonged sedation. Numerous case reports, however, describe findings of various metabolic derangements and organ system failures known collectively as propofol infusion syndrome (PRIS) with long-term high-dose infusions of propofol.[61] This has not occurred in anesthesia, even with prolonged administration of relatively high doses, because it seems to require long-duration infusions of increasing doses, as only encountered in critical care units.[62] This syndrome is associated with significant morbidity and mortality. A precise mechanism of action of PRIS has yet to be demonstrated.[63] Risk factors include young age, doses greater than 4 to 5 mg/kg/hr, duration greater than 48 hours, critical illness,

BOX 9-2

Clinical Features of Propofol Infusion Syndrome

Cardiovascular
- Hypotension
- Widening of the QRS complex
- Bradycardia
- Ventricular tachycardia or fibrillation
- Asystole

Respiratory
- Hypoxia (preexisting)

Renal
- Acute kidney injury
- Hyperkalemia

Musculoskeletal
- Rhabdomyolysis

Metabolic
- Hyperthermia
- Metabolic acidosis

Hepatic
- Hepatomegaly
- Transaminitis
- Steatosis
- Hypertriglyceridemia
- Lipidemia

high-fat low-carbohydrate intake, inborn errors of mitochondrial fatty acid oxidation, concomitant catecholamine infusion, and steroid administration. Many of the patients who developed this syndrome have been children, but several cases in adults have been identified as well.

The syndrome has occurred in patients with acute inflammatory disease with infection or sepsis or acute neurologic disease. One common denominator was the presence of impaired systemic microcirculation with tissue hypoperfusion and hypoxia. Propofol seemed to be a triggering agent when catecholamines and corticosteroids are also administered. Fatty acid metabolism and mitochondrial activity are impaired, creating an oxygen supply-and-demand mismatch that results in cardiac and peripheral muscle necrosis. The current theory proposes that propofol inhibits oxidative phosphorylation by (1) inhibition of the transportation of long-chain fatty acids into the cell as well as (2) inhibitory effects on the mitochondrial respiratory chain. Symptoms include severe metabolic acidosis, refractory cardiac failure, persistent bradycardia refractory to treatment, fever, and severe hepatic and renal disturbances.[64] The clinical features are noted in Box 9-2. Treatment is supportive and includes discontinuing the propofol, improving gas exchange, cardiac pacing for bradycardia, phosphodiesterase inhibitors, glucagon, extracorporeal membrane oxygenation, and renal replacement therapy.[63]

Key points regarding propofol are listed in Box 9-3. Induction doses of the intravenous anesthetics are shown in Table 9-6.

BOX 9-3

Key Points for Propofol Anesthesia

- Propofol is the most commonly used intravenous anesthetic as an induction drug and for sedation.
- Respiratory effects include transient respiratory depression or apnea, depending on dose. Although not a bronchodilator, safe use in asthmatics has been well established.
- Propofol is unique among induction agents in that it exhibits mild antiemetic properties.
- Propofol has a rapid onset and emergence after bolus or continuous infusions of the drug.
- Patients emerge with a mild euphoria followed by rapid dissipation of the sedative effects.
- Propofol reduces cerebral blood flow, $CMRO_2$, and ICP.
- Propofol decreases blood pressure, cardiac output, and systemic vascular resistance to a greater extent than etomidate at equipotent doses.
- The induction dose is 1-2 mg/kg followed by a maintenance infusion of 100-200 mcg/kg/min. Conscious sedation doses are 25-75 mcg/kg/min.

$CMRO_2$, *Cerebral metabolic rate of oxygen consumption*; ICP, *intracranial pressure*.

TABLE 9-6 Induction Doses of the Intravenous Anesthetics

Agent	Dose (mg/kg)
Etomidate	0.2-0.3
Propofol	1-2
Fospropofol (Lusedra)	6.5
Ketamine	(see Box 9-5)
Dexmedetomidine	1 mcg/kg infused over 10 minutes followed by 0.2-0.7 mcg/kg/hr
Midazolam	0.1-0.2

Etomidate

Etomidate (1-[1-phenylethyl]-1*H*-imidazole-5-carboxylic acid ethyl ester) is an intravenous induction agent whose current clinical niche is as an alternative to propofol with little if any cardiorespiratory effects. No intrinsic analgesic properties are associated with the use of this drug.[65] Side effects such as pain on injection, myoclonia, nausea and vomiting, and adrenocortical suppression, however, have limited wider acceptance of the drug. Etomidate is a carboxylated imidazole derivative that was synthesized in 1965 and introduced to European anesthesia practice in 1972.[66] Etomidate has two isomers, but the (+) isomer is the only one with hypnotic properties (see Figure 9-1 for the chemical structure of etomidate).[67]

Etomidate is currently supplied as a 2-mg/mL preparation; each milliliter contains 35% propylene glycol as a solvent and has a pH of 8.1 and a pK_a of 4.2. This formulation has been changed over the years in an effort to decrease the incidence of pain on injection and spontaneous muscle movements or myoclonia. It is also supplied as a lipid emulsion, Etomidate-Lipuro.[68] The lipid emulsion is associated with significantly less injection pain than propofol with added lidocaine in children.[69] Previously used preparations included polyethylene glycol, aqueous ethanol, Cremophor EL, and an aqueous solution.[70]

New formulations are in clinical trials that are designed to maintain the favorable clinical features of etomidate while reducing the primary undesirable effect of prolonged inhibition of adrenal steroidogenesis. Methoxycarbonyl (MOC) etomidate is a "soft" analog that contains a second ester bond distal to the existing etomidate ester linkage.[71] MOC etomidate is rapidly metabolized by nonspecific esterase enzymes in blood and tissue to inactive metabolites. The elimination half-life is a few minutes. No adrenal suppression is found 30 minutes after bolus administration because of the rapid elimination.[72]

Pharmacokinetics

Etomidate is rapidly metabolized in the liver by hepatic microsomal enzymes and plasma esterases. Ester hydrolysis is the primary mode of metabolism in the liver and plasma. Etomidate is hydrolyzed to form inactive carboxylic acid metabolites. Approximately 10% of the administered dose can be recovered in bile, 13% can

be recovered in feces, and the remainder of the metabolites are eliminated by the kidney.[73]

The rapid redistribution of etomidate accounts for its extremely short duration of action (see Table 9-2). The drug is lipid soluble and has a volume of distribution that is several times greater than its body weight. Shortly after intravenous injection (within 1 minute), the brain concentration rises rapidly because of the drug's lipid solubility, and over the next several minutes extensive redistribution to other organs and tissues occurs and the patient regains consciousness.

The total body clearance of etomidate is rapid. The hepatic extraction ratio is 67%. Studies examining dose-response relationships have found a lack of accumulation with this compound.[65] The terminal half-life is 2 to 5 hours.[72]

Awakening occurs 5 to 15 minutes after bolus administration. Like other intravenous induction drugs, this occurs secondary to rapid redistribution to non-nervous sites. Etomidate is 76% protein bound, mostly to albumin. Variations in the amount of available plasma protein alter the amount of free drug available to exert pharmacologic actions. Disease states that produce alterations in plasma protein content could theoretically effect the action although this rarely happens clinically. Compensatory increases in metabolism and elimination can readily compensate for changes in protein binding.

The mechanism of action of etomidate, like many other CNS depressants, involves GABA modulation (see Figure 9-5).[74] In a clinical investigation of 2500 cases, Doenicke et al.[75] confirmed that no histamine is released by etomidate.

Pharmacodynamics

Central Nervous System Effects. Etomidate produces a dose-dependent CNS depression within one arm-brain circulation. Its duration of action is also dose dependent,[65] with awakening occurring 5 to 15 minutes after a 0.2- to 0.4-mg/kg dose. The drug is devoid of analgesic properties.

Cerebral blood flow and cerebral metabolic rate of oxygen consumption are both decreased by etomidate.[76,77] In a study of fully alert patients without neurologic deficit or impaired consciousness, an etomidate induction was followed by an infusion of 2 to 3 mg/min. Cerebral blood flow decreased 34%, and cerebral metabolism was also reduced (mean decrease of 45%). Decreased oxygen consumption and the associated decrease in carbon dioxide production can cause cerebrovascular vasoconstriction, decreased cerebral blood flow, and decreased intracranial pressure. Also noted during this trial was the maintenance of cerebral blood vessel responsiveness to changes in carbon dioxide levels.[76]

In a study of patients with intracranial pathology, etomidate (0.2 mg/kg given intravenously) was shown to decrease intracranial pressure while maintaining cerebral perfusion pressure. Because of the cardiovascular stability of this drug, mean arterial pressure did not decrease below cerebral autoregulation values at which cerebral blood flow would become pressure dependent. Cerebral perfusion pressure was maintained adequately in all study subjects.[77]

The electroencephalographic changes that follow administration of etomidate are similar to those that follow administration of other intravenous induction anesthetics. When compared with thiopental, a lack of beta-wave activity was present during induction, along with a longer duration of stages III and IV.[78]

One negative characteristic of etomidate is its excitatory phenomenon of muscle movements and tremors.[78,79] Referred to as *myoclonia*, this phenomenon is defined as sudden, generalized, asynchronous muscle contractions.[80] Myoclonia can affect many muscle groups or a single muscle. The movements can be so severe that they resemble, and are often mistaken for, seizures. In EEG patterns monitored during etomidate anesthesia, no specific EEG disturbances occurred during or after myoclonic episodes.[78] The origin of these muscle movements is thought to be related to uneven drug distribution into the brainstem or deep cerebral structures and not to CNS stimulation.[78,81] The incidence of myoclonia ranges between 10% and 60% and varies with the type and the amount of premedication given. Investigators associated the 35% incidence of myoclonic movement with painful stimuli (e.g., drug injection, mandibular lifting). Horrigan et al.[79] reported that premedication with fentanyl (100 mg) given intravenously 2 minutes before induction did not significantly decrease motor activity. However, pretreatment with small doses of etomidate, dexmedetomidine, midazolam, rocuronium, and lidocaine are all effective in reducing myoclonia.[82-86] Etomidate is shown to decrease intraocular pressure.

Electroencephalographic changes with etomidate are similar to those of other intravenous induction drugs. Bispectral index (BIS) monitor values decrease after a bolus of etomidate and correlate well with sedation scores. Etomidate decreases the amplitude and increases latency of auditory evoked potentials. The duration of epileptiform activity after ECT is longer after induction with etomidate versus propofol. Somatosensory-evoked potential amplitudes are enhanced by etomidate and motor-evoked potential amplitudes are suppressed less by etomidate than propofol.[87-89]

Cardiovascular Effects. The primary clinical advantage of etomidate over propofol is the hemodynamic stability upon induction in healthy or modestly debilitated patients. In patients with compensated heart disease, changes in heart rate, pulmonary artery pressure, cardiac index, systemic vascular resistance, and systemic blood pressure were not significant.[90] In one study of high-risk patients with significant cardiac disease, hemodynamic stability was maintained with induction doses of 0.3 mg/kg. Also, minimal changes in heart rate, blood pressure, central venous pressure, and intrapulmonary shunting have been demonstrated after etomidate administration.[91] Patients with aortic and mitral valve disease, however, are noted to have significant decreases in systemic blood pressure (17% to 19%), pulmonary artery pressure (11%), and pulmonary capillary wedge pressure (17%).[92] Slight decreases in blood pressure are thought to be caused by decreases in systemic vascular resistance. The hemodynamic stability seen with etomidate has been attributed to a unique lack of depression of sympathetic nervous system and baroreceptor function.[93] Myocardial oxygen supply and demand are kept constant by a balance of decreased myocardial blood flow and decreased oxygen consumption.[94] No significant cardiac dysrhythmias are associated with etomidate administration. Both renal and hepatic blood flows are maintained by the stability of cardiac output (see Table 9-5). In summary, at equivalent anesthetic doses, propofol depresses cardiorespiratory function to the greatest degree and etomidate depresses it the least.

Respiratory Effects. Etomidate affects the respiratory system in a dose-dependent manner. Minute volume decreases, but respiratory rate increases. The respiratory depression seen with propofol use is significantly greater than that seen with etomidate.[94] The ventilatory response to carbon dioxide is decreased, and etomidate administration may cause brief periods of apnea following induction. Etomidate has little effect on bronchial tone and does not cause histamine release (see Table 9-5).[95,96]

Adrenocortical Effects. Adrenal cortical suppression by etomidate has been widely studied, and this effect significantly limits it clinical use. It is useful as a single-dose anesthesia induction

agent, but infusions are no longer used. The issue elicited widespread concern after 10 years of use in Europe. Researchers found an increased mortality rate in critically ill patients who received etomidate infusions. This phenomenon was attributed to adrenocortical hypofunction, demonstrated by decreased levels of plasma cortisol.[97] Multiple studies have shown adrenal hormone levels to be decreased for up to 8 to 24 hours after a single induction dose or more than 24 hours with infusion.[98-104] These effects are caused by a reversible dose-dependent inhibition of adrenal steroidogenesis. The enzymes inhibited are the cytochrome P-450–dependent mitochondrial enzymes and 11β-hydroxylase. To a lesser degree, 17α- and 18-hydroxylases are also affected. This results in an increase in cortisol precursors but a decrease in cortisol, aldosterone, and corticosterone levels. This enzyme inhibition results in decreased ascorbic acid synthesis, which is necessary for steroid production.[105] In summary, these effects are primarily caused by a reversible dose-dependent inhibition of the adrenocortical enzyme 11β-hydroxylase. The mechanism for the adrenocortical hypofunction following administration of etomidate is shown in Figure 9-6.

The clinical significance of this pharmacologic effect continues to be discussed. There have been several reports of single doses of etomidate resulting in patient morbidity. Critically ill patients given corticosteroid therapy for septic shock had poorer results when etomidate was also administered.[106] A large-scale follow-up study (CORTICUS) evaluating low-dose corticosteroid therapy in septic shock suggested that patients receiving etomidate before enrollment had a 28-day mortality, significantly higher than other patients in the trial, and that steroids provided no benefit to those who received etomidate.[107,108] A further analysis of the data led the authors to report that the use of a bolus dose of etomidate in the 72 hours before inclusion in the study was associated with an increased incidence of inadequate response to corticotropin and an increase in mortality. They recommend that clinicians exercise caution in the use of etomidate in critically ill patients with septic shock.[108] The duration of adrenal insufficiency after single-dose etomidate and its effect on outcomes in this population is longer than 24 hours and may last up to 72 hours.[109] The administration of supplemental steroids to counter this effect is controversial. It did not appear effective in septic patients[108]; however, others suggest that the empirical use of steroid supplementation for 48 hours after a single dose of etomidate in critical patients without septic shock should be considered.[109] Further research is needed to define the safe use of single boluses of etomidate in critical patients. The use of new formulations such as methoxycarbonyl (MOC)-etomidate with short durations of adrenal suppression of less than 1 hour may help alleviate this issue.

Adverse Effects

Other than the adrenal suppression and myoclonia that were discussed previously, the primary adverse effects of etomidate are pain on injection, thrombophlebitis, and nausea and vomiting. Etomidate has been formulated in various solvents in an effort to decrease pain on injection and also thrombophlebitis. The current formulation containing propylene glycol results in burning and pain on injection in up to 90% of patients.[110,111] The incidence of subsequent venous sequelae up to 7 days postoperatively is 50%.[110] Some of the variables identified as contributing to pain on injection include site and speed of injection, size of vessel used, and type of premedication. The incidence of injection pain is significantly less with the lipid formulation.[112] As with other venous irritating drugs, injection pain can be decreased with lidocaine 20 to 40 mg pretreatment and use of larger veins. No vascular injury occurs after intraarterial injection of etomidate.

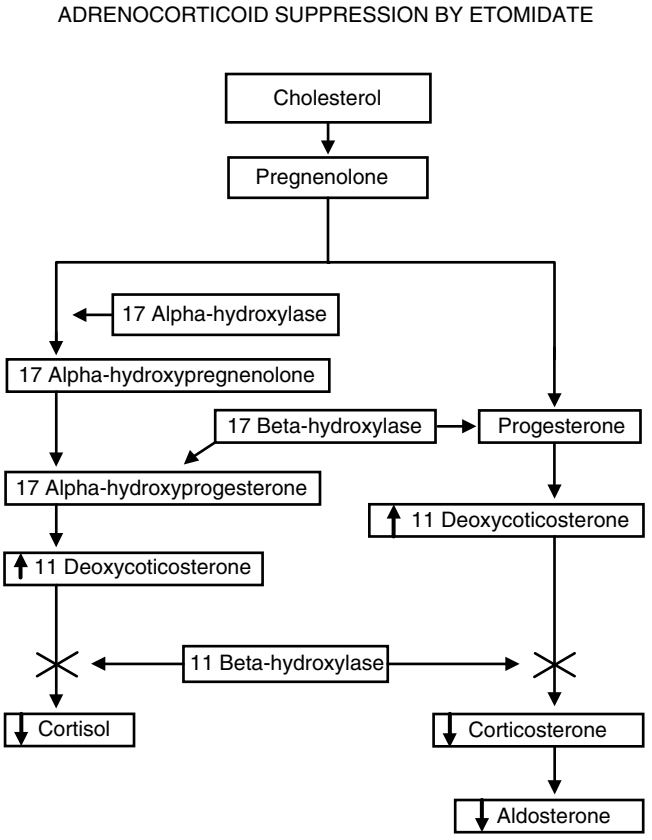

FIGURE **9-6** Adrenocorticoid suppression by etomidate. Etomidate produces prolonged inhibition of 11β-hydroxylase, which leads to reductions in cortisol and aldosterone.

Nausea and vomiting is common with etomidate (30% to 40%).[113,114] Nausea and vomiting are less common with the lipid emulsion of etomidate.[115] Opioids also increase the susceptibility to nausea and vomiting.

Contraindications

Etomidate is contraindicated in patients with a known sensitivity, adrenal suppression, and acute porphyrias.

The porphyrias are a group of rare metabolic conditions caused by deficiencies in the enzymes involved in the biosynthetic pathway of heme, a building block of hemoglobin. They are usually inherited but may be acquired diseases. Depending on deficient enzymatic steps, various porphyrins and their precursors accumulate in tissues and may lead to toxicity. They are classified as acute or nonacute and according to the specific biosynthetic step deficiency. The acute types of porphyria are inducible by various enzyme-inducing drugs that may precipitate an attack. The acute forms are acute intermittent porphyria; variegate porphyria; hereditary coproporphyria, and plumboporphyria. The nonacute forms are porphyria cutanea tarda; erythropoietic porphyrias; congenital erythropoietic porphyria, and erythropoietic protoporphyria.

The rate limiting enzyme in the biosynthetic pathway of porphyrins is ALA-synthetase. Drugs that induce this enzyme must be avoided. Symptoms of an attack may include skin lesions and neurovisceral symptoms such as abdominal and nonabdominal pain, vomiting, psychological symptoms, convulsions, muscle weakness, sensory loss, hypertension, tachycardia, and hyponatremia.

Etomidate and barbiturates are contraindicated. General anesthesia can be readily accomplished, however, with the current agents. Propofol is the induction agent of choice. Ketamine is safe

BOX **9-4**

Key Points for Etomidate

- Etomidate is used in compromised patients when the use of the other intravenous anesthetics may be problematic.
- The major advantage of etomidate is minimal cardiorespiratory depression.
- Etomidate reduces intracranial pressure, cerebral blood flow, and $CMRO_2$.
- The mechanism of action of etomidate appears to be GABA-mimetic.
- Involuntary movements or myoclonia during onset is common.
- Etomidate frequently causes burning on injection.
- Etomidate inhibits the enzyme 11β-hydroxylase, which is essential in the production of both corticosteroids and mineralocorticoids. Clinically significant reductions in steroid production may occur with single doses or prolonged infusions.
- Etomidate increases postoperative nausea and vomiting.
- The induction dose is 0.2-0.3 mg/kg.

$CMRO_2$, *Cerebral metabolic rate of oxygen consumption*.

as well. Most muscle relaxants appear to be reasonably safe, and all of the current inhalational agents may be used. Analgesia can be provided with any of the currently used opiates. Local anesthetics may also be safely used.[116,117]

Key points of etomidate pharmacology are shown in Box 9-4.

Ketamine

Ketamine has a long history of anesthetic use although its popularity has varied over the years. In modern practice several specific situations exist in which it has unique advantages as an alternative to the more commonly used drugs. Recent research has led to new uses as well as a renewed interest in possible untoward effects. It can be very useful for anesthesia and sedation in high-risk, pediatric, and asthmatic patients. Ketamine also has excellent analgesic properties that can be exploited for treatment of perioperative pain.

Ketamine was introduced into clinical practice in 1970 and has a mechanism of action and pharmacologic effects that differ greatly from the classic anesthetic drugs. The anesthetic state is unique because it does not encompass the usual signs and stages of anesthesia with a typical CNS depressant. It produces a cataleptic state in which the patient feels separated from the environment and has profound analgesia and amnesia yet retains most protective reflexes. This ketamine-induced anesthetic state was coined *dissociative anesthesia*, a concept described by Corssen and Domino.[118]

Chemical Structure

The structural formula for ketamine is shown in Figure 9-1. The chemical structure of ketamine is 2-(O-chlorophenyl)-2-(methylamino)cyclohexanone. It has a pK_a of 7.5, is partially water soluble, and is slightly acidic (pH 3.5 to 5.5). Ketamine is an optically active drug with a chiral center that exists as two optical isomers.[119] A racemic mixture is available in the United States and the S(+) isomer is available elsewhere. The S(+) isomer was believed to have a better safety profile, but the advantages of this pure enantiomer are minor.[120]

Mechanisms of Action

Ketamine causes antagonism at *N*-methyl-D-aspartate amino acid (NMDA) receptors in the brain, resulting in a selective depressant effect on the medial thalamic nuclei that is responsible for blocking afferent signals of pain perception to the thalamus and cortex. The primary site of the analgesic action of ketamine is the thalamoneocortical system. Ketamine has been shown to enhance opioid-induced analgesia and prevent hyperalgesia.[121] The NMDA receptor is a ligand-gated ion channel where anions Ca^{2+} and Na^+ are voltage dependent. L-glutamate, an amino acid, is probably the most important excitatory neurotransmitter in the CNS. At the NMDA receptor, it causes the opening of the ion channel. A rapid influx of Na^+, Ca^{2+}, and K^+ results in the depolarization of the normally negative postsynaptic membrane that initiates the action potential. Ketamine is a noncompetitive antagonist at this receptor.[122,123] Afferent impulses are transmitted to cortical regions of the brain but are not interpreted, so responses to visual, auditory, and pain stimuli are inappropriate.[124] Although cortical association areas are depressed, the limbic system, which is thought to cause excitatory behavior, is simultaneously activated. Ketamine also has effects on opiate, monoamine, cholinergic, purinergic, and adenosine receptors.[125,126] It inhibits tumor necrosis factor-alpha (TNF-alpha) and interlukin-6 (IL-6) gene expression, which may account for the antiinflammatory and antihyperanalgesic effects.[127,128] The NMDA receptor is shown and described in Figure 9-7.

The analgesia produced by ketamine has a spinal cord component. By injecting bradykinin intraarterially as a noxious stimuli, Nagasaka et al.[129] were able to demonstrate that ketamine blocked the stimulated excitatory activity of wide-dynamic-range neurons in the dorsal horn, thereby preventing transmission of noxious stimuli to the brain.

Metabolism

Hepatic microsomal enzyme systems are responsible for the biotransformation of ketamine. The primary pathway for ketamine metabolism by the cytochrome P-450 system is demethylation to form the metabolite I, norketamine. Hydroxylation of norketamine occurs at one of two positions in the cyclohexone ring to form hydronorketamine metabolites I, II, and III. These metabolites form a glucuronide derivation via conjugation to produce a more water-soluble compound that is eliminated primarily via renal excretion. Thermal dehydration forms dehydroxynorketamine, a cyclohexene derivative (metabolite II).[67,130]

The pharmacologic activity of the metabolite norketamine is approximately 20% to 30% of the activity of ketamine. The activity of the other metabolites is unknown.[131]

Pharmacokinetics

The distribution kinetics of ketamine follows a two-compartment model. Ketamine is able to cross the blood-brain barrier quickly to achieve rapid pharmacologic effect.[132] The onset of a standard 2 to 2.5 mg/kg dose is slower than propofol or etomidate, and it can take 3 to 5 minutes to achieve clinical anesthesia. Reawakening usually occurs within 15 minutes; however, there is wide patient variability. A much longer duration can be seen with high or repeat doses. Ketamine is protein bound approximately 12%. Like other induction drugs, brain concentrations decrease rapidly as ketamine is redistributed from the central compartment to peripheral tissue compartments. Redistribution to low-blood-flow tissue compartments accounts for the termination of drug effect and return to consciousness. The slow elimination half-life of the drug is the result of hepatic metabolism and excretion. A large amount of ketamine remains in peripheral tissues as active drug and may be responsible for prolonged or cumulative effects.[133] The elimination half-life is 2 to 3 hours. Hepatic extraction of ketamine is high

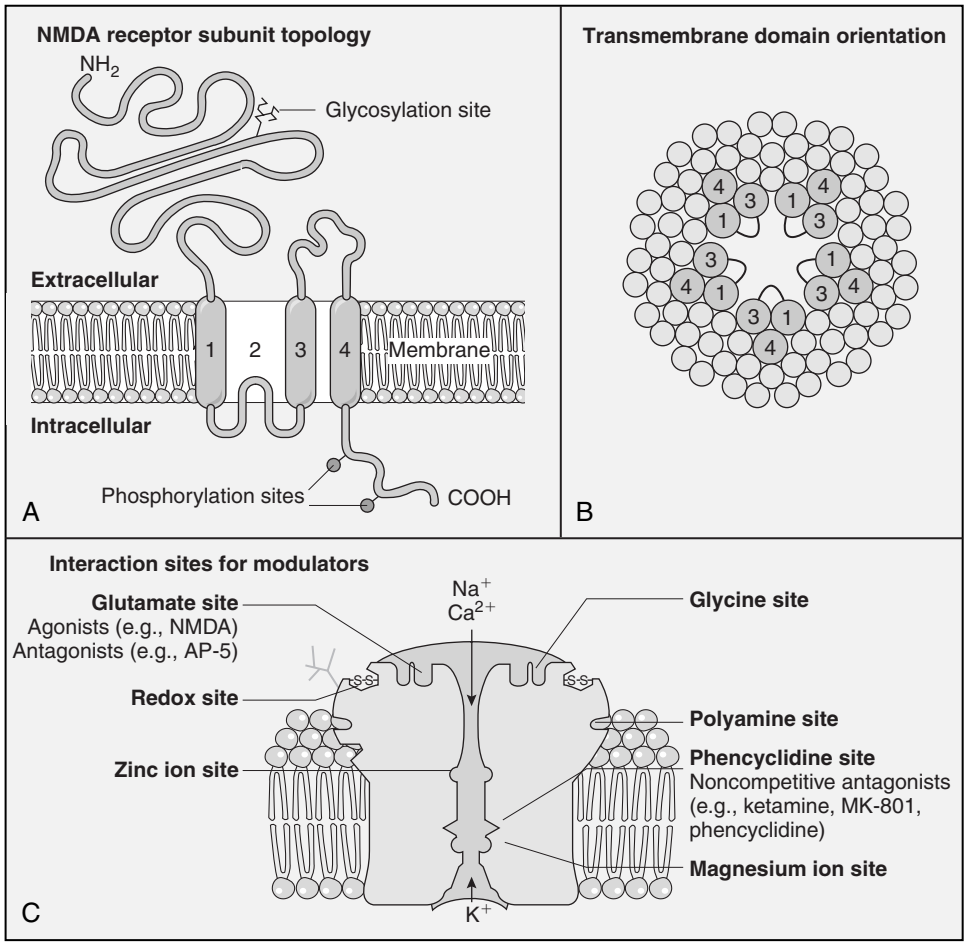

FIGURE **9-7** The *N*-methyl-D-aspartate amino acid (NMDA) receptor. **A,** The NMDA NRI receptor has three transmembrane segments and a fourth hydrophobic segment *(designated 2)* that loops into the membrane without traversing it. Mutation studies suggest that this loop is the putative channel-lining segment and that blockade by dizocilpine (MK-801), phencyclidine, and ketamine occurs through binding to a site that overlaps the Mg^{2+} site in the pore. The C-terminal domain undergoes phosphorylation, which regulates channel activity and mediates interactions with intracellular anchoring proteins. **B,** Transmembrane hydrophobic segments interact to form a central ion-conducting pore lined by the second hydrophobic segments. The stoichiometry of the heterooligomer is not known but may be four or five (as shown), by analogy with the homologous nicotinic cholinergic receptor. **C,** The NMDA receptor gates a cation channel that is permeable to Na^+, Ca^{2+}, and K^+ and is gated by Mg^{2+} in a voltage-dependent fashion. Agonists (glutamate, NMDA) and the coagonist glycine, required for full activation, bind to the extracellular domain. *(From Hemmings HC, Hopkins PM, (eds):* Foundations of Anesthesia Basic and Clinical Sciences*, 2nd ed. St Louis: Mosby; 2006.)*

because the mean total body clearance is approximately the same as the hepatic blood flow.[134] Ketamine elimination is therefore dependent on hepatic blood flow. Pharmacokinetic values remain consistent with analgesic and anesthetic doses of ketamine, which implies that distribution of ketamine is not dose dependent. Anesthetic levels are present with plasma levels of 640 to 1000 mcg/mL, and analgesic levels are present with plasma ketamine concentrations of 100 to 150 mcg/mL (see Table 9-2).[130]

Intramuscular and Oral Route. Given intramuscularly, ketamine reaches peak plasma concentrations within 22 minutes.[135] Dosages range from 4 to 6 mg/kg.[122] The onset of anesthetic effects is seen within 5 to 15 minutes depending on dose. Analgesic doses of ketamine (0.44 mg/kg) can be used for painful procedures without causing loss of consciousness and psychic disturbances.[67] After intramuscular administration, approximately 93% of the drug is bioavailable.[136] A consideration with the intramuscular route is the delayed onset of anesthesia. Ketamine can also be used orally in doses of 10 mg/kg. It is usually mixed in cherry syrup or soda to facilitate ingestion. Onset is 10 to 20 minutes. Box 9-5 gives complete dosing information.

Pharmacodynamics

Central Nervous System Effects. Ketamine produces a dissociative state of anesthesia, so called because the patient appears to be dissociated from the environment. The onset of anesthesia is slower than with propofol or etomidate and may make judgments regarding the onset of sleep and analgesia difficult. In the dissociative state, as originally described by Corssen,[67] the patient is cataleptic: the eyes remain open, the pupils are reactive to light, the corneal reflexes are intact, and horizontal nystagmus is present. Lacrimation and eye blinking continue, and salivary gland secretions are increased. Airway reflexes also remain intact (e.g.,

BOX **9-5**

Recommendation Doses of Ketamine

Premedication
- A benzodiazepine such as midazolam is administered if patient status allows. An antisialagogue may also be given to decrease secretions.

Induction of Anesthesia
- Ketamine 2-4 mg/kg IV, or 4-6 mg/kg IM (Oral dose is 10 mg/kg).

Maintenance of Anesthesia
- Ketamine 15-45 mcg/kg/min (1-3 mg/min) by continuous IV infusion or 0.5-1.0 mg/kg supplemental IV doses as needed.

Sedation and Analgesia
- Ketamine 0.2-0.8 mg/kg IV (over 2-3 min) followed by a continuous ketamine infusion (5-120 mcg/kg/min) 10-20 mg may produce preemptive analgesia.

IM, *Intramuscular;* IV, *intravenous*.

laryngeal reflex, pharyngeal reflex, coughing, sneezing, and swallowing). Skeletal muscle tone is increased, and occasional purposeless movements occur that are unrelated to painful stimuli.

Because the usual signs of anesthesia are not evident with ketamine, movement in response to painful stimuli is often required for judgments of adequate anesthesia. After administration of a single dose, full reorientation to person, place, and time takes place in 15 to 30 minutes, though as noted earlier, wide variability in durations have been noted.[137] Ketamine is a profound analgesic that has a preference for skin, bone, and joint pain. Analgesia occurs with subanesthetic doses, and it is widely used for sedation in combination with low doses of benzodiazepines, propofol, and other analgesics.[138,139]

Cerebral blood flow (CBF) and regional and possibly global $CMRO_2$ and ICP are increased by ketamine. The effect on glucose utilization varies by brain region.[140-142] The response of cerebral vessels to carbon dioxide is left intact. For these reasons ketamine has traditionally been thought to be contraindicated in patients with a head injury or an increased ICP. Recently, however, it has been noted that ketamine can be used safely in neurologically impaired patients under conditions of controlled ventilation, coadministration of a GABA receptor agonist such as midazolam or propofol, and avoidance of nitrous oxide.[141] Trauma patients with multiple injuries may still benefit from the favorable cardiovascular effects while avoiding untoward neurologic adverse actions.[139] Ketamine produces atypical anesthesia; thus EEG patterns also differ from standard anesthetics. On loss of consciousness and onset of analgesia, ketamine induces a transition from alpha to theta waves (slow waves with moderate to high amplitude) on the EEG. Alpha waves do not reappear until after consciousness returns and analgesia is lost.[124,143] Ketamine alone does not decrease the bispectral index (BIS) even when patients are unconscious. Several researchers have in fact noted an increase in BIS levels when ketamine is added to a propofol, fentanyl, or sevoflurane anesthetic.[144-146] Ketamine does not alter auditory evoked potentials (AEPs), mid-latency auditory evoked potential (MLAEP), or A-line autoregressive index monitors based on MLAEPs.[143] Ketamine appears advantageous for use in ECT.[147]

Ketamine anesthesia emergence is associated with psychic disturbances immediately on return of consciousness.[148] These emergence reactions are the result of visual, auditory, proprioceptive, and confusional illusions. Descriptions of this phenomenon include vivid illusions, sensations of drunkenness, delirium, restlessness, altered states of consciousness, extracorporeal sensations, and combativeness.[149] The onset occurs with the first verbal contact and usually resolves in a few hours with full return of orientation to person, place, and time. The incidence of emergence reactions is approximately 12%.[150] The incidence appears to be influenced by age, dose, gender, and psychological predisposition and concurrent medications. Recurrent dreams have been reported to occur weeks after a ketamine anesthetic.[151] The benzodiazepines diazepam, lorazepam, and midazolam were found to significantly decrease the incidence of these reactions. Subanesthetic doses of ketamine are being used for short-term treatment of acute and chronic pain. Low doses of ketamine are being used for sedation, postoperative pain relief, analgesia during regional or local anesthesia, and opioid-sparing effect.[150] Emergence reactions with low-dose ketamine are less frequent, but vivid dreaming may still occur. The use of positive mood elevating suggestion helps reduce the recall of unpleasant dreaming.[151,152] Ketamine has little effect on postoperative nausea and vomiting (PONV). Subanesthetic doses used for analgesia may reduce opioid requirements.[153]

Cardiovascular Effects. Ketamine, unlike other intravenous anesthetics, acts as a circulatory stimulant, producing increases in systemic blood pressure, heart rate, cardiac contractility and output, and central venous pressure.[148] Systemic vascular resistance responded differently among patients undergoing cardiac catheterization and angiography (±25%), possibly because of patient variability in autonomic tone and disease states. Other studies have failed to show significant effects in systemic vascular resistance but have found evidence of an increase in pulmonary vascular resistance (42%), pulmonary artery pressure (47%), and right ventricular stroke work. These values persisted throughout the 12-minute measurement period, although they were somewhat decreased (pulmonary vascular resistance 42% at 3 to 5 minutes and 25% at 12 minutes; mean pulmonary arterial pressure 47% at 3 to 5 minutes and 23% at 12 minutes). In patients with congenital heart disease and increased pulmonary pressure and resistance, ketamine administration did not adversely affect myocardial function (ejection fractions remained constant).[154]

Ketamine administration causes an increase in myocardial contractility, thereby affecting the myocardial oxygen balance. This increase in myocardial oxygen consumption has not been shown to cause inadequate myocardial perfusion, because a concomitant rise in coronary artery perfusion occurs.[154]

Ketamine-induced activation of the sympathetic nervous system that results in endogenous catecholamine release is believed to be one of the mechanisms for the cardiostimulatory properties experienced after administration of the drug. Injection of ketamine directly into the CNS via the carotid artery causes an immediate increase in blood pressure, heart rate, and cardiac output.[155] The positive inotropic effect of ketamine also results from an inhibition of neuronal and extraneuronal uptake of norepinephrine.[156] The in vitro negative inotropic effects of ketamine are the result of a decrease in the available calcium ions (Ca^{2+}) intracellularly, caused by an interference with Ca^{2+} delivery mechanisms (net transsarcolemmal Ca^{2+} influx).[157] When the positive inotropic effects of ketamine are blocked, the negative inotropic effects predominate and may result in decreased blood pressure and cardiac output. This phenomenon may be seen clinically in the critically ill patient who, as a result of protracted illness, has decreased available catecholamine stores and limited ability to compensate. With an intact sympathetic nervous system, the positive inotropic effects dominate and counteract the negative inotropic effects. By

decreasing sympathetic responses, some inhalation anesthetics are able to block the cardiovascular effects of ketamine to produce a decrease in systemic blood pressure and cardiac output.[158] The cardiovascular stimulation produced by ketamine may be deliberately decreased by the prior administration of benzodiazepines in patients in whom that response should be avoided.[148]

Ketamine has been used successfully in patients who are hemodynamically compromised because of shock, trauma, debilitation, or hypovolemia.

Changes in systemic blood pressure are dose related; systolic and diastolic blood pressures increase when larger doses of ketamine are administered (0.5 to 2.0 mg/kg). However, the heart rate response to different dosages reaches a plateau, with no significant change in rate occurring between doses of 0.5 and 2 mg/kg.

Ketamine has been used successfully for both pediatric and adult cardiac surgery patients with congenital and acquired disease processes.[154,159] The cardiac and respiratory actions of ketamine are summarized in Table 9-5.

Respiratory Effects. The effects of ketamine on the respiratory system are minor and of short duration. Ventilation is generally preserved, as is normal respirations. Transient apnea upon initial administration may occur with rapid administration of larger doses although it is rare. Arterial blood gases remain within normal limits, and the central response to carbon dioxide is maintained.[148]

Ketamine increases pulmonary compliance and decreases pulmonary resistance in patients with bronchospastic disease. It is the only active bronchodilating induction agent and the agent of choice in any patient with active asthma who requires surgery. Increased catecholamine levels stimulated by ketamine, along with bronchial smooth muscle relaxation and vagolytic actions, are thought to be the reason for the bronchodilating effects of the drug. Tracheal, bronchial, and salivary muscle gland secretions are increased with ketamine, which may require the use of an antisialagogue. Atropine is superior to glycopyrrolate for this application.[160] The muscle tone of the tongue and jaw is retained, and protective pharyngeal and laryngeal reflexes are left intact. Coughing, gagging, swallowing, and vomiting reflexes remain intact in response to airway stimulation, although some diminution may be present and silent pulmonary aspiration has occurred in some patients (see Table 9-5).

Intraocular Effects. Research into the effects of ketamine administration on intraocular pressure (IOP) has yielded varied results.[161-164] Measurement techniques and adjunctive anesthetics may play a role in the conflicting reports. Ketamine usually increases IOP, but the effect appears dose dependent.[165] A 6 mg/kg dose raises IOP but a 3 mg/kg dose does not. Ketamine causes nystagmus, increased muscle tone, and muscle spasms, which may not be appropriate for some ophthalmic procedures.[166] It blocks oculocardiac reflex-induced arrhythmias better than propofol during sevoflurane anesthesia for strabismus surgery.[167] The common clinical effects of ketamine are shown in Box 9-6.

Obstetric and Pediatric Use. Ketamine can be used in obstetrics for analgesia or anesthesia. It is a highly lipid soluble and readily crosses the placenta into fetal tissue. As an induction agent, ketamine in doses of 0.5 to 1 mg/kg produces rapid anesthesia without compromising uterine tone, uterine blood flow, or neonatal status at delivery. For analgesia, 0.25 mg/kg of ketamine provides pain-related relief, airway stability, and a sustained maternal blood pressure and uninhibited uterine contractions. Use of doses reserved for surgical procedures (2 to 2.5 mg/kg) results, however, in a depressed neonate on delivery.[168,169] Decreasing this dose to 0.2 to 1 mg/kg spared the newborn this CNS depression because of the rapid redistribution of the drug in the mother and less fetal transfer.

Ketamine is a very popular drug for neonates and children. Sedation, analgesia, amnesia, cardiac and respiratory stability, and a short duration offer advantages in many procedures in these patients.[170] Clinicians have noted it may be the agent of choice for children with a difficult airway or reactive airway diseases

BOX 9-6

Primary Clinical Characteristics and Effects of Ketamine

- Phencyclidine derivative
- Causes unconsciousness; amnesia referred to as *dissociative anesthesia*
- Increases cerebral metabolic rate, cerebral blood flow, and intracranial pressure
- Causes nystagmus; increased intraocular pressure
- Moderate analgesic
- Increases blood pressure and pulse
- Potent bronchodilator
- Maintains respirations and airway reflexes (NOTE: A period of initial apnea may occur, especially with high doses and rapid administration.)
- Increases salivation and respiratory secretions
- Increases muscle tone
- Associated with emergence delirium, nightmares, and hallucinations
- Requires caution in patients with hypertension, angina, congestive heart failure, increased intracranial pressure, increased intraocular pressure, psychiatric disease, and airway problems

BOX 9-7

Clinical Uses of Ketamine

Induction of Anesthesia in High-Risk Patients
- Shock or cardiovascular instability
- Hypovolemia
- Cardiomyopathy
- Trauma
- Bronchospasm

Obstetric Patients

Induction of General Anesthesia
- Severe hypovolemia/trauma
- Acute hemorrhage
- Acute bronchospasm

Low Dose for Analgesia
- To supplement regional anesthetic techniques
- As an additive to opioids in patient-controlled analgesia

Adjunct to Local and Regional Anesthetic Techniques
- For sedation and analgesia during intravenous sedation or when a regional block is used
- To supplement an inadequate block

Outpatient Surgery
- For brief diagnostic and therapeutic procedures
- To supplement local and regional block techniques

Use Outside the Operating Room
- In burn units (e.g., débridement, dressing changes)
- In emergency rooms for minor procedures
- In intensive care units (e.g., sedation, painful procedures)
- During radiology procedures

such as asthma. It can be used intramuscularly or orally for an uncooperative child requiring intravenous access.[171]

A controversy exists with regard to anesthetic neurotoxicity caused by ketamine. Neuroapoptosis has been noted in several animal models when ketamine is used in the developing brain.[172] How this relates to the use of ketamine and other anesthetics in newborns and children is unclear. This is an area of intense research interest.[173,174]

Clinical uses of ketamine are given in Box 9-7. Recommendations for using ketamine as a sedative, analgesic, or anesthetic during the postoperative period are listed in Box 9-5. Key points of ketamine pharmacology are given in Box 9-8.

BENZODIAZEPINES

Benzodiazepines are used in many clinical situations due to their desirable pharmacologic properties, including sedation, hypnosis, muscle relaxation, anxiolysis, anticonvulsant effects, and amnesia. They also have a low incidence of side effects. Benzodiazepines used clinically in the United States are listed in Table 9-7.

BOX 9-8

Key Points for Ketamine Anesthesia

- Site of action of ketamine appears to be the NMDA receptor, where it inhibits glutamate as a noncompetitive antagonist. Other actions are likely.
- Ketamine produces an anesthetic state referred to as *dissociative anesthesia.*
- Onset of effect is relatively slow compared to other induction drugs (2-5 min).
- Ketamine produces a rise in cerebral perfusion pressure.
- Ketamine is a bronchodilator, preserves airway reflexes, and increases secretions.
- Emergence phenomena—including vivid dreams, floating sensations, and delirium—can occur after ketamine administration. They are more common in adults than children and are reduced by benzodiazepine or other sedative administration.
- Ketamine is an indirect sympathomimetic, releasing catecholamines. This action accounts for the cardiac stimulation and bronchodilation

NMDA, N-*methyl*-D-*aspartate*.

Although similar compounds were first synthesized in 1933, the first benzodiazepine synthesized was chlordiazepoxide (Librium) in 1955. It was not introduced into clinical practice until 1960, when it was found to have antianxiety and hypnotic effects. Diazepam was synthesized in 1959, and its metabolite, oxazepam (Serax), was synthesized in 1961. Lorazepam (Ativan) was derived from oxazepam in 1971.[175] The last benzodiazepine to be developed was midazolam (in 1976, by Fryer and Walser), which was the first of the benzodiazepine group to be formulated with anesthesia as its target clinical use. The benzodiazepines available for clinical use have many similarities but there are differences in potencies, pharmacokinetics, and intensities of clinical properties. Midazolam is widely used in anesthesia and other areas as an anxiolytic, sedative, hypnotic, and amnestic drug. It is rarely used to induce anesthesia due to a prolonged effect at the high doses required. Diazepam and lorazepam, which are also available as intravenous preparations, are occasionally used as well. They are usually reserved for inpatients requiring prolonged sedation.

Chemical Structure and Pharmaceutics

The chemical structures of the benzodiazepines share some common features: (1) the benzodiazepine ring system; (2) the presence at positions 1 and 4 of two nitrogen atoms; (3) a phenyl group at position 5; and (4) an electronegative group at position 7 (see Figure 9-1).[175]

Midazolam has a unique chemical structure in comparison with the other benzodiazepines. The imidazole ring is responsible for its basic formulation, which permits the preparation of salts that are water soluble at a pH of 4.0. In a chemical reaction that depends on the environmental pH, the diazepine ring opens reversibly between positions 4 and 5. Midazolam is water soluble and does not require a lipoidal vehicle (such as propylene glycol) for parenteral use. Minimal if any side effects of venous irritation or phlebitis occur. Once in physiologic solution with a pH greater than 4.0, the diazepine ring closes, and midazolam becomes lipophilic, an effect that accounts for its rapid onset of action.[175,176]

Injectable midazolam is compounded with 0.8% sodium chloride and 0.01% disodium edetate and 1% benzyl alcohol as a preservative. A pH of 3 is adjusted with hydrochloric acid and, if necessary, sodium hydroxide. Each milliliter of preparation contains 1 or 5 mg of midazolam. An oral solution is also available for pediatric sedation.

In each milliliter of solution of diazepam, 0.4 mL of propylene glycol and 0.1 mL of ethyl alcohol are present as solvents, 0.015 mL

TABLE 9-7 Benzodiazepines Used Clinically in the United States

Generic Name	Trade Name	Half-Life (hr)	Clinical Application
alprazolam	Xanax	12-15	Anxiolysis
chlordiazepoxide	Librium	8-18	Treatment of alcohol withdrawal, etc.
clonazepam	Klonopin	18.7-39	Treatment of epilepsy
clorazepate	Tranxene	2.4	Treatment of epilepsy and alcohol withdrawal
diazepam	Valium	36-50	Sedation; induction and maintenance of anesthesia
estazolam	ProSom	14	Treatment of insomnia
flurazepam	Dalmane	2-3	Treatment of insomnia
lorazepam	Ativan	10-22	Anxiolysis and sedation
midazolam	Versed	1.7-2.6	Sedation; induction and maintenance of anesthesia
oxazepam	Serax	3-21	Anxiolysis
quazepam	Doral	25-41	Treatment of insomnia
temazepam	Restoril	10-21	Treatment of insomnia
triazolam	Halcion	2-3	Treatment of insomnia
flumazenil	Romazicon	0.7-1.3	Reversal of benzodiazepine agonists

of benzyl alcohol is present as a preservative, and sodium benzoate or benzoic acid in water is present as a buffer. Each milliliter contains 5 mg of diazepam and the pH is 6.2 to 6.9.[175]

Each milliliter of lorazepam solution contains 0.18 mL of polyethylene glycol and 2% benzyl alcohol, a preservative. Lorazepam is available in solutions of 2 or 4 mg/mL (see Table 9-1 for the preparations of the benzodiazepines).[176]

Mechanisms of Action

The clinical effects of benzodiazepines are a result of an agonist action at what are termed *benzodiazepine receptor binding sites* on the $GABA_A$ receptor throughout the CNS. Gamma amino butyric acid is the major inhibitory neurotransmitter in the CNS. The receptor complex is composed of a pentameric array of protein subunits that contain binding sites for GABA itself, benzodiazepines, barbiturates, ethanol, propofol, and many other sedatives. The $GABA_A$ receptor exerts its actions by modulating chloride channels. Many different families of the $GABA_A$ receptors exist and these subtypes vary in location, function, and pharmacologic effects. When these binding sites are occupied by an agonist, GABA receptor modulation increases the frequency of chloride channel opening, which results in postsynaptic membrane hyperpolarization, and neuronal transmission is inhibited.[177-179]

Three classes of ligands that bind to the benzodiazepine receptors have been identified: agonists, antagonists, and inverse agonists. Midazolam, diazepam, and lorazepam are receptor agonists that allosterically increase binding affinity for GABA, resulting in the opening of the chloride channels. Antagonists (e.g., flumazenil) form reversible bonds with the agonist receptor but produce no agonist activity. Inverse agonists cause CNS stimulation by interfering with GABA transmission, which is inhibitory.[176,180] Because the benzodiazepines work allosterically to enhance endogenous GABA binding and not directly, there is a physiologic ceiling to their effect. Their safety and low toxicity is attributed to this built-in limit on their effect.[181] Peripheral benzodiazepine binding sites, not associated with the $GABA_A$ receptor, exist in the mitochondrial membranes of many cells and may modulate cardiovascular and immune function (see Figure 9-5).[182]

Pharmacokinetics

The introduction of new generations of benzodiazepines since their initial release in the 1960s has largely focused on chemical alterations that improve the clinical pharmacokinetics. These changes have resulted in simplified metabolism with fewer active metabolites and thus more predictable time courses. The elimination pharmacokinetics of benzodiazepines can be examined in both two- and three-compartment models. Benzodiazepines have been classified according to their elimination half-lives. These classifications take into account the elimination half-lives of both the parent drug and the active metabolites. Diazepam is long acting ($T_{½}$ greater than 24 hours) lorazepam is intermediate ($T_{½}$ 6-24 hours) and midazolam is short acting ($T_{½}$ less than 6 hours).[183] The pharmacologic effects of the benzodiazepines, as with the other anesthesia induction drugs, are terminated primarily by redistribution of the drug out of the CNS.

Their pharmacokinetics are influenced by age, gender, obesity, race, and hepatic and renal status to varying degrees. The pharmacokinetics of the three intravenous benzodiazepines are similar with a few important differences. Midazolam exhibits a higher clearance rate and therefore is shorter acting. Lorazepam is less dependent on hepatic cytochrome enzymes for metabolism because it is undergoes phase 2 conjugation to a significant extent. Liver disease as well as hepatic enzyme induction or inhibition therefore does not influence lorazepam as much as other drugs. Diazepam has a very slow distribution half-life, which limits its usefulness as an acceptable induction agent. Diazepam is extremely lipid soluble, a characteristic that promotes extensive distribution to the tissues. The volume of distribution is large, a characteristic of all benzodiazepines. Also characteristic is extensive protein binding, which theoretically may be affected by disease states that decrease plasma protein levels. All three drugs are primarily bound to albumin. Diazepam is 99% protein bound, lorazepam 85% to 90%, and midazolam 95%. The total body clearance of diazepam is 0.24 to 0.53 mL/min/kg and is totally dependent on hepatic metabolism.

Diazepam exhibits a near-linear relationship between elimination half-life and patient age.[184] Pharmacokinetics in the elderly are altered as a result of slowed drug absorption; increased percentage of adipose tissue in body mass; decreased plasma proteins, hepatic blood flow, and metabolism; and decreased cardiac output and circulation time. A prolonged circulation time allows for a slower onset and a higher plasma drug level that remains in the CNS longer before it redistributes; this phenomenon exaggerates the effects of the drug.[185]

Hepatic microsomal enzymes are responsible for the metabolism of diazepam. Diazepam is demethylated to dimethyl diazepam (nordiazepam), which is an active metabolite that, although less potent, is responsible for prolonged drug effect as a result of its slower metabolism. Diazepam can also be hydroxylated to 3-hydroxydiazepam, which is then demethylated to oxazepam, which is also pharmacologically active and commercially marketed. The termination of action of diazepam is caused by redistribution and eventual metabolism. The terminal half-life is 20 to 50 hours, much longer than that of other benzodiazepines and induction agents.

Pharmacodynamics

Central Nervous System Effects. All three intravenous drugs produce the characteristic dose-dependent CNS depressant effects of the benzodiazepines, from anxiolysis to sedation, sleep and with high enough doses of anesthesia. They all produce anticonvulsant effects, amnesia, and muscle-relaxing properties and are useful for inhibiting alcohol withdrawal symptoms. They are not antiemetic; however, lorazepam is used for its sedative, amnestic, and anxiolytic effects in reducing anticipatory chemotherapy-induced nausea and vomiting.

At higher doses they reduce $CMRO_2$ and CBF. They increase the threshold to local anesthetic-induced seizure activity, and midazolam is frequently used as a premedicant in patients having regional anesthesia requiring large volumes of local anesthetics.

All benzodiazepines produce dose-related anterograde amnesia. They generally do not produce reliable retrograde amnesia. Intravenous administration of midazolam produces anterograde amnesia in low doses. Amnesia occurs within 2 to 5 minutes of administration and remains for 20 to 30 minutes.[186-189] Deficits are seen in both short- and long-term memory. These include interfering with episodic, semantic, and iconic memory function.

Benzodiazepines also possess anticonvulsant activity and are effective in the treatment of status epilepticus and sedative-hypnotic withdrawal syndromes. EEG changes include disappearance of the alpha rhythm and the onset of higher-frequency beta-rhythm activity.[190] Tolerance, dependence, and withdrawal

BOX **9-9**

Alpha$_2$ Receptors Subtype and Functions

Alpha-2A receptors (α_{2A})
- Presynaptic feedback
- Inhibition of norepinephrine release
- Sedation
- Hypnosis
- Analgesia
- Neuroprotection
- Hyperglycemia
- Diuresis
- Sympatholysis
- Hypotension
- Anticonvulsant
- Hypothermia
- Modulation of insulin secretion

Alpha-2B receptors (α_{2B})
- Presynaptic feedback
- Inhibition of norepinephrine release
- Vasoconstriction, antishivering
- Analgesia
- Analgesic effect of nitrous oxide
- Hypertension
- Placenta angiogenesis

Alpha-2C receptors (α_{2C})
- Presynaptic feedback
- Inhibition of norepinephrine release
- Learning and stress responses
- Feedback inhibition of adrenal epinephrine release
- Modulation of insulin secretion

symptoms occur and vary among the benzodiazepines. Midazolam produces synergistic CNS, cardiovascular, and respiratory effects with fentanyl (see Table 9-4).

Cardiovascular Effects. In commonly used clinical doses the benzodiazepines have minimal cardiovascular effects. A decrease in blood pressure is occasionally seen when midazolam is given with opioids in patients with heart disease or the elderly.

Respiratory Effects. Benzodiazepines produce dose-dependent respiratory depression. Midazolam is the most respiratory depressing. Some respiratory depression occurs with diazepam, as evidenced by a decrease in minute ventilation and slope of the carbon dioxide response curve.[191] Increased respiratory depression and apnea are possible when benzodiazepines are combined with other CNS depressants such as opioids.

Contraindications and Precautions

The most common adverse effects of the benzodiazepines are unexpected respiratory depression and oversedation. In the doses used currently, other adverse actions are rare. They should be avoided in patients with acute porphyrias.

Uses

Midazolam is the standard drug given for preoperative medication. Its rapid onset and short duration and half-life and lack of adverse effects make it ideal for use as a preoperative anxiolytic, sedative, and amnestic.[192]

Flumazenil

Flumazenil is the sole benzodiazepine antagonist available in the United States (see Figure 9-1). It is a competitive antagonist with a high affinity for the receptor site. It produces prompt and effective specific reversal of benzodiazepine agonist effects after anesthesia and overdose.[193,194] As with any drug antagonist, its antidotal efficacy depends on the amount of free benzodiazepines at the receptor sites. Its relatively short duration and half-life make the possibility of resedation clinically relevant, especially in overdose situations. A slow titration of 0.2-mg doses (2 mL) is given intravenously (up to 1 mg) until the desired level of consciousness is achieved. Doses rarely exceed 1 mg for the reversal of midazolam-induced sedation and 3 mg for suspected benzodiazepine overdose. Onset is 1 to 2 minutes and duration of action is 45 to 90 minutes depending on total flumazenil dose and the amount of agonist requiring reversal. Withdrawal reactions are possible in patients who are benzodiazepine dependent, and its use in these patients is contraindicated. Flumazenil does not reverse the actions of ethanol or barbiturates.[195] Side effects are rare, although mild anxiogenic effects have been reported.[196] Seizures have been reported in patients with suspected tricyclic and antidepressant overdose, and the use of flumazenil in these situations and in patients with a known history of seizures should be avoided.[197,198]

Dexmedetomidine

The sedative and analgesic effects of alpha-2 (α_2) receptor agonists were long recognized from the use of clonidine and the veterinary anesthetic xylazine. Dexmedetomidine was developed as a more selective α_2 agonist, which allows for greater sedation. There are three main chemical classes of α_2 receptor agonists: the phenylethylates such as methyldopa and guanabenz; the imidazolines such as clonidine, dexmedetomidine, mivazerol, and azepexole; and the oxaloazepines. The imidazolines are used in anesthesia. Stimulation of imidazoline receptors account for the hypotensive side effects. The primary effects of dexmedetomidine are sedation, analgesia, anxiolysis, reduced postoperative shivering and agitation, and cardiovascular sympatholytic actions.[199,200]

Mechanism of Action

Alpha-2 adrenoreceptors are involved in various physiologic functions, particularly in the cardiovascular and central nervous systems. There are three subtypes of α_2 receptors. The subtypes and their putative functions are noted in Box 9-9.[201,202] Dexmedetomidine is highly specific for α_2 versus α_1 receptors at a ratio of 1600:1. Alpha-2 presynaptic receptors function as autoreceptors in the negative feedback loop controlling neurotransmitter release. When α_2 receptors are stimulated by an agonist such as dexmedetomidine, it results in a decreased catecholamine release. The main site of action for the sedative actions of dexmedetomidine is the pontine noradrenergic nucleus the locus coeruleus. The α_2 receptors are G-protein–coupled receptors, which when activated, result in the inhibition of calcium channels, the activation of potassium channels, and the direct modulation of the exocytic release of proteins. This produces hyperpolarization of the cells and thus inhibition.[201,203]

Chemistry and Pharmaceutics

Precedex (dexmedetomidine hydrochloride injection) is a sterile, nonpyrogenic solution for intravenous infusion following

dilution. Dexmedetomidine hydrochloride is the S-enantiomer of medetomidine and is chemically described as (+)-4-(S)-[1-(2,3-dimethylphenyl)ethyl]-1H-imidazole monohydrochloride. Dexmedetomidine HCl is freely soluble in water and has a pK_a of 7.1. Its partition coefficient (n-octanol/water) at pH 7.4 is 2.89. Precedex is supplied as a clear, colorless, isotonic solution with a pH of 4.5 to 7.0. Each 1 mL of Precedex contains 118 mcg of dexmedetomidine HCl (equivalent to 100 mcg dexmedetomidine base) and 9 mg of sodium chloride in water. The solution is preservative free and contains no additives or chemical stabilizers. Prepare by adding 2 mL of dexmedetomidine (100 mcg/mL) to 48 mL of 0.9% sodium chloride injection for a total of 50 mL. The final concentration is 4 mcg/mL. The loading dose is 1 mcg/kg infused over 10 minutes followed by maintenance infusions of 0.2 to 0.7 mcg/kg/hr. It is approved for up to 24 hours use for sedation in critical care and for nonintubated patients requiring sedation for short-term surgical procedures. It is used for numerous off-label applications.

Pharmacokinetics

Dexmedetomidine exhibits a rapid distribution phase with a distribution half-life ($T_{½}$) of approximately 6 minutes; a terminal elimination half-life ($T_{½}$) of approximately 2 hours; and steady-state volume of distribution (Vss) of approximately 118 L. Clearance is estimated to be approximately 39 L/hr. The mean body weight associated with this clearance estimate was 72 kg. Dexmedetomidine exhibits linear kinetics in the dosage range of 0.2 to 0.7 mcg/kg/hr when administered by IV infusion for up to 24 hours. Target concentrations are usually in the range of 0.3 to 0.6 ng/mL. Protein binding to both albumin and α_1 acid glycoprotein is 94%.[204] Dexmedetomidine undergoes almost complete biotransformation with very little unchanged in urine and feces. Biotransformation involves both direct glucuronidation as well as cytochrome P450–mediated metabolism. There are no active metabolites. Similar kinetic data was noted in pediatric patients.[205,206] Onset of action with loading infusion is 10 to 20 minutes, and the duration of action after the infusion is stopped is 10 to 30 minutes.

Central Nervous System Effects. Dexmedetomidine produces a dose-dependent sedation that resembles natural sleep, unlike the classic GABA receptor agonists. Patients do not experience respiratory depression and are readily arousable.[207,208] An advantage of this type of sedation is that procedures requiring "wake up" tests can be more readily accomplished compared to usual anesthetic regimens.[209,210] Dexmedetomidine does not interfere with electrophysiologic monitoring allowing brain mapping during awake craniotomy and microelectrode recording during implantation of deep-brain stimulators.[211] Motor and somatosensory evoked potentials are maintained when added to a desflurane and remifentanil technique.[212] Decreases in the amplitude of motor evoked potentials may occur at high doses.[213] Bispectral index (BIS) values are decreased in a dose-dependent manner to a greater extent than with propofol.[214]

Dexmedetomidine does not change cerebral metabolism ($CMRO_2$). Cerebral blood flow (CBF) is decreased due to cerebral vasoconstriction. This suggests uncoupling between cerebral metabolism and flow due to decreases in central catecholamine turnover. Effects on intracranial pressure are not clinically significant.[215]

The central sympatholytic effects also result in an antishivering action, hypothermia, and a reduction in the neuroendocrine stress response to surgery.[199] A reduction in postoperative agitation and emergence delirium in children and adults is an increasingly used clinical action.[205] A neuroprotective effect has been proposed, but benefits in patients with head injuries remain to be clarified.[216] Reductions in the withdrawal symptoms from sedatives, opioids, and alcohol have been noted.[199] Analgesic- and anesthetic-sparing effects are well documented and are produced at both the brain and spinal cord level. Dexmedetomidine enhances the analgesic effects of nitrous oxide.[217]

Cardiovascular Effects. The main cardiovascular effects of dexmedetomidine are hypotension and bradycardia. This results from CNS alpha receptor stimulation and systemic vasodilation. Occasionally, transient hypertension is seen with rapid initial loading doses or administration of high maintenance doses due to vasoconstriction; however, dose-dependent hypotension is the norm. There is no direct effect on myocardial contractility. There is a reduction in myocardial oxygen demand, an antianginal effect.[199] Transient profound hypertension was noted when using glycopyrrolate to treat dexmedetomidine-induced bradycardia in children and caution is advised when coadministering these drugs.[205]

Respiratory Effects. A unique advantage of dexmedetomidine sedation is that respirations are maintained. Brain respiratory responsiveness to carbon dioxide is normal. Airway patency and reflexes are present or only slightly diminished. These properties allow for convenient use in out-of-operating room procedures and difficult airway situations. Dexmedetomidine completely blocked histamine-induced bronchoconstriction in dogs. It appears beneficial to decrease airway reactivity in patients with chronic obstructive pulmonary disease or asthma.[218] It improves tolerance, agitation, and weaning and lessens the time required for sedation in mechanically ventilated patients.[219,220]

Other Effects. Dexmedetomidine has a mild diuretic effect mediated via $alpha_2$ receptor stimulation. Additional beneficial actions include renal and gastroprotective and antiinflammatory effects. Dexmedetomidine is being widely used for many surgical and diagnostic procedures in both adults and children. Which clinical situations become established as the best places to use this unique drug is still evolving. Some key points for the clinical use of dexmedetomidine are noted in Box 9-10.

BOX 9-10

Key Points for Clinical Use of Dexmedetomidine

- Dexmedetomidine is an $alpha_2$ receptor agonist that results in central sympatholysis.
- Dexmedetomidine sedation allows for an arousable patient to ascertain neurologic status.
- Dexmedetomidine does not interfere with neurologic monitoring.
- Hypotension and bradycardia are the most frequent cardiovascular adverse effects.
- It is useful for procedural sedation.
- Respirations are maintained.
- Reduces postoperative agitation and emergence reactions.

SUMMARY

The availability of a variety of unique intravenous drugs that contain the necessary properties for use in induction has allowed the clinician to tailor the induction to fit the needs of the patient and surgeon. This characteristic has made it much easier to care for an increasingly diverse and complex patient population. Intravenous anesthetics can be chosen with consideration for the health status of the patient, the type of procedure to be performed, and the patient's susceptibility to possible adverse effects to produce the remarkably safe techniques and excellent outcomes achieved today.

Local Anesthetics

◆ *John J. Nagelhout*

CHAPTER 10

Local anesthetics are drugs that reversibly block the conduction of electrical impulses along nerve fibers. Their ability to perform this function depends on various factors, including the nerve or nerves being blocked and the chemical structure and physicochemical properties of the local anesthetic. These drugs have always been used as a major component of clinical anesthesia and are increasingly being used to treat acute and chronic pain in new and innovative ways.

ANATOMY OF THE PERIPHERAL NERVE

To fully address the action of local anesthetics, a brief review of the anatomy and physiology of nerve fibers is appropriate. The axon, an extension of a centrally located neuron, is the functional unit of peripheral nerves. A cell membrane, or axolemma, and intracellular contents, or axoplasm, are the major components of the axon. Schwann cells, whose functions are support and insulation, surround each axon. In unmyelinated nerves, single Schwann cells cover several axons. Conversely, in larger nerves the Schwann cell sheath covers only one axon and has several concentric layers of *myelin*.

Between Schwann cells are periodic segments of nerve that do not contain myelin. These areas, known as *nodes of Ranvier*, are where conduction is propagated. Voltage-gated sodium channels (Na_v) are located in these nonmyelinated segments and are the primary site at which local anesthetics exert their action. Action potentials jump from node to node, and this phenomenon is known as *saltatory conduction*, which significantly facilitates conduction speed along the axon.[1,2] Myelinated nerves are larger, conduct impulses faster, and are more difficult to block with local anesthetics than are unmyelinated nerves[3,4] (Figure 10-1).

Peripheral nerves have structures containing bundles of axons called *fasciculi*. Three layers of connective tissue—the endoneurium, perineurium, and epineurium—also are components of the peripheral nerve.[4,5] The endoneurium, which is a delicate connective tissue composed of longitudinally arranged collagen, surrounds and embeds the axons in the fasciculi. The perineurium, which consists of layers of flattened, overlapping cells, binds a group of fascicles together. The epineurium, which surrounds the perineurium, is composed of areolar connective tissue that functionally holds the fascicles together to form the peripheral nerve.[5] These layers of connective tissue are important because they serve as barriers through which local anesthetics must diffuse if they are to exert their pharmacologic action (Figure 10-2).

NEURON ELECTROPHYSIOLOGY AND THE ACTION MECHANISM OF LOCAL ANESTHETICS

Electrophysiology

Measurement with an electrode placed in the axoplasm of a resting peripheral nerve demonstrates a negative membrane potential of −70 to −90 mV.[3,5] This voltage difference across the neuronal membrane at steady state is called the *resting membrane potential* (Figure 10-3). An ionic imbalance between the axoplasm and the extracellular fluid causes the electrical potential. Several physiologic mechanisms create the ionic gradient; the primary one is an active, energy-dependent process executed by a sodium-potassium pump (Na^+-K^+/ATPase) located in the axolemma.[6,7]

Although the membrane is relatively permeable to the outward diffusion of K^+, an intracellular-to-extracellular K^+ ratio of 150:5 mmol, or 30:1, exists. An important contributor to this concentration difference is the impermeability of the membrane to other cotransported ions such as Na^+.[7] In addition, the movement of K^+ out of the neuron leaves an excess of intracellular negatively charged organic ions. The negative charge results in an electrostatic counterforce that limits K^+ movement out of the neuron.

Two opposing forces influence K^+ movement into and out of the neuron. First, a concentration gradient pushes K^+ outward. Second, an electrostatic gradient, created by the impermeability of the membrane to cations, tends to keep the K^+ in the cell. The net effect of these counterforces is modest movement of K^+ out of the cell, and this movement creates an intracellular negative charge. The Nernst equation expresses the charge created by the K^+ concentration gradient[3]:

$$\text{Membrane potential} = -58 \log \frac{(K^+ 30 \text{ inside})}{(K^+ \text{ outside})}$$

Determination of the resting membrane potential is not as simple as the Nernst equation for K^+ indicates, because Na^+ and chloride (Cl^-) ions have a minor role in establishing the intracellular resting potential.[3]

When an electrical impulse is applied to a resting nerve, the membrane potential is reversed because of the intracellular movement of Na^+. This occurs because of the higher concentration of Na^+ outside the cell and the stimulation-induced increase in membrane permeability to this ion. The sudden influx of Na^+ that occurs in response to stimulation overrides the efflux of K^+ directed at maintaining the resting membrane potential. Once the process has reversed the membrane potential to 20 mV, an outward electrochemical gradient develops; this gradient resists the concentration-dependent, inward diffusion of Na^+.[5] This state of equilibrium causes the Na^+ channels to close. Shortly after Na^+ enters the cell, K^+ channels begin to open, and the ion rapidly diffuses out of the neuron, according to its concentration gradient. The active removal of intracellular Na^+ by the Na^+-K^+ pump and the passive diffusion of K^+ outward restore the resting membrane potential. During repolarization, three Na^+ ions leave the cell for each two K^+ ions that enter[8] (Figure 10-4).

The sequence of events that results in an action potential results from the passage of ions through pores, or "channels," located in the axolemma. These channels, which are composed of globular proteins, have transmural orientation to the phospholipid molecules that constitute the axolemma.[9] Although K^+ and

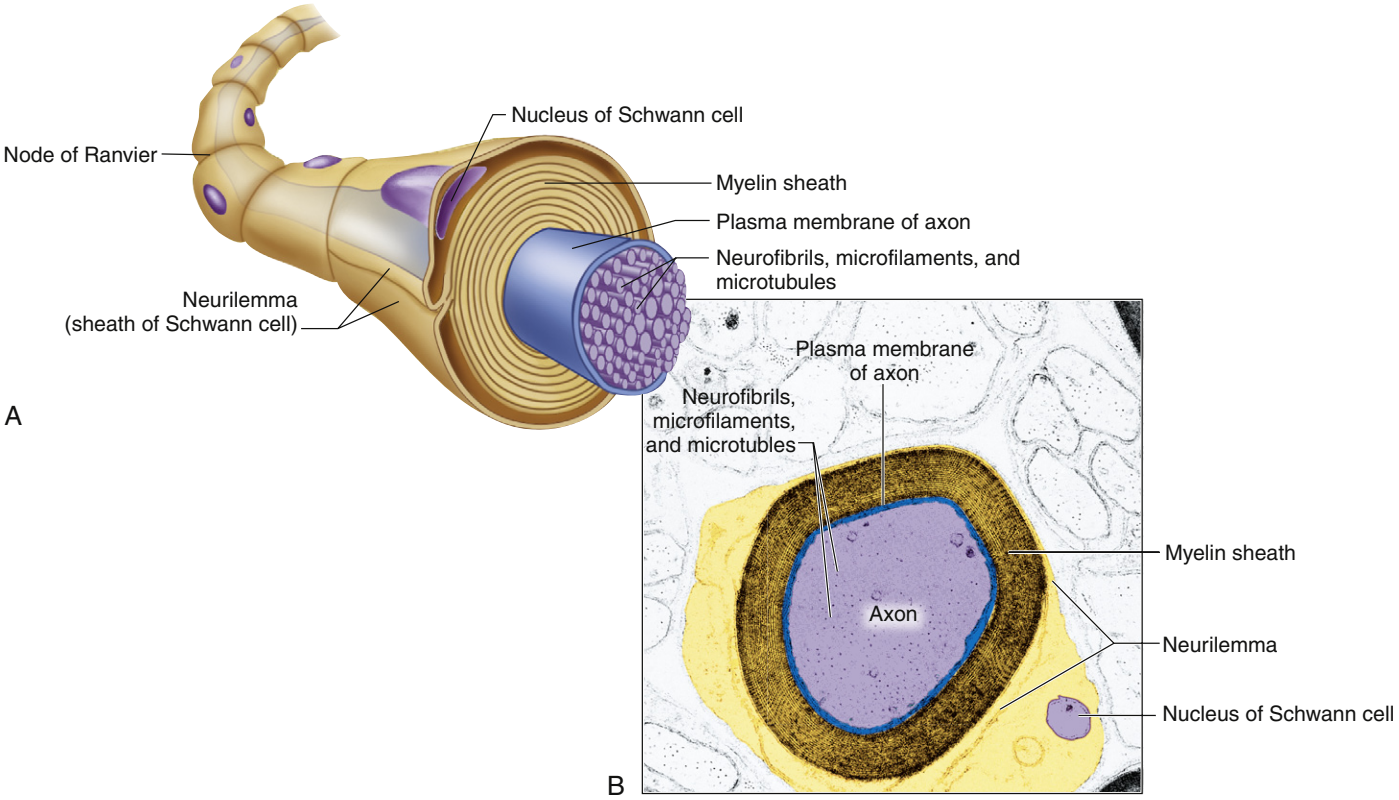

FIGURE **10-1** Myelinated axon. **A,** The diagram shows a cross section of an axon and its coverings formed by a Schwann cell: the myelin sheath and neurilemma. **B,** Transmission electron micrograph showing how the densely wrapped layers of the Schwann cell's plasma membrane form the fatty myelin sheath. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 8th ed. St. Louis: Mosby; 2013:388.)

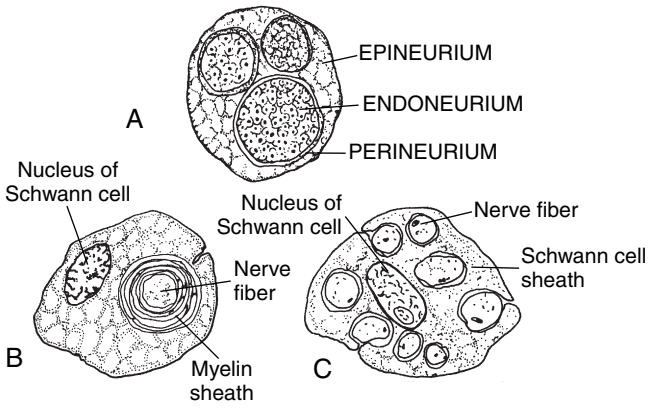

FIGURE **10-2** Transverse sections of a peripheral nerve **(A)** showing the outermost epineurium; the inner perineurium, which collects nerve axons in fascicles; and the endoneurium, which surrounds each myelinated fiber **(B),** and is encased in the multiple membranous wrappings of myelin formed by one Schwann cell, each of which stretches longitudinally over approximately 100 times the diameter of the axon. The narrow span of axon between these myelinated segments, the node of Ranvier, contains the ion channels that support action potentials. Nonmyelinated fibers **(C)** are enclosed in bundles of 5 to 10 axons by a chain of Schwann cells that tightly embrace each axon with but one layer of membrane. (From Miller RD. *Miller's Anesthesia*. Vol 1, 7th ed. Philadelphia: Churchill Livingstone; 2010:918.)

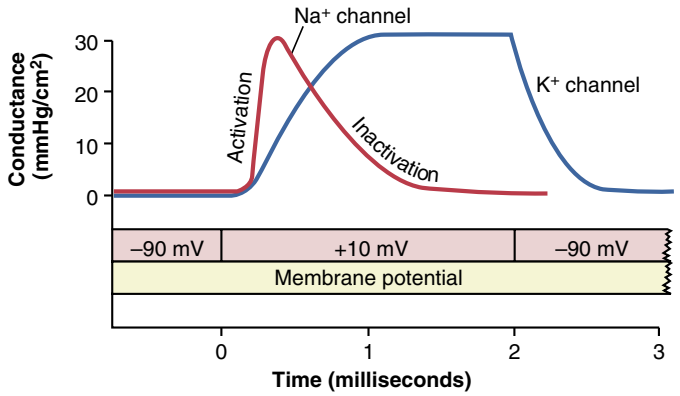

FIGURE **10-3** Typical changes in conductance of sodium and potassium ion channels when the membrane potential is suddenly increased from the normal resting value of −90 millivolts to a positive value of +10 millivolts for 2 milliseconds. This figure shows that the sodium channels open (activate) and then close (inactivate) before the end of the 2 milliseconds, whereas the potassium channels only open (activate), and the rate of opening is much slower than that of the sodium channels. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. St. Louis: Saunders; 2011:62.)

calcium (Ca^{2+}) channels are important, the Na^+ channels are the most significant and best understood with respect to the initiation and propagation of the action potential.[3,10-14]

Mechanism of Action

As noted earlier, local anesthetics work by reversibly binding to the voltage-gated sodium channels (Na_v). Sodium channels have three functional states: resting (closed), open, and inactive. The resting state exists when the membrane is at its resting potential. When a nerve is stimulated, reversal of the membrane potential occurs until the threshold potential is reached. When this happens, a conformational change in the proteins that compose the channel occurs resulting in the open state. An inactive state, characterized by the return of the Na^+ channel to an impermeable state, follows the open state. This state, which prevents initiation of an action potential, lasts until the restoration of the resting membrane potential.[10] This three-state concept describes the changes in the Na_v that occur during depolarization and repolarization. Local anesthetics preferentially bind to both the open or inactivated states and not to the closed state. This is referred to as the guarded receptor or modulated receptor hypothesis of local anesthetic action. The open or inactive state may increase the affinity for binding, the physical access of the drug to the receptor, or both.[11,15] In addition, it has long been noted that local anesthetics work faster as the Na_v is repetitively depolarized. This is termed as *use-dependent* or *phasic block*. The more frequently the channel is depolarized, the more time it is available in the open and inactive states and thus available to local anesthetic blockade[16] (Figure 10-5).

Local anesthetics block the propagation of the action potential by binding reversibly to specific receptors within or adjacent to the internal opening of the Na_v channel.[17] Studies have indicated that these receptors, located on the intracellular side of the cell membrane, have a greater affinity for the charged or ionized form of the local anesthetics.[8,10,18] The uncharged or nonionized portion of the local anesthetic must first penetrate the cell membrane entering the axoplasm before they produce their effects. Figure 10-6 shows the penetration of local anesthetic into a nerve and subsequent access to the receptor. The sequence is as follows:

1. Almost all clinically useful local anesthetics (except benzocaine) are tertiary amines and when injected, will exist in both nonionized (lipid soluble) and ionized (water soluble) forms according to their particular pK_a (negative logarithm of the acid ionization constant) and the pH of the tissue or compartment they are in.
2. Local anesthetics must gain access to the interior of the neuron to reach their receptor. This occurs by the diffusion of the lipid soluble nonionized fraction across the cell membrane.
3. Once inside the neuron, a new equilibrium forms between ionized and nonionized fractions. The ionized fraction binds to the receptor on the inside of the Na_v.

Benzocaine is a secondary amine and thus is permanently nonionized or neutral. It penetrates the lipid bilayer and can directly inhibit the Na_v without entering the axoplasm first.[12]

Local anesthetics have additional effects on G-protein–coupled receptors affecting intracellular calcium signaling pathways. The inflammatory modulating action of local anesthetics may result from interruptions in these pathways. The antiinflammatory response to local anesthetics also occurs due to suppression of polymorphonuclear leukocyte priming, which prevents overactive inflammatory responses without impairing host defenses or suppressing normal inflammation.[16,19]

It must be noted that many questions remain as to the mechanism of the clinical effects of local anesthetics in different

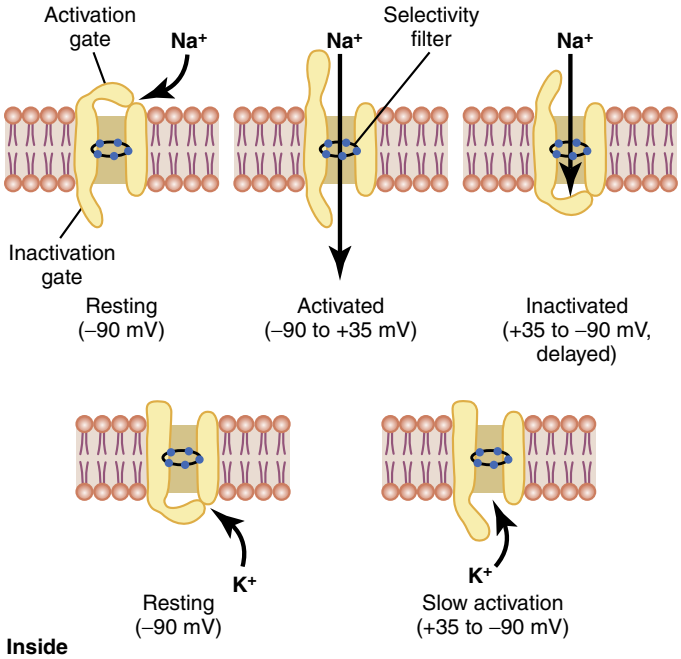

FIGURE 10-4 Characteristics of the voltage-gated sodium (*top*) and potassium (*bottom*) channels, showing successive activation and inactivation of the sodium channels and delayed activation of the potassium channels when the membrane potential is changed from the normal resting negative value to a positive value. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. St. Louis: Saunders; 2011:61.)

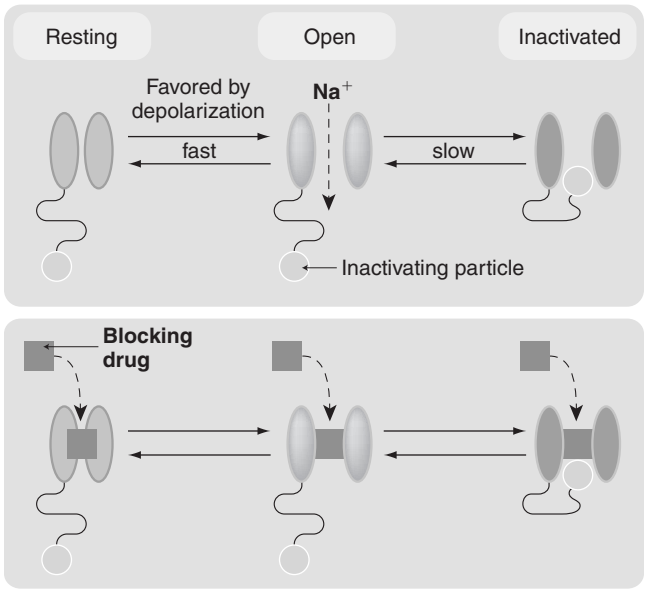

FIGURE 10-5 Resting, activated, and inactivated states of voltage-gated channels, exemplified by the sodium channel. Membrane depolarization causes a rapid transition from the resting (closed) state to the open state. The inactivating particle (part of the intracellular domain of the channel protein) is then able to block the channel. Blocking drugs (e.g., local anesthetics and antiepileptic drugs) often show preference for one of the three channel states, and thus affect the kinetic behavior of the channels, with implications for their clinical application.

types of nerve blocks. Different receptors may be involved in their action in peripheral nerves as opposed to spinal or epidural effects.[20]

Nerve Fiber Sensitivity and Differential Block

It has been observed that nerves functionally have different sensitivity or rates of effect when exposed to local anesthetics. For example, in most major nerve blocks, loss of autonomic function occurs first, followed in sequence by perception of superficial pain, touch, and temperature, motor function, and proprioception.[21] This phenomenon is termed *differential block*. Seen clinically, an excellent example of differential block occurs with the use of bupivacaine. When administered epidurally for labor pain, this local anesthetic spares motor function while providing adequate analgesia.[22,23]

Essential to the understanding of differential block is the concept that the diameter and myelination of nerve fibers influence the sensitivity to local anesthetics. For simplicity, nerve fibers are separated into three groups—A, B, and C—on the basis of diameter.[24,25]

The A fibers are further divided into four subgroups known as *alpha*, *beta*, *gamma*, and *delta fibers*. The alpha fibers are the largest in diameter (12 to 20 μm) and the most heavily myelinated; they have the fastest conduction velocity of all the fibers, including B and C fibers. Alpha fibers are responsible for motor functions and proprioception. The A beta (5-12 μm) and A gamma fibers (3-6 μm) have conduction velocities second only to A alpha fibers. The A beta fibers provide motor function, touch, and pressure sensation; the A gamma fibers innervate muscle spindles and are responsible for reflexes. The A delta fibers provide pain and temperature sensation. These fibers have a smaller diameter (1-5 μm) and slower conduction velocity than other A fibers. The beta, gamma, and delta fibers are all myelinated to a similar extent.[26]

B fibers have a similar diameter (less than 3 μm) to A delta fibers; however, they exhibit slower conduction velocity and less myelination than the A fibers. These fibers constitute the preganglionic autonomic nerves. The C fibers, which conduct pain and temperature impulses, are the smallest of all fibers (0.3-1.3 μm) and have the slowest speed of conduction. These are the only fibers that are unmyelinated.[8] Nerve fiber characteristics and local anesthetic sensitivity are summarized in Table 10-1.

It was first believed that nerve fiber diameter was the sole determinant of differential blockade.[27] This assumption came from the results of isolated in vitro studies performed only on myelinated nerves. Subsequent isolated studies on the small, unmyelinated C fibers revealed that they were more resistant to blockade than the larger A delta or B fibers.[8]

This apparent inconsistency can possibly be explained by the concept of conduction safety. This concept refers to the voltage change needed for the propagation of the action potential along the nerve. This voltage change is significantly greater than the action potential threshold and provides a safety factor for impulse conduction. Gissen et al.[28] defined this safety factor as the "ratio between the magnitude of the action potential and the magnitude of the critical membrane potential." Research has indicated that the margin of safety for transmission is greater in small, slow fibers than in large, fast fibers.

Lastly, differential block may be influenced by the rate of diffusion of local anesthetic molecules across multilayered lipoprotein membranes of the myelin sheath. For example, the clinical resistance to blockade observed in A fibers may be the result of a slower onset resulting from a greater diffusion barrier. As discussed in more detail later, diffusion can be influenced by such factors as the pK_a and the concentration of the local anesthetic, as well as the pH of the surrounding tissue and nerve fiber.[28]

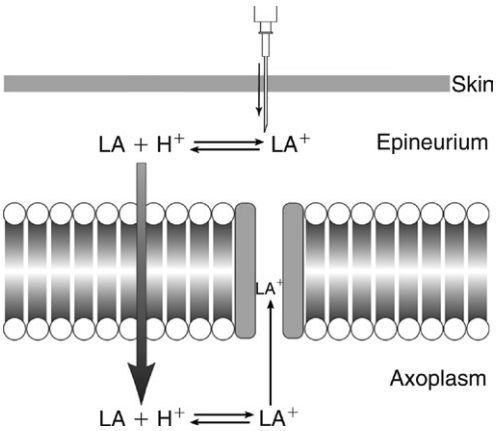

FIGURE **10-6** Schematic conceptualization of local anesthetic action. Equilibrium forms outside the nerve between the ionized and nonionized portions. The nonionized portion *(LA)*, which is lipid soluble, enters the nerve. Once inside the axoplasm, the drug re-equilibrates, and the ionized fraction *(LA^+)* attaches to the local anesthetic receptor on the inside of the sodium channel. *LA*, Nonionized form of the local anesthetic; *LA^+*, ionized form.

TABLE **10-1** Nerve Fiber Characteristics and Sensitivity to Local Anesthetics

Fiber Type	Function	Diameter (μm)	Myelination	Anesthetic Block Onset
Type A				
Alpha (A_α)	Proprioception, motor	12-20	Heavy	Last
Beta (A_β)	Touch, pressure	5-12	Heavy	Intermediate
Gamma (A_γ)	Muscle tone	3-6	Heavy	Intermediate
Delta (A_δ)	Pain, cold temperature, touch	1-5	Heavy	Intermediate
Type B				
	Preganglionic autonomic vasomotor	<3	Light	Early
Type C				
Sympathetic	Postganglionic vasomotor	0.3-1.3	None	Early
Dorsal root	Pain, warm and cold temperature, touch	0.4-1.2	None	Early

As the preceding discussion indicates, the concept of differential block is more complex than originally proposed. Future research will probably indicate that an isolated mechanism does not explain this phenomenon, but rather several factors interact to produce the effect.[22]

CHEMICAL STRUCTURE OF LOCAL ANESTHETICS

The local anesthetics used clinically for neural blockade are aminoesters or aminoamides and are similar in chemical structure. In general, these drugs have three characteristic segments: (1) an intermediate ester or amide carbon group separates (2) an unsaturated (aromatic) ring system from (3) an amine end (Figure 10-7). The aromatic ring provides lipophilic characteristics, whereas the tertiary/quaternary amine gives hydrophilicity to the molecule. The amine portion is able to become ionized in physiologic pH and thus hydrophilic.

Chemically, the major difference among local anesthetics is in their ester or an amide linkage that binds the aromatic ring to the amine group. This linkage is responsible for the classification of these drugs as either esters or amides. The type of linkage is important clinically because it has implications for metabolism, duration, and allergic potential (Figure 10-8). Box 10-1 lists the local anesthetics according to chemical class. The chemical structures are important in determining the pharmacologic effects of these drugs. Minor chemical alterations to drugs within these two "bond-related" groups can result in significant changes in drug potency, speed of onset, and duration of action and potential for producing differential block (Figure 10-9).[5,16,29] These changes are discussed in detail as the specific pharmacologic factors associated with local anesthetics are noted. Table 10-2 summarizes the clinical differences between the ester and amide local anesthetics.

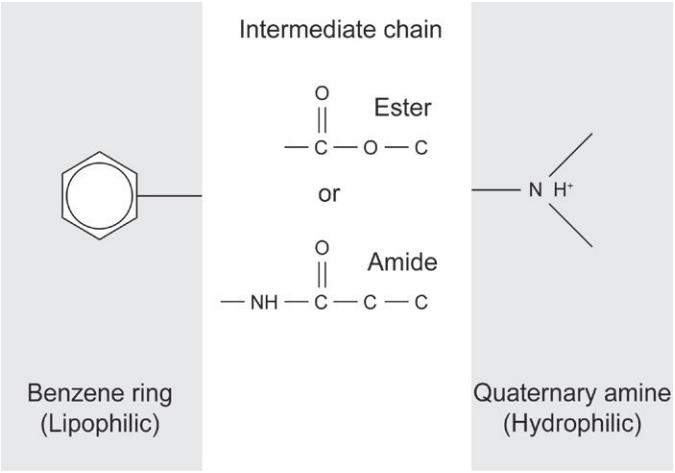

FIGURE **10-7** Core structure for local anesthetics, which includes a benzene ring and a quaternary amine separated by an intermediate carbon group. The bond between the benzene ring and the carbon group determines whether the drug is an amide or an ester.

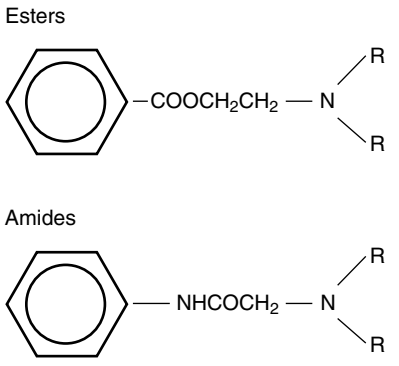

FIGURE **10-8** Representative chemical formula for ester and amide local anesthetic drugs.

PHARMACODYNAMICS AND PHARMACOKINETIC CONCEPTS

An important difference to note when describing the pharmacokinetics of local anesthetics is intuitive yet bears discussion. Unlike most medications, these agents are meant to remain localized in the area of injection or application. The higher the concentration (number of molecules) of drug injected that remain in the area of the nerve or nerves to be blocked, the faster the onset of action. If multiple nerves are being blocked, a greater intensity may also be evident. Therefore, systemic absorption away from the deposition site results in the offset and termination of drug effect, rather than the onset as with most other drugs. Factors that affect absorption, such as the vascularity and blood flow of the injection area, lipid and protein binding, and addition of vasoconstrictors, greatly influence duration of action. The same local anesthetic dose and concentration injected in different areas of the body, with or without added epinephrine, can result in vastly different durations of action. Absorption also influences toxicity. The slower a local anesthetic is systemically absorbed, the less likely that high blood levels and therefore central nervous system (CNS) or cardiac toxicity will result. Drug metabolism and elimination more readily "keep up" with absorption, ensuring that toxic blood levels are avoided. A conceptual kinetic depiction of the fate of an injected local anesthetic is given in Figure 10-10.

Potency

There is a strong relationship between the lipid solubility of local anesthetics and their potency.[28,29] This finding is understandable, considering that the axolemma and myelin sheath are composed primarily of lipids[29,30]; therefore, lipid-soluble drugs pass more readily through the nerve membrane. Larger, more lipid-soluble local anesthetics are relatively water insoluble, highly protein bound, and less readily washed out from nerves and surrounding tissues. They bind to Na_v channels with a higher affinity than agents with lower lipid solubility. Increased lipid solubility correlates with increased protein binding, increased potency, longer duration of action, and a higher tendency for severe cardiac toxicity.[12,29] It follows that fewer molecules or lower concentrations of these drugs are required for the production of blockade than if non–lipid-soluble anesthetics are used.[31] Changes in either the aromatic or amine moieties of the local anesthetic molecule can affect the lipid-water partition coefficient. In the amide series, for example, the addition of a butyl group to the amine end of mepivacaine leads to the formation of bupivacaine. Bupivacaine is 26-fold as lipid soluble and fourfold as potent as mepivacaine. In

Ester and Amide Local Anesthetics

Esters	Amides
Procaine	Lidocaine
Chloroprocaine	Mepivacaine
Tetracaine	Prilocaine
Cocaine	Bupivacaine
Benzocaine	Ropivacaine
	Articaine

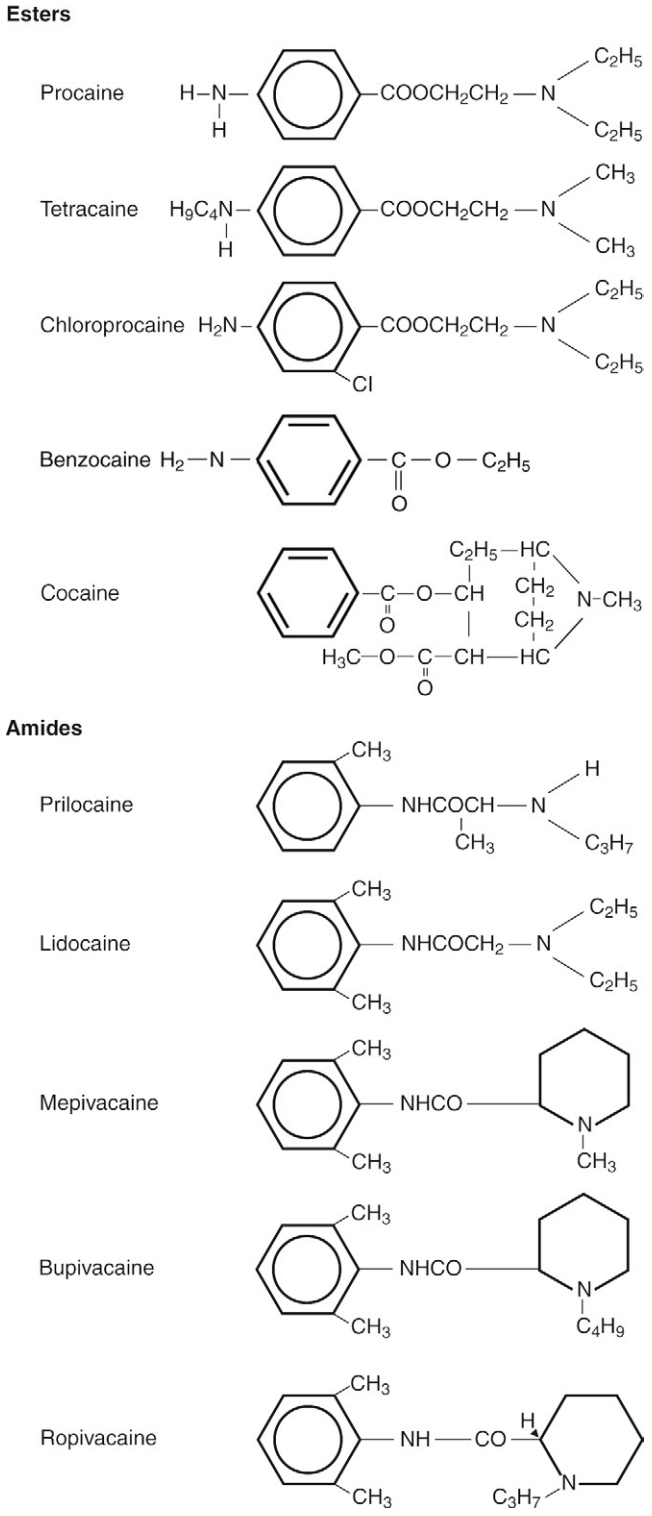

FIGURE **10-9** Chemical structure of the most commonly used local anesthetics. Note the chemical substitutions on the benzene ring and the amine end of the molecules.

TABLE 10-2 Clinical Differences Between the Ester and Amide Type Local Anesthetics

Esters	Amides
Ester metabolism is catalyzed by plasma and tissue cholinesterase via hydrolysis; occurs throughout the body and is rapid	Amides are metabolized in the liver by CYP1A2 and CYP3A4 and thus a significant blood level may develop with rapid absorption
Although local anesthetic allergy is uncommon, esters have a higher allergy potential, and if patients exhibit an allergy to any ester drug, all other esters should be avoided	Allergy to amides is extremely rare; there is no cross allergy among the amide class or between the ester and amide agents
Ester drugs tend to be shorter acting due to ready metabolism; tetracaine is the longest acting ester	Amides are longer acting because they are more lipophilic and protein bound and require transport to the liver for metabolism

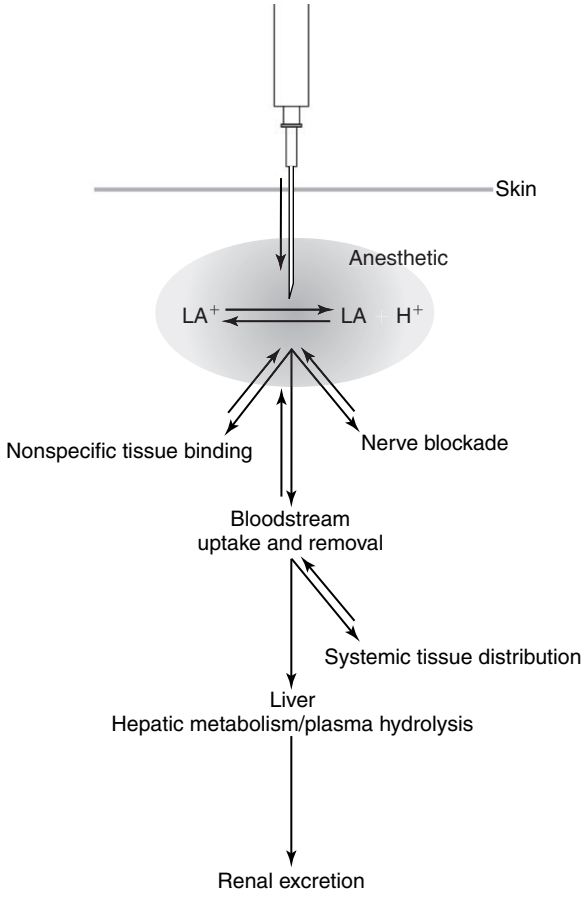

FIGURE **10-10** Representation of the fate of a local anesthetic injected into tissue.

the case of the esters, the addition of a butyl group to the aromatic end of procaine produces tetracaine, which is considerably more lipid soluble and potent than procaine.[16]

Factors other than lipid solubility can affect potency. For example, the potency of local anesthetics as demonstrated in isolated in vitro studies is not always the same as that observed in vivo. The discrepancy between in vitro and in vivo findings may be the result of many factors, including the vascular and tissue distribution properties of the drug.[32] For example, the results of in vitro studies show that lidocaine is twice as potent as prilocaine; however, clinical use indicates that they have similar potencies. This may be explained by the fact that lidocaine has greater vasodilating properties than prilocaine and therefore may be absorbed away more rapidly, leaving less drug available for interaction with the neuron.[33-35]

TABLE 10-3 Classification of Local Anesthetics Based on Onset, Duration of Action, and Potency

Characteristics	Drug (generic name)	Common Brand Name	Onset	Duration of Action (min)
Low potency, short duration of action	procaine	Novocaine	Slow	60-90
	chloroprocaine	Nesacaine	Fast	30-60
Intermediate potency, duration	mepivacaine	Carbocaine	Fast	120-240
	lidocaine	Xylocaine	Fast	90-120
High potency, long duration	tetracaine	Pontocaine	Slow	180-600
	bupivacaine	Marcaine, Sensorcaine	Slow	180-600
	ropivacaine	Naropin	Slow	180-600

Duration of Action

The duration of action of local anesthetics demonstrates a relationship to protein binding and lipid solubility.[29,36] In theory, drugs that have a high affinity for protein and lipids attach more firmly to these substances in the vicinity of the Na_v channel receptor. This means that the drug remains in the channel and surrounding areas for a longer time, producing prolonged conduction blockade.[29]

It appears therefore that there is a correlation between the degree of protein binding and duration of the local anesthetic. The addition of larger chemical radicals to the amide or aromatic end of the drugs results in greater protein binding. The duration is directly proportional to plasma protein binding, presumably because the local anesthetic receptor on the neural membrane is also composed of protein.[3,5,37] It has been posited that local anesthetics that have increased protein-binding properties (e.g., ropivacaine 94%, bupivacaine 97%) produce longer-duration anesthesia as a consequence of more efficient binding of the anesthetic to the Na_v channel.[38] For example, bupivacaine is more than 90% bound to plasma protein; however, its homologue, mepivacaine, is only 65% bound.[36] The duration of action of bupivacaine is significantly longer than for mepivacaine. Local anesthetics are weak bases and bind mainly to α_1-acid glycoprotein (AAG). Secondary binding to albumin also occurs.

As in the case of potency, the effect local anesthetics have on the vasculature at the injection site influences the duration of action. This is discussed in detail in the section on vasomotor action and absorption.

Onset of Action

As stated previously, local anesthetics must diffuse through the axolemma before they can interact with receptors. How readily they diffuse through the nerve membrane depends on their chemical structure, lipid solubility, and state of ionization. Of these, ionization is the most important, because the charged or ionized form of a drug does not penetrate membranes well.[30,32,37] In other words, the more ionized a local anesthetic, the slower it will penetrate a nerve.

Local anesthetics are bases. The pK_a of a drug is the pH at which 50% of the drug is in the charged, or ionized, and water soluble form while the remaining half is uncharged, or nonionized, and lipid soluble. A basic drug becomes predominantly ionized if it is placed in an environment with a pH that is significantly less than its pK_a. Therefore drugs that have a greater pK_a are ionized to a greater extent at body pH than those with a lower pK_a. For example, if lidocaine (pK_a 7.74) is placed in plasma (pH 7.4), 65% of the drug is ionized and 35% remains un-ionized. Similarly, if tetracaine (pK_a 8.6) is placed in plasma, 95% of the drug becomes ionized and 5% remains un-ionized.[29]

Because their ionization is less, local anesthetics with lower pK_a (7.6 to 7.8), such as lidocaine, mepivacaine, and prilocaine tend to have a more rapid onset of action than drugs with a greater pK_a (8.1 to 8.6), such as bupivacaine, tetracaine, and procaine. Chloroprocaine is one exception; it has a high pK_a but retains a rapid onset, probably because of the clinical use of high concentrations of the drug, which attenuates the ionization effect. In general, the closer the pK_a is to pH 7.4, the more rapid the onset. Some researchers downplay the role of pK_a on onset.[29]

The classification presented in Table 10-3 assists in the selection of an appropriate drug with respect to pharmacokinetic properties.[39]

Vasomotor Action and Absorption

All local anesthetics except cocaine, ropivacaine, and lidocaine produce relaxation of vascular smooth muscle.[33,40] The resultant vasodilation increases blood flow to the tissue in which the drug is deposited. This results in an increase in the drug's absorption, which limits its duration of action and increases the probability of toxic effects. It is interesting to note that ropivacaine and lidocaine are the only parenterally administered local anesthetics with mild vasoconstrictive properties.[40] Cocaine also has vasoconstrictive properties because of its ability to block reuptake of norepinephrine. It is used only topically.

All local anesthetics are not affected equally when epinephrine is added to the solution. There is a definite benefit in extending the duration of analgesic effects with both short- and intermediate-acting agents. The prolongation of the duration with long-acting drugs is less well defined.[40]

The speed of absorption and entry of the local anesthetic into the systemic circulation obviously has significant implications for toxicity. Absorption of drugs generally occurs in the following order of rapidity: interpleural blocks > intercostal > caudal > epidural > brachial plexus > sciatic-femoral and subcutaneous blocks.[16] Thus blood levels measured after an interpleural block will be higher with a greater potential for toxicity than with a subcutaneous block.

The total dose of local anesthetic, rather than the volume or concentration, linearly determines the peak plasma concentration.[41] For example, 400 mg of lidocaine yields the same peak plasma concentration regardless of whether 40 mL of a 1% or 80 mL of a 0.5% is injected.

Local anesthetic additives include α_2-adrenergic agonists, opioids, sodium bicarbonate, ketorolac, and hyaluronidase. These are variously added to increase the safety, quality, intensity, duration, and rate of onset of anesthesia, as well as reduce blood loss. $Alpha_2$-adrenergic agonists such as clonidine and dexmedetomidine have local anesthetic properties and can alter the nerve block characteristics.[42,43] The addition of 100 mcg of clonidine to a local

anesthetic solution prolongs the duration of the long-acting agents approximately 100 additional minutes with minimal side effects. The effect is produced by inhibition of the hyperpolarization-activated cation current (I_h current). This current normally restores nerves from the hyperpolarized state to resting potential. The effect is more pronounced in C-fibers (sensory) than Aδ (motor). That makes the effects mostly sensory specific. Cost has limited the routine use of clonidine.[40]

The addition of a vasoconstrictor (e.g., epinephrine) to local anesthetics can reduce the rate of vascular absorption, allowing more of the drug to stay in the local area where it was injected. The availability of the drug for neuronal uptake is increased, resulting in a longer and more profound block. Of importance, the slower rate of absorption also attenuates the peak plasma concentration of the drug, thereby reducing systemic toxicity. The magnitude of this effect depends on the drug, dose, and concentration of both the local anesthetic and the vasoconstrictor, as well as the site of injection.[7] For example, addition of epinephrine to mepivacaine prolongs the time to maximum arterial plasma drug concentration in all situations; however, adding epinephrine to a 2% solution used for an intercostal block has the greatest effect.[44]

Epinephrine does not prolong the duration of blockade to the same extent with all local anesthetics. For example, it prolongs the duration for local infiltration, peripheral nerve block, and epidural anesthesia with procaine, mepivacaine, and lidocaine.[30,45-48] Research indicates that adding epinephrine to lidocaine solutions increases the intensity and duration of block.[48] The early increase in intensity is not matched with an increase in intraneural lidocaine content at these early times, although the prolonged duration of block by epinephrine appears to correspond to an enlarged lidocaine content in a nerve at later times, as if a very slowly emptying "effector compartment" received a larger share of the dose. The increase in early analgesia without increased lidocaine content may be explained by a pharmacodynamic action of epinephrine that transiently enhances potency of lidocaine, but also by a pharmacokinetic effect that alters the distribution of the same net content of lidocaine within the nerve. In the case of prilocaine and bupivacaine, infiltration and peripheral nerve blocks are prolonged with epinephrine, whereas no significant effect occurs with epidural anesthesia.[49] The rationale for this discrepancy might be that epidural fat significantly absorbs ropivacaine and bupivacaine because of their high lipid solubility. These drugs are released slowly from the fat deposit, which could prolong the block.[47,49-51] This process overrides the effects of epinephrine on duration of action. In addition, the drug concentration can contribute to the differential effect seen with epinephrine. For example, epinephrine can prolong epidural blocks with 0.125% or 0.25% bupivacaine when used in patients in labor.[50,51] Conversely, epinephrine has less effect with the epidural administration of 0.5% or 0.75% bupivacaine.[52]

The addition of epinephrine does not attenuate the peak plasma level of all local anesthetics; for example, epinephrine significantly reduces the peak plasma concentration of lidocaine and mepivacaine, regardless of the site of administration. On the other hand, epinephrine does not significantly affect the peak plasma level of prilocaine or bupivacaine after epidural anesthesia. The lack of effect seen with prilocaine may be explained by its slower absorption and rapid tissue redistribution. In the case of bupivacaine, it may be explained by the significant lipid solubility and uptake in the epidural adipose tissue.[28] There is some controversy as to whether epinephrine may produce neurotoxicity when added to local anesthetics. Some clinicians only recommend its use for nerve blocks done without ultrasound guidance or where the needle tip and local anesthetic spread are not adequately visualized as a safety measure to detect intravascular injection.[40]

Studies that have compared vasoconstrictors conclude that epinephrine is superior to drugs such as phenylephrine and norepinephrine in producing vasoconstriction with local anesthetics.[53,54] The usual concentration of epinephrine used for this purpose is 1:200,000 or 5 mcg/mL.

Miscellaneous Factors That Influence Onset and Duration

Local anesthetics are basic drugs. As discussed previously, they have both water- and lipid-soluble properties. Factors that raise the pH of their environment increase their lipid solubility, and, conversely, lower pH environments result in increased water solubility. These changes to pH result in altered proportions of lipid- and water-soluble fractions of the drugs, which may have clinical consequences. At times, the term used for this phenomenon is *ion trapping*. Ion trapping results from changes in pH in relationship to the pK_a of the agent. Instances in which ion trapping may have clinical consequences are noted in Box 10-2.

Local anesthetics have been carbonated to speed onset. In isolated nerve preparations, carbonation gives a more rapid onset and greater intensity of block.[55] Diffusion of carbon dioxide through the nerve membrane can lower the intracellular pH. When local anesthetics accompany this process, they become more ionized within the neuron; this results in an increase in the concentration of the drug in the ionized form at the intracellular binding site.

Controversy exists concerning whether carbonation improves onset time in the in vivo situation.[56] Separate double-blind studies of lidocaine and bupivacaine have failed to yield positive results.[57] This inconsistency may exist because the injected carbon dioxide is rapidly buffered in vivo, so intracellular pH is not greatly affected.[56.57] This practice has been largely abandoned in modern clinical practice.

The addition of sodium bicarbonate to local anesthetics is widely used in epidural anesthesia to speed onset of sensory and motor block.[58-60] The effects of the addition of sodium bicarbonate to peripheral blocks is unclear.[40] In theory, the mechanism is that addition of bicarbonate increases the pH of the local anesthetic solution, resulting in the presence of more drug in the nonionized state. As stated previously, this form of the drug readily diffuses across the cell membranes and would therefore speed onset. Studies done with bupivacaine and lidocaine have indicated that this alteration does facilitate the onset and prolong duration of action.[58,59] Other researchers, however, have noted variable effects on onset and duration depending on whether epinephrine was contained in the solution.[60]

The major limitation to the addition of bicarbonate is the precipitation that can occur in the local anesthetic solution. It also should be noted that the amount of bicarbonate that can be added without precipitation depends on whether the epinephrine is commercially or "freshly" mixed.[58] Manufacturers acidify local anesthetic solutions to increase solubility and stability (the free base is more susceptible to photodegradation and aldehyde formation), which results in a longer shelf-life. For example, the pH range of plain lidocaine is 6.5 to 6.8, compared with 3.5 to 4.5 for preparations that contain epinephrine. The lower pH is used with epinephrine because of the instability of this compound in alkaline solutions.

Another benefit of alkalization is that it may result in less pain or stinging on injection. The mechanism of action for this effect could be more complex than just an increase in pH. It may be that the nociceptive nerve fibers may not be as sensitive to the

BOX **10-2**

Ion Trapping: Clinical Situations in Which Differences Between pK_a and pH May Affect Patient Response

- In the event of local anesthetic overdose, associated respiratory depression may occur, resulting in hypoxia and acidosis. The acidosis resulting from hypoxia may increase the ionized fraction of local anesthetic within the cerebral circulation, thereby decreasing the ability of the anesthetic to cross the blood-brain barrier, leave the brain, and reenter the systemic circulation. This phenomenon may prolong and enhance the central nervous system toxicity of local anesthetics.
- Local anesthetic accumulation in the fetal circulation is enhanced by the fact that fetal pH is lower than maternal pH, which may result in high fetal levels of local anesthetics.
- Local anesthetics injected into acidotic, infected tissues are rendered ineffective because of the loss of lipid solubility. The lipid solubility of local anesthetics is diminished in an acidotic environment because of an increased concentration of the ionized, water-soluble form of the drug. The loss of lipid solubility prevents absorption into the nerve, thereby preventing access to the site of action.
- Carbonation of local anesthetics speeds the onset and intensity of action of neural blockade. Carbon dioxide readily diffuses into the nerve, lowering the pH within the nerve. The lipid-soluble form of local anesthetic, after passing through the neuronal membrane, receives protons from the intraneuronal environment and ionizes. An increase in the ionized fraction within the neuron produces a higher concentration of the active form of the anesthetic available at the sodium channel, the site of action. This practice has been largely abandoned in modern clinical practice.
- Commercially available local anesthetics are prepared in a slightly acidic formulation that improves the stability of the drug by increasing the concentration of the ionized, water-soluble form of the drug. Addition of sodium bicarbonate to the local anesthetic mixture increases the pH of the solution, thereby increasing the concentration of the un-ionized, lipid-soluble form of the drug. Improving the lipid solubility of the local anesthetic improves diffusion of the local anesthetic through the neuronal membrane, leading to a more rapid onset of action. This seems to be most effective in epidural blocks and least effective in peripheral blocks.

un-ionized form of the drug. It also is possible that the un-ionized drug diffuses so rapidly through the tissue and axolemma that a sensory block occurs almost instantaneously.[61,62]

The addition of hyaluronidase to local anesthetics as a spreading factor facilitates the diffusion of the drugs in tissues. This additive accomplishes this effect via the hydrolysis of hyaluronic acid, which is a glycosaminoglycan found extensively in the interstitial matrix and basement membranes of tissue. Hyaluronic acid is the main component of interstitial gel, which inhibits the spread of substances through tissue.[63] It is has long been used in ophthalmic blocks to improve quality, speed onset, limit the acute increase in intraocular pressure with periocular injections, and reduce the incidence of postoperative strabismus.[64] Also, it has been suggested that hyaluronidase reduces hematoma size if a needle that is used with the regional technique punctures a major blood vessel. Other common uses are to facilitate the spread of fluids during hypodermoclysis and radiopaque agents in subcutaneous urography.[63] The addition of hyaluronidase can result in certain undesirable effects, such as the initiation of allergic reactions, a shortening of the duration of anesthetic action, and an increase in drug toxicity.[65-67]A new human recombinant product Hylenex is now available that may improve the safety profile.[68] Currently available hyaluronidase products are listed in Table 10-4. Recent off-label use for cosmetic applications, to reduce edema, epidural adhesions, and chronic lower back pain have led to an increased interest in this agent.[63]

Most current local anesthetics possess either a fast onset but intermediate duration or a slow onset and long duration. Clinicians frequently mix local anesthetics to obtain a more rapid onset and a longer duration of action. The use of intermediate-acting mepivacaine combined with long-acting bupivacaine for an ultrasound-guided interscalene block was recently reported.[69] Onset was not improved compared to bupivacaine alone, but duration was longer than mepivacaine alone. The duration was shorter than bupivacaine alone. Some clinicians have suggested that the use of combinations reduces the risk of toxicity; however, drug errors may increase when using more complex dosing schemes. In addition, the toxicity of local anesthetic combinations appears to be additive.[70-72] The authors suggest that the increased use of ultrasound-guided techniques allows for the use of lower doses and more precise deposition of drug, which may diminish the use of combined local anesthetics.[69]

TABLE **10-4** Available Formulations of Hyaluronidase

Drug	Source	Dosing
Vitrase	Lyophilized, ovine	A wide range of doses are used depending on the type of regional block and the goals; the dose can vary from 0.75 to 300 units/mL.
Amphadase	Bovine	
Hydase	Bovine	
Hylenex	Human (recombinant)	

Data from Dunn AL, et al. Hyaluronidase: a review of approved formulations, indications and off-label use in chronic pain management. *Expert Opin Biol Ther*. 2010;10(1):127-131; Adams L. Adjuvants to local anaesthesia in ophthalmic surgery. *Br J Ophthalmol*. 2011;95(10):1345-1349.

Distribution

The absorption or injection of local anesthetics into the systemic circulation results in rapid distribution throughout the body. Distribution results in a rapid decrease in the plasma concentration as the drug moves into highly perfused tissue. Rapid distribution into the brain and heart can be a concern because this can lead to systemic toxicity. A secondary, slower disappearance follows, which reflects a combination of distribution into tissues with a more limited blood supply, drug metabolism, and excretion.

Although local anesthetics are distributed throughout the body, their concentration varies in different tissues. Immediately after vascular uptake, more greatly perfused tissues, such as the brain, heart, and lungs, receive more of these drugs than do less perfused tissues. Once equilibration occurs, the local anesthetic leaves the highly perfused tissue and is deposited in tissue with less perfusion. As with many drugs, as they redistribute in the body over time, muscle tissue receives the greatest amount of local anesthetic from redistribution.

TABLE 10-5 Clearance Half-Life of Local Anesthetics

Drug	Clearance (L/min)	Half-Life (min)
Chloroprocaine	N/A	6
Procaine	N/A	6
Tetracaine	N/A	20
Cocaine	N/A	42
Prilocaine	2.84	90
Lidocaine	0.95	90
Mepivacaine	0.78	114
Bupivacaine	0.47	210
Ropivacaine	7.2	114

N/A, Not applicable. The ester compounds are rapidly broken down in the plasma and tissue so clearance is not a factor.

TABLE 10-6 Pharmacokinetics of Amide Local Anesthetics

Drug	Half-Life Alpha (min)	Half-Life Beta (min)	V_{dss} (L)	Clearance (L)
Prilocaine	0.5	90	261	2.84
Lidocaine	1	90	91	0.95
Mepivacaine	0.7	114	84	0.75
Bupivacaine	2.7	210	72	0.47
Ropivacaine	2.7	114	66.9	0.73

V_{dss}, Volume of distribution at steady state.

The distribution process varies significantly with different local anesthetics. For example, the disappearance rate of prilocaine is more rapid than that of mepivacaine or lidocaine. Ropivacaine also has a shorter half-life than bupivacaine. Distribution of the ester local anesthetics is similar to the amides; however, their rate of metabolism in plasma is very rapid, resulting in much lower and shorter duration systemic plasma concentrations.[16]

Metabolism

The metabolism of local anesthetics differs according to their chemical structure as either amides or esters. Plasma cholinesterase catalyzes the hydrolysis of ester local anesthetics. The hydrolysis occurs through the action of cholinesterase in plasma, red blood cells, and the liver.[73-75] The plasma half-lives of procaine and chloroprocaine are shorter than 1 minute. The rapid rate of clearance of these drugs significantly reduces the potential of toxicity. Conversely, hydrolysis of tetracaine is slower and it has limited clinical use (Table 10-5). Saturated, inhibited, or genetically atypical plasma cholinesterase can significantly prolong the plasma half-life of ester local anesthetics.[73,76] This would have little effect on duration of the ester agent because absorption away from the site of injection would occur as usual; however, this effect could theoretically increase the chance for systemic toxicity. For example, atypical plasma cholinesterase has been shown to significantly reduce the rate of procaine metabolism.[77]

Metabolism of the amide local anesthetics occurs primarily in the liver predominantly by microsomal cytochrome P-450 enzymes CYP1A2 and CYP3A4.[78] Table 10-6 presents pharmacokinetic data for the amide local anesthetics.[16]

Hepatic clearance is a function of the hepatic extraction ratio and hepatic blood flow and is the primary factor that determines the rate of elimination of amide local anesthetics. The hepatic extraction ratio is dependent on the ratio of free to protein-bound drug and represents the activity level specific to the liver for removing a drug from plasma. This ratio indicates the percentage of drug removed with each pass through the liver. The clearance of drugs that have higher hepatic extraction ratios depends on adequate hepatic blood flow. Hepatic enzyme activity is important when drugs with lower ratios, such as bupivacaine, are used.[79] Pathologic conditions that influence hepatic function may prolong the elimination half-life of these drugs by a reduction in hepatic blood flow, enzyme activity, or both. For example, lidocaine has a plasma half-life of 1.6 hours; however, in severe hepatic disease, its half-life is 4.9 hours. This probably results from both an enzymatic and a perfusion effect. Flow-limited clearance is affected by upper abdominal and laparoscopic surgery, inhalation anesthetics, hypovolemia, and congestive heart failure. Heart failure significantly reduces the rate of elimination of lidocaine because of a concomitant reduction in hepatic blood flow.[80] Clinically, hepatic dysfunction does not necessitate a reduction of dose for a single injection nerve block. Doses of amides used in continuous infusions or repeat blocks should be reduced 10% to 50%.[81]

Only 1% to 5% of the injected dose of local anesthetic is accounted for by unchanged renal and hepatic excretion. However, the inactive, more water-soluble metabolites of local anesthetics appear in the urine. Although renal dysfunction affects the clearance far less than does hepatic failure, it can result in the accumulation of potentially toxic metabolites.[82] It may also affect protein binding to both α_1-acid glycoprotein (AAG) and albumin. Some authors have suggested a 10% to 20% reduction in patients with severe renal disease.[83]

Pregnancy

The use of local anesthetics in pregnancy deserves some special pharmacokinetic and pharmacodynamic consideration. Clinical observations and studies both indicate that the spread and depth of spinal and epidural anesthesia are increased in pregnant women. Spread of neuraxial anesthesia increases during pregnancy due to decreases in thoracolumbar cerebral spinal fluid (CSF) volume and increased neural susceptibility to local anesthetic. At first this was thought to be the result of only mechanical factors produced by a gravid uterus. For example, mechanical factors result in dilation of epidural veins, which leads to narrowing of the epidural and subarachnoid space, thereby reducing the dose requirement.[84] However, hormonal changes appear to also play a role because there is a greater segmental spread of local anesthetics administered in the epidural space during the first trimester of pregnancy when little compression is evident.[85] A relationship appears to exist between the progesterone level in CSF and an increased segmental spread and sensitivity of nerves to these drugs. Studies performed on isolated nerves taken from pregnant animals demonstrate more sensitivity to local anesthetic block than in nonpregnant animals.[86,87]

LOCAL ANESTHETIC SYSTEMIC TOXICITY

Local anesthetic systemic toxicity (LAST) is a serious but rare consequence of regional anesthesia. It most commonly results from an inadvertent vascular injection or absorption of large amounts of drug from certain nerve blocks requiring large volume injections. It can also occasionally result from continuous infusion and accumulation of drug and metabolites over many days. The subsequent high systemic blood levels lead to LAST. Widespread

FIGURE **10-12** The timing for onset of signs of local anesthetic systemic toxicity after a single injection of local anesthetic (from a total of 77 incidents). (Data from Di Gregorio G, et al. Clinical presentation of local anesthetic systemic toxicity: a review of published cases, 1979 to 2009. *Reg Anesth Pain Med.* 2010;35[2]:181-187; Neal JM, et al. ASRA practice advisory on local anesthetic systemic toxicity. *Reg Anesth Pain Med.* 2010;35[2]:152-161; Mercado P, Weinberg GL Local anesthetic systemic toxicity: prevention and treatment. *Anesthesiol Clin.* 2011;29[2]:233-242.)

attention to this adverse effect is attributed to Albright, who wrote an editorial in 1979 outlining the risks of bupivacaine use in intravenous regional blocks.[88] Subsequently, 49 cases of cardiac toxicity from local anesthetics were reported to the Food and Drug Administration (FDA).[89] Worldwide concern followed with a renewed research and clinical interest and safety recommendations.[81] The American Society of Regional Anesthesia and Pain Medicine (ASRA), Panel on Local Anesthetic Systemic Toxicity has recently reevaluated the available research and clinical data from 1979 to 2009 and issued recommendations regarding prevention, diagnosis, and treatment of this complication. Many traditional concepts were reevaluated in light of new data, and practice advisories were formulated. Fortunately, the incidence is dropping as awareness, new practice techniques, and new drugs are instituted.[90]

Incidence and Clinical Presentation

Standard randomized controlled trials of LAST are obviously not ethical, so our knowledge is primarily derived from epidemiologic studies, case reports, and animal research. Data from animal and laboratory studies can vary widely depending on the model used, so comparisons as well as extrapolation to clinical situations can be difficult.

There has been a significant reduction in the incidence of LAST in the past 30 years.[91] The estimate of clinically important LAST is from 7.5 to 20 occurrences per 10,000 peripheral nerve blocks and approximately 4 per 10,000 epidurals.[81] This is a dramatic drop, for example, from the previously reported toxicity of 100 per 10,000 epidurals.[92]

As mentioned earlier, ASRA has evaluated data from 1979 to 2009 and identified 93 separate LAST events. The classic typical clinical presentation of LAST is a progression of subjective symptoms of CNS excitation such as agitation, tinnitus, circumoral numbness, blurred vision, and a metallic taste followed by muscle twitching, unconsciousness, and seizures and with very high drug levels, cardiac and respiratory arrest (Figure 10-11). The sequence occurs because the inhibitory pathways in the brain are affected first, leaving unopposed excitation. This is sometimes referred to as *disinhibition*. As the blood (therefore brain) levels increase, the more resistant excitatory pathways are inhibited, leading to unconsciousness and coma.[81] This was the presentation in about 60% of cases, although the types of CNS symptoms varied greatly. An atypical presentation was evident in about 40% of the patients. This was defined as LAST that is delayed for more than 5 minutes or with isolated cardiovascular symptoms alone. Most of the atypical presentations were for delayed symptoms.[90,91,93]

The most common regional block techniques associated with LAST were epidural (33%), axillary (17%), and interscalene (13%). Seventy-seven cases followed a single injection and 14 occurred with continuous infusion. Two cases involved both continuous infusions with a supplementary single injection. Of the continuous infusion cases, half were pediatric cases. Fifty-two events were related to bupivacaine (55%), 28 to ropivacaine (30%), 4 to levobupivacaine (4%), and 9 were attributed to other local anesthetics (11%). The patient characteristics were as follows: 63% female; 16% under 16 years old; 29% older than 60 years; 5 newborns receiving epidural anesthesia, and 37% of all patients had significant comorbidities such as diabetes, renal failure, or isovaleric acidemia.[93]

The timing of the onset of symptoms after a single injection varied from 30 seconds to 60 minutes (Figure 10-12). It is usually very rapid. In over half the cases, it happened in less than 50 seconds, and 75% of the cases occurred within 5 minutes of injection. The onset of symptoms following continuous infusion occurred hours or days after starting the drug.[93]

Central Nervous System and Cardiovascular Signs of Toxicity

The newly evaluated data point to a more varied presentation of toxicities. Symptoms of CNS toxicity occurred in 89% of cases either alone (45%) or together with significant cardiovascular symptoms (44%) (Figure 10-13). The spectrum of CNS signs of toxicity are given in Figure 10-14. It is interesting to note that the most frequent symptom was seizures (68%), whereas only 18% exhibited the typical prodromal symptoms. The spectrum of cardiovascular signs of toxicity are given in Figure 10-15. The most common involved various arrhythmias.[93]

Prevention of Local Anesthetic Systemic Toxicity

Adaption of suggested safety steps such as the use of test doses, incremental injection with frequent aspiration, and the use of pharmacologic markers such as epinephrine or fentanyl have lowered the incidence of LAST in recent years. Additional practices that have been suggested to improve safety include

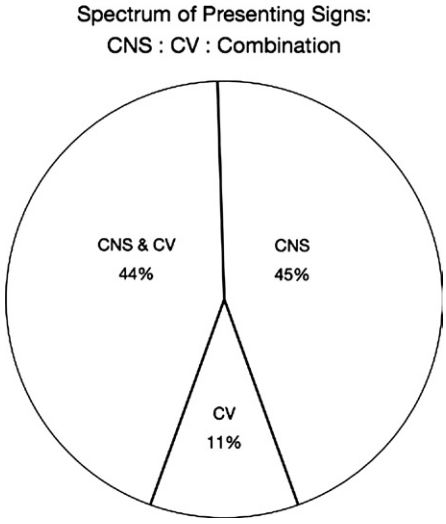

FIGURE **10-13** The frequency of symptoms and signs referable to cardiovascular (CV), central nervous system (CNS), or both is given for the 93 cases in this review. (Data from Di Gregorio G, et al. Clinical presentation of local anesthetic systemic toxicity: a review of published cases, 1979 to 2009. *Reg Anesth Pain Med* 2010;35[2]:181-187; Neal JM, et al. Local anesthetic systemic toxicity: prevention and treatment. *Anesthesiol Clin*. 2011;29[2]:233-242.)

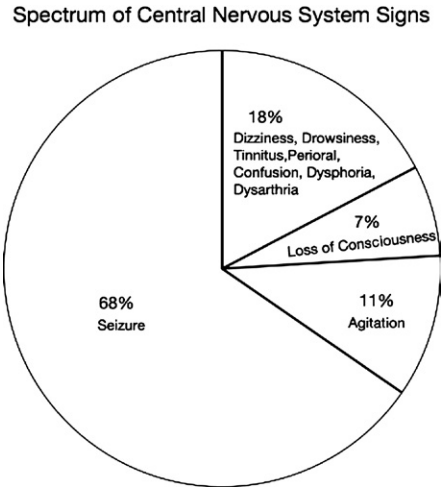

FIGURE **10-14** The distribution frequencies of all reported signs of central nervous system toxicity among published cases of local anesthetic systemic toxicity. Totals exceed 100% due to patients exhibiting more than one initial symptom. (Data from Di Gregorio G, et al. Clinical presentation of local anesthetic systemic toxicity: a review of published cases, 1979 to 2009. *Reg Anesth Pain Med.* 2010;35[2]:181-187; Neal JM, et al: ASRA practice advisory on local anesthetic systemic toxicity. *Reg Anesth Pain Med.* 2010;35[2]:152-161; Mercado P, Weinberg GL: Local anesthetic systemic toxicity: prevention and treatment. *Anesthesiol Clin*. 2011;29[2]:233-242.)

limiting the total dose of local anesthetic by restricting the use of 0.75% bupivacaine in obstetrics. The clinical principle in any regional technique is to use the lowest dose possible (the product of the concentration and volume) to produce a satisfactory block.[94] The use of generalized maximum recommended doses has been questioned.[83] Systemic blood levels of the same dose of anesthetic vary greatly depending on the area of blockade, technique, and specific drug. Blood levels are difficult to predict when dosing on a milligram per kilogram basis. Body weight as a guide should be used only in pediatric patients (Table 10-7). The use of ultrasound-guided techniques has the potential to further improve safety, although definitive studies are lacking to date.[95] The current ASRA recommendations for recognizing, preventing, and treatment of LAST are given in Box 10-3.[94] Further recommendations for preventing LAST are noted in Box 10-4.

Diagnosis and Treatment of Local Anesthetic Systemic Toxicity

Prompt recognition and treatment are essential to minimizing adverse outcomes of LAST. Airway management remains the primary intervention because preventing hypoxia and acidosis are essential first steps. As noted in Box 10-2, acidosis may enhance toxicity by ion trapping local anesthetic in the brain. Seizure suppression is essential to facilitate immediate airway control and prevent or reduce metabolic acidosis. Benzodiazepines are considered the drugs of choice because they are anticonvulsant without causing significant cardiac depression. When benzodiazepines are not available, small doses of propofol are appropriate. Succinylcholine may be useful to suppress intractable seizure-induced tonic-clonic muscle activity in spite of the lack of CNS effects. Cardiovascular support is essential to maintaining adequate coronary perfusion. The local anesthetics do not irreversibly damage the cardiac cells. Avoiding tissue hypoxia is essential in reversing the progression of toxic cardiac events.[96] Local anesthetic cardiotoxicity, especially with bupivacaine, involves both electrophysiologic disturbances and depression of contractility. The electrical disturbances appear to occur at lower doses and are more contributory to poor outcomes than contractile depression, but differences among specific local anesthetics exist.[97] Lipid emulsion therapy is recommended as a standard part of LAST resuscitation. There is some evidence that it is able to restore spontaneous circulation without the use of vasopressors. In fact, large doses of vasopressors may decrease the effectiveness of lipid emulsions.[98] Vasopressors may be required to maintain adequate blood pressure, but they can worsen local anesthetic-induced arrhythmias. Small doses of epinephrine, less than 1 mcg/kg, are recommended. Vasopressin should be avoided even though it is now part of Advanced Cardiac Life Support guidelines.[96]

As noted above, lipid emulsion therapy for LAST is the newest and most promising therapy that has emerged. Both laboratory and clinical use has shown it to be instrumental in facilitating successful recovery. The exact mechanisms for the beneficial effects is not clear. The mechanisms of action of lipid infusion can be broadly separated into intracellular (metabolic, signaling), intravascular (partitioning, sink), and membrane (channel) effects.

Six mechanistic actions may contribute to lipid resuscitation including: (1) capture of local anesthetic in the blood (lipid sink); (2) increased fatty acid uptake by mitochondria (metabolic effect); (3) interference with local anesthetic binding of sodium channels (membrane effect); (4) activation of Akt cascade A) serine/threonine protein kinase important in cell survival, proliferation, and migration, also called protein kinase B) leading to inhibition of GSK-3 which is glycogen synthase kinase (cytoprotection); (5) promotion of calcium entry via voltage-dependent calcium channels (ionotropic/inotropic effect); and (6) accelerated shunting (pharmacokinetic effects).[99–101] Lipid emulsion is also recommended in pregnant patients.[102] The recommendations for diagnosing LAST are given in Box 10-5.[90] Treatment recommendations are given in Box 10-6.[96]

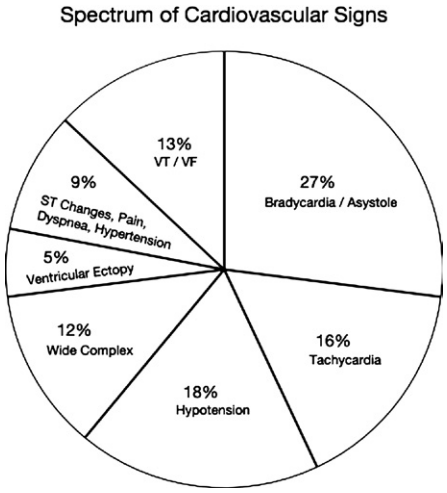

FIGURE **10-15** The distribution frequencies of all reported signs of cardiovascular toxicity during local anesthetic systemic toxicity. Totals exceed 100% due to patients exhibiting more than one initial symptom. (Data from Di Gregorio G, et al. Clinical presentation of local anesthetic systemic toxicity: a review of published cases, 1979 to 2009. *Reg Anesth Pain Med*. 2010;35[2]:181-187; Neal JM, et al. Local anesthetic systemic toxicity: prevention and treatment. *Anesthesiol Clin*. 2011;29[2]:233-242.)

Other Adverse Effects

Allergic Reactions

True allergic reactions to local anesthetics are rare, making up no more than 1% of reactions.[103] The frequency is decreasing with the lower use of the ester-type local anesthetics. Adverse reactions are most commonly due to anxiety, panic attacks, intravascular injection, vasovagal responses, or epinephrine. Local anesthetics can, however, produce allergic, hypersensitivity, and anaphylactic reactions. The use of ester local anesthetics is associated with a greater incidence of allergic reactions than the use of amides. This is likely because esters are derivatives of and metabolized to para-aminobenzoic acid (PABA), which is an allergenic compound.[104] Multidose vials also contain methyl and propylparaben as well as sulfites as preservatives. The parabens are additives in many cosmetics, lotions, and foods, and patients who are sensitized may exhibit cross-reactivity with the local anesthetics.[105] Preservative-free solutions are available. Cross-reactivity among the ester-type local anesthetics is high. Allergy to the amides remains largely anecdotal. Cross-reactivity within the amides as a class is extremely rare and between esters and amides is absent.[106] A thorough history of allergy may be difficult because many patients call all local anesthetic drugs "novocaine." They may not be aware of the specific agent administered. Clinicians use amides when possible because the incidence of allergy is extremely low, and they are not cross-reactive with other amides or esters. If a true allergy is suspected, referral to an allergist for skin testing and incremental dose challenges is necessary.[103,107,108]

Methemoglobinemia

Methemoglobinemia is a disorder characterized by high concentrations of methemoglobin (metHb) in the blood, which can lead to tissue hypoxia. The ferrous form of hemoglobin (Fe^{2+}) is oxidized to the ferric form (Fe^{3+}). Methemoglobin is an oxidized form of hemoglobin with reduced capacity to carry oxygen, which causes a shift to the left of the oxygen-hemoglobin dissociation curve. Normal methemoglobin levels are less than 1%. Signs and symptoms of developing methemoglobinemia include pale gray or blue-colored cyanosis, chocolate-colored blood, tachypnea, confusion, headache, dizziness, tachycardia, coma, and death. Decreasing oxygen saturation via pulse oximetry, which is unresponsive to oxygen

TABLE **10-7** Local Anesthetic Agents Used Commonly for Infiltrative Injection

Agent	Duration of Action	Maximum Dosage Guidelines (Total Cumulative Infiltrative Injection Dose per Procedure*)
Esters		
Procaine (Novocain)	Short (15-60 min)	7 mg/kg; not to exceed 350-600 mg
Chloroprocaine (Nesacaine)	Short (15-30 min)	Without epinephrine: 11 mg/kg; not to exceed 800 mg total dose With epinephrine: 14 mg/kg; not to exceed 1000 mg
Amides		
Lidocaine (Xylocaine)	Medium (30-60 min)	Without epinephrine: 4.5 mg/kg; not to exceed 300 mg
Lidocaine with epinephrine	Long (120-360 min)	With epinephrine: 7 mg/kg
Mepivacaine (Polocaine, Carbocaine)	Medium (45-90 min) Long (120-360 min with epinephrine)	7 mg/kg; not to exceed 400 mg
Bupivacaine (Marcaine)	Long (120-240 min)	Without epinephrine: 2.5 mg/kg; not to exceed 175 mg total dose
Bupivacaine with epinephrine	Long (180-420 min)	With epinephrine: Not to exceed 225 mg total dose
Prilocaine (Citanest)	Medium (30-90 min)	Body weight less than 70 kg: 8 mg/kg; not to exceed 500 mg Body weight less than 70 kg: 600 mg
Ropivacaine (Naropin)	Long (120-360 min)	5 mg; not to exceed 200 mg for minor nerve block

*Nondental use, administer by small incremental doses; administer the smallest dose and concentration required to achieve desired effect; avoid rapid injection.

BOX **10-3**

American Society of Regional Anesthesia and Pain Medicine Checklist for Managing Local Anesthetic Systemic Toxicity

For patients experiencing signs or symptoms of local anesthetic systemic toxicity (LAST), the pharmacologic treatment of LAST is different from other cardiac arrest scenarios.

- Get help.
- Initial focus:
  - *Airway management:* ventilate with 100% oxygen.
  - *Seizure suppression:* benzodiazepines are preferred.
  - *Basic and Advanced Cardiac Life Support (BLS/ACLS) will require adjustments of medications and perhaps prolonged effort.*
- Infuse 20% lipid emulsion (values in parenthesis are for a 70-kg patient).
  - Bolus 1.5 mL/kg (lean body mass) intravenously over 1 min (≈100 mL)
  - Continuous infusion at 0.25 mL/kg/min (≈18 mL/min; adjust by roller clamp)
  - Repeat bolus once or twice for persistent cardiovascular collapse.
  - Double the infusion rate of 0.5 mL/kg/min if blood pressure remains low.
  - Continue infusion for at least 10 min after attaining circulatory stability.
  - Recommended upper limit: approximately 10 mL/kg lipid emulsion over the first 30 min
- Avoid vasopressin, calcium channel blockers, β-blockers, or local anesthetic.
- Reduce individual epinephrine doses to less than 1 mcg/kg.
- Alert the nearest facility having cardiopulmonary bypass capability.
- Avoid propofol in patients having signs of cardiovascular instability.
- Post LAST events at www.lipidrescue.org and report use of lipid to www.lipidregistry.org.

Be Prepared

- We strongly advise that those using local anesthetics (LAs) in doses sufficient to produce systemic toxicity (LAST) establish a plan for managing this complication. Making a local anesthetic toxicity kit and posting instructions for its use are encouraged.

Risk Reduction (Be Sensible)

- Use the lowest dose of LA necessary to achieve the desired extent and duration of block.
- Local anesthetic blood levels are influenced by site of injection and dose. Factors that can increase the likelihood of LAST include advanced age, heart failure, ischemic heart disease, conduction abnormalities, metabolic (e.g., mitochondrial) disease, liver disease, low plasma protein concentration, metabolic or respiratory acidosis, and medications that inhibit sodium channels. Patients with severe cardiac dysfunction, particularly very low ejection fraction, are more sensitive to LAST and also more prone to receive "stacked" injections (with resulting elevated LA tissue concentrations) because of slowed circulation time.
- Consider using a pharmacologic marker and/or test dose, for example, epinephrine 5 mcg/mL of LA. Know the expected response, onset, duration, and limitations of a "test dose" in identifying intravascular injection.
- Aspirate the syringe prior to each injection while observing for blood.
- Inject incrementally, observing for signs and querying frequently for symptoms of toxicity between each injection.

Detection (Be Vigilant)

- Use standard American Society of Anesthesiologists (ASA) monitors.
- Monitor the patient during and after completing the injection, as clinical toxicity can be delayed up to 30 min or longer after tumescent procedures.
- Consider LAST in any patient with altered mental status, neurologic symptoms, or cardiovascular instability following a regional anesthetic.
- Central nervous system signs (may be subtle or absent):
  - Excitation (agitation, confusion, muscle twitching, seizure)
  - Depression (drowsiness, obtundation, coma, apnea)
  - Nonspecific (metallic taste, circumoral numbness, diplopia, tinnitus, dizziness)
- Cardiovascular signs (often the only manifestation of severe LAST):
- Initially may be hyperdynamic (hypertension, tachycardia, ventricular arrhythmias), then:
  - Progressive hypotension
  - Conduction block, bradycardia, or asystole
  - Ventricular arrhythmia (ventricular tachycardia, torsades de pointes, ventricular fibrillation)
- Sedative hypnotic drugs reduce seizure risk, but even light sedation may abolish the patient's ability to recognize or report symptoms of rising LA concentrations.

Treatment

- Timing of lipid infusion in LAST is controversial. The most conservative approach, waiting until after ACLS has proven unsuccessful, is unreasonable because early treatment can prevent cardiovascular collapse. Infusing lipid at the earliest sign of LAST can result in unnecessary treatment because only a fraction of patients will progress to severe toxicity. The most reasonable approach is to implement lipid therapy on the basis of clinical severity and rate of progression of LAST.
- There is laboratory evidence that epinephrine can impair resuscitation from LAST and reduce the efficacy of lipid rescue. Therefore it is recommended to avoid high doses of epinephrine and use smaller doses, for example, 1 mcg/kg for treating hypotension.
- Propofol should not be used when there are signs of cardiovascular instability. Propofol is a cardiovascular depressant with lipid content too low to provide benefit. Its use is discouraged when there is a risk of progression to cardiovascular collapse.
- Prolonged monitoring (up to 12 hr) is recommended after any signs of cardiac toxicity because cardiovascular depression due to LAs can persist or recur after treatment.

Data from Neal JM, et al. ASRA practice advisory on local anesthetic systemic toxicity. *Reg Anesth Pain Med.* 2010;35(2):152-161; Weinberg GL. Treatment of local anesthetic systemic toxicity (LAST). *Reg Anesth Pain Med.* 2010;35(2):188-193; Neal JM, et al. American Society of Regional Anesthesia and Pain Medicine checklist for managing local anesthetic systemic toxicity: 2012 version. *Reg Anesth Pain Med.* 2012;37(1):16-18.

BOX **10-4**

Recommendations for Preventing Local Anesthetic Systemic Toxicity (LAST)

- There is no single measure that can prevent LAST in clinical practice.
- Use the lowest effective dose of local anesthetic (dose = product of volume × concentration).
- Use incremental injection of local anesthetics—administer 3- to 5-mL aliquots, pausing 15 to 30 seconds between each injection.
  - When using a fixed needle approach, for example, landmark, paresthesia-seeking, or electrical stimulation, time between injections should encompass 1 circulation time (approximately 30-45 sec); however, this ideal may be balanced against the risk of needle movement between injections. Circulation time may be increased with lower extremity blocks. Use of larger dosing increments would dictate the need for longer intervals to reduce the cumulative dose from stacked injections before an event of LAST. Incremental injection may be less important with ultrasound guidance, given that frequent needle movement is often used with the technique.
- Aspirate the needle or catheter before each injection, recognizing that there is approximately 2% false-negative rate for this diagnostic intervention.
- When injecting potentially toxic doses of local anesthetic, use of an intravascular marker is recommended. Although epinephrine is an imperfect marker and its use is open to physician judgment, its benefits likely outweigh its risks in the majority of patients:
  - Intravascular injection of epinephrine 10 to 15 mcg/mL in adults produces a 10-beat or greater heart rate increase or a 15 or greater mmHg systolic blood pressure (SBP) increase in the absence of β blockade, active labor, advanced age, or general/neuraxial anesthesia.
  - Intravascular injection of epinephrine 0.5 mcg/kg in children produces a 15 or greater mmHg increase in SBP.
  - Appropriate subtoxic doses of local anesthetic can produce subjective symptoms of mild systemic toxicity (e.g., auditory changes, excitation, metallic taste) in unpremedicated patients.
  - Fentanyl 100 mcg produces sedation if injected intravascularly in laboring patients.
- Ultrasound guidance may reduce the frequency of intravascular injection, but actual reduction of LAST remains unproven in humans. Individual reports describe LAST despite the use of ultrasound-guided regional anesthesia. The overall effectiveness of ultrasound guidance in reducing the frequency of LAST remains to be determined.

Data from Mulroy MF, Hejtmanek MR. Prevention of local anesthetic systemic toxicity. *Reg Anesth Pain Med*. 2010;35(2):177-180; Neal JM, et al. ASRA practice advisory on local anesthetic systemic toxicity. *Reg Anesth Pain Med* 2010;35(2):152-161; Mercado P, Weinberg GL. Local anesthetic systemic toxicity: prevention and treatment. *Anesthesiol Clin*. 2011;29(2):233-242.

BOX **10-5**

Recommendations for Diagnosing Local Anesthetic Systemic Toxicity (LAST)

- Classic descriptions of LAST depict a progression of subjective symptoms of central nervous system (CNS) excitement (e.g., agitation, auditory changes, metallic taste, or abrupt onset of psychiatric symptoms) followed by seizures or CNS depression (e.g., drowsiness, coma, or respiratory arrest). Near the end of this continuum, initial signs of cardiac toxicity (e.g., hypertension, tachycardia, or ventricular arrhythmias) are supplanted by cardiac depression (e.g., bradycardia, conduction block, asystole, decreased contractility). However, there is substantial variation in this classic description, including the following:
  - Simultaneous presentation of CNS and cardiac toxicity
  - Cardiac toxicity without prodromal signs and symptoms of CNS toxicity

  Thus the practitioner must be vigilant for atypical or unexpected presentation of LAST.
- The timing of LAST presentation is variable. Immediate (less than 60 sec) presentation suggests intravascular injection of local anesthetic (LA) with direct access to the brain, whereas presentation that is delayed 1 to 5 minutes suggests intermittent or partial intravascular injection, delayed circulation time, or delayed tissue absorption. Because LAST can present more than 15 minutes after injection, patients who receive potentially toxic doses of LA should be closely monitored for at least 30 minutes after injection.
- Case reports associate LAST with underlying cardiac, neurologic, pulmonary, renal, hepatic, or metabolic disease. Heightened vigilance is warranted in these patients, particularly if they are at the extremes of age.
- The overall variability of LAST signs and symptoms, timing of onset, and association with various disease states suggests that practitioners should maintain a low threshold for considering the diagnosis of LAST in patients with atypical or unexpected presentation of CNS or cardiac signs and symptoms after receiving more than a minimal dose of LA.

Data from Di Gregorio G, et al. Clinical presentation of local anesthetic systemic toxicity: a review of published cases, 1979 to 2009. *Reg Anesth Pain Med*. 2010;35(2):181-187; Neal JM, et al. ASRA practice advisory on local anesthetic systemic toxicity. *Reg Anesth Pain Med*. 2010; 5(2):152-161; Mercado P, Weinberg GL. Local anesthetic systemic toxicity: prevention and treatment. *Anesthesiol Clin*. 2011;29(2):233-242.

BOX **10-6**

Recommendations for Treatment of Local Anesthetic Systemic Toxicity (LAST)

- If signs and symptoms of LAST occur, prompt and effective airway management is crucial to preventing hypoxia and acidosis, which are known to potentiate LAST.
- If seizures occur, they should be rapidly halted with benzodiazepines. If benzodiazepines are not readily available, small doses of propofol are acceptable. Future data may support the early use of lipid emulsion for treating seizures.
- Although propofol can stop seizures, large doses further depress cardiac function; propofol should be avoided when there are signs of cardiovascular compromise. If seizures persist despite benzodiazepines, small doses of succinylcholine or similar neuromuscular blocker should be considered to minimize acidosis and hypoxemia.
- If cardiac arrest occurs, we recommend standard advance cardiac life support with the following modifications:
  - If epinephrine is used, small initial doses (10- to 100-mcg boluses in adults) are preferred.
  - Vasopressin is not recommended.
  - Avoid calcium channel blockers and beta-adrenergic receptor blockers.
  - If ventricular arrhythmias develop, amiodarone is preferred; treatment with local anesthetics (lidocaine or procainamide) is not recommended.
- Lipid emulsion therapy:
  - Consider administering at the first signs of LAST, after airway management.
  - Dosing
    - 1.5 mL/kg 20% lipid emulsion bolus.
    - Infusion of 0.25 mL/kg per minute, continued for at least 10 minutes after circulatory stability is attained.
    - If circulatory stability is not attained, consider giving another bolus and increasing infusion to 0.5 mL/kg per minute.
    - Approximately 10 mL/kg lipid emulsion over 30 minutes is recommended as the upper limit for initial dosing.
- Propofol is not a substitute for lipid emulsion.
- Failure to respond to lipid emulsion and vasopressor therapy should prompt institution of cardiopulmonary bypass. Because there can be considerable lag in beginning cardiopulmonary bypass, it is reasonable to notify the closest facility capable of providing it when cardiovascular compromise is first identified during an episode of LAST.

Data from Neal JM, et al. ASRA practice advisory on local anesthetic systemic toxicity. *Reg Anesth Pain Med*. 2010;35(2):152-161; Weinberg GL. Treatment of local anesthetic systemic toxicity (LAST). *Reg Anesth Pain Med*. 2010;35(2):188-193; Mercado P, Weinberg GL. Local anesthetic systemic toxicity: prevention and treatment. *Anesthesiol Clin*. 2011;29(2):233-242.

supplementation, may occur. It can be diagnosed by CO-oximetry, laboratory testing, or implied by symptoms.[109-111] Two local anesthetics, benzocaine and prilocaine, can produce this adverse effect.

Benzocaine and benzocaine-containing mixtures are widely used for topical anesthesia. The FDA has issued two safety bulletins warning of benzocaine-induced methemoglobinemia.[112] In a 2006 communication, the FDA reported 247 cases of methemoglobinemia from benzocaine sprays including three deaths. Since then the number of cases has risen to 319. The development of methemoglobinemia does not seem to be dose related. Symptoms appear within minutes up to 2 hours after benzocaine use. Benzocaine sprays are marketed as different brand names such as Cetacaine, Hurricaine, Exactacain, and Topex. A 2011 safety bulletin warned of serious adverse events associated with over-the-counter benzocaine gels, sprays, and liquids. They are applied to the throat and gums for pain relief. The cases were primarily in children less than 2 years old. Benzocaine gels and liquids are marketed under the names Anbesol, Hurricaine, Ora-Jel, Baby Ora-Jel, Orabase, and some store brands. Benzocaine should not be used in children under 2 years old.

Prilocaine can produce methemoglobinemia because of one of its metabolites, o-toluidine, which oxidizes hemoglobin to methemoglobin. The tendency of prilocaine to produce methemoglobin is dose related. Current recommendations are that prilocaine should not be used in children younger than 6 months old, in pregnant women, or in patients taking other oxidizing drugs. The dose should be limited to 2.5 mg/kg.[113,114] Treatment of methemoglobinemia consists of methylene blue 1 to 2 mg /kg IV.

Local Tissue Toxicity

Past formulations of chloroprocaine were reported to produce prolonged cauda equina syndrome when large doses were given by inadvertent intrathecal injection.[16,115-117] The neurotoxicity was due to a combination of large intrathecal doses, low pH, and the preservative sodium metabisulfite. This problem disappeared with the introduction of preservative-free chloroprocaine.

Lidocaine has been associated with cauda equina syndrome when used for continuous spinal anesthesia, and it is no longer used in this anesthetic technique in the United States.[118,119] Single dose spinal administration of lidocaine has also been implicated in transient neurologic syndrome (TNS), which results in back and lower extremity pain for up to 5 days postoperatively. No permanent problems occur. Symptoms include a burning, aching, cramplike, and radiating pain in the anterior and posterior aspect of the thighs. Pain radiates to the lower extremities, and lower back pain is common. Other anesthetics have been implicated, but it is much more prevalent following spinal lidocaine.[120] Surgical positioning may be a factor as well.[121] The exact mechanism is unclear. Newer techniques and agents other than lidocaine are being used now, and this has diminished this problem as a clinical issue.[122] Treatment is supportive and should include nonsteroidal antiinflammatory agents when possible.

CLINICAL USE OF LOCAL ANESTHETICS

Topical Anesthesia

Anesthesia with a number of diverse topical formulations is used for a variety of clinical applications. These include decreasing the pain of venipuncture, circumcision, dressing changes, dentistry, minor surgical procedures, laser procedures, and multiple injection regional blocks. Some available products are listed in Table 10-8 and described below.[123,124]

Cocaine

Cocaine is derived from the coca plant and is the only naturally occurring local anesthetic. Other unique properties include the

TABLE 10-8 Topical Anesthesia Products

Product	Composition	Time to Efficacy	Occlusion	Potential
TAC	0.5% tetracaine, 1:2000 epinephrine, and 11.8% cocaine	30 min	No	Seizures; cardiac arrest
LET	0.5% tetracaine, 1:2000 epinephrine, and 4% lidocaine	15-30 min	No	None
Topicaine	4% lidocaine	30 min	No	Contact dermatitis
EMLA	2.5% lidocaine and 2.5% prilocaine	30 min to 2 hr	Yes	Contact dermatitis; methemoglobinemia
LMX 4/5	4% or 5% liposomal lidocaine	15-40 min	No	None
BLT	20% benzocaine, 6% lidocaine, and 4% tetracaine	15-30 min	No	None

ability to block the monoamine transporter in adrenergic neurons. The neuronal transporter is responsible for the termination of the action of catecholamines. This catecholamine reuptake blockade results in significant vasoconstriction. This action in the CNS also accounts for cocaine's analeptic actions. It is used primarily for topical anesthesia of the nose and throat. A maximum of 5 mL of 4% solution or 200 mg should be used. It is frequently administered with other epinephrine-containing preparations so arrhythmias, hypertension, and tachycardia may occur. Caution is advised for possible drug interactions in patients taking other catecholamine-enhancing drugs such as tricyclic antidepressants or monoamine oxidase inhibitors.[125,126]

Eutectic Mixture of Local Anesthetics

Eutectic mixture of local anesthetics (EMLA) is a mixture of lidocaine and prilocaine that is applied to the skin as either a cream or patch. A eutectic mixture of chemicals has a lower melting point and solidifies at a lower temperature when combined. Pharmacokinetic studies indicate that satisfactory dermal analgesia is achieved 1 hour after application with an occlusive dressing; maximal analgesia occurs 2 to 3 hours after application.[123] When EMLA is applied to areas of abnormal skin (e.g., where psoriasis or eczema is present), absorption is faster, plasma levels are higher, and the duration of anesthesia is shorter. Systemic absorption of lidocaine and prilocaine is dependent on the duration and surface area of application. Toxicity is more likely to occur in infants and small children than in adults. Guidelines for the use of EMLA are given in Table 10-9.

TABLE 10-9 Guidelines for Application of EMLA

Age and Body Weight Requirement	Maximum Total Dose of EMLA	Maximum Application Area
0-3 months or less than 5 kg	1 g	10 cm^2
3-12 months and more than 5 kg	2 g	20 cm^2
1-6 years and less than 10 kg	10 g	100 cm^2
7-12 years and more than 20 kg	20 g	200 cm^2

EMLA, Eutectic mixture of local anesthetics.

Tetracaine, Epinephrine, and Cocaine

Three available agents—tetracaine, epinephrine, and cocaine (TAC)—have been combined for use on traumatic lacerations. The relative concentration of each component is as follows: tetracaine 1%, epinephrine 1:200, and cocaine 4%. This combination has been as effective as infiltration of local anesthetics for the closure of certain types of laceration. Tetracaine and cocaine can produce excellent topical anesthesia, and cocaine and epinephrine result in vasoconstriction at the site of application. TAC is much more expensive to administer than lidocaine. The drug combination in TAC can produce significant toxicity.[123]

Local Wound Infiltration

Pain can be effectively alleviated with local anesthetics; however, their clinical usefulness is limited by their relatively short duration of action. Even long-acting local anesthetics such as bupivacaine and ropivacaine have durations less than 8 to 16 hours. Wound infiltration prior to closing is a common practice for immediate short-term postoperative pain relief. Direct application of local anesthetic and opiate drugs via continuous infusion indwelling catheters provides long-term analgesia. Wound catheters are commonly placed in the subcutaneous, fascial, intraarticular, pleural, and periosteal areas. Local anesthetic systemic toxicity has not been reported.[127,128] Problems associated with the use of indwelling catheters are blockage or breakage, migration away from the intended area, and infection. Chondrotoxicity when intraarticular bupivacaine is used in high concentrations for long periods has been reported.[129]

Sustained Release of Local Anesthetics

A sustained-release formulation of the local anesthetic bupivacaine that does not require an indwelling catheter to achieve a long duration of action is available. Bupivacaine extended-release liposome injection, Exparel, consists of bupivacaine encapsulated in DepoFoam. It provides continuous and extended postsurgical analgesia for up to 72 hours.[130]

Tumescent Anesthesia

Tumescent local anesthesia (TLA) involves the use of lidocaine, sodium bicarbonate, and epinephrine diluted in normal saline.[131,132] Very dilute solutions of lidocaine 0.1% or less are used so that large volumes may be infiltrated subcutaneously. The volume of tumescent anesthesia solution used is determined by

the achievement of palpable tumescence (uniform swelling) of the surgical field. The maximum dose of lidocaine in TLA can approach 50 mg/kg. Peak serum levels occur 12 hours postinfiltration, and complete elimination is usually within 36 hours. Strict adherence to liposuction guidelines has minimized adverse reactions from this technique. Specific regional anesthetic techniques and blocks are discussed in detail in Chapters 44 and 45.

SUMMARY

Local anesthetic techniques are becoming more commonplace in outpatient procedures, obstetrics, and pain services. A thorough understanding of the pharmacologic properties of local anesthetics is essential in order to administer and manage local, topical, and regional anesthesia appropriately. The selection of a drug with an appropriate dose, concentration, time to onset, and duration of action for a selected regional technique are critical for a clinically successful block. A thorough evaluation of the data on local anesthetic systemic toxicity has led to new insights into the clinical presentation, prevention, and treatment of this adverse event. Lipid resuscitation is expected to offer a new and efficacious approach to clinical management of this problem. Continued efforts to develop new drugs and formulations of existing agents will broaden our ability to address pain management needs.

Opioid Agonists and Antagonists

◆ *John J. Nagelhout*

CHAPTER 11

In the past, opium was used as a topical, intravenous, and inhaled analgesic. One of the earliest uses of opium is found in Greek literature dating from 300 BCE. Opium sponges, referred to as *soporific sponges*, were used for the control of pain as early as the fourteenth century. An attempt to administer opioids by the intravenous route was attributed to Elscholtz in 1665, approximately 200 years before the invention of the syringe and needle. The first attempt to administer an opium vapor by inhalation was documented in 1778. It was not until 1853, when the syringe and needle were introduced into clinical practice by Wood, that an accurate dose of opioid could be administered intravenously.

In 1803, Sertürner reported the isolation of a pure substance from opium that he named *morphine*, after Morpheus, the Greek god of dreams. Other opium alkaloids were soon discovered—codeine by Robiquet in 1832 and papaverine by Merck in 1848. Abuse of opium and isolated alkaloids led to the synthetic production of potent analgesics. The goal of synthetic manufacture of analgesics was the creation of potent analgesics that would have high specificity for receptors, were not addictive, and were free of side effects. Synthetic production led to the development of opioid agonists, partial agonists, agonists-antagonists, and antagonists.[1,2]

OPIOIDS

Opioid is a term used to refer to a group of drugs, both naturally occurring and synthetically produced, that possess opium- or morphine-like properties. Opioids exert their effects by mimicking naturally occurring endogenous opioid peptides or endorphins. *Narcotic* is derived from the Greek word *narkōtikos*, "benumbing," and refers to potent morphine-like analgesics with the potential to produce stupor, insensibility, and dependence. The term *narcotic* is not useful in a pharmacologic or clinical discussion because of its legal connotations.

Several systems of classification are used to describe opioids. One common method divides the opioids into four categories: agonists, partial agonists, agonists-antagonists, and antagonists (Table 11-1). Another system of categorization is based on the chemical derivation of the opioids and divides them into naturally occurring, semisynthetic, and synthetic compounds, with each group having subgroups (Box 11-1).[3] Other classification systems describe the drugs as either weak or strong or hydrophilic and lipophilic.

The term *opioid* is derived from the word *opium* (from *opos*, Greek for "sap"), an extract from the poppy plant *Papaver somniferum*. The properties of opium are attributable to the 20 different isolated alkaloids, and the alkaloids are divided chemically into two types: phenanthrene (from which morphine and codeine are derived) and benzylisoquinoline (from which papaverine, a nonanalgesic drug, is derived). Modification of the morphine molecule with retention of the five-ring structure results in the semisynthetic drugs heroin and hydromorphone. When the furan ring is removed from morphine, the resulting four-ring synthetic opioid levorphanol is formed. The phenylpiperidines (e.g., fentanyl) and the diphenylheptane derivatives (e.g., methadone) all have only two of the original five rings of the basic morphine molecular structure. A close relationship exists between the stereochemical structure and potency of opioids, with the *levo*-isomers being the most potent. All opioids, despite the diverse molecular structures, share an *N*-methylpiperidine moiety, which seems to confer analgesic activity.[1] Figure 11-1 illustrates the structures of the commonly used opioids.

Opioid drugs produce pharmacologic activity by binding to opiate receptors primarily located in the central nervous system (CNS), supraspinal and spinal; and several peripheral sites. These include the gastrointestinal (GI) system, vasculature, lung, heart, and immune systems. Supraspinal analgesia occurs through activation of opioid receptors in the medulla, midbrain, and other areas, which causes inhibition of neurons involved in pain pathways. Spinal analgesia occurs by activation of presynaptic opioid receptors, which leads to decreased calcium influx and decreased release of neurotransmitters involved in nociception. Clinically, supraspinal and spinal opioid analgesic mechanisms are synergistic.[3] This explains why opioids such as fentanyl and sufentanil produce more profound analgesia when delivered epidurally than when delivered systemically, despite the similar blood concentrations measured with both routes of administration.[1,4]

Opiate Receptors

Opiate receptors are from the rhodopsin family of G-protein–coupled receptors (GPCRs). They have been DNA and amino acid sequenced and cloned. The discovery of opioid receptors can be traced back to the 1950s, when pharmaceutical companies were involved in research in anticipation of the development of an effective nonaddictive analgesic. In 1973, the examination of vertebrate species led to the discovery of three opiate receptor classes that mediate analgesia.[5] Questions emerged as to why the receptors existed, and further research led to the hypothesis that the receptors possess endogenous functions.

After the discovery of opiate receptors in the early 1970s, the search began for endogenous substances that were their agonists. In 1975, three such agonists were identified: enkephalins, endorphins, and dynorphins.[5] Each group is derived from a distinct precursor polypeptide and has a characteristic anatomic distribution. By the early 1980s, three precursor molecules to these agonists were identified and named after the active fragments: proenkephalin, proadrenocorticotropic hormone (ACTH)–endorphin (now called *proopiomelanocortin*), and prodynorphin.[1,5] Opioid peptides share the common amino-terminal sequence of Try-Gly-Gly-Phe-(Met or Leu), which has been labeled the *opioid motif* or *message* and is necessary for interaction at the receptor site. The peptide selectivity resides in the carboxy-terminal extension, providing

BOX 11-1

Classification of Opioids Based on Derivation of Drug

Naturally Occurring Opium Alkaloids

Phenanthrene Derivatives
- Morphine
- Codeine
- Thebaine

Benzylisoquinoline Derivatives
- Papaverine

Semisynthetic Derivatives of Opium Alkaloids

Morphine Derivatives
- Oxymorphone
- Hydromorphone
- Heroin
- Naloxone
- Naltrexone
- Methylnaltrexone

Thebaine Derivatives
- Buprenorphine
- Oxycodone

Synthetic Opioids

Morphinans
- Levorphanol
- Nalbuphine
- Dextromethorphan

Phenylheptylamines
- Methadone

Piperidines

Anilinopiperidine
- Meperidine

Phenylpiperidines
- Alfentanil
- Fentanyl
- Sufentanil
- Remifentanil

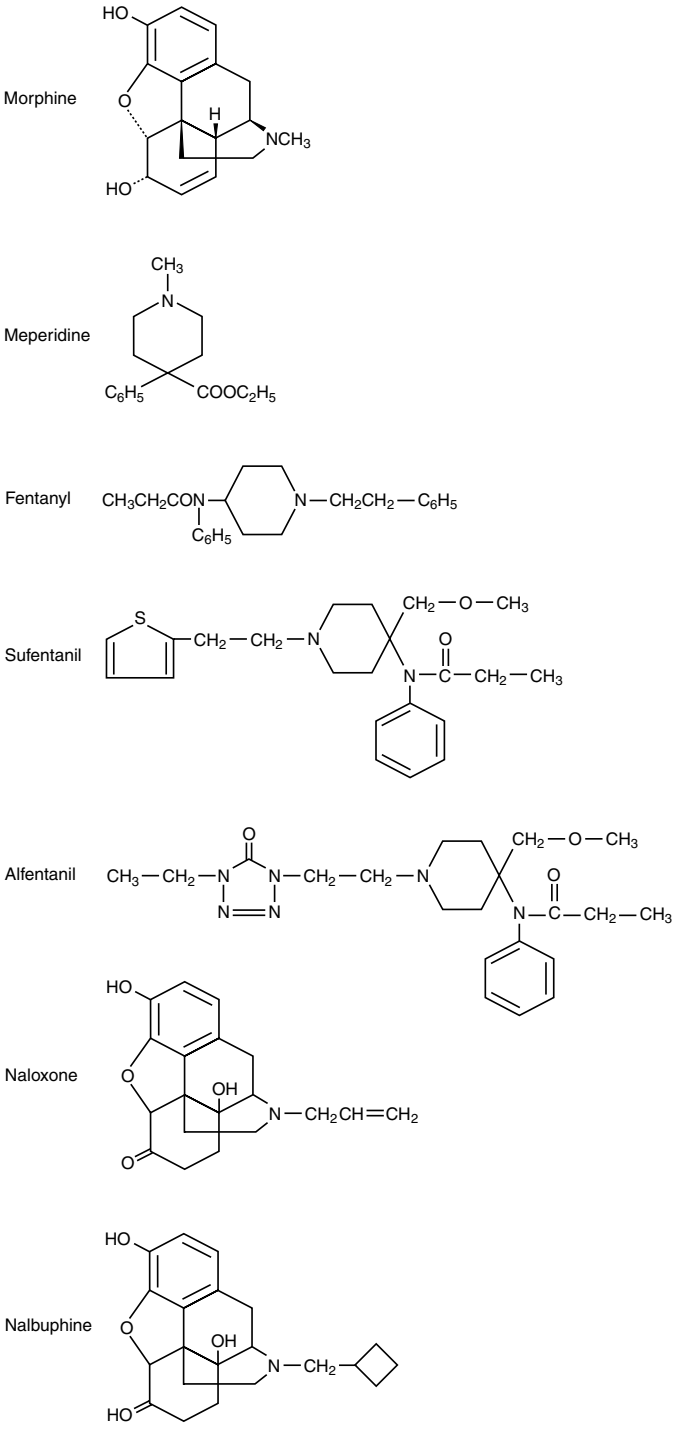

FIGURE 11-1 Selected opioid agonists and antagonists used as anesthesia adjunct drugs.

the *address*.[1] Since then an additional precursor pronociceptin that results in nociceptin has been identified. Endomorphin 1 and 2, which are highly selective agonists at μ receptors, have been identified, but the precursor's molecule has not yet been defined.[3] In 1975, Hughes and Kosterlitz[6] identified the first endogenous substance with opioid activity.

Martin et al.[7] were the first to provide evidence for opiate receptor subtypes (Table 11-2). Their findings provided evidence for the existence of three opiate receptors: mu (μ), kappa (κ), and sigma, named after their respective agonists—morphine, ketocyclazocine, and SK&F 10047. The sigma receptor was later determined not to be an opiate receptor. A delta (δ) receptor was subsequently identified. Each major opioid receptor has a unique anatomic distribution in the brain, spinal cord, and periphery.[8] The three receptor subtypes share 55% to 58% sequence homologies. Their diversity is greatest in their extracellular loops.[1] A fourth receptor has been cloned and named opiate receptor like (ORL1) or the nociceptin orphanin FQ peptide receptor (NOP). Because this receptor family awaits further clarification as to its role in pain signaling and does not display opioid pharmacology, discussion of this category is not included here.

Stimulation of the mu receptor produces supraspinal analgesia, euphoria, and a decrease in ventilation and most of the classic clinical actions of the opioid agonists. Kappa receptor stimulation produces spinal analgesia, sedation, and miosis. Currently, kappa-opioid drugs are being investigated for antiinflammatory actions that reduce disease severity of arthritis and other inflammatory diseases.[9-11] The delta receptor is responsible for spinal analgesia,

TABLE 11-2 Actions Produced at Each Opioid Receptor Subtype

Effects	Mu (μ) Receptor	Kappa (κ) Receptor	Delta (δ) Receptor
IUPHAR name	**MOP**	**KOP**	**DOP**
Analgesia	Supraspinal Spinal	Supraspinal, spinal	Supraspinal, spinal; modulates mu-receptor activity

FIGURE **11-2** Mechanism of opioid drugs. *(1)* Opioid agonist such as fentanyl binds to a opiate receptor. *(2)* A G protein is activated that produces a conformational change in the intracellular effectors such as cAMP, potassium, and calcium. *(3)* This results in a decrease in cAMP, K^+, and CA^{2+}, preventing neuropeptide release and excitation of the neuron. *cAMP*, Cyclic adenosine monophosphate.

responds to enkephalins, and serves to modulate activity of the mu receptors.[3] Various subtypes of each of the three opiate receptors have been proposed but have not been well defined.[8]

At the cellular level, endogenous peptides and exogenous opioids produce effects by altering patterns of interneuronal communications. Receptor binding initiates a series of biochemical changes that result in cellular hyperpolarization and inhibition of neurotransmitter release, effects mediated by second messengers. Opioid receptors are GPCRs and inhibit the activity of adenylate cyclase inside of cells. This results in a decrease in intracellular cyclic adenosine monophosphate (cAMP), which decreases conductance of the voltage-gated calcium channels and opens potassium channels, resulting in decreased neuronal activity. This leads to a decrease in neuronal excitation and an inhibition of neurotransmitter or neuropeptide release.[3] The mechanism of action of opioid drugs is shown in Figure 11-2. The endogenous ligands for opioid receptors are noted in Table 11-3.

Pharmacokinetics

Pharmacodynamic and pharmacokinetic considerations must be combined to reach an ideal analgesic clinical state. Surgical requirements for analgesic drugs are much different than nonoperative uses. These differences include a much higher analgesic requirement, the coadministration of potent anesthetic and sedative drugs and the ability to support respirations so that respiratory depression is not an issue until the patient emerges from anesthesia.

In anesthesia, opioids are most commonly administered by the parenteral, intrathecal, and epidural routes. They may also be given by oral, nasal, intramuscular, and transdermal administration. Physiochemical properties of opioids influence their pharmacokinetics. To reach effector sites in the CNS, opioids must cross biologic membranes from the blood to receptors on neural cell membranes. The ability of opioids to cross the blood-brain and placental barriers depends on molecular size, ionization, lipid

solubility, and protein binding. The physicochemical characteristics, pharmacokinetic variables, and partition coefficients (octanol and water as a measure of lipid solubility) for several of the commonly used opioid analgesics are summarized in Table 11-4.

The wide variation in dosing of the opioids in anesthesia depending on the patient and surgical situation leads to vastly different durations even with the same drug. Fentanyl, for example, can last 30 minutes to 18 to 24 hours, depending on how and how much is given. The pharmacokinetic parameters are important, but the context of how they are used in clinical practice is a major factor in the ultimate patient response.

Opioids are modestly absorbed orally. Some opioids undergo extensive first-pass metabolism in the liver, greatly reducing their bioavailability and therapeutic efficacy after oral dosing. Orally administered morphine has limited absorption from the GI tract. Drugs with greater lipophilicity are better absorbed through nasal and buccal mucosa and the skin.

When small doses of the opioids are used, the effects are usually terminated by redistribution rather than metabolism. Larger or multiple doses or continuous infusions are much more dependent on metabolism for offset.[12] Like most drugs, opioids are usually metabolized in the liver to more polar and less active or inactive compounds by both phase 1 and phase 2 processes. Some opioids, such as morphine, have active metabolites such as morphine 6 glucuronide, that can prolong the therapeutic effects of the parent compound. The meperidine metabolite, normeperidine, is neurotoxic and may accumulate in the elderly or in patients with decreased renal or hepatic function. This has led to a decline in its use. It is avoided in the elderly or patients with renal or hepatic dysfunction and where chronic use may be needed.[1] The opioid drugs are metabolized by the usual cytochrome enzymes including CYP3A4, CYP2D6, and CYP2B6.[13-15] Remifentanil was designed with an ester group in its structure and is metabolized by hydrolysis in the plasma and tissues by non-specific esterases. Remifentanil has a low volume of distribution and a large clearance, which results in a short half-life of approximately 10 minutes. Opioids and their metabolites are excreted primarily by the kidneys and secondarily by the biliary system and GI tract.[16] Clinicians become very adept in the art of administering opioids by bolus, incremental injection, or infusion to maximize analgesia during surgery as needed yet allowing for safe and rapid recovery and residual postoperative analgesia.

*Presumed to exist, awaiting discovery.

ACTH, Adrenocorticotropic hormone; *MSH*, melanocyte-stimulating hormone.

Pharmacogenetics

The wide variations in dosing and patient responses have both pharmacodynamic and pharmacokinetic causes. Pharmacogenetics appears to be an important factor as well. Opioids have a narrow therapeutic index, calling for a fine balance between optimizing pain control and sedative effects (without respiratory depression) and recognizing great variability from patient to patient in response and dose requirements. Genetic factors regulating their pharmacokinetics (metabolizing enzymes, transporters) and pharmacodynamics (receptors and signal transduction) contribute to this variability and to the possibility of adverse drug effects, toxicity, or therapeutic failure of pharmacotherapy. Significant variation in conversion of the prodrug codeine into the active metabolite morphine has been noted. Polymorphisms in CYP2D6 are responsible for the wide variations among different populations.[17]

The clinical use of opioids involves knowledge regarding patient characteristics, their perception, severity and likely duration of pain, lifestyle variables such as smoking habits and alcohol intake, and opioid drug and dosing regimen selection.[17] Other factors affecting pharmacokinetics and pharmacodynamics of opioids include age, body weight, renal failure, hepatic failure, cardiopulmonary bypass, acid-base changes, and hemorrhagic shock.

In adults, advancing age requires lower opioid doses for the treatment of postsurgical pain. Also, in relatively similar patient groups, dosage requirements vary. Aubrun et al.[18] reported that in more than 3000 patients, morphine dosage requirements for postoperative hip replacement therapy varied almost 40-fold. Large

variabilities have been reported in cancer patients receiving morphine via various routes.[17] Variability is contributed to by inherent pain sensitivity, tolerance, and other factors, including pharmacogenetics influencing the clinical pharmacology of opioids.[19]

Clinical Effects of Opioids

The common clinical effects of opioid agonists are listed in Box 11-2.

Central Nervous System Effects: Analgesia, Sedation, and Euphoria

Opiate analgesia results from actions in the CNS, spinal cord, and peripheral sites (Table 11-5). They are most effective for visceral continuous dull pain; however, at high doses they will relieve any pain. They are less effective against neuropathic pain that requires chronic multimodal therapy.[20] The sedative and euphoric actions contribute to the feeling of well-being in awake patients. The analgesic effects of opioids come from their ability to (1) directly inhibit the ascending transmission of nociception information from the spinal cord dorsal horn and (2) activate pain control pathways that descend from the midbrain, via the rostral ventromedial medulla to the spinal cord dorsal horn.[1] The effect of opioids on electroencephalographic and evoked-potential activity is minimal; therefore neurophysiologic monitoring can be conducted during opioid anesthetic techniques. The opiates can increase intracranial pressure if respiratory depression–induced hypercarbia occurs. They have variable effects on cerebral vascular tone depending on the background anesthetic present. Possible untoward CNS effects when the opioids are used in neurosurgery are easily managed by controlling ventilation and maintaining adequate blood pressures.[21] The comparative potency of the opioid agonists that are used in anesthesia is as follows: sufentanil > fentanyl = remifentanil > alfentanil.

The sedative and euphoric effects of the opiates vary depending on the agent. Patients will exhibit sedation and euphoria that is different with mu versus kappa agonists. Dysphoria can occur and appears more prominent with drugs that have strong kappa receptor effects or when opioids are taken in the absence of pain. Physical and psychological dependence occur with repeat administration as evidenced by physical withdrawal with abstinence and drug-seeking behaviors.[1,22] The opiates are not anesthetics, so awareness under anesthesia is a concern when even high doses of opiates are used.[23,24] Both acute and chronic tolerance occur with the opiates. Cross-tolerance among mu agonists will occur. Usually a decrease in duration is noted first, followed eventually by a decrease in effect. The mechanism of tolerance is complex and does not appear to be due to a change in receptor number. Receptor internalization, activation of *N*-methyl-D-aspartate (NMDA) receptors, second messenger changes, and G-protein uncoupling may all play a role. Hyperalgesia that can result from chronic administration may be related to these same mechanisms.[1,22]

Respiratory Depression

All opiate agonists produce a dose-dependent depression of respirations via effects on mu and delta receptors in the respiratory centers in the brainstem. They reduce the responsiveness of the respiratory centers to increasing carbon dioxide and decreasing oxygen. It requires higher partial pressure of carbon dioxide (pCO_2) levels to maintain normal respiration. Stated in pharmacologic terms, they produce a shift to the right in the CO_2 response curve for respiration. Respiratory rate is affected first, and a classic "narcotized" patient will take slow deep breaths. As doses increase, apnea is produced. Because both analgesia and respiratory depression are mediated via the same receptors, reversal of respiratory depression with antagonists such as naloxone also reverses analgesia. The goal of most clinical anesthetics is to leave some residual analgesia without respiratory depression upon emergence to address postoperative pain.[1]

Miosis

Miosis, or pinpoint pupils, is a prominent action of opioids and is usually present under general anesthesia as a result of the high doses of high potency opiates used. Tolerance does not develop to this effect. It is produced by effects in the pupillary reflex arc. Opiate depression of inhibitory gamma-aminobutyric acid (GABA) interneurons leads to stimulation of the Edinger Westphal nucleus, which sends a parasympathetic signal via the ciliary ganglion to the oculomotor nerve to constrict the pupil.[1] Clinicians note the degree of miosis as somewhat indicative of the presence of opiates.

Antitussive Effects

The opiates produce cough suppression via a depressant effect on the cough center in the medulla. Protective glottal reflexes are not

Gigantocellular reticular	Mu = kappa = delta
Spinal	
Spinal cord	Mu = delta = kappa
Dorsal root ganglia	Mu = delta = kappa

affected. Although they all produce this effect, codeine and heroin are especially good suppressants. D-isomers such as dextromethorphan are also effective. Anesthetic use of opiates can assist the patient in tolerating airway devices and ventilators.

Nausea and Vomiting

The emetic effect of the opioids is complex. They elicit nausea and vomiting by stimulating the chemoreceptor trigger zone in the area postrema of the medulla. A vestibular component is also probable because the incidence is much higher in ambulatory patients. Nausea and vomiting are rare in the preoperative area and operating room where patients are recumbent. A separate action with higher repeat doses can have an antiemetic effect by depressing the vomiting center. Clinically, when opiates are used as part of the anesthetic plan, there is an increased incidence of postoperative nausea and vomiting.[25] The effect is less frequent with repeat doses although individual patient response is highly variable. Figure 11-3 depicts the centers in the brain involved with nausea and vomiting and the types of receptors involved.

Cardiac Effects

The usual result of anesthetic use of opioids in healthy patients is bradycardia with little effect on blood pressure. Bradycardia results from medullary vagal stimulation.[1] All opioids induce some degree of dose-dependent peripheral vasodilation. Myocardial contractility, baroreceptor function, and autonomic responsiveness is not affected. Opiate anesthesia is often used in patients with cardiovascular compromise because of this minimal depression. Much of the hypotension produced by morphine, codeine, and meperidine is attributed to histamine release, which is absent with fentanyl, sufentanil, alfentanil, and remifentanil. $Histamine_1$ and $histamine_2$ antagonists, when combined, block the cardiovascular effects of vasodilation, tachycardia, and hypotension that results.[12]

Opioids usually produce an antidiuretic effect. Opioids that are agonists at kappa receptors can cause diuresis. They decrease tone at the bladder detrusor muscle and constrict the urinary sphincter. This results in urinary retention. Urinary retention is a common side effect with intrathecal and epidural opioid administration.

Muscle Rigidity

Opioids have no major effects on nerve conduction at the neuromuscular junction or at the skeletal muscle membrane. A generalized hypertonus of skeletal muscle can be produced by large intravenous doses of most opioid agonists. Although morphine can produce rigidity, the problem is most often associated with fentanyl, alfentanil, sufentanil, and remifentanil. The difficulty is caused in part by loss of chest-wall compliance and by constriction of pharyngeal and laryngeal muscles. It becomes very difficult to ventilate the patient unless the rigidity is reversed. It is commonly referred to as *tight chest* or *truncal rigidity*. This effect most often occurs during anesthesia induction when high doses of potent opiates are administered rapidly. Remifentanil, which is administered by infusion, may be especially prone to producing this effect. Administration of nitrous oxide also increases the frequency.[26] Opioid-induced muscle rigidity is thought to be mediated by central mu receptors interacting with dopamine and GABA pathways. This rigidity is easily reduced or eliminated by the administration of muscle relaxants or naloxone.[27]

Pruritus

Opiates frequently produce a rash, itching, and a feeling of warmth in the "blush" area of the face, upper chest, and arms. This occurs

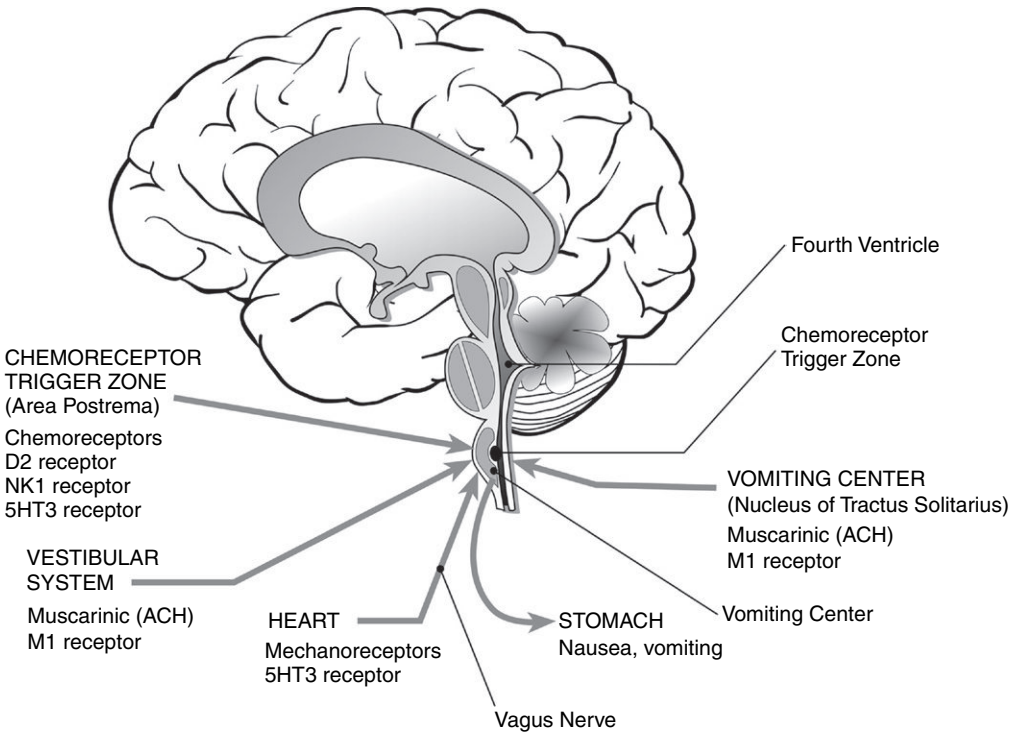

FIGURE **11-3** The vomiting center and chemoreceptor trigger zone are shown. Inputs from sites outside the central nervous system are noted. Type and location of various receptors involved in nausea and vomiting are given. Anti-emetic drugs act on these receptor targets. *D2*, Dopamine receptors; *NK1*, neurokinin; *5HT3*, serotonin; *M1*, muscarinic; *ACH*, acetylcholine.

with both histamine and nonhistamine-releasing drugs and is especially prominent with neuraxial administration. The mechanism appears to be through central mu receptors and not local histamine release.[28] Pruritus can be treated with antagonists such as naloxone or naltrexone; however, they also decrease analgesia. Nalbuphine, droperidol, antihistamines, and ondansetron may also be effective. Many clinical pain services have established protocols to treat this problem.[29,30]

Gastrointestinal Effects

Opioids have multiple effects on the gastrointestinal (GI) function. They decrease gastric motility and intestinal propulsive activity, prolong gastric emptying time, and reduce secretory activity throughout the GI system. This leads to the common problems of opiate-induced constipation and postoperative ileus. Alvimopan (Entereg) and methylnaltrexone (Relistor) are both locally acting opiate receptor antagonists approved for use in treating these GI side effects.[31,32]

Opioids produce a dose-dependent increase in biliary duct pressure and sphincter of Oddi tone via opioid receptor-mediated mechanisms. They also increase urinary sphincter tone. This has led to a few clinical concerns. The use of opiates for the treatment of biliary or renal colic may be compromised by this action. Meperidine, which produces this effect the least among opiate agonists or nonsteroidal antiinflammatory drugs (NSAIDs), is considered the agent of choice for this situation.[33] In anesthesia, the use of opiates during surgery may produce false positive cholangiograms. The clinical relevance of this effect is questionable because the opiates are used routinely without problems.

Endocrine Effects

Opiates reduce the stress response to surgery and have an immunosuppressant effect.[3] Endocrinologic effects of opioids include the release of vasopressin and inhibition of the stress-induced release of corticotropin and gonadotropins from the pituitary. Release of thyrotropin from the adrenohypophysis is also inhibited. Basal metabolic rate and temperature may also be decreased in patients receiving chronic opioids, although animal data indicate that acute administration either systemically or intrathecally can increase temperature. Opioids slightly decrease body temperature by resetting the equilibrium point of temperature regulation in the hypothalamus.[1]

Neuraxial Effects

The epidural and intrathecal routes have become common for the administration of pain medication. Opioids delivered by epidural or subarachnoid routes behave differently in onset, duration, and side effects than the same drugs given systemically. Pain that is unresponsive to systemic opioids may respond to the same drugs given centrally, reducing some side effects while increasing the incidence of others. Systemic opioids suppress nociception in lamina II and V cells of the dorsal horn of the spinal cord, leaving lamina IV and VI cells, which mediate nonnociceptive information, relatively unaffected.[34]

Spinal administration of opioids is a selective and potent means of producing analgesia. Intrathecal administration allows injection of the opioids directly into the cerebrospinal fluid (CSF), a more efficient method of delivering the drug to the spinal cord opiate receptors. The analgesic response is the result of activity at spinal opiate receptors, especially kappa receptors in the substantia gelatinosa, lamina II of the dorsal horn.[34] Opioids can be given with local anesthetics or other adjuncts intraoperatively at the initiation of spinal anesthesia or postoperatively for pain control.[35] Side effects with spinal administration are similar to those described previously with systemic administration, except that pruritus and urinary retention occur with much greater frequency. Less lipid-soluble agents such as morphine and hydromorphone produce a delayed ventilatory depression, the result of migration of opioid via the CSF to the midbrain vestibular centers.

Respiratory depression is the most common serious complication associated with intrathecally and epidurally administered opioids. Two different levels of respiratory depression can occur after neuraxial morphine administration. An early phase observed soon after administration reflects rapid systemic absorption and is similar to parenteral dosing. A later, more insidious depression that occurs over a period of 8 to 12 hours has been related to rostral flow of CSF and delivery of morphine to the brainstem respiratory center.[36] Awareness of delayed respiratory depression has resulted in increased monitoring of patients and dose reductions, thereby greatly reducing the incidence of serious respiratory depression to that seen with patient-controlled analgesia (PCA) opioids.

Generalized pruritus has been observed with neuraxial morphine and to a lesser extent with other opioids. Mild itching, usually involving the face or chest, is common; however, the intensity of itching can become so annoying that it interferes with sleep. Pruritus is commonly seen with opioids such as fentanyl and sufentanil that do not release histamine. Pruritus can be treated with antihistamines or with opiate receptor antagonists. The incidence of postoperative nausea and vomiting increases for patients treated with neuraxial opioids. Nausea may result either from the rostral spread of the drug in the spinal fluid to the brainstem or vascular uptake and delivery to the chemoreceptor trigger zone in the area postrema of the medulla.

Urinary retention after spinal opioid analgesia has been related to inhibition of sacral parasympathetic outflow, which results in relaxation of the bladder detrusor muscle and an inability to relax the sphincter.[34]

Opioids with a higher lipid solubility (see Table 11-4) tend to be rapidly absorbed into the spinal tissues after central administration, resulting in a faster onset of action. However, higher lipid solubility is associated with a small area of distribution of the drug along the length of the spinal cord and therefore a more limited area of analgesia.[4] Higher lipid solubility is also associated with faster clearance of the drug out of the epidural and intrathecal space, resulting in a shorter duration of action and higher blood concentrations of the opioid.[34,36] Spinal opioids are advantageous in selective analgesia, which occurs in the absence of motor and sympathetic blockade.

Epidural anesthesia and analgesia have been successfully used in obstetric patients and surgical patients. Epidural doses of opioids, however, are much higher than doses of opioids for intrathecal use. Small portions of epidural opioids cross the dura, enter the CSF, and penetrate spinal tissue in amounts proportional to their lipid solubility. The remaining drug is absorbed by the vasculature, producing plasma levels comparable to those after intramuscular injections and providing supraspinal analgesia.[36] Neuraxial administration of opioids is a selective and potent means of producing analgesia in many surgical and obstetric procedures.[37] Table 11-6 gives neuraxial opioid dosages.[34,36]

Opioid Techniques and Delivery

In clinical practice, opioids are used to relieve pain during monitored anesthesia care and regional anesthesia and as a component of balanced anesthesia, as well as a primary component of general anesthesia. The inclusion of opioids reduces pain and anxiety, decreases somatic and autonomic responses to airway

TABLE 11-6 Doses of Neuraxial Opioids*

Opioid	Single Dose	Infusion Rate
Epidural		
Morphine	2-5 mg	0.1-1 mg/hr
Meperidine	25-50 mg	5-20 mg/hr
Methadone	5 mg	0.3-0.5 mg/hr
Fentanyl	50-100 mcg	25-100 mcg/hr
Sufentanil	25-50 mcg	10-50 mcg/hr
Butorphanol	2-4 mg	0.2-0.4 mg/hr
Subarachnoid		
Morphine	0.25-0.3 mg	
Meperidine	10 mg	
Fentanyl	10-20 mcg	
Sufentanil	5-10 mcg	

*Doses adjusted for age and level of regional injection.

manipulation, improves hemodynamic stability, lowers requirements for inhaled anesthetic agents, and provides postoperative analgesia.[38]

The most common method of administering opioids in the practice of anesthesia is intermittent bolus injection, which although effective for many procedures, produces wide swings in drug plasma concentration. Intermittent periods of deep and light anesthesia are produced. Continuous opioid infusion results in plasma concentration that can be maintained more accurately and consistently. Continuous infusion of opioids is associated with hemodynamic stability, reduces the total necessary dose of opioids, and decreases the need for opioid reversal agents.

Continuous intravenous administration involves the infusion of a loading dose that "fills" the volume of distribution, followed by continuous drug replacement that keeps the volume of distribution "filled" as the drug is eliminated.[39]

$$\text{Loading dose (mcg/kg)} = V_d \text{ (mL/kg)} \times C_p \text{ (mcg/mL)}$$

$$\text{Maintenance infusion (mcg/kg/min)} = \text{Cl (mL/kg/min)}$$

where V_d is volume of distribution, C_p is plasma concentration, and Cl is drug clearance. See Table 11-4 for the V_d and Cl of various opioids.

The rate of continuous infusion does not remain constant, but rather is adjusted to meet the patient's needs and to control varying surgical stimuli. The volume of distribution is decreased for patients with hypovolemia and trauma and for geriatric patients. Factors such as enzyme induction, hepatic failure, and adjunctive drug use are also considered. Table 11-7 provides dose ranges for continuous infusions.

Continuous intravenous infusion can be administered by gravity flow with a manual control device (e.g., Buretrol), an infusion pump, or a syringe pump. Syringe pumps are advantageous because they are programmed to administer drug in units of micrograms per kilogram per minute. Some advantages of continuous infusion techniques are listed in Box 11-3.

Nonparenteral routes of opioid delivery are also used. Fentanyl is the prototypic opioid for transdermal application. Transdermal administration of fentanyl does not require cooperation from the patient; also, first-phase hepatic metabolism is not a factor, and the route does not produce discomfort. Currently available formulations permit delivery of 25 to 100 mcg per hour for 24 to 72

TABLE 11-7 Infusion Rates*

Opioid	Induction (mcg/kg)	Maintenance (mcg/kg/min)
Fentanyl	5-10	0.01-0.05
Sufentanil	1-30	0.005-0.015
Alfentanil	8-100	0.5-3
Remifentanil	0.5-1	0.05-2

*Doses will vary depending on coadministered drugs, patient characteristics, and surgical procedure.

BOX 11-3
Advantages of Continuous Opioid Infusion

- Hemodynamic stability
- Decreased side effects
- Reduced need for opioid-reversal agents
- Reduced use of vasopressor drugs
- Suppression of cortisol and vasopressin response to cardiopulmonary bypass: stress-free anesthesia
- Reduced total dosage of opioids
- Decreased recovery time

hours. The transdermal fentanyl patch provides a relatively constant plasma concentration for 72 hours. It is not currently recommended for use in managing postoperative pain.

Oral transmucosal fentanyl citrate is occasionally used for providing analgesia in children. Its primary use is for treating breakthrough pain in cancer patients.[40] Fentanyl is dissolved in a sucrose solution and shaped into a lozenge. The transmucosal route is effective, owing to the characteristics of the oral mucosa. The oral mucosa is thinner than the skin and is supplied by numerous blood and lymphatic vessels. The opioid administered transmucosally is also absorbed directly into the systemic circulation without passing through the liver. A high incidence of pruritus is a problematic side effect with transmucosal administration.

The Food and Drug Administration has approved a nasal spray formulation of fentanyl (Lazanda) for management of breakthrough pain in adult cancer patients who are already receiving and are tolerant to opioid therapy. Nasal administration of sufentanil preoperatively in the pediatric patient has also been studied. The children remained calm, and some experienced somewhat decreased ventilatory compliance. Recovery room time was not increased, and the highest incidence of nausea and vomiting occurred in the group that received the highest dose of sufentanil. Nasal butorphanol is currently available and is widely used in the management of migraine headaches. Table 11-8 compares dosages for various routes of opioid administration.[41]

INDIVIDUAL OPIOIDS

Agonists

Naturally Occurring Opioids

Morphine. Morphine, the prototype for opioid agonists, is the most abundant alkaloid in raw opium. The primary therapeutic use of morphine is the abatement of moderate to severe pain. Morphine can be administered via the intramuscular, intravenous, subcutaneous, oral, intrathecal, and epidural routes. Effects of intravenous morphine on the time course

TABLE 11-8 Opioid Dose Comparisons

Opioid	Route	Onset	Peak	Duration of Action	Half-Life
Morphine	PO	60 min	30-60 min	4-5 hr	Neonates 4.5-13 hr
	IM	30-60 min	30-60 min	4-5 hr	Adults 3-5 hr
	IV	20 min	30-60 min	4-5 hr	
	Epidural	60-90 min	30-60 min	8-24 hr	
Codeine	PO	30-60 min	60-90 min	4-6 hr	2.5-3.5 hr
	IM	10-30 min	30-60 min	4-6 hr	2.5-3.5 hr
Hydromorphone	IV	15-30 min	30-90 min	4-5 hr	1-3 hr
Oxycodone	PO	10-15 min	30-60 min	4-5 hr	3.2-4.5 hr
Methadone	PO	30-60 min	30-60 min	6-8 hr	15-30 hr
	IV	5-10 min	15-20 min	4-6 hr	15-30 hr
Meperidine	PO	10-15 min	30-60 min	2-4 hr	2.5-4 hr
	IM	10-15 min	30-60 min	2-4 hr	2.5-4 hr
	IV	5 min	30-60 min	2-4 hr	2.5-4 hr
Alfentanil	IV	Immediate	Immediate		1.5 hr
Fentanyl	Transmucosal	5-15 min	20-30 min	Related to blood levels	6.6 hr
	IM	7-15 min	20-30 min	1-2 hr	2-4 hr
	IV	2-5 min	20-30 min	0.5-1 hr	2-4 hr
	Epidural	20-30 min		2-3 hr	2-4 hr
Remifentanil	IV	1 min	1 min	5-10 min	9 min
Sufentanil	IV	1-3 min		Dose dependent	6 hr
Tramadol	PO	60 min	120 min	9 hr	2-3 hr
Buprenorphine	IM	10-30 min	60 min	6 hr	2-3 hr
	IV	10-30 min	60 min	6 hr	2.5-4 hr
Butorphanol	IM	10-15 min	30-60 min	3-4 hr	2.5-4 hr
	IV	Immediate	30-60 min	3-4 hr	2.6-2.8 hr
Dezocine	IM	15-30 min	60 min	4-6 hr	2.6-2.8 hr
	IV	15-30 min	60 min	4-6 hr	3.5-5 hr
Nalbuphine	IM		30 min		3.5-5 hr
	IV		1-3 min		2-3 hr
Pentazocine	PO	15-30 min		4-5 hr	2-3 hr

Nalmefene	IM	5-15 min	120 min	8 hr	10.8 hr
	IV	2 min	2-3 min	8 hr	6-10 hr
Naltrexone	PO	45-60 min	60 min	24-72 hr	

IM, Intramuscularly; *IV*, intravenously; *PO*, by mouth.

of sedation and analgesia occur with sedation first, followed by analgesia.[42] Morphine-induced sedation, therefore, should not be considered as an indicator of appropriate analgesia. When given intrathecally, morphine has the longest duration of action of the specific opioids. Morphine is among the least lipophilic of the opioids, resulting in slow penetration of biologic membranes, less accumulation in lipid membranes or fatty tissues, and slower onset.

Morphine undergoes phase 2 glucuronide conjugation in the liver at both the 3 position (which produces morphine-3-glucuronide, M3G) and the 6 position (which produces morphine-6-glucuronide, M6G), in a 2:1 ratio.[43] As a result of the active metabolite, M6G, morphine appears to produce a more prolonged effect, often excessive sedation, in the patient with renal failure. Within the CNS, M6G metabolite is more potent than the parent drug, whereas M3G metabolite is inactive.[43,44] The greater hydrophilicity of M6G than the parent drug normally impedes its passage into the CNS. However, after chronic administration or in patients with renal failure, M6G at a high blood level can enter the CNS.

Morphine produces a nonimmunologic release of histamine from tissue mast cells, resulting in local itching, redness, or hives near the site of intravenous injection or generalized flushing. When sufficient histamine is released, the patient may exhibit signs of decreased systemic vascular resistance, hypotension, and tachycardia. Localized histamine release after a morphine injection is not uncommon. Morphine is primarily used for preoperative or postoperative pain relief. The delayed onset and peak effects and large patient variability make it less useful for intraoperative use than fentanyl and its analogs.

Codeine. Considered a weak opioid, codeine is generally not used for treatment of severe pain. Approximately 10% of the administered dose of codeine is O-demethylated to morphine, which accounts for most of its analgesic activity.[37] It has good antitussive activity, but on a weight basis, codeine is a less potent antitussive than morphine. Combinations of codeine with acetaminophen remain very popular as prescribed analgesics.

Semisynthetic Opioids

Hydromorphone. Derived from morphine in the 1920s, hydromorphone has a pharmacokinetic profile similar to that of morphine but it is more potent. Hydromorphone is absorbed from the oral, rectal, and parenteral sites. Because of its lipid solubility, it is sometimes used instead of morphine for epidural or spinal administration when a wide area of analgesia is needed.[45] Studies performed on parenteral hydromorphone relative to morphine tend to demonstrate similar analgesia and side-effect profiles. Because of the lack of any known active metabolites, it is often recommended for patients with renal failure.[1] It is available in high potency and sustained release preparations.

Synthetic Opioids

Methadone. Introduced in the 1940s, methadone is used primarily for relief of chronic pain, treatment of opioid abstinence syndromes, and treatment of heroin addiction. Compared to other common opioids, it is well absorbed orally and produces less euphoria. Supplied as a racemic mixture of two optical isomers, most of methadone's activity comes from the *l*-isomer. Unlike most opioids, it has a long half-life, allowing less frequent dosing. It has a prolonged effect in part due to extensive protein binding (90%) with slow release and a lower intrinsic ability of the liver to metabolize it. It also has the advantage of a high bioavailability and no active metabolites. Disadvantages include accumulation and a longer time to reach steady state than other opioids.[46]

Meperidine. Meperidine is a synthetic mu-receptor agonist. It is structurally similar to atropine and has an atropine-like antispasmodic effect. After demethylation in the liver, meperidine is partially metabolized to normeperidine, which is half as analgesic as meperidine but lowers the seizure threshold and induces CNS excitability. Normeperidine's elimination half-life is significantly longer than that of meperidine. With accumulation of normeperidine, subjects may experience a CNS excitation characterized by tremors, muscle twitches, and seizures. Because of accumulation of normeperidine, limitations on its use should be considered in patients with renal failure and for chronic use in cancer patients who may require high doses. There is a significant drug interaction that can occur between meperidine and the first-generation monoamine oxidase (MAO)-inhibiting drugs isocarboxazid (Marplan, others), phenelzine (Nardil, others), and tranylcypromine (Parnate, others). Hyperthermia, seizures, and death have been reported.[47,48]

Meperidine is effective in reducing shivering from diverse causes, including general and epidural anesthesia.[49] This appears to result from kappa receptor stimulation. It reduces or eliminates visible shivering, as well as the accompanying increase in oxygen consumption.[22] Anesthetic uses of meperidine have declined in recent years due to the availability of safer, more convenient techniques.

Alfentanil. After bolus injection, alfentanil has a more rapid onset of action and shorter duration than fentanyl, even though it is less lipid soluble. The high nonionized fraction (90%) of alfentanil at physiologic pH and its small volume of distribution increase the amount of drug available for binding in the brain. Although alfentanil is effective epidurally, the duration of analgesia is short, and for this reason, it has never achieved popularity. Alfentanil is metabolized in the liver by oxidative *N*-dealkylation and *O*-demethylation in the cytochrome P-450 system, and the inactive metabolites are excreted in the urine. Alfentanil has great patient-to-patient variability, as seen in the original studies, in which a high coefficient of variation was reported. Erythromycin has been shown to prolong the metabolism of alfentanil and interact with alfentanil to produce clinical symptoms of prolonged respiratory depression and sedation. Its popularity in current practice is limited.

Fentanyl. Fentanyl is the most widely used opioid analgesic in anesthesia. A single administered dose of fentanyl has a short duration of action (approximately 20 to 40 minutes). It produces a profound dose-dependent analgesia, ventilatory depression, and sedation. The action of a single dose of fentanyl is terminated by redistribution. The high lipid solubility of fentanyl allows for rapid tissue uptake.[12] Fentanyl and its derivatives all undergo significant first-pass uptake in the lungs with temporary accumulation before release. When fentanyl is given in multiple doses or as a continuous infusion, the termination of action reflects elimination but not redistribution. Clearance of fentanyl is dependent on hepatic blood flow. Fentanyl is metabolized by *N*-dealkylation and hydroxylation to inactive metabolites that are eliminated in urine and bile. Fentanyl elimination is prolonged in the elderly and the neonate.

Initially used intravenously during surgery, fentanyl has many other uses. It is administered for intrathecal, epidural, and postoperative patient-controlled analgesia (PCA) intravenous use. Fentanyl transdermal patches deliver 75 to 100 mcg/hr, resulting in peak plasma concentrations in approximately 18 hours because a subcutaneous depot of drug must be saturated before the drug is consistently absorbed into the bloodstream.[12] The dose remains stable during the presence of the patch. After removal, the decline in blood concentration follows an apparent 17-hour half-life; the true elimination half-life of fentanyl remains at approximately 3 hours, but continued absorption from the subcutaneous depot during elimination makes it appear longer.

Transmucosal fentanyl (Fentanyl Oralet) was initially developed in the form of a lollipop as an adjunct to pediatric anesthesia. A similar fentanyl product is available in higher strengths and is used for relief of breakthrough cancer pain. The pharmacokinetics of this form are dose related, with an apparent elimination half-life of approximately 6 hours. Not all opioids are absorbed sublingually. Hydromorphone, oxycodone, and heroin are minimally absorbed, whereas absorption for morphine is 18%; fentanyl, 51%; and methadone, 34%.[50]

Remifentanil. Remifentanil use in anesthesia has increased tremendously in recent years as new applications are being discovered for its unique profile.[51,52] Its rapid onset and ultra-short duration, titratability, and simple metabolism make it very convenient for many modern clinical perioperative situations. Remifentanil is a moderately lipophilic, piperidine-derived opioid with an ester link. The addition of the ester group allows the drug to be easily and rapidly metabolized by blood and tissue esterases. Kinetic studies indicate that the drug has a small volume of distribution (V_d 0.39 ± 0.25) and an elimination half-life of 8 to 20 minutes. It is metabolized by hydrolysis catalyzed by general esterase enzymes to a less active compound. It is not dependent on cholinesterase enzyme for metabolism and therefore is not influenced by quantitative or qualitative changes in cholinesterase. Succinylcholine metabolism does not influence remifentanil breakdown.

Because of the potential for respiratory depression and muscle rigidity, bolus dosing in the preoperative or postoperative care unit is not recommended. Due to its unique metabolic pathway, remifentanil has a short duration of action, a precise and rapid titratable effect because of rapid onset, and noncumulative effects and results in rapid recovery after discontinuation of its administration by infusion. However, because of the rapidity of emergence from remifentanil anesthesia, it is important to develop and start a plan for alternative analgesic therapy in the postoperative period.[53]

The commercial preparation of remifentanil is a water-soluble, lyophilized powder that contains a free base and glycine as a vehicle

to buffer the solution. Because of potential glycine neurotoxicity, remifentanil should not be administered epidurally or intrathecally.[1]

Sufentanil. Sufentanil is the most potent of the phenylpiperidines and is used for situations in which profound analgesia is required such as in cardiac or other major surgical procedures. The patients are usually in-hospital patients requiring significant analgesia and postoperative care. Sufentanil is a mu agonist that produces effective analgesia via both the intravenous and intrathecal routes. It has a high lipophilicity and potency and a shorter elimination half-life than fentanyl. Hepatic clearance of sufentanil approaches liver blood flow. Sufentanil metabolism involves *O*-demethylation and *N*-dealkylation, with minimal amounts being excreted unchanged in the urine.

The effects of age on the distribution and elimination of sufentanil are reflected in a decrease in the initial volume of distribution for the elderly. The reduced volume of distribution of sufentanil in elderly patients is associated with increased respiratory depression.

Tramadol. Tramadol is a synthetic codeine analog that is a weak mu opioid receptor agonist, with analgesic effects produced by inhibition of norepinephrine and serotonin neuronal reuptake as well as presynaptic stimulation of 5-hydroxytryptamine release.[1] Tramadol is a racemic mixture; the (+) enantiomer binds to the mu receptor and inhibits serotonin uptake, whereas the (−) enantiomer inhibits norepinephrine uptake and stimulates α_2-adrenergic receptors. It has an elimination half-life of 5 to 6 hours and is an effective analgesic for the treatment of mild to moderate pain. Tramadol can cause seizures and possibly exacerbate them in patients with predisposing factors. Tramadol-induced analgesia is not entirely reversed by naloxone, but tramadol respiratory depression can be reversed. In overdose situations, most of the toxicity is related to the amine uptake inhibition rather than to opioid effects.[1]

Partial Agonists and Agonists-Antagonists

Buprenorphine. Buprenorphine, a synthetic derivative, is a potent partial agonist opioid that binds mainly to the mu receptors.[54] Its slow dissociation from the receptor is a result of its long duration of action (approximately 8 hours). Its high affinity for the mu receptor accounts for the reduced ability of naloxone to reverse the effects of buprenorphine. Clinically significant respiratory depression can occur with therapeutic doses. Buprenorphine exhibits a ceiling effect in which an increase in the dose does not increase respiratory depression; this is believed to result from the fact that the drug's antagonistic effects become more apparent at higher doses. It also has minimal effect on GI motility and smooth muscle sphincter tone. A transdermal system of buprenorphine was developed for treatment of moderate to severe cancer pain.[55] Administered transdermally, it provides analgesia and has a low incidence of adverse events.

Butorphanol. Butorphanol, a highly lipophilic opioid, acts as an agonist at the kappa receptors and as a weak antagonist at mu receptors. It is more potent than morphine in the production of analgesia. It produces respiratory depression, but its ceiling effect is below that of mu agonists. Intranasal butorphanol is used for the treatment of migraine headaches and postoperative pain. Butorphanol has also been studied for epidural use, although it tends to produce significant sedation. It has been shown to be effective in the treatment of postoperative shivering, but the mechanism of this effect is unknown.

Nalbuphine. Nalbuphine has the ability to reverse respiratory depression that results from opioid use and to maintain analgesia. Nalbuphine acts as both an agonist and an antagonist at the opioid receptors. Nalbuphine's analgesic response is equal to that of morphine. Nalbuphine provides an agonist effect at the kappa receptors and an antagonist effect at the mu receptors. A ceiling effect for respiratory depression and difficulty with reversal with naloxone has been demonstrated with both nalbuphine and butorphanol.[56] Nalbuphine has been used to antagonize pruritus induced by epidural and intrathecal morphine. Nalbuphine effectively antagonizes fentanyl-induced respiratory depression, maintains analgesia, and does not produce adverse circulatory changes.

Antagonists

Naloxone. Naloxone, an oxymorphone derivative, is a pure opioid antagonist. Naloxone blocks the opioid receptor sites and reverses respiratory depression and opioid analgesia. The reversal of respiratory depression and analgesia occurs as a result of competitive antagonism at the mu, kappa, and delta receptors. The duration of action of naloxone is less than that of most opioid agonists, allowing the return of respiratory depression in some patients treated with naloxone. Naloxone is effective only when it is administered intravenously or intramuscularly.

Naloxone may antagonize intrinsic analgesic systems, as evidenced by its ability to blunt the placebo effect and inhibit the analgesia of electroacupuncture. Studies have demonstrated that naloxone's effect on reversing the effects of morphine is in fact titratable. Administration of low doses of naloxone can reverse the side effects of epidural opioids while preserving some of the analgesic effects.

The effects of naloxone use range from discomfort to pulmonary edema to sudden death. Pulmonary edema after naloxone administration has been observed in patients with a documented history of cardiovascular disease. Prough et al.[57] reported two cases of acute onset of pulmonary edema in young male patients who received either 100 or 200 mcg of naloxone. The report discusses the ability of naloxone to inhibit endogenous pain suppression pathways and to allow unopposed noradrenergic transmission from medullary centers that can produce neurogenic pulmonary edema. Neurogenic pulmonary edema results from an increase in catecholamine levels in healthy patients, as well as in patients with a history of cardiovascular disease. Cautious titration of naloxone is of paramount importance. Andree[58] reported two cases of sudden death after naloxone administration. This study suggests that naloxone produces increases in blood catecholamine levels that predispose patients to ventricular fibrillation and subsequent cardiac arrest.

Nalmefene. Structurally similar to naloxone, nalmefene (Revex) is a long-acting parenteral opioid antagonist. It has an elimination half-life of approximately 10 hours (compared with naloxone's half-life of 1 hour) and duration of action of 8 hours when it is given in the usual doses.[59] The clinical effects of nalmefene are similar to those of naloxone.

Reversal of postoperative respiratory depression is accomplished with the administration of nalmefene 0.1 to 0.5 mcg/kg titrated at 2- to 5-minute intervals. In acute opioid overdose, it is recommended that 0.5 to 1.6 mcg be given intravenously. Administration of doses higher than 1.6 mcg does not elicit additional effects and is not recommended. As with all antagonists, slow titration of small doses may minimize side effects. As with naloxone, nalmefene should not be administered to opioid-dependent patients.[60]

Naltrexone. As a synthetic congener of oxymorphone, naltrexone has antagonist and receptor-binding properties similar to those of naloxone but higher oral efficacy and longer duration of action. Its activity is the result of both the parent drug and its 6-beta metabolite. The parent and metabolite have half-lives of 6 and 13 hours, respectively. Naltrexone has a duration of action of approximately 24 hours. An extended release formulation is routinely used in alcohol withdrawal programs.[61]

Naltrexone is administered to patients addicted to opioids so that the euphoric effects of opioids can be prevented. When doses greater than 100 mg are administered to the opioid-addicted patient, plasma concentrations are reached within 2 hours, and the agent's half-life is approximately 10 hours. Naltrexone produces an active metabolite with a half-life even longer than that of naltrexone.[1]

Non-Narcotic Analgesics

The nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen (paracetamol outside the United States) are primarily used in anesthesia as postoperative pain medications. Aspirin is used as an antiplatelet drug for cardiac patients and is rarely given as an analgesic. They are effective for mild to moderate pain. Acetaminophen, ibuprofen, and ketorolac are available as intravenous preparations and are used for select intraoperative and postoperative applications. The mechanism of both the NSAIDs and acetaminophen is inhibition of the cyclooxygenase enzyme, which prevents the production of prostaglandins and thromboxanes. Some important differences exist. The NSAIDs are analgesic, antipyretic, and antiinflammatory, whereas acetaminophen is analgesic and antipyretic but only minimally antiinflammatory. In anesthetic uses more than one or two doses are rarely given so many of the adverse effects of chronic administration are not a concern.[62,63]

Ketorolac. Ketorolac (Toradol) is an intravenous NSAID that has been used for many years in anesthesia. It is very effective for mild to moderate pain. It can be administered via both intramuscular and intravenous routes. The primary advantages over the opioids are the very low incidence of nausea and vomiting and lack of respiratory depression. It is frequently given near the end of surgical procedures such as laparoscopy to provide postoperative analgesia. It is also used for minor procedures where avoiding opioids is desirable. The usual dose is 30 to 60 mg either intramuscularly (IM) or intravenously (IV). The onset is 30 minutes and the duration of action is 4 to 6 hours.[62] It should not be used in atopic or asthmatic patients, in the elderly, or in patients with renal or GI dysfunction or bleeding disorders. Some clinicians feel that bone healing is delayed by the NSAIDs and do not use them in orthopedic procedures.[64] Bleeding may also be a problem in intracranial surgery.[65]

Ibuprofen. An intravenous formulation of ibuprofen (Caldolor) is available as an analgesic and antipyretic. Its clinical effects are similar to ketorolac. The usual dose is 400 to 800 mg IV over 30 minutes. Onset is 30 minutes and duration is 4 to 6 hours.[66,67] Contraindications and precautions are similar to ketorolac.

Acetaminophen. Acetaminophen (Ofirmev) is available as an IV analgesic and antipyretic drug for use in both adults and children over 2 years old. It also has a significant opiate sparing effect. Acetaminophen does not exhibit the significant gastrointestinal and cardiovascular side effects associated with nonsteroidal antiinflammatory drugs. The dose in patients over 13 years old is 1000 mg infused over 15 minutes. The dose in children is 15 mg/kg. Onset is approximately 10 minutes with a peak effect in 1 hour. The duration of action is 4 to 6 hours.[68,69] Side effects are rare. Hepatotoxicity is a concern with acetaminophen but not expected with doses less than 4000 mg/day.

SUMMARY

Opioids are a group of drugs that bind to receptor sites in the CNS, supraspinal and spinal, and at peripheral sites, producing morphine-like effects. Opioid analgesia results from the inhibition of nociceptive reflexes and the release of neurotransmitters. Because of their multiplicity of sites and mechanisms of action, opioids are a uniquely valued means for analgesia and anesthesia. Opioids are used for preoperative medication, as induction agents, as maintenance anesthetics, and for treatment of postoperative pain. The newer methods of opioid delivery have been growing in popularity. Opioids provide the anesthesia practitioner with a multitude of delivery modalities.

CHAPTER 12

Neuromuscular Blocking Agents, Reversal Agents, and Their Monitoring

◆ *John J. Nagelhout*

The neuromuscular blocking drugs (NMBDs) are an integral part of anesthesia practice. They allow for easy airway and operative field manipulation, which is essential in today's sophisticated and complex surgical environment. As with many other types of anesthetic drug components, no single agent or agents are ideal in all situations. For example, the development of a rapid onset, ultrashort-acting nondepolarizing replacement for succinylcholine has eluded researchers for decades. In addition, reversal of the NMBDs is too complex, and residual paralysis in the postanesthesia care unit (PACU) remains a problem. Despite these challenges, our knowledge regarding the safe use of these drugs in anesthesia continually evolves. This chapter updates the clinician with the latest information and concepts on the use of these drugs in modern clinical practice.

HISTORY

In the nineteenth century, Claude Bernard, a famous French physiologist and philosopher, carried out experiments with curare, then in use by the Amazonian Indians of South America.[1] He noted that animals the Indians hunted for food were paralyzed by arrows poisoned with curare and subsequently died of asphyxiation.[2] Bernard's experiments with the poison the Indians tipped their arrows with formed the basis for our ideas of the neuromuscular junction, neuromuscular transmission, and neuromuscular pharmacology.[3] Indeed, curare had been used since 1857 as an anticonvulsant treatment in tetany and other types of spastic disorders.[4]

Laewen also described the use of curare in anesthetized humans in a German report in 1912.[3] For readers who are interested in historical aspects of this topic, a fascinating and more complete report of the earliest work of these and other researchers, beginning as early as the year 1548, is available in an outstanding review article by Bisset.[5]

In 1936 Dale and colleagues found that acetylcholine (ACh) was the chemical neurotransmitter that activated the postjunctional muscle membrane receptors after excitation of the nerve terminal.[5] This finding contradicted the once widely held theory that direct electrical transmission from the nerve to the muscle occurs.[6] This discovery provided the impetus for further research concerning pharmacologic agents that could either enhance the action of ACh or prevent it, thereby causing a temporary and reversible state of therapeutic paralysis.

Griffith and Johnson[7] of Montreal, Canada, are universally acknowledged as the persons responsible for the introduction of neuromuscular blockers into anesthetic practice. Their groundbreaking report laid the foundations for other studies that followed. Within a year of their study, Cullen reported on the use of curare in 131 general anesthetic procedures. His only report of an adverse reaction dealt with a 44-year-old woman who experienced "complete paralysis and severe salivation," accompanied by muscular twitching.[4]

Despite initial successes with the neuromuscular blockers, an early study nearly doomed their use before they became widely accepted. Henry Beecher and Donald Todd, two physicians in the anesthesia department of Harvard Medical School, reviewed 599,548 anesthetic procedures administered at 10 institutions between 1948 and 1952. As part of this review, they examined the death rate in patients receiving *curares* (the term by which they described any neuromuscular blocking agent, including tubocurarine chloride, decamethonium bromide, succinylcholine chloride, gallamine triethiodide, and dimethyl-tubocurarine [*d*-tubocurarine] iodide). Beecher and Todd[8] found that the overall death rate for persons treated with neuromuscular blockers was 1:370, compared with a death rate of 1:2100 in patients who did not receive these agents.

After reviewing the conditions of the patients; the educational background and training of the practitioners who administered the anesthetic (e.g., physician, nurse anesthetist, or physician-in-training); the size of the institution; the sexes, races, and ages of the patients; and numerous other combinations of these factors, the investigators reached the following conclusions:

> *[I]n our judgment the situation is one where neither experience of individual nor experience of institution appears to protect. This adds up to evidence that neither mistakes nor preventable error of any kind are involved in the main, but rather the inherent toxicity of the "curares" themselves.*[8]

In the litigious environment of modern anesthetic practice, such a statement may have ended the administration of these agents. It would certainly have slowed their development. The positive attributes of the agents, however, were discussed later in the same paper, as Beecher and Todd added this caveat:

> *Having presented the foregoing evidence and comment, one can ask what, then, is to be done about these agents? Are they to be banned as a practical solution of the problem? We believe not. These data strongly suggest that great caution in the use of muscle relaxants should be exercised, that the agents available at present be considered as on trial, and that they be employed only when there are clear advantages to be gained by their use, that they not be employed for trivial purposes or as a corrective for generally inadequate anesthesia.*[8]

Beecher and Todd's admonition still echoes through the halls of anesthetic practice today. Although the safety and efficacy of neuromuscular blocking agents have markedly increased, the sage advice is still germane for the practitioner: Neuromuscular blocking agents, like all anesthetic agents, are best used where and when they are indicated. Nevertheless, as one leg of the anesthetic objectives that includes anesthesia, analgesia, amnesia, and muscle relaxation, neuromuscular blockade has become an integral part of most modern anesthetic techniques. A broad spectrum of these agents now exists, although no single agent has all of what would be the ideal properties. Their individual pharmacokinetic and pharmacodynamic attributes enable the anesthetist to tailor

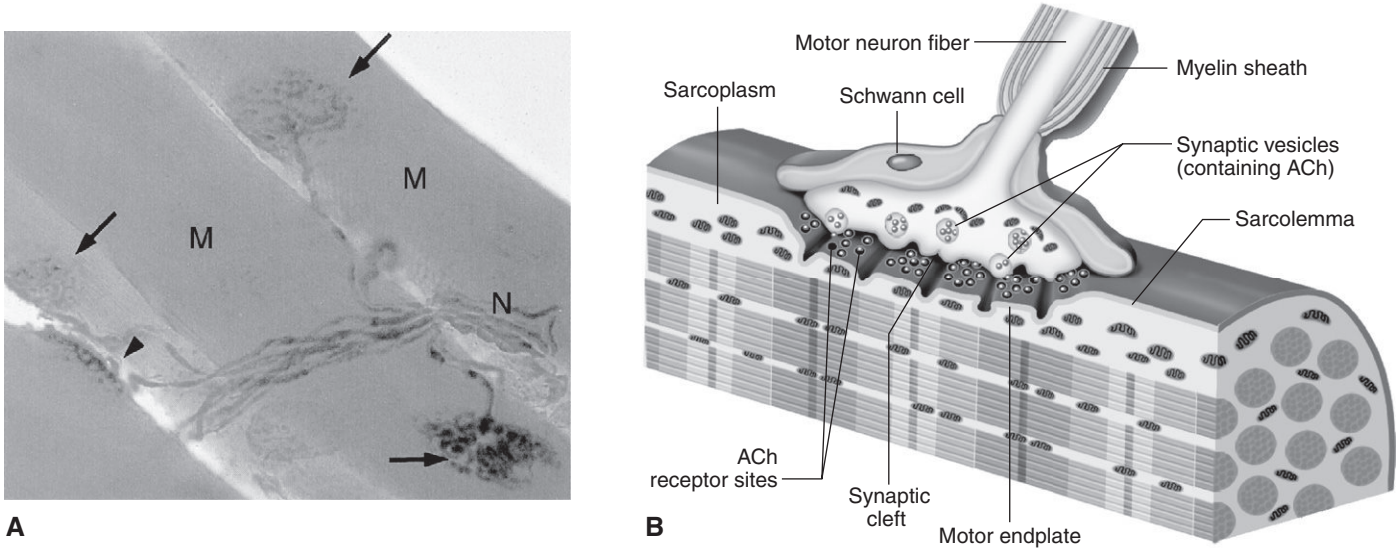

FIGURE **12-1** Neuromuscular junction (NMJ). **A,** Micrograph showing four neuromuscular junctions (NMJs). Three are surface views (*arrows*) and one is a side view (*arrowhead*). *N*, Nerve fibers; M, muscle fibers. **B,** This sketch shows a side view of the NMJ. Note how the distal end of a motor neuron fiber forms a synapse, or "chemical junction," with an adjacent muscle fiber. Neurotransmitter molecules (specifically, acetylcholine, or ACh) are released from the neuron's synaptic vesicles and diffuse across the synaptic cleft. There they stimulate receptors in the motor endplate region of the sarcolemma. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 8th ed. St Louis: Mosby; 2013:353.)

the use of the agent to the physiologic needs of the patient and the requirements of the surgeon.

MONITORING OF NEUROMUSCULAR BLOCKADE

Monitoring of neuromuscular blockade should be the standard during most anesthetics when a relaxant is administered. Combining objective data from nerve monitoring with clinical signs of paralysis offers obvious advantages when dosing relaxants intraoperatively and assessing postoperative recovery. An important anesthetic discussion has been taking place on the gap between the scientific knowledge on effective monitoring and use of muscle relaxants in anesthesia and actual current clinical practice.[9-12] Expert consensus strongly recommends the routine monitoring of neuromuscular block in the perioperative period as a safety issue. They feel this guides intraoperative relaxant dosing by avoiding over-paralysis and helps reduce the incidence of residual weakness in the postanesthesia care unit (PACU). A recent extensive survey of clinicians in the United States[13] and Europe indicate that many practitioners are not using these monitors in everyday practice.[14-16] Several explanations are given: the current quantitative monitors are cumbersome and difficult to use, qualitative monitoring is unreliable, residual paralysis is not a problem in their practice, and clinical signs can be used to assess paralysis in most patients, among others. Survey respondents felt that the incidence of residual paralysis in their practice was usually less than 1%. Objective studies estimate the incidence at about 35%.[13] The discrepancy may exist because most patients recover safely in spite of residual paralysis and their problem is not noticed. Many patients may have had some difficulty or discomfort but manage to compensate until full recovery occurs and do not need specific interventions. There is no question however, that residual paralysis in the PACU represents a significant potential hazard for airway complications and aspiration. A complete discussion of neuromuscular blockade reversal is later in this chapter.

The response to a peripheral nerve monitor indirectly infers the relaxation of musculature. The neuromuscular monitor is an electrical device that delivers a series of electric shocks or impulses to the patient through electrodes applied to the skin near a nerve. There are several methods for monitoring neuromuscular blockade intensity, including acceleromyography (AMG), electromyography (EMG), phonomyography (PMG), mechanomyography (MMG), and kinemyography (KMG). Visual and tactile response to evoked electrical stimulus as assessed by the clinician, or *qualitative* monitoring, is the most common method. On activation of the stimulator, various predictable muscle contraction patterns are visible in the presence and absence of neuromuscular blockers. *Quantitative* monitoring where the stimulator is coupled with a displacement transducer as a movement measuring device and a number value is displayed is preferred but less common. Quantitative monitoring can be accomplished with MMG, AMG, KMG, or EMG.[9]

Depolarization and contraction of a muscle are caused by an action potential traveling along the course of a nerve. As the impulse reaches the motor endplate, acetylcholine (ACh) is released across the synaptic cleft. It subsequently travels toward the receptor sites on the muscle membrane, resulting in depolarization and subsequent contraction of the muscle.[2] The stimulator elicits the same activity, which makes it useful for the monitoring of neuromuscular blockade (Figure 12-1).

The proper administration of neuromuscular blocking agents (NMBAs) is essential for patient safety and efficient perioperative workflow. Inadequate doses of NMBAs may result in complications during surgical procedures because of unexpected patient movement and a less than ideal operative field. In contrast, overdosage may result in residual paralysis in the postoperative period, increasing morbidity and the need for labor-intensive interventions (e.g., mechanical ventilation).

Contraction of the adductor muscle of the thumb via stimulation of the ulnar nerve is the preferred site for determining the level of neuromuscular blockade. It is usually accessible and convenient.

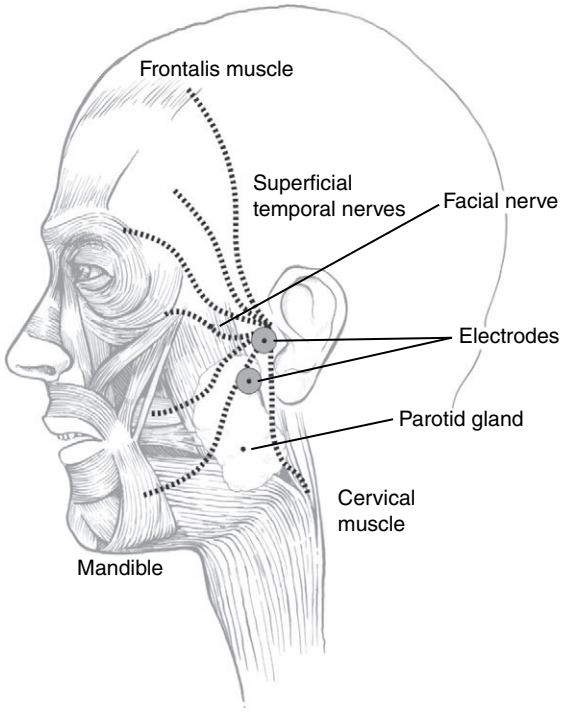

FIGURE **12-2** Facial neuromuscular blockade testing.

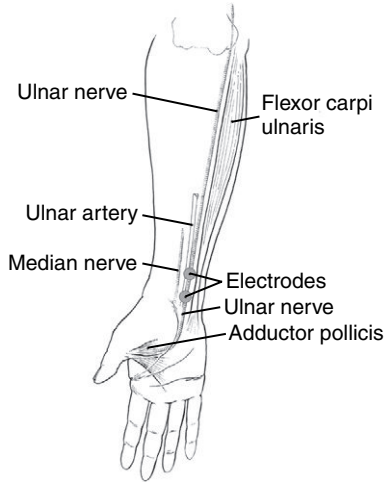

FIGURE **12-3** Ulnar neuromuscular blockade testing.

Disposable electrodes are applied over the ulnar nerve. The distal electrode is placed over the proximal flexor crease of the wrist, and the other electrode is placed over and parallel to the carpi ulnaris tendon. On stimulation of these electrodes with the monitoring device, adduction of the thumb is visible. When access to the arm and hand is not practical, other monitoring sites include the nerves of the foot and the facial nerve. Facial nerve monitoring generally involves stimulation of the temporal branch of the facial nerve that supplies the orbicularis oculi muscle around the eye or the orbicular muscle that contracts the lip.[10] The facial and ulnar nerves sites are shown in Figures 12-2 and 12-3, respectively. Table 12-1 gives a comparison of the ulnar and facial nerve monitoring sites.

A few contrasting factors involving blood flow versus muscle sensitivity must be considered when assessing paralysis and interpreting responses from the ulnar nerve or face. During onset of a relaxant, the muscle group sensitivity exhibits the following pattern: The eye muscles are the most sensitive and are the first group to be affected, followed by the extremities, the trunk of the body with the neck and chest first, then abdominal muscles, and lastly the diaphragm. During recovery, muscle function returns in the opposite pattern with the diaphragm first and the eye muscles last. Blood flow, however, is greater to the head, neck, and diaphragm so more of the drug is distributed to these areas upon initial distribution and onset.

Due to these conflicting influences, the facial nerves should be used when assessing relaxant onset. Blood, thus drug, distribution to the facial muscles mirrors distribution in the larynx and diaphragm where relaxation is required for intubation and airway manipulation. Recovery is best measured in the hand. The hand muscles are more sensitive to relaxant than the diaphragm, so if recovery is evident in the hand, the larynx and diaphragm will be recovered as well.[17]

TABLE 12-1 A Comparison of Neuromuscular Monitoring Sites

Monitoring Site	Response	Comments
Ulnar nerve innervation of the adductor pollicis	Thumb adduction	Usually have easy access Best site to measure recovery
Facial nerve	Eyelid movement	Easily accessed when arm is not available Best site to measure onset

Tests of Neuromuscular Function

There are five clinical tests of neuromuscular function: single twitch, train-of-four (TOF), double-burst stimulation (DBS), tetanus, and posttetanic count (PTC). The TOF, DBS, and tetanic stimulation are the most commonly used.[18] The ability to evaluate muscle function with each mode of stimulation varies (Table 12-2).

A brief explanation of the concept of *fade* is required to understand the responses to nerve monitoring. The inability to sustain a response, known as fade, to repetitive nerve stimulation is seen in several of the clinically used monitoring tests. This is a sign of drug-induced muscle paralysis. Fade occurs because the nondepolarizing drugs block presynaptic acetylcholine receptors in addition to their classic antagonist effect at postsynaptic ACh neuromuscular junction sites. The function of presynaptic ACh receptors is to facilitate the release of ACh from the nerve terminal via a positive feedback mechanism. During high impulse rates of nerve stimulation this positive feedback mechanism prevents the decrease (fade) of transmitter release. The facilitated ACh release associated with this positive feedback mechanism is blocked by the relaxants.[19] This inhibition is detected as fade during the use of the monitoring tests as described below.

Single Twitch

The first (and simplest) type of stimulation is a single twitch at 0.1 to 1 hertz (Hz) for 0.1 to 0.2 milliseconds (ms). These impulses can be delivered automatically every second, every 10 seconds, or manually, depending on the sophistication of the neurostimulating apparatus.

Unless you have a comparison twitch response before any relaxant is given, this test simply indicates whether 100% paralysis is present. If the patient's muscle moves when stimulated, less than

TABLE 12-2 Common Neuromuscular Monitoring Tests

Monitoring Test	Definition	Comments	Stimulation Characteristics
Single twitch	A single supramaximal electrical stimulus ranging from 0.1-1.0 Hz	Requires baseline before drug administration; generally used as a qualitative rather than quantitative assessment	
Train-of-four	A series of four twitches at 2 Hz every ½ second for 2 sec	Reflects blockade from 70%-100%; useful during onset, maintenance, and emergence Train-of-four ratio is determined by comparing T_1-T_4	
Double-burst simulation	Two short bursts of 50 Hz tetanus separated by 0.75 sec	Similar to train-of-four; useful during onset, maintenance, and emergence; may be easier to detect fade than with train-of-four; tactile evaluation	
Tetanus	Generally consists of rapid delivery of a 30-, 50-, or 100-Hz stimulus for 5 sec	Should be used sparingly for deep block assessment; painful	Posttetanic count	50-Hz tetanus for 5 sec, a 3-sec pause, then single twitches of 1 Hz	Used only when train-of-four and double-burst stimulation is absent; count of less than eight indicates deep block, and prolonged recovery is likely	

100% muscle paralysis exists. If no movement is detected, 100% paralysis is present.

Train-of-Four

The second and most widely used means of stimulation is the train-of-four (TOF), which delivers four separate stimuli every 0.5 second at a frequency of 2 (Hz) for 2 seconds.[20] A comparison is made of the four stimulated responses. Each of the four twitch responses are referred to as T_1 through T_4, respectively. Upon the onset of paralysis with a nondepolarizing relaxant, there is a progressive diminution of the twitch responses with visible fade. Fade refers to the fact that each of the successive twitch responses from T_1 through T_4 is smaller. When partial paralysis is present yet all four twitch responses can be elicited, with fade from T_1 through T_4, an assessment can be made regarding the size of T_4 compared to T_1. This T_4:T_1 ratio is referred to as the *train-of-four ratio*, or TOFR. Train-of-four testing can aid in approximating the degree or percent of paralysis present. It is most sensitive between 70% and 100% paralysis. The fourth twitch (T_4) disappears first, which represents a block of 75% to 80%. Progressive disappearance of the third twitch (T_4 and T_3 absent) indicates 80% to 85% block. When three twitches are abolished (T_4, T_3, and T_2 are absent), 90% to 95% neuromuscular blockade is present. When 100% paralysis is achieved, no responses can be elicited. Figure 12-4 correlates the responses to TOF stimulation with the approximate degree of paralysis present. Intraoperatively, the ideal degree of paralysis necessary for any procedure with sufficient anesthetic depth is 85% to 95%. That correlates with 1 to 2 twitch responses present upon TOF stimulation. Avoiding total 100% paralysis intraoperatively ensures a successful operative procedure while avoiding overdosing of the relaxant. Less total relaxant administered lessens the chances of residual paralysis upon reversal.[20]

A representative assessment of the TOF test during onset and recovery of a nondepolarizing relaxant is shown in Figures 12-5 and 12-6, respectively.

Double-Burst Stimulation

Double-burst stimulation was conceptualized as an analog to TOF with some improvements. It consists of two short bursts of a 50-Hz tetanus separated by 0.75 seconds. The use of DBS seems to improve the ability to detect residual paralysis during recovery. The suggestion is that DBS relies on the direct comparison of the muscle contraction in response to two rapidly sequential minitetanic bursts rather than the indirect comparison of the fourth twitch with the first twitch as in the TOFR. It is thought that the comparison of the fourth to the first twitches when assessing the TOFR is hindered by the second and third twitches that provide no useful information. Evaluating two rather than four twitch responses facilitates detection of fade. Tactile evaluation is suggested to improve the ability to detect fade. Responses are similar to the TOF. Fade of the second impulse is comparable to a TOFR of less than 0.6 and indicates significant paralysis.[17] A comparison is shown in Figure 12-7.[18,21,22]

Tetanus

Tetanus consists of continuous electrical stimulation for 5 seconds at 50 or 100 Hz. The 100-Hz current is more reliable for detecting fade but is not always specific.[17,23] If the muscle contraction produced is sustained for the entire 5 seconds of stimulation without fade, significant paralysis is unlikely. If fade is present, clinically significant block remains.[18,24] The higher intensity of stimulation produced by tetanic frequencies as compared to TOF, DBS, or a single twitch makes it useful when other tests such as TOF or DBS are equivocal. The test is painful and should not be repeated too often to avoid muscle fatigue.

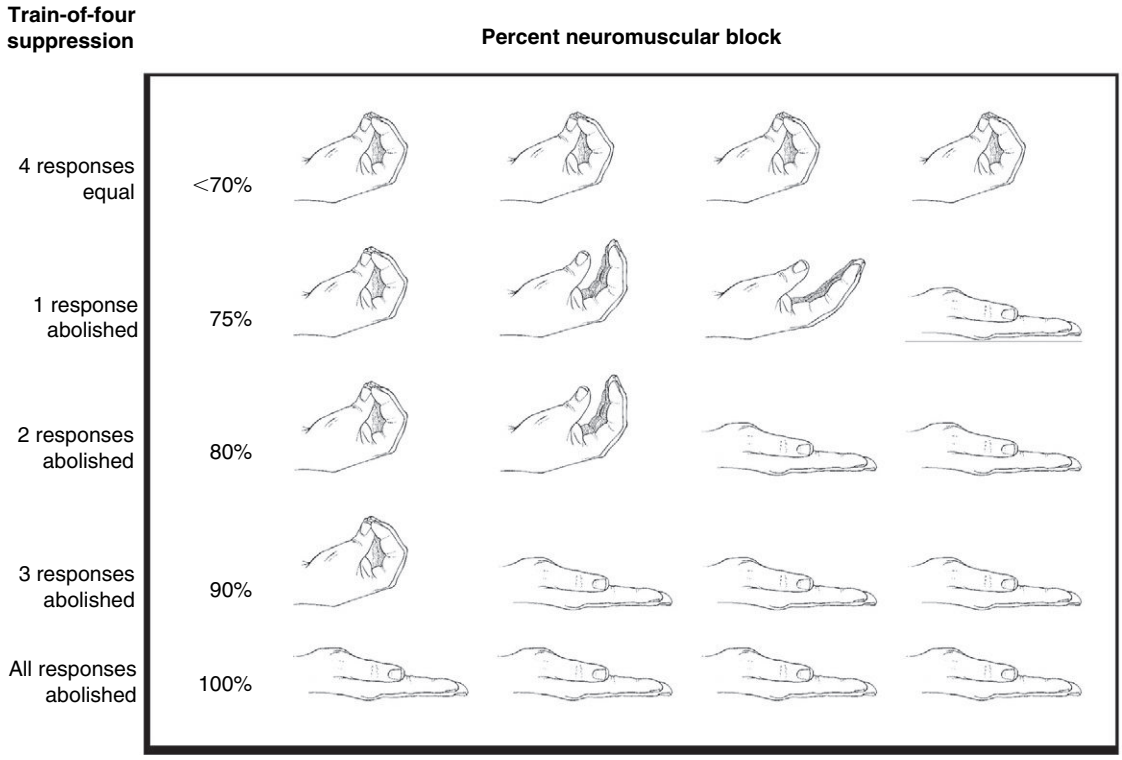

FIGURE **12-4** Train-of-four test.

BOX **12-1**

Commonly Used Neuromuscular Terminology

- *Onset time:* Time from drug administration to maximum effect
- *Clinical duration:* Time from drug administration to 25% recovery of the twitch response
- *Total duration of action:* Time from drug administration to 90% recovery of twitch response
- *Recovery index:* Time from 25% to 75% recovery of the twitch response
- *Train-of-four ratio:* Compares the fourth twitch of a TOF with the first twitch; when the fourth twitch is 90% of the first, recovery is indicated

TOF, Train-of-four.

Posttetanic Count

The posttetanic count (PTC) is rarely used clinically but will be described for completeness. It is only performed when there is no response to any of the commonly used tests due to presence of 100% paralysis. Because you are already aware that the patient is completely paralyzed, the value of the PTC is to attempt to give a rough time estimate as to when recovery may occur. The PTC mode involves the use of a 50-Hz tetanic stimulation for 5 seconds, followed in 3 seconds by a series of single 1-Hz twitch stimulations.[22] An understanding of the phenomenon of posttetanic potentiation (also referred to as posttetanic stimulation or facilitation) is necessary to comprehend the PTC test. When the 50-Hz tetanus is applied, there is no response because the patient is completely blocked. Application of the 50-Hz tetanus, however, transiently mobilizes excesses of acetylcholine so that after a 3-second pause, you are able to produce a short series of single-twitch responses. Because they only occur after a tetanic stimulation and not before, this single-twitch response is termed *posttetanic potentiation*. This extra acetylcholine will in effect "transiently reverse" the relaxant by competing for the receptor at the local monitoring site. This augmented response will only last several seconds until the excess acetylcholine dissipates. The number of twitches elicited is counted. The higher the count, the less intense the block. The usual count is between 0 (deep block) and 8 (less intense block where TOF response should return). With rocuronium, for example, neostigmine reversal of an intense block where the PTC was 1 to 2 takes more than 50 minutes.[25] At a PTC of 6 to 8, reversal should occur in less than 10 minutes.

Neuromuscular monitoring terminology and tests are summarized in Box 12-1, Figure 12-2, and Table 12-3. Some key points related to successful use of tests of neuromuscular transmission are given in Box 12-2.[26]

DEPOLARIZING AGENTS

Succinylcholine Chloride

Succinylcholine chloride (Anectine, Quelicin, and others) is very familiar to every clinician, having been a standard for several decades of practice. Although its widespread use in clinical anesthesia represents the standard of care for a variety of situations, opinions regarding its use remain divided because of some of its untoward effects.

Stephen Thesleff at the Karolinska Institute in Stockholm was one of the pioneers who introduced the drug into clinical practice to induce neuromuscular paralysis in humans. Initial description of the neuromuscular blocking properties of succinylcholine is credited to Daniel Bovet. (Bovet was awarded the Nobel Prize for Physiology and Medicine in 1957 for his discovery of synthetic compounds that act on the vascular system and skeletal muscle.)[27] The first use of succinylcholine in the United States occurred in 1952. Foldes et al.[28] described this agent in the following manner:

> *Compared to other muscle relaxants used in anesthesiology, succinylcholine possesses several advantages, the outstanding one, in our experience, being its easy controllability, which permitted almost instantaneous changes in degree of muscular relaxation. With succinylcholine, both increasing and decreasing muscular relaxation took less than a minute.*[28]

The disadvantages of succinylcholine have been well recorded through years of clinical experience. It has no action in the ganglionic nicotinic receptors but may cause bradycardia by an action on cardiac cholinergic muscarinic receptors.[29,30] Prolonged neuromuscular blockade can result from excessive doses of succinylcholine in patients with atypical, inhibited, or deficient levels of plasma cholinesterases.[3,29]

Succinylcholine is the only remaining depolarizing muscle relaxant licensed for use in the United States. Remembering the composition of the drug is helpful in better understanding its effects and side effects. Succinylcholine results from the joining of two ACh molecules and is represented by the chemical formula $C_{14}H_{30}N_2O_4$. Although succinylcholine mimics the action of ACh by depolarizing the motor endplate, its degradation is distinct. In contrast with the degradation of ACh by acetylcholinesterase (AChE), succinylcholine is hydrolyzed by plasma cholinesterase (pseudocholinesterase). The popularity of this muscle relaxant is

TABLE 12-3 Key Points Related to Tests of Neuromuscular Transmission and Reversal

Test	Acceptable Clinical Result to Suggest Normal Function	Approximate Percent of Receptors Occupied When Response Returns to Normal Value	Comments, Advantages, and Disadvantages
Tidal volume	At least 5 mL/kg	80	Necessary, but insensitive as an indicator of neuromuscular function
Single-twitch strength	Qualitatively as strong as baseline	75-80	Uncomfortable; need to know twitch strength before relaxant administration; insensitive as an indicator of recovery, but useful as a gauge of deep neuromuscular blockade
Train-of-four (TOF)	No palpable fade	70-75	Uncomfortable, but more sensitive as indicator of recovery than single twitch; used as a gauge of depth of block by counting the number of responses perceptible
Sustained tetanus at 50 Hz for 5 sec	At least 20 mL/kg	70	Very uncomfortable, but a reliable indicator of adequate recovery
Vital capacity	At least 20 mL/kg	70	Requires patient cooperation, but is the goal for achievement of full clinical recovery
Double-burst stimulation	No palpable fade	60-70	Uncomfortable, but more sensitive than TOF as an indicator of peripheral function; no perceptible fade indicates TOF of at least recovery of 60%
Inspiratory force	At least −40 cm H_2O	50	Difficult to perform with endotracheal intubation, but a reliable gauge of normal diaphragmatic function
Head lift	Must be performed unaided with patient supine and sustained for 5 sec	50	Requires patient cooperation, but remains the standard test of normal clinical function
Hand grip	Sustained at a level qualitatively similar to preinduction	50	Sustained strong grip, though also requires patient cooperation; is another good gauge of normal function
Sustained bite	Sustained jaw clench on tongue blade	50	Very reliable with patient cooperation; corresponds with TOF of 85%

BOX 12-2

General Guidelines for Successful Neuromuscular Monitoring

- Objective (quantitative) monitoring of neuromuscular function should be used when possible.
- Peripheral nerve stimulator units should display the delivered current output, which should be at least 30 mA.
- During onset, paralysis begins with the eye muscles, followed by the extremities, trunk (from the neck muscles downward through the intercostals), abdominal muscles, and finally the diaphragm. Recovery returns in the opposite manner. Protective reflex muscles of the pharynx and upper esophagus recover later than the diaphragm, larynx, hands, or face.
- Monitoring of the facial nerve for determination of onset and readiness for intubation may be preferable to monitoring of the ulnar nerve.
- Monitoring of the offset and recovery from neuromuscular blockade is probably better at the ulnar nerve.
- Tactile evaluation of train-of-four (TOF) and double-burst stimulation (DBS) fade reduces but does not eliminate the incidence of postoperative residual paralysis compared with the use of clinical criteria to assess readiness for tracheal extubation.
- Adequate spontaneous recovery should be established before pharmacologic antagonism of neuromuscular blocking drug (NMBD) block with anticholinesterases. This requirement does not apply to reversal with sugammadex.
- When there is only one response to TOF stimulation, successful reversal may take as long as 30 minutes.
- At a TOF count of two or three responses, recovery usually takes 4 to 15 minutes after intermediate-acting drugs and may take up to 30 minutes after administration of the long-acting relaxant pancuronium.
- When the fourth response to TOF stimulation appears, adequate recovery can be achieved within 5 minutes of reversal with neostigmine or 2 to 3 minutes after use of edrophonium.
- When the fourth twitch of the TOF returns, the train-of-four ratio (TOFR) may be determined. Compare the size of the fourth twitch (T_4) with the size of the first twitch (T_1), using T_4:T_1 as a ratio. The timing of tracheal extubation should be guided by quantitative monitoring tests such as TOF greater than 0.9 or DBS_3 greater than 0.9.

TABLE 12-4 Neuromuscular Blocking Agents: Dose, Onset, and Duration*

Agent	ED_{95} (mg/kg)	Intubating Dose (mg/kg)	Time to Onset	Duration of Action (min)
Succinylcholine (Anectine)	0.3	1-1.5	30-60 sec	Ultrashort, 5-15
Atracurium (Tracrium)	0.15	0.5	2-4 min	Intermediate, 30-60
Cisatracurium (Nimbex)	0.05	0.1	2-4 min	Intermediate, 30-60
Rocuronium (Zemuron)	0.3	0.6-1	1-1.5 min	Intermediate, 30-60
Vecuronium (Norcuron)	0.05	0.1	2-4 min	Intermediate, 30-60
Pancuronium (Pavulon)	0.05	0.08-1.8	2-4 min	Long, 60-90

*All data for adult patients without significant disease.
ED_{95}, Effective dose for 95% paralysis.

rooted in its unique ability to provide a quick onset and short duration of effect. A bolus of 0.5 to 1.5 mg/kg is the recommended dose for adequate adult paralysis and relaxation for intubation.[31] The dose of succinylcholine that provides the desired paralytic effect in 95% of the population (ED_{95}) is approximately 0.30 mg/kg.[32]

Pharmacokinetics

Onset. Succinylcholine has an extremely rapid onset and remains the gold standard against which other agents are compared. In general, muscle relaxants exhibit an inverse relationship between potency and onset speed. The lower the potency, the faster the speed. A lower potency drug requires larger doses so a muscle gradient will be achieved more quickly.[33] A typical intubating dose of 1 to 1.5 mg/kg results in a maximum suppression of muscle twitch and good to excellent intubating conditions within 1 to 1.5 minutes of administration.[34,35] Onset of action of succinylcholine at the larynx with administration of 1 mg/kg is 34 seconds.[36,37] The onset as measured at peripheral sites such as the adductor pollicis is slightly longer at 1 minute.[38] The rapid onset of succinylcholine is based on its action as an initial agonist at the nicotinic receptor, rather than as a competitive antagonist. Succinylcholine works by activating the muscle-type nicotinic cholinergic receptors, followed by desensitization.[30] This action results in the need for significantly less drug at the receptor site to produce neuromuscular block. In contrast, most NMBAs require 75% or more receptor occupancy for clinically useful paralysis to result. Variable onset must be considered in patients with altered physiology. Patients with atypical plasma cholinesterase may exhibit prolonged onset after succinylcholine administration.[39] A summary of the dose, onset, and duration of the neuromuscular blocking drugs is given in Table 12-4.

Duration. The plasma half-life of succinylcholine is 2 to 4 minutes.[40] The clinical duration of succinylcholine (i.e., the length of time during which its clinical effects can be recognized) is 5 to 10 minutes, with full recovery evident at 12 to 15 minutes. Twitch recovery of 25%, as measured by the laryngeal adductor pollicus responses, is 4.3 minutes, whereas 90% to 95% twitch recovery has been reported to occur in 8 minutes.[36] Other studies have yielded similar results, with researchers citing a range of duration of 7 to 12 minutes.[29,34]

Elimination. Succinylcholine is degraded via hydrolysis by plasma cholinesterases. These enzymes, although found in the plasma, are produced by the liver. Initially, hydrolysis results in the transformation of succinylcholine into succinylmonocholine and choline (Figure 12-8). Succinylmonocholine is further degraded by plasma cholinesterase into succinic acid and choline. Succinylcholine metabolism is so rapid that only 10% of the injected dose ever reaches the neuromuscular junction.[31] A summary of the elimination routes for the neuromuscular blocking drugs is given in Table 12-5.

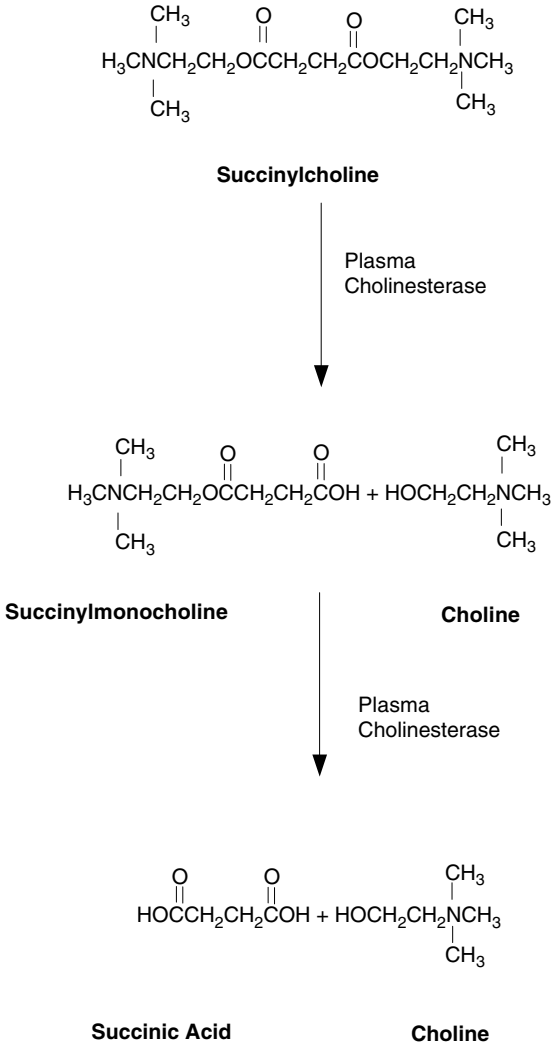

FIGURE 12-8 Metabolism of succinylcholine.

Central Nervous System

Like all muscle relaxants, succinylcholine contains a quaternary ammonium in its structure, rendering it water soluble in the body. It does not therefore pass the blood-brain barrier and has no direct central nervous system (CNS) effects. Succinylcholine indirectly increases intracranial pressure (ICP), and therefore concern has always existed as to the appropriateness of its use in certain neurosurgical procedures and in patients with brain pathology and increased intracranial pressure.[36] Research conducted in animals shows a small and transient rise of 10 to 15 mmHg for 5 to

TABLE 12-5 Neuromuscular Blockers: Elimination Mechanism

Agent	Elimination Mechanism	Comments
Atracurium	Hofmann elimination; nonspecific esterases	Non–organ-dependent elimination produces consistent duration in patients with significant hepatic and renal disease, as well as the elderly
Cisatracurium	Hofmann elimination; nonspecific esterases	Similar to atracurium but without the histamine release
Rocuronium	Renal; hepatic	May be prolonged with hepatic and renal disease
Vecuronium	Renal (20%-30%); hepatic (40%-80%)	May be prolonged with hepatic disease
Pancuronium	Renal primarily; some hepatic	May be prolonged with renal disease
Succinylcholine	Plasma cholinesterase	Prolonged in patients with cholinesterase deficiency

8 minutes after administration.[40] The rise is associated with an increased cerebral blood flow, muscle spindle afferent activity, and electroencephalogram arousal. Fasciculation of the neck muscles causing jugular vein stasis appears to be a factor.[41] The ICP effects are blocked by pretreatment with a small dose of nondepolarizing relaxant.[42] In clinical practice, the administration of succinylcholine is preceded by an anesthetic induction agent that lowers ICP, so that may help counteract this effect as well. Nevertheless, the routine use of succinylcholine in neurosurgery has declined. It remains widely used, with nondepolarizing relaxant and lidocaine pretreatment, for emergency procedures requiring rapid airway control via rapid sequence induction.[29]

Cardiovascular System

Succinylcholine usually results in slight tachycardia; however, sudden abrupt bradycardia may result from repeat dosing in adults and any dose in children. Many types of arrhythmias have been reported. The bradycardia results from autonomic ganglia and parasympathetic muscarinic receptor stimulation. Another possible mechanism for the bradycardia associated with succinylcholine administration is thought to be related to its metabolite, succinylmonocholine, which causes stimulation of cholinergic receptors in the sinoatrial node.[43]

An intubating dose of succinylcholine increases serum potassium levels by 0.5 to 1 mEq/L.[40] Although this may not be significant in the normokalemic patient, it may be life threatening in patients with preexisting hyperkalemia.[44] Gronert[45] presents a case that involved an 11-year-old girl who experienced cardiac arrest after receiving succinylcholine. Her cardiac arrest and eventual death were directly attributed to a high potassium release after the succinylcholine administration (10.2 mEq/L). The exaggerated potassium release after the succinylcholine administration in this case was determined to be related to a familial myopathy evidenced by extremely high patient levels of creatine kinase. Succinylcholine administration, hyperkalemia, and myopathy are discussed later. Some clinicians believe that a second dose of succinylcholine indicated by any event should be preceded by intravenous (IV) atropine or glycopyrrolate for its anticholinergic effects; however, others do not.[44,46]

Hepatic System

Cholinesterase enzyme subtypes are produced in the liver. Pseudocholinesterase (PChE) degrades succinylcholine; therefore certain types of liver damage may prolong the effects of the drug.[43] Ester compounds like succinylcholine are metabolized by adding water, the process referred to as *hydrolysis*. The basic reaction is ESTER + $H_2O \leftrightarrow$ ACID + ALCOHOL. Three esterase enzymes that can act as catalysts for these hydrolysis reactions exist in the plasma: cholinesterase, paraoxonase, and albumin esterase. Paraoxonase and albumin esterase are frequently referred to as *nonspecific esterases*. Additionally, red blood cells (RBCs) contain two esterase enzymes in their cytosol. One is referred to as *RBC esterase*, *esterase D*, or *S-formylglutathione*, and the other is AChE in small amounts.[47]

Cholinesterase is a generic term used for a family of related enzymes that hydrolyze choline esters at a faster rate than other esters under optimal conditions. The major function of cholinesterase is to terminate the action of ACh at cholinergic nerve endings in synapses or in effector organs.[48] Two subtypes of cholinesterase exist in the human body, with several variations and a confusing set of names. One type of cholinesterase is acetylcholinesterase, AChE, also known as *true*, *specific*, *genuine*, and *type I cholinesterase*. This enzyme is found in erythrocytes, nerve endings, the lungs, the spleen, and the gray matter of the brain. It is a membrane-bound glycoprotein and exists in several molecular forms. The other subgroup pseudocholinesterase, PChE, also known as *plasma*, *serum*, *benzoyl*, *false*, *butyryl*, *nonspecific*, and *type II cholinesterase*, exists in plasma and has more than 11 isoenzyme variants. PChE is also present in the liver, smooth muscle, intestines, pancreas, heart, and white matter of the brain.

Measurements of PChE activity can serve as a sensitive measure of the synthetic capacity of the liver. In the absence of known inhibitors, any decrease in activity reflects impaired synthesis of the enzyme. A moderate decrease (30% to 50%) is seen in acute hepatitis and long-standing chronic hepatitis, whereas a severe decrease (50% to 70%) is seen in advanced cirrhosis and in some carcinomas with metastases to the liver. Decreased levels of PChE are also found in pregnant women and newborns and in patients with acute infections, pulmonary embolism, muscular dystrophy, myocardial infarction, and after certain surgical procedures.[48] Essentially normal levels are noted in patients with mild cirrhosis or obstructive jaundice. Increased levels have been observed in cases of nephrotic syndrome, thyrotoxicosis, and hemochromatosis, in obese patients with diabetes, and in patients with anxiety and other psychiatric states. Patients generally develop neuromuscular symptoms at approximately 60% of normal activity, and serious neuromuscular effects are seen at approximately 20% of normal. Reference intervals are 2900 to 7100 units/L, although they vary with the analysis method.[49]

Table 12-6 lists some common anesthesia-related drugs that undergo hydrolysis, with the enzyme catalyst involved.

Genetic Variants of Pseudocholinesterase and the Dibucaine Inhibition Test

Some patients exhibit genetic variations in PChE that result in a prolonged response and apnea when the patient is exposed to succinylcholine. Although such individuals may lead a normal life in every other respect, their atypical variants of cholinesterase are unable to hydrolyze certain ester-containing drugs in the usual

TABLE 12-6 Common Esterase-Dependent, Anesthesia-Related Drugs

Drug	Enzyme
Succinylcholine	Pseudocholinesterase
Ester local anesthetics: Cocaine Procaine Chloroprocaine Tetracaine	Pseudocholinesterase
Neostigmine	Pseudocholinesterase
Edrophonium	Pseudocholinesterase
Atracurium	Nonspecific esterases (plasma)
Cisatracurium	Nonspecific esterases (plasma)
Remifentanil	Nonspecific esterases (plasma)
Esmolol	Nonspecific (RBC esterases) plasma
Clevidipine	Nonspecific estaerases (plasma)
MOC—Etomidate	Nonspecific esterases (plasma)

fashion. The most frequent variations in the PChE gene are the atypical (A) and Kalow (K) variants.[50] Over 60 mutations in the coding sequence have been reported; however, most are extremely rare.[49,51,52] The fluoride resistant (F), silent (S), and K variants are not tested for clinically because of assay difficulty and lack of clinical relevance. Phenotype-genotype concordance studies have recently been reported that allow detailed genetic mapping and clinical data to be evaluated.[49]

In the usual clinical scenario, a patient completes surgery and is unable to breathe. If succinylcholine was used to facilitate intubation, differential diagnosis leads the anesthesia provider to conclude that a potential atypical pseudocholinesterase may be present.[53-55] The patient is taken to the PACU, placed on a ventilator, sedated, and monitored until the succinylcholine wears off. The patient recovers and is subsequently discharged, but prior to discharge, a blood sample is taken to perform a dibucaine inhibition test to help determine (1) whether an atypical enzyme was present and (2) the cause of the prolonged apnea. The dibucaine number and enzyme activity are both determined. By treating the patient's serum with dibucaine and measuring the residual PChE activity compared with the PChE of an untreated sample, the metabolic sensitivity to succinylcholine can be measured. The patient is contacted post-discharge and counseled as appropriate, according to the findings. The administration of whole blood, fresh frozen plasma, or purified human cholinesterase has been suggested as a treatment for the prolonged apnea. Although they may be successful, there are additional transfusion risks and cost issues.[43] It is safer to let the effects of succinylcholine dissipate on their own with sedation and ventilation as noted earlier.

Dibucaine is an amide local anesthetic that inhibits typical or usual PChE but not atypical PChE. For example, the normal dibucaine number of 80 means that 80% of the PChE activity was inhibited by dibucaine. If a dibucaine number of 20 is obtained, the patient has atypical enzyme because dibucaine did not inhibit the patient's enzyme activity. If a patient experiences prolonged apnea after succinylcholine administration, it is imperative to differentiate between an atypical genetic variant of PChE or simply low levels of normal PChE enzyme. Possible interpretations of a dibucaine test are given in Box 12-3.

Patients with acute or chronic liver disease, organophosphate poisoning, or chronic renal disease, patients in the late stages of pregnancy, and those undergoing estrogen therapy may have markedly decreased PChE activities but normal enzyme. PChE phenotype interpretation is based on the total PChE activity and the percent of inhibition caused by dibucaine (Table 12-7).

BOX 12-3

Dibucaine Inhibition Test Outcomes

1. Low dibucaine number + slightly lower activity = atypical enzyme and prolonged apnea
2. Normal dibucaine number + low activity = normal enzyme with low levels present and prolonged apnea
3. Low dibucaine number + very low activity = possible rare variant-type enzyme with very low levels present and prolonged apnea
4. Normal dibucaine number + normal activity = normal enzyme and amount (Another reason for the prolonged apnea must be investigated.)

Gene sequencing combined with biochemical testing can provide patients and their families with a comprehensive assessment of the likelihood of this type of event.[49,50,52]

Renal System

Succinylcholine may be used in surgical patients with renal disease when preoperative potassium levels are normal. The use of succinylcholine in patients with elevated preoperative potassium levels is contraindicated.[56] Patients with renal failure and end-stage renal disease are frequently dialyzed prior to surgery, so as long as the serum potassium is within normal limits, succinylcholine may be used safely.[57] Patients with renal disease may have lower cholinesterase levels.[58]

Effects in Special Populations

Elderly Patients. The onset of succinylcholine may be slightly prolonged in the elderly due to a slower circulation time, but the clinical relevance is minimal.[59] Reduced plasma cholinesterase levels in elderly men may allow for a reduced dose of succinylcholine. A unique possible drug interaction has been noted in elderly patients taking tacrine (Cognex), donepezil (Aricept), rivastigmine (Exelon), or galantamine (Razadyne). These are anticholinesterase drugs used to treat Alzheimer's disease and select forms of dementia. They increase acetylcholine levels in the CNS and are referred to as *cognitive enhancers*. Theoretically, the inhibition of cholinesterase produced by these agents may prolong the action of succinylcholine. The amount of systemic cholinesterase inhibition, however, does not produce clinically significant prolongation of succinylcholine[60] (Box 12-4).

Obese Patients. No contraindication to the use of succinylcholine exists in obese patients. The utility of rapid-sequence induction in anesthetic management of the obese patient makes its use common.[61] The recommended dose of succinylcholine is 1.0 mg/kg, based on total body weight, to produce excellent intubating conditions.[62] In a 2003 study by Brodsky and Foster,[63] succinylcholine was given to 14 morbidly obese patients (body mass indices ranging from 35.8 to 58) who underwent laparoscopic gastric bypass surgery. The authors administered doses ranging from 120 to 140 mg and successfully intubated all of the patients. Only 2 of the 14 patients complained of postoperative myalgia. Dosing should be based on total body weight. Because succinylcholine is water soluble, it would seem that doses based on lean body weight would suffice. Morbidly obese patients have increased

TABLE 12-7 Select Inherited Variants of Plasma Cholinesterase

PChE Variant	Genetic Label	Frequency (%)	Population Incidence	Enzyme Activity	Duration of Succinylcholine
Usual	Homozygote U	96	Normal	Normal	Normal; dibucaine number 70-80
—	Heterozygote U/A	3	1 in 480	Decreased	Slightly prolonged; dibucaine number 50-69
Atypical	Homozygote A	0.3	1 in 3200	Decreased by 70% or more	Significantly prolonged; dibucaine number 16-30
Fluoride	Homozygote F	0.03	Extremely rare	Decreased by 60%	Moderately prolonged
Silent	Homozygote S	0.04	Extremely rare	No activity	Significantly prolonged

PChE, Plasma cholinesterase.

BOX 12-4

Drugs That May Inhibit Cholinesterase

Agents Used to Treat Alzheimer's Disease

- Donepezil (Aricept)
- Rivastigmine (Exelon)
- Galantamine (Razadyne)—herbal medicine also available over the counter
- Tacrine (Cognex)—rarely used due to high number of adverse effects

fluid compartments and pseudocholinesterase levels, however, and require higher doses to ensure adequate paralysis.[64,65]

Pediatrics. In children, succinylcholine is used only in emergency situations to secure an airway. Routine use in elective procedures was abandoned in the early 1990s, owing to several widely reported cases of severe hyperkalemia and rhabdomyolysis in what appeared to be healthy children. The cases involved routine procedures in children with undiagnosed Duchenne muscular dystrophy (DMD).[66-70] This is an X chromosome–linked disorder with onset of symptoms usually around 5 years of age. Patients exhibit a typical progression of weakness and atrophy that starts in the legs and pelvis, spreads to the shoulders and neck, and finally involves the upper extremities and respiratory muscles. Life expectancy is rarely more than 30 years; death is often a consequence of cardiac and respiratory diseases. Children with DMD frequently require orthopedic surgery for repair of scoliosis or contractures.[71,72]

The Food and Drug Administration, in conjunction with the anesthesia community, placed the following warning on the use of succinylcholine:

RISK OF CARDIAC ARREST FROM HYPERKALEMIC RHABDOMYOLYSIS.

There have been rare reports of acute rhabdomyolysis with hyperkalemia followed by ventricular dysrhythmias, cardiac arrest, and death after the administration of succinylcholine to apparently healthy children who were subsequently found to have undiagnosed skeletal muscle myopathy, most frequently Duchenne muscular dystrophy.

This syndrome often presents as peaked T-waves and sudden cardiac arrest within minutes after the administration of the drug in healthy appearing children (usually, but not exclusively, males, and most frequently 8 years of age or younger). There have also been reports in adolescents.

Therefore, when a healthy appearing infant or child develops cardiac arrest soon after administration of succinylcholine not felt to be due to inadequate ventilation, oxygenation, or anesthetic overdose, immediate treatment for hyperkalemia should be instituted. This should include administration of intravenous (IV) calcium, bicarbonate, and glucose with insulin, with hyperventilation. Due to the abrupt onset of this syndrome, routine resuscitative measures are likely to be unsuccessful. However, extraordinary and prolonged resuscitative efforts have resulted in successful resuscitation in some reported cases. In addition, in presence of signs of malignant hyperthermia, appropriate treatment should be instituted concurrently.

Since there may be no signs or symptoms to alert the practitioner to which patients are at risk, it is recommended that the use of succinylcholine in children should be reserved for emergency intubation or instances where immediate securing of the airway is necessary (e.g., laryngospasm, difficult airway, full stomach) or for intramuscular use when a suitable vein is inaccessible.[73]

Because neither succinylcholine nor halothane is routinely used in children, the incidence of masseter spasm and malignant hyperthermia has decreased. Older studies have been reported in which jaw-opening ability and the presence or absence of masseter spasm, often considered a precursor of malignant hyperpyrexia, were studied. Research was conducted on 63 children anesthetized with halothane, then relaxed with succinylcholine, pancuronium, or vecuronium. Although vecuronium and pancuronium did not cause problems with jaw opening, succinylcholine was associated with this problem, and some of the succinylcholine patients were difficult to intubate.[73] Masseter spasm was noted to be more frequent in children administered succinylcholine concomitantly with halothane, compared with children who received succinylcholine and thiopental.[33,74]

A random sample of 6500 anesthetic records (53% of 12,169 anesthetic procedures performed) was reviewed. Fifteen cases of masseter spasm were identified. In each case, the patient underwent halothane induction and was then given succinylcholine intravenously. Seven of the 15 cases of masseter spasm developed in children between ages 8 and 10 years.[75] Researchers noted an increased incidence of masseter spasm in children with strabismus who were anesthetized with halothane and received IV succinylcholine. Of 1468 halothane anesthetic procedures, 15 cases of masseter spasm were discovered, and of these 15 cases, 6 occurred in the 211 patients with strabismus.[76]

In current practice, masseter spasm, although rare, is seen in adults during anesthesia induction and often in emergency rooms or critical care units during emergency airway management.[77,78] Common side effects of succinylcholine and contraindications for its use are noted in Table 12-8 and Box 12-5, respectively.

TABLE 12-8 Side Effects of Succinylcholine

Side Effect	Probable Cause
Hyperkalemia	Normally, serum K^+ is increased by up to 0.5 mEq/L secondary to potassium leaking from the depolarized muscle; in up-regulated patients, levels may rise much higher
Dysrhythmias	Tachycardia (usually mild) is the most common effect; bradycardia secondary to hyperkalemia, especially with repeat doses, can occur (Wide electrocardiographic complexes leading to cardiac arrest have been seen in children with Duchenne muscular dystrophy and other muscle disorders)
Myalgia	Secondary to fasciculation, even though some patients complain of muscle pain without having shown visible evidence of fasciculation
Myoglobinemia	Rare complication after extensive fasciculation or in malignant hyperthermia
Elevated intragastric pressure	Secondary to transient contraction of abdominal muscles during fasciculation; however, elevations of intragastric pressure seen after succinylcholine are not clinically relevant; less significant than occur with CO_2 insufflation during laparoscopic procedures
Elevated intracranial pressure (ICP)	Postulated to be secondary to fasciculation, increased central venous pressure; associated with increased cerebral blood flow secondary to muscle-spindle afferent activity and actions on peripheral neuromuscular junctions (ICP effects can be blocked by pretreatment with a small dose of nondepolarizing relaxant and the usual initial administration of an induction agent; may safely be used in neurosurgical procedures)
Elevated intraocular pressure (IOP)	Increases IOP within 1 minute and peaks at an increase of 9 mmHg within 6 min after administration; increase is a vascular event, with choroidal vascular dilation or a decrease in drainage secondary to elevated central venous pressure, temporarily inhibiting the flow of aqueous humor through the canal of Schlemm; generally considered safe in ocular emergencies
Malignant hyperthermia	Associated with a genetic predisposition; mechanism by which succinylcholine triggers the syndrome is not understood
Masseter spasm	Seen in adults in anesthetic and emergency use; sometimes followed by malignant hyperthermia

BOX 12-5

Contraindications to the Use of Succinylcholine

- Hyperkalemia
- Burn patients with injuries of over 35% total body surface area (TBSA), third-degree burn
- Severe muscle trauma
- Neurologic injury (e.g., paraplegia, quadriplegia)
- Hyperkalemia resulting from renal failure
- Severe sepsis (e.g., abdominal)
- Muscle wasting, prolonged immobilization, extensive muscle denervation
- Malignant hyperthermia
- Duchenne muscular dystrophy
- Selected muscle disorders (see Table 12-9)
- Should be used in children under 8 years old only in emergency situations; not for routine intubation
- Genetic variants of pseudocholinesterase
- Allergy

Other Factors

Intraocular Pressure. Intraocular pressure (IOP) is known to increase by 5 to 15 mmHg for as much as 10 minutes after succinylcholine administration.[40,79] The average is about 10 mmHg for approximately 6 minutes. The exact mechanism of this increase is unknown. Some feel that tonic contractions of the extraocular muscles via fasciculation may explain this IOP increase. It is now thought, however, that succinylcholine-induced IOP increase is a vascular event, with choroidal vascular dilation or a decrease in drainage secondary to elevated central venous pressure temporarily inhibiting the flow of aqueous humor through the canal of Schlemm.[79]

This rise in IOP with succinylcholine administration is significantly less than the IOP increase associated with coughing or bucking. Patients who receive succinylcholine and are intubated 1 minute after its administration had IOPs that were not significantly higher than baseline. There are no documented reports of the extrusion of globe contents following the use of succinylcholine in open-eye emergency procedures. A recent review has essentially refuted the issue of eye damage after succinylcholine administration in open-globe injuries. It appears as a theoretical but not a clinical concern. Securing the airway remains the primary issue.[33,40,79] A thorough discussion of the use of succinylcholine and eye injuries is found in Chapter 39.

Hyperkalemia. Succinylcholine administration results in a transient hyperkalemia. A 0.5- to 1-mEq/L increase in serum potassium levels within 3 minutes after administration is usual. The effects were reported as lasting fewer than 10 to 15 minutes.[56]

A muscle receives signals to perform various functions from action potentials. As the action potential traverses the neuron, an influx of sodium and release of potassium occur. This mechanism of potassium release during normal muscle signaling is the same mechanism by which serum potassium increases because of the depolarization associated with receiving succinylcholine.[56]

Hyperkalemia may be profound in certain patients. In a review, Martyn and Richtsfeld[80] noted that lethal hyperkalemic responses to succinylcholine continue to be reported, although the mechanisms have not been completely elucidated. In the normally innervated mature muscle, acetylcholine receptors (AChRs) are located only in the junctional area. But in certain pathologic states—including upper or lower motor denervation, infection, direct

BOX **12-6**

Pathologic Conditions with Potential for Hyperkalemia with Succinylcholine

- Upper or lower motor neuron defect
- Spinal cord trauma
- Prolonged chemical denervation (e.g., muscle relaxants, magnesium, clostridial toxins)
- Direct muscle trauma, tumor, or inflammation
- Select muscular dystrophies and myopathies
- Thermal trauma
- Disuse atrophy
- Stroke
- Tetanus
- Severe infection

muscle trauma, muscle tumor, muscle inflammation, burn injury, immobilization, and prolonged chemical denervation by muscle relaxants, drugs, or toxins—there is an up-regulation (increase) of AChRs spreading throughout the muscle membrane. There is also an additional expression of two new isoforms of AChRs. The depolarization of these AChRs by succinylcholine and its metabolites leads to potassium efflux from the muscle and severe hyperkalemia. The nicotinic (neuronal) α7 acetylcholine receptors, which are also in muscle, are depolarized not only by acetylcholine and succinylcholine but by choline. Persistent choline stimulation may play a critical role in the hyperkalemic response to succinylcholine in patients with up-regulated AChRs.[80] Pathologic conditions with the potential for producing hyperkalemia associated with succinylcholine use are listed in Box 12-6.

Succinylcholine has been implicated in hyperkalemia after its administration to burn patients, so it is contraindicated in these patients.[81] Receptor up-regulation resulting from thermal trauma has been associated with several documented cases of cardiac arrest involving succinylcholine administration.[45] Indeed, plasma potassium levels as high as 15 mEq/L have been reported after the administration of succinylcholine, with this effect occurring 4 to 10 days after the burn and lasting for years after the burn.[82] The burn injury–related increase of AChRs is probably related to inflammation and local denervation of muscle. Major third-degree burns involving extensive body surface area may up-regulate AChRs throughout the body because of the extent and direct inflammation and injury to muscle. Hyperkalemia after burn injury to a single limb (8% body surface area) has been observed, indicating that burn size alone is not the only contributing factor. It is generally reported that the administration of succinylcholine to a burn patient more than 24 hours after the burn is unsafe; however, others note that succinylcholine can be safely used with burn patients for several days after the burn, because receptor up-regulation does not begin until 24 to 48 hours after the burn.[83,84] Changes in responses to both succinylcholine and the nondepolarizing agents have been noted for years after a major burn injury. Immobilization due to contractures may play a role. Succinylcholine should never be used in these patients, regardless of the time post-burn.[79,85]

Treatment of succinylcholine-induced hyperkalemia involves the emergency administration of drugs that promote the cellular uptake of potassium; these include insulin with glucose, catecholamines, and sodium bicarbonate.

The use of various muscle relaxants in patients with muscle disorders is reviewed in Table 12-9.

Malignant Hyperthermia. Malignant hyperthermia (MH) is a pharmacogenetic skeletal muscle disorder triggered by volatile anesthetics, succinylcholine, and stress. Succinylcholine is absolutely contraindicated in patients with known or suspected MH or who have MH in their families.[86] The mechanism for the possible triggering action remains unclear.[87] Mutations in the skeletal muscle ryanodine receptor gene may result in altered calcium release from sarcoplasmic reticulum stores, giving rise to MH. Patients who develop MH show signs such as muscle rigidity, rhabdomyolysis, increased carbon dioxide production, convulsions, metabolic acidosis, tachycardia, and a rapid increase in temperature.[88-90] A complete discussion of the physiologic and treatment aspects of MH can be found in Chapter 32.

Myalgias and Fasciculations. Postoperative muscle pain, particularly in the subcostal region, trunk, neck, upper abdominal muscles, and shoulders, is a common occurrence after succinylcholine administration.[91] A meta-analysis that included 52 randomized clinical trials found several interesting results.[92] The incidence of succinylcholine-induced myalgia is high, and symptoms sometimes last for several days. Small doses of nondepolarizing muscle relaxants, approximately 10% to 30% of the ED_{95} (effective dose, 95% response), reduce the incidence of fasciculations and myalgia, although pretreatment side effects occur. Higher doses of succinylcholine decrease the risk of myalgia compared with lower doses, and opioids do not have any impact; however, there is less myalgia with thiopental compared with propofol. There is no clear relation between succinylcholine-related fasciculation and myalgia. Pretreatment with sodium channel blockers (i.e., lidocaine) or nonsteroidal antiinflammatory drugs (diclofenac and aspirin) may prevent myalgia.

Myalgias are generally attributed to the occurrence of fasciculations resulting from repetitive firing of the motor nerve terminals, which causes uncoordinated muscle contractions. Patients who experience muscle pain most often are women and those persons who rarely participate in muscular activity. Conversely, patients at extremes of age, as well as pregnant patients, are least affected. Postoperative myalgias associated with succinylcholine increase in severity with early ambulation, which may consequently delay postoperative healing.[91]

Prevention is the key to avoiding postoperative muscle pain. Although not always effective, the incidence of myalgia is greatly reduced with nondepolarizer pretreatment. Use of no more than 10% of the ED_{95} is safe and effective and will avoid most of the difficulties of the patient experiencing weakness prior to loss of consciousness. Effective and equivalent doses have been reported as 2 mg rocuronium, 1.5 mg atracurium, and 0.3 mg vecuronium.[93]

Phase II Block. Administration of large doses of succinylcholine results in an alteration in the characteristics of the block.[44] Succinylcholine produces specific unique responses to nerve stimulation when compared with the nondepolarizing agents. These include a sustained response to tetanic stimulation, no fade with TOF or double-burst stimulation (DBS), and no posttetanic potentiation. Figures 12-9 and 12-10 show the characteristic train-of-four responses during onset and recovery from succinylcholine-induced block, respectively. Box 12-7 compares the characteristics of depolarizing and nondepolarizing neuromuscular blockade. Large doses of succinylcholine cause changes that resemble more of a nondepolarizing block, as evidenced by fade in response to tetanic stimuli, TOF, and DBS, the appearance of posttetanic potentiation, and theoretically, antagonism with drugs such as neostigmine. This commonly is referred to as a *desensitization, dual*, or *phase II block*. Some experts do not use these terms interchangeably.[43]

TABLE 12-9 Response of Neuromuscular Blocking Agents in Select Muscle Disorders

Neuromuscular Disorder	Succinylcholine	Nondepolarizing Neuromuscular Blocking Agents
Multiple sclerosis	Contraindicated	Increased sensitivity; anesthetic stress may increase rate of relapse
Motor neuron disease (amyotrophic lateral sclerosis [ALS, Lou Gehrig disease])	Contraindicated	Increased sensitivity
Guillain-Barré syndrome	Contraindicated	Increased sensitivity; avoid agents with cardiac side effects
Charcot-Marie-Tooth disease	Contraindicated	Response to atracurium and mivacurium normal; all others, increased sensitivity
Muscular dystrophies	Contraindicated	Increased sensitivity
Myotonias	Contraindicated	Increased sensitivity; anticholinesterase agents may precipitate myotonia
Myasthenic syndromes	Resistant; prolonged duration of action may be present with plasmapheresis or anticholinesterase therapy	Extreme sensitivity
Mitochondrial myopathies	Contraindicated	Increased sensitivity
Hyperkalemic periodic paralysis	Contraindicated	Normal response
Hypokalemic periodic paralysis	Contraindicated	Normal response
Malignant hyperthermia	Contraindicated	Normal response
Myasthenia gravis	Resistant	Increased sensitivity
Huntington chorea	Increased sensitivity	Increased sensitivity
Up-regulation of acetylcholine receptors because of spinal cord trauma, stroke, or prolonged immobility	Contraindicated	Usually resistant, but depends on time since injury

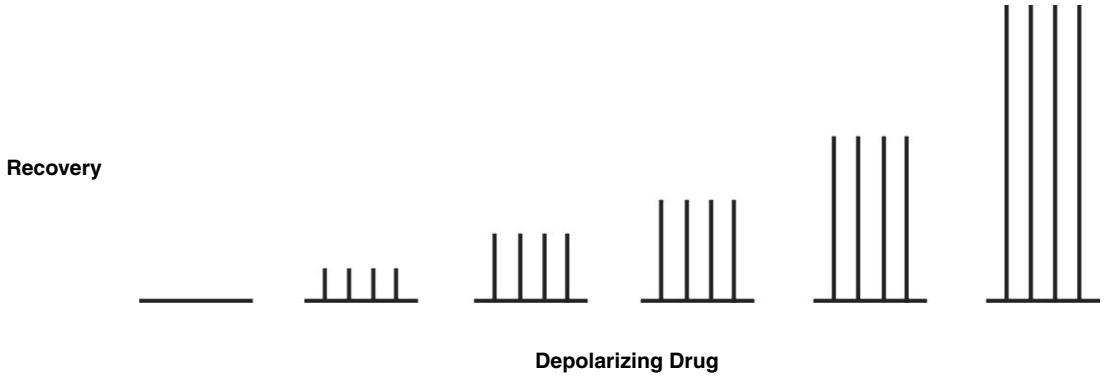

FIGURE 12-10 Characteristic train-of-four response during recovery from succinylcholine.

BOX **12-7**

Characteristics of Neuromuscular Blockade

Depolarizing (Phase I) Block

- Muscle fasciculation precedes onset of neuromuscular blockade
- Sustained response to tetanic stimulation
- Absence of posttetanic potentiation, stimulation, or facilitation
- Lack of fade to tetanus, train-of-four, or double-burst stimulation
- Block antagonized by prior administration of nondepolarizer as pretreatment (approximately 20% more succinylcholine required)
- Block potentiated by anticholinesterase drugs

Nondepolarizing (Phase II) Block

- Absence of muscle fasciculation
- Appearance of tetanic fade and posttetanic potentiation, stimulation, or facilitation
- Train-of-four and double-burst fade
- Reversal with anticholinesterase drugs
- In rare cases may be produced by an overdose and desensitization with succinylcholine at doses greater than 6 mg/kg

As explained earlier, tetanic fade is caused by an interaction with cholinergic presynaptic receptors mediating positive feedback–induced acetylcholine release from the motor nerve end.[30,80] The finding that high doses of succinylcholine inhibited presynaptic $\alpha_3\beta_2$ AChRs (i.e., the compound behaved like a nondepolarizing relaxant) may help explain how high or repeated doses of succinylcholine result in a nondepolarizing type of block (phase II block) characterized by fade and posttetanic potentiation.[94] The exact mechanism is unclear; however, an electrical imbalance caused by repeated opening of junctional channels has been proposed.[43] Development of a desensitization block is a historical discussion because doses exceeding 6 to 8 mg/kg are required, and high doses, as seen with succinylcholine infusions, are rarely used in current practice.

NONDEPOLARIZING AGENTS

The efficacy of the nondepolarizing relaxants is similar, so the choice of one drug over another is largely made on other factors. Specific patient characteristics, type of surgical procedure, pharmacokinetics, and side-effect profile guide the selection of an individual relaxant for a given situation. The intermediate duration nondepolarizing relaxants are almost exclusively used in current clinical practice.

Rocuronium Bromide

Rocuronium is the most widely used nondepolarizing relaxant in the United States.[13] The introduction of vecuronium and atracurium, both of which were marketed as intermediate-acting neuromuscular blocking agents (NMBAs) improved the flexibility of the clinician in matching the agent to the expected duration of surgery.[95] Slow onset, solution stability, and histamine release remained problems to be overcome.[96] Rocuronium (Zemuron) has been developed to partially fill this void. It combines a duration and cardiovascular profile comparable to those of vecuronium, with an onset that is only slightly longer than that of succinylcholine.[95-97]

A derivative of vecuronium, rocuronium bromide is chemically designated as 1-[17β-(acetyloxy)-3α-hydroxy-2β-(4-morpholinyl)-5α-androstan-16β-yl]-1-(2-propenyl) pyrrolidinium bromide, and

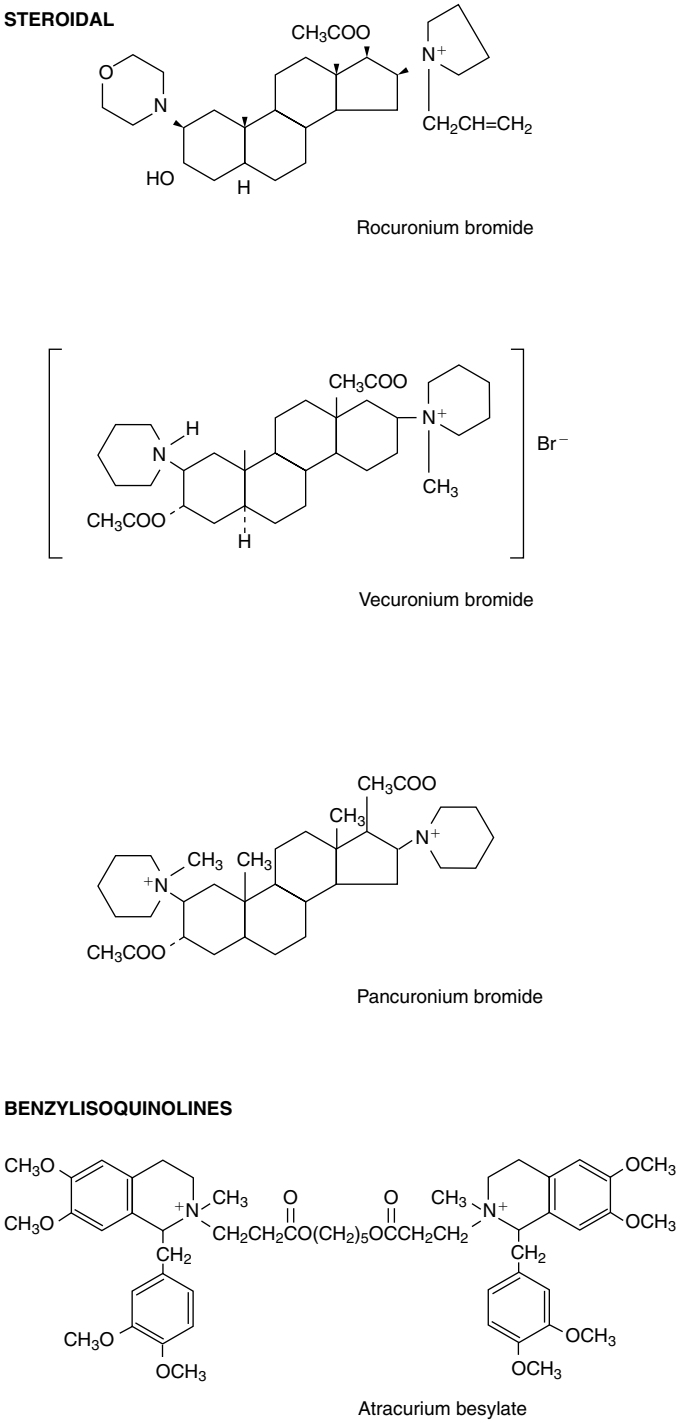

FIGURE **12-11** Chemical structures of nondepolarizing muscle relaxants.

it has one seventh to one eighth the potency of its derivative.[35,44,97] It is a monoquaternary structure that also shares its aminosteroid structure with pancuronium.[98] It has a molecular weight of 609.7 and a molecular formula of $C_{32}H_{53}BrN_2O_4$ (Figure 12-11). The pH of rocuronium is adjusted to 4.0, and the agent contains no preservative. It exists in a solution that is stable at room temperature for up to 30 days.[99] Each 1 mL of solution contains 10 mg of rocuronium bromide and 2 mg of sodium acetate.

Results of clinical studies of both healthy children and healthy adults suggest an ED_{95} of approximately 0.3 mg/kg.[34] Its steady-state volume of distribution in healthy adults is 207 (14) mL/kg

and is slightly smaller for children ages 4 to 8 years. Rocuronium is approximately 46% bound to human plasma proteins, somewhat less than other neuromuscular blockers. This decreased plasma protein binding may lead to a more rapid onset because more unbound drug is readily available at the neuronal binding sites.[100]

Pharmacokinetics

Onset. Rocuronium is the drug of choice and is widely used as the NMBA for rapid sequence induction (RSI) when succinylcholine is contraindicated. A disadvantage of using rocuronium during RSI is its long duration of action.[101,102]

Administration of rocuronium with doses ranging from 0.6 to 1.2 mg/kg provides good to excellent intubating conditions within 45 to 90 seconds.[36,103,104] A meta-analysis noted that there was no statistical difference in intubation conditions when succinylcholine was compared to 1.2 mg/kg rocuronium.[105-107] The onset of muscle relaxants is related to potency. The less potent an agent, the faster the onset. Rocuronium has an onset of action that is inversely proportional to its potency,[97] and it is less potent than other steroidal-based neuromuscular blockers.[108,109] This decreased potency together with the decrease in the amount of drug that is protein bound allow a larger mass of drug at the prejunctional and postjunctional cholinoreceptors.[36,108] This large drug mass at the receptor site yields a faster onset.[110,111]

One method used clinically to accelerate the onset of rocuronium when administering it to intubate during RSI is referred to as *priming*. Priming involves giving 10% of the calculated intubating dose prior to inducing anesthesia. After a period of 1 to 3 minutes, the patient is anesthetized, and the remaining rocuronium is given. Giving a small portion of the relaxant dose in this manner speeds the onset by valuable seconds.[112-114] Priming, however, produces respiratory distress in 10% of the patients in which it is used.[115]

Duration. Rocuronium is classified as an intermediate duration relaxant.[38] In usual ED_{95} doses, it lasts 30 to 60 minutes. The duration of action is similar to that of vecuronium, and its duration depends, like that of any other agent, on the dose administered.[35] An intubating dose of 0.6 to 1 mg/kg provides a clinical duration of 30 to 90 minutes.[35,36] The administration of 0.6 mg/kg resulted in 10% recovery of T_1 within 27.2 (5.5) minutes, whereas 25%, 75%, and 90% recovery of T_1 occurred in 31.1 (5.6) minutes, 39.3 (6.2) minutes, and 41.2 (6.1) minutes, respectively.[116] Recovery of the TOF ratio to 0.8 when rocuronium was administered with sevoflurane, isoflurane, and propofol occurred in 103 (30.7), 69 (20.4), and 62 (21.1) minutes, respectively.[117]

Elimination. Rocuronium undergoes both hepatic and renal elimination. The primary means of rocuronium elimination is biliary elimination of unchanged drug. It also undergoes deacetylation via the liver.[116-118] Renal excretion accounts for 33% of elimination.[44] Plasma levels of rocuronium follow a three-compartment open model. This results in extensive redistribution after IV injection. Therefore before elimination occurs, serum levels of the drug are low enough to result in recovery.[34] The elimination half-life of rocuronium is 60 to 120 minutes. The elimination half-lives of the agent in children, normal adults, and elderly persons are 38.3 minutes, 56 minutes, and 137 minutes, respectively.[108,119] Patients with significant liver or kidney disease will have a prolonged effect.[48,58]

Vecuronium Bromide

Vecuronium bromide (Norcuron) is a potent nondepolarizing neuromuscular blocker. Studies comparing vecuronium with pancuronium, its predecessor, found vecuronium to be 1.5 times more potent than its parent compound.[120] Both agents were developed by manipulation of the steroid nucleus. The molecule was successfully altered from bisquaternary pancuronium to a monoquaternary compound, creating an agent with a more rapid onset and a shorter duration. Vecuronium is more lipophilic than pancuronium, although it is still predominantly a hydrophilic compound. This change in its solubility is thought to be the cause of its differing pharmacokinetic profile.[121-123]

The chemical formula of vecuronium bromide is $C_{34}H_{57}BrN_2O_4$, and the drug has a molecular weight of 637.74 (see Figure 12-11). It is chemically designated as piperidinium 1-[(2β, 3α, 5α, 16β, 17β)-3, 17-bis(acetyloxy)-2-(1-piperidinyl) androstan-16-yl]-1-methyl bromide.[122]

Vecuronium is available as a 10- or 20-mg, sterile, nonpyrogenic powder for IV use only. Once reconstituted, the solution has a pH of 4.0 and is stable for 24 hours at 25° C.[122] Miller et al.[121] constructed dose-response curves to derive the ED_{95}, which they found to be 0.03 mg/kg. The agent has a steady-state volume of distribution of 0.21 to 0.27 L/kg.[123]

Pharmacokinetics

Onset. Vecuronium has an onset of action that is 1.5 times that of pancuronium, a proportion similar to that of its potency.[124,125] At a dose of twice the ED_{95}, 0.1 mg/kg, the maximum suppression of muscle twitch occurs within 3 minutes of administration. The onset varies with the concurrent anesthetic administered and is inversely proportional to the dose.[126] With balanced anesthesia, a 0.1-mg/kg dose of vecuronium resulted in an onset of 3.1 minutes, whereas in patients receiving isoflurane, N_2O-O_2 anesthesia, the onset time decreased to 1.8 minutes.[123,127-129]

Duration. Duration of action varies with the type of anesthetic being administered and the dose of the agent. This phenomenon has been noted with other nondepolarizing agents, as well as with vecuronium.[129] Haines[127] reported a duration of 36.2 ± 6.4 minutes after a dose of 0.1 mg of vecuronium per kilogram was given patients undergoing balanced anesthesia. The time from 25% twitch recovery to 75% twitch recovery at a dose of 0.1 mg/kg was 11 to 12 minutes and the duration 30 to 45 minutes.

Elimination. Vecuronium is eliminated via hepatic and renal mechanisms. Vecuronium undergoes elimination via an orthodox three-compartment model. Because it is more lipophilic than other agents in its class, vecuronium does not depend solely on the kidneys for elimination. Only 20% to 30% of the administered dose is recovered unchanged in the urine within 24 hours.[121] A major portion of the dose, 40% to 80%, is taken up by the liver and excreted in bile.[125] Small amounts of its metabolites (3-hydroxy, 17-hydroxy, and 3,17-hydroxy) can be detected by thin-layer chromatography. The 3-desacetyl metabolite is thought to have around 50% the potency of vecuronium.[9] It is avoided in critical care units for long-term administration because of accumulation. Reported elimination half-lives range from 51 to 90 minutes in healthy adults. Total clearances have been reported from 3 to 5.6 mL/kg/min.[120,130,131]

Pancuronium Bromide

Pancuronium bromide was first synthesized for Organon in England in 1966. Researchers, especially Lewis and colleagues, were searching for an agent that was nondepolarizing, had a rapid onset, had an intermediate duration of action, was easily reversed, and had no significant unwanted side effects.[6] After clinical use by Baird and Reid in 1967 in Europe, the agent was introduced in the United States in 1972.[132-135]

The chemical designation of pancuronium bromide is 2β, 16β-dipiperidine-5α-androstane-3α, 17-β-diol diacetate dimethobromide (see Figure 12-11). It has a volume of distribution of 0.18 to 0.26 L/kg; is an odorless, white, crystalline powder; and has a melting point of 215° C. Extensive testing revealed an effective dose of 0.02 to 0.05 mg/kg in mice, rats, rabbits, cats, and dogs.[6] Further research determined the ED_{95} of pancuronium to be 0.075 mg/kg in humans.[130,131]

Pharmacokinetics

Onset. The mean time to depression of twitch to 5% of control values after a dose of twice the ED_{95} (0.14 mg/kg) is 4.4 (0.5) minutes.[136] At a dose of 1.5 ED_{95}, which is estimated as 0.08 mg/kg, an onset time to 90% blockade was 2.3 ± 0.3 minute.[137,138]

Duration. Pancuronium is a long-acting nondepolarizer that does not release histamine.[133] At an ED_{90} dose of 0.062 mg/kg, the mean duration of blockade was 109 minutes.[139] The average duration is 60 to 90 minutes.

Elimination. Pancuronium is excreted mainly via the kidney. Thirty-five percent of the drug is also released in the bile.[88] Up to 24 hours after the injection of pancuronium, anywhere from 43% to 67% of unchanged drug may be found in the urine.[135] Its half-life is prolonged and clearance is reduced in patients with renal failure.[140] A summary of the selected properties of the neuromuscular blocking agents is given in Table 12-10.

Atracurium Besylate

Atracurium (Tracrium) was developed as a result of a joint venture between the Department of Pharmaceutical Chemistry at the University of Strathclyde and Wellcome Research Laboratories.[141] The objective of the investigators was to develop an agent with the following characteristics:

- Competitive bisquaternary neuromuscular blocker
- Highly selective in action
- Degradable without renal or hepatic intervention[141,142]

The resulting agent was a bisquaternary competitive neuromuscular blocker in the form of a besylate salt.[121,141] Atracurium besylate is designated as 2,2′-[1,5-pentanediylbis[oxy(3-oxo-3,1-propanediyl)] bis[1-[(3,4-dimethoxyphenyl) methyl]-1,2,3,4-tetrahydro-6,7-dimethoxy-2-methylisoquinolinium] dibenzenesulfonate. It has a molecular weight of 1243.49 and a molecular formula of $C_{65}H_{82}N_2O_{18}S_2$ (see Figure 12-11). The pH of atracurium is adjusted to 3.25 to 3.65, and the agent contains the preservative benzyl alcohol. Atracurium loses potency at the rate of 6% per year when it is refrigerated at 5° C. At room temperature, the agent degrades approximately 5% per month, and its recommended unrefrigerated shelf life is 14 days. It was developed with an intermediate duration in mind, and it spontaneously degrades to inactive products. It is well absorbed intravenously, with an ED_{95} of 0.10 to 0.25 mg/kg.[121,143]

Atracurium is rapidly distributed throughout the extracellular space after IV injection and has a volume of distribution of 153 (13) mL/kg. It is approximately 82% protein bound and does not distribute into the fat, because it is ionized.[144] Obese patients who received atracurium according to ideal body weight demonstrated no difference in recovery indices or recovery times when compared with control patients of normal weight because of the agent's lack of organ dependency for elimination.[145-147] The chemical structure of atracurium besylate is shown in Figure 12-11.

Pharmacokinetics

Onset. As expected, atracurium has an onset time that is inversely proportional to dosage, in the range of 1.2 to 2.8 minutes. When various doses of atracurium were given to 70 patients anesthetized with fentanyl, thiopental, and nitrous oxide–oxygen (N_2O-O_2) anesthesia, clinical effects were seen at doses of 0.3 to 0.6 mg/kg. Other investigators, however, have found the onset to be longer, in the range of 2.31 to 3.55 minutes.[126,127,148]

Duration. The duration of atracurium increases as its dose increases. Duration of maximum effect and duration to 95% recovery of peak contraction are reported in the range of 5.6 to 69.5 minutes.[127,149,150] On average, as an intermediate relaxant, the duration of action is 30 to 60 minutes.

Elimination. The development of atracurium arose from the discovery of the plant *Leontice leontopetalum* and one of its components, designated *petaline*. This component was similar to tubocurarine and was observed to undergo an unexpectedly facile degradation in mild alkali by the well-known Hofmann elimination pathway, with loss of water and formation of a tertiary base.[143] Stenlake's pursuit of this research led to the development of atracurium, which does not rely on any organ system for its breakdown and elimination. Study of the clinical pharmacology of atracurium reveals that its molecules decompose by Hofmann elimination, as well as by nonspecific ester hydrolysis.[141,143,145,151]

Hofmann elimination is a temperature- and pH-dependent breakdown of the drug molecule. In the vial, atracurium is at room temperature in an acidic medium. When injected, the pH rises to blood pH of 7.4, and the temperature increases to body temperature. These increases in pH and temperature allow the Hofmann elimination to ensue. Atracurium degrades via Hofmann elimination (10% to 40%). In mild alkaline states, fission occurs at the quaternary nitrogen position, and laudanosine is subsequently released.[151,152] The agent then degrades further. Ester hydrolysis also occurs, and it is catalyzed by nonspecific esterases into a quaternary alcohol and a quaternary acid.[141,151] These metabolites are excreted primarily in bile and urine.

Cisatracurium Besylate

The most notable of the 10 stereoisomers of atracurium, cisatracurium besylate (Nimbex) has gained popularity in the clinical arena since the mid-1990s. It is a nondepolarizing muscle relaxant, three times more potent than atracurium with a slower onset of action. The agent is available as a sterile, nonpyrogenic aqueous solution in 5-, 10-, and 20-mL vials. The pH is 3.25 to 3.65, and the concentration is 2 mg/mL (except in the 20-mL vial, in which the concentration is 10 mg/mL for convenience in the intensive care unit setting).[153] Advantages of cisatracurium include maintenance of cardiovascular stability, non-organ–dependent elimination, and a lack of histamine release after injection.[154,155]

Pharmacokinetics

Onset. Cisatracurium is regarded as intermediate in its onset and duration of action. In adults the ED_{95} is 0.05 mg/kg during N_2O-O_2 opioid anesthesia.[156] It has been noted to be five times more potent than rocuronium, with a slower onset of action, longer duration, and slower spontaneous recovery.[157,158] An IV bolus of 0.1 mg/kg (twice the ED_{95}) produces desired levels of relaxation within 3.1 minutes.[159] Doses of three to four times the ED_{95} (0.15 to 0.2 mg/kg) decrease the mean time of onset to 3.4 and 2.8 minutes, respectively.[160]

Duration. After doses of three to four times the ED_{95}, the average time for the first twitch in a TOF to recover to 25% of control is 65 minutes.[161] Further studies report that the duration of cisatracurium with an intubating dose of 0.25 mg/kg is 55 to 75 minutes. Full recovery at the aforementioned dose occurs in 75 to

TABLE **12-10** Summary of Select Properties of Neuromuscular Blocking Agents

Classification	ED_{95} (mg/kg)	Intubating Dose Usually 2-3 × ED_{95} (mg/kg)	Onset	Duration	Metabolism	ELIMINATION		AUTOMATIC GANGLIA EFFECT	CARDIAC MUSCARINIC EFFECT	Histamine Release	Resulting Cardiac Action
						Kidney (%)	Liver (%)	(SNS & PNS)	(Vagal Block)		
Ultrashort											
Succinylcholine (Anectine, Quelicin)	0.3	1-1.5	30-60 sec	5-10 min	Plasma cholinesterase	<2	0	Stimulates	Stimulates and/or blocks	0 ?	Usually tachycardia, bradycardia with repeat doses
Intermediate											
Atracurium (Tracrium)	0.15	0.5	2-4 min	30-60 min	Hofmann elimination, nonspecific esterase hydrolysis	10-40 metabolites	0	0	0	yes	Hypotension, tachycardia, flushing
Cisatracurium (Nimbex)	0.05	0.1	2-4 min	30-60 min	Hofmann elimination, nonspecific esterase hydrolysis	Up to 77 metabolites	0	0	0	0	0
Rocuronium (Zemuron)	0.3	1	1-3 min	30-60 min	Hepatic and renal	10-30	70-90	0	0	0	0
Vecuronium (Norcuron)	0.05	0.1	2-4 min	30-60 min	Hepatic and renal	40-50	50-60	0	0	0	0

100 minutes. Additional sources report the duration as 55 to 61 minutes.[162]

Elimination. Cisatracurium, like atracurium, undergoes Hofmann elimination (which is pH and temperature dependent) in the plasma and tissues. Hofmann elimination accounts for 77% of total body clearance, and nonspecific esterases are responsible for 23% of total body clearance. Of the organ-dependent clearance, 16% occurs through renal pathways.[163] Studies have demonstrated a half-life of approximately 26 to 36 minutes, with an increase in the rate of degradation as pH increases.[164] As with atracurium, one of the metabolites of cisatracurium is laudanosine along with acrylates. However, cisatracurium liberates one fifth as much laudanosine as atracurium.[165]

Nondepolarizing Agents' Effect on Various Organ Systems

Central Nervous System

All muscle relaxants are quaternary ammonium compounds and therefore water soluble at physiologic pH. As such, they are unable to cross physiologic barriers such as the blood-brain, placental, and gastric, and therefore have no CNS effects.

Cardiovascular System

The NMBAs have no direct effect on cardiac muscle. Any cardiovascular changes that occur with the administration of a muscle relaxant are caused by indirect actions such as histamine release or effects on the autonomic nervous system. Of the current nondepolarizing relaxants, only atracurium and pancuronium exhibit any cardiac effects. Atracurium has been associated with increases in heart rate and decreases in blood pressure at doses of 0.5 mg/kg and greater because of histamine release.[166,167] Systolic and diastolic pressures significantly decrease, and cardiac output was significantly increased at 2, 5, and 10 minutes after a bolus dose. The increase in cardiac output is the result of a markedly decreased systemic vascular resistance. Nearly all of the hemodynamic changes associated with the administration of atracurium have been linked to the release of histamine.[132,166,167] Administration of cisatracurium does not result in histamine release. The effects of stimulation of histamine receptors and the resulting effects are listed in Box 12-8.

Pancuronium produces tachycardia. Significant increases in heart rate 3 minutes after the administration of the agent were noted in patients with coronary artery disease who were scheduled for coronary artery bypass graft and who received a dose of 0.1 mg/kg, despite administration of narcotics.[166,168,169] Increases in heart rate are often accompanied by mild increases in mean arterial pressure. The tachycardia results from a vagolytic and an indirect sympathomimetic action. The other steroidal relaxants vecuronium and rocuronium have no significant cardiac effects at clinical doses. The cardiovascular effects of the neuromuscular blocking agents are summarized in Box 12-9.

Hepatic System

The steroidal relaxants rocuronium, vecuronium, and pancuronium are affected by changes in hepatic status. They are primarily eliminated by a combination of liver metabolism and biliary and renal excretion, and therefore their duration of action is prolonged in patients with hepatic disease. Vecuronium, which is metabolized in the liver, has been administered to patients with hepatic disease.[170-174] Lebrault et al.,[170] for example, compared patients with cirrhosis who received 0.2 mg of vecuronium per kilogram with healthy control patients and found that elimination half-life was prolonged approximately 60%. This effect resulted in a time to return of 50% twitch height of 130 minutes in the cirrhotic group, compared with 62 minutes in healthy patients. Differences in clearance among alcoholic patients with liver disease are dose dependent and usually not significant.[174] Rocuronium and pancuronium have an increased volume of distribution and elimination times, resulting in significantly longer durations.[170-173] The duration of action of rocuronium, as well as the onset, is typically prolonged in patients with hepatic disease such as cirrhosis. Patients with hepatic dysfunction demonstrate an elimination half-life that is increased to 173 minutes, compared with the normal 60 to 120 minutes. This supports the finding that the route of plasma clearance of rocuronium is predominantly hepatic with much of the drug excreted being unchanged in bile.[175] Cautious dosing is warranted, along with vigilant monitoring of neuromuscular function in these patients.

An active desacetyl metabolite results from the breakdown of each of the steroidal relaxants. These metabolites exhibit relaxant activity and accumulate with prolonged use. Although this does not pose a problem perioperatively, prolonged paralysis and myopathies in patients with multiorgan failure in critical care units has been a problem with multiday use. Practice guidelines for sustained neuromuscular blockade in critically ill adults and children have been published.[176,177] Nondepolarizing relaxants are used in intensive care to immobilize patients for procedural interventions, decrease oxygen consumption, facilitate mechanical ventilation, reduce intracranial pressure, prevent shivering, and manage

BOX 12-8

Effects of Stimulation of Histamine Receptors by Neuromuscular Blockers

H_1 Receptors	H_2 Receptors
Increased capillary permeability	Increased gastric acid production
Bronchoconstriction	Systemic and cerebral vasodilation
Intestinal contraction	Positive inotropic effects
Negative dromotropic effects	Positive chronotropic effects

Atracurium releases modest amounts of histamine. Slight histamine release may occur with succinylcholine. The amount of histamine release is dependent on dose and speed of injection.

With endogenous histamine release, all receptor responses are elicited.

Prophylaxis against histamine release requires administration of both H_1- and H_2-receptor blockers.

H, Histamine.

BOX 12-9

Cardiac Effects of Neuromuscular Blocking Drugs

- Atracurium causes histamine release and may produce hypotension and tachycardia.
- Pancuronium is vagolytic and causes slight catecholamine release (indirect sympathomimetic), producing tachycardia.
- Succinylcholine usually results in slight tachycardia. Repeat dosing in adults and any dose in children may produce sudden, abrupt bradycardia. Many types of arrhythmias have been reported.

tetanus and acute respiratory distress syndrome (ARDS). Emerging data may support the use of cisatracurium in select patients with ARDS.[178,179] Cisatracurium may be kinetically preferred for patients with organ dysfunction. Close monitoring with peripheral nerve stimulation is recommended with sustained use of nondepolarizing relaxants to avoid drug accumulation and minimize the risk for adverse drug events. Reversal of paralysis is best achieved by discontinuing therapy.[178]

Atracurium and cisatracurium are not affected by changes in liver function and are the agents of choice for use in patients with liver disease because of their unique method of metabolism, specifically their breakdown pathway via Hofmann elimination and nonesterase-dependent hydrolysis.[121] Cisatracurium is preferred for its lack of histamine release. The pharmacokinetics of atracurium in patients with hepatic and renal disease was compared with those in nonimpaired control subjects. No differences in plasma elimination half-lives were noted.[134,180] The effect of atracurium infusions in patients with fulminant hepatic failure who were awaiting liver transplantation, as well as during liver transplantation, has been studied. Plasma clearances and half-lives were similar to those reported in healthy individuals, and no cumulative effects were noted.[181,182]

Renal System

The steroidal relaxants rocuronium, vecuronium, and pancuronium are affected by changes in renal status. Because all three drugs depend to varying degrees on renal and hepatic elimination, their duration of action is prolonged in patients with decreases in renal function. Pancuronium is largely (80% to 85%) dependent on renal elimination, which is markedly decreased in patients with chronic renal failure and therefore leads to the prolongation of neuromuscular blockade.[183] A small portion of rocuronium is excreted unchanged in the urine, resulting in a prolonged elimination half-life in patients with renal disease.[175] The onset time of rocuronium is not affected by renal failure.

Atracurium and cisatracurium are considered the agents of choice in patients with renal disease. Onset and duration are not affected by changes in renal function. Doses of three times the ED_{95} (0.15 mg/kg) of cisatracurium were given to 39 patients with decreased renal function, all of whom were induced with fentanyl and thiopental. Onset time, mean arterial blood pressure, heart rate, and time to recovery of 25% T_1 were assessed, and there was no significant variation in the drug effects compared with patients with normal renal function.[184]

Effects in Special Populations

Elderly Patients. The onset times of the NMBAs are generally delayed in the elderly due to slower circulation times and other kinetic changes associated with aging.[185] This is true for all relaxants. The dosing interval and duration of action of the steroidal relaxants rocuronium, vecuronium, and pancuronium are prolonged in the elderly due to decreased hepatic and renal clearance and an increased volume of distribution.[185-188] The duration of atracurium and cisatracurium is not affected by aging, making these the most predictable NMBAs in the elderly.

Obese Patients. The use of the NMBAs in obese patients raises some special clinical considerations. Obese patients require a rapid-sequence induction more frequently than nonobese patients, owing to their higher risk for gastroesophageal reflux disease and pulmonary aspiration. A difficult airway is more often encountered. It is especially important to ensure full reversal of the relaxant actions in this patient group because of the higher occurrence of breathing abnormalities and lung compromise. Sleep apnea syndrome and the associated anesthetic management must be considered.[189-192] The duration of action of the steroidal relaxants rocuronium, vecuronium, and pancuronium are all prolonged. This is likely due to a decrease in elimination.

The kinetics of atracurium and cisatracurium are not significantly changed in obese patients, making these the most reliable agents. Cisatracurium is preferred for its lack of histamine release. Several authors recommend that to avoid overdosing, NMBAs should be dosed at ideal body weight, except for succinylcholine, which is given according to total body weight.[64,65,191,193-196]

Pediatrics. When compared with adults, several differences exist among neonates, infants, and children in relation to their response to NMBAs. A more complete discussion of neonatal and pediatric pharmacology is given in Chapters 47 and 48. A few general observations can be made here. The neuromuscular junction is incomplete at delivery and continues to mature throughout infancy.[197] The sensitivity to any relaxant may change from birth through childhood. Neonates and infants have a higher volume of distribution and differences in redistribution, elimination, and metabolic rates, which vary with age. Infants appear to be more sensitive to nondepolarizing drugs than adults. The onset of action of the relaxants tends to be faster in children than adults. The duration of action of the intermediate NMBAs is longer in infants younger than 10 months of age than in children 1 to 5 years of age.[198] Recovery is faster in children than adults.[199]

Other Factors

Hypothermia. The importance of keeping the patient's core body temperature normothermic cannot be overstated. Hypothermic patients exhibit a prolonged duration of action to all muscle relaxants. This is due to decreased metabolism and delayed hepatic and renal clearance.[43] Severe (but not mild) hypothermia makes it more difficult to antagonize a neuromuscular block.[200-202]

Allergy. The role of muscle relaxants in perioperative anaphylaxis is well established. An ongoing report from France reported on 1861 cases of IgE-mediated anaphylaxis. The most common causes were NMBAs (n = 1067, 58.08%), latex (n = 361, 19.65%), and antibiotics (n = 236, 12.85). Succinylcholine (n = 356, 33.40%) and rocuronium (n = 313, 29.30%) were the most frequently involved, and pancuronium and cisatracurium are the least. Cross-sensitization among the different agents is common and is more frequent with aminosteroid than with the benzylisoquinoline drugs.[203,204] Quaternary and tertiary ammonium ions in the relaxant molecules are the main component of the allergenic sites on the reactive drugs. The flexibility of the chain between the ammonium ions as well as the distance between the substituted ammonium ions might be of importance during the elicitation phase of IgE-mediated reactions. Flexible molecules, such as succinylcholine, were considered more potent in stimulating sensitized cells than rigid molecules, such as pancuronium.[204] Skin testing and follow-up guidelines have been published.[205] A complete discussion of anaphylaxis management and anesthesia is given in Chapter 41.[206,207]

REVERSAL OF NEUROMUSCULAR BLOCKADE

Complete and effective reversal of the action of the muscle relaxants is one of the most important aspects of clinical practice. Incomplete relaxant reversal and the resulting difficulties continue to be a challenge. The use of nerve stimulators and our knowledge of relaxant pharmacology continue to evolve; however, a significant incidence of postoperative residual paralysis stubbornly remains. Three anticholinesterase agents for reversal of the relaxants are available, although neostigmine is used overwhelmingly.

BOX **12-10**

Adverse Effects of Residual Neuromuscular Block

Volunteer Studies

- Impairment of pharyngeal coordination and force of contraction
- Swallowing dysfunction/delayed initiation of the swallowing reflex
- Reductions in upper esophageal sphincter tone
- Increased risk of aspiration
- Reductions in upper airway volumes
- Impairment of upper airway dilator muscle function
- Decreased inspiratory airflow
- Upper airway obstruction
- Impaired hypoxic ventilatory drive
- Profound symptoms of muscle weakness (visual disturbances, severe facial weakness, difficulty speaking and drinking), generalized weakness

Clinical Studies in Surgical Patients

- Increased risk of postoperative hypoxemia
- Increased incidence of upper airway obstruction during transport to the postanesthesia care unit (PACU)
- Higher risk of critical respiratory events in the PACU
- Symptoms and signs of profound muscle weakness
- Delays in meeting PACU discharge criteria and achieving actual discharge
- Prolonged postoperative ventilatory weaning and increased intubation times (cardiac surgical patients)
- Increased risk of postoperative pulmonary complications (atelectasis or pneumonia)

BOX **12-11**

Reversal Considerations in Clinical Practice

Considerations When Return of Muscle Function Is Incomplete

- As with any reversal agent, the ability to counteract a nondepolarizing blocking agent depends on the amount of spontaneous recovery before the administration of a reversal drug.
- Has enough time been allowed for the anticholinesterase to antagonize the block (at least 15 to 30 minutes)?
- Is the neuromuscular blockade too intense to be antagonized?
- Even if recovery appears clinically adequate, a small dose of neostigmine may be prudent if the time since relaxant administration is less than 4 hours.
- Has an adequate dose of antagonist been given?
- Are the other anesthetics and adjunctive agents contributing to patient weakness?
- Has metabolism or excretion of the relaxant been reduced by a possibly unrecognized process?
- Have acid-base and electrolyte status, temperature, age, drug interactions, and other factors that may prolong relaxant action been contemplated?
- The safest approach when any question as to successful reversal remains is to provide proper sedation and controlled ventilation until adequate recovery is ensured.

Edrophonium may be used when a faster onset is desired, but its efficacy is less than that of neostigmine. This lower effectiveness limits its use to situations in which significant recovery has already occurred. Pyridostigmine is largely historical and rarely used. Fortunately, a new paradigm is unfolding with the introduction of the selective relaxant binding agent (SRBA) sugammadex.[208]

A thorough evaluation of the current data on the clinical use of relaxants and their reversal has been reported and discussed in several publications.[9,12,13,18,20] The criteria for determination that successful recovery has taken place have been clarified and factors that can affect recovery have been noted. The decision faced by the clinician at the end of a procedure involves determining when the relaxant effects have dissipated and the patient can safely control his or her own airway. A convenient and reliable bedside clinical test for evaluating reversal is needed but not yet available. A number of factors combining objective monitoring with clinical signs must be obtained to assure safe recovery. Several studies have indicated that the incidence of residual paralysis may be as high as 45%.[13] Debaene et al.[209] noted that 45% of patients arrived in the recovery room with residual muscular block after intermediate-duration relaxant administration. Residual paralysis is evident even up to 4 hours after use of an intermediate relaxant.[210] This phenomenon is frequently referred to as *recurarization*, implying that adequate reversal was obtained but the drug effect was reestablished. This term is a misnomer because the noted effect is most likely unrecognized residual paralysis. Reversal should not be attempted unless spontaneous recovery of 1 to 2 twitches of the TOF has occurred because the block may be too deep to obtain adequate reversal.[9-12] A TOFR of 0.7 along with additional clinical signs such as strong hand grip and 5-second head lift were used as criteria for adequate reversal for many years. It since has been shown that a TOFR of 0.9 should be attained because even small degrees of residual block increase the incidence of adverse respiratory events and may increase longer-term morbidity as well.[211,212] This is due to previously unrecognized decreases in airway patency and swallowing unless a TOFR of 0.9 is present. An increased incidence of adverse effects such as hypoxia, hypercarbia, atelectasis, and airway obstruction may occur in the PACU.[11] A study by Murphy et al.[213] suggests the incidence of significant respiratory adverse events in the PACU is 0.8%. Qualitative assessments of the signs of recovery are frequently misinterpreted by even the most experienced clinicians. It can be difficult to detect subtle differences in fade of TOF and tetanus with subjective qualitative tests.[9]

Some adverse effects of residual neuromuscular block are noted in Box 12-10.

General principles for avoiding residual paralysis are given in Box 12-11. Factors influencing the incidence of postoperative residual neuromuscular blockade are shown Box 12-12.

CHOLINESTERASE INHIBITORS

The mechanism of action of the cholinesterase inhibitors is primarily the result of its structural relationship and interaction with AChE, a protein with a molecular weight of approximately 320,000 and the capacity to hydrolyze an estimated 300,000 molecules of ACh per minute.[214,215]

BOX **12-12**

Factors Influencing the Incidence of Postoperative Residual Neuromuscular Blockade

Definition of Residual Neuromuscular Blockade
- Objective train-of-four (TOF) measurements (TOF ratio less than 0.9)
- Clinical signs or symptoms of muscle weakness

Type and Dose of Neuromuscular Blocking Drug (NMBD) Administered Intraoperatively
- Intermediate-acting NMBD
- Long-acting NMBD

Use of Neuromuscular Monitoring Intraoperatively
- Qualitative monitoring (TOF and double-burst stimulation studied)
- Quantitative monitoring (acceleromyography studied)
- No neuromuscular monitoring (clinical signs)

Degree of Neuromuscular Blockade Maintained Intraoperatively
- TOF count of 1 to 2
- TOF count of 2 to 3

Type of Anesthesia Used Intraoperatively
- Inhalation drugs
- Intravenous anesthesia (total intravenous anesthesia [TIVA])

Type and Dose of Anticholinesterase Reversal Drug
- Neostigmine
- Edrophonium

Duration of Anesthesia
Time Interval Between Anticholinesterase Administration and Objective
- TOF measurements

Patient Factors
- Metabolic derangements in the postanesthesia care unit (PACU) (acidosis, hypercarbia, hypoxia, and hypothermia)

Drug Therapy in PACU
- Opioids
- Antibiotics

From Murphy GS, Brull SJ. Residual neuromuscular block: Lessons unlearned. Part I: Definitions, incidence, and adverse physiologic effects of residual neuromuscular block. *Anesth Analg.* 2010;111(1):120-128.

Edrophonium, pyridostigmine, and neostigmine all contain an ionized center that actively combines either at the active center or at the site specifically removed from the active center of AChE. Edrophonium is a simple alcohol that contains a quaternary ammonium group.[215] It is considered a reversible inhibitor of cholinesterase because it electrostatically attaches to the anionic site of AChE and is stabilized by hydrogen binding at the esteratic site of the enzyme. Because a true chemical bond is not formed, ACh competes with edrophonium for the binding site of AChE, and therefore it has a shorter duration of action than those of compounds that form a bond.[216]

Neostigmine and pyridostigmine are carbamic acid esters of alcohols and contain a quaternary or tertiary ammonium group.[215] These agents form a carbamyl-ester complex at the esteratic site of cholinesterase. This drug-enzyme complex then degrades in the same manner as the ACh-cholinesterase complex. The carbamate group is transferred to AChE, leaving it unable to hydrolyze ACh.[214]

The indirect-acting cholinesterase inhibitors exert their effect by inhibiting AChE, thereby increasing the concentration of endogenous ACh around the cholinoreceptors.[215] They act as alternative substrates for the enzyme. This provides a twofold mechanism in the reversal of neuromuscular blockade. First, increasing the concentration of ACh in the junctional cleft changes the agonist-antagonist ratio, thereby increasing the likelihood that the ACh will reoccupy the receptor site once occupied by the neuromuscular blocker, as well as occupying sites not previously engaged. Second, the life of the ACh within the cleft is increased. The increased concentration of ACh prolongs the time it remains in the cleft, allowing time for the antagonist dissociation and the reactivation of the receptor site. Evidence also suggests that these agents have direct influences on neuromuscular transmission independent of enzyme inhibition. These include at least three distinct although possibly interacting mechanisms, including a weak agonist action, the formation of desensitized receptor complex intermediates, and the alteration of the conductance properties of active channels.[217]

Although the result of inhibition of AChE is the same when edrophonium, neostigmine, or pyridostigmine is administered, the means by which these agents accomplish the task varies. Edrophonium binds reversibly with the negatively charged enzyme site by electrostatic attraction of its positively charged nitrogen. This effect prevents catalytic binding with ACh for the short time that edrophonium occupies the binding site. Although the duration of receptor site occupation is short for edrophonium, the duration of its effects is prolonged by the fact that once it leaves the receptor site, it finds another to occupy and continues with this process until eliminated.[218]

Enzymatic inactivation is accomplished by neostigmine and pyridostigmine. Electrostatic interaction between the ionized centers of drug and enzyme takes place initially as with edrophonium. This phenomenon then leads to a hydrolytic chemical reaction in which a shift in covalent bonds occurs, resulting in the formation of a carbamylated enzyme. This methyl-carbamyl AChE is much more stable and resistant to hydrolysis than the acetyl enzyme, resulting in an enzyme that is incapable of inactivating ACh.

These differences in chemical deactivation of AChE result in differing pharmacokinetic profiles. Edrophonium, neostigmine, and pyridostigmine are all quaternary ammonium compounds that are poorly lipid soluble. At moderate doses, penetration through lipid barriers (e.g., gastrointestinal tract, placenta, and blood-brain barrier) is minimal if present at all.

Edrophonium is the most rapid acting of these agents, with an onset time of 30 to 60 seconds after IV administration and a duration of 5 to 10 minutes. Intramuscular administration results in an onset of 2 to 10 minutes.[219] Renal excretion accounts for approximately 75% of the edrophonium eliminated, although in the absence of renal function, hepatic metabolism accounts for the inactivation of 30% of the injected dose; this amount undergoes conjugation to inactive edrophonium glucuronide. The elimination half-life of edrophonium is 110 minutes in the healthy patient and 304 minutes in the anephric patient. The volume of distribution is 1.1 and 0.7 L/kg in normal and anephric patients, respectively.

TABLE 12-11 Commonly Used Anticholinesterase, Anticholinergic, and Select Relaxant Binding Agents

Agent	Dose Range	Onset (min)	Duration	Comments
Neostigmine	25-75 mcg/kg	5-15	45-90 min	Most commonly used reversal agent; may increase incidence of postoperative nausea and vomiting
Pyridostigmine	100-300 mcg/kg	10-20	60-120 min	Slow onset, long duration, and slow reversal Rarely used
Edrophonium	500-1000 mcg/kg	5-10	30-60 min	Not recommended for deep block; rapid onset, short duration
Atropine	15 mcg/kg	1-2	1-2 hr	Should be combined with edrophonium because of more rapid onset
Glycopyrrolate	10-20 mcg/kg	2	2-4 hr	Less initial tachycardia than atropine; no central nervous system effects; most frequently used
Sugammadex	2-16 mg/kg	1-2	2-16 hr	Selective relaxant binding agent; up to 16 mg/kg has been safely used

Although similar in structure and mechanism of AChE deactivation, neostigmine is more potent than pyridostigmine and has a more rapid onset of action. After IV administration of neostigmine, onset occurs within 4 to 8 minutes. Duration of action is 0.5 to 2 hours, although other sources suggest durations from 60 minutes to 4 hours. Renal excretion accounts for roughly 50% of the neostigmine eliminated, primarily by glomerular filtration. The remaining 50% of the neostigmine dose is hydrolyzed by plasma esterases and hepatic metabolism to 3-hydroxyphenyltrimethyl ammonium (3-OH PPM) and conjugated 3-OH PPM. These metabolites have approximately one tenth the activity of the parent compounds and are renally eliminated. The elimination half-life of neostigmine is 70 to 80 minutes, increasing to 181 to 183 minutes in anephric patients. The volume of distribution of 0.7 L/kg in healthy patients increases to 0.8 L/kg in those with renal failure.[215,218] Successful reversal is usually attained in 10 minutes.

Pyridostigmine is the cholinesterase inhibitor with the longest onset and duration. The slow onset limits its clinical popularity. Onset of action after IV administration is from 2 to 5 minutes. Duration of action has been reported to be from 90 minutes to 3 to 6 hours.[215] Pyridostigmine is 75% eliminated by the kidneys.[25,193] The remaining 25% is metabolized by the hepatic microsomal enzyme system to 3-hydroxy–methyl pyridinium, its major metabolite, and six other minor metabolites. All of these metabolites are excreted in the urine. The elimination half-life and volume of distribution are 113 minutes and 1.1 L/kg, respectively. In patients with renal failure, the elimination half-life dramatically rises to 379 minutes, whereas the volume of distribution decreases slightly to 1 L/kg. As discussed previously, the efficacy of the reversal drugs is dependent on (1) the depth of blockade at the time of reversal; (2) the dose and specific drug used; (3) the duration of action of the relaxant being reversed; and (4) the anesthetic drugs being used.[218]

The pharmacology of the reversal agents is summarized in Table 12-11. The common clinical signs of muscle recovery after administration of a muscle relaxant are listed in Box 12-13. Some considerations that apply when reversal is incomplete are noted in Box 12-10. Factors that may prolong paralysis are listed in Box 12-14.

BOX 12-13

Common Clinical Signs of Recovery from Neuromuscular Blockers

- Adequate tidal volume and rate
- Respirations smooth and unlabored
- Opens eyes widely on command; no diplopia
- Sustained protrusion and purposeful movement of tongue
- Effective swallowing and sustained bite
- Able to sustain head or leg lift for at least 5 seconds (In small children, a strong knee-to-chest movement is equivalent.)
- Arm lift and touch the opposite shoulder
- Strong, constant hand grip
- Effective cough
- Adequate vital capacity of at least 15 mL/kg
- Adequate inspiratory force of at least 25 to 30 cm H_2O negative pressure
- Sustained tetanic response to 50 Hz for 5 seconds
- Train-of-four ratio greater than 0.9 with no fade
- No fade to double-burst stimulation

ANTICHOLINERGICS

Atropine or glycopyrrolate are used in combination with neostigmine or edrophonium to prevent the parasympathomimetic side effects of the anticholinesterase drugs. If given alone, neostigmine and the other anticholinesterase drugs would cause severe vagal effects due to the systemic buildup of acetylcholine. These would include bradycardia and arrhythmias, hypotension, bronchoconstriction, hypersalivation, diarrhea, and an increase in postoperative nausea and vomiting. Glycopyrrolate is used more often because it produces less initial tachycardia and has no CNS effects. The antimuscarinic can be given first or the glycopyrrolate and neostigmine may be mixed in the same syringe.

Anticholinergic, *antimuscarinic*, and *parasympatholytic* are three common terms used to describe compounds that originate from alkaloids of the belladonna plant. Each group name divides these compounds into subgroups that have a more similar mechanism of action. For the purposes of this section, all of the compounds are referred to as *antimuscarinics*. Atropine (*dl*-hyoscyamine) is the prototype of this group, and many of the currently available products are structural derivatives obtained both naturally and synthetically.[220] Atropine is found in the plant *Atropa belladonna*, or deadly nightshade, and in *Datura stramonium*, also known as *jimson weed*.[144] Preparations of these plants have been used by clinicians for centuries; belladonna was used as a poison during the time of the Roman Empire and in the Middle Ages. In 1867, Bezold and Bloebaun began to study the cardiac effects of bella donna's vagal inhibition, and in 1931 Mein isolated atropine in the pure form.[22]

BOX 12-14

Factors That May Prolong Paralysis

Pathophysiologic Causes
- Acid maltase deficiency
- Adrenocortical dysfunction
- Acute intermittent porphyria
- Amyotrophic lateral sclerosis
- Anoxia and ischemia
- Carcinomatous polyneuropathy
- Cholinesterase deficiency or genetic variance
- Compressive neuropathy
- Critical illness polyneuropathy
- Diphtheria
- Eaton-Lambert syndrome
- Guillain-Barré syndrome
- Hypokalemia and hypocalcemia
- Hypomagnesemia
- Hypophosphatemia
- Hypothermia
- Motor neuron disease
- Multiple sclerosis
- Muscular dystrophy
- Myasthenia gravis
- Myotonic syndromes
- Neurofibromatosis
- Nonspecific nutritional deficiency
- Poliomyelitis
- Pyridoxine abuse
- Polymyositis
- Renal failure (variable prolongation)
- Respiratory acidosis
- Sepsis
- Thiamine deficiency
- Tick bite paralysis
- Trauma
- Vitamin E deficiency
- Wound botulism

Pharmacologic Causes
- Aminoglycoside toxicity
- Penicillin toxicity
- Steroid myopathy

Antihypertensives
- Calcium channel blockers
- β-blockers
- Furosemide

Antidysrhythmics
- Quinidine
- Procainamide
- Local anesthetics in large doses

Antibiotics
- Aminoglycoside antibiotics
- Polymyxin B
- Clindamycin
- Tetracycline

Miscellaneous Drugs
- Cyclosporine
- Steroids
- Volatile anesthetics
- Dantrolene
- Magnesium
- Lithium
- Azathioprine
- Organophosphate (poisoning)

Modified from Kirby RR, et al, eds. *Clinical Anesthesia Practice*. 2nd ed. Philadelphia: Saunders; 2002.

Atropine and scopolamine are naturally occurring tertiary amines. Semisynthetic congeners of the belladonna alkaloids represented by glycopyrrolate are usually quaternary ammonium derivatives. These quaternary ammonium derivatives often have potent peripheral effects without CNS activity.

All the antimuscarinics are absorbed orally to some extent, although this route is often unpredictable. Intramuscular or IV administration is usually the route used. Scopolamine has the additional advantage of transdermal absorption. Atropine is well absorbed from the gastrointestinal tract by inhalation via endotracheal administration and by IV and intramuscular routes. Given orally, 90% of the dose is absorbed and reaches peak plasma levels within 1 hour. Intramuscular and IV administration results in peak plasma levels within 30 minutes and 2 to 4 minutes, respectively. Atropine is well distributed throughout the body. It crosses both the blood-brain barrier and the placental barrier. Both the kidneys and liver aid in the elimination of atropine. Although elimination is biphasic, the terminal half-life is 2 to 3 hours. Metabolism by the liver results in several metabolites: tropic acid, tropine, and glucuronide conjugates. Approximately 30% to 50% of a dose is excreted unchanged in the urine. Small amounts of atropine may also be eliminated in expired air as carbon dioxide and in feces.[220]

Glycopyrrolate is a quaternary ammonium compound whose ionization limits gastrointestinal absorption, blood-brain barrier, and placental penetration. After IV administration, glycopyrrolate has an onset of 1 minute. Intramuscular and subcutaneous administration results in an onset of 15 to 30 minutes. Vagal blockade can persist for 2 to 3 hours. Serum levels of glycopyrrolate decline quickly, and less than 10% of the drug remains in the serum after 5 minutes. Glycopyrrolate is excreted in feces and urine, primarily as unchanged drug. Small amounts are metabolized to inactive metabolites. Eighty-five percent of an IV dose is excreted in the urine within 48 hours.[144]

Atropine and glycopyrrolate are commonly administered to prevent the muscarinic effects of anticholinesterase inhibitors. Atropine induces its vagolytic effect more rapidly than glycopyrrolate. Atropine appears to be somewhat better suited for use with edrophonium, whereas the onset times of glycopyrrolate and neostigmine are more closely matched. When administered with edrophonium, the usual recommended dose of atropine is 7 mcg/kg.[144,221] With 0.5 to 2.5 mg of neostigmine, the recommended dose of atropine is 0.6 to 1.2 mg, and that of glycopyrrolate is 0.2 to 0.6 mg.[220] (See Chapter 13, Table 13-7 for a comparison of the anticholinergics.)

Selective Relaxant Binding Agents—Sugammadex

Sugammadex (Bridion) is the first selective relaxant binding agent (SRBA) to be introduced as a reversal for clinical neuromuscular blockade. The name sugammadex is a contraction of *sugar* and *gamma*-cyclo*dex*trin. It is a modified gamma-cyclodextrin that works by encapsulating and forming very tight water-soluble complexes at a 1:1 ratio with steroidal neuromuscular blocking drugs. Once encapsulation occurs, it does not dissociate and the sugammadex-relaxant complex is excreted in the urine. Reversal occurs independent of the depth of block; therefore, even deep blockade can be reversed with the appropriate dose. The concentration of free muscle relaxant falls rapidly, and muscle strength is reestablished. It is most effective reversing rocuronium, vecuronium, and pancuronium in that order. It does not affect the bezylisoquinolones atracurium and cisatracurium.[222,223] Used in appropriate doses, sugammadex can reverse any depth of rocuronium or vecuronium block within 3 minutes.

Pharmacokinetics

Sugammadex is biologically inactive. The pharmacokinetics of sugammadex show a linear dose relationship in doses up to 8.0 mg/kg. Clearance is approximately 120 L per minute and the volume of distribution is 18 liters. The elimination half-life is 2.3 hours. Up to 80% of an administered dose of sugammadex is eliminated in the urine within 24 hours. Sugammadex does not bind to plasma proteins or erythrocytes. Due to the dependence on renal elimination, the drug should be avoided in patients with significant renal disease.[218,223]

Clinical Use

The dosage range of sugammadex varies from 2 to 16 mg/kg according to the depth of blockade at the time of reversal. The dose for reversal of shallow or moderate block (2 responses to TOF present) is approximately 2 mg/kg. Deeper blocks (PTC 1-2) in which there is little recovery require a dose of 4 mg/kg. A larger dose of sugammadex (16 mg/kg) is used when reversing high doses of rocuronium in the range of 1 to 1.2 mg/kg, such as the doses used for intubation.

The 16 mg/kg dose is also used in an immediate rescue situation such as a "can't intubate, can't ventilate" scenario.[224,225]

Sugammadex appears to be safe and well tolerated. The most commonly reported adverse drug reactions included dry mouth, dysgeusia, nausea, vomiting, allergy, chills, and postural hypertension.[223] Allergy is rare but possible, and the clinical significance remains to be clarified. In the rare event that neuromuscular block needs to be reestablished, a bezylisoquinolone such as atracurium or cisatracurium should be given. Succinylcholine is also not affected.[225] Recurarization is rare but has been reported.[226] As the clinical use of sugammadex evolves, it is expected to produce significant benefits in current practice.[227] The cost of sugammadex is a concern and economic assessments are uncertain.[228]

SUMMARY

Like every other agent used in the practice of anesthesia, neuromuscular blocking agents are useful tools in the hands of skilled clinicians. It should go without saying that these agents ought never to be administered without first appropriately sedating the patient. The exception is if the patient's condition is so marginal that even the most careful use of sedation could increase the chance for morbidity or death. The decision to use neuromuscular blockers in the absence of sedation should be made only after the most careful and thorough consideration. Prevention of movement should provide the surgeon with the optimum field on which life-saving skills can be practiced.

13 CHAPTER Autonomic and Cardiac Pharmacology

◆ *John J. Nagelhout*

Cardiovascular medicine continues to be one of the most rapidly changing specialties in modern clinical practice. Management guidelines are continuously being refined as data from large-scale clinical trials are reported. The number of patients requiring noncardiac surgery who have had coronary interventions is increasing. Many patients are being managed with complex management plans that require consultation with their cardiologists. Providing high-quality anesthetic care involves continuous monitoring of all the body's systems, with a special emphasis on the cardiovascular status of the patient. Complex anesthetic plans and invasive surgical intervention can produce profound stress on patients' cardiovascular balance and require careful manipulation of vital signs. The array of diagnostic tests, monitors, and drugs available makes a thorough understanding of autonomic and cardiac pharmacology essential. A well-devised treatment plan will make the anesthetic course flow smoothly. Intraoperative planning for the immediate and late postoperative periods is critical to avoiding untoward outcomes. The number and variety of medications in a patient's profile require a delicate balance between the anesthetic requirements and maintaining a successful continuum of therapy for the long-term needs of the patient. This chapter presents a broad overview of the many autonomic and cardiovascular medicines that may be encountered during the perioperative period and their important anesthetic considerations.

AUTONOMIC DRUGS—SYMPATHOMIMETIC AMINES

The sympathomimetic amines include the three naturally occurring catecholamines epinephrine, norepinephrine, and dopamine and a number of synthetic agents such as phenylephrine and dobutamine. These drugs are used in a variety of situations, including the treatment of anesthesia-induced hypotension, bradycardia, anaphylaxis, shock, heart failure, and cardiac resuscitation.

The basic structure of the sympathomimetic amines is β-(3,4-dihydroxyphenyl)-ethylamine. This structure consists of a substituted benzene ring and an ethylamine side chain.[1] The effects elicited by this pharmacologic class are the result of the stimulation of β-adrenergic, α-adrenergic, and dopamine adrenergic receptors. The innervation of the effector organs by the autonomic system is outlined in Table 13-1.

The efficacy of a particular sympathomimetic amine depends on its concentration at the receptor site, its affinity for specific receptors, and the population of receptors available for binding. The effects of the common autonomic drugs are summarized in Table 13-2.

Epinephrine

Epinephrine, one of the naturally occurring catecholamines, is the final product in the chain of catecholamine synthesis. (See Chapter 33 for a complete description of catecholamine synthesis.) Although both epinephrine and norepinephrine have agonistic activity at both α- and β-receptors, norepinephrine has minimal β_1 activity in low doses, whereas epinephrine strongly stimulates both β_1- and β_2-receptors.

Epinephrine is useful not only in the treatment of anaphylaxis and cardiopulmonary resuscitation, but also its combination of α and β effects makes it an appropriate choice for the treatment of some shock states in which poor tissue oxygen delivery and hypotension are combined. In small doses, epinephrine may well be useful as a sympathomimetic agent in patients unresponsive to indirect-acting agents and in those in whom simultaneous β_1 (cardiac stimulation) and β_2-receptor stimulation (vasodilation) may be helpful. With epinephrine, the dominance of α or β effects is dose related.

Epinephrine's β_1 effect produces marked positive inotropic (force of contraction), chronotropic (heart rate), and dromotropic (conduction velocity) actions. It should be noted that as heart rate, left ventricular stroke work, stroke volume, and cardiac output increase, so does myocardial oxygen consumption. In addition, the corresponding increased automaticity of all foci, including those that are ectopic, may lead to arrhythmia. Marked vigilance must be maintained in an effort to ensure that an imbalance of myocardial oxygen supply and demand does not occur. It should be recalled that the effects resulting from epinephrine administration are capable of both increasing myocardial demand and decreasing supply.

Beneficial effects of β_2 stimulation include bronchodilation, vasodilation, and stabilization of mast cells, with a resultant diminution of histamine release. Concurrently, α stimulation promotes a decrease in bronchial secretion. The net effect is a decrease in airway resistance with an improvement in oxygenation.

With low doses of epinephrine (10 mcg/min) the peripheral vasculature promotes the redistribution of blood flow to skeletal muscle, thereby producing a decrease in systemic vascular resistance. As the dose of epinephrine is increased, the α effect predominates, with resultant vasoconstriction and an increase in systemic pressures. The systolic pressure is increased, whereas the diastolic pressure remains relatively unchanged, with a resultant increase in pulse pressure. It should be noted that if the coronary arteries are not obstructed, autoregulation increases oxygen delivery to meet the increased demand.[2] However, in the presence of a coronary artery lesion, oxygen delivery may be insufficient to meet demand, and myocardial ischemia results.[3]

The increased α effect that occurs with greater doses of epinephrine also results in renal and splanchnic vasoconstriction. Renal vascular resistance and ultimately renal blood flow are decreased. Beta stimulation leads to activation of the renin-angiotensin system and also to an increase in lipolysis, glycogenolysis, gluconeogenesis, ketone production, and lactate release by skeletal muscle. Insulin secretion is inhibited by an overriding β_2 stimulation. Epinephrine-induced β_2 stimulation also can cause a transient hyperkalemia as potassium follows glucose out of hepatic cells. This is followed by a longer hypokalemia as β_2 stimulation then forces this extracellular potassium into red blood cells.[4]

TABLE 13-1 Typical Autonomic Influences on Peripheral Effector Organs

Organ System	Sympathetic Effect	Adrenergic Receptor Type	Parasympathetic Effect	Cholinergic Receptor Type
Eye				
Radial muscle, iris	Contraction (mydriasis)	α_1		
Sphincter muscle, iris			Contraction (miosis)	M_3, M_2
Ciliary muscle	Relaxation for far vision	β_2	Contraction for near vision (accommodation)	M_3, M_2
Heart				
Sinoatrial node	Increase in heart rate	β_1	Decrease in heart rate	M_2
Atria	Increase in contractility and conduction velocity	β_1	Decrease in contractility	M_2
Atrioventricular node	Increase in automaticity and conduction velocity	β_1	Decrease in conduction velocity; AV block	M_2
His-Purkinje system	Increase in automaticity and conduction velocity	β_1	Little effect	M_2
Ventricle	Increase in contractility, conduction velocity, automaticity	β_1	Slight decrease in contractility	M_2
Blood Vessels				
Arteries				
Coronary	Constriction; dilation	α; β_2	None	—
Skin and mucosa	Constriction	α_1; β_2	None	—
Skeletal muscle	Constriction; dilation	α_1; β_2	None	—
Cerebral	Constriction (slight)	α_1	None	—
Pulmonary	Constriction; dilation	α_1; β_2	None	—
Abdominal viscera	Constriction; dilation	α_1; β_2	None	—
Salivary glands	Constriction and reduced secretions	α_1; α_2	Dilation and increased secretions	M_3
Renal	Constriction +++; dilation	α_1, α_2; β_1, β_2	None	—
Veins	Constriction; dilation	α_1, α_2; β_2	None	—
Lung				
Tracheal and bronchial smooth muscle	Relaxation	β_2	Contraction	M_2, M_3
GI Tract				
Motility and tone	Decrease	α_1, α_2; β_1, β_2	Increase	M_2, M_3
Sphincters	Contraction	α_1	Relaxation	M_3, M_2
Secretion	Inhibition	α_2	Stimulation	M_3, M_2
Gallbladder and ducts	Relaxation	β_2	Contraction	M
Kidney				
Renin secretion	Increase	β_1	None	—
Urinary Bladder				
Detrusor	Relaxation	β_2	Contraction	M_3, M_2
Trigone and sphincter	Contraction	α_1	Relaxation	M_3, M_2
Uterus	Contraction (pregnant)	α_1	None	—
	Relaxation (pregnant and non-pregnant)	β_2		
Liver	Glycogenolysis and gluconeogenesis; increased blood sugar	α_1; β_2		
Pancreas				
Islets (β cells)	Decreased insulin secretion	α_2	None	—
	Increased insulin secretion	β_2	None	—
Adipocytes	Lipolysis	α_1; β_1, β_2, β_3	None	—

α, Alpha receptor; β, beta receptor; GI, gastrointestinal; M, muscarinic receptor.

TABLE 13-2 Effects of Autonomic Drugs

Organ Systems	Alpha Agonists	Alpha Blocker	Beta Agonists	Beta Blocker	Cholinergic Agonists	Anticholinergic
Eye	Mydriasis	Miosis (slight)	NCRE	↓ Intraocular pressure	Miosis, ↓ intraocular pressure	Mydriasis, cycloplegia, ↑ intraocular pressure
Heart						
Rate	Bradycardia (reflex)	Tachycardia (reflex)	Tachycardia	Bradycardia	Bradycardia	Tachycardia
Contractility	NCRE	Slight increase (reflex)	↑	↓	↓ (slight)	↑ (slight)
Conduction velocity	NCRE	NCRE	↑	↓	↓	↑
Blood (vessels)	Vasoconstriction	Vasodilation	Vasodilation	Vasoconstriction	NCRE	NCRE
Lungs	NCRE	NCRE	Bronchodilation	Bronchoconstriction	Bronchoconstriction	Bronchodilation (slight)
GI Tract	↓ Motility and secretion	NCRE	↓ Motility and secretion	NCRE	↑ Motility and secretion	↓ Motility and secretion
Uterus	Contraction	NCRE	Relaxation	NCRE	NCRE	NCRE
Liver	↑ Blood sugar	NCRE	↑ Blood sugar	Hypoglycemia	NCRE	NCRE

↑, Increase; ↓ decrease; *GI*, gastrointestinal; *NCRE*, no clinically relevant effect.

Norepinephrine

Norepinephrine is a potent vasopressor. Although it is not as potent as epinephrine in stimulating α-receptors in equal doses, it has little β_2 activity at low doses, and the end result is, for the most part, unopposed α stimulation. The chronotropic effect seen with β_1 stimulation is generally absent with norepinephrine in low doses because of the increase in systemic vascular resistance, which induces reflex vagal activity.

The aforementioned combination of adrenergic stimulation results in a decrease in vital organ flow; however, coronary artery perfusion may be increased because of the increase in diastolic pressure. Renal vascular resistance is increased, and urine output may fall. An increase in preload may be seen because norepinephrine is a venoconstrictor.[5,6]

Both norepinephrine and dopamine are used as first-line therapy for shock. There is an ongoing debate as to whether one is superior. A recent large multicenter clinical trial suggests that they are equally effective, although dopamine produces more adverse events such as arrhythmias.[7] Norepinephrine is generally used in patients with adequate cardiac output but low systemic vascular resistance. In this group of patients, however, the underlying problem of peripheral tissue perfusion-oxygenation may be exacerbated by the intense norepinephrine-induced peripheral vasoconstriction, even if adequate blood pressure has been achieved.

Norepinephrine does have some generalized metabolic effects, such as a decrease in insulin production, but these metabolic effects are present to a lesser degree than those seen with epinephrine. Adverse effects are usually a result of the intense vasoconstriction associated with norepinephrine.

Dopamine

Dopamine is an endogenous central and peripheral neurotransmitter that is derived from dopa in the chain of catecholamine synthesis. Pharmacologically, dopamine stimulates dopamine receptors, β-receptors, and α-receptors in a dose-dependent manner because of differing receptor affinities. Dopaminergic receptors are stimulated with low doses of less than 2 mcg/kg/min. At moderate doses of 2 to 5 mcg/kg/min, β effects are elicited, and α effects are seen with high infusion rates of greater than 10 mcg/kg/min. Dopamine also has an indirect sympathomimetic effect, eliciting the release of norepinephrine via β_1 stimulation.[8]

Dopamine is often the first inotropic agent chosen for a patient in shock. Some clinicians have found dopamine to have a poor response in cases of gram-negative sepsis because of a down-regulation in which the sensitivity of β-receptors is diminished.[9,10]

During surgery and anesthesia, dopamine is administered for its dopaminergic effect. The stimulation of dopamine receptors in the renal artery promotes an increase in renal blood flow and a resultant increase in glomerular filtration rate and urine output. Benefits, however, of so-called "renal" dopamine are in doubt, and many clinicians have abandoned the practice.[11-14] The urine output is increased but long-term morbidity and mortality are not improved. Dopamine also inhibits aldosterone, resulting in an increase in sodium excretion and urine output.

Dopamine has been implicated in several cases of severe limb ischemia. If dopamine is administered through a peripheral line, increased vigilance in pediatric patients and in patients with any type of vascular disease such as diabetes, atherosclerosis, or Raynaud's phenomenon is advised. The presence of an arterial line in the affected limb also increases the incidence of limb ischemia with concurrent dopamine infusion. Other metabolic and central nervous system (CNS) effects, similar to those seen with epinephrine but less extensive, have been attributed to dopamine administration.[4]

The monoamine oxidase enzymes metabolize dopamine; therefore, the effects of dopamine can be prolonged in patients receiving a monoamine oxidase inhibitor. Tricyclic antidepressants may also augment the activity of sympathomimetic drugs.

Isoproterenol

Isoproterenol is a synthetic catecholamine with the same underlying chemical structure as the endogenous catecholamines. It is a potent nonselective agonist of β_1- and β_2-receptors but has no agonistic activity at α-receptors or dopamine receptors. The current use of isoproterenol is limited since the emergence of dobutamine and milrinone. In current practice, it is occasionally used in the treatment of bradycardia with heart block and torsades de pointes ventricular tachycardia.[15] Isoproterenol is also used after

heart transplant for chronotropic support. The mechanism is in part due to β_2-receptor stimulation.[16]

The profound β_1 stimulation of isoproterenol results in both positive inotropic and chronotropic effects. In combination with the peripheral β_2-induced vasodilation and resultant drop in systemic vascular resistance, an increase in cardiac output is seen. However, the positive inotropic and chronotropic effects dramatically increase myocardial oxygen consumption, which may already be compromised by the β_2-induced peripheral vasodilation, causing a decrease in diastolic blood pressure and ultimately a decrease in coronary artery perfusion. These effects are especially detrimental in patients with coronary artery disease. Isoproterenol is also a potent bronchial dilator and pulmonary vasodilator.

The detrimental effects of isoproterenol on the heart, such as excessive tachycardia, induction of myocardial ischemia, and arrhythmia production are the major factors limiting its use to the treatment of significant heart block unresponsive to atropine. Other side effects are similar to those seen with epinephrine but occur to a lesser extent.

Dobutamine

Dobutamine is a synthetic sympathomimetic amine. It is a modification of isoproterenol, but its use is much more widespread. Dobutamine is primarily a β_1-agonist with some β_2 effects.[17] Dobutamine displays a strong inotropic response with minimal chronotropy. It also produces a slight drop in systemic vascular resistance, owing to peripheral vasodilation. The resultant increase in cardiac output compensates for the decrease in systemic vascular resistance, and the blood pressure is increased or, at low doses, relatively unchanged. Pulmonary artery pressure decreases, and an increase in left ventricular stroke work index is observed.[18]

The positive inotropic effects, coupled with the lack of chronotropy and maintenance of normal blood pressure, have made this agent an option in cardiogenic and septic shock and in select patients with mild heart failure.[19] It is also frequently used for heart stimulation for cardiac stress testing.[15] Recent evidence indicates significant adverse effects when dobutamine is used in cardiac surgery, and clinicians have stopped using it for inotropic support in this situation.[20]

DIRECT-ACTING α-AGONISTS

α_1-Agonists

Phenylephrine

Phenylephrine (Neo-Synephrine) is the most commonly employed pure α-agonist. Phenylephrine has strong α-stimulating effects, with virtually no β stimulation. A sharp rise in blood pressure is produced as a result of a significant increase in peripheral resistance secondary to the α_1 stimulation. A reflex bradycardia can be elicited secondary to baroreceptor stimulation. Careful titration of intravenous (IV) boluses of phenylephrine is necessary to avoid large changes in blood pressure and decreases in heart rate. The onset of action of IV phenylephrine is immediate, with the duration of action ranging from 5 to 20 minutes. Because of its vasoconstricting effects, phenylephrine is frequently used topically for the prevention of nosebleeds during nasal intubation or for a reduction in bleeding in ear, nose, and throat surgery. Severe hypertension may occur with excessive doses. It is recommended that the topical dose should not exceed 0.5 mg (4 drops of 0.25% in adults) and 20 mcg/kg in children.[21]

Other Inotropes

Vasopressin

Arginine vasopressin is an endogenous hormone that is produced in the hypothalamus, stored in the posterior pituitary, and released from the magnocellular neurons of the hypothalamus. It functions to control osmoregulation. Its release is stimulated by an increased osmolality and hypovolemia. It is also referred to as antidiuretic hormone. Vasopressin deficiency and down-regulation of vasopressin receptors are common in septic shock.[22] Vasopressin is a potent vasoconstrictor; however, it selectively dilates renal afferent, pulmonary, and cerebral arterioles. Low-dose vasopressin infusion (0.03 to 0.04 units/min) increases blood pressure, urine output, and creatinine clearance and decreases the dosage of norepinephrine required to maintain blood pressure in patients with septic shock. It is mostly used as an add-on therapy with catecholamine vasopressors. Increases in blood pressure occur in the first hour of administration, and the catecholamine vasopressor can then be titrated down. In a randomized trial, low-dose vasopressin added to norepinephrine was not significantly better than as-needed norepinephrine alone although added vasopressin may be useful in patients with less severe shock. Complications of vasopressin include gastrointestinal ischemia, decreased cardiac output, skin or digital necrosis, and cardiac arrest (especially at doses greater than 0.04 units/min).[23-25] Vasopressin agonists such as terlipressin and desmopressin have a variety of uses including bleeding reduction, antidiuresis in diabetes insipidus, and treatment of enuresis.[26]

Phosphodiesterase Inhibitors

Milrinone. The phosphodiesterase 3 (PDE 3) inhibitors, also known as *nonglycoside noncatecholamines*, include milrinone (Primacor). They differ structurally and functionally from the catecholamines and are generally used as alternatives or adjuncts to the standard inotropes in cardiac surgery and heart failure.[27-30]

Phosphodiesterases (PDEs) are a group of enzymes that play a role in a variety of physiologic actions. Eleven subfamilies have been identified.[31] They break down the second messengers, cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP), in various cells. The PDE 3 inhibitors such as milrinone prevent the breakdown of cAMP and thus enhance its action. Milrinone produces a positive inotropic action and vasodilation without producing tachycardia. It is occasionally referred to as an *inodilator*.[32] Milrinone substantially improves left ventricular function in association with an acceleration of calcium uptake by the sarcoplasmic reticulum. This acceleration appears to result from an inhibition of membrane-bound PDE 3 in the sarcoplasm, which induces a local elevation of cAMP. This allows for the buildup of cAMP and a subsequent increase in the uptake of intracellular calcium. Adrenergic receptors are not used to achieve the inotropic effect. It follows that these drugs retain their inotropic effect even in the presence of β-blocking agents or the phenomenon of β-receptor down-regulation, situations frequently encountered in patients with heart failure. Therefore PDE 3 inhibitors may be used, by virtue of their alternative pathway, to augment the effect of direct-acting β-agonists such as dobutamine or dopamine. Milrinone improves weaning of high-risk patients from cardiopulmonary bypass.[29,30]

These agents act as vasodilators because of the differential mechanism of cAMP in the smooth muscle versus its actions in the myocardium. In the smooth muscle, cAMP causes an efflux of calcium, with a resultant relaxation of the muscle and vasodilation. The clinical result is a decrease in both preload and afterload. This effect, along with the absence of an associated increase in heart rate, probably contributes to the absence of an increase in myocardial oxygen consumption. Sildenafil (Viagra, Revatio) is a PDE 5 inhibitor that produces vasodilation and is being used to treat pulmonary arterial hypertension. Pulmonary vasodilation reduces the workload of the right ventricle and improves symptoms of right-sided heart failure.

TABLE 13-3 Vasopressor Agents

		PERIPHERAL VASCULATURE		CARDIAC EFFECTS			
Agent	**Dose Range**	**Vasoconstriction**	**Vasodilation**	**Heart Rate**	**Contractility**	**Dysrhythmias**	**Typical Use**
Dopamine	1-4 mcg/kg/min	0	1+	1+	1+	1+	"Renal dose" does not improve renal function; may be used with bradycardia and hypotension
	5-10 mcg/kg/min	1-2+	1+	2+	2+	2+	
	11-20 mcg/kg/min	2-3+	1+	2+	2+	3+	Vasopressor range
Vasopressin	0.04-0.1 units/min	3-4+	0	0	0	1+	Septic shock, as an add-on to conventional inotropes such as norepinephrine
Phenylephrine	20-200 mcg/min	4+	0	0	0	1+	Vasodilatory shock
Norepinephrine	1-20 mcg/min	4+	0	2+	2+	2+	First-line vasopressor for septic shock, vasodilatory shock
Epinephrine	1-20 mcg/min	4+	0	4+	4+	4+	Refractory shock, shock with bradycardia, anaphylactic shock
Dobutamine	1-20 mcg/kg/min	1+	2+	1-2+	3+	3+	Cardiogenic shock, septic shock
Milrinone	37.5-75 mcg/kg bolus followed by 0.375-0.75 mcg/min	0	2+	1+	3+	2+	Cardiogenic shock, right heart failure, dilates pulmonary artery; caution in renal failure

From Rivers EP. Approach to patient with shock. In: Goldman L, Schafer AI. *Goldman's Cecil Medicine*. 24th ed. Philadelphia: Saunders; 2012:645-653.

Milrinone acts to enhance diastolic function, increases cardiac output, and decreases pulmonary wedge pressure. Side effects can include arrhythmias. Elimination is via the kidney; therefore, milrinone should be used with caution in patients in renal failure because of the potential for life-threatening arrhythmias. The current manufacturer's recommendation for the administration of milrinone is an IV loading dose of 50 mcg/kg, administered slowly over 10 minutes, followed by an infusion of 0.5 mcg/kg as needed. Table 13-3 outlines the current vasopressors and some of their uses.

MIXED FUNCTION AGONISTS

Ephedrine

Ephedrine is a synthetic noncatecholamine sympathomimetic commonly used in anesthesia practice. It stimulates both α- and β-receptors directly, and it indirectly causes release of endogenous catecholamines, leading to multiple mechanisms of action. It has both central and peripheral actions. Ephedrine's effects are similar to those seen with epinephrine; however, they are lesser and not accompanied by a dramatic increase in serum glucose concentrations. The duration of action of ephedrine is also longer than that of epinephrine, owing to its lack of a basic catechol structure; this characteristic makes it resistant to metabolism by monoamine oxidase.[15]

Ephedrine produces dose-related increases in blood pressure, cardiac output, heart rate, and systemic vascular resistance. Ephedrine often is the first sympathomimetic chosen for alleviation of hypotension because of the cardiac-depressant effects of anesthetic agents or vasodilation resulting from spinal anesthesia. Intravenously administered ephedrine, in doses ranging from 5 to 25 mg, has an immediate onset and a duration of action of 15 minutes to 1.5 hours depending on dose. This drug should be used cautiously in patients with questionable coronary perfusion, because myocardial oxygen consumption may be more dramatically increased than is anticipated as a result of ephedrine's positive inotropic effect. In obstetrics, ephedrine has long been considered the drug of choice to address maternal hypotension after regional anesthesia because it was felt that it maintains uterine blood flow better than phenylephrine. Newer data are questioning this long-standing practice, with phenylephrine being recommended over ephedrine.[33-35] Ephedrine produces increases in fetal metabolic rate leading to fetal acidosis due to beta stimulation and phenylephrine does not.[36] As with any indirect-acting agent, tachyphylaxis may develop with subsequent dosing, because catecholamine stores become depleted.[37] Ephedrine also may be administered by oral, intramuscular, or subcutaneous routes.

SELECTIVE β_2-AGONISTS

The β_2-agonists include albuterol (Proventil, Ventolin, others), levalbuterol (Xopenex), pirbuterol (Maxair), and salmeterol (Serevent). These "selective" β_2-agonists are effective in treating obstructive airway diseases such as asthma, chronic obstructive pulmonary disease, and acute bronchospasm. Long-acting formulations include formoterol (Foradil) and salmeterol (Serevent).[38,39]

The selectivity of these agents for β_2-receptors results in the desired response of bronchodilation and a lower incidence of the undesired β_1 responses of tachycardia and arrhythmia. None of these agents are, however, completely selective. These agents are available in aerosol form, and it is widely accepted that aerosol delivery is as effective as subcutaneous or other means of administration. Drugs of this class also have an increased duration of action because of their noncatecholamine structure; this renders them resistant to methylation by catechol-O-methyltransferase. Two puffs of nebulized or metered-dose inhaler–administered albuterol,

TABLE 13-4 Doses of Select Vasoactive Drugs

Drug	Bolus Dose	Infusion Dose Rate	Comments
Calcium chloride ($CaCl_2$) or gluconate	500-1000 mg (chloride)		Onset: <1 min Peak effect: <1 min Duration: 10-20 min
Dobutamine (Dobutrex)	500-2000 mg (gluconate)	2-20 mcg/kg/min	Onset: 1-2 min Peak effect: 1-10 min Duration: 10 min
Dopamine		1-2 mcg/kg/min (renal doses) 2-10 mcg/kg/min (cardiac doses) 10-20 mcg/kg/min (vasopressor doses)	Onset: 2-4 min Peak effect: 2-10 min Duration: <10 min
Ephedrine	5- to 10-mg incremental doses		Dilute to 5 or 10 mg/mL Onset: <1 min Peak effect: 2-5 min Duration: 10-60 min
Epinephrine	10-100 mcg	0.01-0.03 mcg/kg/min (β doses) 0.03-0.15 mcg/kg/min (α and β doses) 0.15-0.3 mcg/kg/min (α doses)	Onset: <1 min Peak effect: 1-2 min Duration: 5-10 min
Fenoldopam		0.1-1.6 mg/kg/min	Onset: 4-5 min Peak effect: 7 min Duration: 15 min
Glucagon	1-5 mg over 2-5 min		
Isoproterenol (Isuprel)	1 mL over 1 min *after diluting* in 10 mL (= 0.02 mg/mL)	0.015-0.15 mcg/kg/min	Onset: <1 min Peak effect: 1 min Duration: 1-5 min
Milrinone (Primacor)	50 mcg/kg	0.375-0.75 mcg/kg/min	
Nesiritide (Natrecor)		0.01 mcg/kg/min	Onset: 15 min Peak effect: 1 hr Duration: 60 min
Norepinephrine (Levophed)		0.01-0.2 mcg/kg/min	Onset: <1 min Peak effect: 1-2 min Duration: 2-10 min
Phentolamine	5 mg (50-100 mcg/kg) Repeat as required	1-10 mcg/kg/min	Onset: 1-2 min Peak effect: 2 min Duration: 10-15 min
Phenylephrine (Neo-Synephrine)	40-100 mcg	0.15-0.75 mcg/kg/min	Onset: <1 min Peak effect: 1 min Duration: 15-20 min
Sodium nitroprusside (Nitropres)		0.1-10 mcg/kg/min	Onset: <1 min Peak effect: 1-2 min Duration: 1-10 min
Vasopressin (Pitressin)	10-20 units	0.1-1.0 units/min	Onset: 1-5 min Peak effect: 5 min Duration 10-30 min

or salmeterol, 10 to 15 minutes before exercise have been shown to have similar efficacy in preventing exercise-induced asthma. Long-acting β_2-agonists should be used in combination with an inhaled corticosteroid.[40]

Chronic use of these agents can result in tachyphylaxis secondary to down-regulation (i.e., diminished quantity) of β-receptors. Increased hyperresponsiveness of the airway also has been suspected with chronic use of these agents. A black box warning about a higher risk of asthma-related death was added to the package inserts of all preparations containing a long-acting β_2-agonist.[41,42]

The β_2-agonists have been given to delay premature labor although there use has declined dramatically because of a high frequency of adverse events and lack of efficacy. This is referred to as a *tocolytic effect*. Uterine relaxation is achieved through increases in the levels of cAMP; this decreases intracellular calcium levels and ultimately diminishes the level of actin-myosin coupling. Terbutaline is the agonist used.

The effectiveness of tocolytic therapy was recently reviewed, with the following practice points: (1) β_2-agonists are effective in delaying delivery for 48 hours but have no effect on perinatal mortality. (2) There is no evidence to support the use of magnesium sulfate or the nitric oxide donors such as nitroglycerin. (3) Indomethacin is an effective tocolytic, but there are concerns about possible fetal and neonatal effects. (4) Nifedipine is an effective tocolytic with a low maternal side effect profile and positive effects on neonatal outcomes. (5) The oxytocin receptor antagonist atosiban is no better than other tocolytics in delaying or preventing preterm birth and has significant side effects.[43,44] Women with failed tocolysis often need emergency surgery. In such cases, regional anesthesia may be preferable. Epidural blockade produces less hypotension than spinal anesthesia and is preferred. If vasopressors are necessary, phenylephrine is the drug of choice because it does not increase the heart rate.[45] Doses of selected vasoactive drugs are listed in Table 13-4. A complete discussion of tocolysis is in Chapter 46.

α_2-Agonists

Clonidine

Clonidine (Catapres) is a presynaptic α_2-agonist. Clonidine decreases blood pressure by acting as an agonist at peripheral presynaptic α_2-receptors and central α_2-receptors. Stimulation of the peripheral presynaptic α_2-receptors causes inhibition of catecholamine release, with subsequent vasodilation. Stimulation of the central α_2-receptors, which is considered the main antihypertensive mechanism of action, results in diminished sympathetic outflow and a resultant decrease in circulating catecholamines and renin activity. It is usually reserved for short-term oral treatment of severe hypertension as an add-on drug.[46] Rebound hypertension, seen after abrupt discontinuation of clonidine use, is a major concern. The resultant increase in catecholamine levels manifests as tachycardia and hypertension. Continuing the medication throughout the perioperative period is essential. Tapering the dose and discontinuation may occasionally be indicated. Patches may also be used during surgery to prevent withdrawal.

Clonidine is available in oral, transdermal, and epidural forms. The transdermal form is frequently encountered and administered at a fixed rate for a period of 1 week. Additional uses of clonidine include premedicant sedative, an analgesic combined with opiates for epidural treatment of severe pain (Duraclon), and suppression of alcohol withdrawal symptoms.[47] Clonidine is used as a catecholamine suppression test in the diagnosis of pheochromocytoma.

Dexmedetomidine

Dexmedetomidine is an α_2-agonist that is marketed for short-term sedation in critical care. It is being used as an adjunct to anesthesia in a variety of situations.[48] Dexmedetomidine provides dose-dependent sedation, analgesia, sympatholysis, and anxiolysis without significant respiratory depression. The side effects are predictable from the pharmacologic profile of α_2-adrenoceptor agonists and include hypotension, bradycardia, oversedation, and delayed recovery. Dexmedetomidine is discussed in detail in Chapter 9. The mechanism of presynaptic α_2-agonism is shown in Figure 13-1.

α-RECEPTOR ANTAGONISTS

The α-receptor antagonists are used for treatment of hypertension, benign prostatic hyperplasia, pheochromocytoma, Raynaud's phenomenon, and ergot alkaloid toxicity.[49] Common side effects include orthostatic hypotension and baroreceptor-mediated reflex tachycardia, which may make their use in the treatment of hypertension somewhat difficult in the ambulatory patient. In addition, because of the significantly longer duration of action of the α-receptor antagonists, other agents are considered more predictable in the treatment of emergent episodes of hypertension.

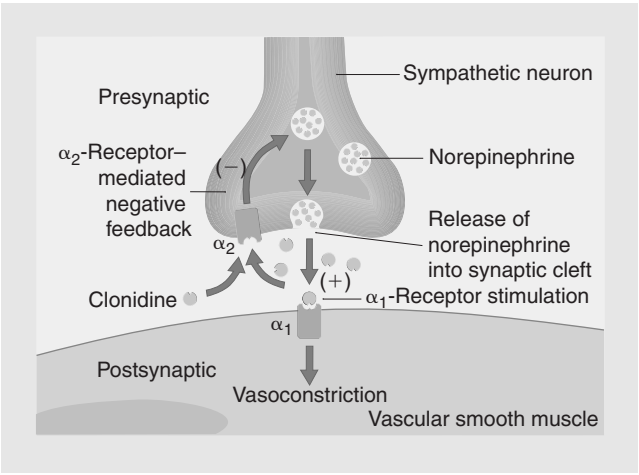

FIGURE **13-1** Presynaptic α_2-agonism. (From Page C, et al. *Integrated Pharmacology.* 3rd ed. Edinburgh: Mosby; 2006:420.)

Phenoxybenzamine

Phenoxybenzamine (Dibenzyline) is a halo alkylamine with both α_1- and α_2-blocking activity. The α-receptors are noncompetitively, irreversibly bound by phenoxybenzamine, and its action is terminated only by metabolism of the drug and generation of new α-receptors. Clinically this drug is used preoperatively in patients with pheochromocytoma for diminishing the response to endogenous catecholamines. The preoperative course is started 1 to 3 weeks before surgery, with the oral dosage titrated up to 40 to 120 mg in two or three divided daily doses. It may be combined with the tyrosine hydroxylase inhibitor metyrosine (Demser). Phenoxybenzamine also prevents the sympathomimetic response expected from phenylephrine. The response to norepinephrine is limited to its β_1-agonist activity, and epinephrine may show "epi-reversal," which is an enhanced β_2 response with a worsening of hypotension and tachycardia. The primary side effect is orthostatic hypertension. Nasal stuffiness has been frequently associated with phenoxybenzamine use.[15,50]

Phentolamine

Phentolamine, an imidazole, is a competitive antagonist of α_1- and α_2-receptors. It has a rapid onset after IV administration and a much shorter duration of action when compared with phenoxybenzamine. It can be used for the short-term control of hypertension in patients with pheochromocytoma. The recommended dose is 1 to 5 mg by slow IV push. Phentolamine has also been used in the treatment of local infiltrations of vasoconstricting agents. Phentolamine (5-10 mg) can be mixed with 10 mL of normal saline and injected directly into the site of the infiltration.[50]

Prazosin and Other α-Receptor Antagonists

Prazosin (Minipress), doxazosin (Cardura), and terazosin (Hytrin) are selective α_1-antagonists used in the chronic treatment of hypertension. Their lack of α_2-blocking activity indicates that they have no effect on norepinephrine levels. Therefore, selectivity for α_1-receptors leaves the inhibitory action of α_2-receptors on norepinephrine release intact, and less norepinephrine-induced tachycardia results than when a nonselective α-antagonist is used. Prazosin induces vasodilation in both arterioles and veins. Peripheral vascular resistance and cardiac preload and afterload are diminished. The drugs are administered orally, and orthostatic hypotension can be a major side effect.

Tamsulosin (Flomax), alfuzosin (Uroxatral), and silodosin (Rapaflo) are alpha 1_α-selective antagonists that produce relaxation of bladder neck and prostate, helping relax smooth muscle tone and relieve obstructive urinary symptoms. They are commonly used with 5α-reductase inhibitors such as finasteride (Proscar) and dutasteride (Avodart) for the treatment of benign prostatic hyperplasia (BPH). Because they do not antagonize alpha 1_β-receptors, they have less risk of hypotension.[51] Tamsulosin and possibly other α-antagonists have been noted to produce floppy iris syndrome, which may complicate cataract surgery. Discontinuing them prior to surgery is not required as long as the ophthalmologist is aware of their administration.[52,53]

Droperidol

Droperidol (Inapsine), a butyrophenone, is used as an antiemetic in anesthesia practice. It produces both dopamine and α-adrenergic blockade and thus small reductions in blood pressure may occur, especially in volume-depleted patients. The use of droperidol has

decreased markedly as a result of the "black box" warning required by the U.S. Food and Drug Administration (FDA) as part of the package insert for this drug. Use of droperidol has been associated with prolongation of the corrected Q-T interval in certain patients, increasing the probability of the development of torsades de pointes, which has led to serious morbidity and death. There has been considerable debate regarding the relationship between the anesthetic administration of droperidol in very low doses as an antiemetic and the complications described.[54] Little doubt remains, however, that the potential for administrative and legal difficulties added to issues of patient safety have led to significant changes in the pattern of use of this drug.[55,56] A 12-lead electrocardiogram is required by the FDA prior to the use of droperidol. Off-labeled use of very low doses as an antiemetic may still be useful. Evidence suggests that the serotonin type 3 receptor antagonists have a similar frequency of Q-T interval prolongation.[54,57]

β-ADRENERGIC BLOCKING AGENTS

The β-blockers are one of the most widely prescribed classes of drugs. Common applications of these agents include the treatment of angina pectoris, hypertension, postmyocardial infarctions, supraventricular tachycardias (including Wolff-Parkinson-White syndrome), and atrial fibrillation; the suppression of increased sympathetic activity (e.g., as occurs with intubation); the management of hypertrophic obstructive cardiomyopathies and congestive heart failure (CHF); the treatment of migraine headaches; and the preoperative preparation of hyperthyroid patients. They are also effective in the treatment of digitalis-induced arrhythmias and in the management of select atrial and ventricular arrhythmias.[58] The perioperative use of β-blockers in vascular and select general surgery patients to reduce morbidity and mortality has been an area of tremendous discussion, and many large-scale clinical trials have been reported. They also prevent detrimental cardiac remodeling, which occurs in many cardiac diseases.[59] The use of perioperative β-blockade in high-risk patients is discussed as follows and in Chapter 25.

The β-blockers are structurally related to isoproterenol. They bind β-receptors in a competitive manner and prevent the actions of catecholamines and other β-agonists. Because these agents are competitive antagonists if an agonist is present in sufficient concentration at the receptor, the blocking actions of the β-antagonists can be overcome.

The β-blockers are subdivided on the basis of their selectivity for cardiac β_1-receptors and other notable clinical differences such as their ability to vasodilate by additional mechanisms or whether they have partial agonist activity. Table 13-5 lists the beta blockers according to classification subtype.[60]

TABLE 13-5 Antihypertensive Drugs

Drug	Daily Adult Maintenance Dosage	Frequent or Severe Adverse Effects
Angiotensin-Converting Enzyme (ACE) Inhibitors		
Benazepril (Lotensin)	10-80 mg in one or two doses	Cough; hypotension, particularly with a diuretic or volume depletion; rash; acute renal failure with bilateral renal artery stenosis or stenosis of the artery to a solitary kidney; angioedema; hyperkalemia if also taking potassium supplements or potassium-sparing diuretics; loss of taste, usually not severe; blood dyscrasias and renal damage rare, except in patients with renal dysfunction; increased fetal mortality with second- and third-trimester exposure; may decrease excretion of lithium
Captopril (Capoten)	12.5-150 mg in two or three doses	
Enalapril (Vasotec)	2.5-40 mg in one or two doses	
Fosinopril (Monopril)	10-80 mg in one or two doses	
Lisinopril (Prinivil or Zestril)	5-40 mg in one dose	
Moexipril (Univasc)	7.5-30 mg in one or two doses	
Perindopril (Aceon)	4-8 mg in one or two doses	
Quinapril (Accupril)	5-80 mg in one or two doses	
Ramipril (Altace)	1.25-20 mg in one or two doses	
Trandolapril (Mavik)	1-8 mg in one or two doses	
Angiotensin-Receptor Antagonists		
Azilsartan (Edarbi)	80 mg once a day	Similar to ACE inhibitors but do not cause cough
Candesartan (Atacand)	8-32 mg in one dose	
Eprosartan (Teveten)	400-800 mg in one or two doses	
Irbesartan (Avapro)	150-300 mg in one dose	
Losartan (Cozaar)	25-100 mg in one or two doses	
Olmesartan medoxomil (Benicar)	20-40 mg in one dose	
Telmisartan (Micardis)	40-80 mg in one dose	
Valsartan (Diovan)	80-320 mg in one dose	
β-Adrenergic Blocking Drugs		
Atenolol (Tenormin)	25-100 mg in one or two doses	Fatigue; depression; bradycardia; decreased exercise tolerance; congestive heart failure; aggravate peripheral arterial insufficiency; aggravate allergic reactions; bronchospasm; mask symptoms of and delay in recovery from hypoglycemia; Raynaud's phenomenon; insomnia; vivid dreams or hallucinations; acute mental disorder; impotence; increased serum triglycerides

Continued

TABLE 13-5 Antihypertensive Drugs —cont'd

Drug	Daily Adult Maintenance Dosage	Frequent or Severe Adverse Effects
Betaxolol generic	5-40 mg in one dose	
Bisoprolol (Zebeta)	5-20 mg in one dose	
Metoprolol (Lopressor, Toprol-XL)	50-200 mg in one or two doses; extended release 25-400 once	
Nadolol (Corgard)	20-320 mg in one dose	
Propranolol (Inderal)	40-240 mg in two doses	
Timolol generic	10-60 mg in two doses	
β-Adrenergic Blocking Drugs with Intrinsic Sympathomimetic Activity		
Acebutolol (Sectral)	200-1200 mg in one or two doses	Similar to other β-adrenergic blocking drugs but with less resting bradycardia and lipid changes; acebutolol has been associated with positive antinuclear antibody test and occasional drug-induced lupus
Penbutolol (Levatol)	10-80 mg in one dose	
Pindolol generic	10-60 mg in two doses	
α- and β-Blockers		
Carvedilol (Coreg)	12.5-50 mg in two doses	Similar to other β-adrenergic blocking drugs, but more orthostatic hypotension; no affect on serum lipids
Labetalol generic	200-1200 mg in two doses	
β-Blocker with Vasodilating Nitric Oxide–Mediated Activity		
Nebivolol (Bystolic)	5-40 mg once	Vasodilator due to nitric oxide-mediated action
Thiazide-Type Diuretics (Usually Once Daily)		
Chlorothiazide (Diuril)	125-500 mg once	Hyperuricemia; hypokalemia; hypomagnesemia; hyperglycemia; hyponatremia; hypercholesterolemia; hypertriglyceridemia; pancreatitis; rashes and other allergic reactions; sexual dysfunction; photosensitivity reactions; may decrease excretion of lithium
Hydrochlorothiazide (Microzide)	12.5-50 mg once	
Chlorthalidone (Thalitone)	12.5-50 mg once	
Indapamide generic	1.25-5 mg once	
Metolazone (Zaroxolyn)	1.25-5 mg once	
Loop Diuretics		
Bumetanide generic	0.5-2 mg in two doses	Dehydration; circulatory collapse; hypokalemia; hyponatremia; hypomagnesemia; hyperglycemia; metabolic alkalosis; hyperuricemia; blood dyscrasias; rashes; lipid changes as with thiazide-type diuretics
Ethacrynic acid (Edecrin)	25-100 mg in two or three doses	
Furosemide (Lasix)	20-320 mg in two doses	
Torsemide (Demadex)	5-20 mg in one or two doses	
Potassium-Sparing Diuretics		
Amiloride (Midamor)	5-10 mg in one or two doses	Hyperkalemia; GI disturbances; rash; headache
Eplerenone (Inspra)	25-100 mg in one or two doses	Hyperkalemia; hypernatremia
Spironolactone (Aldactone)	12.5-100 mg in one or two doses	Hyperkalemia; hyponatremia; mastodynia; gynecomastia; menstrual abnormalities; GI disturbances; rash
Triamterene (Dyrenium)	50-150 mg in one or two doses	Hyperkalemia; GI disturbances; nephrolithiasis
Calcium Channel Blockers		
Diltiazem (Cardizem CD)	120-360 mg in one dose	Dizziness; headache; edema; constipation (especially verapamil); AV block; bradycardia; heart failure; lupus-like rash with diltiazem
(Tiazac)	120-540 mg in one dose	
Verapamil (Calan)	120-480 mg in one or two doses	
(Calan SR)	120-480 mg in one or two doses	
(Isoptin SR)	120-480 mg in one or two doses	
(Verelan PM)	120-480 mg in one dose	
(Covera-HS)	180-540 mg in one dose	
Dihydropyridines		
Amlodipine (Norvasc)	2.5-10 mg in one dose	Dizziness; headache; peripheral edema (more than with verapamil and diltiazem; more common in women); flushing; tachycardia; rash; gingival hyperplasia
Felodipine (Plendil)	2.5-10 mg in one dose	

TABLE 13-5 Antihypertensive Drugs —cont'd

Drug	Daily Adult Maintenance Dosage	Frequent or Severe Adverse Effects
Isradipine (DynaCirc, DynaCirc CR)	5-10 mg in two doses	
Nicardipine generic Nicardipine extended release (Cardene SR)	60-120 mg in two or three doses	
Nifedipine (Adalat CC, Procardia XL)	30-90 mg once	
Nisoldipine (Sular)	17-34 mg once	
α-Adrenergic Blockers		
Prazosin (Minipress)	1-20 mg in two or three doses; first dose is 1 mg at bedtime	Syncope with first dose; dizziness and vertigo; headache; palpitations; fluid retention; drowsiness; weakness; anticholinergic effects; priapism
Terazosin (Hytrin)	Maintenance: 1-20 mg once; first dose is 1 mg at bedtime	Both similar to prazosin, but with less hypotension after first dose
Doxazosin (Cardura)	1-2 mg in one dose; first day: 1 mg at bedtime	
Central α-Adrenergic Agonists		
Clonidine (Catapres)	0.1-0.6 mg in two or three doses	CNS reactions similar to methyldopa, but more sedation and dry mouth; bradycardia; heart block; rebound hypertension (less likely with patches); contact dermatitis from patches
(Catapres TTS)	One patch weekly (0.1-0.3 mg/day)	Similar to clonidine
Guanfacine generic	1-3 mg in one dose	Drowsiness; sedation, fatigue; depression; dry mouth; heart block; autoimmune disorders, including colitis, hepatitis, hepatic necrosis; Coombs-positive hemolytic anemia; lupus-like syndrome; thrombocytopenia; red cell aplasia; impotence
Methyldopa generic	250 mg-2 g in two doses	
Direct Vasodilators		
Hydralazine generic	40-200 mg in two to four doses	Tachycardia; aggravation of angina; headache; dizziness; fluid retention; nasal congestion; lupus-like syndrome; hepatitis
Minoxidil generic	2.5-40 mg in one or two doses	Tachycardia; aggravation of angina; marked fluid retention; pericardial effusion; hair growth on face and body
Renin Inhibitor		
Aliskiren (Tekturna)	150-300 mg once daily	First direct renin inhibitor for treatment of hypertension; avid binding of renin and long half-life could lead to hypotension unresponsive to discontinuing drug

The degree of receptor selectivity is important because antagonism of β_1-receptors results in lowered heart rate, decreased myocardial contractility, and diminished atrioventricular conduction velocity; it also has beneficial effects with regard to decreasing myocardial oxygen consumption and the treatment of arrhythmias. However, antagonism of β_2-receptors can result in adverse effects such as bronchoconstriction, hypoglycemia, and peripheral vasoconstriction. It is important to note that as the dose of the selective β-blockers is increased, the degree of selectivity is diminished.

Some of the β-blockers act as partial agonists and as such possess intrinsic sympathomimetic activity. A partial agonist does not stimulate β-receptors to the extent that a full agonist does, and in the presence of a full agonist, the partial agonist acts as a competitive antagonist. It follows that β-blockers with intrinsic sympathomimetic activity (ISA) competitively antagonize the effects of a full agonist (e.g., endogenous catecholamines released during times of maximal sympathetic tone) down to the activity level of its partial agonist component. Intrinsic sympathomimetic activity minimizes the risk of bronchoconstriction in patients with reactive airway disease who require β-blockade. Pindolol, acebutolol, penbutolol, and carteolol are β-adrenergic blocking agents that possess intrinsic sympathomimetic activity.

Membrane-stabilizing activity is another property of some β-blockers. These agents diminish arrhythmogenicity by exerting a quinidine-like effect in the heart. However, membrane-stabilizing activity is seen only with high drug concentrations.[61] Propranolol and pindolol are two β-blockers with membrane-stabilizing activity. Labetalol and carvedilol are mixed β- and α-receptor antagonists. The added α-receptor blockade makes them vasodilators. Nebivolol (Bystolic) is a new cardioselective β-blocker approved for the treatment of hypertension. It is unique in that it has nitric oxide–mediated vasodilating properties.[62]

Some potential problems with β-adrenergic blocking agents have already been mentioned. β-blockade can result in both bronchospasm and the development of overt cardiac failure in some patients with high doses or IV administration. Other potential problems arise with β_2-receptor blockade in patients with peripheral vascular disease and Raynaud's disease because of the possible potentiation of peripheral vasoconstriction. In diabetic patients, signs of hypoglycemia may be masked, and the patient's ability to

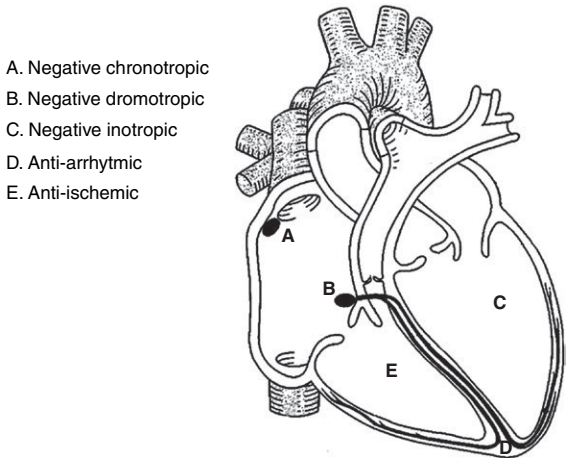

FIGURE **13-2** Cardiac effects of beta adrenergic blocking drugs. **A,** Negative chronotropic. **B,** Negative dromotropic. **C,** Negative inotropic. **D,** Antiarrhythmic. **E,** Antiischemic.

increase serum glucose levels may be impaired. Serum potassium levels may also become elevated with β_2-blockade, because uptake into skeletal muscle is inhibited. In patients whose heart rate is controlled to maintain cardiac output, β-blockade may have a significant impact on blood pressure.

The β-receptors are considered to be "labile" receptors—that is, they are subject to significant up- and down-regulation. Chronic therapy with β-blockers can lead to up-regulation of β-receptors or an increase in the absolute number and activity of receptors. This phenomenon is suspected to be the underlying cause of the withdrawal syndrome seen with abrupt discontinuation of β-adrenergic antagonist use. Raynaud's phenomenon is characterized by increased sympathetic activity for up to 2 days. Obviously this means the patient receiving β-blockers should continue to receive them without interruption throughout the perioperative period. The effects of the β-blocking agents on the ischemic heart are summarized in Figure 13-2.

Anesthetic Uses

Metoprolol, Esmolol, and Labetalol

Three β-adrenergic blocking agents, which are available IV, are especially useful in the perioperative period. They are metoprolol, esmolol, and labetalol. Esmolol has replaced propranolol in most instances of β-blocker application in anesthesia because of its rapid onset and short duration of action. Esmolol has an onset time of 2 minutes and an elimination half-life of approximately 9 minutes. Its rapid onset and short half-life, as well as its duration of action of 10 to 15 minutes, make it easily and reliably titratable in acute-care situations. The recommended IV loading dose of esmolol is 500 mcg/kg; this is followed by an infusion of 100 to 300 mcg/kg/min as needed. Small boluses of 10 to 15 mg may be given with repeat administration according to patient response. Esmolol is metabolized by nonspecific plasma esterases found in the cytosol of red blood cells. Metoprolol is frequently used after myocardial infarction or in some types of angina and hypertension, once the patient is stable, to normalize vital signs. Administration of 5-mg doses intravenously at 5-minute intervals to a maximum dose of 15 mg is recommended.[60]

Labetalol (Normodyne, Trandate) is classified as a nonselective β-blocker but is unique in that it also possesses an α-blocking component. It provides β-blockade along with α-blockade in a ratio of 7:1. Unlike the standard β-blocker, labetalol produces vasodilation secondary to its α-blocking properties. This action can be extremely beneficial in situations in which an acute rise in blood pressure could be devastating to the clinical outcome. The usual IV dose of labetalol is 0.25 mg/kg; this dose can be repeated every few minutes as indicated and followed by an infusion, if indicated, at a rate of 2 mg/min. In clinical practice, a bolus dose of labetalol (5-10 mg) is titrated and repeated on the basis of patient response. Labetalol can have a duration of action ranging from 2 to 6 hours, depending on dose. Because labetalol provides both β- and α-blockade, an adequate heart rate must be present before labetalol can be used in the acute management of hypertension. It is recommended for hypertensive episodes in obstetric patients. Uterine blood flow is not affected in obstetric patients, even in the event of a dramatic decrease in systemic blood pressure.[62] Labetalol undergoes hepatic metabolism and renal elimination.[63]

Prophylactic β-blockers showed a positive benefit in reducing major postoperative cardiac events in select high-risk patients. A large-scale clinical trial (POISE) of extended-release metoprolol indicated that there was a lower incidence of perioperative myocardial infarction (MI), clinically significant atrial fibrillation, and the need for coronary revascularization, but an increase in strokes and overall mortality secondary to more hypotension and bradycardia.[64] There are concerns that anemia might complicate perioperative β-blockade by further limiting oxygen delivery. β-blockade is associated with worse outcomes when hemoglobin levels are decreased by greater than 35%. In elderly patients, this is a potential mechanism for the increased stroke rate found in the POISE trial. Gender differences exist as well. Men benefited from β-blockade with reduced MI, but women suffered from clinically significant increases in CHF. Evidence for pharmacogenetic variation in metabolism suggests that metoprolol might not be the best choice of β-blocker in the perioperative period.[65] Many other studies have noted conflicting results, and the proper use of β-blockers has been a much discussed and researched area.[66,67] The American College of Cardiology Foundation and the American Heart Association (ACCF/AHA) have issued revised guidelines on the use of perioperative β-blockers.[68]

In general, β-blockers should be continued in surgical patients who are already taking them. β-blockers may benefit vascular surgery patients at high risk for MI but not for stroke. They are more likely to be beneficial when started at a lower dose well in advance of surgery and titrated to a heart rate of 55 to 70 beats per minute (bpm). Avoid starting β-blockers immediately before surgery, in emergency surgery, or in patients with prior cerebrovascular disease or sepsis. A protocol for perioperative β-blocker therapy is listed in Box 13-1. The detailed recommendations for the use of β-blockers in noncardiac surgery can be found in the ACCF/AHA guidelines.[68] In situations where β-blockers are contraindicated, such as patients with asthma, bradyarrhythmias, acute heart failure, or advanced heart block, an α_2-adrenergic agonist such as clonidine may have some benefit.[69]

Statins reduce endovascular inflammation and plaque. Current data suggest they should be continued perioperatively and started prophylactically in select patients.[70,71]

CHOLINERGICS

Cholinergic agents mimic the actions of the neurotransmitter acetylcholine but have been developed to differ in terms of comparative nicotinic and muscarinic activity and duration of action. Acetylcholine (Miochol) has no clinical application, owing to its generalized enhancement of cholinergic effects throughout the body and its extremely short duration of action (approximately 1 msec), which is a result of its rapid metabolism by acetylcholinesterase.

BOX 13-1

Protocols for Prophylactic Perioperative β-Blockers

General Principles

- Start β-blocker at least 1 week before surgery (if possible).
- Titrate the dose to an ideal target heart rate of 55 to 70 bpm.
- Use half the dose if the heart rate is less than 65 bpm, if systolic blood pressure is less than 120 mmHg, or the patient is small and elderly or frail.
- Hold the dose if the heart rate is less than 55 bpm or systolic blood pressure is less than 100 mmHg.
- Continue β-blocker postoperatively for at least 1 to 4 wk (or indefinitely if independent criteria such as known coronary artery disease, peripheral arterial disease, or hypertension are present). Taper the dose if discontinuing.
- Before increasing the dose for postoperative tachycardia, evaluate the patient for other potential causes, including pain, bleeding, and sepsis (where β-blockers may be detrimental).

Specific Drugs: Atenolol, Bisoprolol, or Metoprolol

- Preoperatively (recommended starting dose, then titrate to the target heart rate):
  - Atenolol: Start at 25 mg orally daily
  - Bisoprolol: Start at 5 mg orally daily at least 7 days before surgery
  - Metoprolol: Start at 25 to 50 mg orally twice daily up to 30 days preoperatively
- Day of surgery—continue the usual dose or increase the oral dose to control the heart rate or give additional intravenous (IV) doses (atenolol or metoprolol, 5-10 mg) as needed if unable to take orally. Esmolol can also be used (500 mcg/kg IV loading dose over a 1-min period; then infuse at 50-200 mcg/kg/min and titrate to the target heart rate).
- Postoperatively—continue the usual preoperative dose:
  - *Atenolol:* 25 to 100 mg orally daily for at least 7 days
  - *Bisoprolol:* 2.5 to 5 mg orally daily for at least 30 days
  - *Metoprolol:* 25 to 100 mg orally twice daily for at least 14 days
  - Substitute IV atenolol or metoprolol (5-mg doses) as needed if unable to take medication orally

Methacholine (Provocholine), carbachol (carbamylcholine chloride), and bethanechol (carbamylmethylcholine) are choline esters that have limited clinical applications. Methacholine can be used as an aerosol in the diagnosis of reactive airway disease, whereas carbachol, because of its significant muscarinic and nicotinic activity, is used only as a topical ophthalmic solution in the treatment of narrow-angle glaucoma and for inducing miosis during diagnostic testing and surgery. Bethanechol is theoretically useful in instances of ileus and urinary retention, such as in postvagotomy and postpartum patients, respectively. Bethanechol's relative lack of nicotinic activity makes it the most attractive of these three agents, and it is the agent most frequently encountered in clinical practice. Potential side effects of these agents include any cholinergic-induced response such as bradycardia, varying degrees of heart block, hypotension, bronchoconstriction, and an increase in gastric secretions.[72]

ANTICHOLINERGICS

The anticholinergics are familiar agents in anesthesia practice. Atropine, scopolamine, and glycopyrrolate are the three anticholinergics used in anesthesia practice. These agents are competitive antagonists of acetylcholine at muscarinic receptors. A comparison of the basic properties of the anticholinergic agents is given in Table 13-6. Subtypes of muscarinic and nicotinic receptors are summarized in Table 13-7 and Table 13-8.

TABLE 13-6 Comparative Effects of Anticholinergic Drugs

Effect	Atropine	Scopolamine	Glycopyrrolate
Sedation	+	+++	0
Antisialagogue	+	+++	++
Increase heart rate	+++	+	++
Relax smooth muscle	++	+	++
Mydriasis, cycloplegia	+	+++	0
Prevent motion-induced nausea	+	+++	0
Decrease gastric hydrogen ion secretion	+	+	+

Atropine

Atropine, a belladonna alkaloid, is the prototype anticholinergic. The anesthetist can use atropine for its antisialagogue effects, for the prevention or treatment of bradycardia, and concurrently with anticholinesterase agents in the reversal of muscle relaxants for preventing the resultant bradycardia from anticholinesterase-induced acetylcholine buildup. The usual adult IV dose for increasing heart rate during anesthesia is 0.4 to 0.6 mg, with the time to onset being 1 to 2 minutes. Atropine is a tertiary amine; this allows it to cross the blood-brain barrier freely and may result in transient bradycardia during onset when low doses are given. However, at usual clinical doses, significant CNS effects are rarely evident. Hepatic metabolism accounts for approximately half of a dose of atropine, with the remainder being eliminated unchanged in the urine. The elimination half-life of atropine is approximately 4 hours. Atropine should be avoided in patients with narrow-angle glaucoma because it increases intraocular pressure. Atropine poisoning or belladonna alkaloid toxicity manifests with extreme antimuscarinic effects, with potential progression to CNS depression and coma. The decades-old mnemonic "red as a beet, blind as a bat, dry as a bone, mad as a hatter, and hot as a hare" was devised to be an easy way to remember the signs and symptoms of belladonna overdose. These include flushing ("red as a beet"); extreme mydriasis ("blind as a bat"); lack of secretions and dry mouth ("dry as a bone"); confusion ("mad as a hatter"); and hyperthermia ("hot as a hare").[72]

Scopolamine

Scopolamine (Isopto Hyoscine) is another belladonna alkaloid with anticholinergic effects. Scopolamine is a tertiary amine. Compared with atropine, scopolamine has CNS effects that are much more pronounced at lower doses. Compared with atropine, it does not substantially increase heart rate. It can be used as a preoperative medication, with sedation and amnesia being a desirable effect. Scopolamine also is used to diminish the incidence of postoperative nausea and vomiting. A scopolamine patch (Transderm Scōp) containing a total dose of 1.5 mg is usually applied behind the ear. The patches have an onset of 4 hours and a duration of 3 days.[73]

TABLE 13-7 Properties of Muscarinic (M_1-M_5) Receptors

	M_1	M_2	M_3	M_4	M_5
Location	CNS Stomach	Heart CNS	Glands GI, CNS	CNS Heart	CNS
Important clinical effects	Increased cognition and memory; gastric acid production	Bradycardia, smooth muscle contraction	Salivary secretions, bladder contraction	Promotes dopamine release	Promotes dopamine release, dilation of cerebral arteries

CNS, Central nervous system; *GI*, gastrointestinal.

TABLE 13-8 Characteristics of Subtypes of Nicotinic Acetylcholine Receptors (nAChRs)

Receptor Subtype	Main Synaptic Location	Membrane Response
Skeletal muscle (N_M)	Skeletal neuromuscular junction (postjunctional)	Excitatory; endplate depolarization; skeletal muscle contraction
Peripheral neuronal (N_N)	Autonomic ganglia; adrenal medulla	Excitatory; depolarization; firing of postganglion neuron and secretion of catecholamines
Central nervous system (CNS)	CNS; pre- and postjunctional	Pre- and postsynaptic excitation Prejunctional control of transmitter release

Tiotropium

Tiotropium (Spiriva) is a long-acting inhaled muscarinic antagonist that is used as a bronchodilator for patients with chronic obstructive pulmonary disease (COPD). Tiotropium improves lung function, quality of life, and decreases exacerbations of COPD but does not significantly reduce the rate of decline in the forced expiratory volume (FEV1).[74]

Glycopyrrolate

Glycopyrrolate (Robinul), a synthetic quaternary ammonium compound, has become the most frequently used anticholinergic in anesthesia practice. It has an excellent antisialagogue action,[75] with a longer duration of action than belladonna alkaloids. It prevents bradycardia without inducing significant levels of tachycardia. The quaternary ammonium structure of glycopyrrolate prevents it from crossing the blood-brain barrier to any significant degree; therefore, CNS effects are not seen. This is an important advantage of glycopyrrolate because atropine and scopolamine cross the blood-brain barrier and have CNS effects that can contribute to postoperative delirium.[76] This property also makes it the agent of choice in obstetrics because it does not pass the placental barrier. Adult IV doses are generally 0.1 to 0.2 mg for antisialagogue activity and for the treatment of bradycardia. Onset of action is rapid, and the duration of action is up to 4 hours. It is used in combination with neostigmine for reversal of nondepolarizing neuromuscular blockers. It produces less tachycardia than atropine in the period in which you are awaiting the onset of neostigmine.[72]

DIRECT VASODILATORS

Within the category of direct vasodilators, sodium nitroprusside, nitroglycerin, and hydralazine are the three drugs most commonly employed (Table 13-9). All three produce direct vasodilation. Sodium nitroprusside produces arterial and venous relaxation; nitroglycerin has a greater effect on venous than arterial relaxation; and hydralazine produces primarily arterial relaxation. The mechanism of action of all three agents is believed to be primarily an induced increase in the concentration of vascular nitric oxide, although that has not been confirmed with hydralazine.[77] The mechanism of action is depicted in Figure 13-3. The vasodilators nitroprusside and nitroglycerin are frequently used for controlled hypotension under anesthesia. Combined with the inhalation and intravenous anesthetics, they facilitate a reduction in blood loss and need for transfusions during a variety of surgical procedures.[78]

Nitrovasodilators

Sodium Nitroprusside

Sodium nitroprusside is frequently used for the emergent control of hypertension, for inducing hypotension to decrease blood loss during surgical procedures, and for the treatment of acute cardiac disorders. Its rapid onset (within seconds) and its short duration of action (1-3 min) make it unique among agents for the rapid control of blood pressure. Sodium nitroprusside reduces both afterload and preload, which results in a decrease in cardiac filling pressures and an increase in stroke volume and cardiac output. Left ventricular volumes are decreased, and diminished myocardial wall tension should contribute to a decrease in myocardial oxygen consumption.

Usually, sodium nitroprusside is started as an infusion at 0.3 mcg/kg/min and is titrated until a response occurs. An infusion rate of 3 mcg/kg/min is rarely exceeded, but young, normotensive patients may require up to 5 mcg/kg/min to achieve the desired response.[79] The maximum recommended infusion rate is 10 mcg/kg/min. Sodium nitroprusside is mixed with 5% dextrose in water, and the bottle and tubing are covered in a protective wrap; light causes the sodium nitroprusside to decompose. An infusion pump should always be used with sodium nitroprusside because of its potency and the associated risk of cyanide toxicity.

Cyanide Toxicity. Sodium nitroprusside contains five cyanide ions within its chemical structure, and its metabolism by plasma hemoglobin causes the release of these cyanide ions. One cyanide ion binds methemoglobin to form cyanmethemoglobin, whereas the other four cyanide ions undergo rhodanese-catalyzed conversion to thiocyanate in the liver, with the thiocyanate undergoing renal elimination. This conversion to thiocyanate requires the cofactor thiosulfate B_{12}. Cyanide toxicity results when these metabolic pathways are quantitatively overwhelmed. Preventing cyanide toxicity from sodium nitroprusside begins with awareness of maximum doses and lengths of administration. In general, when more than 500 mcg/kg of sodium nitroprusside is administered faster than 2 mcg/kg/min, cyanide is generated faster than the patient can eliminate it. Chronic administration should not exceed 0.5 mcg/kg/min.

TABLE 13-9 Parenteral Drugs for Treatment of Severe Hypertension

Drug	Class	Route and Dose	Onset	Duration	Comments
Fenoldopam (Corlopam)	Dopamine-1 receptor agonist	IV infusion pump: 0.1-1.6 mcg/kg/min	4-5 min	<10 min	May cause reflex tachycardia; may increase intraocular pressure
Labetalol (Trandate Normodyne)	α- and β-adrenergic blocker	IV: 20 mg initially, then 40-80 mg every 10 min (300 mg max)	5 min or less	3-6 hr	Not for patients with bronchospasm, congestive heart failure, first-degree heart block, cardiogenic shock, or severe bradycardia
Nicardipine (Cardene IV)	Calcium channel blocker	IV: 5 mg/hr, increased by 2.5 mg/hr every 15 min up to 15 mg/hr	1-5 min	3-6 hr	May cause reflex tachycardia
Clevidipine (Cleviprex)	Calcium channel blocker	IV infusion: 1-2 mg/hr initially; double the dose at 90-sec intervals until desired results are achieved (16 mg/hr/max)	2-4 min	5-15 min	Rapidly degraded by tissue and blood esterases; contraindicated with allergy to soy or eggs; may cause reflex tachycardia
Nitroglycerin	Venous arteriolar vasodilator	IV infusion pump: 5-100 mcg/min	2-5 min	5-10 min	Headache, tachycardia can occur; tolerance may develop with prolonged use
Sodium nitroprusside	Arteriolar and venous vasodilator	IV infusion pump: 0.3-10 mcg/kg/min	Seconds	3-5 min	Thiocyanate or cyanide toxicity with prolonged or too rapid infusion
Esmolol	β-blocker	IV: 500 mcg/kg/min for 1 min titration to effect, usually 50 mcg/kg/min	1-2 min	5-10 min	Cardioselective; however, use with caution in patients with asthma
Labetalol	Combined α- and β-blocker	5-80 mg bolus titrated to effect; 2 mg/min infusion	1-2	3-6	Generally used in 5-10 mg incremental doses titrated to effect in the perioperative period

From Medical Letter Treatment Guidelines. Cardiovascular drugs in the ICU. *Med Lett.* 2002;4:19-24; Aggarwal M, Kahn IA. Hypertensive crises: hypertensive emergencies and urgencies. *Cardiol Clin.* 2006;24:135-146; Clevidipine (Cleviprex) for IV treatment of severe hypertension. *Med Lett. 2011*;50(1295):73-75.

Clinically the development of metabolic acidosis, increased mixed venous oxygen content, tachycardia, and tachyphylaxis during sodium nitroprusside use are signs of cyanide toxicity.

Treatment of cyanide toxicity consists of discontinuing the sodium nitroprusside infusion, administering oxygen, and treating metabolic acidosis. Sodium nitrite 3%, 4 to 6 mg/kg, can be administered over 3 to 5 minutes to promote the production of methemoglobin so that excess cyanide ions can be bound. Sodium thiosulfate, 150 to 200 mg/kg over 15 minutes, can be administered every 2 hours as needed; vitamin B_{12} also can be administered. If available, hydroxycobalamin can be used. Methylene blue 1 to 2 mg/kg may also be useful. A new prodrug, sulfanegen sodium, is also being tested.[80]

Nitroglycerin

Nitroglycerin is used in the treatment of angina pectoris and ischemia under anesthesia and also can be used for lowering blood pressure. It has a rapid onset and short duration so it is easily titratable. Nitroglycerin causes venodilation, with an increase in venous capacitance and a resultant decrease in preload. This results in a lowering of cardiac filling pressures, a lessening of myocardial wall tension, and ultimately a decrease in myocardial oxygen requirements. Nitroglycerin's primary mechanism of action in the relief of angina is a decrease in preload and cardiac work. Some of the larger coronary vessels may become dilated, with a resultant redirection and increase in blood flow to ischemic myocardium. It also relieves coronary spasm. At higher concentrations of nitroglycerin, arterial vasodilation also can occur.[81]

Use of sublingual nitroglycerin (0.3-mg tablets), up to a total of three tablets, is the most efficient treatment for acute angina. Relief is generally achieved in 1 to 2 minutes and lasts up to 30 minutes. Intravenous nitroglycerin also has an onset time of 1 to 2 minutes and duration of action of up to 10 minutes. Nitroglycerin is extensively metabolized in the liver and has a half-life of only 3 minutes.[80] Intravenous nitroglycerin is used for "unloading" of the heart in CHF and myocardial infarction.[82] Guidelines suggest that intravenous infusions should be instituted following three sublingual doses of 0.4 mg every 5 minutes in patients having a ST-segment elevation myocardial infarction (STEMI). Nitroglycerin infusions are usually started at 10 to 20 mcg/min and are titrated up until effective. Intravenous nitroglycerin can also be used for controlled hypotension but is not as effective as an infusion of sodium nitroprusside. Because nitroglycerin exerts its main effect on venous capacitance, any decrease in blood pressure is more volume dependent when compared with sodium nitroprusside–induced hypotension. Nitrates should be avoided in patients with a blood pressure less than 90 mmHg, a heart rate less than 50 bpm or above 100 bpm, and in patients with right ventricular infarction. Of note to the anesthesia provider is the ability of nitroglycerin to relax the smooth muscle of the biliary tract and provide relief from narcotic-induced biliary spasm. Generally, 50 mg of nitroglycerin

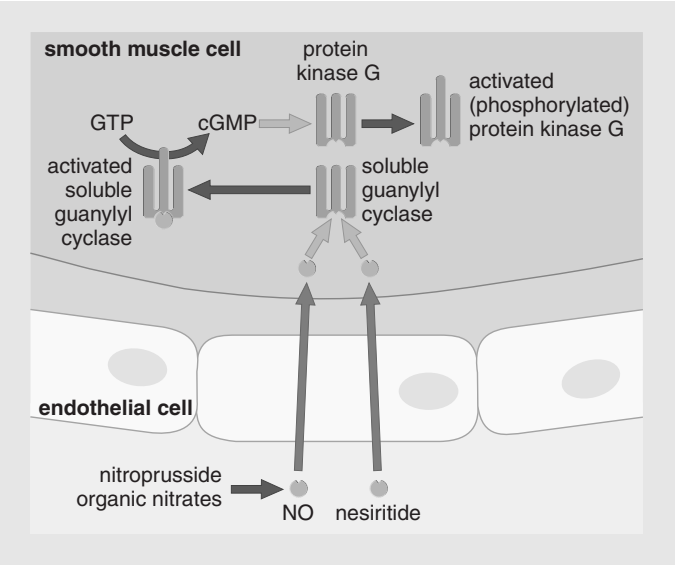

FIGURE **13-3** Molecular and cellular mechanisms of action of nitrate and nitrite vasodilators, nitric oxide (NO) and nesiritide. The primary molecular target, soluble guanylyl cyclase, is accessed by drug or NO diffusion between cells. The product, phosphorylated protein kinase, causes vascular smooth muscle relaxation by phosphorylating (and inactivating) myosin light chain kinase. (From Page C, et al. Integrated Pharmacology. 3rd ed. Elsevier: Edinburgh; 2006: 391.)

is mixed with 250 mL of dextrose 5% in water.[83] For extended coverage, nitroglycerin patches and ointments are also available. A summary of antihypertensive agents dosing information is found in Table 13-5.

Hydralazine

Hydralazine causes direct relaxation of arterial smooth muscle. It can be administered intravenously for the control of hypertension in doses ranging from 2.5 to 20 mg. Tachycardia frequently accompanies the decrease in blood pressure secondary to the preferential reduction in afterload. It is important to remember that the onset of action can occur from 2 to 20 minutes after administration; therefore, adequate time should be allowed before the initiation of repeat dosing so that profound decreases in blood pressure can be prevented. The elimination half-life in plasma is approximately 1 hour, but the duration of vasodilating action can be as long as 12 hours.[84-86] Hydralazine undergoes hepatic metabolism with renal excretion. Acetylation is partly responsible for the metabolism of hydralazine. Slow acetylators may be more prone to a drug-induced lupus syndrome that can result from high serum concentrations of hydralazine during chronic treatment. Currently, hydralazine is usually reserved for hypertensive episodes during pregnancy.

CALCIUM CHANNEL BLOCKERS

The calcium channel antagonists, also referred to as calcium channel blockers (CCBs) have proved to be useful pharmacologic agents in the treatment of angina, hypertension, arrhythmias, peripheral vascular disease, esophageal spasm, cerebral vasospasm, and controlled hypotension.[87] There are three chemical classes of calcium channel blockers: 1,4-dihydropyridine derivatives, such as Nifedipine (Adalat, Procardia); diltiazem (Cardizem) is a benzothiazepine derivative; and verapamil (Calan, Isoptin) is a phenylalkylamine derivative.

All CCBs have negative inotropic and chronotropic actions. They are class 4 antiarrhythmics that block calcium channels; therefore they depress electrical impulses in the sinoatrial (SA) and atrioventricular (AV) nodes. They produce coronary and systemic vasodilation. Different drugs in the three classes vary as to their individual ability to produce each of these effects.[61]

A discussion of the generalized mechanism of action of the calcium antagonists is necessary for a better understanding of their role. Depolarization of the sinoatrial and atrioventricular nodes is dependent on the inward flux of calcium during the depolarization phases of the cardiac action potential. Calcium channel antagonists "block" these channels, diminishing the inward flux of calcium and prolonging phase 2, and in this way exert a negative chronotropic effect on the heart. Ventricular pacemaker foci are dependent on the inward flux of sodium, which is minimally if at all affected by the calcium antagonists. It then follows that the calcium antagonists are effective in patients with atrial tachyarrhythmias. Verapamil and diltiazem are the most commonly used CCBs as antiarrhythmics. They are effective in treating atrial tachyarrhythmias (including Wolff-Parkinson-White syndrome) and in controlling the ventricular response to atrial fibrillation and flutter. Verapamil is not indicated for the treatment of atrial fibrillation associated with Wolff-Parkinson-White syndrome, nor is it indicated for the treatment of "simple" atrial tachycardia, for which β-blockers may be a better choice.

Calcium channel blockers also exert a negative inotropic effect on the heart, which can be beneficial in patients with angina. Cardiac contractility is dependent on the influx of calcium into cardiac cells and this is slowed by the CCBs. This negative inotropic effect then leads to a decrease in myocardial oxygen consumption. Calcium channel antagonists produce relaxation of vascular smooth muscle resulting in vasodilation. Systemic vasodilation of both arteries and veins result in a decreased preload and afterload, which contributes to an increase in cardiac output and a decrease in myocardial work and oxygen consumption. The negative inotropic action and vasodilation account for the antihypertensive effect.[88] Coronary arteries also are affected, with an increase in coronary blood flow. The CCBs are especially beneficial in the prevention of angina resulting from spasm of the coronary arteries, such as Prinzmetal's angina.

Nimodipine has been a long-standing treatment for treatment of cerebral vasospasm associated with neurologic emergencies such as ruptured aneurisms and neurosurgery.[89-91]

Verapamil, 2.5 to 10 mg intravenously (dose can be repeated every 30 minutes), can be given for the treatment of atrial tachyarrhythmias. The onset time is up to 10 minutes, and the duration of action ranges from 2 to 4 hours. Verapamil is metabolized hepatically, has an elimination half-life of 4 to 7 hours, and is renally eliminated. Verapamil has been largely replaced by adenosine as the first-line drug of choice in the treatment of supraventricular tachycardias. Nicardipine is also useful as an IV preparation for the treatment of perioperative hypertension.[92,93] The effects of calcium channel blockers on the ischemic heart are summarized in Figure 13-4.

Varying degrees of atrioventricular block, myocardial depression, and hypotension are associated with the use of the calcium antagonists. An additive effect should be anticipated if the calcium channel antagonists are used with other cardiodepressant agents such as anesthetics.[94]

Clevidipine (Cleviprex) is a dihydropyridine L-type calcium channel blocker indicated as an IV antihypertensive. It is highly selective for vascular muscle and does not affect myocardial contractility or conduction. Its antihypertensive effect

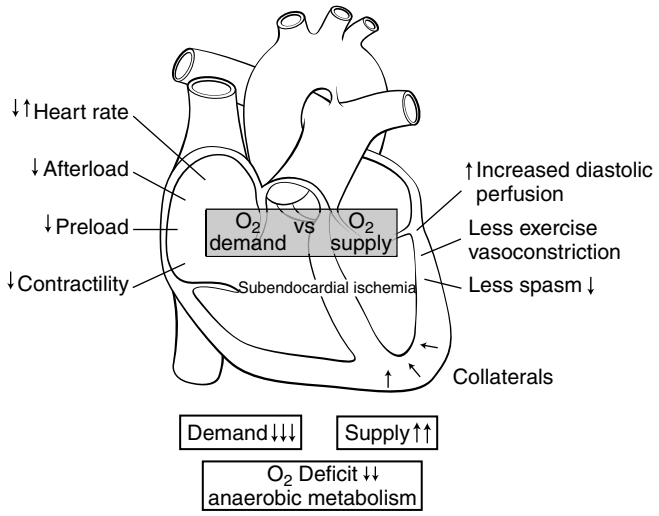

FIGURE **13-4** Effects of calcium channel blockers on the ischemic heart.

is largely due to vasodilation. Clevidipine is rapidly metabolized by nonspecific esterases in the blood. The terminal half-life is approximately 15 minutes. It is formulated as a lipid emulsion so careful handling is essential. Starting dose is 1 to 2 mg/hr titrated up to 16 mg/hr or less according to patient response. Onset is 2 to 4 minutes and duration is 5 to 15 minutes[95,96] (see Table 13-9).

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) inhibitors are widely prescribed for the treatment of hypertension, angina, diabetic neuropathy, CHF, and in the management of the postmyocardial infarction patient.[97,98] These drugs exert their action by inhibiting the ACE. A brief description of the renin-angiotensin system is necessary for a full understanding of the actions of the ACE inhibitors (Figure 13-5).

Renin, a proteolytic protein, is released from the juxtaglomerular apparatus in the kidney in response to diminished blood pressure. Renin is responsible for the conversion of precursor angiotensinogen, which is released from the liver to the decapeptide angiotensin I. Angiotensin I is then converted to the octapeptide angiotensin II by the ACE. Angiotensin-converting enzyme is primarily located in the endothelial tissue of the lung. Angiotensin II is a potent vasopressor that also stimulates the release of endogenous norepinephrine and aldosterone. The end result is an increase in peripheral vasoconstriction, with an increase in blood pressure and a resultant decrease in cardiac output. The higher aldosterone level results in increased sodium and water reabsorption, with concomitant secretion of potassium.[97] The ACE inhibitors block this action and produce vasodilation. Common ACE inhibitors are listed in Table 13-5. Enalapril is a prodrug, and it undergoes hepatic metabolism to its active form of enalaprilat. Enalaprilat is available for IV administration for use in perioperative hypertension but it is rarely used. All of these agents are renally eliminated, and their elimination half-lives can be expected to be prolonged in renally compromised patients.

Adverse effects with the ACE inhibitors include cough, angioedema, renal failure, hyperkalemia, neutropenia, and proteinuria. The dry cough resulting from the ACE inhibitors occurs in up to 25% of patients and is the most common reason for discontinuation

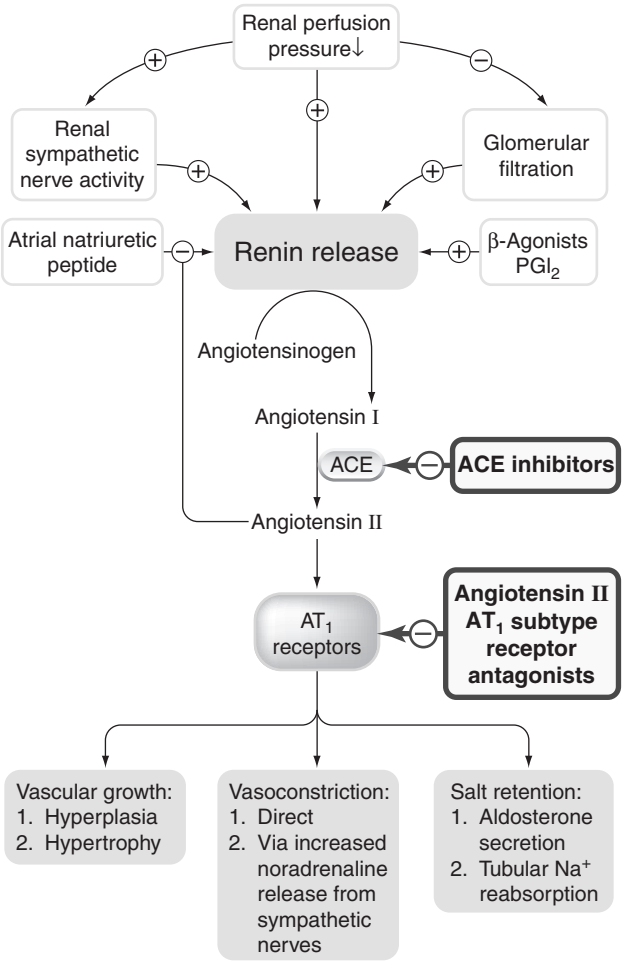

FIGURE **13-5** Control of renin release and formation, and action of angiotensin II. Sites of action of drugs that inhibit the cascade are shown. *ACE*, Angiotensin-converting enzyme; *AT_1*, angiotensin II receptor subtype 1. (From Rang HP, et al. *Rang and Dale's pharmacology.* 7th ed. Edinburgh: Churchill Livingstone; 2012:270.)

of the drug. If an ACE inhibitor cannot be tolerated, an angiotensin receptor blocker is substituted. The reason for the cough has been determined. Angiotensin-converting enzyme is also responsible for the metabolism of bradykinin, which is blocked by these drugs. The resulting buildup of bradykinin is felt to contribute to the cough.[99-101]

There has been a controversy for many years about whether the ACE inhibitors should be withheld the morning of surgery. Most, if not all, cardiac medications are continued preoperatively up to and including the day of surgery.[102] The ACE inhibitors were reported to result in an increase in refractory hypotension during induction of anesthesia if not discontinued prior to surgery. This phenomenon is referred to as vasoplegic syndrome. Vasoplegic syndrome (VS) is defined as unexpected refractory hypotension under general anesthesia with a mean arterial pressure <50 mmHg, a cardiac index >2.5 L/min/m^2, and a low systemic vascular resistance despite adrenergic vasopressor administration. It is most commonly seen with cardiac surgery, but can occur during any anesthetic. The incidence of VS in cardiac surgical patients is 8% to 10%, but may increase to upwards of 50% of patients taking renin-angiotensin system (RAS) antagonists. In cardiac surgical patients with persistent hypotension into the postoperative period, the associated mortality approaches 25%. Some clinicians

suggest, however, that there is a lack of evidence for withholding RAS antagonists preoperatively in order to prevent VS. Clear guidelines have not been established. The proposed mechanism involves selective depression of the three blood pressure support systems: the sympathetic nervous system, renin angiotensin, and vasopressin systems. Sympathetic nervous system depression under anesthesia leaves maintenance of blood pressure dependent on the renin-angiotensin and the vasopressinergic systems. Angiotensin converting enzyme inhibitors and angiotensin receptor blockers inhibit the RAS, leaving only vasopressin to maintain blood pressure. Other proposed mechanisms for developing VS include: cytokine and nitric oxide–mediated smooth muscle relaxation, catecholamine receptor down-regulation, cell hyperpolarization, and endothelial injury. Treatment of VS can be difficult. When conventional therapies such as decreasing the anesthetic agent, volume expansion, phenylephrine, ephedrine, norepinephrine, and epinephrine are not effective, the administration of vasopressin may increase blood pressure. A 0.5-1.0 unit bolus of vasopressin may be given followed by an infusion dose of 0.03 units/min for vasopressin or 1-2 mcg/kg/hr for terlipressin as needed. Methylene blue is suggested as a second-line therapy. A bolus dose of 1-2mg/kg over 10-20 minutes followed by an infusion of 0.25mg/kg/hr for 48-72 hours is recommended with a maximum dose of 7 mg/kg. Methylene blue is believed to interfere with the nitric oxide (NO)-cyclic guanylate monophosphate (cGMP) pathway, inhibiting the vasodilating effect on smooth muscle. Withholding the RAS antagonists the morning of surgery appears to reduce the incidence in noncardiac surgical patients.[103,104] It has recently been suggested that withholding these drugs prior to non-cardiac surgery is not necessary. If hypotension occurs, it is treatable and it simplifies patient instructions if they are told to continue all of their cardiac medications as normal.[105,106] The issue of how to manage patients on the RAS antagonists remains to be clarified.

ANGIOTENSIN II RECEPTOR ANTAGONISTS

Angiotensin receptor blockers (ARBs) are a class of drugs useful for the treatment of hypertension and congestive heart failure. Their pharmacologic actions are similar to the ACE inhibitors, but their mechanism of action is competitive blockade of type 1 angiotensin II (AT_1) receptors[107] (see Table 13-5 and Figure 13-5). They are effective for lowering blood pressure without the cough and angioedema associated with ACE inhibitors. Unlike the ACE inhibitors, they do not prevent the breakdown of bradykinin, and therefore do not produce cough. There are no intravenous preparations currently marketed. Due to cost, the ARBs are usually reserved for patients who cannot tolerate an ACE inhibitor.[108]

CATECHOLAMINE-DEPLETING AGENTS

Catecholamine-depleting agents are rarely encountered in modern anesthesia practice, but the anesthetist should be familiar with their mechanism of action. The classic member of this group is reserpine. Reserpine blocks the uptake of catecholamines into storage vesicles within the presynaptic adrenergic neuron by inhibiting the vesicular monoamine transporter (VMAT). This exposes the catecholamines to metabolism by monoamine oxidase in the axoplasm. This "catecholamine depletion" is responsible for the antihypertensive action of reserpine.[109]

TYROSINE HYDROXYLASE INHIBITORS

Metyrosine (Demser) is a tyrosine hydroxylase inhibitor. Tyrosine hydroxylase is responsible for catalyzing the conversion of tyrosine to dopa and is considered the rate-limiting step in the synthesis of catecholamines. Inhibition of tyrosine hydroxylase results in a decrease in circulating catecholamine levels. It is used as an add-on drug to the α- and β-receptor blockers for the control of the blood pressure in patients with pheochromocytoma.[110]

CATECHOL-*O*-METHYLTRANSFERASE INHIBITORS

Tolcapone (Tasmar) and entacapone (Comtan) are used for the treatment of Parkinson's disease as an adjunct to levodopa or carbidopa therapy. A third drug nebicapone is in clinical trials. They are selective and reversible inhibitors of catechol-*O*-methyltransferase (COMT). They enhance the action of levodopa and produce less fluctuation in drug response. There are concerns that COMT inhibitors may interact with various cardiac drugs by reducing their metabolism. Caution should be taken when administering such drugs as isoproterenol, dobutamine, dopamine, norepinephrine, and epinephrine. Reduced doses should be started initially until the response can be assessed.[111,112]

CARDIAC GLYCOSIDES

Characterized by the digitalis preparations, the cardiac glycosides have been used to treat CHF for two centuries. The most common preparation used is digoxin. The primary inotropic effect of digitalis is achieved by the binding to the α-subunit of the sodium-potassium adenosine triphosphatase (Na/K ATPase) in cardiac cells. The Na/K ATPase is somewhat erroneously referred to as the *sodium/potassium pump*.[32] This results in an increase in the concentration of intracellular calcium during systole, which augments myocardial contractility. Normally the Na/K ATPase exchanges intracellular sodium for extracellular potassium against their concentration gradients. Inhibition of this exchange results in an increase in intracellular sodium that results in a decreased calcium exchange and a higher intracellular calcium. The mechanism of action of digitalis is shown in Figure 13-6. The additional calcium enhances contraction. Digitalis produces an increase in both diastolic filling and ejection fraction.

Electrophysiologically, enhancement of vagal tone, another prominent effect of digitalis, results in slowing of the heart rate and prolongation of AV conduction. Because of its vagal effects, digitalis also is used to control the ventricular response to atrial fibrillation and other atrial tachyarrhythmias. The digitalis-induced enhancement of vagal tone leads to slowing of impulse conduction through the atrioventricular node and prolongation of the effective refractory period of the atrioventricular node. Its use as both an antiarrhythmic and inotrope has decreased significantly in recent years with the introduction of more efficacious and safer drugs.

Digitalis preparations have a narrow therapeutic index, great variability in action among patients, and several serious side effects. Hypokalemia greatly enhances the effects of digoxin, whereas hyperkalemia has the opposite effect.[113] A patient with hypokalemia whose digitalis level is within a therapeutic range may show toxic effects. Digoxin serum levels are also mediated by the P-glycoprotein transporter. All known arrhythmias have been attributed to digitalis toxicity. Other signs and symptoms of digitalis toxicity include nausea, vomiting, diarrhea, headache, fatigue, and colored vision. Under anesthesia the first sign is usually an arrhythmia, frequently premature ventricular contractions (PVCs). Close monitoring of electrolytes should be performed in digoxin-treated patients receiving a preoperative preparation of the bowel. Calcium administration is contraindicated in digoxin-treated patients because it may lead to cardiac arrest. Preoperatively, in select patients, the serum levels of potassium and digitalis can be monitored.[114]

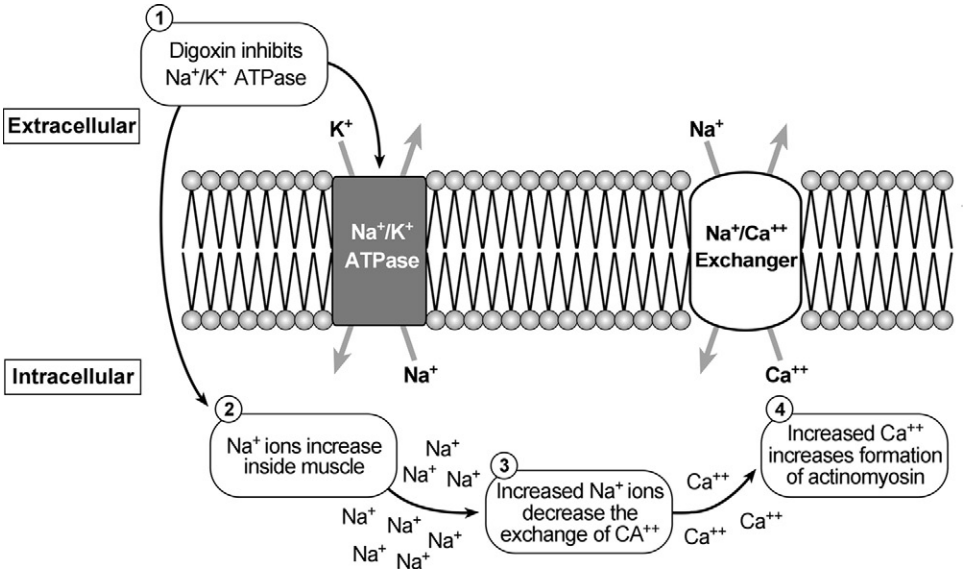

FIGURE **13-6** The mechanism of action of digitalis. *(1)* Sodium potassium ATPase is inhibited resulting in increased intracellular sodium; *(2)* increased intracellular sodium produces a decrease in the exchange of sodium and calcium; *(3)* intracellular calcium increases; and *(4)* muscle contraction is enhanced.

Some common mechanisms for drugs affecting the sympathetic nervous system are shown in Figure 13-7.

MANAGEMENT OF SPECIFIC DISEASES

In past decades, the treatment of cardiovascular diseases under anesthesia was difficult and limited. The lack of specific cardiac drugs and the limited selection of anesthetic agents warranted symptomatic therapy designed to facilitate surgery until the patient was in the postanesthesia care unit. Currently, with the vast array of cardiac drugs, the improved sophistication of anesthetic management, and monitoring that provides extensive hemodynamic information, the anesthesia provider is able to treat patients in a manner that is

BOX **13-2**

Clinical Predictors of Increased Perioperative Cardiovascular Risk

Major Risk Factors

Unstable Coronary Syndromes

- Acute or recent myocardial infarction with evidence of important ischemic risk by clinical symptoms or noninvasive study*
- Unstable or severe angina (Canadian class III or IV)

Decompensated Heart Failure

- New York Heart Association functional class IV; worsening or new onset heart failure

Significant Arrhythmias

- High-grade atrioventricular block
- Mobitz II atrioventricular block
- Third-degree atrioventricular block
- Symptomatic ventricular arrhythmias
- Supraventricular arrhythmias, including atrial fibrillation with uncontrolled ventricular rate greater than 100 at rest
- Symptomatic bradycardia
- Newly recognized ventricular tachycardia

Severe Valvular Disease

- Severe aortic stenosis with mean pressure gradient greater than 40 mmHg; aortic valve area less than 1 cm^2; or exhibiting symptoms
- Symptomatic mitral stenosis; progressive dyspnea on exertion, exertional presyncope, or heart failure

Intermediate Risk Factors

- Mild angina pectoris (Canadian class I or II)
- Previous myocardial infarction identified by history or pathologic Q waves
- Compensated or previous heart failure
- Diabetes mellitus (particularly insulin dependent)
- Renal insufficiency

Minor Risk Factors

- Advanced age
- Abnormal ECG (left ventricular hypertrophy, left bundle-branch block, ST-T abnormalities)
- Rhythm other than sinus (e.g., atrial fibrillation)
- Low functional capacity (e.g., inability to climb one flight of stairs with a bag of groceries)
- History of stroke
- Uncontrolled systemic hypertension

ECG, Electrocardiogram.
*The American College of Cardiology National Database Library defines recent myocardial infarction as having occurred more than 7 days previously, but less than or equal to 1 month (30 days); acute myocardial infarction is defined as having occurred within the last 7 days; may include "stable" angina in patients who are unusually sedentary.

BOX **13-3**

Cardiac Risk* Stratification for Noncardiac Surgical Procedures

High Risk (Reported Cardiac Risk Often Greater Than 5%)

- Aortic and other major vascular surgery
- Peripheral vascular surgery

Intermediate Risk (Reported Cardiac Risk Generally 1% to 5%)

- Carotid endarterectomy
- Head and neck surgery
- Intraperitoneal and intrathoracic surgery
- Orthopedic surgery
- Prostate surgery

Low Risk (Reported Cardiac Risk Generally Less Than 1%)†

- Endoscopic procedures
- Superficial procedures
- Cataract surgery
- Breast surgery
- Ambulatory surgery

From Fleisher LA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2009:54:e13-118.
*Combined incidence of cardiac death and nonfatal myocardial infarction.
†These patients do not generally require further preoperative cardiac testing.

appropriate for management of their diseases. Therapies can be chosen that fit into a patient's plan of care. The anesthetic process can safely and effectively continue the care management of the individual patient. To assist in predicting possible poor outcomes, ACCF/AHA and the European Society of Cardiology have classified the cardiovascular and surgical risks[115,116] (Boxes 13-2 and 13-3).

The drugs listed for therapy of the cardiovascular disorders that follow are presented not so much for their specific intraoperative use but as a means of continuing the patient's current drug profile. Patient treatment mirrors general nonoperative indications and considerations. Anesthetic techniques take into account the combined effects of cardiac drugs and anesthetic agents when administered together.

Congestive Heart Failure

In the United States, 4 to 5 million people have chronic CHF, with 600,000 to 700,000 new cases occurring each year. The incidence will undoubtedly increase as the population ages. Heart failure results in almost 1 million hospitalizations each year. It is the most common hospital discharge diagnosis in patients older than age 65 years. More than 280,000 patients die as a direct or an indirect consequence of heart failure each year, a sixfold increase during the past 40 years.[117] It is the only major cardiovascular disorder that is increasing in prevalence, with an estimated annual cost of $40 billion. Once cardiac failure has been diagnosed, 5-year survival rates are typically 25% to 40%, similar to the survival rates for cancer. Fortunately, recent data suggests that hospitalization and mortality rates are declining, which may indicate that aggressive interventions and management are yielding positive results.[118] The classification of heart failure is given in Box 13-4.

Heart failure is a major independent predictor of adverse perioperative outcome in noncardiac surgery.[119] Mortality estimates

BOX **13-4**

New York Heart Association Functional Classification for Heart Failure

Class I (Mild)
- No limitation of physical activity.
- Ordinary physical activity does not cause undue fatigue, palpitation, or dyspnea.

Class II (Mild)
- Slight limitation of physical activity.
- Comfortable at rest, but ordinary physical activity results in fatigue, palpitation, or dyspnea.

Class III (Moderate)
- Marked limitation of physical activity.
- Comfortable at rest, but less than ordinary activity causes fatigue, palpitation, or dyspnea.

Class IV (Severe)
- Unable to carry out any physical activity without discomfort.
- Symptoms of cardiac insufficiency at rest.
- If any physical activity is undertaken, discomfort is increased.

Adapted from Greenberg B, Kahn AM. Clinical assessment of heart failure. In: Bonow RO, et al. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 9th ed. Philadelphia: Saunders; 2012:507.

BOX **13-5**

Causes of Intraoperative Rhythm Disturbances

Structural Heart Disease
- Coronary artery disease
- Myocardial infarction
- Valvular and congenital heart disease
- Cardiomyopathy
- Sick sinus or long Q-T interval syndrome
- Wolff-Parkinson-White syndrome
- Heart disease secondary to systemic disease (e.g., uremia, diabetes)
- Sinus bradycardia
- Atrioventricular node heart block

Transient Imbalance
- Stress: electrolyte or metabolic imbalance
- Laryngoscopy, hypoxia, hypercarbia
- Device malfunction, microshock
- Diagnostic or therapeutic intervention (pacemakers, cardioverter-defibrillators)
- Surgical stimulation
- Central vascular catheters

Adapted from Atlee JL. *Complications in Anesthesia*. 2nd ed. Philadelphia: Saunders; 2007:319-335.

range from 3% to as high as 30% in patients undergoing abdominal surgery.[120] In patients with CHF and renal failure undergoing emergency surgery, mortality rates as high as 76% have been reported.

Congestive heart failure is a syndrome resulting from a cardiac malfunction that impairs the ability of the heart to eject blood and meet the circulatory demands of the body. It is defined as a complex clinical syndrome that can result from any structural or functional cardiac disorder that interferes with the ability of the ventricle to fill with or eject blood. Alterations associated with CHF include impairment-induced complex changes in the structure of the ventricle called *ventricular remodeling*, along with hormonal and physiologic alterations.[121] The chamber dilates, hypertrophies, and becomes more spherical. Substantial evidence suggests that activation of the body's endogenous neurohormonal systems, such as the renin-angiotensin system, plays an important role in cardiac remodeling and the progression of heart failure. Treatment is complex and tailored to the patient's age, current disease state, and associated concurrent disorders. It involves a polypharmaceutical approach that is referred to as triple therapy. This includes ACE inhibitors, β-blockers, and diuretics. Statins are usually added as well. Other agents useful in select patients may include digoxin, ARBs, nitrates, nesiritide, aldosterone, and hydralazine. Mechanical support devices may be added as well.[117]

In the perioperative period, anesthesia providers are faced with managing therapy for all degrees of severity of CHF. The goal can range from prevention of symptom progression to surviving an emergency procedure in life-threatening cases. When appropriate, regional nerve block techniques should be considered, but patients may have difficulty lying flat during surgery. No single general anesthetic technique has proven superior. Invasive arterial blood pressure monitoring and transesophageal echocardiography (TEE) are useful for guiding intraoperative decision making and fluid management. TEE is especially useful in diagnosing whether hypotensive episodes are the result of inadequate circulating blood volume, worsening ventricular function, or arterial vasoconstriction.

Drugs such as the inotropes, phosphodiesterase inhibitors, diuretics, and vasodilators are commonly used intraoperatively in acute episodes[114,120,122] (see Tables 13-3 and 13-9).

Arrhythmias

The incidence of serious arrhythmias requiring intervention during general anesthesia is relatively low. A large multicenter study found that not counting simple tachycardia, bradycardia, or clinically minor rhythm disturbances, the frequency of serious arrhythmias was 1.6% in a series of more than 17,000 patients who underwent general anesthesia.[123] It is surprising that the incidence is not higher, because several contradictory factors are involved; most drugs given during anesthesia are cardiac depressants; therefore they tend to be antiarrhythmic. However, patients with multiple drug profiles in combination with the anesthetics may experience drug interactions that lead to rhythm disturbances. Add to these pharmacologic factors the stresses of surgery and anesthesia, and a multitude of effects on cardiac rhythms may be expected.

In recent years, new pharmacologic and nonpharmacologic management approaches for cardiac arrhythmias have emerged. New drugs, implantable cardiac devices (ICDs), and ablation therapy are available for managing these disorders. The use of antiarrhythmic drugs in the United States is declining because of the increasing use of ablation therapy and implantable devices.[61] Some causes of intraoperative rhythm disturbances are listed in Box 13-5.

The goal of drug therapy for arrhythmias during anesthesia should be to treat immediate hemodynamic problems and prevent progression of serious arrhythmias. Treatment is similar to that in the nonoperative setting, with the caveat that most therapies should be carefully titrated to avoid unexpected proarrhythmic or excessive hypotensive outcomes. Some cautionary statements should precede any discussion on the use of antiarrhythmic agents during anesthesia:

- The cause of the arrhythmia should be explored before any treatment is instituted. A cardiology consult should be obtained when possible.

TABLE 13-10 Classification of Antiarrhythmic Drugs

Class	Electrophysiologic Effect	Drug
I	Depression of phase 0 depolarization (block sodium channels)	
IA	Moderate depression and prolonged repolarization	Quinidine, procainamide, disopyramide
IB	Weak depression and shortened repolarization	Lidocaine, mexiletine, phenytoin, tocainide
IC	Strong depression with little effect on repolarization	Flecainide, propafenone, moricizine
II	β-Adrenergic blocking effects	Esmolol, propranolol, metoprolol, timolol, pindolol, atenolol, acebutolol, nadolol, carvedilol
III	Prolongs repolarization (blocks potassium channels)	Amiodarone, bretylium, sotalol, ibutilide, dofetilide
IV	Calcium channel–blocking effects	Verapamil, diltiazem
Other		Adenosine, adenosine triphosphate, digoxin, atropine

- Adequacy of ventilation, depth of anesthesia, acid-base balance, and fluid and electrolyte balance must be verified before appropriate therapy can be formulated.
- Multiple-drug administration, which constitutes modern anesthesia practice, may result in unexpected drug interactions. Analysis of complex arrhythmias with the commonly used three- or five-lead electrocardiograph system during a surgical procedure is less than ideal for proper diagnosis and treatment. Nonetheless, rhythm disturbances that compromise hemodynamic stability or may progress to more severe dysfunction must be addressed.

Classification of antiarrhythmic drugs is given in Table 13-10. The drugs of choice for the common arrhythmias are given in Table 13-11.

Hypertension

Hypertension is a major health problem in the United States; an estimated 70 million Americans have hypertension or should be monitored for elevated blood pressure.[46] The classification of hypertension is given in Table 13-12. The optimal blood pressure is believed to be less than 120 systolic and less than 90 diastolic, although many clinicians consider less than 130 systolic to be adequate. Patients are categorized as having either prehypertension, or either stage 1 or 2 hypertension.[124] A large number of drugs are available for the treatment of high blood pressure. Those that are considered as initial therapy include diuretics, calcium channel blockers, ACE inhibitors, and angiotensin receptor antagonists (ARBs).[125,126] β-receptor blockers are frequently included as initial therapy but may not be preferred in uncomplicated hypertensive patients.[127,128] Most patients with hypertension are taking two or more drugs to control their blood pressure. The most important aspect of treatment is to reduce blood pressure to goal levels. Which drug combinations appear less important. Unfortunately, despite the remarkable progress in therapy, blood pressure remains inadequately controlled in more than half of patients with hypertension in the United States.[129,130]

Drugs available for the treatment of hypertension are listed in Table 13-5. Antihypertensive drugs that are safe for use during pregnancy are listed in Table 13-13.

Manipulation of the patient's blood pressure is an ongoing task during anesthesia, and many drugs are available to increase and decrease blood pressure when indicated. Improved monitoring and sophistication of anesthetic techniques has made control of blood pressure almost routine.

The problem of hypertension has varying significance in preoperative, intraoperative, and postoperative situations. Mild hypertension probably represents only a minor risk for anesthesia and surgery.[131] Patients with more severe hypertensive episodes are at greater risk and will benefit from acute therapy combined with postoperative long-term follow-up.[132] Hypertensive episodes during the perioperative period occur most often during emergence from anesthesia and may be associated with pain, airway stimulation, hypoxia-hypercarbia, hypothermia and shivering, bladder distention, withdrawal from preoperative medications, and intraoperative use of vasopressors. Drugs useful for the treatment of perioperative hypertension are listed in Table 13-9.

Ischemic Heart Disease

Ischemic heart disease (IHD) is the most common cardiac disease encountered in the operating room. Approximately 18 million people in the United States have either angina or a past myocardial infarction.[133,134]

The goal of any anesthetic in a cardiac-compromised patient is hemodynamic optimization tailored to each patient's unique disease and surgical profile. No single anesthetic technique or agent has been shown to be superior.[135] Finding a balance that avoids increases in myocardial work while maintaining proper perfusion is essential.[136,137]

The causes of coronary artery disease and management of patients with the disorder are discussed in detail in Chapters 23 and 24. The classification of angina pectoris is given in Table 13-14.

Usual pharmacotherapy includes nitrates, β-blockers, calcium channel blockers, aspirin, and lipid lowering or "statin" drugs (Table 13-15). Nitrates are given for symptomatic relief of acute anginal episodes. Positive benefits have been noted for perioperative statin use.[138] Preoperative statin use was associated with reduced cardiac mortality after primary, elective coronary artery bypass grafting. Postoperative statin discontinuation was associated with increased in-hospital mortality.[139] The β-blockers, ACE inhibitors, and calcium channel blockers are listed in Table 13-5. The HMG-CoA (3-hydroxy-3-methylglutaryl–coenzyme A) reductase inhibitors ("statins") are listed in Table 13-16.

PREOPERATIVE ADMINISTRATION OF CARDIAC DRUGS

Continuation of the patient's cardiac medications throughout the perioperative period is now considered routine practice. It is better to have the patient's disease state under proper control than to discontinue any medications before surgery and risk having the patient in unstable condition. Withdrawal after abrupt discontinuation of β-blockers and clonidine is especially severe. This also includes aspirin, which adds little bleeding risk to surgical procedures.

Aspirin is recommended as a lifelong therapy that should never be interrupted for patients with cardiovascular disease. The abrupt withdrawal of aspirin can cause a platelet rebound phenomenon and prothrombotic state leading to major adverse cardiovascular event.[140] Clopidogrel therapy is mandatory for 6 weeks after placement of

TABLE 13-11 Drugs of Choice for Common Arrhythmias

Arrhythmia	Drug of Choice	Alternatives	Remarks
Atrial fibrillation or flutter	*Rate control:* IV verapamil, diltiazem, β-blocker, or digoxin	IV procainamide or ibutilide; dofetilide; single large oral dose of propafenone or flecainide	Amiodarone also may slow ventricular response, and conversion to normal rhythm can occur, but generally after delay of several hours
Acute management	*Conversion:* DC cardioversion		Ibutilide infusion may increase effectiveness of DC cardioversion Incidence of atrial fibrillation following cardiac surgery can be reduced by preoperative sotalol, amiodarone, or a β-blocker
Chronic treatment	*Rate control:* Verapamil, diltiazem, a β-blocker, or digoxin *Maintenance of sinus rhythm:* Amiodarone, sotalol, flecainide, propafenone, or dofetilide	Quinidine, procainamide, disopyramide	Radiofrequency ablation may be effective in selected patients
Supraventricular tachycardias *Acute management*	IV adenosine, verapamil, or diltiazem	IV esmolol, another β-blocker, or digoxin for termination	Direct current cardioversion or atrial pacing may be effective for some patients; only rarely required
Long-term suppression	β-blockers, verapamil, diltiazem, flecainide, propafenone, amiodarone, sotalol, or digoxin	Quinidine, procainamide, or disopyramide	Radiofrequency ablation can cure many patients
Premature ventricular complexes (PVCs) or nonsustained ventricular tachycardia	*Asymptomatic patients:* Without structural heart disease: no drug therapy indicated *Symptomatic patients:* β-blocker	Lidocaine IV for acute suppression under anesthesia	No evidence that prolonged suppression with drugs improves survival; for post-MI patients, treatment with a β-blocker has decreased mortality, treatment with flecainide or moricizine has increased it
Sustained ventricular tachycardia	Amiodarone	Procainamide, lidocaine	Long-term therapy ICD, amiodarone
Ventricular fibrillation	*Prevention of recurrence:* Amiodarone	Procainamide, lidocaine	Long-term therapy ICD, amiodarone
Cardiac glycoside-induced ventricular tachyarrhythmias	Digoxin-immune Fab (digoxin antibody fragments—Digibind, DigiFab)		Self-limited if digoxin stopped; avoid direct current cardioversion, except for ventricular fibrillation or sustained ventricular tachycardia. A β-blocker or procainamide can make heart block worse
Drug-induced torsades de pointes	IV magnesium sulfate	Cardiac pacing, isoproterenol	Causative agents should be discontinued; magnesium sulfate may be effective, even in absence of hypomagnesemia; potassium should be used to raise serum K to 4.5 to 5.0 mEq/L

ICD, Implantable cardioverter device/defibrillator; *IV*, intravenous; *MI*, myocardial infarction.

bare-metal stents, 3 to 6 months after myocardial infarction, and at least 12 months after placement of drug-eluting stents. Elective surgery should be postponed for at least 6 weeks and optimally 3 months in a patient who has had a bare-metal stent placement and at least 1 year for a drug-eluting stent. Because of the hypercoagulable state induced by surgery, early withdrawal of antiplatelet therapy for secondary prevention of cardiovascular disease increases the risk of postoperative myocardial infarction and death. The risk of a cardiovascular event when stopping antiplatelet agents preoperatively is higher than the risk of surgical bleeding when continuing these drugs.

In surgical patients, antiplatelet therapy should be maintained in all situations in which the risk of surgical bleeding is low, which is usually the case in the ambulatory setting. The exception is surgery in a closed space such as intracranial or in the posterior eye chamber, middle ear, intramedullary spine, and possibly transurethral prostatectomy or surgeries associated with massive bleeding and difficult hemostasis.[140-142] A complete discussion of the anesthesia management of patients on antiplatelet drugs can be found in Chapter 34.

SUMMARY

Both advances in diagnostic and screening tests for heart disease and improvements in cardiac disease management continue to make impressive strides. Angioplasty is more effective and widely available, and electrophysiologic treatment of rhythm disorders is now considered routine. The number and diversity of cardiac medications we encounter in the perioperative period continues to grow in number and complexity. These advances require that anesthesia clinicians stay abreast of ever more complex clinical techniques but at the same time improve anesthesia quality and safety for our patients.

TABLE 13-12 Classification and Management of Blood Pressure for Adults

Blood Pressure Classification	Systolic Blood Pressure (mmHg)	Diastolic Blood Pressure (mmHg)
Normal	<120	and <80
Prehypertension	120-139	or 80-89
Stage 1 hypertension	140-159	or 90-99
Stage 2 hypertension	≥160	or ≥100

From Joint National Committee on Prevention, Detection and Treatment of High Blood Pressure: *Seventh Report of the National Committee on Detection, Evaluation and Treatment of High Blood Pressure* (JNC-7) (NIH Publication No. 03-5233). Washington, DC: U.S. Department of Health and Human Services; National Institute of Health; National Heart, Lung and Blood Institute; National High Blood Pressure Education Program, May 2003.

TABLE 13-13 Antihypertensive Drugs Used in Pregnancy*

Suggested Drug	Comments
Central α-agonists	Methyldopa is the drug of choice
β-Blockers	Atenolol, metoprolol, and labetalol
Diuretics	Diuretics recommended for chronic hypertension if prescribed before gestation or if patients appear to be salt sensitive; diuretics not recommended in patients with preeclampsia
Direct vasodilators	Hydralazine is the parenteral drug of choice, based on its long history of safety and efficacy

From Joint National Committee on Prevention, Detection and Treatment of High Blood Pressure: *Seventh Report of the National Committee on Detection, Evaluation and Treatment of High Blood Pressure* (JNC-7) (NIH Publication No. 03-5233). Washington, DC: U.S. Department of Health and Human Services; National Institute of Health; National Heart, Lung and Blood Institute; National High Blood Pressure Education Program, May 2003.
*Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers should not be used. Fetal abnormalities and death have been reported.

TABLE 13-14 Classification of Angina Pectoris

Class	New York Heart Association Functional Classification	Canadian Cardiovascular Society Functional Classification	Specific Activity Scale
I	Patients with cardiac disease but without resulting limitations of physical activity Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain	Ordinary physical activity, such as walking and climbing stairs, does not cause angina Angina with strenuous or rapid or prolonged exertion at work or recreation	Patients can perform to completion any activity requiring ≥7 or more metabolic equivalents, e.g., can carry 24 lb up eight steps; carry objects that weigh 80 lb; do outdoor work (shovel snow, spade soil); do recreational activities (skiing, basketball, squash, handball, jog or walk 5 mph)
II	Patients with cardiac disease resulting in slight limitation of physical activity They are comfortable at rest Ordinary physical activity results in fatigue, palpitations, dyspnea, or anginal pain	Slight limitation of ordinary activity Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, in wind, or when under emotional stress, or only during the few hours after awakening Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal conditions	Patient can perform to completion any activity requiring ≥5 or more metabolic equivalents but cannot and does not perform to completion activities requiring ≥7 or more metabolic equivalents, e.g., have sexual intercourse without stopping, garden, rake, weed, roller skate, dance foxtrot, walk at 4 mph on level ground
III	Patients with cardiac disease resulting in marked limitation of physical activity They are comfortable at rest Less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain	Marked limitation of ordinary physical activity Walking one or two blocks on the level and climbing more than one flight in normal conditions	Patient can perform to completion any activity requiring ≥2 or more metabolic equivalents but cannot and does not perform to completion any activities requiring ≥5 or more metabolic equivalents, e.g., shower without stopping, strip and make bed, clean windows, walk 2.5 mph, bowl, play golf, dress without stopping
IV	Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest If any physical activity is undertaken, discomfort is increased	Inability to carry on any physical activity without discomfort—anginal syndrome may be present at rest	Patient cannot or does not perform to completion activities requiring ≥2 or more metabolic equivalents; cannot carry out activities listed above (Specific Activity Scale, class III)

From Goldman L, et al. Comparative reproducibility and validity of systems for assessing cardiovascular functional class: advantages of a new specific activity scale. *Circulation*. 1981;64:1227-1234.

TABLE 13-15 Drug Therapy for Angina

Drug	Comments
Nitrates	First-line therapy for acute attacks; mechanism is a decrease in oxygen demand via a reduction in preload and some beneficial redistribution in blood flow
β-Blockers	Cornerstone therapy for chronic prophylaxis; decrease cardiac demand via lower heart rate, blood pressure, and contractility
Calcium channel blockers	Especially effective in variant angina and in patients intolerant to β-blockers; reduce preload, afterload, and increase coronary flow
Antiplatelet drugs	Aspirin inhibits platelet and endothelial cyclooxygenase; reduces coronary thrombosis; clopidogrel (Plavix) may be substituted in patients with contraindications to aspirin
Statins	HMG-CoA reductase inhibitors, commonly referred to as *statins*; reduce C-reactive protein, thrombogenicity, and adverse cardiac events
Angiotensin-converting enzyme inhibitors	May be useful in patients with coronary artery disease and diabetes or other vascular diseases
Ranolazine	Ranolazine (Ranexa) is usually given in conjunction with the standard antianginal agents; blocks the late inward sodium current reducing intracellular calcium overload

HMG-CoA, 3-hydroxy-3-methylglutaryl–coenzyme A.

TABLE 13-16 HMG-CoA Reductase Inhibitors ("Statins")

Drug	Initial Dosage	Maximum Dosage	Comments
Atorvastatin (Lipitor)	10 mg once	80 mg once	Statins are generally tolerated better than other lipid-lowering drugs. Mild transient gastrointestinal disturbances, muscle pain, rash, and headache have occurred. Some patients have reported sleep disturbances. An increase in liver enzymes and creatine phosphokinase may occur with significant myalgia and muscle weakness.
Fluvastatin (Lescol)	20 mg once	40 mg bid	
Lovastatin (Mevacor)	20 mg once	80 mg once	
Pravastatin (Pravachol)	40 mg once	80 mg once	
Rosuvastatin (Crestor)	10 mg once	40 mg once	
Simvastatin (Zocor)	20 mg once	80 mg once

14 CHAPTER Chemistry and Physics of Anesthesia

◆ *Mark D. Welliver*

The dynamics of much of anesthesia practice lie within the framework of chemical and physical science. Chemistry, the study of matter composition, properties, and behavior at the atomic and molecular level, and physics, the study of motion, matter, and energy interaction, are two foundations for nurse anesthetist practice. Chemistry and physics explain such actions as pressure, flow, diffusion, expansion, contraction, and other processes that are intimately intertwined with the delivery of anesthetics. From the ancient philosophical beginnings of atomic theory and the proverbial falling apple of Newtonian physics (Sir Isaac Newton, 1642-1727) to current advances in quantum mechanics, discoveries have led to advances and application for anesthesiology. To understand these laws and theories is to understand the how and why of our practice, give us rationale for clinical interventions, and allow us the ability to manipulate dynamic processes to our patients' favor.

The dynamics of anesthesia herein are explained primarily by the atomic and kinetic molecular theories, Newtonian physics, thermodynamics, and the quantum mechanics of electromagnetic radiation. This chapter provides a short, concise resource that focuses on the chemistry and physics of anesthesia.

GENERAL CHEMISTRY: MATTER AND ENERGY

The universe is composed of two main constituents, matter and energy. Energy is explored more thoroughly in the section on physics. Matter is the tangible composition of the universe that may be solid, liquid, gas, or plasma. Solids are defined as material that resists changes in shape and volume. Liquids are fluids that exhibit minimal to no compressibility and may change volume with changes in pressure and temperature. Gases are also fluids but are compressible and easily change volume with changes in pressure and temperature. Plasma is a mixture of ionized gas and free-floating electrons. It has been postulated that more than 99% of the universe's matter is plasma.

International System of Measurement

When studying and interacting with matter and energy, it is necessary to have a system of standardized units of measurement. The Systéme International (SI) is a set of standardized units of measure based on the metric scale. The SI uses 7 base quantities for measurement (Table 14-1) and 12 standard prefixes for naming units of measure to denote quantity (Table 14-2). Other units or combinations of units may be used in addition to those shown. Additionally, temperature and pressure affect the behavior of matter, and a standardized reference has been established for both. The standard temperature and pressure (STP) is 100.00 kilopascals at 273 kelvin.

Elements

Elements are matter that possess similar atoms containing the same protons. The periodic chart of the elements lists these elements according to their chemical characteristics. Vertical columns known as *groups* list elements with similar properties. Horizontal rows are known as *periods*. Atomic size progresses up across rows from left to right. Atomic weights are listed with each element on the chart (Figure 14-1).

TABLE 14-1 Systéme International Seven Base Quantities for Measurement

ATOMIC STRUCTURE

Atomic theory has its origins in the philosophical musings of the ancient Greek philosopher Democritus, who described indivisible building blocks of matter referred to as "atomos."[1] The orbital theory of atomic structure was later put forth by Ernesto Rutherford (1871-1937) and improved upon by Neils Bohr (1885-1962), who described electron orbits in terms of energy levels and ability to emit quantized energy by stimulated emission. The atomic theory describes atoms as having a central core, the *nucleus*, with orbiting particles called *electrons* (Figure 14-2). Electrons are negatively charged. The nucleus contains protons and neutrons. *Protons* have

a positive charge and are larger than electrons. *Neutrons* lack a charge and are similar in size to protons. The number of protons in an atom constitutes its *atomic number*. Electrons, much smaller than protons and neutrons, orbit around the nucleus and are negatively charged.

Electron Configuration

Atoms have electrons that orbit in shells around the nucleus. Each shell can contain only a set number of electrons. These shells have been designated K, L, M, N, O, P, Q. The corresponding maximal number of electrons that may occupy each shell is 2, 8, 18, 32, 32, 18, and 8. Electrons must fill lower shells before occupying higher shells. Quantum physics has refined the electron shell model by designating the K, L, M, N, O, P, Q shells with n-values 1, 2, 3, 4, 5, 6, and 7, which correspond with increasing energy levels. Electron shells are further divided into subshells with the designations s, p, d, f, and g. Subshells may hold only the following number of electrons: s(2), p(6), d(10), f(14), and g(18). Subshells are further subdivided into orbitals. Orbitals may only contain two electrons that spin in opposite directions. An s subshell has 1 orbital, a p subshell has 3 orbitals, a d subshell has 5 orbitals, and so forth. Electrons occupy lower energy level orbitals but may temporarily jump to higher level orbitals when they absorb energy. Electrons that jump to higher levels will emit their excess energy and return to their lower energy state. (See discussion on lasers later in this chapter.)

Angular Momentum/Spin

Nuclei and electrons have an angular momentum also known as *spin*. Atomic particles possess an intrinsic axis upon which they rotate (spin). Spin is analogous to the axis on which the earth rotates. The spin of an electron or proton is not directly measurable, but the uneven distribution of charge it produces is measurable. A magnetic moment is created and is essentially a minute electric current loop. (See discussion on magnetic resonance imaging later in this chapter.)

Ions

Ions are atoms that have gained or lost electrons from their natural composition. An atom that has gained an electron(s) is called an *anion*. Conversely, an atom that has lost an electron(s) is called a *cation*. Ions are important in chemical bonding and aqueous solubility. Mass number/atomic mass number is the amount of protons and neutrons in an atom. Isotopes of the same element have the same number of protons but different numbers of neutrons. Isotopes of the same element have differing mass numbers.

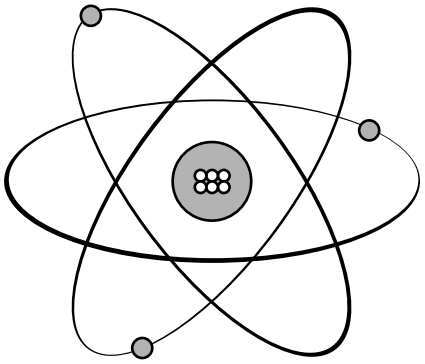

FIGURE **14-2** Atomic structure showing nucleus containing protons and neutrons with orbiting electrons.

MOLECULAR BOND TYPES

Molecules are composed of two or more bonded atoms. Electrons in the outermost shell are called *valence electrons* and are involved in molecular bonding. Molecular bonding may occur by direct sharing of electrons or by thermodynamic interaction due to distribution of electron charge. Atoms with unpaired valence electrons are reactive and tend to form bonds that will fill their outer shell. Covalent and electrostatic are two general types of bonds. Atoms may bond to atoms of the same element (e.g., oxygen) or to different element atoms (e.g., water). Compounds are bonded atoms of differing elements.

Covalent Bonds

The physical sharing of electrons between atoms constitutes a *covalent bond*. The sharing of one pair of electrons is called a *single bond*, sharing two pairs of electrons is a *double bond*, and sharing three pairs of electrons is a *triple bond*. Often covalent bonds are stronger than electrostatic bonds. Covalent bonding may be between same or different atoms that share similar electronegativity.

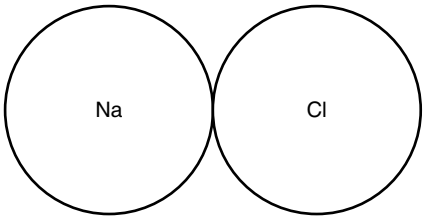

FIGURE **14-3** Ion-to-ion bond representation between sodium and chloride ions.

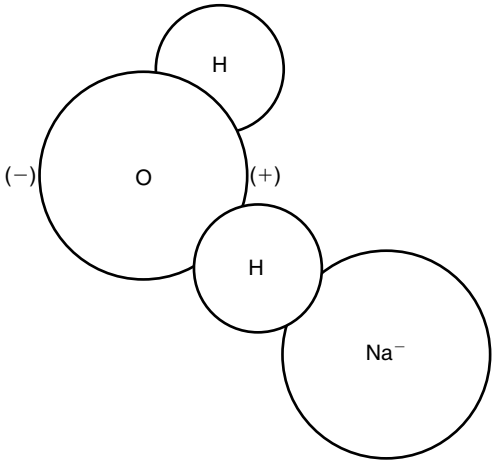

FIGURE **14-4** Ion-to-dipole bond representation between a water molecule and sodium ion.

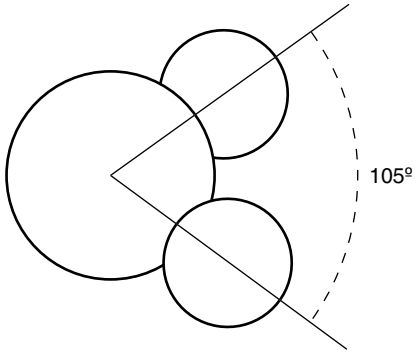

FIGURE **14-5** Hydrogen atoms' bond angle in a water molecule.

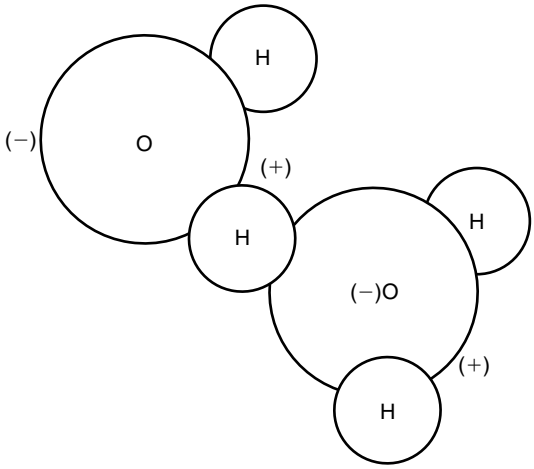

FIGURE **14-6** Dipole-to-dipole bond representation between two water molecules.

Electrostatic Bonds

Electrostatic bonds are made by attraction of electrons between atoms. Electrostatic bonding may be ion-to-ion interaction, ion-to-dipole interaction, or dipole-to-dipole interaction and follow the general rule of "opposites attract," with negative charges attracting positive charges.

Ion-Ion Bonding

Ion-to-ion bonds are the strongest of the electrostatic bonds. These bonds are not directional and occur anywhere along the outer electron shell of an atom. Molecules with ionic bonds have high melting and boiling points. Sodium chloride (table salt) is an example of ion-to-ion bonding (Figure 14-3).

Ion-Dipole Bonding

Ion-to-dipole bonds are weaker than ion-ion bonds, with only partial charges involved. Some molecules have structural arrangements that produce an uneven distribution of electrons. This uneven distribution of charges creates a dipole in which there is a more positive or more negative side to the molecule, although the molecule does not have a formal charge. An example of a molecule with an uneven charge distribution is water. The spatial arrangement of water's hydrogens toward one side of an oxygen atom causes that side to have a more positive character and the opposite side to have a more negative character. This dipole of water may bond to an ion of opposite charge. The ions of sodium and chlorine bond to water by ion-to-dipole interaction (Figure 14-4).

Dipole-Dipole Bonding

Water is an example of dipole-to-dipole molecular bonding. The spatial arrangement of water's hydrogens at a 105-degree angle to each other causes this molecule to be dipolar (Figure 14-5). The dipolar nature of water molecules allows them to form weak bonds with one another (Figure 14-6). The polar sides of water molecules also enable them to bond to ions and other polar molecules. For this reason, water is a convenient solvent for many substances such as drugs. Surface tension of water is a physical characteristic that is caused by water's dipole-to-dipole intermolecular attractions.

Some molecules may have *induced dipoles* caused by momentary uneven spatial distribution of electrons. Induced dipoles are not permanent. These temporary dipoles may lead to weak bonding between nonpolar molecules. Oils represent nonpolar molecules that display induced dipole bonding, often called *London dispersion forces*. London dispersion forces are the weakest of all molecular bonds. Despite this weakness, London dispersion forces at very low temperatures allow oxygen and nitrogen to become liquids.

Molecular Bonding Representations

There are several ways to denote bonding and electron distribution. The Lewis structure (electron dot structure) shows the valence electrons as they bond among atoms. Lewis structures may show dots or lines to represent electrons. Again, only outer shell valence electrons are represented and not lower, fully filled shells. Skeletal diagrams are another frequently used method to represent molecular bonding. In organic chemistry, skeletal diagrams use lines to show atom bonding often omitting the letter C for carbon (Figure 14-7).

The Valence Shell Electron Pair Repulsion diagrams (VSEPR) are more descriptive Lewis structures based on the theory of the same name. These diagrams represent electron repulsions, and the

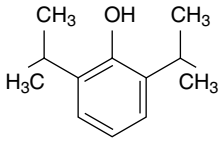

FIGURE **14-7** Skeletal diagram of diisopropyl phenol molecule.

FIGURE **14-9** Molecular model of sugammadex encapsulating a rocuronium molecule. (From Zhang M-Q, et al. *Angew Chem Int Ed.* 2002;41(2):265. © Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission.)

resultant approximation of the geometric distribution of atoms in covalently bonded molecules (Figure 14-8).

Molecular Modeling

Molecular models are detailed representations of molecules. Electrons are in constant "orbit" in an atom, and attempts have been made to graphically represent their space-occupying possible locations (Figure 14-9). Space-filling models reflect the "electron cloud" of specific atoms in a molecule. These models can appear as spherical, ball and stick, or ribbon-like representations of atoms and molecules that are affixed to one another. Molecular modeling is expanding our understanding not only of molecular geometries but also molecular behavior.[2]

Isomers

Isomers are molecules that have the same chemical formula but different structural formulas. The number and type of atoms and bonds are the same in isomers, but the arrangement of the atoms is different. Isomers may be *structural* or *stereoisomers*. Structural isomers have the same molecular formula, but their atoms are located in different places. Enflurane and isoflurane are examples of structural isomers. Structural isomers are truly different molecules with differing physical and chemical properties. Stereoisomers are molecules that have a similar geometric arrangement of atoms but differ in their spatial position. Stereoisomers may be *enantiomers* or *diastereomers*. Enantiomers are mirror images of one another, cannot be superimposed, and possess similar chemical and physical properties. Enantiomers are optically active and can rotate polarized light in a clockwise fashion (prefix + or dextro) or counterclockwise fashion (prefix − or levo). Racemic chemical compositions contain 50% of the levo form isomer and 50% of the dextro form isomer. Diastereomers are not mirror images and may have differing physical and chemical properties.

BOND BREAKING

Bond energy is the amount of energy needed to make or break a bond. Energy is released when a bond is formed, and energy is consumed with breaking a bond. The energy released when a bond is formed is the same amount of energy needed to break that same chemical bond. Short bonds, such as covalent bonds, tend to possess greater bond energies than longer, electrostatic bonds. When molecular bonds are broken, new molecular bonds are often formed and energy is released. An example of this is adenosine triphosphate (ATP) conversion to adenosine diphosphate (ADP). Energy is actually consumed in the process of breaking an ATP bond. A greater amount of energy is released when the free phosphate forms new bonds with hydrogen.[3] Bond energies are measured as an enthalpy change.

Enthalpy

Enthalpy is the total amount of energy possessed by a system. A system can be on the atomic scale or the macroscopic scale. The enthalpy of a system is the total of all kinetic and potential energy. The stored, or potential, energy includes its height in relation to the force of gravity and the energy stored in the bonds of molecules and atoms and even subatomic particles. All movement, as well as stored energy, must be accounted for and summated to know the enthalpy of a system. Thus the total amount of energy contained within a system is increasingly difficult to quantify, especially with increasing complexity of a system. The difficulty in measuring all the energy in a particular system requires a simpler method to evaluate energy involved in chemical reactions. Therefore, *change of energy (ΔH)* rather than total energy (enthalpy) of a system is measured.

ORGANIC COMPOUNDS

Organic chemistry is the study of carbon-containing molecules. Biological life on earth is based on carbon-containing compounds. Carbon is a unique atom that combines with many atoms in multiple arrangements, owing to its four valence electrons available for bonding. Carbon may make single, double, or triple covalent bonds with other atoms or molecules.

Hydrocarbons

Hydrocarbons are molecules composed entirely of carbon atoms with hydrogen atoms attached. These molecules are often found in straight chains, with or without branches. *Saturated hydrocarbons* are single-bonded carbon chains with all available carbon bonds attached to hydrogen. Hydrocarbons containing only single-bonded carbon atoms are called *alkanes*. The six-carbon hydrocarbon shown in Figure 14-10 is called a *hexane*. The *hex-* prefix denotes six carbons and the *-ane* suffix denotes an alkane with all single bonds.

Unsaturated hydrocarbons have one or more double or triple bonds between carbon atoms. Hydrocarbons containing double-bonded carbons are called *alkenes* and triple-bonded carbons are

FIGURE **14-10** Hexane.

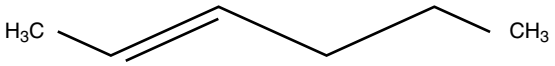

FIGURE **14-11** Hexene.

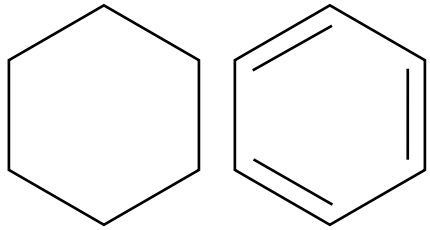

FIGURE **14-12** Hexane and benzene.

called *alkynes*. The six-carbon hydrocarbon containing a double bond is called *hexene* (Figure 14-11).

Cyclic hydrocarbons are carbon chains in a ring structure. They may contain multiple carbon atoms and may have single, double, or triple bonds. The cyclic hydrocarbons hexane and benzene (1,3,5 cyclohexatriene) are shown in Figure 14-12.

Saturated and unsaturated hydrocarbons that have hydrogens omitted are known as *alkyls*, are very reactive, and bond to functional groups. Cyclic hydrocarbons omitting a hydrogen on any carbon atom are called *aryls*, are reactive, and also bind with functional groups.

Functional Groups

Functional groups impart unique characteristics to molecules. There are many functional groups in organic chemistry, and several have importance in anesthesia.

Amines are derivatives of ammonia (NH_3) and have the general formula NR_3. Only one or two of the R groups may be hydrogen. All amines have a lone pair of electrons on the nitrogen.

Alcohols have the general formula ROH, where *R* represents any alkyl group. The hydroxyl group (OH) of alcohols is highly polar and easily forms hydrogen bonds with other polar molecules. The polarity of the hydroxyl group allows alcohols to dissolve many other polar molecules.

Phenols are similar to alcohols in that they both have the general formula ROH. The *R* in phenols instead represents an aryl group (benzene). A simple phenol is polar due to the hydroxyl group, but more complex phenols such as propofol (diisopropyl phenol) are not water soluble (Figure 14-13).

Ethers have the general formula ROR′, where *R* and *R′* are alkyl groups attached by oxygen. Ethers are inert and do not react with oxidizing or reducing agents but are highly flammable. The outdated anesthetic agent diethyl ether clearly shows both alkyl groups bonded to oxygen (Figure 14-14). Halogen substitution on ethers alters anesthetic characteristics, such as blood solubility and potency, while lowering flammability.

Several functional groups contain a structural arrangement of carbon double bonded to oxygen. This is known as a carbonyl group and structurally identified as C=O. The carbonyl group is polar, with the oxygen being more electrically negative. This polar characteristic is imparted to functional groups that contain a carbonyl group. The carbonyl group, though not a functional group

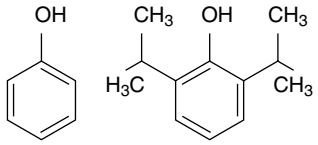

FIGURE **14-13** Phenol and disopropyl phenol molecules.

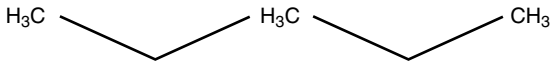

FIGURE **14-14** Diethyl ether.

by itself, is a key component of the following functional groups: aldehydes, ketones, carboxylic acids, esters, and amides.

- *Aldehydes* have the general formula RCHO.
- *Ketones* have the general formula RCOR′.
- *Carboxylic acids* have the general formula RCOOH.
- *Esters* have the general formula RCOOR.
- *Amides* have the general formulas $RCONH_2$, RCONHR, or $RCONR_2$.

SOLUBILITY

Solubility is the maximum amount of one substance (solute) that is able to dissolve into another (solvent). The factors that may affect solubility of solutes in solvents are the intermolecular interactions between the substances, temperature, and pressure.

Solids and Liquids

Solubility is enhanced by intermolecular interactions between substances that have similar electron configurations. "Like dissolves like" is often used to describe solubility. Salt (NaCl) in water is an example. The similar polarity of water and salt's constituent parts promote dissolving. Temperature also affects solubility. Energy is required to break the bonds of substances that are dissolving. Most often this is an endothermic reaction, which means it requires more energy than it produces. It consumes heat rather than produces heat. With endothermic reactions, solubility is increased with increased temperature; the additional energy (heat) drives greater dissolving. Most reactions of solids dissolving in liquids are endothermic. Occasionally the process may be exothermic, meaning energy is released in excess of the energy required to break the bonds of the solute. In this unique scenario, increases in temperature will decrease solubility. Pressure exerts little to no influence on solubility of solids and liquids.

Gases

Gas solubility in liquids is inversely related to temperature. As temperature increases, less gas is able to dissolve into a liquid. An increased temperature represents greater kinetic energy. Greater kinetic energy allows dissolved gas molecules to escape and prevents further dissolving. Lower temperature slows the kinetic energy of gas molecules, allowing them to dissolve into liquids. A clinical example of temperature affecting solubility is seen with the slower emergence of hypothermic patients receiving volatile-agent general anesthetics. The hypothermic patient retains anesthetic gases in the blood because of increased solubility related to temperature.[4] Gas solubility in a liquid is directly proportional to pressure and is described by Henry's law.[5]

Henry's Law

Henry's law (William Henry, 1775-1836) states "at constant temperature, the amount of gas dissolved in a liquid is directly

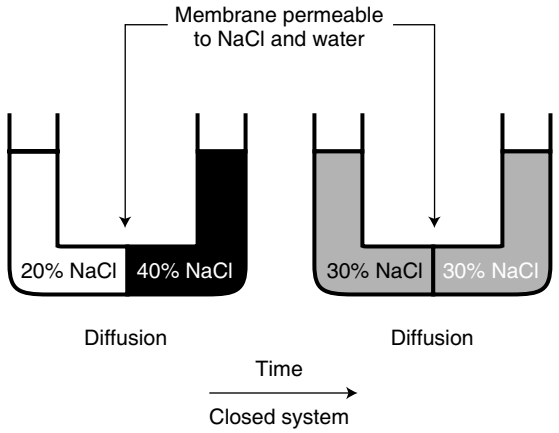

FIGURE **14-15** Diffusion of water and NaCl.

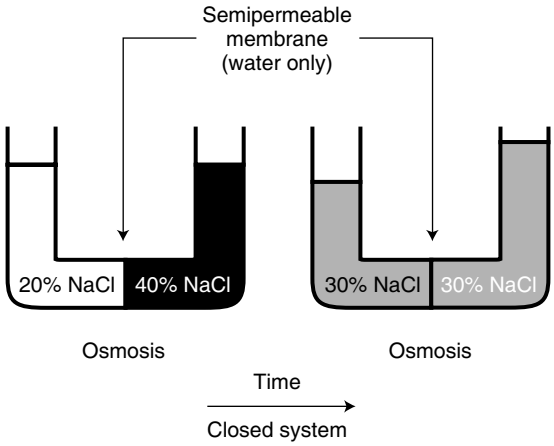

FIGURE **14-16** Osmosis of water through a semipermeable membrane.

proportional to the partial pressure of that gas at equilibrium above the gas-liquid interface." The formula is:

$$p = kc$$

where **p** is the partial pressure of the solute above the solution, **k** is Henry's constant, and **c** is the concentration of the solute in solution. Increasing the partial pressure of a gas above a liquid will increase the amount of gas that dissolves in the liquid. Increased delivery of oxygen (FIO_2) to patients to improve arterial oxygenation (PaO_2) and overpressurizing (high concentration) anesthetics reflect the direct relationship of pressure and solubility described by Henry's law. "Overpressurizing" is the process of significantly increasing a volatile anesthetic concentration (partial pressure) delivered to a patient to increase the alveolar concentration, and therefore the amount dissolved in the blood, to speed uptake.

DIFFUSION

Diffusion is the process of net movement of one type of molecule through space as a result of random motion intended to minimize a concentration gradient (Figure 14-15). This basic process occurs by Brownian (Robert Brown, 1773-1858) motion, which is driven by the inherent kinetic energy of the molecules.[6] Temperature is directly proportional to kinetic energy. Kinetic energy allows molecules to move freely in a fluid, and therefore mixtures of fluids tend to evenly distribute. The velocity at which a molecule may distribute is determined by its molecular weight. Every molecule at a given temperature will have the same kinetic energy, independent of its size, but its velocity may differ. From the formula for kinetic energy, KE = (½) mv^2, we can determine that if the mass of a molecule is changed, there must be an opposite change in velocity. Greater velocity correlates with faster diffusion. Thus, molecules with smaller mass will diffuse faster.

Graham's Law

Thomas Graham (1805-1869) determined that the rate of effusion (gas diffusion through an orifice) of a gas is inversely proportional to the square root of its molecular weight. The formula is:

$$r = 1/\sqrt{mw}$$

where **r** is the rate of diffusion, and **mw** is the molecular weight. Graham's law determines the faster diffusion of smaller molecules compared to larger molecules. Graham's law is helpful in understanding the effect of molecular weight on diffusion but is limited in fully describing all the factors influencing diffusion.

Diffusion Through Permeable and Semipermeable Membranes

Diffusion may occur through open space or through permeable membranes (tissues). If a fluid (gas or liquid) is permeable through a membrane, then the diffusion that occurs is dependent on five factors. These factors include concentration gradient, tissue area, and fluid tissue solubility, which are all directly proportional to diffusion. Membrane thickness and molecular weight are factors that are inversely proportional to diffusion.

Osmosis

Osmosis is the movement of water across a semipermeable membrane to equilibrate a concentration gradient (Figure 14-16). Semipermeable membranes are permeable to water only and not to solute. *Osmotic pressure* is the force needed to stop osmosis from occurring. *Oncotic pressure* is the osmotic pressure by plasma proteins and electrolytes in capillaries. Oncotic pressure balances the hydrostatic pressure tendency to push water out of capillaries. Normal oncotic pressure is approximately 28 mmHg. Our vascular system is a semipermeable membrane that responds to intravascular delivery of colloids by sequestering fluid.[7,8]

Diffusion in Anesthesia

Diffusion is a passive process driven by entropy (see Entropy in this chapter). The diffusion of oxygen and nitrous oxide represents both positive and negative consequences of this process. Nitrous oxide diffuses into air-filled cavities; therefore, delivery of nitrous oxide is contraindicated in patients with pneumothorax or where air-filled cavity expansion is undesirable.[9] Nitrous oxide expansion of endotracheal cuffs may cause tracheal mucosal damage.[10,11] Distention of bowel during nitrous oxide delivery also has been documented.[12,13] Apneic oxygenation is well known and exemplifies the beneficial process of diffusion.[14] An intubated patient who has previously been ventilated with 100% oxygen and remains connected to the ventilation circuit with 100% oxygen flow will maintain an acceptable PaO_2 if ventilation is ceased. The continual diffusion of oxygen into the blood is driven by a concentration gradient that continually diffuses oxygen into the alveoli via the ventilator circuit. The diffusion of gases across biological tissues is expressed by Fick's law.

Fick's Law

Fick's law for diffusion of a gas across a tissue plane is an encompassing law that accounts for molecular weight, concentration gradient, solubility, and membrane interactions. Fick's law states that diffusion

of a gas across a semipermeable membrane is directly proportional to the partial pressure gradient, the membrane solubility of the gas, and the membrane area and is inversely proportional to the membrane thickness and molecular weight of the gas. Specific application of the Fick equation for diffusion of respiratory gases is as follows:

$$J = \alpha D / \Delta x (Pao_2 - Pcapo_2)$$

where **J** is diffusion flux, **α** is the solubility constant for oxygen, **D** is diffusivity, **Δx** is the membrane thickness, and **(Pao_2 − $Pcapo_2$)** is the alveolar-capillary oxygen partial pressure difference. Fick's equation allows determination of pulmonary gas exchange.[15,16] The diffusion hypoxia that occurs after the delivery of nitrous oxide is discontinued, and low inspired oxygen is administered as explained by Fick's equation.[17]

NEWTONIAN PHYSICS

GRAVITY

All life on earth is well aware of gravity. From our first steps to our last, gravity affects every facet of our daily lives. It is a unidirectional force pulling objects down toward earth's center. Gravity appears to pull on heavy objects with greater force than lighter objects, but this is not necessarily true. Aristotle saw gravity this way and felt it was due to an object's desire to return to its natural position at rest on the earth. It took 2000 years to change that perspective. Gravity pulls on all objects with a force of 9.81 m/sec/sec (32 ft/sec/sec). Sir Isaac Newton's law of gravity derived that, "Each particle of matter attracts every other particle with a force which is directly proportional to the product of their masses and inversely proportional to the square of the distance between them." The formula for gravity is:

$$\text{Gravitational force} = (G \times m1 \times m2) / (d^2)$$

where **G** is the gravitational constant ($6.67 \times 10^{-11} Nm^2/kg^2$), **m1** and **m2** are the masses of the two objects for which you are calculating the force, and **d** is the distance between the centers of gravity of the two masses. Remember that mass and weight are not the same. Mass is the total of all matter in an object—the sum of all the electrons', protons', and neutrons' equal mass. Weight is the total effect of gravity pulling on all these electrons, protons, and neutrons of an object. An example often cited is that you may weigh 70 kilograms on earth due to the gravitational pull on all your atoms, but you would weigh less on the moon, which has less gravitational pull. Your mass or total amount of matter remains the same on earth or the moon.

$$\text{Mass} \times \text{force of gravity} = \text{weight}$$

The earth attracts all other objects around it with a force of 9.81 m/sec/sec, and those objects in turn attract the earth in relation to their mass and distance from the planet. The formula for gravitational acceleration is:

$$g = GM_e / r^2_e$$

where **g** is gravitational acceleration, **G** is the gravitational constant, $\mathbf{M_e}$ is the mass of earth, and $\mathbf{r^2_e}$ is the mean radius of earth. Earth's attraction for objects is proportional to mass for all objects at the same distance. One might want to say that larger-mass objects would accelerate or be pulled faster to earth, but objects also resist movement proportional to their mass (third law of motion). Gravity pulls on one atom of carbon with 9.81 m/sec/sec force, and the carbon atom resists this pull with a force of *x*. Gravity pulls on two carbon atoms with a force of 9.81 m/sec/sec on each atom for a total gravitational force of 9.81 m/sec/sec × 2, or 19.62 m/sec/sec. Two carbon atoms resist movement twice (2×) as much as one carbon atom, thus the net gravitational effect (falling) is the same. This is how greater-mass objects are pulled by gravity with the same force and fall at the same acceleration as lesser-mass objects.

This equal attraction on objects is often hidden in everyday life, owing to the effect of air molecules interacting with falling objects. Assuredly, all objects fall due to gravity at the same speed in a vacuum that is devoid of other molecules. Air molecules possess energy, move about, and interact with other matter. This causes friction. Greater friction equals greater force against the pull of gravity and slowing of a fall, but in a vacuum all objects fall equally at equal velocities.

NEWTON'S LAWS OF MOTION

- *Newton's first law* (law of inertia): A body in motion tends to stay in motion unless acted upon by another force.
- *Newton's second law* (law of acceleration): Acceleration of a body is in the direction of and proportional to the force (**F**), and that acceleration (**a**) is inverse to the mass (**m**) of the body, **F = ma.** If multiple forces exist, the direction and acceleration are proportional to the sum of all the forces. These are called *vectors*.
- *Newton's third law* (law of reciprocal action): For every action, there is an equal and opposite reaction. It states that objects exert equal but opposite forces on one another.[18] Example: An apple on a desk pulls down with a gravitational force equal to the force that the table resists.

FORCE

Force is the amount of energy required to move an object. From the understanding that the force of gravity pulls equally on all objects proportional to mass, a standardization of force became possible. Because we know that gravity pulls (accelerates) all objects with a force of 9.81 m/sec/sec, this force would also be 9.81 m/sec/sec if applied to any given weight. The force of gravity applied to 1 kg weight creates a standard by which other forces may be compared, quantified, and measured. Thus the force required to accelerate a 1 kg weight 1 meter per second became known as the *newton*.

The newton is the standard measure of force derived from the force of gravity.

$$\text{newton} = 1 \text{ meter} / \text{sec} / \text{sec}$$
$$= 1 / 9.81 \text{ kg weight or } 102 \text{ g weight}$$
$$\text{gravity} = 9.81 \text{ meter} / \text{sec} / \text{sec}$$

One newton is equivalent to 1/9.81 kg weight or 102 g weight. Force is mass multiplied by acceleration. The formula for force is:

$$F = ma$$

where **F** is force, **m** is mass, and **a** is acceleration. Often in settings of small measures of force, the newton is too large. A dyne is 1000th of a newton. A dyne is the force required to move a 1-g weight 1 cm per second. Dynes are used in calculating systemic and pulmonary vascular resistance.[19,20]

Pulmonary vascular resistance (PVR) is the measure of the pulmonary vascular system's resistance to flow from the right ventricle. Normal PVR is 100 to 200 dyne sec/cm^5. Systemic vascular resistance (SVR) is the measure of the peripheral vascular system's resistance to flow that must be overcome for flow to occur. The left ventricle must therefore pump blood with a force greater than the resistance of the vascular system. The formula for calculating SVR is 80 × (MAP − CVP)/CO = SVR. Normal SVR is 900 to 1200 dyne sec/cm^5.

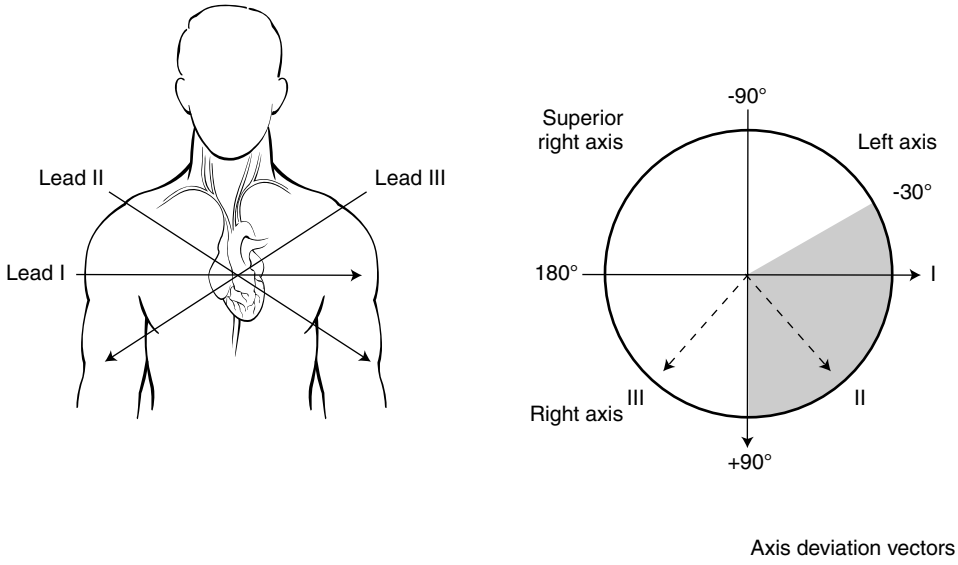

FIGURE **14-17** Electrocardiogram lead placement with vector direction and location of normal and abnormal axes.

Another application of force measurement in anesthesia is the technology of accelerometry used to measure the degree of neuromuscular blockade.[21,22] Accelerometry uses a piezoelectric disk to generate an electric current in proportion to acceleration (see Piezoelectric Effect in this chapter). An accelerometer measures the acceleration caused by the contraction of the adductor pollicis muscle after ulnar nerve stimulation. A comparison of baseline stimulated muscle twitches (forces) to twitches suppressed by neuromuscular blocking agents allows the quantification of the degree of neuromuscular blockade.[23] Accelerometers provide objective twitch data referenced to the patient's baseline twitch response.[24] Visual or tactile assessment of twitch heights is subjective and less reliable than accelerometry.[24,25]

Force is a basic phenomenon of physics that permeates the universe. Because all matter possesses mass, and all mass has some degree of acceleration, force exists everywhere. All forces possess direction. The study of force direction is explored with vectors.

Vectors

Two basic types of values describe our physical world: *scalar* and *vector*. Scalar values are fully described by magnitude alone, they possess no motion, and they include mass, energy, and work. Vector values are fully described by magnitude and direction. Vectors express motion and are described by the mathematics of force, speed, velocity, acceleration, distance, and displacement. Vector diagrams are scaled representations of vectors, with an arrow starting at a given magnitude and pointing in the direction of the force summation.

An electrocardiogram (ECG) is an example of a type of vector diagram that allows us to calculate the predominant direction of electrical force in the myocardium. An ECG records electrical flow as an upward or downward deflection on graph paper. When the flow is toward the positive electrode, an upward deflection will record. When the flow is away from the positive electrode, a downward deflection will record. Twelve-lead ECGs are scaled graphs with multiple points of reference used to measure the force direction of the electrical conductance. As multiple points of reference are recorded, direction of electrical flow predominance may be determined (vector summation). This is the principle behind determining axis deviation of the heart.

TABLE **14-3** Axis Deviation Determination Methods

Vector Method	Inspection Method	Grant Method
I+, aVF+ = Normal axis	I+, III+ = Normal axis	I+, II+ = Normal axis
I–, aVF– = Superior right	I– = Right axis	I+, II– = Left axis
I–, aVF+ = Right axis	III–, II– = Left axis	I–, II+ = Right axis
I+, aVF– see lead II (if II+ = Normal; if II– = Left axis)		I–, II– = Superior right

TABLE **14-4** Axis Deviations from Normal

Normal Axis	–30 to +90 degrees
Left axis deviation	–30 to –90 degrees
Right axis deviation	+90 to ±180 degrees
Superior right axis deviation	–90 to ±180 degrees

Axis deviation estimates the summation of forces that shift from the normal direction of electrical flow in the heart. Electrocardiogram vector diagrams are scaled clockwise from 0 degrees in the east position. The normal axis of electrical flow summation in the heart is between −30 degrees and +90 degrees. The axis determination steps that follow are based on identifying the positive (upward) deflections of the 12-lead electrocardiogram, which represents electrical flow toward the positive electrode. Because the normal axis of electrical flow is between −30 and +90 degrees, positive deflections in leads I and II would represent electrical flow in the normal direction. Negative deflections in lead I or lead II would reflect a deviation of normal axis and requires determination of the electrical flow vector. Vector deviations are described as *left*, *right*, or *right superior*. Several methods are available for quick determination of myocardial electrical axis deviation. Figure 14-17, Table 14-3, and Table 14-4 offer help in determining axis deviation.

PRESSURE

Pressure is defined as force over area, where **P** is pressure, **f** is force, and **a** is area.

$$P = f/a$$

Increasing the area in which a given force is applied will result in a lower pressure. The smaller the area to which the set force is applied, the greater the pressure. The standard unit of measurement for pressure is the pascal (Pa). A pascal is the force of 1 newton (N) over 1 square meter.

$$Pa = 1\ N/1\ m^2$$

A pascal equals 102 g weight acting over an area of 1 square meter. Remember, a newton equals 102 g weight. This is a very small unit of pressure. As the newton was fractionalized to the dyne for the purpose of establishing a more convenient unit of force measurement, the pascal was increased a thousand times to create the kilopascal (kPa) unit. A kilopascal is more convenient to use for measuring pressures. A kilopascal equals 1000 N or 102 kg acting over an area of 1 m^2.

$$Pa = 102\ g/m^2$$

$$kPa = 102\ kg/m^2$$

Syringes represent an example of the pressure generated by a force over a given area. Equal force (20 N) applied to the plungers of different syringes generates different pressures, depending on the area over which the force was applied. The force applied will cause greater pressure on injection with a tuberculin (TB) syringe (plunger area = 8.55×10^{-6} m^2) than with a larger 10-mL syringe (plunger area 3.42×10^{-5} m^2). As you increase the area to which a fixed force (20 N) is applied, the product of the equation, pressure (in atmospheres), becomes smaller.

$$P = f/a$$

$$\text{TB syringe: } 20\ N/8.55 \times 10^{-6}\ m^2 = 2339.18\ kPa,\ 17,543.94\ mmHg,\ \text{or } 23.08\ atm$$

$$\text{10-mL syringe: } 20\ N/3.42 \times 10^{-5}\ m^2 = 584.79\ kPa,\ 4386.28\ mmHg,\ \text{or } 5.77\ atm$$

$$\text{30-mL syringe: } 20\ N/5.99 \times 10^{-5}\ m^2 = 334.16\ kPa,\ 2506.40\ mmHg,\ \text{or } 3.29\ atm$$

These calculations show the extremely high pressures that can be generated by exerting a force over a small area. The tuberculin syringe generates more than 20 atmospheres of pressure and can rupture catheters if used to flush or dislodge blockages. Larger syringes are recommended for flushing or unclogging enteral feeding tubes because of the potential for generating high pressures with smaller syringes.[26-28]

Atmospheric Pressure

As previously discussed, gravity pulls on all objects, including the atoms and molecules of the atmosphere. Because these atoms and molecules have low mass, they have low gravitational pull but nonetheless are pulled toward Earth. The cumulative effect of gravity on atmospheric gases gives rise to atmospheric pressure. Atmospheric gases are less concentrated at altitude and more concentrated at sea level. Atmospheric pressure is the column of gravitational force on gases over a given area. This can be measured and is equivalent at sea level to 100 kPa (or 14.7 lb per square inch, 1020 cm of H_2O, or 760 mmHg—all equivalent to one another). *Standard pressure* in the SI is 100 kPa. Other units of pressure measurement include the following with their equivalents. It is best to memorize these:

1 torr = 1 mmHg
1 kPa = 10.2 cm H_2O = 7.5 mmHg

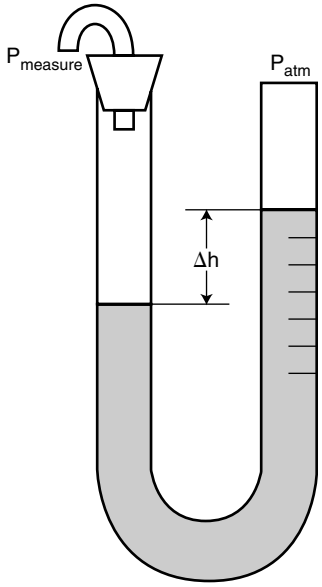

FIGURE **14-18** Manometer showing change in liquid column height *(Δh)* related to pressure applied.

1 atm = 760 mmHg = 760 torr = 1 bar = 100 kPa = 1020 cm H_2O = 14.7 lb/$inch_2$

Pressure Measurement

The simplest method for determining pressure is the manometer. A manometer is a liquid-filled tube that is open to atmospheric pressure on one end and exposed to a pressure for measurement on the other end (Figure 14-18). A pressure greater than atmospheric pressure (760 mmHg) will displace the column of liquid proportional to the pressure difference (Δh). Calibrating the column of liquid allows for quantification of the pressure.

A sphygmomanometer uses an inflatable cuff connected to a mercury-filled manometer to measure blood pressure. As the inflated cuff is slowly deflated, the arterial flow resumes, causing a pressure wave that is transmitted to a mercury column. The mercury column is calibrated to show the measured pressure in millimeters of mercury. A more recent advancement in blood pressure measurement is oscillometry. Oscillometry automates noninvasive blood pressure measurements by recording the oscillations in pressure caused by arterial pulsation.[29] As an inflated cuff is deflated, multiple measurements are made of these oscillations. Oscillations increase at systolic pressure and are maximal at the mean arterial pressure. Algorithmic computation of systolic and diastolic pressures is derived from the mean arterial pressure. Often these noninvasive automated blood pressure monitors use the piezoelectric principle to record the pressure oscillations and a microprocessor to derive the systolic and diastolic measurements.[30] Invasive blood pressure monitors use a piezoelectric transducer that converts pressure waves into electrical signals. Blood pressure measurements are gauge pressures that are zeroed to atmospheric pressure.

Gauge and Absolute Pressure

Different pressure measurements may use different zero reference points. The zero reference point may be a complete vacuum devoid of all molecules and molecular collisions that impart pressure. This is true zero pressure and is the reference point used when measuring absolute pressure. Absolute pressure is atmospheric pressure plus gauge pressure. Gauge pressure is zero

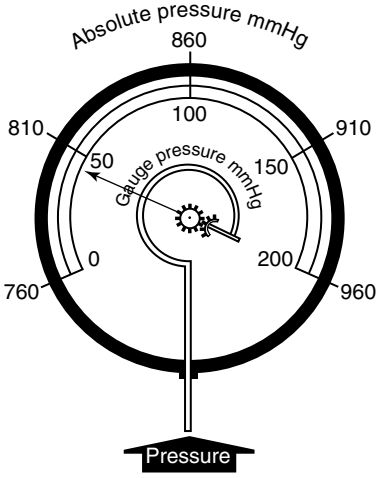

FIGURE **14-19** Bourdon gauge showing gauge pressure *(inside pressures)* referenced to absolute pressure *(outside pressures)*.

referenced at atmospheric pressure and reads zero at 760 mmHg at sea level. Gauge pressure is absolute pressure minus atmospheric pressure.

Bourdon gauges are often used in anesthesia to measure high pressures, such as in gas cylinders, and are zero referenced to atmospheric pressure (Figure 14-19). Bourdon gauges contain a coiled tube that expands as pressure is applied. A linkage connects the coil to a rotating arm that records the pressure. The American Society for Testing Materials International mandates that the zero reading of Bourdon gauges lie between the 6 o'clock and 9 o'clock positions. Other methods of pressure measurement in anesthesia include manometers.

THERMODYNAMICS

The three laws of thermodynamics explain the relationship between heat and energy and their exchange during work processes:

1. *Law of conservation of energy.* Energy cannot be created or destroyed. The increase in the internal energy of a thermodynamic system is equal to the amount of heat energy added to the system minus the work done by the system on the surroundings.
2. *Energy moves toward greater entropy or randomness*. The entropy of an isolated system not in equilibrium will tend to increase over time, approaching a maximum value at equilibrium.
3. *Absolute zero (0° K or −273.15° C) is void of all energy.* Absolute zero is theoretical, because it has been impossible to achieve. As a system approaches absolute zero of temperature, all processes cease, and the entropy of a system approaches a minimum value.

ENERGY

Energy can be defined as the exertion of force (kinetic) or the capacity (potential) to do work. Energy can be expressed as mechanical work, chemical reactions, or heat. The unit of measurement for energy is the joule. A joule is the force of 1 newton that moves its point of application 1 meter in the direction of that force. Two types of energy are potential and kinetic. Potential energy is energy waiting to be used. It is energy that is stored and available to be converted into power. Potential energy is defined as mass (**m**) times gravity (**g**) times height (**h**).

$$PE = mgh$$

Kinetic energy is energy of movement. *Kinetic* means movement. *Kinetic energy* is defined as one half the product of mass times the velocity squared.

$$KE = (1/2)\, mv^2$$

ENTROPY

Entropy is the universe's trend to equilibrate all things. It is the process that allows everything from ice melting to gas expansion. Sleep and the induction of general anesthesia have been proposed to be entropic processes.[31-34] All of these processes involve the equilibration of energy. Even matter is a form of energy. Entropy is unidirectional; it is the movement of energy from high concentration to lower concentration. It moves because of a gradient. The difference in the gradient influences the speed of the flow. Greater difference usually equals greater flow, and always from higher concentration to lower concentration. All energy and matter tend to follow this rule. An example of this unidirectional action is ice added to lemonade. Ice does not make lemonade colder, lemonade makes ice warmer. Diffusion, which will be covered later, is also a process driven by entropy. Entropy ends when all energy is equally distributed. Entropy is the underlying process promoting spontaneous and elicited movement in our everyday lives and the universe in general. Essentially, entropy drives the universe. This process should be kept in mind when learning or reviewing any dynamic concepts of anesthesia.[35]

TEMPERATURE

Matter may change form with the addition of greater heat energy. An example we see every day is the melting of an ice cube into liquid water, and liquid water into vapor with the addition of greater heat energy. Liquid water, with the addition of heat energy, expands. This is due to the water molecules moving apart with greater kinetic energy that ultimately allows them to escape individually as a vapor. Another liquid, mercury, also expands with the addition of heat energy. When placed in the bottom of a closed glass cylinder, the expansion is limited to one direction in relation to the energy applied. This is a simple application of heat energy (kinetic energy) interacting with matter to allow analysis of the thermal state: a thermometer.

Temperature is the measurement of the thermal state of an object. Heat is thermal energy; temperature is the quantitative measurement of that energy. Several temperature scales exist: Fahrenheit, Celsius, and Kelvin (Figure 14-20). Gabriel Daniel Fahrenheit (1686-1736) is credited with inventing the mercury thermometer (1714) and devising the Fahrenheit temperature scale. The Celsius (Anders Celsius, 1701-1744) or centigrade scale is the primary scale used for everyday temperature measurements. The Kelvin scale (William Thompson Lord Kelvin, 1824-1907) was developed to better reflect mathematically the temperature/pressure relationship of gases and is used when calculating their behaviors. Water freezes at 273.15° K and boils at 373.15° K. Conversion among temperature scales is as follows:

Celsius to Kelvin: °K = °C + 273
Celsius to Fahrenheit: °F = 1.8 (°C) + 32
Fahrenheit to Celsius: °C = (°F − 32)/1.8
Standard temperature is 273.15 K (0° C)

Heat Loss

Heat and energy are the same. Heat loss (energy loss) of a system, as discussed previously, is unidirectional from higher concentration to lower concentration, from hotter to less hot. Even ice possesses heat (energy). Remember absolute zero, 0° K (−273.15° C

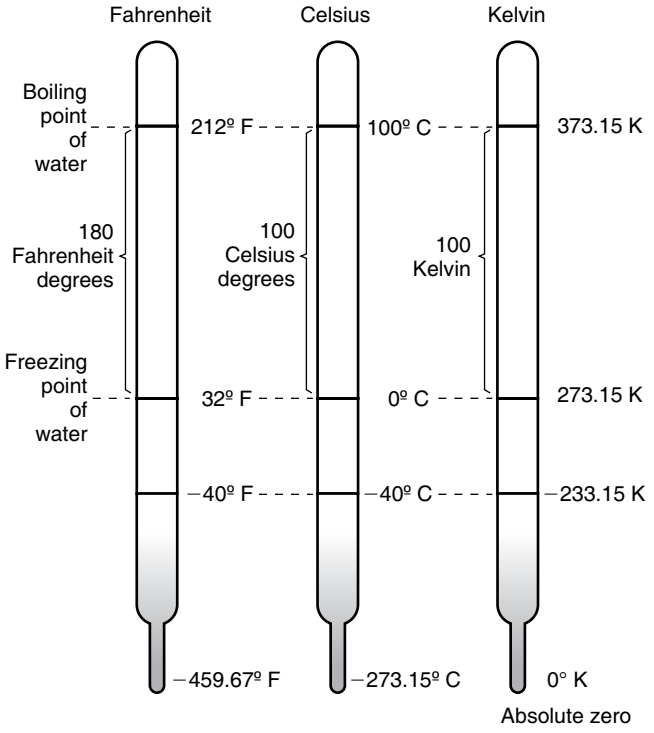

FIGURE **14-20** Temperature scales referenced to Kelvin.

or −459.67° F), is the absence of all energy and therefore absence of all heat. The human body is a system that contains energy. Much of this energy is in the form of heat. Our bodies continually exchange heat with the environment from high concentration to lower concentration. On a very hot day or in a very hot room, we could become hyperthermic. Similarly, in a cool room our bodies could become hypothermic, especially with exposed body surface. We will focus on heat loss in the cool operating room environment. Clothes, hair, skin, and fat insulate us from heat loss. Protective mechanisms exist that further lessen heat loss.

Vasoconstriction of peripheral vessels slows heat loss from our bodies. An example is the vasoconstriction seen in our limbs when exposed to a cold environment. The reverse thermoregulatory mechanism to promote heat loss is vasodilation when exposed to a hotter environment. The directing of blood to or away from our periphery aids in the removal or conservation of our body's heat energy. This thermoregulatory mechanism is disrupted under anesthesia by vasodilating drugs, specifically volatile anesthetics. Volatile and regional anesthetics vasodilate vessels, including those in the periphery, causing greater blood flow to the surface of our bodies.

Core Temperature Redistribution

Core temperature redistribution is the process of increased heat loss from the body resulting from the vasodilating effects of volatile and regional anesthetics, which cause greater blood flow and therefore heat flow to the body's surface from the core.[36-38] A patient's core temperature can quickly drop by the vasodilating actions of anesthetics, with the greatest decrease in the first hour.[37] It is imperative that one be cognizant of this heat loss mechanism and take measures to decrease it.[39-41] Covering all exposed areas of a patient minus the surgical site, wrapping the head in blankets, and warming the operating room all decrease heat loss. The use of forced warm air devices is effective at decreasing heat loss in the operating room environment.[42-44]

Blood flow to our body's surface encourages heat loss by four primary processes. In decreasing order they are:

1. Radiation
2. Convection
3. Conduction
4. Evaporation

Radiation

Radiation is the most significant mechanism of heat loss by our bodies, especially by patients under anesthesia. Radiation of the infrared electromagnetic wavelength transfers heat energy from our warm bodies to the less warm operating room environment (walls, ceiling, equipment, etc.). Electromagnetic radiation is pure energy. (See discussion on this later in the chapter.) Infrared radiation from our bodies is greatest in areas of highest blood flow. Our heads lose the greatest amount of heat due to the high percentage of blood flow. Blood carries body heat, and the greater amount of blood and heat transported to the head facilitates greater heat loss by radiation.

Convection

Convection is the process of creating air currents by heat. Our bodies transfer kinetic energy to air molecules on the surface of our skin. The heated air molecules then move about with greater kinetic energy, rise, and are replaced by colder (less kinetic energy) air molecules. Our bodies then transfer more kinetic energy to these molecules, they rise, and again are replaced by cooler air molecules. When thinking of convection, it helps to think in terms of *currents*.

Conduction

Conduction is the transfer of heat by physically touching a less warm object. Where two objects are in direct contact, heat exchange occurs from high concentration to lower concentration (entropy). An example would be holding a cold soda can. The sensation of cold is the direct loss of heat from your hand to the can. Cold is not transferred to your hand; heat is transferred to the can. A patient on a cold operating room table will conduct his or her heat to the less hot table wherever physical contact is present. This is not a significant process in adult patients, but for pediatric patients who have large body surface area to mass, it is quite significant. Use of warming blankets on operating room tables stops or reverses this heat transfer. Warming blankets may add heat energy to a patient, depending on the temperature and establishment of a thermal gradient.

Evaporation

Evaporation is not usually a large contributor to patient heat loss. Heat loss from evaporation includes moisture evaporated from the patient's skin, as well as exhaled water vapor. The process of evaporation, causing a phase change from liquid to gas, requires energy. The source of energy needed for this process comes from the surrounding environment of the evaporating substance. *Latent heat of vaporization* is the amount of heat energy per unit mass required to convert a liquid into the vapor phase. The energy withdrawn from the environment to convert one gram of water into vapor is 2500 joules, or approximately 600 calories. An example of this is the cooling off we feel after getting out of a swimming pool. The energy used to change the water into a vapor comes mostly from our bodies. Our body loses heat energy to this process, and we experience a state of lower thermal energy. Patients who have areas of their bodies surgically prepped with liquids (e.g., isopropyl alcohol, povidone-iodine, and chlorhexidine gluconate) experience heat

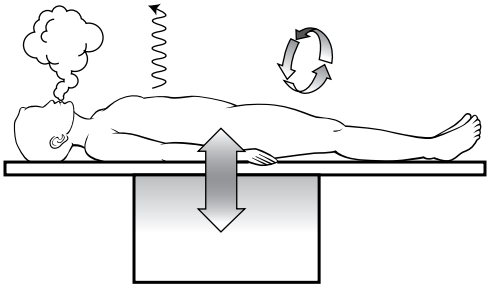

FIGURE **14-21** Heat loss mechanisms of radiation, convection, conduction, and evaporation in patients under anesthesia.

loss by this method. The process of breathing also causes heat loss through exhaled water vapor. This is not usually a high heat loss method in adult patients, but may become significant in pediatric patients when using high carrier gas flow rates. Lower carrier gas flows, when appropriate, and use of in-line humidifying apparatus decrease the evaporation of pulmonary water content and limit heat loss by this mode. One should consider these interventions with all intubated general anesthetics to prevent not only heat loss but also the pulmonary drying effects of dehydrate carrier gases.

Heat loss from patients is primarily due to radiation of infrared electromagnetic radiation.[45] Convection is the second largest method of heat loss in anesthetized patients.[45,46] Conduction and evaporation cause heat loss to lesser extents but remain a concern. Prevention of heat loss is extremely important to decrease higher morbidity experienced by hypothermic patients.[47-49] As Figure 14-21 illustrates, the use of forced warm air devices, lower gas flow rates, humidification systems, warming the operating room, and covering and insulating patients all are effective methods to decrease patient heat loss.[43,50]

Vaporization. Vaporization is the process of converting liquids or solids into vapors. Evaporation is the specific process of vaporizing liquids. Vaporization requires energy. As stated previously, the latent heat of vaporization is the energy needed to transform a given amount of liquid into a gas and is measured in kilojoules (kJ). The temperature at which the bulk of a liquid at a given pressure converts to a vapor is the *boiling point*. The temperature of a liquid will not rise above its boiling point; instead, the energy is used to transform the liquid into gas. Heating a liquid to its boiling point increases the kinetic energy of the liquid's molecules. Further addition of heat energy, above the boiling point, is transferred to molecules so they may break away from the surface and become a gas. "The rate of vaporization depends only on the temperature, the vapor pressure of the liquid, and the partial pressure of the vapor above the evaporating liquid."[51] As gas molecules escape the liquid, they exert a pressure known as *vapor pressure*, measured in millimeters of mercury. Increasing heat will increase molecular kinetic energy, which will increase the rate of vaporization. In a closed container, equilibrium will be achieved between molecules in the gaseous phase and those in the liquid phase.

All liquids that have high vapor pressures at room temperatures are known as *volatile liquids*. Vapor pressure and boiling points are inversely related. Vapor pressures of the volatile anesthetics at standard temperature and pressure (STP) are as follows:

- *Isoflurane:* 238 mmHg
- *Sevoflurane:* 160 mmHg
- *Desflurane:* 660 mmHg

Vapor pressures are unique characteristics of liquids that depend solely on temperature. Different liquids exert different vapor pressures at a given temperature. Because different volatile anesthetics have differing vapor pressures, vaporizers must be calibrated for each specific agent. Placing the wrong agent into a vaporizer will cause a greater or lower delivered concentration than dialed. If a high-vapor-pressure volatile anesthetic agent is placed inside a vaporizer calibrated for a lower-vapor-pressure volatile anesthetic, the output of that vaporizer will be higher than indicated on the control dial. If a volatile anesthetic agent with a lower vapor pressure is placed inside a vaporizer calibrated for a higher-vapor-pressure anesthetic, the output of that vaporizer will be lower than indicated on the control dial.[52]

Absolute Zero

The preceding discussion has covered the first and second laws of thermodynamics, with examples applied to the practice of anesthesia. With a unidirectional perspective and an understanding that energy cannot be created nor destroyed, the third law becomes self-evident. Absolute zero is the theoretical state devoid of all energy. No matter how much energy is distributed, it will still be present. Entropy to its universal maximum distribution will possess energy, even though it would be very low. There is energy in the universe, and therefore it will always be present in some form and to some degree. The absolute absence of energy is therefore impossible. That does not prevent us from calculating the theoretical temperature that would be devoid of energy. The theoretical temperature of absolute zero is −273° C (0° K, −460° F).

KINETIC MOLECULAR THEORY

Thermodynamics set the foundation for explaining the overall action of a system's energy. The kinetic molecular theory builds on Newtonian physics and thermodynamics and focuses on molecular movement (energy) and forces between these molecules. This theory explains how molecules behave as they follow the previously described laws of thermodynamics. Kinetic molecular theory was created to have a conceptual framework that encompassed the findings of Charles, Boyle, and Gay-Lussac and the *universal gas law* that unified their studies. A review of basic matter characteristics is as follows:

- *Matter* is composed of small particles called *molecules* and molecules are composed of atoms. Matter can take the form of solid, liquid, or gas.
- *Solids*—Molecules in a solid are held close together by intermolecular forces. They may move about slightly and vibrate.
- *Liquids*—Molecules in a liquid are held together by intermolecular forces and may slide or flow by one another.
- *Gases*—Molecules in a gas move linearly, and the attractive forces between molecules are less than their kinetic energy. They move almost completely free of one another.

The kinetic molecular theory, which best describes the action of gases, makes some generalized assumptions for simplicity:

1. Molecules have no volume.
2. Gas molecules exert no force on each other unless they collide.
3. Collisions of molecules with each other or the walls of the container do not decrease the energy of the system.
4. The molecules of a gas are in constant and random motion.
5. The temperature of a gas depends entirely on its average kinetic energy. The energy of a gas is entirely kinetic.

The kinetic molecular theory was created to explain the ideal gas law. Though the ideal gas law adequately explains the general behavior of gases, it does omit a gas molecule's small volume and intermolecular interactions. These flaws are further addressed in the section covering Van der Waal's equation.

TABLE 14-5 Gas Laws: Gas Properties and Relationships

Property Constant	Studied Properties	Property Relationship	Law
Pressure	Temperature, volume	Directly proportional	Charles
Temperature	Pressure, volume	Indirectly proportional	Boyle
Volume	Pressure, temperature	Directly proportional	Gay-Lussac

GAS LAWS

The foundations for the kinetic molecular theory were based on the discoveries of three scientists, Jacques Charles (1746-1823), Robert Boyle (1627-1691), and Joseph Louis Gay-Lussac (1778-1850). They each studied isolated components of pressure, volume, and temperature to explore the relationship of these components. Charles studied the relationship of volume and temperature when pressure is maintained constant. He found that the volume-to-temperature relationship is directly proportional. This means that at a constant pressure, volume will increase as temperature increases and vice versa. Boyle studied the relationship of pressure and volume when temperature is maintained constant. Boyle found that the pressure-to-volume relationship is indirectly proportional. Thus at a constant temperature, pressure will increase as volume decreases and vice versa. Gay-Lussac studied the relationship of pressure and temperature when volume is maintained constant. Gay-Lussac found that the pressure-to-temperature relationship is directly proportional. As pressure increases, temperature will increase and vice versa. The gas laws allow us to calculate the behavior of gases when one of the three factors of pressure, volume, or temperature is maintained unchanged. The clinical significance of these laws is expressed by the ability to calculate the available liters of oxygen from a cylinder of any known pressure. This and other examples are available at the end of the chapter. Table 14-5 summarizes the laws and the interrelationship of pressure, volume, and temperature.

Universal Gas Law

As the universal gas law unified the findings of Charles, Boyle, and Gay-Lussac, it also became known as the *unified gas law* or *ideal gas law*. The formula is as follows:

$$PV = nrT$$

where at standard temperature, **P** is pressure, **V** is volume, **n** is the number of moles, **r** is the constant 0.0821 liter-atm/K/mole, and **T** is temperature. A *mole* is a gram molecular weight of a gas. Atomic, or molecular, weight is the addition of all atomic particles, protons, neutrons, and electrons in an atom or molecule. An example is a mole of helium. Helium has a molecular weight of 4. Placing "gram" after helium's atomic weight gives us a "mole" of helium. Four grams of helium is a mole of helium. This amount of gas establishes a standard reference for calculations.

Using the universal gas law, you can calculate the volume for which 1 mole of a gas will expand at any given temperature or pressure. In the example given, we will calculate the volume in liters that 1 mole of oxygen will expand to at 1 atmosphere pressure at standard temperature (0° C). Celsius is converted to Kelvin.

$$1 \text{ atm } (x) = 1 \text{ mole } (0.0821 \text{ L atm / mol K}) (273 \text{ K})$$
$$x = 22.4 \text{ L}$$

One mole of any gas at 0° C will expand to 22.4 liters volume.

As this is a conceptual text, it is easier to view the universal gas law as PV = T to focus on the relationship between pressure, volume, and temperature. It is easy to see mathematically how increasing or decreasing any value would affect the other values as described previously. The universal gas law can be rearranged as follows:

$$PV = T \text{ or } T/P = V \text{ or } T/V = P$$

Increasing one value will increase or decrease the other values to maintain balance in the formula. The universal gas law allows understanding and quick determination of such things as: How much oxygen is available to be released from a partially full oxygen cylinder, and at what temperature will a full oxygen cylinder exceed its recommended pressure when heated?

Avogadro's Number

Amedeo Avogadro (1776-1856) was able to show that in a mole of any gas there are 6.023×10^{23} molecules. A mole of gas is equal to the molecular weight of the gas expressed in grams. A mole of helium would be 4 g and contain 6.023×10^{23} atoms. Similarly, a mole of oxygen (O_2) would be 32 g and contain 6.023×10^{23} molecules of oxygen. Oxygen is a molecule composed of two oxygen atoms bonded together, and therefore the molecular weight of the diatomic oxygen molecule is 32, not 16.

Van der Waal's Forces

Unfortunately, the simplicity of the universal gas law is not 100% accurate in fully describing the interaction of gases with their environment. The universal gas law is also called the *ideal gas law* because it explains the behavior of gases if they were "ideal." An ideal gas would possess molecules that occupy no volume and never interact with other molecules. Gas molecules do have volume and do occupy space, and therefore the volume they occupy must be taken into account when calculating a gas's expansion or contraction. The universal gas law does not account for gas molecule volume because Charles, Boyle, and Gay-Lussac did not account for this in their studies. (Remember, the universal gas law unified the work of Charles, Boyle, and Gay-Lussac.) An ideal gas also assumes no intermolecular forces. However, molecules do interact with one another, and this behavior alters the net effect of kinetics as calculated by the universal gas law. Van der Waal's (Johannes Diderik van der Waal, 1837-1923) equation corrects the universal gas law and accounts for molecular volume and molecular interaction in a gas. Van der Waal's equation is as follows:

$$(P + n^2a/V^2)(V/n - b) = RT$$

where **P** is the pressure of the fluid, **V** is the total volume of the container containing the fluid, **a** is a measure of the attraction between the particles, **b** is the volume excluded by a mole of particles, **n** is the number of moles, **R** is the gas constant, and **T** is the absolute temperature.

Because the deviations are not clinically significant, the universal gas law and molecular kinetic theory become immensely valuable in their simplicity to describe the behavior of gases.

Dalton's Law of Partial Pressures

Pressure in the kinetic molecular theory is purely the result of molecular collisions on the walls of a container. If there are more molecules in a container, there will be more collisions and thus greater pressure. Dalton's law (John Dalton, 1766-1844) states that the total pressure of a system is the additive pressures of each

individual gas in a mixture. Multiple gases in a mixture each will exert a pressure in proportion to its percentage in the mixture. The total pressure is the summation of individual molecular collisions upon the walls of a container.

$$P_t = P_1 + P_2 + P_3 + P_4 + P_5 + \ldots$$

An example is the mixture of gases that compose medical air at atmospheric pressure:

79% Nitrogen: 0.79 × 760 mmHg = 600.4 mmHg partial pressure nitrogen

21% Oxygen: 0.21 × 760 mmHg = 156.6 mmHg partial pressure oxygen = 760 mmHg total atmospheric pressure

Adiabatic Changes

Entropy in any system takes time. Rapid expansion or compression of gases may exceed the speed of energy equilibration with the surrounding environment. A rapid expansion or compression of a gas without equilibration of energy with the surrounding environment is called an *adiabatic* process and entails no increase or decrease in a system's energy.

Remember that the energy of a gas is almost entirely kinetic. Temperature is the measurement that quantifies the energy distribution among the molecules in a system. One could think of temperature measurement as a quantification of a system's kinetic energy per area. An example would be the experience of placing your hand into sunlight. The surface area of that sunlight measured is equal to the surface area of your hand. It is warm. Now place a magnifying glass of surface area equal to your hand into the sun and focus that same amount of sunlight energy onto a pinpoint area of your hand. Ouch! The same amount of energy experienced over less area is measured as a higher temperature. The temperature measurement is higher, but the system's energy total has not increased or decreased. The total sunlight energy hitting your hand is the same but distributed over different areas.

Energy Concentration Effect

Compressing a gas quickly will intensify the kinetic energy (molecular movement) such that the thermal measurement of the gas will be higher. This quick compression of the gas's area does not allow the system's energy to dissipate into the surrounding environment. Thus the temperature will quickly rise, proportional to the decreased volume. Although the temperature will be higher, the total energy of the system has not increased. A gas that is compressed quickly has little time to distribute any of its energy, so the thermal measurement becomes higher. This is the mechanism a diesel engine uses to ignite diesel fuel. Quick compression of fuel vapor intensifies the kinetic energy of the gas, with a corresponding increase in temperature, until the ignition temperature is achieved and spontaneous ignition occurs. This effect, though unlikely, could happen with a compressed gas cylinder that is quickly opened. The rapid reexpansion and recompression of gas as it rushes through the outlet channels of a cylinder could increase the temperature significantly. The high temperature generated could cause a burn or ignite any grease placed on the O-ring. Oil or grease is not recommended for use on any cylinder of compressed gas. Usually, rapid recompression in the cylinder stem is not a concern. It is possible and has occurred, but more likely the opposite will occur with rapid expansion of the gas as it leaves the cylinder.

Energy Dilution, Joule-Thompson Effect

The Joule-Thompson effect, named after James Prescott Joule, (1818-1889) and William Thompson Lord Kelvin, explains the cooling effect that occurs with adiabatic expansion of a gas. Rapid expansion of a gas causes the temperature measurement to decrease in the exact opposite process as explained previously. When we lower the pressure of a gas (increase its volume) quickly, we lower the energy per area. The temperature measurement will be lower when the volume is rapidly expanded. The total energy of the gas has not changed, but the expression, or thermal measurement, is decreased related to the increased volume. The temperature may be so low that frosting may occur at the cylinder outlet. Potentially, one could suffer a freeze injury. So why does this not always occur? If done slowly, energy from the environment will move into the gas, and ambient temperature will equalize with the less kinetic energy per area of expanding gas. The second law of thermodynamics, entropy, explains the maintenance of temperature when opening a gas cylinder slowly. Opening a cylinder slowly, therefore, would not be an adiabatic process. The slow opening of a gas cylinder allows the expansion of gas to draw energy from the environment to maintain an equal distribution of energy, and we observe no changes in temperature of the gas.

FLUID FLOW

Basic Principles of Fluid Mechanics

Fluids are defined by their response to stress. Stress is the distribution of force per unit area. The stress, or force distribution, may be tangential, and thus designated a shear stress, or it may be perpendicular and designated as a normal force. Strain is the deformation caused by stress. Fluids continuously change shape (flow) when subjected to shear stress, and respond in one of two ways to perpendicular forces:

1. Resist compression (e.g., liquids)
2. Become compressible and easily expandable (e.g., gases)

Both liquids and gases are fluids. Forces associated with fluids are gravity, pressure, and friction. Friction is resistance to flow from surface interaction and is proportional to viscosity. Viscosity is the physical property of a fluid that relates shear stress to rate of strain. Viscosity is the inherent property of a fluid that resists flow. Flow is the result of pressure forces in a fluid established by differences in pressure from one point to another, which creates a pressure gradient. All flow moves from higher pressure, or resistance, to lower. The following laws and principles apply to both compressible (gas) and incompressible (liquid) fluids. *Flow* is defined as the quantity of a fluid passing a point per unit of time, where **F** is the mean flow, **Q** is quantity, and **t** is time.

$$F = \frac{Q}{t}$$

Types of Flow

The three types of flow that occur through tubes and orifices are laminar, turbulent, and transitional. Laminar flow is a type of flow in which all molecules of a fluid travel in a parallel path within the tube. The molecules in the center of the tube encounter the least adhesive force of the walls of the tube and therefore move at a velocity twice that of the mean flow. Flow decreases approaching the walls and ceases at the wall. True laminar flow predominates in the smallest airways (terminal bronchioles). Transitional flow is a mixture of laminar flow along the walls of a tube with turbulent flow in the center. Turbulent flow is described as chaotic with irregular eddies throughout. Laminar, transitional, and turbulent airflow are illustrated in Figure 14-22.

Poiseuille's Law

Laminar flow is described mathematically by Poiseuille's law (Jean Louis Marie Poiseuille, 1797-1869). Poiseuille's law is:

$$F = (\pi r^4 \ \Delta P) / (8 \ n \ l)$$

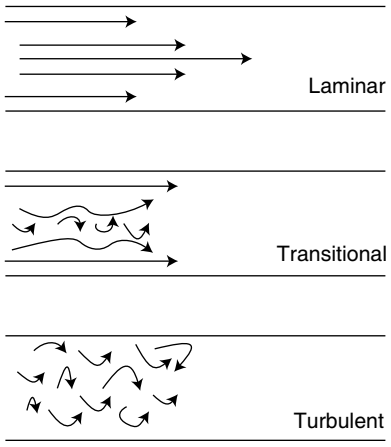

FIGURE **14-22** Three types of flow: laminar, transitional, and turbulent.

where **F** is flow, π is the constant *pie*, $\mathbf{r^4}$ is radius to the fourth power, **ΔP** is the pressure gradient, **n** is viscosity of fluid, and **l** is the length of tube. According to Poiseuille's law, radius will have the most dramatic effect on flow. Doubling the radius will result in a 16-fold increase in flow. A tripling of the radius increases flow 81-fold. Therefore, flow through a 16-gauge (1.65 mm) intravenous catheter is much greater than through a 20-gauge (0.89 mm) catheter. If the viscosity of a fluid is increased, flow decreases. Patients with polycythemia have decreased blood flow due to increased viscosity of blood. Increasing the length of a tube decreases the flow. If the length of a tube is decreased by 50%, there will be a corresponding doubling of the flow. If the length of a tube is doubled, flow decreases by half.

Clinical application of Poiseuille's law in anesthesia is exemplified as follows. To improve flow when delivering a unit of packed red blood cells, a large-diameter intravenous catheter (18 gauge or larger) is recommended, a pressure bag may be placed on the unit of packed red blood cells to increase the driving pressure (pressure gradient), and the packed red blood cells may be diluted with normal saline to lower viscosity.[53] These interventions are a direct manipulation of the factors associated with Poiseuille's law and significantly improve flow. Of all the changes that may be made, increasing the diameter of the intravenous catheter will have the most dramatic improvement of flow. Large-bore intravenous lines, such as an introducer central line, are best for rapid, large-volume infusion.

Mechanical ventilation of patients also reflects the factors associated with Poiseuille's law. The larger the endotracheal tube, the better flow of gas for ventilation. Delivery of β_2 receptor agonists, such as albuterol, have the effect of increasing the diameter of the bronchial tubes of the lungs to improve flow. Increasing the peak inspiratory pressure establishes a higher pressure gradient, which improves flow and delivered tidal volumes. Increases in the pressure gradient and flow velocity may initially improve flow but risks converting that flow to turbulent flow. Turbulent flow also may result when molecules of a fluid encounter rough, irregular walls or angles greater than 25 degrees. Turbulent flow often occurs in medium to large airways of the lung and predominates during periods of peak flow, coughing, and phonation. Orifice constrictions, such as glottic closure, cause laminar flow to become turbulent. Smaller bronchial tubes of the lung have slower velocities, and laminar flow is maintained. The presence of laminar, turbulent, or transitional flow is determined by Reynolds number.

Reynolds Number

Reynolds number (Osborne Reynolds, 1842-1912) is an index that incorporates the factors of Poiseuille's law with the addition of a fluid's density to determine whether a given flow will be laminar or turbulent. Reynolds number is directly proportional to the density of the fluid, linear velocity of the flow, and tube diameter; flow is inversely proportional to fluid viscosity. The equation is:

$$\text{Reynolds number} = \frac{vpd}{\eta}$$

where **v** is the linear velocity of fluid, **p** is density of fluid, **d** is diameter of tube, and **η** is viscosity. A calculated Reynolds number greater than 2000 will reflect a predominantly turbulent flow. Conversely, a Reynolds number less than 2000 will reflect predominantly laminar flow. Delivery of helium-oxygen mixtures to status asthmaticus patients, who are refractory to standard treatments, is based on the understanding of density's role in reestablishing laminar flow.[54] Helium, which has a significantly lower density (0.1786 g/L at STP) than nitrogen, (1.251 g/L at STP) improves flow by restoring laminar flow through the significantly narrowed airways of a severe asthma attack.

Bernoulli's Principle

Bernoulli's principle (Daniel Bernoulli, 1700-1782) describes the effect of fluid flow through a tube containing a constriction. As flow passes through a narrowing in a tube, the velocity of that flow increases and there is a corresponding decrease in pressure at the area of narrowing (Figure 14-23, A). This drop in pressure is explained by the conservation of energy law. For a steady flow of incompressible fluids, the sum of pressure, potential energy, and kinetic energy per unit of time must remain constant. The relationship of the pressure gradient to mass flow requires the pressure to decrease when the velocity increases. The Bernoulli equation is:

$$P + \tfrac{1}{2}\,\Delta V^2 + pgh = \text{constant}$$

where **p** is pressure, **Δ** is density, **V** is velocity, **g** is gravitational acceleration, and **h** is height. Bernoulli's equation is useful in determining flow through tubes that narrow, but it does not account for friction and assumes no changes in density or flow rate. The simplicity of this equation allows an explanation of the pressure velocity relationship if fluid flows across a constriction. The velocity of a fluid is the product of the flow rate divided by the area of flow.

$$\text{Velocity} = \frac{\text{Quantity of flow per unit of time}}{\text{area}}$$

If a given quantity of flow is 4 liters per minute over an area (tube) of 2 liters volume, the fluid velocity would be 2 liters per minute. If this flow meets a narrowing in its path that decreases the cross-sectional area to 1 liter volume, the fluid velocity would increase to 4 liters per minute.

$$V1 = \frac{4\ \text{L/min}}{2\ \text{L/min}} = 2\ \text{L/min}$$
$$V2 = \frac{4\ \text{L/min}}{1\ \text{L/min}} = 4\ \text{L/min}$$

This shows the increase in velocity associated with a narrowing in a tube for a given fluid flow (assuming no changes in density or height), and the conservation of energy law dictates there must be a corresponding decrease in pressure. The energy of the flowing system does not change because of a constriction, but rather the expression of that energy has changed. Essentially, more energy is imparted toward velocity as opposed to pushing on the walls of

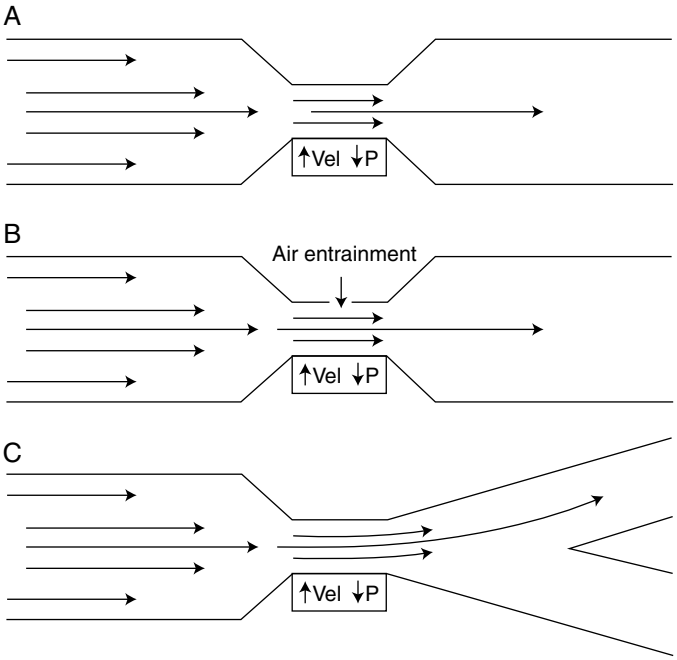

FIGURE **14-23** **A,** Bernoulli principle; **B,** Venturi effect; **C,** Coanda effect. *Vel,* Velocity; *P*, pressure.

the tube (pressure). Thus velocity increases and pressure drops to maintain conservation of energy.

Metered-dose inhalers (MDIs) use the Bernoulli principle to create a jet past a constriction that aerosolizes a drug in the expanding flow of gas. The necessity for large and sometimes cumbersome equipment is obviated by MDIs, which are able to consistently deliver aerosolized particles of medication into a fluid stream.[55] A more applicable example of the Bernoulli principle is the advantage taken of the pressure drop across the narrowing in a tube of fluid flow. The Venturi effect relies on the lower pressure at a constriction to entrain air or fluid into a fluid path.

Venturi Effect

The Venturi effect (Giovanni Battista Venturi, 1746-1822) utilizes the pressure drop across a narrowing in a tube. By placing an orifice at the narrowed region of flow, air is allowed to be entrained and enter the flow (see Figure 14-23, *B*). Air may be entrained into a flow of liquid, or a liquid may be entrained into the flow of a gas.[56] Jet ventilation uses this entrainment of air to augment lung ventilation volumes.[57-59] Nebulizers use the Venturi effect to deliver both humidification and medications such as albuterol.[60] Nebulizers effectively deliver medications into fluid paths, such as ventilator circuits, but have been replaced to a large extent by MDIs.

Coanda Effect

The Coanda effect (Henri Coanda, 1885-1972) explains the tendency of a fluid flow to follow a curved surface upon emerging from a constriction (see Figure 14-23, C). This may cause a preferential flow in one tube at a bifurcation just past a narrowing in a tube.[61] Beyond a narrowing in a tube, pressure will increase corresponding with a decrease in velocity of the fluid flow. If at a widening in a tube there is a division of flow with different angles, the return to a higher pressure will be at different points along the bifurcated tube. The bifurcated tube with the delayed reestablishment of higher pressure (and corresponding lower velocity) may preferentially attract a greater percentage of the total flow toward its path. The path with the greater flow will be at the expense of the other path. In situations in which the flow is blood in vessels or gas flow in the lungs, this diversion of flow could be consequential.[62-64]

Laplace's Law

Laplace's law (Pierre Simon Laplace, 1749-1827) describes the relationship of wall tension (**T**) to pressure (**P**) and radius (**r**) in cylinders and spheres.

- Cylinders: $T = Pr$
- Spheres: $2T = Pr$

Tension is a stress force exerted over a given area. It is measured in newtons per centimeter (N/cm). In cylinders, wall tension is increased with increased radius; similarly, increasing pressure will increase wall tension.[65] Laplace's law shows why smaller-diameter capillaries do not burst during periods of hypertension and larger vessels or aneurysms may. An abdominal aorta maintains a mean arterial pressure along its length, including an aneurysm if present. Aneurysms, which have a greater radius than the rest of the aorta, have a corresponding greater tension and are more likely to rupture. Laplace's formula, when rearranged, reflects the direct relationship of tension to radius in both the aorta and an aortic aneurysm at a constant pressure.

$$P = \frac{T}{r}$$

Example 1—Cylinders: If the mean aortic pressure is 100 mmHg with a normal radius of 2 cm and an aneurysm radius of 4 cm, the tension calculates as follows:

$$Pr = T$$

1. Normal aorta: 100 mmHg (P) × 2.0 cm (r) = (T)
   1.33 N/cm^2 (100 mmHg) × 2.0 cm = 2.66 N/cm
2. Aortic aneurysm: 100 mmHg (P) × 4.0 cm (r) = (T)
   1.33 N/cm^2 (100 mmHg) × 4.0 cm = 5.32 N/cm

The aortic aneurysm in this example has twice the wall tension of the normal aorta. (Millimeters mercury were converted to newtons in the formula). Any increases in blood pressure will increase the already high wall tensions of an aneurysm, and wall failure may result in dissection or rupture.[66]

In spheres, wall tension is increased twice as much, with increasing radius compared to cylinders. Applying Laplace's law to saccular aneurysms shows the relationship of increasing tension with increasing radius:

Example 2—Spheres: If the mean saccular aneurysm's pressures are 100 mmHg, with one radius 0.5 cm and the other 1 cm, the tension for each calculates as follows:

$$Pr = 2T$$

1. Small saccular aneurysm:

$$100\ \text{mmHg (P)} \times 0.5\ \text{cm (r)} = (2\ T)$$
$$1.33\ \text{N/cm}^2 (100\ \text{mmHg}) \times 0.5\ \text{cm} =$$
$$2 \times 0.665\ \text{N/cm} = 1.33\ \text{N/cm}$$

2. Large saccular aneurysm:

$$100\ \text{mmHg (P)} \times 1.0\ \text{cm (r)} = (2T)$$
$$1.33\ \text{N/cm}^2\ (100\ \text{mmHg}) \times 1.0\ \text{cm} =$$
$$2 \times 1.33\ \text{N/cm} = 2.66\ \text{N/cm}$$

Greater wall tension would be present in a large saccular aneurysm versus a small saccular aneurysm, and any increases in pressure would risk further increases in wall tension and rupture. Decreasing pressure will have the effect of decreasing wall tension across both cylinders and spheres and is the rationale for controlling blood pressure in patients with aneurysms.[67]

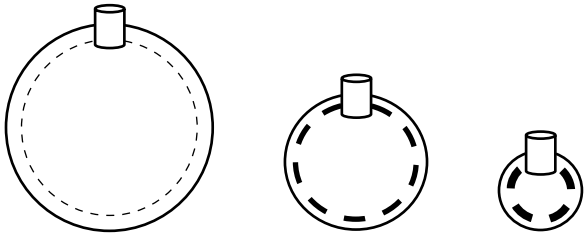

FIGURE **14-24** Increased surfactant concentration *(dashed line)* with decreasing alveolar size.

Laplace's law applied to a cardiac ventricle of increasing size explains the necessary inotropic response but eventual failure of contractility with increasing wall tension and pressure:

$$Pr = 2T$$

Increased pressure = Increased wall tension
Increased radius = Increased wall tension
Increased wall tension = Increased contractility (Frank-Starling curve)

Surfactant is a substance that lowers surface tension in alveoli to prevent the effects observed with Laplace's law. By lowering surface tension, the pressure in alveoli is lowered. Surfactant lowers surface tension more in smaller alveoli than in larger alveoli, owing to the effect of concentration when an alveolus contracts.[68] Greater surfactant concentration has greater surface tension–lowering ability. Surfactant therefore has the ability to equilibrate surface tension among different-sized alveoli and create stabilized alveolar pressures (Figure 14-24).

WAVES

Waves are a very important phenomenon in everyday life, as well as in anesthesia. Waves exist macroscopically, such as ocean waves and sound waves. They also exist within the atom and as light energy. Waves surround us and exist within us. To understand waves and wave action is to hold one key to understanding the basic ripple that permeates the universe. That basic ripple is energy. Waves are a periodic disturbance or motion. Waves are essentially the movement of energy. The "disturbance" is energy, and that is what is transported, or moved, along the wave front.

Wave Types

The two basic types of waves are transverse and longitudinal. *Transverse waves* are composed of up-and-down movement. In a transverse wave, the medium particles move perpendicular (up and down) to wave direction. *Electromagnetic radiation waves are transverse*. *Longitudinal waves* are composed of back-and-forth movement along the direction of the wave. In a longitudinal wave, the medium particles move forward parallel to the wave direction (propagation). There is no up-and-down motion in longitudinal waves. The wave energy causes only compression and decompression (rarefaction) to occur along its path. These are pressure fluctuations. *Sound waves are longitudinal.*

Wave characteristics:

- *Frequency*—Waves per second; measured in cycles per second called *hertz* (Hz)
- *Wave length*—Distance from one wave top (crest) to the next
- *Period or phase shift*—Describes how far the wave "slides"
- *Amplitude*—Height of wave
- *Speed*—Measured in meters per second
- *Wave part*—Crest is the wave top, trough is the wave bottom
- *Pressure waves*—Can be reflected, refracted, diffracted, or absorbed (interfered) by other waves
- *Reflection*—Waves reflect off of a medium in the same but opposite angle. The angle of incidence is the angle at which a wave strikes a medium.
- *Refraction*—Redirected in a new direction by contact with a new medium
- *Diffraction*—Spread or scattered; bending around an object
- *Absorption or interference*—Waves may interfere with other waves or be absorbed by matter. When waves interfere, amplitudes are additive. Constructive interference is when the *crest* of one wave passes through the *crest* of another wave or the *trough* of one wave passes through the *trough* of another wave, and the resultant wave is greater. Addition of two positive amplitudes or two negative amplitudes is a greater value or wave height. Destructive interference is when the *crest* of one wave passes through the *trough* of another wave. Amplitudes from one crest are added to the negative amplitudes from the other wave's trough, and the resultant wave is less.

Pressure Waves (Sound Waves)

Sound waves are pressure fluctuations that deviate from ambient pressure and are measured in pascals (Pa). Sound pressures are measured on a sound pressure level (SPL) that uses a logarithmic decibel scale to narrow the wide range (20 Hz to 20 kHz) of amplitudes audible to the human ear. Sound waves are longitudinal waves that propagate through matter (solid, liquid, gas) at varying speeds determined by the medium's elastic modulus (stiffness), density, and temperature. The speed of sound through air at 0° C is 740 miles per hour. In the absence of matter, there are no sound waves. Sound waves do not exist in a vacuum and only travel through matter.

Ultrasonography. Sound waves above the auditory limit of the human ear (20 kHz) are known as *ultrasound*. Ultrasonography uses ultrasound waves to construct a visual image of internal structures by examining the reflection of sound. Ultrasonography is useful for assisting simple procedures such as intravenous catheter insertion or for more invasive diagnostic assessment such as transesophageal echocardiography.[69-73] Ultrasonography uses a signal generator that transmits sound waves through tissues and a transducer to record the time delay for the returning reflected sound waves. The speed of sound waves in tissues is unique and constant to specific tissue compositions, and therefore the time delay of the returning reflected sound waves allows calculation of the location of different internal structures. Not all sound waves are reflected back to the transducer; some sound waves will have been refracted in a new direction, diffracted in multiple directions, or interfered with by tissues that cause attenuation or conversion to heat and resultant dissipation. The fraction of the original signal that is reflected back to the transducer must be amplified and processed into a visual display. The introduction of ultrasonography has been made possible by piezoelectric crystals that act as both signal generators and signal transducers (see Piezoelectric Effect). The process of a burst of ultrasound pressure waves followed by measurement of the reflected waves is done many times a second, permitting real-time imaging of internal structures by computational analysis.

Piezoelectric Effect. Piezoelectric crystals are unique quartz, ceramic, or polymer compositions that contain a matrix of polarized molecules that (1) respond to electric current by changing shape and (2) respond to mechanical stresses by generating an electric current. Piezoelectric crystals derive their name from the

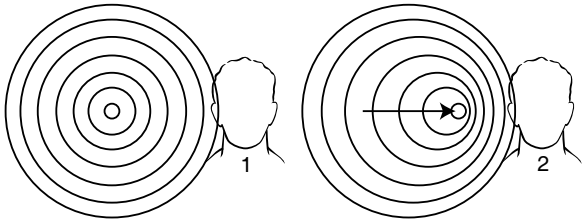

FIGURE **14-25** Doppler effect.

Greek prefix *piezein*, which means "to press tight or squeeze." The shape change caused by an electric current creates a pressure fluctuation around the crystal; this is a pressure wave. If a piezoelectric crystal is subjected to an alternating electric current, it will vibrate, creating many pressure waves in quick succession. The rate at which the crystal vibrates is called its *resonant frequency*. When not responding to an electric current, piezoelectric crystals are at rest and respond to the mechanical stress of the pressure waves by creating a small electric current.

Doppler Effect. The Doppler effect (Christian Johann Doppler, 1803-1853) describes the change in frequency of a propagated wave from a moving object. The sound of a siren changes to a higher frequency as it approaches a listener and lowers in frequency as it departs. Listener 1 in the Doppler effect figure (Figure 14-25) will hear a sound emitted from a stationary object with a fixed frequency. Listener 2 will hear a sound emitted from a moving object with increasing frequency as the sound approaches and lessening frequency when it passes. This is due to the "stacking up" of the wave fronts emitted from an approaching object and the stretching of the wave fronts when it recedes.

The Doppler effect when applied to echocardiography allows the determination of blood flow direction and speed. As blood cells flow to or away from an ultrasound signal, reflected waves are either compressed or expanded. This change in frequency allows calculation of blood velocity:

$$V = \frac{\Delta f}{\cos\theta} \times \frac{c}{2f_t}$$

where velocity of blood is **v,** Δ**f** is the difference in transmitted frequency and received frequency, $\mathbf{f_t}$ is the transmitted frequency, **c** is the speed of sound in blood, and $\boldsymbol{\theta}$ is the angle of incidence between the ultrasound beam and blood. Spectral display presents Doppler ultrasound data in a time-velocity graph that allows greater assessment of hemodynamics on a beat-to-beat basis.

Electromagnetic Waves

The term *electromagnetic* succinctly expresses the dual nature of *electricity* and *magnetism*. The two are intimately intertwined. Where there is electric current, there are also magnetic waves. Where there are changing magnetic waves, there is also an electric current. Electromagnetic radiation is composed of two waves, electric and magnetic, oscillating in unison but perpendicular to one another. The whole electromagnetic wave propagation is perpendicular to these oscillating waves. Electromagnetic waves possess both electric and magnetic potential. Electromagnetic waves (electromagnetic radiation, EMR) are similar to pressure waves in that they both possess frequency and amplitude. Another similarity is that they may be reflected, refracted, diffracted, or absorbed. The unique wave properties of EMR include its composition, velocity, and independence of transport by matter. Electromagnetic radiation differs from pressure waves (sound waves) in their velocity. The speed of EMR in a vacuum is 3×10^8 m/sec (186,000 miles/sec), whereas sound cannot exist in a vacuum. The speed of

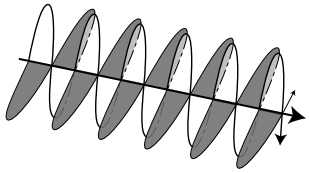

FIGURE **14-26** Electromagnetic wave showing electric wave oscillating perpendicular to magnetic wave.

TABLE 14-6 Comparisons of EMR and Sound Wave Properties

	EMR	Sound Waves
Speed	300,000,000 m/sec	344 m/sec
Wave type	Transverse	Longitudinal
Energy motion	Perpendicular to propagation	Parallel to propagation

EMR, Electromagnetic radiation.

EMR in air closely approaches 3×10^8 m/sec. The speed of sound in air is only 331 m/sec (740 miles/hr). Electromagnetic radiation and sound waves may travel through matter at varying speeds, but only electromagnetic radiation can propagate independently of matter. Sound waves only travel through matter and cannot exist in a vacuum, as shown in Figure 14-26 and Table 14-6.

Inverse Square Law

Waves represent a propagation of energy from a source. As energy moves away from its source, its strength decreases. Newton showed that the strength of the emanating energy is inversely proportional to the square of its distance from its source. Newton originally calculated this for the force of gravity; however, it has application throughout physics.[74]

$$I1 = \frac{(d2)^2}{I2\ (d1)^2}$$

where **I1** equals intensity at the original distance, **I2** is the lower intensity at a new distance, **d1** is the distance from original source, and **d2** is the new distance from the source. This is represented by the inverse square law figure (Figure 14-27), where the y plane is twice the distance from the source than is plane *x*. The energy intensity at I2 is one fourth the intensity at I1. The inverse square law applies to pressure waves, electricity, light, and radiation, with the intensity of each decreasing with increasing distance from its source.

Magnetism

Magnets are unique matter that have charges aligned in an orderly fashion. There are flows of magnetic currents, or field lines, in all magnets. To observe these invisible fields, place a magnet under a piece of paper and spread iron filings on top. The filings will line up along the magnetic fields. Magnetism is a force between electric currents. Flowing charged particles not only move energy along that current but also disrupt, or alter, the surrounding environment. This "altering" is not apparent unless one is looking for it. Hold a compass near a wire carrying an electric current. The needle will move and align itself along the flow of magnetism. Turn the wire, and the compass needle will turn. There is a force between the electric current and the compass needle (magnet). Magnetic fields are measured with a gauss meter in units of teslas; 10,000 gauss (G) equal one tesla (T). The earth's magnetic field

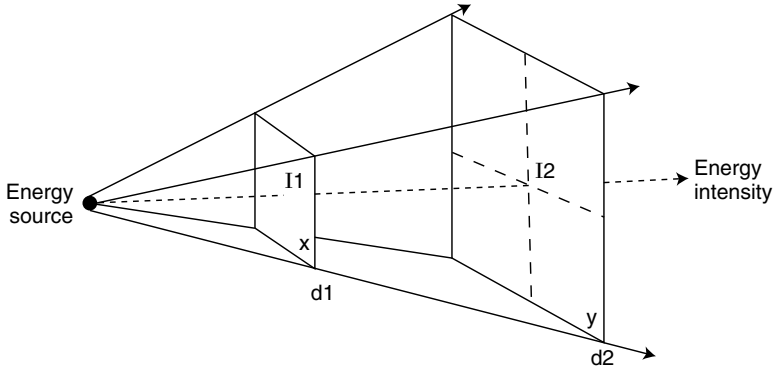

FIGURE **14-27** Inverse square law representation of decreasing intensity with increasing distance.

strength is 0.00005 T (0.5 G). A small magnet's strength is 0.01 T (100 G). The magnet's strength in a magnetic resonance imaging machine is 1 to 3 T (10,000 to 30,000 G).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) uses a strong, continuous magnetic field to uniformly realign the spin of protons within the hydrogen atoms of water. As the axes of protons are pulled into one of two possible positions of realignment, a radiofrequency pulse is delivered at resonant frequency to energize the protons. The protons will then reemit this energy. The radiofrequency pulses are delivered in thin "slices" that may be made in the sagittal, coronal, or axial planes. Computer-generated analysis of data produces very detailed representations of internal tissues. The magnetic field used is very strong, and specific safety considerations need to be addressed when delivering anesthesia care in an MRI suite.

MRI Safety. Because of the high strength of the magnetic field in and around an MRI scanner, special precautions must be observed. Any ferrous material will interact with the magnetic field, gaining kinetic energy and thermal heat. Movable ferrous objects will also be attracted to the MRI magnet and will be pulled into the magnetic field with great force. Patients and personnel are at potential risk for both thermal injuries from implanted ferrous objects and traumatic injury from ferrous objects violently pulled into the magnetic field. The American College of Radiology has designated four safety zones that surround an MRI scanner, with zone 4 representing the immediate area around the scanner. Zone 4 poses the greatest risk of injury and has the most stringent guidelines.[75] All ferrous materials such as pagers, phones, jewelry, identification badges, and pens must be removed before entering zone 4. Patient stretchers, oxygen tanks, IV poles, and any other ferrous objects must be kept outside zone 4. Specially designed stretchers and anesthesia machines are designated for zone 4 to prevent attraction to the magnet.

Implanted ferrous materials such as ferrous foreign bodies, prosthetics, stents, and pacemakers have been studied for MRI safety. Review of current literature for acceptability for scanning is recommended.[75-78] Many implanted devices can be safely scanned in an MRI, and any knowledge or concerns of potential ferrous interaction should be brought to the attention of the designated MRI personnel.[75]

Electricity

Electricity is the change in potential energy caused by the movement of electrons from an area of high concentration (high charge density) to an area of low concentration (low charge density). The fundamental unit of charge is ***e***; it represents one electron's energy and is extremely small. Dealing with the energy of a single electron is difficult, so we use a quantized measurement called a *coulomb* (C): C = 1.6022210^{19} ***e***.

Coulomb's Law

Coulomb's law (Charles-Augustin de Coulomb, 1736-1806) states that like charges repel each other, and opposite charges attract each other inversely to the square of their distance. In short, opposite charges will attract more when closer together, and like charges will repel more when closer together. The electrical potential energy unit is the *volt*. It represents electrical "pressure" or the gradient of charges that could potentially flow. Electric current (I) is the rate of flow of an electric charge through a *conductor*. In operating room electrical equipment, the conductor is usually copper wire. Copper is a good conductor, and therefore the resistance to flow is low. Insulators, also known as *dielectrics*, do not have electrons that are easily moved and therefore resist the flow of electricity. Current is measured in amperes. An *ampere* (A) is the flow of 1 coulomb per second, 1 A = 1 C/s. A *volt* is the SI unit for a joule per coulomb.

Ohm's Law

The potential flow of electric charge is proportional to actual current, after accounting for resistance. Resistance is calculated by Ohm's law (Georg Ohm, 1789-1854):

$$E = IR$$

where **E** represents volts (V) or potential energy, **I** is current, and **R** is resistance. Resistance is measured in ohms (**Ω**). Ohm's law measures resistance to electrical flow (Figure 14-28).

Electrical Flow

The flow of electrons in electricity is from a surplus of electrons to a deficiency of electrons. Electricity must have a complete circuit for electrical flow to occur. A simple circuit is shown with a positive side (live, hot), a negative side (neutral), and a ground. The ground is a conductor that is connected to the earth (ground) and provides a low, resistive, alternate route for electricity to flow in the case of electrical surge. Electricity may be *direct current* (DC) or *alternating current* (AC). In DC circuits, the flow of electrons is always in one direction. In AC circuits, the flow of electrons reverses direction (alternates) at a set frequency, usually 60 Hz (United States) or 50 Hz (Europe) (1 *Hz* equals 1 cycle per second). Electricity is delivered by the power company as AC because its voltage can easily be maintained while traveling long distances to customers via the power grid. Operating

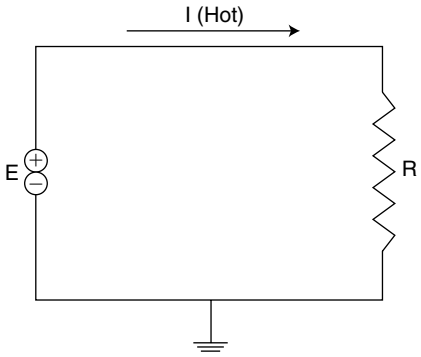

FIGURE **14-28** Basic electric circuit showing a live (hot) wire (*I = current*), a load (*R = resistance*), and a grounded neutral wire (*E = volts*).

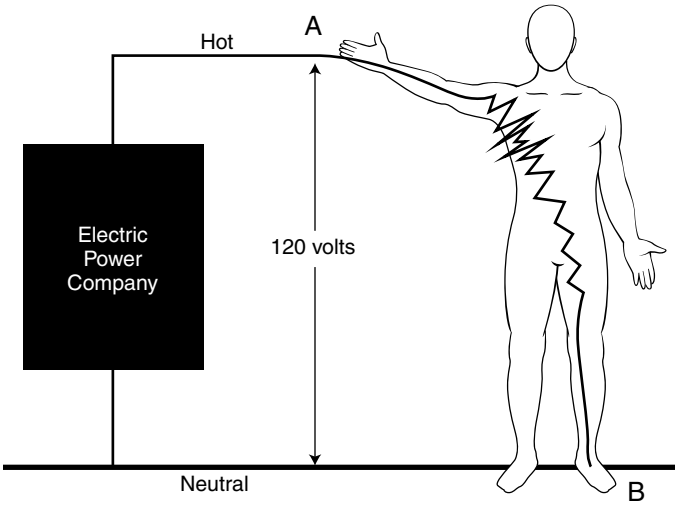

FIGURE **14-29** Electric shock. *A* is point of contact and *B* is connection to ground.

room equipment and most residential and institutional electrical equipment operate on AC. A simple AC circuit is the same as a simple DC circuit, except resistance is more complex with AC circuits, and the positive side alternates between both wires. In AC circuits, resistance is called *impedance* and is the total of all forces that impede electrical flow. In addition to the inherent characteristics of the conductive material, capacitance and inductance contribute to AC impedance. *Capacitance* is the capacity to store charge. A capacitor is composed of two parallel conductive plates separated by an insulator. When a capacitor is exposed to a voltage source in an open circuit, one plate will store a positive charge, and the other will store a negative charge. Capacitors have useful application in electronic devices but have the ability to leak *stray capacitance*. There are no absolute insulators, and stray capacitance may create an unintended charge in the casing of electrical equipment. *Electromagnetic inductance* is the transfer of an electric current between circuits without physical contact, using induced magnetic waves. Any conductors carrying an electric current will also carry a magnetic field. In AC circuits, the charge is alternating and so too will the magnetic field change. This changing magnetic field may induce a small electric current in nearby conductive materials such as equipment metal casings, despite no physical contact between the circuit and the casing.

Electric Shock. Stray capacitance and inductance may contribute a low risk of shock because they are low current flows. Direct contact of exposed electrical wiring constitutes great risk of electric shock because of higher voltages. Current leakage from wires to equipment casing exposes patients and operating room personnel to the risk of shock by three mechanisms:

1. Direct wire contact with metal casing due to insulation damage or faulty construction
2. Inductance due to the flowing alternating current's magnetic field, producing a small electrical flow in the surrounding metal casing despite no direct contact
3. Stray capacitance from the buildup of electrical potentials with an alternating current circuit despite no closed circuit electrical flow[79]

If a patient or operating room personnel make contact with both a live wire and ground they may complete an electric circuit and receive a shock. For a shock to occur, a complete circuit must be made. This can happen if a person is standing on the earth and contacts the live wire in a circuit (Figure 14-29). Shocks may be macroshock or microshock. *Macroshock* refers to large amounts of current conducted through the patient's skin and other tissues. Injuries may be minor or severe, depending on amount of current and duration of exposure. Electric current seeks the path of least resistance and is often dissipated throughout the body tissues. The amount that reaches the heart is often insufficient to cause arrhythmias.

TABLE **14-7** Effects of Macroshock and Microshock

Macroshock (mA)	Effect
1	Perception
5	Maximal harmless current
10-20	"Let-go" current
50	Loss of consciousness
100-300	Ventricular fibrillation
6000	Complete physiologic damage
Microshock (μA)	**Effect**
20	Ventricular fibrillation in dogs
100	Ventricular fibrillation in humans[53]

Conductive materials in a patient's body, though, may place that patient at greater risk by providing a low resistive path for electricity to flow to the heart. *Microshock* is the delivery of small amounts of current directly to the heart. The amount of current that may produce ventricular fibrillation has been found to be 50 microamperes or lower.[80,81] Table 14-7 gives a comparison of how different levels of microshock and macroshock affect the human body.

Electrical Safety. To decrease the risk of shock, operating room electrical systems are isolated from the main grounded electrical supply system. A *transformer* is used to isolate the electrical supply systems from one another. A transformer uses the principle of magnetic inductance to transfer electricity from one system to another system without having physical contact. This allows the operating room power supply to be ungrounded, preventing a circuit from being completed when a person contacts one live wire. However, if a person contacts both wires in a circuit, shock may occur as the path of electricity flows through the person from one line to the other. Operating room equipment casing (housing) is grounded to divert electrical flow in case of internal live wire contact with the metal housing.

If there is contact of the live wires to ground (fault), such as through touching the equipment casing, the system will become

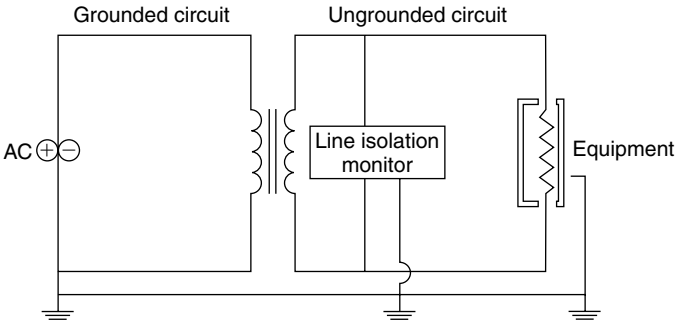

FIGURE **14-30** Ungrounded operating room electric circuit isolated from grounded hospital electrical system. Note that electrical equipment casing and line isolation monitor are connected to ground, but the electric circuit is not.

a grounded system. A second fault will enable a shock, because the newly grounded system will allow a completed circuit to pass through a person in the operating room that is grounded when a live wire is contacted. To prevent a first fault from being unnoticed, a *line isolation monitor* is placed between the live wires and ground to measure their impedance to flow (Figure 14-30).[82] If a live wire has contact or high capacitance to ground, the line isolation monitor will alarm. Line isolation monitors are usually set to alarm at 2 to 5 mA potential leak. If a line isolation monitor alarms, the last equipment plugged in should be disconnected and inspected to verify it is the offending piece of equipment. Equipment that activates a line isolation monitor may still be operational but increase the potential risk of shock should a second fault occur, because it has converted the isolated power supply system to a grounded system. Line isolation monitor alarms may also be activated because of the cumulative effect of minor leakages of many pieces of properly functioning electrical equipment. This does not mean a risk is present. Newer systems alarm at 5 mA to account for this normal leakage.

Electrocautery

Electrocautery devices use high-frequency electric currents to cauterize, cut, and destroy tissue. These devices may be unipolar or bipolar. Bipolar electrocautery devices have two tips, one to supply the electric current and the other to return the current. Bipolar devices do not require a return electrode and are less likely to cause burn or injury apart from the local area of use. Unipolar devices have only one tip to deliver an electric current, and a large-surface-area return electrode with good conductive contact must be placed on the patient. The path of current flow from the unipolar device to the return electrode should not cross the patient's heart.

The high current flows used in electrocautery units may cause electromagnetic inductance, which in turn may cause artifact in other electrical equipment such as ECG monitors. Pacemakers may also sense the electromagnetic inductance as inherent electrical activity and not initiate a paced impulse. This would put the patient at risk for asystole if there is no inherent underlying heart rhythm.[83] Electrocautery interference has also been documented as initiating paced tachycardic rhythms.[84,85] Placing a pacemaker magnet over the patient's pacemaker resets it into a continuous, asynchronous mode. Not all pacemakers are reset into a continuous, asynchronous mode, and pacemaker interrogation to understand its settings and functions should be considered prior to surgery using electrocautery.

QUANTUM PHYSICS

ELECTROMAGNETIC RADIATION

Newtonian physics is helpful in describing the wavelike properties of EMR but is incomplete in its description. Originally it was assumed that EMR, like sound waves, was propagated through a medium. A "luminiferous ether" was thought to fill the universe and was the suspected medium through which EMR traveled. The famous Michelson-Morley[86,87] experiment successfully disproved the existence of the "ether" but left open an explanation of how EMR propagates. Max Planck (1858-1947) later theorized EMR was *quantized*, meaning it was emitted only in discrete quantities of energy, and this revolutionized our perspective of the universe. Planck's constant expresses the quantized nature of EMR defined by energy, time, and frequency:

$$E = h\nu$$

where **E** represents energy, **h** is Planck's constant (6.626068×10^{-34} m^2 kg/sec), and ν is frequency.[88] Albert Einstein introduced the photon concept of Planck's discrete energy quanta and together with others ushered in the study of quantum mechanics.[89,90] Quantum mechanics is a branch of physics that explores the subatomic dynamics of pure energy and the quasi-realm of energy/mass transition.

Electromagnetic radiation is now thought to travel as photons or packets of energy and can be observed as both a particle and a wave, depending on how scientists study and measure it. The dual nature of behaving as both a particle and a wave is unique to EMR.[91] EMR is called a *photon* when it exhibits particle-like behaviors. Despite its behavior, photons have no mass. They are pure energy. The energy of EMR is directly related to its frequency. Higher frequencies correspond to higher energies, and lower frequencies correspond to lower energies. The velocity of EMR in a vacuum remains constant and does not change related to frequency. The understanding of energy as a quantized event promoted numerous advances in physics, which ultimately found application in anesthesia. The perspective of EMR as photons allows us to better explain many dynamic interactions of EMR and matter. Figure 14-31 shows the EMR spectrum.

ELECTROMAGNETIC RADIATION/MATTER INTERACTION

Electromagnetic radiation exists independently of matter. Sound (pressure) waves do not exist without matter through which their energy is transmitted. Both may be reflected, refracted (scattered), diffracted (redirected), or absorbed (interfered) by matter (Figure 14-32). An example of the interaction of EMR with matter is visible light. Visible light is composed of a narrow band of EMR frequencies between 4.3×10^{14} and 7.5×10^{14} (400 to 700 nm). These frequencies of EMR are the only frequencies our eye receptors can detect. When we "see" a color, we see the reflected frequencies that correspond to that color. Visible light is composed of the colors red, orange, yellow, green, blue, indigo, and violet and were first described by Newton. Visualizing the color blue represents the reflected EMR frequencies between 495 and 570 nanometers. The other visible light frequencies are not seen, because they have been absorbed and scattered by the material that appears blue. Materials that absorb EMR increase their vibration energy (kinetic energy), owing to their absorption of energy. We experience an example of this when wearing white or black clothing in sunlight. Black clothing absorbs many more frequencies of visible light and gains greater kinetic energy, which causes heat. White clothing appears white because of the high reflection of the visible light spectrum; it gains less kinetic energy and therefore less heat.

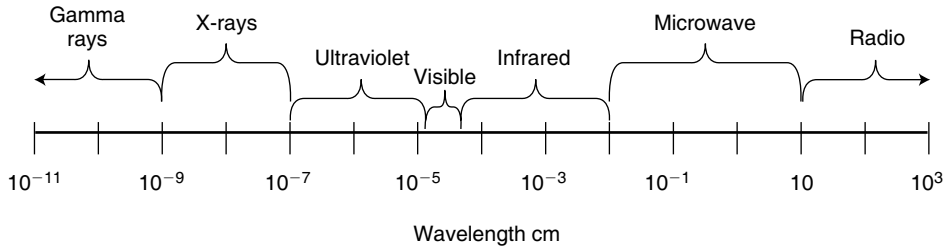

FIGURE **14-31** Electromagnetic radiation spectrum. Increasing energy associated with decreasing wavelength (increasing frequency) along the electromagnetic radiation (EMR) spectrum is shown. Example: X-rays possess shorter wavelengths, greater energy, and greater ability to permeate matter than microwaves, which have longer wavelengths and lower energy.

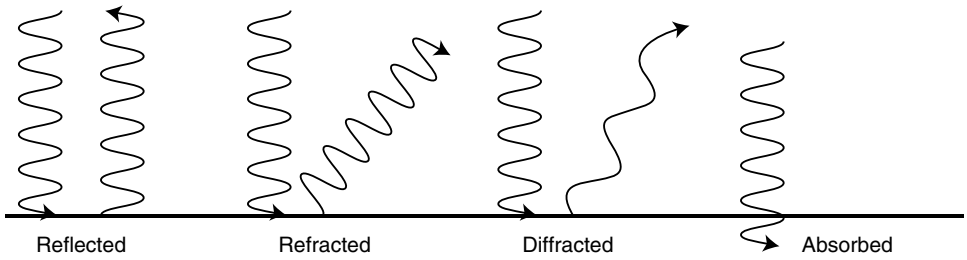

FIGURE **14-32** Electromagnetic radiation interactions with matter.

The phenomenon of matter reflecting, scattering, and absorbing specific EMR frequencies has many applications in health care, anesthesia in particular.

Electromagnetic radiation may also be converted into other forms of energy such as electricity (gas discharge), heat (incandescence), and chemical energy (photoluminescence) but must obey the law of conservation of energy. When matter is exposed to EMR, it too may change form. The analysis of EMR's interaction with matter is the underlying principle of x-ray fluoroscopy, anesthetic gas measurement, pulse oximetry, and lasers.

RADIOGRAPHY

X-Rays

X-rays are able to pass through different organic materials to varying degrees and allow the "photographic" imaging of internal structures. Though x-ray and fluoroscopic imaging offer great medical benefit, they also possess potential for great harm. X-rays are ionizing radiation and lie in the higher-energy frequencies of the electromagnetic radiation spectrum (see Figure 14-31). They possess high energy and have the ability to ionize atoms and molecules. X-rays can cause DNA damage and be mutogenic.[92] Proper protection is imperative for health care personnel when working near or with x-rays. Safety lies within the three factors of distance from source, barriers, and exposure time. The inverse square law explained how energy intensity significantly decreases with distance from its source.[93] X-rays obey this law, and the minimum recommended distance from an x-ray source is 6 feet. The greatest intensity of an x-ray is directly in front of the beam generator. Standing at least 6 feet away and behind or to the side of the beam direction lessens exposure. Although the energy intensity of x-rays decreases significantly with greater distance from the source, proper shielding is also important. Lead barriers are efficient absorbers of x-ray energy, and lead aprons and thyroid shields should be worn. X-ray technicians often wear badges that measure total exposure to x-rays over a period of time. Greater exposure to x-rays is associated with greater risks. Institutional policies establish guidelines of exposure limits. Unless practitioners are exposed to radiographic procedures frequently, the doses received usually fall well below established limits for maximal allowable exposure. Shielding and distance from the x-ray source remain the two most important factors within the control of the practitioner.

GAS ANALYSIS

Gas analysis technologies use several methods to measure organic and inorganic gases. The methods described herein focus on the technologies prevalent in the field of anesthesia. The gas analysis technologies in Box 14-1 show the most common technologies for analysis of anesthetic gases, oxygen, and carbon dioxide.

Organic and Inorganic Anesthetic Gas Analysis

Infrared Absorption Analysis

Infrared absorption analysis uses each anesthetic gas's ability to absorb specific frequencies of EMR in the infrared spectrum. A sample of a gas or mixture of gases is subjected to a known range of infrared frequencies. The frequencies lost due to absorption are measured, and identification of the gas or gases may be made by the specific frequencies each gas absorbs. Anesthetic agents' infrared absorptions are unique but close in frequency. Newer infrared absorption analysis monitors are capable of identifying specific agents without preprogramming the specific agent. Concentration is determined by the amount of infrared absorption (Figure 14-33).

Raman Scattering Analysis

The interaction of electromagnetic radiation with matter is the underlying principle used with Raman scattering analysis of gases. Raman scattering passes a monochromatic laser beam through a gas mixture, causing an increased vibration frequency of the excited gas molecules (Figure 14-34). A laser is a high-intensity beam of a known specific EMR frequency (see laser discussion in this chapter). When this laser beam interacts with an anesthetic gas molecule, it may be absorbed, as previously described with infrared absorption analysis, or it may be scattered. Scattering is a frequency change (energy change) of the initial laser beam after it interacts with gas molecules. The laser frequency interacting with

the molecules may be scattered at higher or lower frequencies. Each anesthetic gas scatters laser frequencies uniquely. Analysis and identification of a gas or gas mixture may be made by comparing the gas sample scattering spectrum to that of known gas-scattering spectrums. The scattered frequencies measured in this spectral analysis are represented as Stokes lines.

Raman scattering technology requires only that a gas molecule be polyatomic for identification. Raman scattering analysis can identify oxygen, carbon dioxide, nitrogen, nitrous oxide, and all volatile anesthetics, including mixtures of volatile anesthetics.[94] Helium cannot be analyzed by Raman scattering. Raman scattering analyzers return the sample to the patient circuit and therefore do not need waste-gas scavenging. Raman scattering analyzers are small and portable but require calibration. They are less accurate with pediatric cases, which use high carrier gas flow rates and small tidal volumes.

Mass Spectrometry

Mass spectrometry historically has been the dominant technology for anesthetic gas analysis, though it has increasingly been replaced by more portable and efficient infrared absorption analysis and Raman scattering analysis technologies. Mass spectrometry ionizes gas molecules and passes them through a magnetic field. The gas molecules with the lowest mass-to-charge ratio are easily deflected by the magnetic field and collected by an ion detector (Figure 14-35). Ionized gas molecules with higher mass-to-charge ratios are deflected less by the magnetic field and detected by other ion detectors. Identification of a gas is based on the amount of deflection.

Piezoelectric Gas Analysis

Piezoelectric gas analysis incorporates both the piezoelectric effect and Henry's law.[95-97] A piezoelectric crystal will vibrate at a set frequency when an electric current is applied to it. A vibrating piezoelectric crystal coated with a liquid solution will alter its resonant frequency when exposed to a gas. As a gas dissolves into the liquid, in proportion to its concentration above the liquid gas interphase, the resonant frequency of the crystal is altered. The degree of frequency change is proportional to the concentration of gas that dissolves into the liquid. The amount of gas that dissolves into the piezoelectric crystal's liquid coating is directly related to the partial pressure of that gas. This is explained by Henry's law.

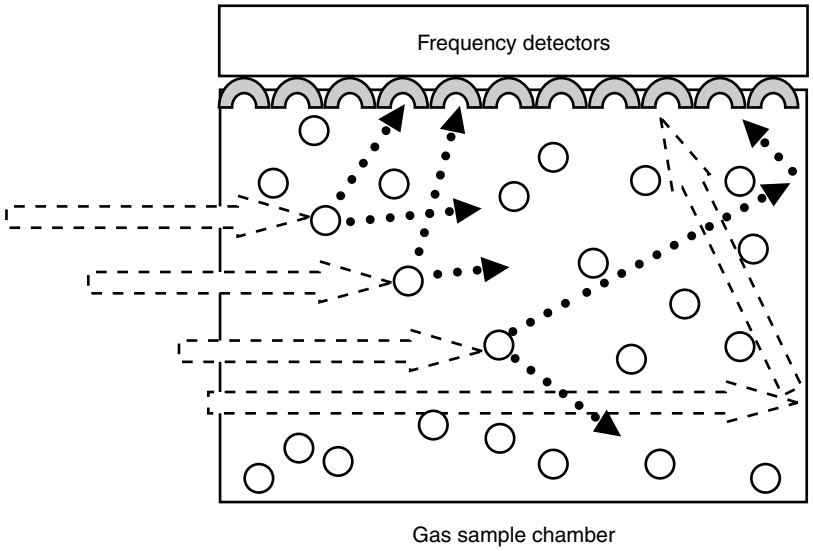

FIGURE **14-34** Raman scattering gas analysis technology.

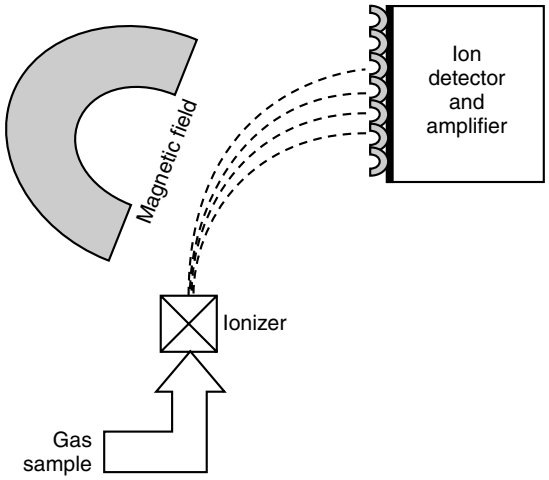

FIGURE **14-35** Mass spectrometry gas analysis technology.

A drawback of this technology is that it does not identify the specific anesthetic agent.[98]

Photoacoustic Gas Analyzer

The photoacoustic gas analyzer subjects a gas sample to a filtered, pulsating infrared light beam in a closed chamber. The pulsating beam causes the gas molecules to increase then decrease in temperature. The increase and decrease in temperature causes the chamber pressure to increase and decrease according to Gay-Lussac's law. Microphones along the chamber measure the pressure waves. A photoacoustic gas analyzer can measure anesthetic gases, mixtures of these gases, and carbon dioxide.[99] The units are small, portable, and accurate.

Oxygen Analysis

The primary role of oxygen in biological systems underscores the importance of identification and measurement of this gas when delivering anesthetics. Purposeful redundancy is used in oxygen measurement, often with more than one technology being used at a time. In the practice of anesthesia, oxygen content analysis is accomplished with several technologies. These technologies take advantage of oxygen's unique physicochemical properties and interaction with EMR. The most often used technologies pertaining to anesthesia practice are reviewed below.

Electrogalvanic Cell (Fuel Cell) Electrochemical-Oxygen Analyzer

The electrogalvanic cell (Figure 14-36) is also called a *fuel cell* because the reaction that takes place creates its own electric current by consuming its "fuel." The electrogalvanic sensor has a membrane permeable to gases but not liquids. At the anode of the sensor, electrons are liberated in an oxidative reaction. This is shown with a lead anode:

$$2Pb \rightarrow (Pb^{+2}) + 4e^{-}$$

The meter measures the current produced by the electrons consumed in the reaction at the cathode (silver or gold):

$$O_2 + 4e^{-} \rightarrow 2O_2,\ 2O_2 + 2H_2O \rightarrow 4(OH)^{-}$$

The electron flow between the anode and cathode is directly proportional to the partial pressure of oxygen in the sample gas. Current flows in proportion to oxygen concentration.

Electrogalvanic cells have a limited life related to the concentration and duration of oxygen exposures. Because of this, some nurse anesthetists remove the oxygen sensor from the circle system if an anesthesia machine is left on and not in use for extended periods of time, such as overnight. Most anesthesia machines have minimal oxygen flow at all times, so removing the electrogalvanic cell from the flow of higher oxygen concentration will extend its duration of usefulness.

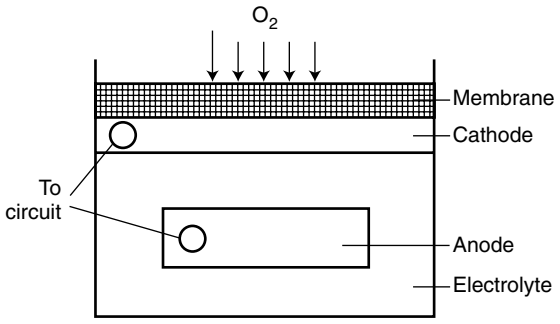

FIGURE **14-36** Electrogalvanic fuel cell.

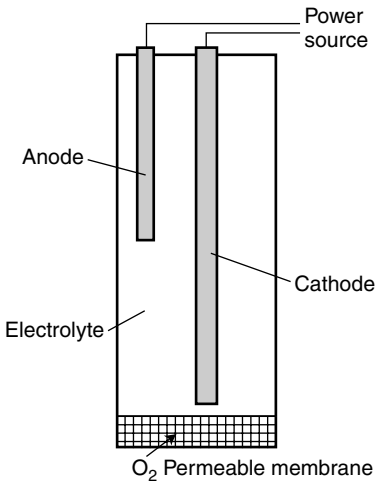

FIGURE **14-37** Polarographic electrode.

Polarographic Electrode (Clark Electrode)

The Clark polarographic oxygen electrode consists of a voltage source and a current meter connected to a platinum cathode and a silver anode (Figure 14-37). The electrodes are immersed in a potassium chloride electrolyte cell. A membrane permeable to oxygen but not electrolytes covers one surface of the cell. A polarizing voltage is applied between the electrodes. At the anode, electrons are liberated by the oxidative reaction of silver with the chloride electrolyte:

$$4Ag \rightarrow 4Ag^{+} + 4e^{-},\ 4Ag^{+} + Cl^{-} \rightarrow 4AgCl$$

The meter measures the current produced by the electrons consumed in the reaction at the cathode:

$$O_2 + 4e^{-} \rightarrow 2O_2,\ 2O_2 + 2H_2O \rightarrow 4(OH)^{-}$$

Current flows in proportion to oxygen concentration. If there is no current applied to these cells, there will be no consumption of the electrodes.[100]

Paramagnetic Oxygen Sensor: Magnetomechanical "Dumbbell Principle"

The paramagnetic oxygen sensor uses oxygen molecules' unique attraction into magnetic fields. Few other gases are attracted by

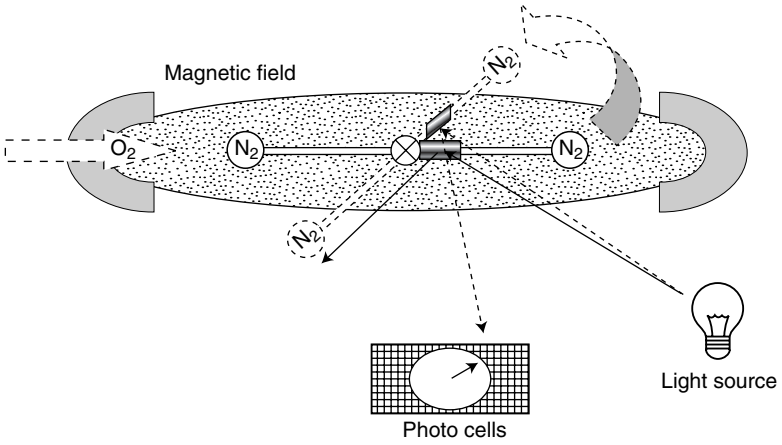

FIGURE **14-38** Paramagnetic oxygen sensor.

magnetic fields. The paramagnetic oxygen sensor is constructed with two nitrogen-filled bulbs attached together by a stem; this resembles a dumbbell. This dumbbell-shaped apparatus is suspended parallel to a magnetic field in its "at-rest" state. Nitrogen is not attracted or repelled by magnetic fields. The introduction of oxygen into this sensor causes the dumbbell apparatus to be displaced out of the magnetic field as oxygen is attracted into the field (Figure 14-38). The amount of displacement of the dumbbell apparatus is directly proportional to the concentration of oxygen. Originally these sensors measured the physical displacement of the dumbbell apparatus but were prone to artifact caused by vibration and external movement. These sensors now incorporate a small optical mirror that reflects a projected light beam. The light beam is reflected onto a photocell that generates a small voltage used to counteract the displacement of the dumbbell apparatus. Increased oxygen concentration increases the displacement of the dumbbell apparatus, which in turn directs a greater reflection of light onto the photocell. By using a generated electric current to counteract the dumbbell apparatus, displacement proportional to the oxygen concentration, external movement, and artifact are eliminated. These sensors are highly accurate, compact, and durable.

Fluorescence Quenching

Fluorescence is caused by a molecule emitting light (photons) in response to being energized. Certain molecules exhibit fluorescence in response to an electric current or exposure to EMR. These molecules are sometimes said to "glow in the dark." Neon lights are an example of noble gas fluorescence initiated by an electric current. Chemical fluorescence is seen in some sea life and in glow sticks. Both electrically and chemically initiated fluorescence is caused by energizing an electron to a higher energy level. The energized (excited) electron then returns to its lower energy level (resting state) by releasing a photon (spontaneous emission). The released photon is observed as light, with its color representing the emitted photon's frequency.[100]

Fluorescence quenching is a technology that uses oxygen's ability to suppress, or quench, certain molecules from fluorescing. When a fluorescent molecule is excited to a higher energy state, it will emit a photon. Oxygen, if present, will absorb this photon and prevent its release. The amount of fluorescence that is quenched is directly proportional to the concentration of oxygen present. By measuring the amount of emitted photons, analysis of oxygen concentration may be made (Figure 14-39).

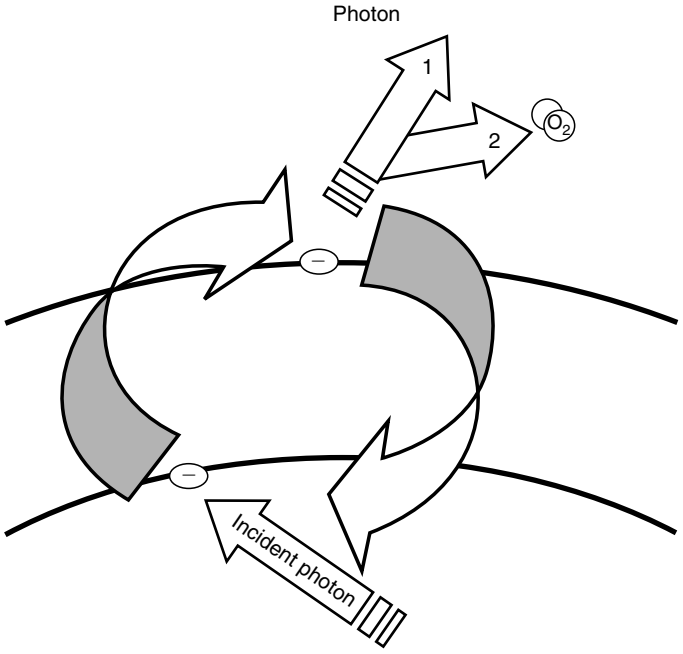

FIGURE **14-39** Fluorescence-quenching principle. *(1)* Photon release as fluorescence. *(2)* Energy absorption by oxygen, which quenches fluorescence.

Carbon Dioxide Analysis

Fluorescence Quenching

Fluorescence-quenching technology also may be used to measure carbon dioxide. Carbon dioxide is not the quencher of fluorescence; instead it causes a change in pH, liberating hydrogen ions, which react with a quenching agent or a fluorescent dye in the sensor. Fluorescence is altered by the protonation of these chemical components. The measured change in fluorescence is proportional to the concentration of carbon dioxide.

Colorimetric CO_2 Sensor

A dry-state sensor that uses a color change in the presence of carbon dioxide is often used to differentiate endotracheal intubation from esophageal intubation. These sensors use the fluorescence principle to indicate carbon dioxide in the gas phase. A paper is impregnated with a fluorescent dye that in the presence of carbon

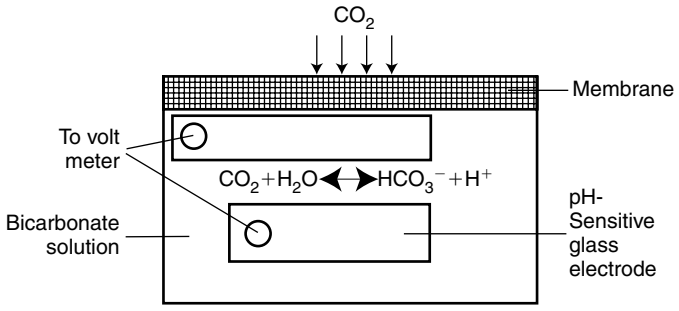

FIGURE **14-40** Severinghaus P_{CO_2} electrode.

dioxide, will fluoresce or change color. A phase-transport agent facilitates the reaction to give an immediate color change (e.g., purple), indicating carbon dioxide. Colorimetric CO_2 sensors indicate the presence, but not the amount, of carbon dioxide.

Severinghaus Pco_2 Electrode

The Severinghaus P_{CO_2} electrode (Figure 14-40) is a frequently used method for analyzing carbon dioxide in anesthesia.[101] It uses a pH-sensitive electrode immersed in a bicarbonate solution with a gas-permeable membrane. Carbon dioxide diffuses into the sensor and is converted into free hydrogen ions, generating a current of electric charge. The current is proportional to CO_2 concentration.

PULSE OXIMETRY

Pulse oximetry makes use of the property of matter that causes it to absorb certain frequencies but not other frequencies of EMR. Oxygenated and deoxygenated hemoglobin are uniquely different molecules and thus interact differently with EMR. By measuring specific frequencies that are absorbed by a pulsatile blood supply, a calculation may be made to determine the percentage of oxygenated and deoxygenated blood in that sample. The algorithm used to make these calculations is derived from the Beer-Lambert law (August Beer, 1825-1863, and Johann Heinrich Lambert, 1728-1777). This law is based primarily on the work of Lambert. Lambert's laws state the following: (1) The luminance of perpendicular light on a surface is proportional to the inverse square of the distance it travels from its source. (2) The luminance intensity of angled light is proportional to the cosine of the angle with the normal. (3) Luminance intensity decreases exponentially as the light travels through a medium. The Beer-Lambert law is as follows:

$$It = Ii \times e^{-DC\alpha}$$

where **It** is the transmitted light, **Ii** is the incident light, and e^{-DC_α} is the distance through the medium, concentration, and absorption coefficient (Figure 14-41). Pulse oximetry applies the Beer-Lambert law to the absorption of two specific frequencies, infrared and visible red, by hemoglobin. Oxygenated hemoglobin absorbs the infrared frequency that corresponds to a wavelength of 940 nanometers, and deoxygenated hemoglobin absorbs the visible red wavelength of 660 nanometers (Figure 14-42). Analysis of the wavelength that is most absorbed corresponds to that form of hemoglobin. If the wavelength of 940 is absorbed, the hemoglobin present is the oxygenated form. Pulse oximeters display a percentage measurement of saturated hemoglobin. Pulse oximeters measure the amount of absorption of these two specific wavelengths many times a second.

Pulse oximetry is inexpensive, portable, and allows early detection of hemoglobin desaturation.[102-104] Probe placement may be on the digits, ears, nose, or even the forehead to detect a pulsatile arterial blood flow. The oxyhemoglobin saturation curve displays

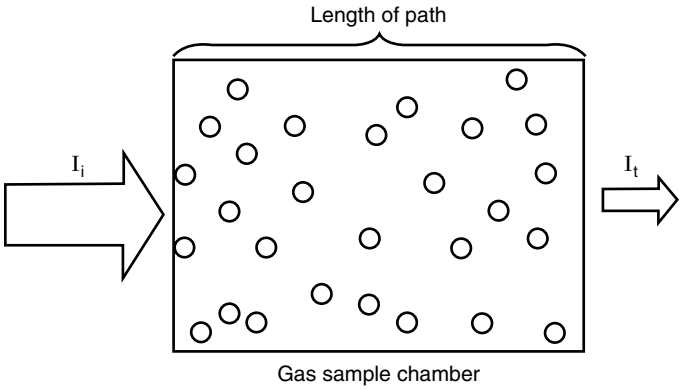

FIGURE **14-41** Incident light intensity change when transmitted through a medium.

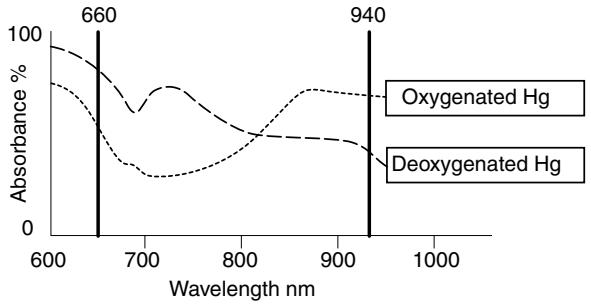

FIGURE **14-42** Oxygenated hemoglobin and deoxygenated hemoglobin wavelength absorption spectra. The intersection where oxygenated and deoxygenated hemoglobin absorb the same frequency amount is the isobestic point.

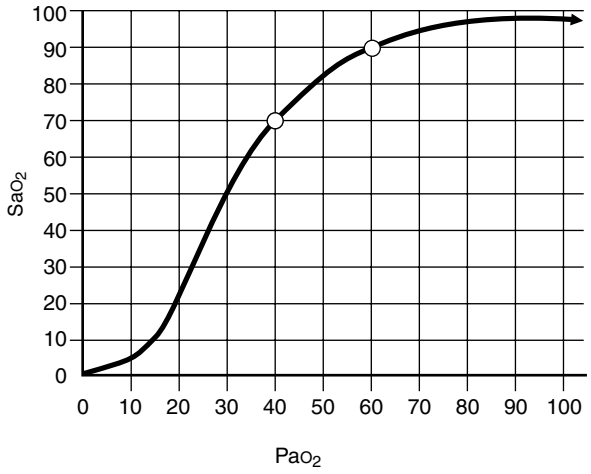

FIGURE **14-43** Oxyhemoglobin dissociation curve.

the oxygen saturation (Sao_2) relationship to Pao_2. Important points along this curve include the Sao_2 of 90%, which corresponds to the critically low Pao_2 of 60 mmHg oxygen tension. The Sao_2 of 70% corresponds to a Pao_2 of 40 mmHg oxygen tension (Figure 14-43) and is the saturation at which cyanosis becomes apparent.[105] Pulse oximetry is of great value and has become a standard of practice. Both a digital display and an auditory tone alert the nurse anesthetist to the patient's hemoglobin saturation.[106]

Disadvantages of pulse oximetry include the susceptibility of artifact from movement and ambient light sources, the risk of burns in poor perfusion states, and the limitation in detecting pulsatile

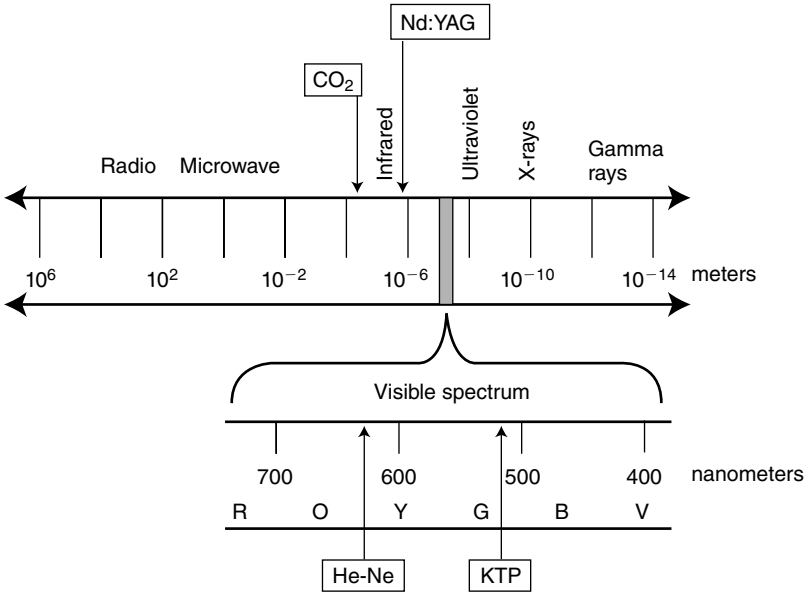

FIGURE **14-44** Common medical laser frequencies. *He-Ne*, Helium neon; *KTP*, potassium titanyl phosphate; *Nd:YAG*, neodymium-doped yttrium aluminum garnet.

TABLE **14-8** Medical Lasers and Uses

Laser	Wavelength	Tissue Penetration	Characteristics/Uses
Helium neon	633 nm	none	Aiming beam for invisible lasers
CO_2	10,600 nm	less than 0.5 mm	Highly absorbed by water Good for superficial lesions Used in airway surgeries
Argon	488 nm 514 nm	0.5-2.0 mm	Selectively absorbed by hemoglobin Good for hemangiomas, moles Used also in eye and ear surgery
KTP	1060 nm	0.5-2.0 mm	Highly absorbed by hemoglobin Multiple uses
YAG lasers	1064-2940 nm	2-6 mm	Variable intensities Used to ablate and destroy tissues Multiple uses

CO_2, Carbon dioxide; *KTP*, potassium titanyl phosphate; *YAG*, yttrium aluminum garnet.

blood flow in hypothermic or vasoconstricted patients. Additionally, some nail polish pigments interfere with accurate estimates of oxygen saturations. During high F_{IO_2} delivery, ventilation-perfusion abnormalities may be masked. A Pa_{O_2} of 100 mmHg and a Pa_{O_2} of 500 mmHg will both give the same pulse oximeter reading of 100%, regardless of the delivered oxygen. Lastly, pulse oximeters do not measure respiratory rate.[107-110]

LASERS

Lasers derive their name from the acronym **L**ight **A**mplification by **S**timulated **E**mission of **R**adiation. Certain atoms that have been energized by an incident photon may move an electron to a higher orbit, but that electron only stays there momentarily, releases a photon, and quickly returns to its resting energy level (see Fluorescence Quenching). This is called *spontaneous emission*. When many incident photons raise many electrons to higher energy levels, the *spontaneous emission* that occurs is chaotic, with photons radiating in multiple directions. However, if many atoms of a particular matter are continually energized by incident photons while their electrons are already in a higher energy state, then photons of the same frequency and direction will be emitted as the electrons are forced down to their natural resting state. This is called *stimulated emission* and is the basis of laser function. Continual energizing of certain atoms forces photons of the same frequency (monochromatic) and direction to be emitted in unison. Population inversion is the condition in which the majority of electrons in an atom are in the higher energy level rather than their natural resting state. The natural balance of resting electrons to energized electrons has been inverted. Population inversion is required to allow continual production of monochromatic, coherent, and unidirectional photons used in lasers. The intensity of lasers and the ability to direct the beam have many applications in medicine and present unique considerations for nurse anesthetists (Figure 14-44 and Table 14-8).

Laser Risks

Lasers have the ability to burn and ignite fires. The patient should have his or her eyes shielded with saline pads and laser goggles. Operating room personnel also should wear appropriate eye protection when lasers are in use.[111] The risk of fire is ever present

with lasers. Three components are needed to produce a fire: fuel, oxygen, and an ignition source. Lasers are a potent ignition source. The nurse anesthetist should be aware of this risk during laser surgeries and be prepared to take rapid action. Drapes, dressings, and linens are a few of the combustible materials that may ignite during surgery.[112] Lasers should never be kept active when not in use. Lasers are often used for otorhinolaryngologic surgeries. Endotracheal tube fires can occur during these cases. Low inspired oxygen concentrations and nonflammable or shielded endotracheal tubes should be used.[113] Some authors recommend placing saline with methylene dye in the endotracheal tube cuff to dissipate heat and signal cuff rupture.[114] A source of saline to extinguish a potential fire should be immediately available. If an airway fire occurs, stop oxygen flow, stop ventilation, extubate the patient, extinguish the fire, mask ventilate, and reintubate the patient.[115] The patient will require airway assessment and medical treatment, including bronchoscopy, lavage, and steroids.

SUMMARY

The historical view of the universe as a machine following fixed specific rules often allowed for unequivocal laws to be discovered. For a time, the actions of the universe seemed destined to be unlocked and forever understood. Unfortunately or fortunately, this is not the case. The mechanistic view of the universe in Newtonian physics loses its ability to describe certain phenomena, and this underscores a significant limitation. Advances in our knowledge of quantum events may shed light on phenomena that remain elusive.[116]

Quantum physics has brought us new insight into the subatomic world and uncovered the limitations of classical physics in fully describing the actions and reactions of the universe. What Newtonian physics has done for the physical world, quantum physics holds for the nonphysical world, the world of pure energy and the quasi-world of energy/mass transition. Events in the quantum world are not determined by fixed, describable outcomes. Quantum events are described by probabilities. Phenomena that remain only partially understood in anesthesia may be clarified by discoveries in quantum study. Consciousness, awareness, and minimum alveolar concentrations (MACs) all are described in anesthesia as probabilities. Consciousness and awareness are not "on-off" phenomena but rather fall within a spectrum. Delivery of anesthetics is sometimes measured not in fixed set doses but rather in ranges, MACs, that provide a guideline of probability for a desired outcome. Though controversial, some have suggested that consciousness is a quantum event with understanding to be found in the study of quantum mechanics.[117-120] Newtonian physics and physical chemistry will remain valued sciences that well describe many processes in the field of anesthesia, but quantum study may someday bring new advances and applications to anesthesia. Safer, more effective anesthesia techniques and technologies may evolve out of quantum understanding, or the mere search itself may stimulate new developments. Regardless, the future is exciting. Chemistry and physics have and will continue to provide a conceptual and analytical framework from which we can derive understanding, establish clinical rationales, and direct the practice of safe and effective anesthetic management of patients under our care.

CHAPTER 15

Anesthesia Equipment

◆ *Michael P. Dosch*

"To a large extent, anesthesia machines are *inherently dangerous*. A machine that has the power to induce anesthesia necessarily has the power to cause death and serious injury. An anesthesia department may want to institute periodic training to make sure that everyone in the department is familiar with *all* of the machines in the hospital."[1] It would disturb any of us to read in the news about an adult, without driver's training, who attempted to drive a car and caused injury or death as a result. Shouldn't it be equally disturbing to learn that only a minority of anesthetists report that they check their gas machines before use?[2,3] Because anesthesia equipment malfunction is so rare, misuse and human error are much more of a threat to patient safety than outright malfunction.[4-7] However, when errors in the use of gas delivery equipment occur, the outcome is often mortality or serious morbidity.[4] Human error can be most effectively combated by a strong individual, department, and industry commitment "to ensure that no patient is harmed by anesthesia" (the mission of the Anesthesia Patient Safety Foundation).[8] The means of accomplishing this goal are educational and motivational. We anesthetize patients with many different kinds of problems, for many different kinds of surgical and diagnostic procedures. But there is one thing that is present in every anesthetic: the anesthesia gas machine. It is the purpose of this chapter to provide timely, accurate, and patient-safety-focused information about this important and ubiquitous patient-safety technology.

As the previous generation of equipment passes out of use (e.g., Excel, Modulus, Narkomed 3), it is deemphasized in this edition to allow more focus on current anesthesia equipment systems. The main additions to this chapter are the new pre-use checklist for the anesthesia gas machine and its impact on patient safety; and new adaptive modes of ventilation (pressure control with volume guarantee, and autoflow). Differences between gas machines are presented here if understanding these differences is important to using the machine safely. Brief descriptions of new gas machines are presented (Aisys, ADU, Aespire, Avance, and Aestiva [GE Healthcare, Madison, Wisconsin]; Fabius GS and Apollo [Dräger Medical, Telford, Pennsylvania]).

A major objective of this chapter is that readers will gain skill and safety in the use of the anesthesia gas machine. Therefore throughout the chapter, explicit directions on how to use the machine safely are presented; these directions are based on manufacturers' guidelines and on reports of mishaps from the anesthesia literature. Because of the variety of machines currently in use, no direction in this chapter can be considered universally applicable. The directions given here must be adapted to individual practice settings only after study of the operator's manuals and appropriate local peer review.

Several factors make learning about gas machines difficult. Each model has unique aspects—even those from the same manufacturer. It is not always possible for the anesthetist to be available when department in-service education is conducted. Also, continuing education content may be too limited, or an opportunity to use new equipment soon after an educational session may not occur. New equipment constantly appears in the anesthesia work area. Although anesthesia equipment is designed to meet all legal and technical requirements, the designers of the equipment are not users. Some designs may be recognized as flawed only when they are used clinically. Instructional materials accompanying equipment often are inadequate. For example, no matter how well written, supplying one instruction manual per *machine* is inferior to supplying one instruction manual per *user*. The potential lack in equipment competency caused by these factors can be a safety problem.[9-11] Users may be legally obligated to know and follow manufacturers' instructions (checklists, operating manuals) and warnings, because these may contribute to the standard of care. Some courts have defined deviation from manufacturers' instructions as *prima facie* negligence.[12]

To make learning the content easier, this chapter views the machine from a systems approach. For example, all machines have systems to provide (and measure) gas composition, including life-sustaining gases (oxygen), anesthetizing gases, and metabolic by-products (carbon dioxide). When this capability of every gas machine is understood, one need only determine how a particular machine accomplishes this, and how this function is checked before use to operate the machine safely (in this respect). Once all the systems—and their interplay—are understood, learning new equipment is easier. High-fidelity patient simulation is a novel approach that holds promise for both learning anesthesia equipment more efficiently, and studying gas-machine hazards. Simulation has allowed exploration of questions that could not be studied in the past because of risks to patients.[13,14]

ORGANIZATION OF THE ANESTHESIA GAS MACHINE

Presenting the anesthesia gas machine as a litany of components does not promote retention, much less aid in the development of a solid concept of the overall organization of the machine. An accurate concept of the overall organization should help one to understand the role of the individual components better, which should in turn promote correct use and thus patient safety. This section presents the *supply, processing, delivery, and disposal (SPDD) model.*

Supply, Processing, Delivery, and Disposal Model

The SPDD model is depicted in Figure 15-1 and Box 15-1. This model is comprehensive in that the path of gases can be followed from their arrival in the operating room to their disposal from it. Most anesthesia gas-machine components can be located easily within the overall scheme. Gas flows in the diagram proceed generally from left to right. The vertical bar separates components within the machine and proximal to the common gas outlet (left side), from external components downstream from the common gas outlet (right). The fact that nitrous

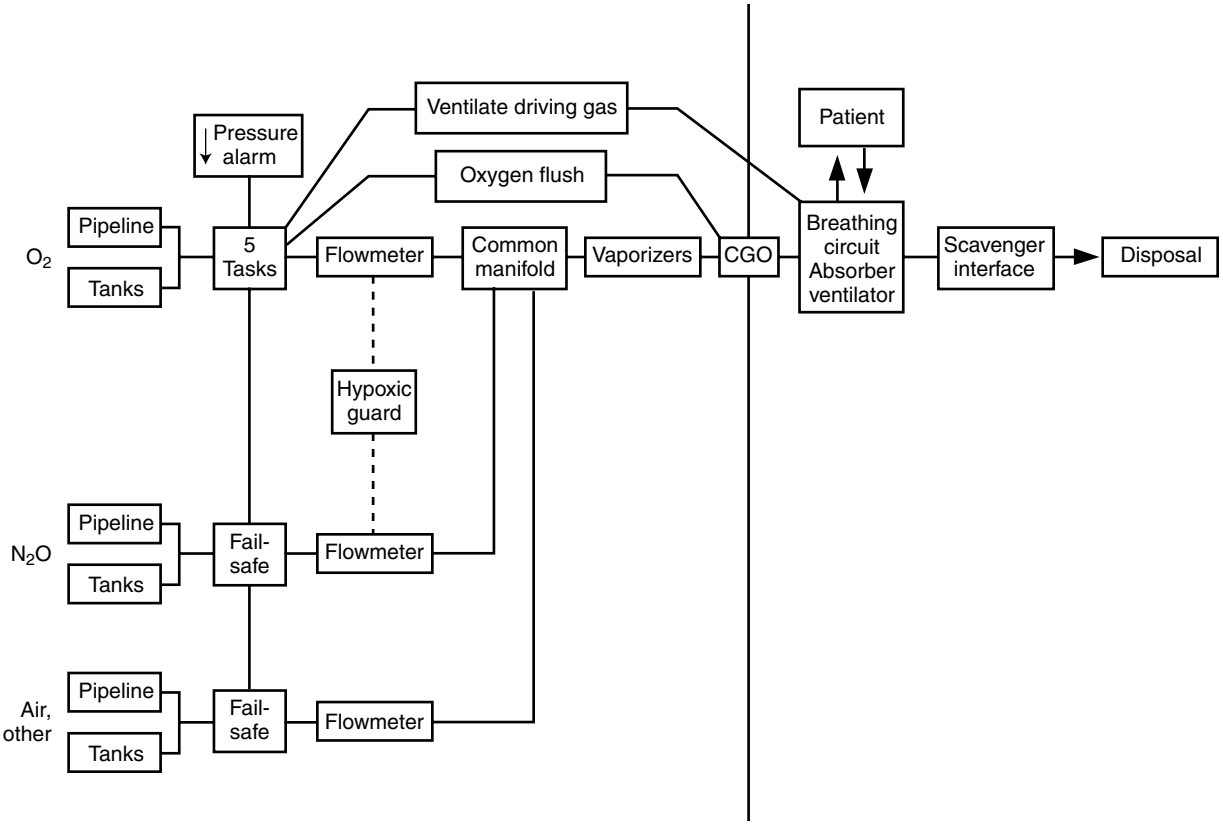

FIGURE **15-1** Supply, processing, delivery, and disposal (SPDD) model. CGO, Common gas outlet. (Courtesy Michael P. Dosch.)

BOX **15-1**

Components in Supply, Processing, Delivery, and Disposal (SPDD) Model

Supply

How do gases come to the anesthesia gas machine? (Site: back of the machine)

- Pipeline
  - Wall outlets
  - Connecting valves and hoses
  - Filters and check valves
  - Pressure gauges
- Cylinders
  - Hanger yokes (yoke block)
  - Filters and check valves
  - Pressure gauge
  - Pressure regulators

Processing

How does the anesthesia gas machine prepare gases before their delivery to the patient? (Site: within the machine, proximal to common gas outlet)

- Fail-safe (oxygen pressure-failure devices)
- Flowmeters (main, auxiliary, common gas outlet, scavenging)
- Oxygen flush
- Low oxygen pressure alarms
- Ventilator-driving gas
- Proportioning systems (hypoxic guard)
- Oxygen second-stage regulator (if present)
- Vaporizers
- Check valves distal to vaporizers (if present)
- Common gas outlet

Delivery

How is the interaction of gases with the patient controlled and monitored? (Site: breathing circuit)

- Gas delivery hose connecting common gas outlet and breathing circuit
- Breathing circuits
- Nonrebreathing
- Circle
- Carbon dioxide absorption
- Ventilators
- Integral monitors
- Oxygen analysis
- Disconnect
- Spirometry (volumes and flows), capnography, airway pressure
- Ventilator alarms
- Addition of positive end-expiratory pressure
- Means of humidification

Disposal

How are gases disposed of? (Site: scavenger)

- Scavenger systems
  - Interface—closed (active and passive) or open
  - Scavenger flowmeter

BOX **15-2**

Components in the High-, Intermediate-, and Low-Pressure Pneumatic Systems

High-Pressure System (Exposed to Cylinder Pressure)
- Hanger yoke
- Yoke block with check valves
- Cylinder pressure gauge
- Cylinder pressure regulators

Intermediate-Pressure System (Exposed to Pipeline Pressure—About 50 psi)
- Pipeline inlets, check valves, and pressure gauges
- Ventilator power inlet
- Oxygen pressure-failure devices
- Flowmeter valve
- Oxygen second-stage regulator (if present)
- Flush valve

Low-Pressure System (Distal to Flowmeter Needle Valve)
- Flowmeter tubes
- Vaporizers
- Check valves (if present)
- Common gas outlet

oxide and air, unlike oxygen, have only one task in the machine is easy to appreciate. The five tasks of oxygen are easy to follow. Understanding the similarities and differences between the fail-safe and hypoxic guard systems is facilitated. The model makes clear that the scavenging system, rather than the patient, is the ultimate destination of gases. Oxygen is central to the figure, because it is the most essential gas delivered. The reader should note that not every component of the SPDD model in Box 15-1 is depicted graphically in Figure 15-1. The reader should make frequent reference to the model while reading this chapter.

The model organizes the information on the basis of how components are used, rather than on the pressures to which they are exposed. From the viewpoint of pressure that components are exposed to, components are classified as part of the high-, intermediate-, or low-pressure systems within (proximal to the common gas outlet) the gas machine (Box 15-2).

Introduction of new gas machines raises questions about the adequacy and safety of older equipment.[1,15] One can determine whether current equipment is obsolete by considering how closely it meets current safety standards and practice needs, by the availability of service, and by the presence of essential safety features.[16,17] Certain systems or components are required by the anesthesia workstation standard, which is a voluntary industry-group consensus standard (Box 15-3).[18]

BOX **15-3**

Required Components of an Anesthesia Workstation

The current anesthesia gas machine (workstation) standard is **ASTM F1850** (a standard promulgated by the American Society for Testing and Materials). F1850 specifies what is needed for an anesthesia workstation. The components are typically built into new gas machines, or they may be added to older machines. Required components include the following:

Battery backup for 30 minutes

Alarms
- Grouped into high, medium, and low priority.
- High-priority alarms may not be silenced for more than 2 minutes.
- Certain alarms and monitors must be automatically enabled and functioning prior to use, either through turning the machine on or by following the pre-use checklist: breathing circuit pressure, oxygen concentration, exhaled volume, or carbon dioxide (or both).
- A high-priority pressure alarm must sound if user-adjustable limits are exceeded, if continuing high pressure is sensed, or for negative pressure.
- Disconnect alarms may be based on low pressure, exhaled volume, or carbon dioxide.

Required monitors
- Exhaled volume
- Inspired oxygen, with a high-priority alarm within 30 seconds of oxygen falling below 18% (or a user-adjustable limit)
- Oxygen supply failure alarm
- A hypoxic guard system must protect against less than 21% inspired oxygen if nitrous oxide is in use.
- Anesthetic vapor concentration must be monitored.
- Pulse oximetry, blood pressure monitoring, and electrocardiogram (ECG) are required.

Pressure in the breathing circuit is limited to 12.5 kPa (125 cm water).

The electrical supply cord must be nondetachable or resistant to detachment.

Cylinder supplies
- The machine must have at least one oxygen cylinder attached.
- The hanger yoke must be pin-indexed, have a clamping device that resists leaks, and contain a filter. It must have a check valve to prevent transfilling and a cylinder pressure gauge.
- There must be cylinder pressure regulators. The machine must use pipeline gas as long as pipeline pressure is greater than 345 kPa (50 psi).

Flowmeters
- Single control for each gas
- Each flow control next to a flow indicator
- Uniquely shaped oxygen flow control knob
- Valve stops (or some other mechanism) are required such that excessive rotation will not damage the flowmeter.
- Oxygen flow indicator is to the right side of a flowmeter bank.
- Oxygen enters the common manifold downstream of other gases.
- An auxiliary oxygen flowmeter is strongly recommended.

An oxygen flush is present, capable of 35 to 75 L/min flow that does not proceed through any vaporizers.

Vaporizers
- Concentration-calibrated
- An interlock must be present.
- Liquid level indicated, designed to prevent overfilling
- "Should" use keyed-filler devices
- No discharge of liquid anesthetic occurs from the vaporizer, even at maximum fresh gas flow.

Only one common gas outlet at 22-mm outer diameter, 15-mm inner diameter, which is designed to prevent accidental disconnection.

Pipeline gas supply
- Pipeline pressure gauge
- Inlets for at least oxygen and nitrous oxide
- Diameter index safety system (DISS) protected
- In-line filter
- Check valve

Checklist must be provided (it may be electronic or performed manually by the user).

A digital data interface must be provided.

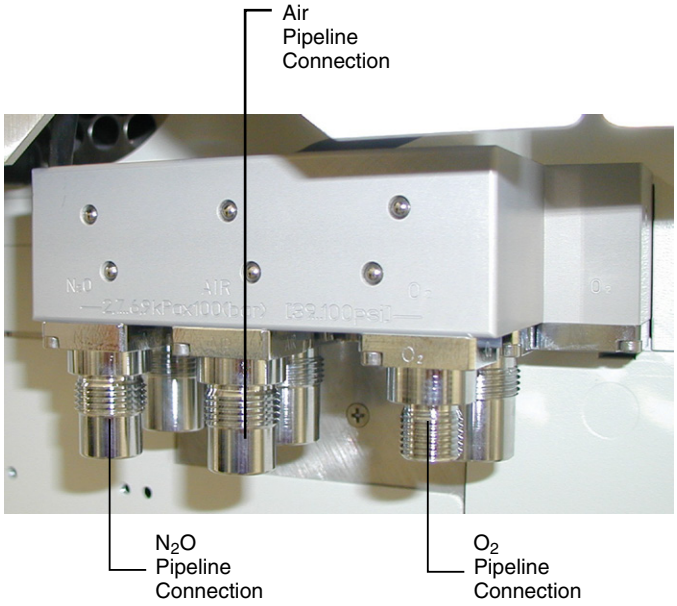

FIGURE **15-2** Pipeline connections using the diameter index safety system (DISS) ensure that only the correct gas hose can be connected to each inlet on the back of the anesthesia gas machine. (From *Apollo Operator's Instruction Manual,* Document No. 90 38 237, Rev. 01. Telford, Penn: Dräeger Medical Inc; 2005. © Drägerwerk AG & Co. KGaA, Lubeck. All rights reserved.)

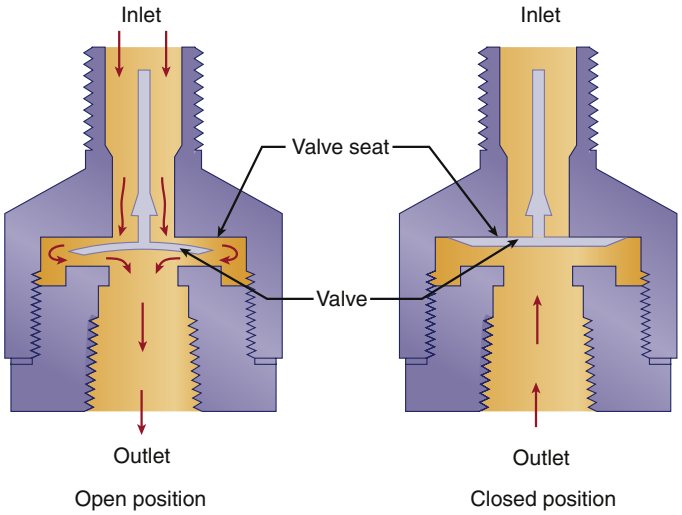

FIGURE **15-3** Check valve in the pipeline gas supply inlet at the back of the anesthesia gas machine. Gas enters from the supply hose at "Inlet" and proceeds (*downwards in the illustration*) into the machine (*left*). The right panel shows that gas cannot leak out of the machine if the supply hose is disconnected. (From Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding.* Madison, Wis: Ohmeda, a Division of BOC Health Care, Ind; 1985. In Miller RD, et al, eds. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010.)

SUPPLY

The concept of supply is concerned with these questions. How do gases (and electrical power) come to the anesthesia gas machine? What are the likely faults and hazards?

Pipeline Supply

Configuration

Oxygen is produced by the fractional distillation of liquid air. It is delivered to facilities and stored as a liquid at a temperature of minus 184° C.[19] The liquid oxygen is converted to a gas and supplied to hospital pipelines at a pressure of 50 psi (344 kPa). In the operating room suite, main and partial-area shutoff valves are present to isolate sections with leaks, interrupt supply in case of fire, and allow repair work on subsections. Wall outlets or hoses dropped from the operating room ceiling are finished with quick-connect couplers. These couplers are used so that the connection of gas machine supply hoses to wall outlets does not require tools. However, the springs and rubber gaskets (O-rings) these couplers contain provide a connection that is less secure than a wrench-tightened connection; thus they are a common source of leaks.[20-22]

Systems processing nitrous oxide are similar. Nitrous oxide is delivered to the hospital in large (size H) cylinders, which are connected to a manifold. Regulators reduce the pressure so that nitrous oxide, like oxygen, is supplied to the pipelines at 50 psi.[19] Consequently, 50 psi is the normal working pressure of the anesthesia gas machine. Shutoff valves and wall outlets with quick-connect couplers are similar for nitrous oxide and oxygen. Delivery piping for both nitrous oxide and oxygen uses the diameter index safety system (DISS) to prevent misconnections. In this system, gas-piping connections are sized and threaded differently so that cross-connection is difficult, though not impossible (Figure 15-2).[20,23]

Supply hoses connect the pipeline inlets on the back of the machine to the wall outlets. At the pipeline inlet, a filter, check valve, and pressure gauge are present. The check valve ensures unidirectional forward flow, so that a machine running on cylinder supplies, with the hoses disconnected at the wall outlet, does not leak (Figure 15-3). The filter is required by the current anesthesia workstation standard (ASTM-F1850) because it may help prevent damage to the anesthesia gas machine from particulate matter present in the pipeline gas supply.[18,24]

Problems with Pipeline Supply

Some of the problems associated with pipeline use can be particularly dangerous because they are occult. Pressure loss, excess pressure, cross-connection of gas delivery pipelines, contamination, leaks, and theft of nitrous oxide (for recreational use) have been reported.[25] These problems continue to be reported, and they have consequences for patient safety. There were 45 deaths related to pipeline problems in the United States from 1972 to 1993, and this number is probably an underestimate.[19] Two patients became hypoxemic during anesthesia due to delivery to a hospital of nitrogen tanks with oxygen fittings in 1996.[23] Seven deaths related to piped medical gases were reported from 1997 to 2001.[26] Two patients became hypoxemic due to purging of oxygen lines with nitrogen in 2000.[27] A serious failure of the bulk liquid oxygen supply was noted in 2004, but no patients were harmed.[28] Complications can arise if oxygen analyzers fail or are misused.[2,11,29] Always trust an oxygen analyzer reporting a low inspired oxygen, until you can prove it wrong.

Pipeline supplies of gas have been reported to contain particulate, gaseous, and bacterial matter; other contaminants; and water.[24,25,30,31] In 1993 the National Fire Protection Association (NFPA) adopted more stringent testing standards. The Joint Commission has established standards that allow site visitors to randomly approach and question operating room staff to ensure they are aware of the location and function of shutoff valves, and alarms related to gas supplies in their area.[30]

Loss of Oxygen Pipeline Pressure

Loss of oxygen pipeline pressure is indicated by the pipeline pressure gauge. In addition, if pressure loss is profound, the oxygen low-pressure alarm sounds, and the fail-safe valves halt the delivery of all other gases. Some newer machines are designed to switch to air to drive the ventilator bellows with loss of oxygen pipeline pressure. With the new electronic alarms, operator response may be delayed because the electronic alarms lack the distinctive and familiar "whistle" of a pneumatic oxygen low-pressure alarm.[32]

Two recent simulation studies point to the need for change in the way we teach and respond to loss of oxygen pipeline pressure.[33,34] In a simulated loss of pipeline oxygen, most residents recognized the oxygen-loss alarms. But less than half knew how to change an empty oxygen cylinder, attempted to change it (even after prompting), or recognized that bag-valve-mask (Ambu) ventilation would lead to patient awakening.[33] A group of volunteer specialist anesthetists (completed residency and in practice) managed a simulated oxygen pipeline failure equally poorly.[34] In their pre-use check, 70% failed to identify an empty oxygen cylinder, and only 25% checked for backup ventilation equipment (a bag-valve-mask) before induction. Most failed to conserve cylinder oxygen (by using low fresh gas flows, and turning off the mechanical ventilator), and all used untested pipeline supplies of oxygen when informed that pressure had been restored.[34] These responses could be categorized as unwise at least, or unsafe at worst. In a third recent report, more than 700 anesthetics were given over a 3-week period without any checks that the emergency oxygen cylinder was full.[35]

Optimal management of loss of oxygen pipeline pressure has the following goals: maintenance of oxygenation, ventilation, and depth of anesthesia; and ensuring the safety of the oxygen supply.[34] Box 15-4 gives a suggested guideline for management.[28,33,34,36-39] With complete loss of oxygen pipeline pressure, the anesthetist should fully open the E cylinder of oxygen, disconnect the pipeline, and consider the use of low fresh gas flows and manual ventilation to conserve the emergency cylinder supply of oxygen. If the E cylinder of oxygen is not opened fully, flow from it may end before the cylinder is empty. The author recommends disconnecting the hose at the quick-connect fitting at the wall during an oxygen pressure-loss event, when doing so is not strictly necessary, for two reasons. First, it *must* be disconnected in the case of a cross-connection (which is more fully described later in the chapter), otherwise the contents of the oxygen cylinder will not flow. Remembering one strategy that is effective for two reasonably similar problems is easier than remembering two different strategies. Second, if the loss of pipeline pressure is followed by the flow of contaminated contents from the oxygen pipeline, disconnecting when pipeline pressure is lost protects the patient from exposure to these contaminants.

Although excessive pipeline pressure will not trigger alarms in the machine, it should do so in the hospital physical plant or engineering department. Excessive pressure can damage respiratory apparatus or machinery of various types connected to the pipeline, including the anesthesia gas machine.

Cross-Connection of Gases

Cross-connection of gases can occur anywhere from the liquid oxygen supply and piping, to the wall outlets, hoses, and internal circuitry of the anesthesia gas machine. Incidents of cross-connection continue to be reported. Mishaps in which cross-connection was a factor have been reported as recently as 2009.[40-43] Fatalities (as recently as 2002) have been associated with the shipment in error to the hospital of liquid nitrogen instead of oxygen, liquid carbon dioxide rather than nitrous oxide, the unintentional cross-connection of oxygen and nitrous oxide pipelines during renovation of an operating room, and alteration of an oxygen flowmeter so that it would fit a nitrous oxide outlet in a cardiac catheterization laboratory. A common factor associated with patient injury has been failure to use an oxygen analyzer.

Although not all of the above incidents involved patients connected to anesthesia gas machines, cross-connections also continue to be reported in anesthetized patients. In 1997 a case was described in which the nitrogen hose from the gas machine was discovered to be fitted with a quick-connect coupler for air (at the end that would be plugged into the wall outlet).[23] This did not result in patient injury, but would have allowed the delivery of 100% nitrogen had the machine been set to deliver air only. The consequences of this type of error in the oxygen wall-outlet hose could be disastrous. In 1995 it was reported in the United States that two patients became hypoxemic as a result of delivery of liquid nitrogen to the hospital in a tank with oxygen fittings.[44] In 2009 a wall fitting for carbon dioxide in a lithotripsy area allowed connection of a nitrous oxide hose from the gas machine, resulting in end-tidal carbon dioxide over 105 mmHg.[40] These incidents underscore our susceptibility to errors of ancillary personnel who install and test gas delivery apparatus. But they also highlight many patient-safety aspects, which anesthetists do control: properly checked oxygen analysis monitors, correctly checking the gas machine before use, and proper response to oxygen-analyzer alarms.

In the event of a suspected crossover, one would see declining inspired oxygen concentration. The anesthetist must open the emergency cylinder oxygen supply, disconnect the pipeline, and use low fresh gas flows and manual ventilation. If the pipeline is not disconnected, the pipeline gas will continue to flow, rather

BOX 15-4

Guideline for Oxygen Pipeline Supply Failure

Always check for the presence of a full E cylinder and an alternative means of ventilation (bag-valve-mask [Ambu] device) before using an anesthesia machine. If pipeline pressure fails or fraction of inspired oxygen drops, follow these steps:

1. Do not attempt to fix the oxygen analyzer—it must be trusted until it can be proved wrong.
2. Turn on backup oxygen cylinder on machine fully, and disconnect pipeline. Ensure that measured fraction of inspired oxygen begins to rise. If the fraction of inspired O_2 does not increase (with fresh gas flow adequate to wash in the O_2 quickly), ventilate the patient by Ambu bag with room air.
3. Use low flows of oxygen. Maintain anesthesia with a volatile agent. Ensure that F_{IO_2} and agent concentration are appropriate.
4. Turn off the ventilator and ventilate manually through the circle system.
5. Call for help if needed; calculate the time remaining for the current cylinder; call for additional oxygen cylinders, and install them on the machine if needed.
6. Find out how long the problem is expected to last; participate in the hospital disaster plan, which may require prioritizing oxygen for those patients who need it most.
7. Do not reconnect patient to pipeline gas until the gas supply is tested.
8. If unable to use the circle, ventilate with an oxygen source (freestanding cylinder) or with room air via a bag-valve-mask device, and institute total intravenous anesthesia.

TABLE 15-1 E Cylinder Characteristics*

Gas	Color, United States (International)	Service Pressure psi (kPa × 10^{-2})	Capacity (L)	Pin Position
Oxygen	Green (white)	1900 (131)	660	2-5
Nitrous oxide	Blue (blue)	745 (51)	1590	3-5
Air	Yellow (black and white)	1900 (131)	625	1-5

Data from Dorsch JA, Dorsch SE. *A Practical Approach to Anesthesia Equipment*. Philadelphia: Lippincott Williams & Wilkins; 2011; *Standard Specification for Particular Requirements for Anesthesia Workstations and Their Components* [F1850-00]. *Note that slightly different values may be found in different sources.

than the cylinder oxygen supply. This is because the pressure distal to the cylinder regulator is set at 45 psi (310 kPa), compared with the typical pipeline pressure of 50 psi (344 kPa). Lower pressure is intentionally set on the cylinder regulator so that flow proceeds from the higher-pressure pipeline source if a cylinder is inadvertently left open after the machine has been checked.[45] This is analogous to the situation with an intravenous main line and a piggyback line: whichever is held higher is the one that will flow (greater hydrostatic pressure). In the case of cross-connection between oxygen and nitrous oxide pipelines, the contents of the oxygen pipeline (now nitrous oxide) continue to flow (because the pipeline pressure is 50 psi), whether or not the oxygen cylinder is open. Thus, regardless of the problem with the pipeline supply (lack of pressure or cross-connection), the cylinder *must* be opened; the author advocates disconnecting the pipeline in any instance of problems with the pipeline. If the pipeline is not disconnected and has pressure within it, the emergency supply of oxygen may not flow from the cylinder.

Cylinder Supply

Cylinders are present on the anesthesia machine as reserves for emergency use. Thus they should be open *only* when they are checked, or when the pipeline supply is unavailable.[46] A fresh oxygen cylinder need not be obtained if the cylinder on the machine has an adequate pressure, the amount of which would depend on the availability of pipeline supplies and additional backup oxygen cylinders (see later in chapter under PreAnesthesia Checklist). Cylinders are labeled, marked, and color coded (Table 15-1).[18,47] Anesthetists who practice outside the United States must be aware that the color scheme may differ from country to country. Service pressure and cylinder contents are reported slightly differently in various sources.[48]

Pin position refers to the pin index safety system (PISS) illustrated in Figures 15-4 and 15-5. In this system, each cylinder valve has a unique arrangement of holes that corresponds to its intended contents. The holes mate with pins in the yoke, which is the point where cylinders are attached to the gas machine. The PISS is thus another means of preventing misconnections. The system can be defeated if the pins are missing, are removed, or if more than one washer is used. Anesthetists should check both pins and washers whenever cylinders are replaced. Furthermore, they should be aware that not all E cylinders are of precisely the right size to fit properly on the

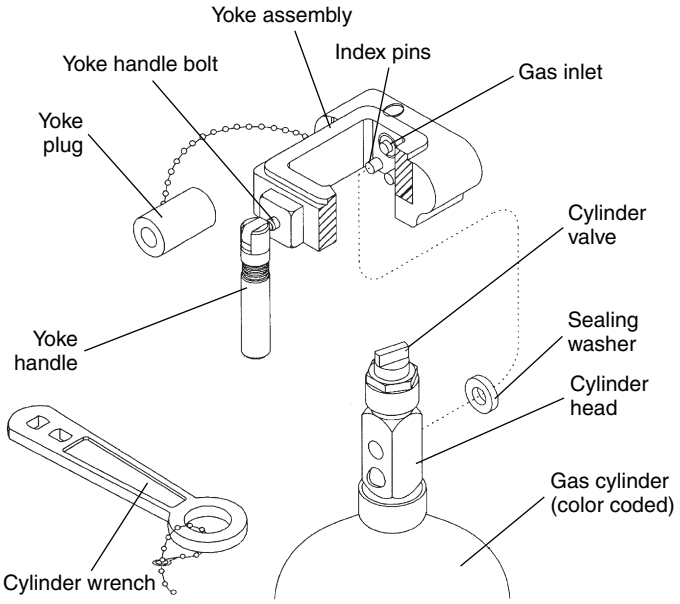

FIGURE 15-4 Pin index safety system, cylinder valve, and yoke. (From Dräger Medical Inc. Apollo Operator's Instruction Manual, Document No. 90 38 237, Rev. 01. Telford, Pennsylvania: Drägerwerk AG & Co. KGaA, Lubeck; 2005.)

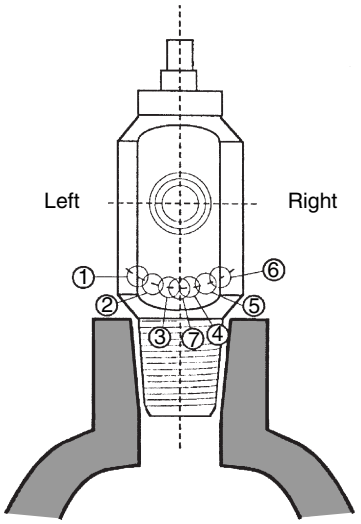

FIGURE 15-5 Pin index safety system: pin positions. (Modified from Eichhorn JH, Ehrenwerth J. Medical Gases: Storage and Supply. In Ehrenwerth J, Eisenkraft JB, eds. *Anesthesia Equipment: Principles and Applications*. St. Louis: Mosby; 1993:1-26.)

machine. Installation of a longer aluminum cylinder has interfered with the casters and prevented an anesthesia gas machine from being moved.[49]

The cylinder valve is the most fragile part of the cylinder, so it must be protected during transport. The cylinder valve consists of a body, the port where gas exits, a conical depression (opposite the port) for the securing screw, the holes where the pins on the yoke fit, and safety relief devices. If a fire causes the temperature and pressure within the cylinder to increase, safety relief devices release cylinder contents in a controlled fashion, rather than explosively. Manufacturers use one or more of the following on cylinder valves: a frangible disk that bursts under pressure, a valve that opens at extreme pressure, or a fusible plug made of Wood's metal (which melts at elevated temperatures).

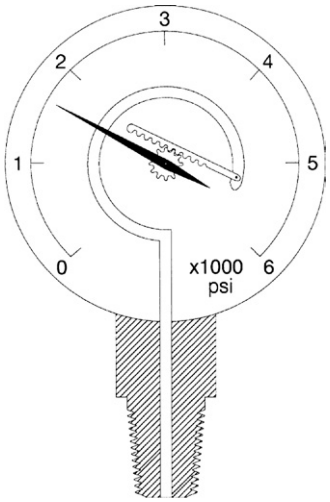

FIGURE **15-6** Bourdon-type pressure gauges are aneroid gauges used for measuring cylinder (and pipeline) pressure. (From Cicman J, et al. *Operating Principles of Narkomed Anesthesia Systems*. Telford, Penn: Dräger Medical Inc; 1993.)

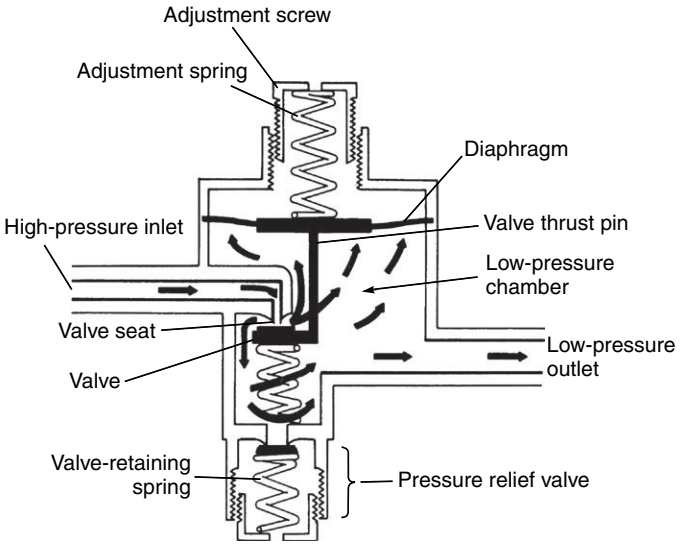

FIGURE **15-7** A schematic view of a cylinder regulator. (From Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, Wis: Datex-Ohmeda; 1985.)

The hanger yoke serves three functions: it orients cylinders, provides a gas-tight seal, and ensures unidirectional flow into the machine. It also contains a filter that is required by standard.[18] The unidirectional valve within the hanger yoke minimizes the likelihood of transfilling, or of leakage to the atmosphere (if a yoke is empty). It also allows cylinders to be replaced during use. If two cylinders are open, transfilling occurs when gas flows from the cylinder with higher pressure into the cylinder with lower pressure, rather than proceeding toward the flowmeters. Transfilling is a potential fire hazard because filling a cylinder generates heat. The cylinder pressure gauge is a Bourdon-type gauge (Figure 15-6).

Immediately distal to the hanger yoke for each gas is a regulator (Figure 15-7). Two diaphragms move together, connected by a rod. The smaller of the two diaphragms opens or closes the high-pressure inlet (from the cylinder). Gas entering the regulator exerts pressure on the larger diaphragm, whose movement tends to close the inlet. Thus gas can enter the regulator only at a rate controlled by a feedback loop. The outlet pressure is adjustable by a screw and spring that bear on the inlet diaphragm. Thus the regulator converts the high (but variable) cylinder pressure to a constant downstream pressure (45 psi [310 kPa]), which is intentionally slightly less than pipeline pressure in order to prevent silent depletion of cylinder contents.[18,30,32] Pipeline pressure varies, depending on the load that is placed on it throughout the facility. If a cylinder is left open, and pipeline pressure drops below 45 psi, gas will flow from the cylinder. No alarm will sound to warn the user of this condition.[25] Further, if the cylinder is left open after checking and the pipeline fails, the operator will not be alerted to the failure at the time it occurs, because gas will simply begin to flow from the cylinder, without alarms. If the mechanical ventilator is in use, a full E cylinder of oxygen may be depleted in as little as 1 hour, because the ventilator-driving gas in a bellows ventilator is usually oxygen.[36,50] The low oxygen supply failure alarm that rings subsequently announces the *end* of the emergency supply, instead of its beginning. This is the rationale for keeping cylinders closed after their pressure has been checked.

The U.S. Department of Transportation issues regulations for the manufacture, handling, transport, storage, and disposal of cylinders. These regulations have binding legal force. Industry advisory groups such as the Compressed Gas Association (CGA) and the National Fire Protection Association also have a role in setting cylinder standards. Cylinders are constructed of steel approximately ¼ inch in thickness. Only nonferrous (aluminum) cylinders may be used in the magnetic resonance imaging (MRI) environment.[48] Fatalities have occurred when steel cylinders have impacted patients in the MRI scanner.[51]

BOX 15-5

Rules for Safe Handling of Cylinders

Always
- Protect the cylinder valve when carrying a cylinder; it is the most fragile part.

Never
- Stand a cylinder upright without support; instead, lay it on its side.
- Leave empty cylinders on the machine.
- Leave the plastic cover on the port while installing the cylinder.
- Use more than one washer between a cylinder port and the yoke.
- Rely only on a cylinder's color for identification of its contents; read its labeling.
- Oil valves.
- Remove a cylinder from a yoke without filling the space with a yoke plug if available (see Figure 15-4), which is a backup strategy for guarding against check valve failure.

Anesthetists must be aware of the rules for the safe handling and use of cylinders.[25,52] Gas under pressure in cylinders has an enormous potential energy, which may be lethal if it is released in a rapid, uncontrolled fashion following damage to the cylinder valve. Selected rules for safe handling of cylinders are presented in Box 15-5.

When installing a cylinder, check the labels, crack the valve, check that both PISS pins are present, check that only one washer is present, place the cylinder in the hanger yoke, observe for the absence of an audible leak, and check for proper gauge pressure. The valve is "cracked" to remove dirt from the port. This is done by opening the valve briefly and carefully before the cylinder is

placed on the machine. While cracking the valve, hold the cylinder securely, and do not point the port toward oneself or other personnel.

When relying on cylinder supplies in an emergency, one must be able to calculate how long an oxygen cylinder will last. The following relationship should be used:

$$\frac{\text{Capacity L}}{\text{Service Pressure psi}} = \frac{\text{Contents Remaining L}}{\text{Gauge Pressure psi}}$$

Remember to consider the oxygen flow rate set on the flowmeter when deciding how long the available liters will last. As an example, if the oxygen flow is 2 L/min, and the cylinder's oxygen gauge pressure is 500 psi, how long will the cylinder last? From Table 15-1, we know that the service pressure is 1900 psi and that the capacity is 660 L. Substituting these values into the previous relationship, we obtain the following:

$$\frac{660\text{ L}}{1900\text{ psi}} = \frac{x\text{L}}{500\text{ psi}}$$
$$\text{and } x = 174\text{ L}.$$

Because 2 L of oxygen flow each minute, the cylinder will last approximately 87 minutes (174 L ÷ 2 L/min). This type of calculation is not applicable to compressed gases stored as liquids (nitrous oxide or carbon dioxide). It should be remembered that this calculation refers only to requirements at the flowmeters, and assumes manual ventilation. Use of a mechanical ventilator consumes approximately a minute volume of driving gas each minute, and thus should be avoided in situations in which oxygen supply is limited to cylinders only.[50]

The contents of cylinders must meet the purity requirements for medical gases established by the United States Pharmacopeia (USP). The contents are also regulated in the United States by the U.S. Food and Drug Administration (FDA). Oxygen is used to power ventilators throughout the hospital because it is dry, readily available, and relatively inexpensive.

Nitrous oxide is stored as a liquid; therefore the cylinder pressure of 745 psi (5136 kPa) represents the vapor pressure of liquid nitrous oxide at room temperature. The nitrous oxide cylinder pressure gauge remains at 745 psi until the liquid is gone; at this point, the cylinder is more than three-quarters empty. After this point, the nitrous oxide cylinder pressure swiftly declines with further use. Thus nitrous oxide cylinders should be changed if their pressure is less than 745 psi. Rapid removal (more than 4 L/min) from a cylinder may cause the formation of frost on its wall or freezing of the valve, owing to the loss of the latent heat of vaporization from the liquid nitrous oxide. Nitrous oxide is nonflammable, but it does support combustion.[25,48] Anesthesia personnel must be alert to the possibility of nitrous oxide abuse.[53]

Compressed air is not entirely dry. Its composition varies from sample to sample, but its major constituents are nitrogen (78%), oxygen (21%), and argon (nearly 1%). Carbon dioxide (0.03%) and other gases are present in trace amounts.

Electrical Power Supply

Electrical power is supplied to the gas machine through a single power cord, which can become dislodged. Because of this possibility, as well as the possibility of loss of main electrical power, new gas machines must be equipped with battery backup sufficient for at least 30 minutes of limited operation.[18] Which systems remain powered during this period is specific to each model, thus users must read the operator's manuals. For example, if you disconnect electrical power from the ADU (anesthesia delivery unit [GE Healthcare]) it loses patient monitors (electrocardiogram, noninvasive blood pressure, gas analysis, pulse oximetry, and other monitors displayed on the right screen), but fresh gas flow, volatile-agent delivery, and ventilation continue during the period that battery backup is used. Once battery power is lost, nitrous oxide and agent delivery are cut off.[54]

Convenience receptacles are usually found on the back of the machine so that monitors or other equipment can be plugged in. These convenience receptacles are protected by circuit breakers or fuses. It is a mistake to plug devices that convert electrical power into heat into these receptacles (air or water warming blankets, intravenous fluid warmers) for two reasons.[55] First, these devices draw a lot of amperage (relative to other electrical devices), so they are more likely to cause a circuit breaker to open. Second, the circuit breakers are in nonstandard locations (so check for their location before your first case). If a circuit breaker opens, all devices that receive power there (such as monitors and, in some configurations, the mechanical ventilator) may cease to function. If one is not familiar with the circuit-breaker location, valuable time may be lost while a search is conducted.

Loss of Main Electrical Power

Devices that typically *require* wall-outlet electrical power include mechanical ventilators, physiologic monitors, room and surgical-field illumination, digital flowmeter displays for electronic flowmeters, cardiopulmonary bypass pump/oxygenators, air warming blankets, gas/vapor blenders (Suprane Tec 6 [GE Healthcare]), and vaporizers with electronic controls (Aladin cassettes in the ADU).

Devices (or techniques) that typically *do not* rely on wall-outlet electrical power include spontaneous or manually assisted ventilation, mechanical flowmeters, scavenging, laryngoscope, flashlights, manual intravenous bolus or gravity-controlled infusions, battery-operated peripheral nerve stimulators or intravenous infusion pumps, monitoring by the anesthetist using the five senses, and variable bypass vaporizers (Tec 7 [GE Healthcare]; Vapor 2000 [Dräger Medical]).

Generally, hospitals have emergency generators that will supply operating-room electrical outlets in the event power is lost. But these backup generators are not completely reliable. A 90-minute interruption in power during cardiopulmonary bypass, complicated by almost immediate failure of the hospital generators, has been described.[56] Injury to personnel as they hurried in the dark to fetch lights and equipment was an unanticipated hazard.

With power failure in older gas machines, the principal problems were loss of room illumination and failure of mechanical ventilators and electronic patient monitoring. In general, new gas machines have battery backup sufficient for 30 minutes of operation—however, typically without patient monitors (e.g., electrocardiogram, pulse oximetry, gas analysis). Mechanical ventilation may or may not be powered by the backup battery (depending on the model). New flowmeters that are entirely electronic (Aisys and Avance [GE Healthcare]) require a backup pneumatic/mechanical (needle-valve and flowtube) flowmeter.[15,57-59] Mechanical flowmeters with digital display of flows have a backup glass flow tube that indicates total fresh gas flow (ADU[54] [GE Healthcare]; Fabius GS[60] and Apollo [Dräger Medical]).

New gas machines with mechanical needle valve flowmeters and variable bypass vaporizers (e.g., Fabius GS, Apollo, or Aestiva [GE Healthcare]) have an advantage during electrical power failure in that delivery of gases and agent can continue indefinitely.[46,60] However, in the event of generator failure, anesthesia would be limited to flashlight illumination and monitoring by the five senses. The Apollo (Dräger Medical) provides gas and vapor delivery, mechanical ventilation, and integrated monitoring

(e.g., oxygen, breathing circuit volume and pressure, gas analysis) for 30 minutes or more if main electrical power is lost.[61,62] Patient monitors will not function on battery power. Pneumatic functions remain even after the battery is exhausted: vaporizers, S-ORC (fail-safe and hypoxic guard), adjustable pressure-limiting (APL) valve, flowmeters, breathing pressure gauge, cylinder and pipeline pressure gauges, and total fresh gas flowmeter.

Because of the differences between models, it remains important to understand and anticipate how each particular anesthesia gas machine type responds when main electrical power is lost. This information must be reviewed in the operator's manual.

PROCESSING

In this section, the various aspects of the anesthesia gas machine's preparation of gases before their delivery to the patient are discussed.

Manufacturers and Models

Manufacturers of anesthesia gas machines in the United States include Dräger Medical and GE Healthcare. There are some imported models in the market as well (e.g., Paragon, Mindray). Dräger Medical Inc. (Telford, Pennsylvania) is the manufacturer of the Narkomed series (6000 and 6400, GS, MRI, Mobile models), the Apollo, and the Fabius GS. GE Healthcare (Madison, Wisconsin) is the manufacturer of the Aestiva, Aestiva MRI, Avance, Aisys, Aespire, and ADU.

Gas machines that are not currently produced remain in widespread use, because the service life is long—10 to 15 or more years. Currently produced models meet or exceed the specifications of the anesthesia workstation standard F1850. The differences among new gas machines are significant; thus what one learns on one may not transfer very well to a different model. This is particularly true of preanesthesia checkout (see below in a later section). The differences are pointed out in this chapter when they are relevant to clinical practice or to demonstrate by comparison how systems function. This section continues with an overview of several current gas machines.

Fabius GS

The Dräger Fabius GS (Figure 15-8) includes volume, pressure, flow, and inspired oxygen monitoring; but not physiologic monitors or gas analysis. The thermal anemometry ("hot wire") flow sensor in the breathing circuit is unique to this machine and a few others.[60] The screen displays tidal and minute volume, respiratory rate, and a respiratory pressure waveform.

The ventilator is piston driven; corrects tidal volume for compliance and leaks; and features manual, spontaneous, volume-controlled ventilation (VCV); pressure-controlled ventilation (PCV); pressure-support ventilation (PSV); and synchronized intermittent mandatory ventilation (SIMV) with PSV.[60] Like the Apollo, the mechanical ventilator is activated in two steps (the mode is chosen, and then confirmed by a second key press). The machine uses a manual checklist with several electronic self-tests (e.g., system, leaks and compliance, flow sensor, oxygen sensor). With the Fabius GS (as with all the new models), users must review the operator's manual to check the machine correctly. Sample preanesthesia checkout procedures are available.[63] The flowmeters are needle valves with electronic capture and display, with a common gas outlet glass flowmeter as backup. Variable-bypass vaporizers are used, and these may be removed without tools.

The Fabius GS breathing circuit is lower volume than older gas machines (2.8 L plus bag; of which 1.2 L is absorbent volume).[64,65] The absorber head is not warmed. Loose carbon dioxide absorbent granules or prefilled canisters may be used. There is an

FIGURE **15-8** Fabius GS. (Courtesy Dräger Medical Inc, Telford, Penn.)

open scavenger interface. Fresh gas decoupling causes the manual breathing bag to fluctuate during the mechanical ventilator cycle, which serves as a further disconnect alarm.

In case of electrical power failure, there is a 45-minute battery reserve with fresh gas, vaporizers, integrated monitors, and ventilator operational. Because they are not part of the gas machine, patient monitors will not function. Several pneumatic functions remain after the battery is exhausted: vaporizers, hypoxic guard, adjustable pressure-limiting (APL or "popoff") valve, flowmeters, breathing pressure gauge, cylinder and pipeline pressure gauges, and common gas outlet flowmeter.

Narkomed 6000/6400

The Dräger Narkomed 6000 (Figure 15-9) includes volume, pressure, flow, and inspired oxygen monitoring. It also includes gas monitoring (infrared agent and carbon dioxide) and an ultrasonic flow sensor in the breathing circuit (unique to this machine). An integrated patient monitoring module is available as an option, so all parameters are displayed on the single-touch screen.[66]

The 6000 includes a piston ventilator (Divan) with tidal volume corrected for leaks, patient and breathing circuit compliance, and fresh gas flow (by fresh gas decoupling). The ventilator is capable of manual, spontaneous, VCV, PCV, and SIMV modes. Like the Fabius GS, there is no "bag/vent" switch, because changing ventilator mode is controlled electronically. Like most new model ventilators, it is accurate to very low tidal volume (range 10 to 1400 mL), which lessens the need for nonrebreathing circuits.

From a cold startup, there is a 1-minute power-on self-test, then a 5-minute ventilator self-test.[66] One can bypass the ventilator test for 10 days (or 10 times) only, after which the ventilator is unavailable until its self-test is performed. The machine checkout, as with most newer machines, is unique is some respects. For example, the manufacturer recommends breathing through each

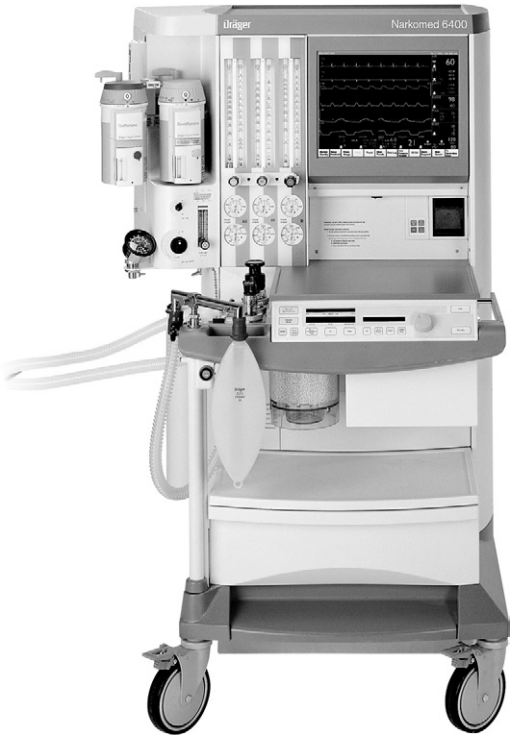

FIGURE **15-9** Dräger Narkomed 6000/6400. (Courtesy Dräger Medical Inc, Telford, Penn.)

FIGURE **15-10** Dräger Apollo. (Courtesy Dräger Medical Inc, Telford, Penn.)

FIGURE **15-11** GE Healthcare Aestiva. (Courtesy GE Healthcare, Madison, Wis.)

circuit limb to test unidirectional valves and disconnecting the oxygen wall hose to check the oxygen pipeline pressure-failure device. Sample checkout protocols are available.[63]

Flowmeters are composed of needle valves and glass flowtubes, but electronic capture of fresh gas flows has been added in the 6400. Variable-bypass vaporizers are used, and these may be removed without tools. The breathing circuit is lower volume (1.5 L absorbent volume), and the absorber head is warmed.[66] Only loose carbon dioxide–absorbent granules may be used. An open scavenger interface or passive evacuation may be used. In case of power failure, there is a 30-minute battery reserve with fresh gas, vaporizers, monitors, and ventilator operational.

Apollo

The Dräger Apollo (Figure 15-10) includes volume, pressure, flow, and inspired oxygen monitoring. It also includes gas monitoring (agent and carbon dioxide). Spirometry is optional.[15,61,62] The piston ventilator corrects tidal volume for leaks, compliance, and fresh gas flow (by fresh gas decoupling). Like the Fabius, the mechanical ventilator is activated in two steps (the mode is chosen, and then confirmed by a second key press). The ventilator is capable of manual, spontaneous, VCV, PCV, PSV, and SIMV modes. SIMV may be used in either volume or pressure modes. It is accurate to very low tidal volume (range 20 to 1400 mL).[62,67] Mechanical needle valves govern fresh gas flow, which is electronically measured and displayed on screen. A backup total fresh gas flowmeter tube is present. An electronic checklist assists the user in pre-use checkout.[61] The scavenger interface is open.

Aestiva

The Aestiva (GE Healthcare; Figure 15-11) has many traditional (i.e., mechanical/pneumatic) systems, but with a modern and capable 7900 ventilator. It includes volume, pressure, flow, and inspired oxygen monitoring. Gas analysis and patient physiologic monitors must be added (like most current machines except ADU, Aisys, Avance, and 6400).[15,68] The 7900 ventilator uses an oxygen-driven standing bellows capable of manual, spontaneous, VCV, PCV, PSV-Pro (which includes apnea backup[69]), and SIMV.

The flow sensors compensate tidal volume for compliance losses and leaks in the absorber head and bellows, so the ventilator is accurate to very low tidal volume (range 20-1500 mL).[67] These variable orifice flow sensors have shown some sensitivity to moisture in the breathing circuit in the past.[70] The "bag/vent" switch activates the mechanical ventilator in one step. The absorber

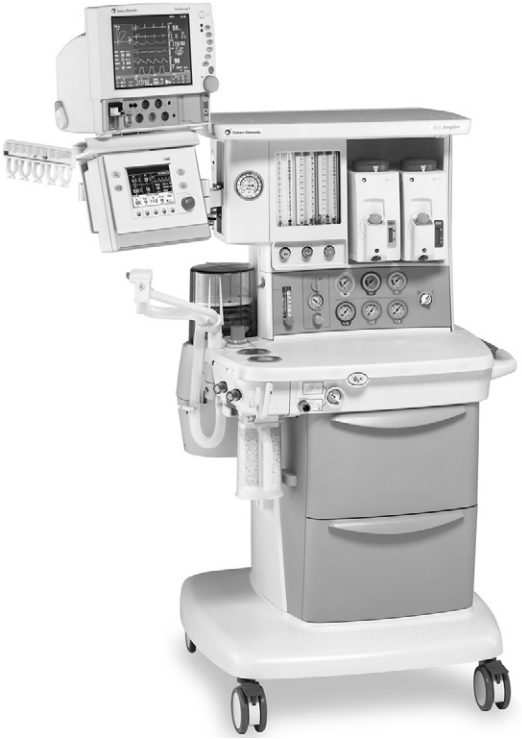

FIGURE **15-12** GE Healthcare Aespire. (Courtesy GE Healthcare, Madison, Wis.)

FIGURE **15-13** GE Healthcare Aisys. (Courtesy GE Healthcare, Madison, Wis.)

head design allows for easier disassembly and cleaning than older models. The Aestiva uses a pre-use checklist that relies on the user to perform more manual procedures than the checklist for the Apollo, Fabius, Aisys, or ADU.

Flowmeters are traditional mechanical needle valves with glass flowmeter tubes. Thus there is no electronic capture of fresh gas flows, as in machines with digital flow display. The oxygen sensor is the galvanic fuel cell type, and the hypoxic guard is mechanical (Link-25).[68] Variable-bypass vaporizers are used, and these may be removed without tools. The breathing circuit is relatively high volume (5.5 L, including dual canisters of 1.35 kg absorbent each).[64,71] Loose fill granules or prepackaged absorbent may be used. The machine is compatible with circle or nonrebreathing circuits. The scavenger is available as a closed scavenger interface. There is a 30-minute battery reserve with fresh gas, vaporizers, and ventilator operational. The Aestiva is also available in a version compatible with the magnetic resonance imaging (MRI) suite.

Aespire

The Aespire (GE Healthcare; Figure 15-12) is like the Aestiva in most of its systems, but is more compact. The standing bellows, oxygen-driven ventilator offers tidal volume compensation. Volume control and pressure control are the two modes of ventilation available.[72]

Aisys

The Aisys (GE Healthcare), along with Avance, ADU, and 6400, is a complete workstation, in that physiologic monitors are included (e.g., electrocardiography, blood pressure, pulse oximetry).[59] The Aisys (Figure 15-13), introduced in 2005, uses the oxygen-driven, standing bellows 7900 Smartvent (like Aestiva) but offers more modes. Modes available include manual, spontaneous, VCV, PCV, pressure control with volume guarantee (PCV-VG, which is unique to Aisys and Avance), PSV-Pro with apnea backup, and SIMV with pressure support of the patient's spontaneous breaths (SIMV-PS) in either volume or pressure mode. Spirometry is included to help monitor and control ventilation. The ventilator can support a very wide range of tidal volumes (20-1500 mL[67]), so there is no need for nonrebreathing circuits for children. Like most modern ventilators, the low circuit volume, freedom from leaks, and microprocessor control support the use of low-flow anesthesia. The fresh gas inlet enters the circle system distal to the inspiratory valve (like Avance and ADU), supporting fast response to changes in desired gas concentrations, even at low flows.[73]

Aisys is similar to the ADU in that it uses Aladin cassette vaporizers, which are electronically controlled. Aisys is similar to Avance—and unique in the North American market—in that it uses electronic control, measurement, and display of fresh gases (Figure 15-14). The user does not control the flow of each gas directly, as is usual, but instead selects the desired carrier gas (nitrous oxide or air), total fresh gas flow, and inspired oxygen concentration. There are no needle valves or glass flowmeter tubes to control individual flows of oxygen, nitrous oxide, or air. In case of electronic failure, there is a backup needle valve and glass flowmeter tube for control and display of total fresh gas flow.[15,58,59]

Avance

The Avance (GE Healthcare; Figure 15-15) is similar to the Aisys in most respects: electronic fresh gas flow controls with backup pneumatic control, modern and capable multimode 7900 ventilator, spirometry, and integrated physiologic monitoring. The pneumatic/mechanical Tec 6 and Tec 7 vaporizers included in the Avance are the primary difference between it and the Aisys.

ADU

The ADU (GE Healthcare; Figure 15-16) includes all monitoring: volume, pressure, flow, inspired oxygen, gas analysis (agent and carbon dioxide), patient physiologic monitoring, and spirometry (flow-volume and pressure-volume respiratory loops). The ventilator is an oxygen-driven standing bellows, with tidal volume

FIGURE **15-14** Electronic control of inspired oxygen, carrier gas, and total fresh gas flow, Aisys. (Courtesy GE Healthcare, Madison, Wis.)

FIGURE **15-15** GE Healthcare Avance. (Courtesy GE Healthcare, Madison, Wis.)

corrected for leaks, compliance, and fresh gas flow (via the D-Lite sensor at the Y-piece). It is accurate to very low tidal volumes (20-1400 mL[74]) and capable of manual, spontaneous, VCV, PCV, SIMV, and PSV. The "bag/vent" switch activates the mechanical ventilator in one step.[54,74]

The ADU (like Aisys, Fabius, and Apollo) uses an almost completely automated checklist routine. Because the D-Lite sensor is removed from the breathing circuit during checkout, one must perform a high-pressure check of the breathing circuit after reassembly.

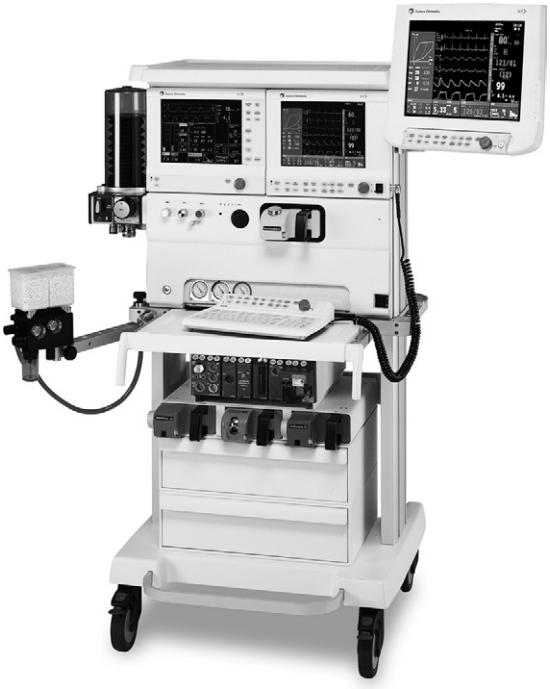

FIGURE **15-16** GE Healthcare Anesthesia Delivery Unit (ADU). Machine monitors are on the left screen (including video screen display of fresh gas flow); patient monitors are on the right (including electrocardiograph and blood pressure). (Courtesy GE Healthcare, Madison, Wis.)

Fresh gas flow control is accomplished by mechanical needle valves. Flow is captured and displayed electronically, with a glass common gas outlet flowmeter as an optional backup. The Aladin vaporizer cassettes may be tipped from the vertical during transport without any risk, because they are merely repositories for liquid anesthetic. The vaporizer's electronic mechanisms, which are within the gas machine, control the delivery of any agent chosen.

The breathing circuit is very low volume, about 2 L (with 600 mL absorbent volume).[74] Only the manufacturer's carbon dioxide absorbent canisters may be used, which are single-use or refillable with loose granules. Certain disposables are only available from the manufacturer (e.g., spirometry tubing, D-Lite sensor, absorbent granule canisters). The machine is technically compatible with nonrebreathing circuits, but the need for them is questionable because the machine can ventilate patients who weigh as little as 3 kg.

The scavenger interface is open. Scavenger suction adequacy is indicated on an optional glass flowmeter below the bellows. There is a 30-minute battery reserve with fresh gas, vaporizers, and ventilator operational. Patient monitoring (right screen) is lost unless main electrical power (or generator backup) is available. In this respect most gas machines, new or old, function similarly.

Path of Gases Through the Machine

Oxygen, nitrous oxide, and air follow similar paths through the anesthesia gas machine (see Figure 15-1). Each passes from its supply point to a flowmeter. All gases (except oxygen and in newer models, air) pass through a fail-safe valve before proceeding to their flowmeters. This valve is held open by pressure in the oxygen circuitry within the anesthesia gas machine. After passing through their respective flowmeters, the gases are joined for the first time in a common manifold. Oxygen is always added to the common manifold downstream of other gases so that the chance of hypoxic

BOX 15-6

Components of Flowmeters

- Knob
- Needle valve
- Valve stops (not present on all machines)
- Flowtube
- Indicator float

breathing mixtures is lessened (e.g., in the event that a flowmeter tube has cracked).[75] The combined gases enter any vaporizer that is turned on, and then pass through the common gas outlet. A delivery hose with a locking connection conducts gases from the common gas outlet to the breathing circuit.

The breathing circuit and ventilator (if used) transport gases to and from the patient. An amount equal to the fresh gas flow per minute (minus patient uptake, plus gases excreted), leaves the breathing circuit and is conducted to the scavenger interface. From there, it is disposed of in the hospital ventilation or suction systems.

Five Tasks of Oxygen

Oxygen has five tasks in the anesthesia gas machine: (1) it proceeds to the fresh gas flowmeter, (2) powers the oxygen flush, (3) activates fail-safe mechanisms, (4) activates oxygen low-pressure alarms, and (5) compresses the bellows of mechanical ventilators (see Figure 15-1). The other gases supplied by the machine have only one pathway; they are transported via flowmeter and breathing circuit to anesthetize the patient (nitrous oxide) or sustain life (oxygen, and the oxygen fraction from the air flowmeter). Newer machines can switch to air as a driving gas for the ventilator bellows if oxygen pressure is lost.

Flowmeter

The first task of oxygen is proceeding through the flowmeter and on to the patient as a life-sustaining gas. Flowmeters have several components (Box 15-6). Control knobs are color and touch coded; thus the oxygen flow control knob is distinct, in visual appearance and tactile form, from the control knobs for the other gases (Figure 15-17).[76,77]

It is not necessary to use more than moderate force to shut off gas flow. The needle valve, which controls gas flow through the flowmeter, can be damaged if excessive force is used. Valve stops (Figure 15-18) are usually incorporated to prevent damage. Note that there are no valve stops in the ADU needle valves. Flow increases when the knob is turned counterclockwise. All current gas machines use mechanical needle valves except Avance and Aisys, which use electronic controls for flow. On these machines, backup oxygen controls using mechanical/pneumatic needle valves are present, in case of electronic or electric failure.

Display of Fresh Gas Flow. An indicator float in a glass tube (Thorpe tube) is the classic way to capture and display fresh gas flow. Oxygen flow and concentration is calibrated to ±5% (or ±20 mL/min) accuracy at room temperature and sea level.[57] Flowmeter tubes are specific for each gas and cannot be interchanged. The flowtube is tapered to be narrower at its bottom. Thus it may be referred to as a *variable orifice flowmeter* because the annular opening around the float is larger at higher flows. If a gas has two tubes, they are connected in series with a single control valve (Figure 15-19). It is standard in the United States (but not in the United Kingdom) for the oxygen flowtube to be placed to the right of other

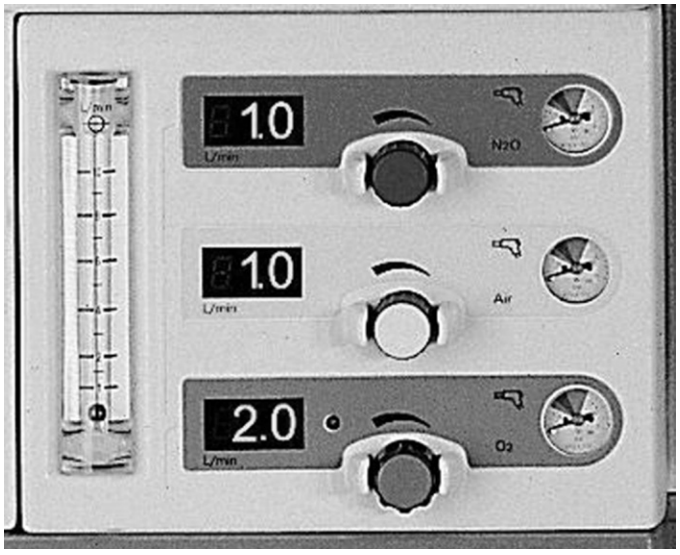

FIGURE **15-17** Flowmeters on the Fabius GS are arranged vertically. The oxygen knob (*at the bottom*) is different visually, and to touch, from control knobs for air and nitrous oxide. To the left of each flow-control knob is a digital display of flow; to the right is the pipeline pressure gauge for each gas. The common gas outlet flowmeter is to the left. flowtubes. Flowmeters on the Fabius GS are unique in that they are arranged vertically, rather than side by side (Figure 15-17).[60,65] The flowtubes are the most fragile part of the machine. They are susceptible to breakage, leaks at their seals, and inaccuracy due to the presence of dirt or static electricity.[25]

Rather than using glass flowtube displays, many newer gas machines capture and display flows electronically by means of an anemometer, or by a transducer and chamber of known volume. The chamber fills to a set pressure, and then the gas is allowed to proceed. The number of times this cycle occurs per minute can be converted to gas flow, which can be saved and sent to the automated medical record. These newer machines dispense with glass flowtubes, instead displaying fresh gas flows as colored bar graphs, with numeric data, on a computer screen (e.g., ADU, Fabius GS, Aisys, Apollo). At the common gas outlet, machines with electronic flow displays have a backup glass flowmeter, to measure total fresh gas flow continuously, and in the event of screen or electrical power failure. The Narkomed 6400 uses regular glass flowtubes for display of flows, but can capture flows electronically.[66]

Setting fresh gas flow on the Aisys and Avance is quite different. The flowmeter controls and display are all electronic. The display is numeric, with an optional bar-graph display. The user sets the inspired oxygen concentration desired, the total fresh gas flow, and what carrier gas is desired (nitrous oxide or air) (see Figure 15-14).[57-59,73]

Care of Flowmeters. Flowmeters with conventional needle valves and glass flowtubes should be turned off before pipelines are connected, cylinders are opened, or the machine is turned on. If a flowtube is left open, the float will shoot to the top of a glass tube and may damage it. Flowmeters should be included in visual monitoring sweeps. Never adjust a flowmeter without looking at it. Read ball-type indicator floats in their center (Dräger) and plumb bob–type floats at the top (older Datex-Ohmeda). Remember to turn off flowmeters after each case, and particularly at the end of the day. Failure to do so may contribute to premature drying of the carbon dioxide absorbent, which not only hastens its exhaustion, but has been implicated in an increased degradation of volatile agent, the generation of carbon monoxide in canisters, and canister fires.[78-86]

Other Flowmeters

Auxiliary Oxygen Flowmeters. Auxiliary oxygen flowmeters are an accessory currently offered on most models of gas machines. They are useful for attaching a nasal cannula or simple face mask. In the past, it was common to attach a nasal cannula to an adapter at the common gas outlet. The auxiliary oxygen flowmeter is advantageous, because the breathing circuit and gas delivery hose (between the common gas outlet and breathing circuit) remain intact while supplemental oxygen is delivered to a spontaneously breathing patient. Thus if the anesthetist needs to switch from a nasal cannula to the circle breathing system during a case, he or she can accomplish this instantaneously and without the possibility of forgetting to reconfigure the breathing circuit properly. Another advantage is that an oxygen source is readily available for the Ambu bag if the patient needs to be ventilated manually for any reason during a case (e.g., breathing circuit failure). One disadvantage is that the auxiliary flowmeter is unusable if the pipeline supply has lost pressure or been contaminated; this is because the auxiliary flowmeter is supplied by the same wall outlet and hose connection that supplies the main oxygen flowmeter. If users do not realize this, time could be wasted while they attempt to use this potential oxygen source.[87] Another disadvantage is that the fraction of inspired oxygen supplied cannot be varied with the auxiliary flowmeter. The chance of fire in sedated patients undergoing head and neck surgery can be lessened with reduced F_{IO_2}, scavenging the oxygen, and tenting the drapes.[88]

Common Gas Outlet Flowmeters. Common gas outlet flowmeters (Figure 15-20; also, to the left in Figure 15-17) are used as a backup on gas machines that electronically capture and display flows on a computer screen. If offered as an option, they are strongly recommended; they are the only indication of oxygen flow if the computer display fails, or in a power-failure situation after battery backup is exhausted.

Scavenging Flowmeters. Scavenging flowmeters are used on most new machines that use scavenging interfaces. An indication that suction is adequate is mandatory with these systems, in order to avoid exposure to waste anesthesia gases (see Disposal section). Unfortunately, the suction indicator is usually not visible from the operator's normal position.[89] On the Fabius GS, for example, it is on the back of the machine near the E cylinders.[60] On the ADU, the scavenger suction flowmeter is behind and beneath the bellows block on the left side of the machine (Figure 15-21).[54] On the Aisys, the adjustment is beneath the bellows block.[90] Even

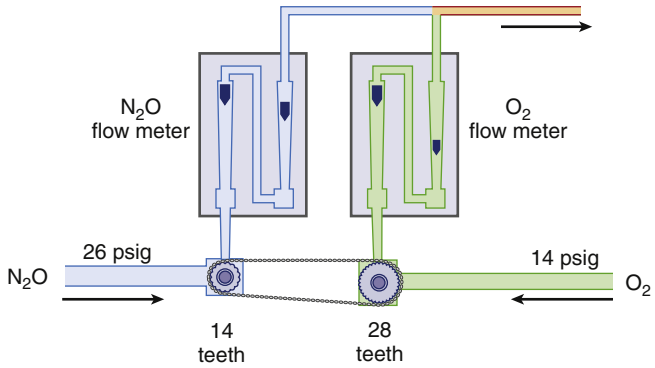

FIGURE **15-19** When two flowmeters are present for one gas, they are arranged in series (gas flows first through fine [calibrated in mL] then coarse [calibrated in liters] flow tubes). The figure also depicts the Link-25 proportioning system. (From Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010.)

FIGURE **15-20** The common gas outlet flowmeter on the ADU is located to the left of the writing surface. (From *S/5 Anesthesia Delivery Unit User's Reference Manual,* Catalog No. 8502304. Madison, Wis: Datex-Ohmeda; 2000.)

though scavenging flowmeters are desirable, they may not be included with the basic package but only as an optional accessory (e.g., the ADU).

Oxygen Flush

The second task of oxygen in the processing area of the machine is to supply the oxygen flush valve. The flush valve is required by standard to deliver from 35 to 75 L/min.[18,91] The purpose of the flush valve is to quickly fill the breathing circuit with oxygen. The flush valve is often protected by a rim that lessens the chance of accidental activation of the flush. Should this occur, barotrauma can result. Users should avoid activating the flush while the mechanical ventilator is in the inspiratory phase; during this phase, the ventilator relief valve closes, preventing gas from exiting to the scavenger.[92] If flushing is necessary for filling the ventilator bellows, it should be done in short pulses, during the expiratory phase.

The oxygen flush line proceeds directly from the gas supply source to the common gas outlet (see Figure 15-1). Activating the flush bypasses the vaporizers, and adds 100% oxygen to the breathing circuit. If partial pressures of nitrous oxide or volatile agent have already been established in the breathing circuit (during maintenance), excessive use of the oxygen flush tends to dilute these inhaled agents and may lessen the depth of anesthesia.

FIGURE **15-21** The scavenger suction flowmeter on the ADU is located behind and beneath the bellows block on the left side of the machine.

Fail-Safe Systems

If pipeline oxygen pressure fails, and other gases such as nitrous oxide keep flowing, the patient might receive a hypoxic gas mixture (less than 21% oxygen). Therefore gas machines incorporate devices that halt the supply of all other gases in the event of oxygen supply pressure failure. These are called *fail-safe systems*. It is required by standard that the set concentration of oxygen at the common gas outlet does not decline if the pipeline pressure decreases.[18] This requirement is satisfied by the presence of gate-like valves in the internal supply line for nonoxygen gases. The "gate" in each is held open by pressure in the oxygen line (Figure 15-22). Flow of nitrous oxide may be shut off with oxygen pressure below a set limit (e.g., Avance, Fabius GS) or proportionally decreased (e.g., Aestiva, ADU).[54,57,68,71,74] It is important to note that fail-safe systems do not analyze oxygen pipeline contents, so they are activated only if oxygen pipeline pressure falls. They do not protect the patient from a crossover, in which oxygen pipeline pressure is intact, but the line does not contain oxygen.

Fail-safe devices were once placed in air lines as well, with the rationale of leaving oxygen (however briefly) as the last gas flowing, even if oxygen pipeline pressure is lost. However, it is not possible to deliver a hypoxic mixture of air, and leaving air flowing is useful to drive the ventilator bellows in case of oxygen pipeline pressure failure. So the trend in newer equipment is to place fail-safe valves in the nitrous oxide line only, and rely on electronic proportioning systems to prevent hypoxic gas mixtures if oxygen pipeline pressure fails. This is accomplished by shutting off nitrous oxide, and leaving agent and air flowing, with air available to drive the ventilator bellows.

Low-Pressure Alarms

The fourth task of oxygen is powering the low-pressure alarms, which signal the operator when pressure is lost in the oxygen circuitry. The older oxygen supply failure alarm was a container with a whistle at its outlet that was pressurized by oxygen when the anesthesia gas machine was turned on. When pipeline pressure decreased to 28 psi, or when the machine was shut off, a characteristic loud whistle was heard as the container released its contents. Newer models lack this distinctive alarm, substituting a variety of visual and auditory alarms.[20,29,32] The proper response to loss of

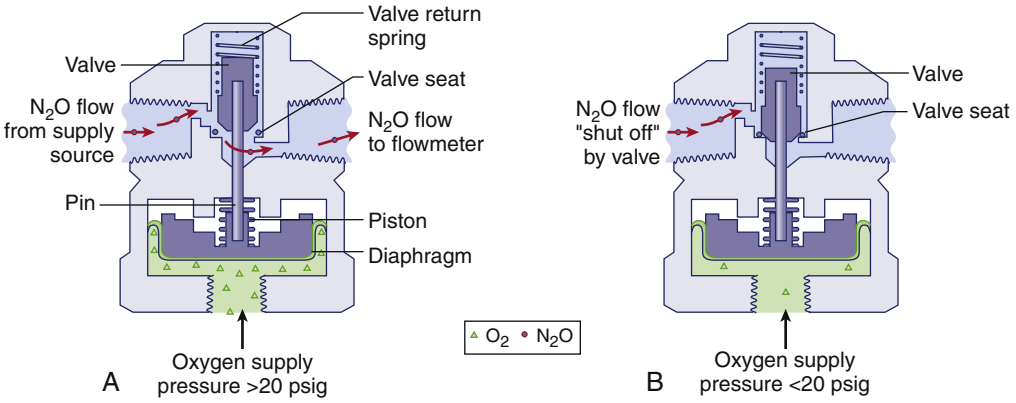

FIGURE **15-22** Fail-safe valve in the nitrous oxide line. (Redrawn from Bowie E, Huffman LM: The Anesthesia machine: Essentials for Understanding. Madison, WI, Ohmeda, A Division of BOC Health Care, Inc., 1985. In RD Miller et al., Eds: *Miller's Anesthesia*, 7th ed, Philadelphia, 2010, Churchill Livingstone.)

pipeline pressure is discussed earlier in this chapter (see Supply section).

Ventilator Driving Gas

The fifth task of oxygen in many anesthesia gas machines is compression of the ventilator bellows. All GE Healthcare anesthesia ventilators use 100% oxygen as their driving gas.[71,74] The ADU may use either air or oxygen, and will switch automatically from oxygen to the secondary drive gas (air) if oxygen pressure is lost.[54,74]

Older Dräger ventilators (e.g., AV-E, AV-2) used oxygen to drive a Venturi device, which augmented the driving gas with entrained room air.[93] Room air enters through a shiny (chrome or stainless steel) cylindrical muffler, which may be seen at the back of some Narkomed models. If this muffler becomes dirty, insufficient gas may enter; the lack can interfere with the ability of the ventilator to compress the bellows. If driving gas is prevented from exiting via the muffler, the bellows may remain compressed and barotrauma results.

Newer model piston ventilators use electric motors to compress the bellows and deliver tidal volume (e.g., Narkomed 6000/6400, Fabius GS, Apollo).[60-62,66] Thus ventilator delivery of tidal volume is unaffected by variation in, or even the absence of, oxygen pipeline pressure. Piston ventilators may operate for prolonged periods with only cylinder supplies of gases because they do not consume oxygen to drive the bellows. This is an advantage in office-based anesthesia, in other settings where pipelines are not available, and in emergency loss of pipeline pressure.[94]

Proportioning Systems (Hypoxic Guard)

All current anesthesia gas machines incorporate nitrous oxide–oxygen proportioning ("hypoxic guard") systems designed to prevent the delivery of hypoxic breathing mixtures. All link oxygen and nitrous oxide flows, so that final breathing mixtures at the common gas outlet are at least 23% to 25% oxygen.* The ratio of nitrous oxide to oxygen is thus kept at not more than 3 to 1.

An example of a pneumatic-mechanical proportioning system is the Link-25 (used on Aestiva and Aespire). In this system, the flowmeter control knobs for nitrous oxide and oxygen are linked by a chain; oxygen flow is increased automatically when nitrous oxide flow is increased. The Link-25 system (Figures 15-19 and 15-23) also incorporates secondary regulators, so it has both pneumatic and mechanical components.

On contemporary machines, these hypoxic guard system controls are primarily electronic. Dräger Medical calls their system a "sensitive oxygen ratio controller" (S-ORC), and uses it in the Apollo, Fabius, and Narkomed 6000.[62] This system also maintains at least 23% oxygen, but does so by limiting nitrous oxide flow. Electronic alarms are incorporated, and the system includes a nitrous shutoff (so a fail-safe system is incorporated as well).

Hypoxic guard systems are not foolproof. Box 15-7 lists four situations in which a hypoxic breathing mixture can be delivered despite the use of these systems. Lack of oxygen in the oxygen pipeline may be detected with an oxygen analyzer. A system that is broken or defective[95] should be detected in the pre-use checklist, as should leaks downstream of the flowmeters. The most dangerous of these circumstances is the last, the administration of a third gas, especially that of an inert gas such as helium. It is not widely appreciated that the hypoxic guard systems link *only* nitrous oxide and oxygen. Perhaps because of the name, the faulty assumption is made that *all* hypoxic breathing mixtures are prevented. These systems would *not* prevent the administration of a hypoxic mixture if a third inert gas (such as helium) is present on the gas machine. The proper use of a calibrated oxygen analyzer in each general anesthetic will always be of vital importance.

Many older Narkomed machines have a switch with two positions: "Nitrous Oxide–Oxygen" and "All Gases." In the Nitrous Oxide–Oxygen position, the hypoxic guard is active, and only these two gases may flow. In the All Gases position, the hypoxic guard and alarms are inactivated, and all gases (except nitrous oxide) may flow.[93] The ADU has a similar switch.

Oxygen Analysis

Systems that warn of trouble with oxygen supply (low pressure alarms) or lessen the chances of hypoxemia (hypoxic guard system, fail-safe system) are based on *pressure* within the oxygen circuitry of the gas machine. They do *not* sample the oxygen lines to determine that *oxygen* is present. There is only one system that ensures that oxygen is present in the oxygen pipeline or cylinder (and ultimately in the breathing circuit and the patient): inspired oxygen analysis. Monitoring inspired oxygen is mandatory in every general anesthetic, and the function of the oxygen monitor must be checked before giving any kind of anesthesia care, because general anesthesia may need to be induced as a backup plan in any anesthetic.[96-99]

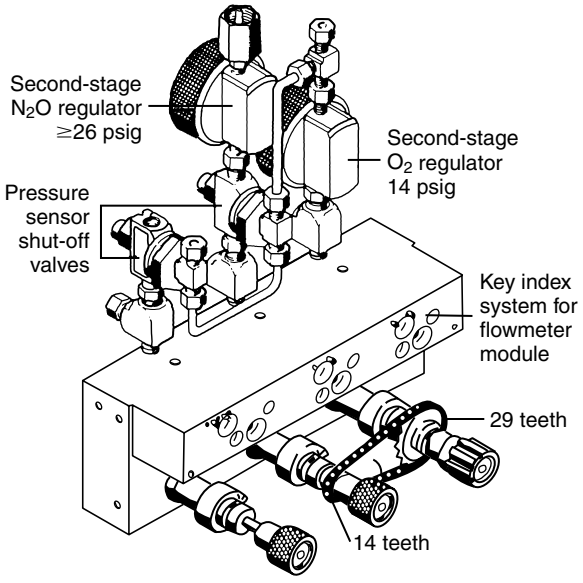

FIGURE **15-23** A chain connects oxygen and nitrous oxide flow controls in the Link-25 proportioning system. Either may be adjusted separately, but the chain enforces at most a 3:1 ratio of nitrous oxide to oxygen. The chain is not normally visible. (Courtesy Datex-Ohmeda, Madison, Wis.)

BOX **15-7**

Circumstances Under Which Hypoxic Guard Systems Can Permit Formation of a Hypoxic Mixture

- Wrong supply of gas in oxygen pipeline or cylinder
- Defective pneumatics or mechanics
- Leaks downstream of flow control valves
- Inert gas administration (e.g., a third gas such as helium)

*References 54, 57, 60, 62, 66, 73, 90.

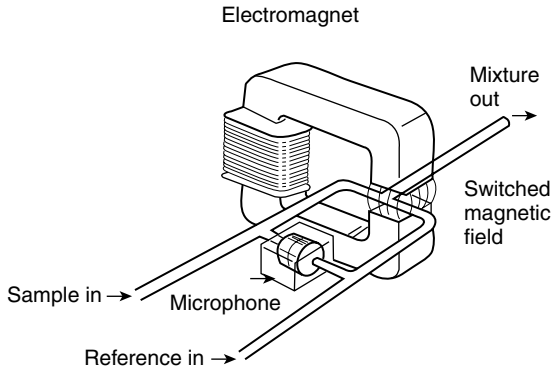

FIGURE **15-24** Paramagnetic oxygen analyzer. (Courtesy Datex-Ohmeda, Madison, Wis.)

Two types of sensors are in current use: electrochemical (galvanic fuel-cell; found in Aestiva, Aespire), and the paramagnetic analyzer (most others). The paramagnetic analyzer (Figure 15-24) is widely used because of its fast response, low cost, and extremely low maintenance requirements.[100] A paramagnetic analyzer is often found in gas analysis monitors (which detect anesthetic agent and carbon dioxide).

Vaporizers

Underlying Physical Principles

A vapor is composed of molecules (in the gaseous phase) of a substance that is a liquid at room temperature and 1 atmosphere of pressure. Vaporization proceeds at a rate that depends on the physical characteristics of the vaporizing liquid and the temperature. Different liquids evaporate at different rates. Elevated temperature increases the rate of evaporation of any liquid, whereas decreased temperature slows the rate. As evaporation proceeds, the remaining liquid and its container cool because heat energy is carried from the liquid with the energetic, mobile, evaporating molecules. An example would be the cooling effect of stepping out of the shower, or the chilling effect of evaporating gasoline or ether on the hand. In both cases, the evaporating molecules acquire the latent heat of vaporization from their surroundings. Thus one would expect an anesthetic vaporizer to cool as vaporization proceeds. This cooling slows the rate of further vaporization. To prevent this, materials such as copper are chosen for containing liquid anesthetics in current vaporizers. Copper has high thermal conductivity (transferring environmental heat easily to the liquid anesthetic) and high thermal capacity (acting as a thermal reservoir to help stabilize liquid anesthetic temperature).[25,77,101]

The rate of vaporization depends only on the temperature, the vapor pressure of the liquid, and the partial pressure of the vapor above the evaporating liquid—not on the ambient pressure of the remaining gases present. For example, water at constant temperature evaporates at the same rate into completely dry air, regardless of whether it is at sea level, in a hyperbaric chamber, or at elevations far above sea level.

Classification and Design

Variable-Bypass. Table 15-2 compares current variable-bypass vaporizers with heated-vapor (Tec 6) types.[25,102-106] All vaporizers blend the combined flow of fresh gases from the flowmeters with sufficient vapor to form clinically useful concentrations. The problem is ensuring that the vapor concentration is appropriately limited. For example, a fully saturated isoflurane vapor consists of nearly 31% isoflurane (238 mmHg [31 kPa], the saturated vapor pressure of isoflurane at 20° C divided by the barometric pressure of 760 mmHg [101 kPa]).[77] To limit vapor output to a clinically useful concentration, only a small portion of the fresh gas flow is allowed to come into contact with the liquid and pick up anesthetic vapor.

TABLE 15-2 Classification of Vaporizers

Characteristic	Variable Bypass	Injector
Example	Datex-Ohmeda Tec 4, 5, 7 ADU Aladin Dräger Vapor 19, 2000	Datex-Ohmeda Tec 6 (Desflurane)
Splitting ratio (carrier gas flow)	Variable-bypass (vaporizer determines carrier gas split)	Dual-circuit (carrier gas is not split)
Method of vaporization	Flow-over	Gas/vapor blender (heat produces vapor, which is injected into fresh gas flow)
Temperature compensation	Automatic temperature compensation mechanism	Electrically heated to a constant temperature (39° C, thermostatically controlled)
Calibration	Calibrated, agent specific	Calibrated, agent specific
Position	Out of circuit	Out of circuit
Capacity	Tec 5, 300 mL; Tec 7, 225 mL; Vapor 19, 200 mL; Aladin, 250 mL	390 mL

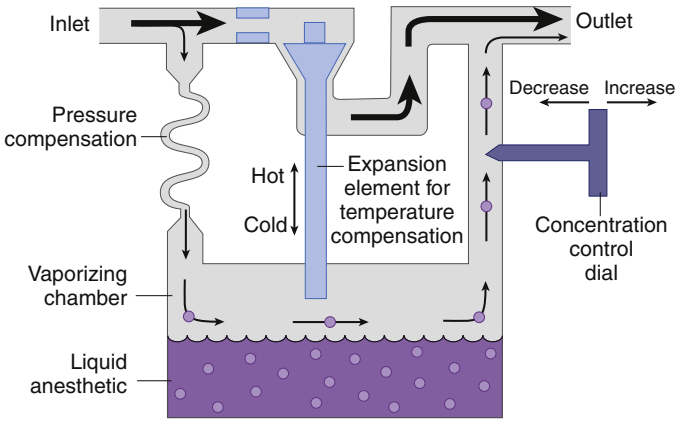

FIGURE **15-25** The Dräger Vapor 19 vaporizer. (Copyright Drägerwerk AG & Co. KGaA, Lubeck. All rights reserved.)

The *splitting ratio* (gas entering the vaporizing chamber, divided by total fresh gas flow) is automatically determined in a variable-bypass vaporizer by the internal resistance to flow; the operator merely has to set the control dial to the desired concentration (Figure 15-25). Setting the dial to a higher percentage increases the amount of flow sent through the vaporizing chamber. The small portion of the gas flow entering the vaporizing chamber ("carrier gas" or "chamber flow") flows over the liquid and picks up anesthetic vapor. Full saturation of the carrier gas is ensured

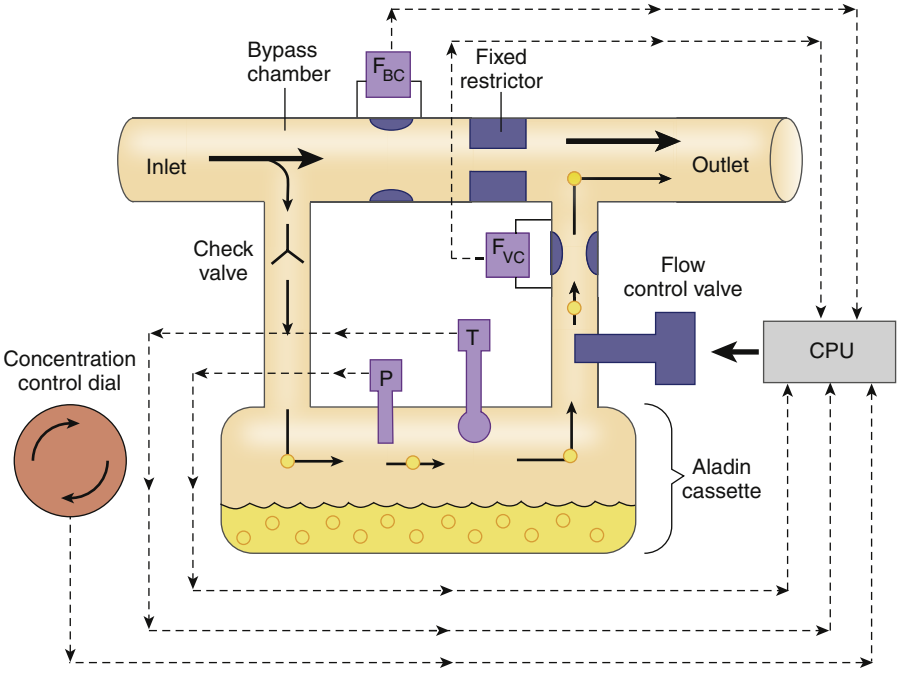

FIGURE **15-26** The ADU vaporizer. A microprocessor controls output by monitoring F_{BC} (bypass chamber flow), F_{VC} (vaporizing chamber flow), P (pressure), and T (temperature) in the vaporizing chamber. (From Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010.)

by means of a series of wicks and baffles. This fully saturated (and thus known) concentration of carrier gas at the vaporizing chamber outlet is then diluted with the balance of the fresh gas that bypassed the vaporizing chamber ("bypass flow") to produce the desired final concentration at the vaporizer outlet.

A temperature-compensation device is built into variable-bypass vaporizers, so that more gas is directed into the vaporizing chamber as the vaporizer cools. Variable-bypass vaporizers are calibrated for concentration and are agent specific. Like the Tec 6, variable-bypass vaporizers are *out of circuit*, meaning out of the breathing circuit. Their capacities for liquid agent are listed in Table 15-2. Variable-bypass vaporizers in the ADU and Aisys are electronically controlled, based on inputs from pressure, flow, and temperature sensors at various sites in the vaporizer (Figure 15-26).

Measured-Flow (Vernitrol). Anesthetists who practice in the military, or who use older equipment on mission trips outside of North America, may encounter *measured-flow* vaporizers. In a measured-flow vaporizer, the operator determines how much gas should be bubbled through the anesthetic liquid by means of a formula; this amount is then set on a second oxygen flowmeter, marked "Oxygen for Vernitrol." If the vaporizer cools, the operator must recalculate and set a new chamber gas flow; this is called *manual temperature compensation*. These devices can be used with multiple agents and are out of the breathing circuit. It is possible to use them safely, but their design is not as inherently safe as that of more modern types.[107] Measured-flow vaporizers are no longer manufactured in the United States, and factory service for them is no longer available. The military still trains anesthetists on the use of these vaporizers, and they may be seen overseas. They are not addressed in the current anesthesia gas machine standard.[18]

Tec 6 Injector. The Tec 6 vaporizer uses a completely different principle of operation as compared with variable-bypass types (Figure 15-27): it is a heated, dual-circuit vaporizer.[103,108-113] Fresh gas flow from the common manifold passes through the vaporizer in one circuit. This fresh gas never flows over, or comes into contact with the liquid agent as it would in a variable bypass vaporizer. Instead, an appropriate amount of vapor is added to the fresh gas as it flows through the vaporizer. The vapor output has two control points. One is the setting on the concentration control dial, and the other is linked to a transducer that is responsive to the amount of fresh gas flow. Thus more vapor is delivered from the vapor circuit if either the desired volume-percent setting, or the fresh gas flow, is increased. To maintain a known vapor pressure in the second circuit, the Tec 6 is heated to 39° C; this produces a vapor pressure of approximately 1500 mmHg (200 kPa). Desflurane is near boiling at room temperature; if it were placed in a variable-bypass vaporizer, it would constitute nearly 100% of the output at first, and a hypoxic breathing mixture would result.[110,114]

The output of any modern vaporizer may be influenced by extremes of fresh gas flow, extremes of temperature, or back pressure from the breathing circuit and ventilator. Current vaporizers function accurately over a wide range of settings, at various ambient temperatures and fresh gas flows (Table 15-3).[102-104,106,115] Furthermore, they are more resistant than previous models to the effects of intermittent back pressure (the so-called "pumping effect") that increases vaporizer output. This can be accomplished by incorporating unidirectional valves at the vaporizing chamber inlet or outlet, or distal to the vaporizer.

Using Vaporizers

Contemporary vaporizers are secured to the anesthesia machine in manifolds that hold two or three units. The operator is prevented from delivering more than one agent simultaneously by an interlock system. The interlock ensures that only one vaporizer is on, that gas enters only the one that is on, that all vaporizers are

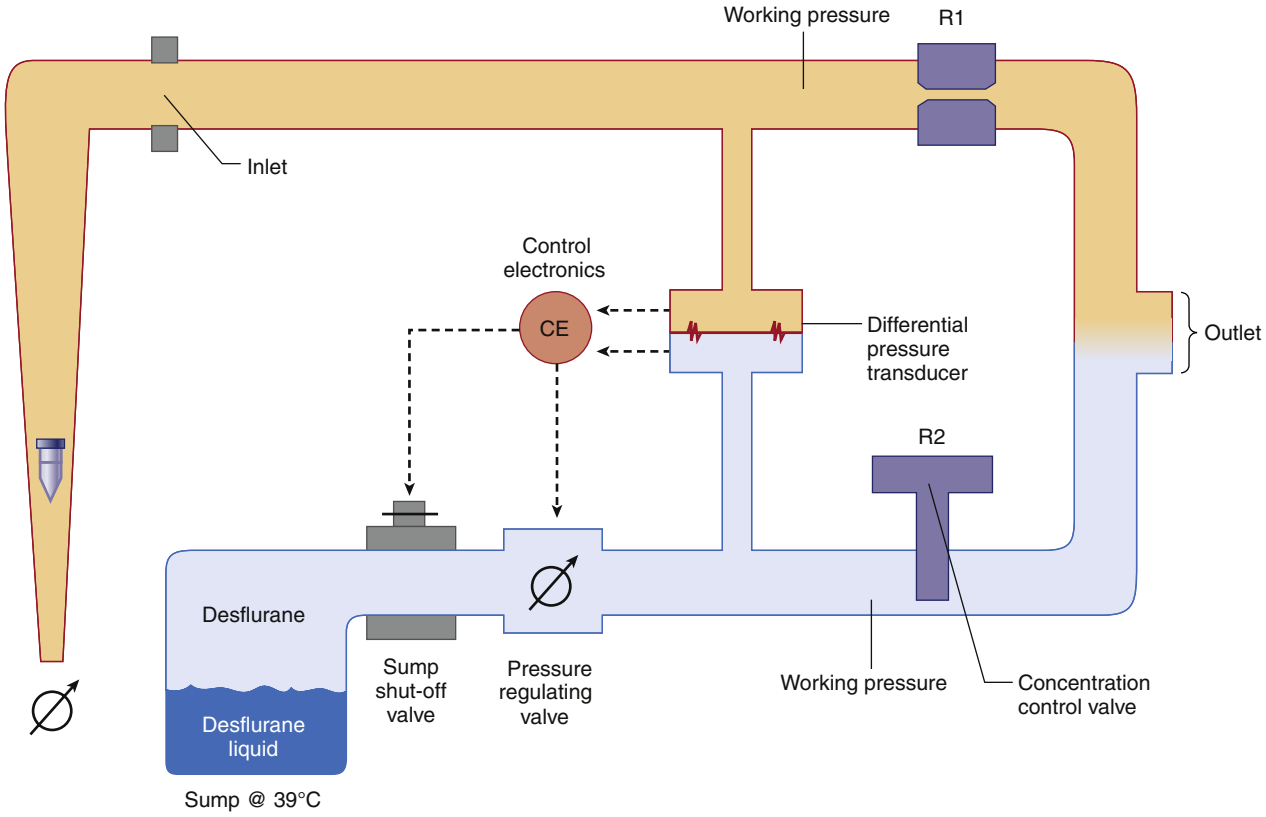

FIGURE **15-27** Principle of operation of the Datex-Ohmeda Tec 6 vaporizer. (From Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010.)

TABLE **15-3** Accuracy of Current Vaporizers*

Characteristic	Datex-Ohmeda Tec 4	Datex-Ohmeda Tec 5	Datex-Ohmeda Tec 6	Datex-Ohmeda Tec 7	Dräger Vapor 19.3	Datex-Ohmeda Aladin (ADU)
Fresh gas flow (L/min)	0.2-10	0.2-15	0.2-10	0.2-15	0.25-15	0.2-8
Temperature (° C)	20-35	17-35	18-30	18-35	15-35	18-25

*The vaporizers listed function accurately within the ranges specified.

locked in so that leaks are decreased, and that trace vapor output is minimal when a vaporizer is off.[77,116]

Variable-bypass and Tec 6 vaporizers are all filled in a similar fashion. Funnel-type (Figure 15-28) and keyed-filler–type (Figure 15-29) systems are permitted by standard.[18] Keyed-filler types are preferred because their use lessens the chance that filling with the wrong agent will occur (although it is still possible).[109,117-122] The standard requires that overfilling be prevented in the normal operating position, and that liquid level indicators be visible to the operator.[18] These indicators usually take the form of a sight glass with two etched lines, corresponding to low and maximum liquid levels within the vaporizer. To fill either the funnel type or keyed-filler vaporizers, the anesthetist should turn the vaporizer off, check the anesthetic liquid (to ensure that the agent and the vaporizer match) and then pour it in. The vaporizer is full when the liquid level reaches the maximum line on the sight glass.[115,123] It is a misconception that while using the keyed-filler vaporizer, one should hold the bottle up until it stops bubbling. If the vaporizer is turned on, is not horizontal, or the keyed-filler device is not perfectly tight on the bottle, this method results in overfilling.[124] Overfilling may result in discharge of liquid anesthetic from the vaporizer outlet, which has caused patient injuries.[25] The Tec 6 uses a similar system, but the desflurane bottle has a permanently attached, noninterchangeable spout. The sight glass on the Tec 6 is a liquid crystal display that indicates when the level of liquid is low enough to allow the addition of a full bottle, and it shows when the sump is full. Although the Tec 6 vaporizer is unique in that it can be filled while in operation,[103] it is safer to turn it off momentarily to do so. All variable-bypass vaporizers *must* be shut off while they are being filled.*

Models

The Dräger Vapor 19 fits in a manifold with an interlock system. If a vaporizer is removed from the machine, a short-circuit block must be added for leaks to be prevented. The interlock protects against simultaneous inhaled agent administration, regardless of

*References 60, 66, 102, 104, 115, 124.

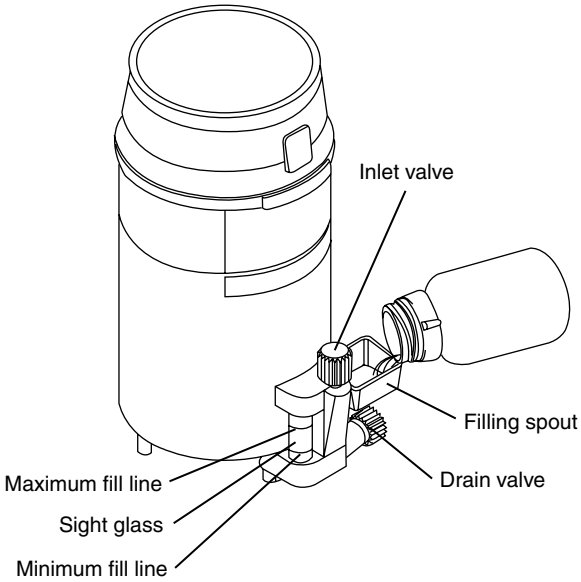

FIGURE **15-28** Filling a vaporizer with a funnel-type filling system. (From Dräger Medical Inc. *Narkomed 2C Anesthesia System—Setup and Installation Manual*. Telford, PA, 1994, Drägerwerk AG & Co. KGaA, Lubeck.)

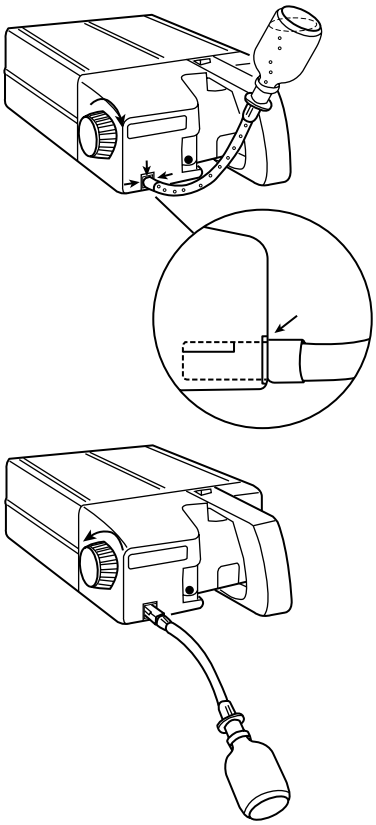

FIGURE **15-29** Filling a vaporizer with a keyed-filler system. (From *S/5 Anesthesia Delivery Unit User's Reference Manual*, Catalog No. 8502304. Madison, Wis: Datex-Ohmeda; 2000.)

which vaporizer is removed. There is no check valve between the vaporizer outlets and the common gas outlet in Dräger gas machines. The Vapor 19 has a button that must be depressed before the control dial can be turned on. All contemporary vaporizers are designed to increase agent concentration as the dial is turned counterclockwise (as viewed from above).

FIGURE **15-30** The Dräger Vapor 2000. Note the "T" (transport) setting to the right of "0."

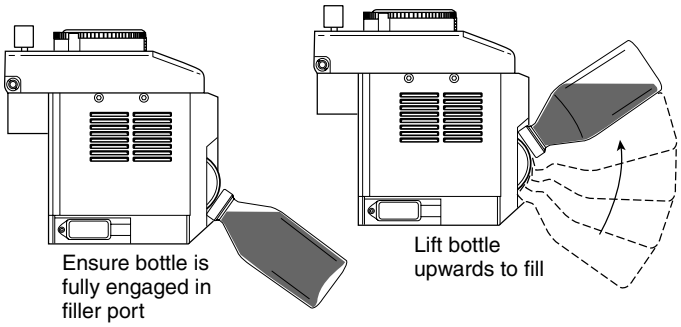

FIGURE **15-31** Filling the Datex-Ohmeda Tec 6 vaporizer. (From *Tec 6 Vaporizer: Operation and Maintenance Manual*. Madison, Wis: Datex-Ohmeda; 1993.)

The Dräger Vapor 2000 (Figure 15-30) is similar to the Vapor 19, except that it is removable by hand. It has a unique "T" (transport) setting that allows the vaporizer to be tipped or transported without liquid anesthetic fouling the control mechanisms.

The Datex-Ohmeda Tec 7 is a variable-bypass vaporizer similar to the older Tec 4 and Tec 5 models. It is designed to require less frequent service.

Use of the Datex-Ohmeda Tec 6 vaporizer is unique, as could be suspected from its unique principle of operation. However, it is not difficult to use. Filling the Tec 6 has been described in general terms. The operator must check the desflurane bottle to ensure that it is the right agent, push it into the vaporizer firmly, and rotate it upward until the display indicates that the vaporizer is full. The operator then rotates the bottle downward and holds it for an instant (to allow any drops to drain back into it). Finally, he or she supports the bottle while withdrawing it from the vaporizer (Figure 15-31).[103] If the Tec 6 leaks as it is being filled, check for the lack of an "O" ring on the bottle spout.[121]

The operator turns the Tec 6 vaporizer on by turning the concentration control dial to the "On" position while depressing the dial release (on the back of the dial, opposite the zero indicator). The vaporizer requires electric power and a warm-up period of approximately 10 minutes before it can be used from a cold start.[103]

The Tec 6 has several visual indicators that are grouped in a status display (Figure 15-32).[103] These include a light that indicates "Operational" status, a "No Output" indicator light (and audible alarm), a "Low Agent" light (and audible alarm), a "Warm-Up" status light, and an "Alarm Battery Low" light. The No Output

BOX 15-8

Hazards of Modern Vaporizers

- Incorrect (unintended) agent administration
- Tipping
- Overfilling with agent
- Reliance on breath-by-breath gas analysis rather than preventive maintenance
- Leaks
- Electronic failures

alarms are activated if the agent level is less than 20 mL, if the vaporizer is tilted more than 10 degrees from the vertical, if there is a power failure lasting longer than 10 seconds, or if an internal malfunction occurs. The cause of a No Output alarm may be sought if it occurs during a case; however, considering the rapid emergence that is characteristic with the use of desflurane, the operator should ensure continued depth of anesthesia by switching to a different agent without undue delay.

Preoperative checkout for variable-bypass vaporizers is relatively straightforward. They are checked to determine whether they are turned off, whether they are full, whether the filling cap is tightly closed, and whether the interlock is functioning. Depending on the machine, they may need to be checked for leaks as well.[46] The Tec 6 requires a more extensive checkout. After performing the appropriate leak test of the machine low-pressure system, the operator checks the amber Alarm Battery Low indicator and replaces the battery if necessary. Next, he or she turns the Tec 6 on to at least 1%, and disconnects its electrical plug. Within 15 seconds of disconnection, the No Output light and alarm should activate. If they do not, the battery must be replaced and the vaporizer retested before use. If everything is functioning correctly, the operator reconnects the power and turns the dial to the "Off" position; he or she then presses the mute button for 4 seconds to test all alarms and the display. When the mute button is pressed, all lights and the alarm should activate.[103]

The Aladin (ADU) vaporizer uses one central electronic control mechanism for all agents.[54,105] Cassettes containing the liquid anesthetic are inserted into a port connected to these control mechanisms, which recognizes the contents of the cassette and dispenses agent into the stream of fresh gas flow (Figure 15-33). The cassettes and control mechanisms are checked as part of the electronic equipment checklist daily. The ADU will not deliver volatile agent or nitrous oxide without main power or battery backup, and adequate oxygen pressure.

Hazards of Contemporary Vaporizers

Many of the hazards historically associated with the use of vaporizers have been corrected by advances in design, but a few hazards remain (Box 15-8). Vaporizer contamination with incorrect agents continues to be noted.[114,117,118] Diligence during filling is not enough to prevent contamination. Departments should strongly consider replacing funnel-type with keyed-filler vaporizers in equipment purchases.

Aladin vaporizers found on ADU and Aisys are not sensitive to tipping. If any other vaporizer tips by more than 45 degrees from the vertical, the operator's manual or a field service technician must be consulted. Tipping is hazardous, because the entry of liquid agent into the control assembly at the top of the vaporizer can have unpredictable effects on its function, including potential overdose to the patient. The vaporizer sump can be drained and gas run through it for a specified time and at a specified concentration before the vaporizer is returned to use. For the recommended corrective action for a particular make and model, the operator's manual must be consulted.

Overfilling may be prevented by following the manufacturer's guidelines for filling (e.g., fill only to the top etched line on the liquid level indicator glass, fill only when the vaporizer is off).[123] Managers should not conclude, in this era of cost constraints, that breath-by-breath agent analysis can substitute for regular preventive maintenance of vaporizers. Vaporizers go out of calibration, and may then deliver too-high or too-low concentrations of agent.[125] Leaks are relatively common, often due to malposition of vaporizers on the back bar, accidental dislodgement, loss of gaskets,

or mechanical damage.[119,126-128] These leaks may not be detected with the standard checklist, unless the negative pressure check is performed. Tec 6 vaporizers can also leak liquid while being filled if the desflurane bottle is missing the rubber O-ring near its tip.[121] This can be mistaken for a defective vaporizer. As vaporizers incorporate electronics, they are susceptible to electronic failure or unanticipated interactions of new designs with each other.[109,119,120] Recent case reports detail ADU vaporizers failing due to fresh gas unit failure, and from copious emesis soaking the machine.[129,130]

New Agents and Low Flows

Low fresh gas flows should not be instituted too early when desflurane or sevoflurane is used. Induction at low flows would be extremely prolonged, creating the risk of awareness in the time interval between offset of inductions, and onset of action of the volatile agent. Overpressure can be combined with low flows, but 18% of 2 L contains far fewer desflurane molecules than 18% of 6 L, and it is the number of molecules presented to the brain per unit time that causes an increase in anesthetic tension within the brain.

Imagine a 1000-mL sink filled with water, with 100 mL/min inflow (of which 1 mL is methylene blue) and 100 mL/min outflow. The goal is turning the initially colorless water in the sink as blue as the inflow solution. Now, imagine the effect of increasing the inflow to 500 mL/min (of which 5 mL is methylene blue) and increasing the outflow to 500 mL/min. Would the 1000 mL in the sink turn blue any faster in the second case? Of course, but not because the concentrations are different (both inflows are 1% methylene blue), but rather because the rate of inflow in the second example is a greater proportion of the capacity of the sink.

Wash-in is based on the concept of a time constant. One time constant (equal to capacity divided by flow) brings a system 63% of the way to equilibrium; two time constants to 86%; and three time constants to 95%. Thus the first sink will reach 63% of equilibrium in 10 minutes (1000 mL ÷ 100-mL flow), whereas the second sink reaches this same state of equilibrium in only 2 minutes (1000 mL ÷ 500-mL flow). In the same way, the volume (capacity) of the functional residual capacity, hoses, and breathing circuit can be brought to equilibrium with the inflow more quickly by using a higher rate of inflow (fresh gas flow). A rational approach for ensuring anesthesia that conserves volatile agents would include a nonrebreathing (semi-open) induction (fresh gas flow, 5 to 8 L/min), followed by low fresh gas flow during maintenance (fresh gas flow, 1 to 2 L/min). This approach helps conserve tracheal heat and humidity, gases, and agent. Emergence, like induction, must occur at higher, nonrebreathing flows; otherwise, it will be unacceptably prolonged.

DELIVERY

This section discusses how the flow of gases to and from the patient is controlled and monitored.

Breathing Circuits

Fundamental Considerations

The purpose of all types of anesthesia breathing circuits is the delivery of oxygen and anesthetic and the elimination of carbon dioxide. Carbon dioxide is eliminated from the breathing circuit by washout with adequate fresh gas flow; or by absorption in carbon dioxide absorbent granules.

Any breathing circuit creates some resistance to gas flow. Resistance in a circuit may be minimized by reducing the circuit's length and increasing its diameter, by avoiding the use of sharp bends, by eliminating valves, and by maintaining laminar flow. It is important to decrease resistance to flow, because added airway resistance is uncomfortable for the conscious patient. Furthermore, the unconscious or anesthetized patient, challenged by increased work of breathing, may not be able to increase respiratory effort, and may hypoventilate. The resistance of the anesthesia breathing circuit is low—typically less than that of an endotracheal tube.

Rebreathing of exhaled gases occurs with the use of anesthesia breathing circuits (as it does in space or submarine environments). In other breathing circuits, such as those in the ventilators used in intensive care units, it is not found. Rebreathing may be useful. Its advantages include cost reduction, an increase in tracheal warmth and humidity, and a decrease in the potential for exposure of operating room personnel to trace and waste gases (because of decreased rate of release of anesthetic gases into the environment). The degree of rebreathing in an anesthesia breathing circuit is increased as the fresh gas flow is decreased, because there is relatively less fresh gas added to the circuit, and more of the next inhalation will be exhaled gas. Higher fresh gas flow is associated with less rebreathing in any type of circuit. The higher the fresh gas flow, the more quickly the composition of gas in the breathing circuit will resemble that at the common gas outlet (the dialed-in concentrations of agent, nitrous oxide, and oxygen).

Patients under anesthesia may re-breathe any component of their exhalations—nitrogen, O_2, CO_2, N_2O, and volatile agent. The effects of rebreathing each of these components differ. Rebreathing of exhaled oxygen has no ill effects. Rebreathing of exhaled nitrogen slows induction. Nitrogen that is not eliminated from the breathing circuit delays the establishment of the desired agent concentration; thus high fresh gas flows are appropriate during induction. In contrast, rebreathing of exhaled agent during maintenance is highly desirable for cost and environmental considerations. Rebreathing of CO_2 has the undesirable effect of producing respiratory acidosis, so it is best avoided. Because higher flows reduce the discrepancy between desired concentrations and the concentrations actually inspired, they are appropriate during emergence as well. At the end of an anesthetic, as the flow of volatile agent and N_2O is turned off, it would be undesirable for exhaled agent and N_2O to be rebreathed, because this would delay emergence. So gas that is free of agent (and nitrous oxide) is supplied at high flow, to create a favorable concentration gradient that speeds elimination of agents from the body.

Dead space is increased to some degree with the use of any respiratory apparatus. The effect of an increase in mechanical (apparatus) dead space is that rebreathing of exhaled CO_2 is more likely. This is one reason that ventilator tidal volumes are set much larger than the volume of a spontaneous breath. To avoid hypercarbia in the face of an acute increase in dead space, a patient must increase minute ventilation (V_E). Conversely, because alveolar ventilation is the minute ventilation minus dead space ventilation ($V_A = V_E - V_D$), if the patient's minute ventilation is fixed (such as by respiratory depression), increasing dead space decreases alveolar ventilation, and increases arterial CO_2 tension.[131] Dead space ends where the inspiratory and expiratory gas streams diverge. In a circle system, dead space ends at the Y-piece. It is not increased by longer inspiratory and expiratory plastic hoses (although, with longer limbs in the breathing circuit, there may be compliance losses than decrease tidal volume). Use of a face mask is associated with greater dead space than is the use of an endotracheal tube.

The anesthesia gas machine uses dry gases so that the problems of internal corrosion and bacterial colonization are avoided. However, provision of completely dry gases to the patient's airway can cause various problems. It is common for anesthesia providers to use various means of passively humidifying and heating

TABLE 15-4 Classification of Breathing Circuits

Type	Reservoir	Rebreathing	Example
Open	No	No	Open drop Insufflation Nasal cannula or simple face mask
Semi-open	Yes	No	Circle at high fresh gas flow (more than minute ventilation); or a nonrebreathing circuit
Semi-closed	Yes	Yes (partial)	Circle at low fresh gas flow (less than minute ventilation)
Closed	Yes	Yes (complete)	Circle at extremely low fresh gas flow, with adjustable pressure-limiting valve closed

inspired gases (with a heat and moisture exchanger, or by using low fresh gas flows). Active humidification has become less common, because it is less effective at preventing hypothermia than heated-air surface warming blankets, and because the added moisture can clog gas-analysis lines and soda lime granules, or obstruct unidirectional valves.[132]

Anesthesia breathing circuits are unique among respiratory equipment in the degree to which they allow manipulation of the inspired concentration of a variety of components for therapeutic benefit. Each component of the breathing mixture follows its own concentration gradient because it is made to wash in to the breathing system, and then to wash in from the breathing system into the patient's lungs. In the lungs, gases flow down their concentration gradients, interchanging with pulmonary and blood gases. Understanding the pharmacokinetics of inhaled agent administration involves not only knowledge of respiratory physiology, but also familiarity with the "physiology" of the patient-machine system. For example, the concentration set on the dial differs from the concentrations in the breathing circuit, in the lungs, in the blood, and in the brain. Furthermore, these concentration differences are not constant but vary over time, depending on a number of patient- and machine-related factors. The concentration inspired most closely resembles that delivered from the common gas outlet when rebreathing is minimal or absent (this is typical at high fresh gas flow). Of course, it is desirable that the alveolar concentration differ from the inspired concentration at times. At the start of the emergence phase, the inspired concentration of anesthetic is decreased so that anesthetic gas is washed out while ventilation is continued. Thus emergence is very different from passively "waking up," and is as much an active process as induction.

Classification of Breathing Circuits

Table 15-4 gives a classification of breathing circuits that is based on whether a reservoir (breathing bag) is present, and on the degree to which rebreathing occurs.[133] Patients have access to the atmosphere only in open systems; this is not true in semi-open, semi-closed, or closed systems. A reservoir is present in these three types to provide for the moments during the inspiratory phase when flow in the trachea is greater than fresh gas flow. Both nonrebreathing (Mapleson, Bain) systems and the circle system, at fresh gas flows greater than minute ventilation, are semi-open.[134] If the fresh gas flow to the circle system is less than V_E, some rebreathing must be occurring. In a closed system, rebreathing is total. The adjustable

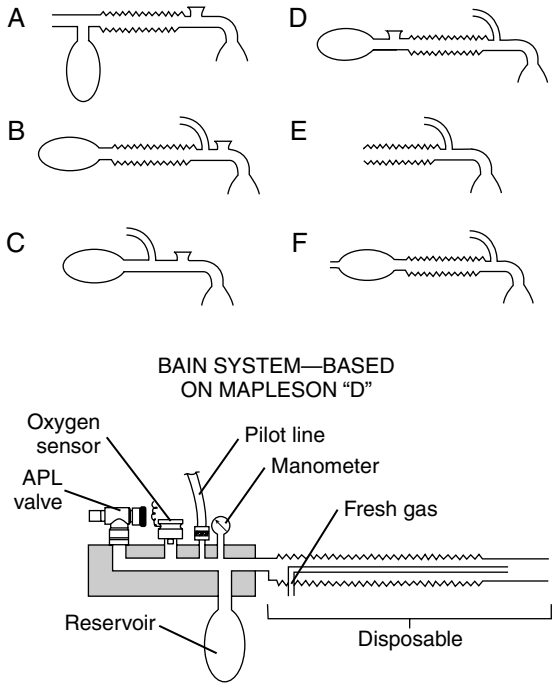

FIGURE 15-34 Mapleson's classification of breathing systems. (From Cicman J, et al. *Operating Principles of Narkomed Anesthesia Systems*. Telford, Penn: Dräger Medical; 1993.)

BOX 15-9

Common Features of Nonrebreathing Systems

- All lack unidirectional valves.
- All lack soda lime carbon dioxide absorption.
- Fresh gas flow determines the amount of rebreathing in all.
- Resistance and work of breathing are low in all (no unidirectional valves; no absorbent granules).

pressure-limiting (APL or "popoff") valve is closed, and the supply of O_2, N_2O, and agent just matches the patient's uptake.[135]

Nonrebreathing Circuits. Mapleson published a classification of nonrebreathing circuits in 1954; this classification is still used today (Figure 15-34).[136] Rebreathing is prevented in systems like the Mapleson D because during the expiratory pause, fresh gas fills the corrugated limb, forcing the previously exhaled gas distally (toward the reservoir). If fresh gas flow is sufficient, no alveolar gas is rebreathed. The Mapleson F circuit is also referred to as the *Jackson-Rees modification of Ayre's T-piece*. The common features of nonrebreathing systems are listed in Box 15-9. These circuits offer very low resistance to breathing, and can be used for patients of almost any age, from premature infants to adults. The fresh gas flow required to prevent rebreathing is two to three times minute ventilation.[77] This number can be calculated; however, in practice, many use a minimum fresh gas flow of 5 L/min.

The Bain system, shown at the bottom of the figure, is often referred to as a *modified Mapleson D circuit*, because the arrangement of its components (entry point of fresh gas, reservoir bag, and APL valve) is similar to that of the Mapleson D. However, in the Bain system the fresh gas hose is directed coaxially within the corrugated limb, and this configuration gives the inhaled gases greater heat and humidity. Unfortunately, unrecognized kinking or disconnection of this relatively hidden fresh gas hose converts the

entire corrugated limb into dead space.[137-139] The resulting respiratory acidosis has been severe enough to cause arrhythmias.[139] Users of Bain systems must test the circuit for these problems before they use the system. Pethick's test and a similar test are available and should be used.[77]

The use of the nonrebreathing circuit has declined for several reasons. Many modern gas machines are not designed to accommodate them (e.g., Fabius GS or Narkomed 6000). It is more common to see a pediatric circle system used, which is characterized by smaller and less compliant corrugated limbs, as compared with the adult circle system. The minimum weight of a child for which a pediatric circle would be suitable has been stated as 10 to 20 kg. However, when infants of mean weight as low as 6 kg were studied, the pediatric circle was equal to a nonrebreathing circuit in preserving blood gas values and end-tidal CO_2, whether assisted or spontaneous breathing was employed.[140] No one guideline applies to all situations, because the decision on whether to use a pediatric circle system in any given child depends on familiarity, clinical judgment, and the anticipated duration of unassisted respiration.

Pediatric circle systems do not place undue burdens (in terms of work of breathing) on spontaneously ventilating patients.[141] The pediatric circle system is low compliance; the work of breathing associated with it is reasonable; it requires less reconfiguration to set up; and it allows the use of lower fresh gas flows (the high fresh gas flow required in nonrebreathing circuits cools children and is more costly).[142] Modern ventilators are accurate to very low tidal volumes (10 to 20 mL), and modern monitoring such as capnography and spirometry allows a high degree of confidence that a child is being ventilated adequately with the pediatric circle.

If a nonrebreathing circuit is used in the middle of a number of adult cases using the circle system, some disassembly and reassembly is required, accompanied by the possibility of error or misconnection. The small amount of resistance offered by the soda lime canisters and unidirectional valves of the circle system is deleterious only during spontaneous respiration, which is limited in duration in most general anesthesia for children. The advantages and disadvantages of nonrebreathing circuits are summarized in Box 15-10. Although they are useful, nonrebreathing circuits are associated with loss of heat from the patient and with greater use of volatile agents, owing to their requirement for relatively high fresh gas flow.

Circle System. The circle system is the breathing circuit most commonly used in the United States, because it prevents rebreathing of carbon dioxide while allowing rebreathing of all other gases. Gas flow during mechanical ventilation is shown in Figure 15-35. The circle system has separate inspiratory and expiratory limbs. Gas in the inspiratory limb only goes towards the patient; gas in the expiratory limb only proceeds away from the patient. The inspiratory and expiratory unidirectional valves enforce this flow pattern, which ensures that all exhaled gas is directed through the absorbent granules, and is thus cleansed of carbon dioxide. Even when rebreathing takes place at low fresh gas flows, if the valves are functioning, and the granules are unexpired, no rebreathing of carbon dioxide can occur.

A single-limb, coaxial circle system is also available in which, like the Bain, the inspiratory limb is contained within the expiratory (Figure 15-36). It is checked and used like any circle system. Like the Bain, the coaxial circle is less bulky, and is thought to provide greater heat and humidity to inhaled gases. Disadvantages include the potential for obstruction or lack of patency of either limb, which may cause respiratory acidosis or even mimic esophageal intubation.[137,138] This respiratory acidosis does not respond to increased minute ventilation—if exhaled gases are not forced through the absorbent granules, no amount of ventilation will cleanse carbon dioxide from the exhaled gases. The tests for inner tube patency that can be used for a Bain circuit are not readily adaptable to the coaxial circle system.

BOX 15-10

Nonrebreathing Systems: Advantages and Disadvantages

Advantages
- Lightweight
- Convenient
- Easily sterilized and scavenged
- Exhaled gases in corrugated limb may give heat and humidity to inhaled gas (Bain)

Disadvantages
- Unrecognized disconnection or kinking of fresh gas hose in the Bain circuit (use Pethick's test)
- Pollution and increased costs of agents and gases, owing to need for higher flows
- Loss of heat from patient
- May require disconnection of circle fresh gas supply hose and scavenger connections for assembly; can be reassembled improperly

Gas enters the circle system from the common gas outlet by way of the fresh gas delivery hose, and it exits the circle to the scavenger via the APL valve (or the ventilator relief valve if mechanical ventilation is used). The APL valve creates an adjustable leak during manual ventilation. If it is completely open and the bag is squeezed, all gas exits to the scavenger, because this is the path of least resistance. If the valve is completely closed, all gas ventilates the lungs, and the volume of the circle increases, because the fresh gas flowing in has no means of escape. The setting of the APL is constantly adjusted during manual ventilation of the lungs so that a variable resistance sufficient to force gas to inflate the lungs is maintained. If gas cannot exit through the APL or ventilator relief valve, pressure will build within the system.[143]

Unidirectional valves enforce a pattern of gas flow that forces exhaled gases through the CO_2 absorbent granules (Figure 15-37). The valve leaflet (disk) is subject to damage, occlusion, foreign body contamination, and sticking with collected moisture or absorbent dust, particularly on the expiratory valve disk.[144-147] Daily performance of a preanesthesia checklist, and regular maintenance, should enable the operator to detect or prevent most of these problems. Thus there are only two common reasons for an increase in inspired CO_2: the absorbent granules have been exhausted, or the unidirectional valves are faulty. Figure 15-38 shows that incompetence of an inspiratory or expiratory valve turns the entire corrugated limb into dead space.[45,148] This usually results in an increase in inspired and expired CO_2.

If inspired CO_2 of more than 1 to 3 mmHg is detected on the capnograph (Figures 15-39 and 15-40), the fresh gas flow should be increased to 5 to 8 L/min; this converts the system to a semi-open configuration, in which rebreathing of exhaled gases is minimized. Similar to the mechanism in the Mapleson nonrebreathing circuits, a high fresh gas flow in the circle dilutes exhalations and sends them to the scavenger. If increasing the fresh gas flow substantially causes the inspired CO_2 to decrease, the absorbent granules are exhausted and should be replaced at the end of the case. Some gas machines (e.g., ADU) with prepackaged granules or canisters allow granules to be changed during the case, although they are not meant to function for more than very brief periods without

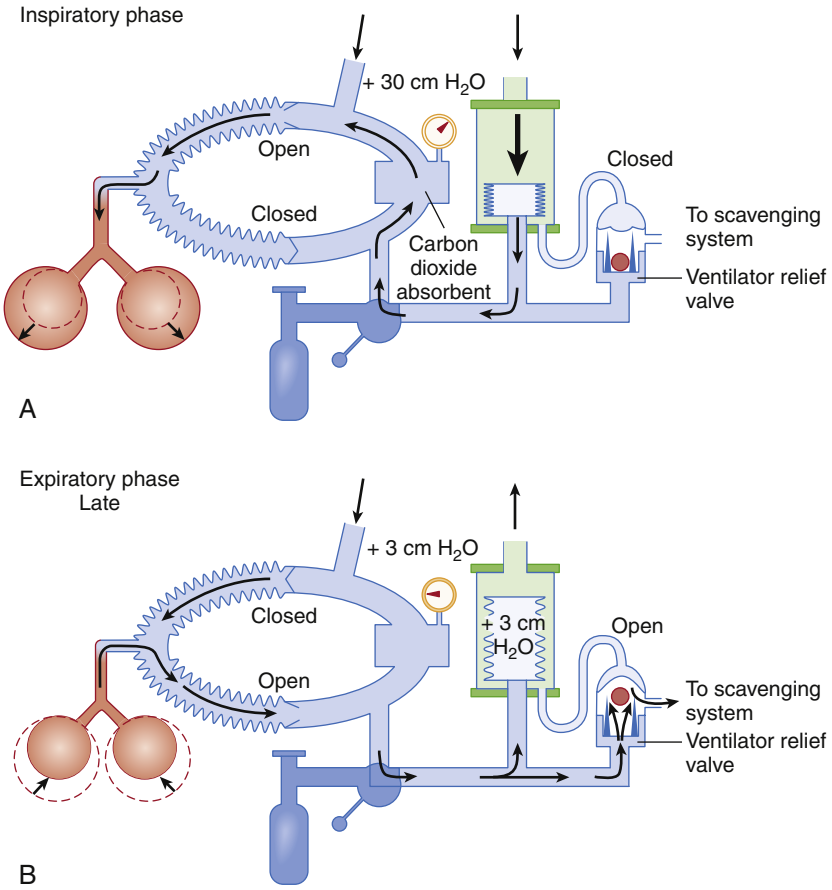

FIGURE **15-35** Gas flow in a circle system during mechanical ventilator inspiration. **(A)** Shows inspiration. As driving gas compresses the bellows, it propels gas into the inspiratory limb past the inspiratory unidirectional valve, inflating the lungs. Driving gas pressure also closes the ventilator relief valve, which is the route to the scavenger. **(B)** Shows expiration. Lung deflation propels gas into the expiratory limb past the expiratory unidirectional valve. The exhaled gases fill the bellows to a small pressure first, then excess gas proceeds to the scavenger via the ventilator relief valve. A small weight within the ventilator relief valve makes filling the bellows the path of least resistance, until a small positive end-expiratory pressure (PEEP) builds up, lifting the weight, and opening the valve. Note (1) Fresh gas flows into the circle continuously and (2) flow in the circle is unidirectional, which forces all exhaled gas through the carbon dioxide absorbent granules. (From Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010.)

a canister attached. If elevated inspired CO_2 persists in spite of the higher fresh gas flow, the unidirectional valves are likely to be incompetent. The operator should remove the expiratory valve, inspect and dry it, and then reassemble it (while ventilating the patient with an Ambu bag).[25,146] Note that this may be more difficult in newer absorber heads (e.g., the ADU), and will always be more difficult when the user has never performed it before. This argues for reading the operator's manual and practicing without a patient attached before the maneuver is attempted, because failure to reassemble the valve quickly will result in hypoventilation and interruption in volatile anesthetic delivery. Perhaps the best recommendation is to bring a new gas machine into the room; any valve adjustment can take place outside the pressure of the clinical situation and will not distract the anesthetist from patient care.

It is mandatory to check unidirectional valves before use. There are a multitude of means proposed to check the unidirectional valves, which vary in ease of performance and complexity.* One suggested method with applicability to a variety of gas machines follows. The daily check of the unidirectional valves is done during the ventilator checkout. A spare breathing bag is placed on the elbow fitting at the patient's end of the Y-piece, and mechanical ventilation of this "artificial lung" is begun. The user carefully observes that the valves lift and fall, and that gas flows back and forth in a tidal fashion between the mechanical ventilator bellows and the artificial lung expected during inspiration and expiration.[54] The test should be repeated using the manual/spontaneous limb of the circuit, simulating assisted ventilation of the artificial lung. Breathing through the elbow or mask of a clean circuit (with a paper mask on) is an alternative method, but presents problems of cross-contamination.

Simulating manual breathing and ventilator breathing checks not just for unidirectional valve function; it checks for obstruction to expiration secondary to mold flash or plastic wrap emboli, problems that have resulted in mortality.[146,150-153] Dräger suggests a similar test, but also breathing through each limb individually as follows.[60,66] If the inspiratory limb is detached and occluded with one's palm, the operator should be able to exhale, but *not* inhale, through the expiratory limb. Similarly, if the inspiratory

*References 60, 66, 93, 144, 146, 149.

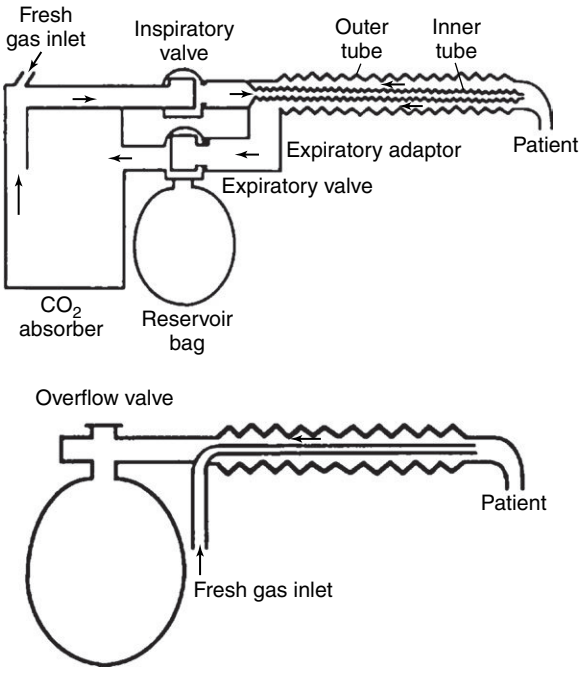

FIGURE **15-36** In the coaxial circle system *(top)*, the inspiratory limb is contained within the expiratory limb, like the Bain *(bottom)*.

limb is replaced and the expiratory limb detached and occluded, the operator should be able to inspire, but *not* expire, through the inspiratory limb. This test may be more sensitive than the first test mentioned. If a preanesthesia check is performed daily, the capnograph is used properly, and the operator is aware of the steps that should be taken in the event of an increase in inspired CO_2, perhaps this more rigorous test need be performed only if unidirectional valve function is in doubt, particularly because it is problematic to perform this more rigorous test in a hygienic fashion.[25]

Newer machines have electronic routines to check for leaks and compliance. This helps the ventilator accurately deliver the set tidal volume. These checks must be repeated when the type of circuit is changed, for example, from adult to pediatric. Dräger does not recommend expandable breathing circuit hoses with the Narkomed 6000, because their volume and compliance may change after the leak and compliance testing is performed, which will degrade the accuracy of the delivered tidal volume.[66] With any newer gas machine, these hoses should be expanded before the leak and compliance test is initiated.

The advantages and disadvantages of the circle system are listed in Box 15-11. One advantage of at least partial rebreathing is relative constancy of inspired concentrations. In a completely nonrebreathing circuit, each breath is fresh gas, so depth can vary much more quickly. The use of lower flows also reduces the rate of release of anesthetic agents into the environment. The circle conserves respiratory tract humidity. Misconnections, although a potential disadvantage, occur much less frequently now than in the past, because the diameter of breathing hoses (22 mm) has been standardized to be different from the diameter of scavenger hoses (19 or 30 mm).[18] Nevertheless, misconnections continue to be reported.[154,155] Maintenance of the circle system is detailed in the operator's manuals, and these must be consulted before one disassembles and cleans the absorber head.

Several design changes in newer circle systems facilitate low-flow anesthesia. Low fresh gas flow is desirable to reduce pollution and the cost of using volatile agents and nitrous oxide, preserve tracheal heat and moisture, delay the drying of carbon dioxide–absorbent

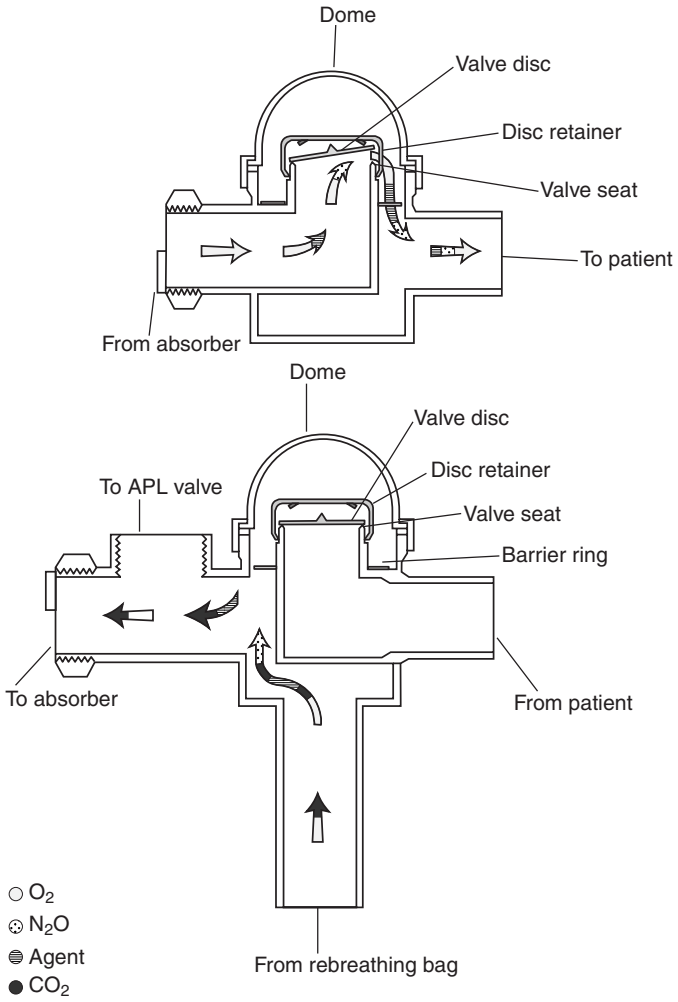

FIGURE **15-37** Gas flows in inspiratory (*top*) and expiratory (*bottom*) unidirectional valves during inspiration. (From Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, Wis: Datex-Ohmeda; 1985.)

granules, and preserve patient body temperature. Factors that enhance the safety and efficiency of low flows in modern circle breathing systems and ventilators are shown in Box 15-12.

A traditional-sized absorber head like the Aestiva is larger than the volume of many of the newer designs.[64,68,74] Circles with smaller volume will have shorter time constants. The time constant equals capacity divided by flow, and measures how quickly a breathing system reaches equilibrium with a change in the inflow. In a circle system with lower volume, changes in dialed concentration of agent will be reflected more quickly in the inspired concentration, at any flow rate, as compared to a higher volume circle system. In a nonrebreathing circuit, or a circle system at flows substantially higher than minute ventilation, each breath reflects the dialed concentration of agent because there is no rebreathing of exhaled gases in either. Thus a circle system with higher flows is suitable when rapid changes are desired, such as at induction and emergence.

There are, however, circumstances in which to avoid low flows (fresh gas flow 1 L/min). Absolute contraindications include patients with smoke inhalation injury, malignant hyperthermia, or other conditions in which washout of potentially dangerous gases or a high oxygen uptake is expected. If equipment breakdown occurs mid-case that would affect the safety of low flows (i.e., failure of inspired oxygen or anesthetic agent monitors, or failure of soda lime granules), higher flows should be used. Relative

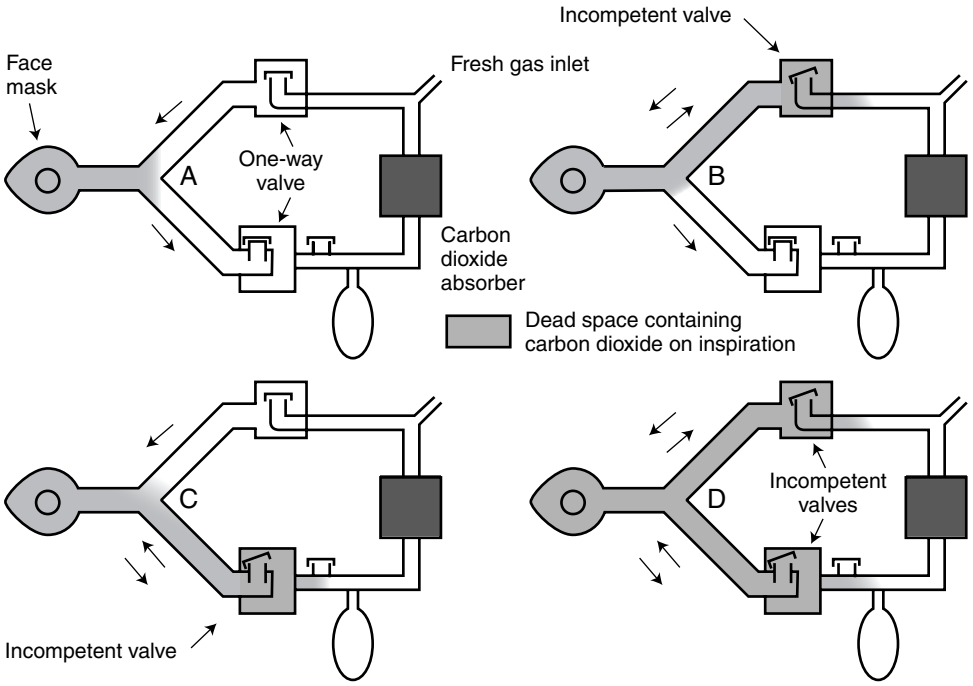

FIGURE **15-38** Incompetence of a unidirectional valve. **A,** Normal function. Incompetence of an inspiratory valve **(B),** an expiratory valve **(C),** or of both unidirectional valves **(D)** creates dead space *(stippled area)* that extends through the entire ipsilateral corrugated breathing hose. (Modified from Gravenstein JS, et al. *Capnography in Clinical Practice*. Boston: Butterworth; 1989.)

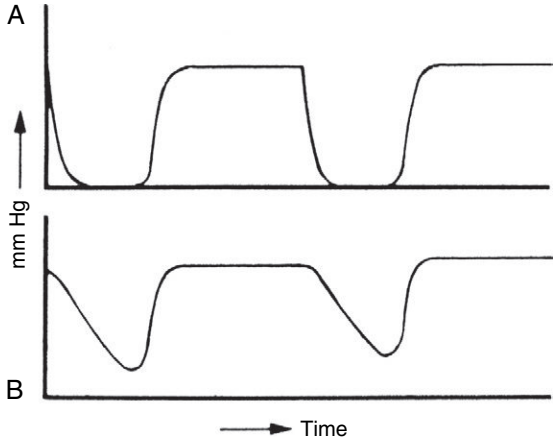

FIGURE **15-39** Compared with a normal capnogram **(A),** a capnogram recorded when the inspiratory unidirectional valve is incompetent **(B)** shows increases in inhaled and exhaled carbon dioxide pressure and an abnormally prolonged downstroke. The prolonged downstroke during the inspiratory phase occurs because the patient inspires mixed alveolar and fresh gas from the inspiratory limb rather than fresh gas alone. (Modified from Gravenstein JS, et al. *Capnography in Clinical Practice*. Boston: Butterworth; 1989.)

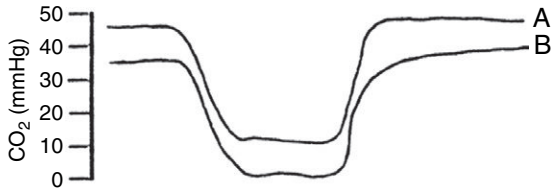

FIGURE **15-40** Compared with a normal capnogram *(B)*, a capnogram recorded with an incompetent expiratory unidirectional valve *(A)* shows increases in inspired and expired carbon dioxide concentration but no changes in morphology. (Modified from Gravenstein JS, et al. *Capnography in Clinical Practice*. Boston: Butterworth; 1989.)

contraindications to low fresh gas flows include when using older equipment that is less leak-proof; face mask anesthesia; during rigid bronchoscopy; and with the use of uncuffed endotracheal tubes.[156]

Humidification, and prevention of nosocomial infection, are desirable with the use of any respiratory apparatus. Both of these goals may be addressed with breathing circuit filters that incorporate heat and moisture exchange with filtration (HMEF).[157] The use of low flows during maintenance results in an increase in circuit humidity and a lower rate of use of volatile agents. Heat- and moisture-exchanging filters precipitate exhaled water vapor

BOX **15-11**

Circle System: Advantages and Disadvantages

Advantages

- Constant inspired concentrations
- Conservation of respiratory tract heat and humidity
- Minimal operating room and environmental pollution
- Useful for closed-system, low-flow, and semi-open configurations
- Low resistance (less than the endotracheal tube; not as low as in nonrebreathing circuits)

Disadvantages

- Relatively complex
- Opportunities for misconnection or disconnection
- Malfunctioning unidirectional valves cause serious problems
  - *Open:* Rebreathing
  - *Closed:* Occlusion
- Less portable than nonrebreathing circuits
- Increased dead space (true of all respiratory apparatus; extends to the point where inspired and expired gas streams diverge, i.e., at Y-piece)

BOX 15-12

Breathing System and Ventilator Design Features That Support Low-Flow Anesthesia

- Compliance and leak testing, automatic leak detection
- Fresh gas compensation or decoupling
- Warmed absorber heads (NM 6000, others)
- Low-volume absorber heads (allow faster equilibration of dialed and delivered agent concentration)
  - Narkomed 6000, Fabius GS—1500-mL canister (Fabius GS volume is 2800 mL, including bag for entire breathing system)
  - Aestiva 2700 mL (canisters alone)
  - ADU 750 mL (canister)
- No mandatory minimum oxygen flows (there are exceptions; Aespire and Aestiva, but these are only 50 mL/min)
- Point in the system where fresh gas enters is distal to inspiratory unidirectional valve (in ADU, Aisys); causes dialed changes to be reflected at airway more quickly when lower fresh gas flows are used

on their filter media. The next inhalation returns this water to the patient. These filters may slow the rate of heat loss from the patient, because they decrease the rate of evaporation of water from the tracheal mucosa. They may also confer the benefit of bacterial and viral filtration.[158,159] Cleaning the bellows is necessary after anesthesia has been provided to a patient with a disease transmitted by air or oral secretions. To limit contamination of the machine, consider avoiding the mechanical ventilator, using bacterial/viral filters on the Y-piece or on each limb, and changing the soda lime after the case.

The AANA (American Association of Nurse Anesthetists) Standards for Nurse Anesthesia Practice call on anesthetists to use safety precautions to minimize the risk of infection for the patient, the anesthetist, and other staff.[97,160] It is certain that anesthesia equipment, and providers, are contaminated with potential pathogens.[161] Furthermore, many of the surfaces of the anesthesia gas machine and monitors have been shown to be contaminated with blood—visible and occult.[162] It is therefore mandatory for patient safety to ensure that departmental cleaning and sterilization programs are adequate, that good housekeeping during administration of anesthesia is practiced, and that universal precautions are observed. For equipment, the AANA advocates a classification system and specific equipment recommendations that are published in their *Infection Control Guide*.[160] In addition, manufacturers include directions for cleaning and sterilizing equipment in their operation and maintenance manuals.

Electrically heated (active) breathing circuit humidifiers are no longer used. Problems associated with heated humidifiers included overhydration, underhydration, hypothermia, hyperthermia, melting of disposable breathing circuits, aspiration, interference with gas analysis accuracy (clogged lines or sensors) and infection.[163]

Carbon Dioxide Absorption

Carbon dioxide absorption makes rebreathing of exhalations possible. Thus it conserves agent, oxygen, nitrous oxide, and tracheal humidity, while preventing the respiratory acidosis that would result from the rebreathing of CO_2.

Fresh gas flow set on the flowmeters determines the amount of rebreathing in the circle system. A circle system with fresh gas flows of 0.3 to 0.5 L/min provides near-total rebreathing, and full reliance on absorbent for prevention of rebreathing of CO_2. At the other extreme, use of a circle system with fresh gas flows above minute ventilation (greater than 5 to 8 L/min for a traditional large, dual-canister absorber head) is associated with little if any reliance on absorbent granules, because exhaled carbon dioxide is rapidly diluted and sent to the scavenger with such high fresh gas inflows.[77,134,164] This relationship can be confusing. When faced with exhausted granules, which cause an increase in expired (and inspired) CO_2, one may be tempted to increase minute ventilation (V_E). This approach is ineffective with exhausted absorbent (even though it is the obvious response for controlling hypercarbia from other causes), because the patient simply inspires more of a gas mixture containing CO_2. The correct response to hypercarbia associated with exhausted absorbent is increasing fresh gas flow (and then changing the absorbent at the end of the case). With the newer absorbent canister designs, of course, this may be accomplished mid-case and without leaks or danger to the patient. Even with these newer designs, if a replacement canister is not immediately available, high fresh gas flows allow one to control inspired CO_2 while waiting for a replacement canister to be obtained.

BOX 15-13

Carbon Dioxide Absorption in Soda Lime

1. $CO_2 + H_2O \longleftrightarrow H_2CO_3$
2. $H_2CO_3 + NaOH \text{ (or } KOH) \longleftrightarrow Na_2CO_3 \text{ (or } K_2CO_3) + H_2O + \text{energy}$
3. $Na_2CO_3 \text{ (or } K_2CO_3) + Ca(OH)_2 \rightarrow CaCO_3\downarrow + NaOH \text{ (or } KOH)$

For soda lime, reaction 1 is also called *the first neutralization reaction;* reaction 3 is also called the *second neutralization reaction*. Note that activator is regenerated in step 3.

Chemistry

The chemistry of soda lime CO_2 absorption is shown in Box 15-13 (barium hydroxide lime reactions are not shown, because it has been withdrawn from the North American market by its manufacturer).[25,131] The ionic reactions take place on the surface of the granules in an aqueous medium. An appropriate water content (10% to 20%) is important for the speed and efficiency of the reactions. Dry granules become exhausted much more quickly than moist granules. Activators (NaOH, KOH) are added to increase the speed of the reaction. Potassium hydroxide is used much less frequently, because it has been implicated in reactions that produce carbon monoxide and compound A from degradation of inhaled anesthetic agents.[77] The activator combines with carbonate ions or CO_2 in a reversible reaction that produces water and energy. The absorption of 1 mole of CO_2 produces 13,000 kcal of heat energy.[131] Absorbents contain ethyl violet as an additive. The ethyl violet serves as an indicator of absorbent pH. Fresh CO_2 absorbent has a caustic alkaline pH because of the sodium hydroxide. As the reactions proceed, the pH becomes less alkaline. At a critical pH of 10.3, the ethyl violet changes from colorless to blue-purple.

Soda lime does not *regenerate* to any extent; in other words, it does not regain capacity to absorb CO_2 during periods when it is not in use. Its capacity is similar whether it is used continuously or intermittently. However, it does exhibit some *color reversion* (a change in appearance from blue-purple to white) during a rest period. The color of the absorbent at the beginning of the day may not reflect its remaining capacity because of this color reversion.[131] When a subsequent anesthetic is begun, the color of absorbent that had not seemed exhausted initially may quickly change

TABLE 15-5 Characteristics of Absorbents

Component	Sodasorb (WR Grace)	Medisorb (GE Medical)	Drägersorb 800 Plus (Dräger Medical)	Amsorb Plus (Armstrong Medical)	Litholyme (Allied Health Care)

to blue-purple. Therefore it is recommended that the user judge the degree of color change at the end of each case, and change the canister before the next case if necessary.[131]

Soda Lime

The characteristics of soda lime and other selected absorbents are listed in Table 15-5.[83,85,165-167] The main constituent of all absorbents is calcium hydroxide. Hardeners (silica and kieselguhr) may be added to soda lime. Soda lime is manufactured to have a water content between 13% and 20% by weight. The size of all absorbent granules is 4 to 8 mesh, meaning they will pass through screens with 4 to 8 holes per linear inch. The selection of granule size involves a compromise between resistance to flow and absorption efficiency. Larger granules have less resistance to gas flow; however, they are also less efficient because their surface area is relatively small with respect to their mass. Fine granules or soda lime dust would have a great deal of resistance to gas flow, but their efficiency would be high because of their increased surface area.

Soda lime degrades most current volatile agents to some extent,[54,85] with sevoflurane degraded most, and desflurane least. Degradation may produce compound A (sevoflurane), carbon monoxide (the ethyl methyl ethers), and other compounds. Degradation is favored by dry absorbent, and the presence and quantity of strong bases (potassium hydroxide more than sodium hydroxide).[82,85,166-170] Sevoflurane may be degraded so much at low flows in desiccated barium hydroxide lime that it is impossible to attain 1 MAC (minimum alveolar concentration) in the breathing circuit, regardless of the dial setting.[81]

Sevoflurane is unstable in soda lime, producing compound A. Compound A is lethal in rats at 130 to 340 ppm, and may cause renal injury at 25 to 50 ppm. Compound A concentrations of 25 to 50 ppm are easily achievable in normal clinical practice if extremely low fresh gas flows are used. The incidence of toxic (hepatic or renal) or lethal effects from sevoflurane, used in millions of humans, are comparable to desflurane.[171] The product insert does not recommend sevoflurane at total fresh gas flows less than 1 to 2 L/min for more than 2 MAC-hours.[172] The production of compound A may be affected by the particular gas machine used. At a constant fresh gas flow, it was least in the gas machine with the lower circuit and absorbent volume.[166]

BOX 15-14

Recommendations on the Safe Use of Carbon Dioxide Absorbents

1. Use carbon dioxide absorbents with lower (or no) amounts of strong bases (particularly potassium hydroxide [KOH]).
2. Create institutional, hospital, and/or departmental policies regarding steps to prevent desiccation of the carbon dioxide absorbent.
3. Turn off all gas flow when the machine is not in use.
4. Change the absorbent regularly—on Monday morning, for instance.
5. Change absorbent whenever the color change indicates exhaustion.
6. Change all absorbent, not just one canister in a two-canister system.
7. Change absorbent when uncertain of the state of hydration, such as when the fresh gas flow has been left on for an extensive or indeterminate time period.
8. If compact canisters are used, consider changing them more frequently.
9. Low flows also have a role in preserving humidity in absorbent granules. Use relatively low fresh gas flows for the majority of procedures, changing flows from high to low as soon as practical in any given case (after the patient has attained maintenance levels of volatile anesthetic).

Carbon monoxide is produced by desflurane, much more than isoflurane, when these agents are in contact with absorbent granules. Halothane or sevoflurane produce little, if any, carbon monoxide. Production of carbon monoxide is greatest in dry absorbent, or with barium hydroxide lime as compared with soda lime. It is recommended that oxygen be turned off at the end of each case, absorbents changed regularly (particularly if fresh gas flow is left on over the weekend or overnight), and low flows used (this will tend to keep granules moist). Current recommendations for avoiding problems with carbon monoxide are summarized in Box 15-14.*

BOX 15-15

Clinical Signs of Carbon Dioxide–Absorbent Exhaustion

Early

- Increase in partial pressure of end-tidal carbon dioxide; may be accompanied by an increase in inspired carbon dioxide
- Respiratory acidosis
- Hyperventilation
- Signs of sympathetic nervous system activation (flushed appearance, cardiac irregularities, sweating)
- Increased bleeding at surgical site
- Color of indicator

Late

- Increase (and later a decrease) in heart rate and blood pressure
- Dysrhythmia

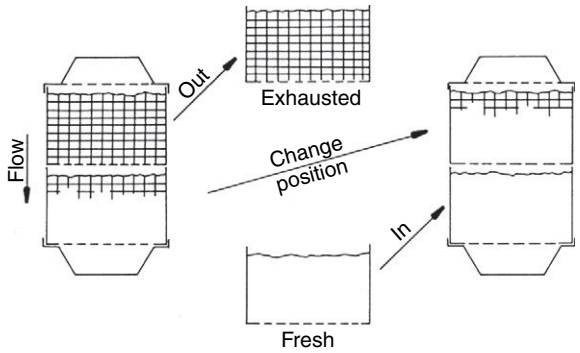

FIGURE **15-41** Changing dual-canister carbon dioxide absorbers. (From Schreiber P. *Safety Guidelines for Anesthesia Systems*. Telford, 1985, Drägerwerk AG & Co. KGaA, Lubeck.)

BOX 15-16

General Steps for Changing Carbon Dioxide–Absorbent Canisters

1. Protect eyes and skin with goggles and gloves. Wear a mask if pouring loose absorbent.
2. Note purple color, date last changed, or both.
3. Loosen clamp or screw.
4. Remove and discard top canister.
5. Remove plastic wrap and seals from new canister.
6. Insert new canister on bottom, and the old bottom canister on top.
7. Retighten screw.
8. Check breathing circuit for leaks.

NOTE: Do not change a dual canister in the middle of a case; convert to a semi-open breathing circuit by using 5 to 8 L/min fresh gas flow.

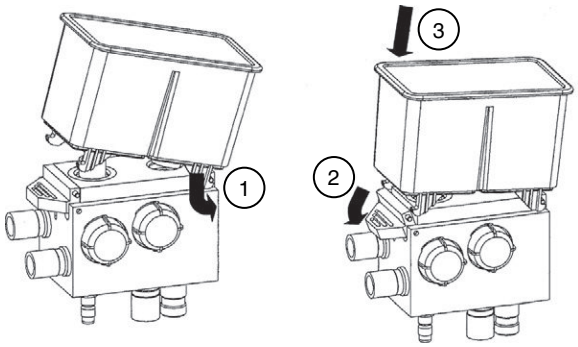

FIGURE **15-42** Changing carbon dioxide cassette in the ADU may be accomplished during a case. (From *S/5 Anesthesia Delivery Unit User's Reference Manual*, Catalog No. 8502304. Madison, Wis: Datex-Ohmeda; 2000.)

New Absorbents Lacking Strong Bases

The strongly basic activators (NaOH, and particularly KOH) have been convincingly implicated in the carbon monoxide problem with the methyl ethyl ethers (especially desflurane) and the generation of compound A by sevoflurane. Many absorbents available in North America lack KOH, and may have reduced amounts of NaOH (see Table 15-5). Eliminating both activators produces an absorbent that has similar physical characteristics and carbon dioxide absorption efficiency (the second is controversial) as compared with soda lime (Amsorb Plus [Armstrong Medical Ltd., Coleraine, Northern Ireland]).[80,85,165,176] Lithium hydroxide is also an effective carbon dioxide absorbent.

Because of the controversial efficiency of absorbents that lack all strong bases, most absorbents have been modified to include less NaOH, and no KOH (see Table 15-5). The goal is to maintain efficiency, while lessening the production of by-products. Dräger Medical makes an absorbent with decreased amounts of NaOH and no KOH: Drägersorb 800 Plus. GE Medical supplies Medisorb, which lacks KOH, in the prefilled canisters for all their gas machines (i.e., ADU, Aestiva, Aisys).

Using Carbon Dioxide Absorbents

Certain similarities are apparent with all absorbents. The resistance of filled canisters in a circle system is low (less than 1.5 cm H_2O at a flow rate of 100 L/min). Resistance of other breathing circuit components, particularly the endotracheal tube, is greater. Inhaled absorbent dust is caustic and a respiratory irritant (it may lead to laryngospasm, bronchospasm, and pneumonia).[131] A trap for water, which also prevents the passage of dust toward the patient, may be incorporated distal to the granules in circle systems; if present, it must be emptied periodically. In addition, when the breathing circuit is pressurized for checkout, the pressure should be released through the APL valve, rather than through the elbow at the patient's end. This technique not only prevents the propulsion of dust toward the patient, but also is useful for checking APL valve function.

Absorbent efficiency is decreased by channeling and the wall effect.[176,177] The amount of CO_2 absorbed varies throughout the canister. The inside edge of the canister wall is a low-resistance pathway. Exhaled gas follows this pathway, or other low-resistance pathways, through the canister, forming channels whose capacity to absorb CO_2 is exhausted before the capacity of the bulk of the absorbent is used. Thus the wall effect and channeling produce exhaustion of absorbent before its theoretic capacity has been reached. To help prevent these two effects, shake the canister before installation in the circle system, to promote uniform packing throughout.[131]

Exhaustion and Replacement of Canisters

The clinical signs of absorbent exhaustion are shown in Box 15-15. Some of these signs (e.g., hyperventilation) may be masked in the anesthetized patient. In practice, capnography and indicator color change are primary indications of exhaustion. It is unwise to rely on color change or canister temperature alone as a measure of exhaustion.[178] The process of canister replacement for Aestiva-style dual-canister absorbers is illustrated in Figure 15-41, and the steps for replacement are shown in Box 15-16. Canister replacement for the ADU is shown in Figure 15-42.

Do *not* change Aestiva-style canisters or loose fill in the middle of a case. If the new canister is placed in its clear plastic holder upside down, or if for any other reason the circuit cannot be reassembled promptly, resumption of ventilation might be delayed. If granules do become exhausted, a safer alternative strategy is to change fresh gas flow to one to two times the minute ventilation; this approach should ensure that expired CO_2 is reduced to acceptable levels. The granules can then be replaced after the case.

Each canister (top or bottom) in an Aestiva-style absorber contains 1.1 kg of granules in a volume of 1400 to 1500 mL.[68,71,179] This compares to 0.8 kg per canister in the Aisys, and 0.6 kg in the ADU canister.[179] Each 100 g of granules can absorb as much as 15 L of CO_2 before the outlet concentration is 1% (7.6 mmHg), assuming that no channeling occurs. The average to maximum production of CO_2 by the anesthetized adult is 12 to 18 L/hr.[131] Therefore, when total rebreathing is occurring during closed circuit anesthesia, the top canister in an Aestiva might be expected to last for 8 to 10 hours of continuous use. A much longer life is observed clinically for these large canisters, principally because higher flows are used (typically in many clinical settings, 2 to 4 L/min of fresh gas flow). These higher flows cause increases in both the dilution of exhaled CO_2, and the rate of washout of exhalations from the breathing circuit to the scavenger. In one study in which fresh gas flows of 4 L/min were used, two canisters were used for 67 and 79 hours (anesthesia time) over 2.5 weeks without exhaustion, with a final minimum water content in some segments of 4% to 8.5%.[180] As lower flows become more common for economic and environmental reasons, and canisters become smaller, anesthetists will need to become more aware of the signs of absorbent exhaustion, and realize that absorbent must be changed more frequently.[181]

The manufacturer of soda lime recommends that the absorbent be changed if it is left in the machine for longer than 48 hours.[131] Dräger recommends that absorbent in the Fabius be changed if the machine has been idle for 48 hours, or at least each week on Monday.[60] These extremely cautious guidelines are based on recognition of two problems that arise with extended use. First, the ethyl violet indicator present along the wall of the canister may be inactivated by drying, or intense light. Second, dehydration of the granules occurs over time, particularly if higher gas flows or an excessive amount of oxygen flush is used. It is not uncommon for gases to be left flowing accidentally overnight or over the weekend. The resultant dehydration of the granules reduces their efficiency, and makes production of carbon monoxide and compound A more likely.[85]

Ventilators

Classification and Theory of Operation—Gas-Driven Bellows Ventilators

Modern ventilators using compressible bellows are multimode, double-circuit, electronically controlled, volume- or pressure-limited ventilators. Because they are electronically controlled, these ventilators cannot operate without main electrical power or a backup battery. Ventilators in current use may be classified with respect to a number of parameters (Box 15-17).* Figure 15-35 shows gas flow in the breathing circuit with mechanical ventilation. The bellows is similar to the anesthetist's hand squeezing a breathing bag to assist the patient's respiration. The mechanical ventilator is a "bag in a bottle"; it uses the force of compressed gas (O_2 or air) as the driving mechanism to compress the bellows. Within the bellows is the gas inspired and expired by the patient. Thus the bellows contains what the patient breathes, and separates it from the surrounding driving gas. Leaks in the bellows may cause dilution of gas within the bellows by driving gas, or loss of agent and oxygen from within it.[182]

Without a means of escape, the continual addition of fresh gas flow into the breathing circuit would cause increased volume and pressure within it (and in the patient's lungs). A ventilator relief valve (also known as the *spill valve*, or *overflow valve*) maintains circuit volume and pressure by releasing gas to the scavenger, in an amount equal to the fresh gas flow per minute. The ventilator relief valve opens only during the expiratory phase (see Figure 15-35). During inspiration, driving gas closes this relief valve, inflating the lungs by preventing gas within the bellows from exiting to the scavenger as the bellows are compressed. During early expiration, a weight within the ventilator relief valve holds the pathway to the scavenger closed until the bellows have filled. This

BOX 15-17

Classification of Modern Ventilators

Power Source
- Gas-driven bellows—compressed gas and electricity
- Piston ventilator—electricity only

Drive Mechanism
- Double-circuit—Bellows compressed by driving gas, which surrounds and compresses the patient circuit gas within. The driving gas is 100% oxygen or compressed air (GE), or a Venturi mix of oxygen and room air (older Dräger).
- Piston ventilators (compression of patient gas is by an electrically driven piston)

Cycling Mechanism
- Electronically time-cycled. Flow can also terminate when a volume or pressure target is achieved.

Modes
- Manual/spontaneous
- Volume-controlled ventilation (VCV)
- Pressure-controlled ventilation (PCV)
- Synchronized intermittent mandatory ventilation (SIMV) in either volume or pressure mode, with or without pressure support of the patient's spontaneous breaths
- Pressure-support ventilation (PSV)
- Pressure–controlled ventilation with volume guarantee (PCV-VG)

Bellows Classification
- Gas-driven bellows
  - Most have ascending (standing) bellows.
  - Descending (hanging) bellows are seen less commonly.
- Piston ventilators are driven by electric motors.

Data from Dosch M. *The Anesthesia Gas Machine: Ventilators*, 2011. Accessed January 29, 2012 at: http://www.udmercy.edu/crna/agm/08.htm; Dorsch JA, Dorsch SE. *Understanding Anesthesia Equipment*. 5th ed. Philadelphia: LWW; 2008; Dorsch JA, Dorsch SE. *A Practical Approach to Anesthesia Equipment*. Philadelphia: LWW; 2011.

creates 2 to 3 cm water of positive end-expiratory pressure (PEEP) within the breathing circuit. This small amount of PEEP is inherent to the design when standing-bellows mechanical ventilation is used.[46,54,77,182,183] Note that the "Bag/Vent" switch set to "Vent" or "Auto" removes the reservoir bag and APL valve from the breathing circuit (not true for ventilators with fresh gas decoupling), so in a standing bellows ventilator, the APL valve can be open during mechanical ventilation without causing a leak.

Hanging Bellows. A few ventilators with gas-driven bellows have "hanging" bellows. To distinguish between ascending (standing) and descending (hanging) bellows, use the mnemonic, "Asc*e*nd and desc*e*nd contain *e*'s, so look at the bellows during *e*xpiration to distinguish them." Both standing and hanging bellows are safe, in that both are capable of alerting the user to a disconnection, so long as appropriate monitoring is used.[184] Standing bellows have an advantage in that they will not fill in the event of a disconnect, whereas hanging bellows may fill with room air even when completely disconnected from the patient.[183]

The hanging design may provide compactness and ease of sterilization of the entire breathing circuit. One machine with a hanging bellows incorporates disconnect alarms based on chemical (capnograph) and mechanical principles (pressure, volume, and flow sensors). Because this design uses fresh gas decoupling, the manual breathing bag is always in the circuit and fluctuates in volume while the mechanical ventilator is operating. Water may gather in the bellows (lessening tidal volume and creating an infection risk), but this should be lessened by the heated absorber head.[185]

Theory of Operation—Piston-Driven Ventilators

Piston ventilators use an electric motor to compress the gas in a rigid piston during inspiration. They use no driving gas and may be used without depleting the oxygen cylinder in case of oxygen pipeline failure.[186] Piston ventilators, like gas-driven bellows, are safe and effective.

In the Narkomed 6000/6400 Divan ventilator, the piston is out of view, because it is placed horizontally under the writing surface. Although the piston can be viewed by lifting the writing surface, the to-and-fro movement is not normally visible during mechanical ventilation. The anesthetist relies on pressure and capnography waveforms, plus the movement of the manual breathing bag, to guard against disconnects or other problems. The Fabius GS has a piston ventilator similar to the Divan, but the bellows travel vertically, and their movement is continuously visible through a window to the left of the flowmeter bank (see Figure 15-8).

The piston ventilator has positive and negative pressure relief valves built in. If the pressure within the piston reaches 75 ± 5 cm H_2O, the positive pressure relief valve opens. If the pressure within the piston declines to −8 cm H_2O, the negative pressure relief valve opens, and room air is drawn into the piston, protecting the patient from negative end-expiratory pressure (NEEP).[60,62]

There are several advantages to a piston ventilator.[186] It is quiet. There is no PEEP (2 to 3 cm H_2O is mandatory on standing bellows ventilators because of the design of the ventilator spill valve). There is great precision in delivered tidal volume, owing to compliance and leak compensation, fresh gas decoupling, and the rigid piston design. There are fewer compliance losses with a piston, as compared with a flexible standing bellows compressed by driving gas. Measuring compliance and leaks with a transducer near the piston eliminates a bulky, costly sensor close to the patient's airway (such as the D-Lite sensor on the ADU). Electricity is the driving force for the piston, so if oxygen pipeline pressure fails, or pipeline supplies are unavailable (as in office-based settings), mechanical ventilation may continue without exhausting the cylinder oxygen simply to drive the bellows. Piston ventilators (like gas-driven bellows) are capable of all modern ventilation modes.

The piston design also has some disadvantages.[25] They do not display the characteristic motions of a standing bellows during disconnects, or when the patient is breathing over and above the ventilator settings. But disconnects can be seen in a piston ventilator with fresh gas decoupling (see later), because the manual breathing bag remains in the breathing circuit during mechanical ventilation with a piston. The piston is quiet, so that it may be harder to hear its regular cycling. The piston ventilator design cannot easily accommodate nonrebreathing circuits, although this is also true of traditional absorber heads like the Ohmeda GMS, or newer ascending bellows ventilators like the ADU. The piston has the potential for NEEP and dilution of the patient's inspired gas with room air.

Typical Ventilator Alarms

Modern ventilators have safety alarms to protect the patient from a number of conditions (Box 15-18). One important safety feature of modern equipment is that apnea (disconnect) alarms are enabled with the first breath sensed.

Ventilator Modes and Settings

Besides increased tidal volume accuracy because of compliance and leak compensation, the most notable advance in current ventilators is their flexibility in modes of ventilation. Pressure-controlled ventilation (PCV) allows more efficient and safe ventilation for certain types of patients. Pressure-controlled ventilation with volume guarantee (PCV-VG) helps to maintain tidal volume in the face of changing lung compliance, for example, when pneumoperitoneum is applied or released. Pressure-support ventilation (PSV) is an important recent addition for patients who are spontaneously breathing, which is seen with much greater frequency since the adoption of the laryngeal mask airway. The improvement in accuracy afforded by modern ventilators at small tidal volumes means that switching of circuits (e.g., to a nonrebreather for small children) are not used as often. This helps avoid potential misconnects.

BOX 15-18

Typical Ventilator Alarms

Pressure Alarms
- High (isolated or continuing)
- Subatmospheric
  - Volume—low tidal or minute volume
  - Rate—high respiratory rate
  - Reverse flow (may indicate incompetence of expiratory unidirectional valve in the breathing circuit)

Apnea/Disconnect Alarms*

These may be based on the following:
- Chemical monitoring (lack of end-tidal carbon dioxide)
- Mechanical monitoring:
  - Failure to reach normal inspiratory peak pressure, or failure to sense return of tidal volume
  - Spirometry
  - Failure of standing bellows to fill during exhalation
  - Failure of manual breathing bag to move and fill during mechanical ventilation (machines with fresh gas decoupling—Apollo, Fabius, Narkomed 6000)
  - Other—lack of breath sounds or visible chest movement.

*Note that low readings of the pulse oximeter is less valuable, because it is a late sign of hypoventilation.

Volume-Controlled Ventilation. All ventilators offer volume-controlled ventilation (VCV). In this mode, the desired tidal volume (V_T) is delivered at a constant flow. The ventilator is volume limited, time cycled, and constant flow in VCV. Inspiration is terminated when the desired V_T is delivered or if an excessive pressure is reached (60 to 100 cm H_2O).[54,60,62,71] Patients under general anesthesia often have decreased functional residual capacity and compliance.[187] Because volume is controlled, alveolar ventilation and arterial carbon dioxide can be maintained despite changes in pulmonary function.[188] However, with VCV the peak inspiratory pressure is uncontrolled, and rises as the patient's compliance decreases, or airway resistance increases.

V_T is adjusted to prevent atelectasis, and respiratory rate (RR) is adjusted to keep end-tidal carbon dioxide at the desired value. Peak inspiratory pressure (PIP) is monitored but not controlled. Typical initial settings for VCV in an adult are V_T 6 to 12 mL/kg, RR 6 to 12 breaths per minute, and inspiratory:expiratory (I:E) ratio 1:2. PEEP of 5 cm H_2O may be added to prevent atelectasis.[189]

Pressure-Controlled Ventilation. In pressure-controlled ventilation (PCV) mode, PIP is limited, and the cycle is controlled by time, with a decelerating flow pattern. Inspiratory pressure is controlled rather than volume (as with VCV).[189,190] Tidal volume is uncontrolled, and increases if compliance increases, or airway resistance falls. The ventilator generates sufficient flow to attain the target pressure early in inspiration, then maintains this set pressure throughout the inspiratory time. High flow is needed at first, and less flow is required to maintain this pressure. If the desired tidal volume is not obtained, inspiratory rise can be increased. Target pressure is adjusted for the desired V_T; RR is adjusted to maintain a reasonable end-tidal carbon dioxide. V_T is monitored but not controlled. In patients with low compliance (e.g., morbidly obese), PCV may result in an increased tidal volume at a lower PIP, especially if PIP had been high when employing VCV (e.g., in laparoscopic abdominal or pelvic surgery). During PCV, if pulmonary compliance drops (e.g., application of pneumoperitoneum) or airway resistance increases (e.g., bronchospasm, kinked endotracheal tube), delivered V_T may drop substantially. Conversely, if pulmonary compliance improves (e.g., release of pneumoperitoneum, return to supine from steep Trendelenburg position) or airway resistance decreases, V_T may increase substantially.

There are several indications for PCV. Patients for whom high inspiratory pressure is particularly dangerous may benefit (e.g., laryngeal mask airway,[191] emphysema, neonates). In patients with low compliance, PCV can often produce higher tidal volumes than VCV (e.g., pregnancy, laparoscopic surgery, morbid obesity, or adult respiratory distress syndrome). PCV can compensate for leaks (e.g., infants with uncuffed endotracheal tubes, laryngeal mask airway). PCV may provide effective ventilation and lower airway pressure during one-lung ventilation.[190,192]

Typical initial settings for PCV in an adult include pressure limit 20 cm H_2O, RR 6 to 12 breaths per minute, I:E ratio 1:2. PEEP 5 cm H_2O may be added to help prevent atelectasis.[189] Pressure control has been incorporated into other modes, such as PCV-VG (which adjusts inspiratory pressure to prevent significant variation in delivered V_T; see later)[57,59] and as SIMV in pressure control mode.[62]

Pressure-Controlled Ventilation with Volume Guarantee. Pressure-controlled ventilation with volume guarantee (PCV-VG) was created to address the problem that V_T in pressure control mode varies, sometimes strikingly, when the patient's compliance changes. Like PCV, the basic controls are target pressure and rate, but in PCV-VG, a desired V_T is also set. Like PCV, the ventilator delivers breaths using a decelerating flow pattern at a constant pressure. But in PCV-VG, the inspiratory pressure is adjusted to deliver the set V_T, using the lowest possible pressure, and staying within the maximum pressure limit. PCV-VG begins by delivering a volume breath at the set V_T. The patient's compliance is determined from this volume breath, and the inspiratory pressure level is then adjusted for the next breath. PCV-VG combines the advantages of pressure-controlled ventilation, yet dynamically compensates for changes in the patient's lung characteristics (Figure 15-43).[73]

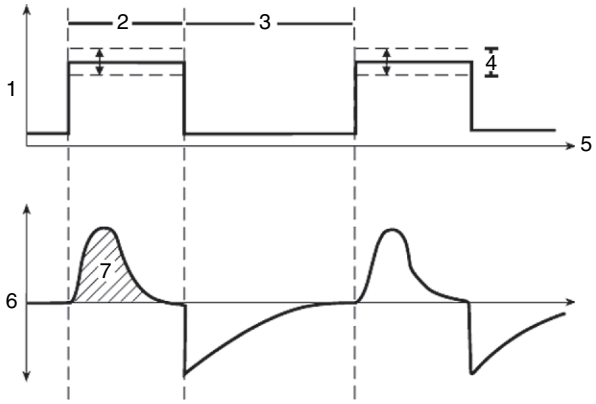

FIGURE **15-43** Pressure-controlled ventilation with volume guarantee. The pressure waveform at top (*1*) shows that peak inspiratory pressure is adjusted up and down to deliver the set tidal volume. The bottom (*6*) is the flow-time waveform. *1*, Paw waveform; *2*, Tinsp; *3*, Texp; *4*, Variable pressure to deliver desired TV; *5*, PEEP; *6*, Flow waveform; *7*, TV. *Paw,* Airway pressure; *Tinsp,* Time for inspiration; *Texp,* Time for expiration; *TV,* Tidal volume; *PEEP,* positive end-expiratory pressure. (From *Aisys User's Reference Manual,* part 2 of 2, Document No. M1122365 10 07 01 04 23. Tewksbury, Mass: Datex-Ohmeda Inc; 2008.)

Synchronized Intermittent Mandatory Ventilation. With the advent of the laryngeal mask airway (LMA) and the prevalence of short, ambulatory, or office-based surgical procedures, spontaneous unassisted breathing has become much more common during general anesthesia. But it is difficult to maintain a light enough plane of anesthesia to permit spontaneous ventilation, while still retaining sufficient depth for surgery to proceed. If the spontaneously breathing patient is maintained in a plane of anesthesia that is too deep, respiratory acidosis will occur; too light, bucking and awareness are risks. The traditional solution was to assist ventilation manually, because synchronized intermittent mandatory ventilation (SIMV) was all the mechanical ventilator could provide. Ventilation modes that could support a spontaneously breathing patient (i.e., provide normocapnia without bucking) include SIMV,[193] PSV,[194] continuous positive airway pressure (CPAP), and airway pressure release ventilation (APRV).[189,195,196] Of these modes, SIMV and PSV are currently available.

SIMV can be used for anything from full to partial support of ventilation. On newer gas machines, SIMV may be selected based on either pressure or volume modes. Whichever is selected, in SIMV the intermittent mandatory breaths are delivered in synchrony with, and triggered by, the patient's spontaneous efforts. Typical initial settings thus include not only volume (or pressure limit) and rate, but trigger window (percent) and sensitivity (Figure 15-44). The spontaneous breaths may also be pressure supported (SIMV-PS).[60]

Trigger window controls the amount of time during each expiratory cycle that the ventilator is sensitive to spontaneous breaths, by sensing the negative pressure generated by the patient's diaphragm. Sensitivity controls how much negative pressure the patient needs to generate before a breath is triggered. If

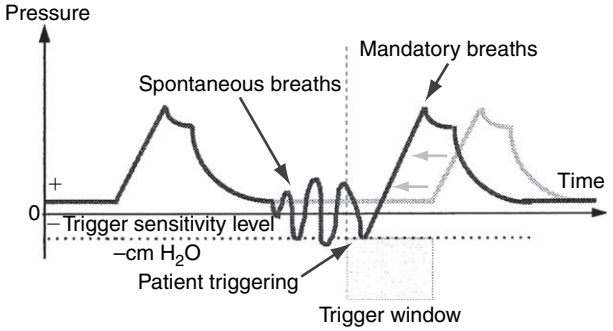

FIGURE **15-44** Trigger window and sensitivity may be set when choosing synchronized intermittent mandatory ventilation (SIMV) mode. (From *S/5 Anesthesia Delivery Unit User's Reference Manual*, Catalog No. 8502304. Madison, Wis: Datex-Ohmeda; 2000.)

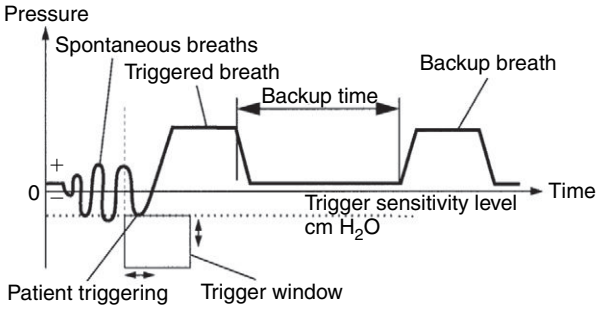

FIGURE **15-45** Trigger window and sensitivity settings interact with the patient's spontaneous breaths in pressure-support ventilation. (From *Datex-Ohmeda ADU Ventilation Supplement*, Document No. M1038740, Issue M1044700. Madison, Wis: Datex-Ohmeda; 2005.)

spontaneous breaths are triggered too often (e.g., by motion in the surgical field), the trigger window should be reduced, or the sensitivity made more negative.

When switching from SIMV to VCV, the I:E ratio does not reset to default values automatically (on the ADU), so I:E ratio should be checked as part of the review of all settings when placing a subsequent patient on the mechanical ventilator. Typical settings for SIMV mirror those used for VCV (or PCV if a pressure-controlled mode is chosen).

Pressure-Support Ventilation. Pressure-support ventilation (PSV) is like PCV in that it is a pressure-targeted ventilation mode—but with a RR of zero. It is like SIMV in that it is responsive to the patient's efforts, delivering a breath within a trigger window, provided the patient's negative inspiratory pressure meets the sensitivity setting. Thus it is *only* useful for patients who are breathing spontaneously. There is no minimum minute ventilation, although some ventilators allow setting an apnea backup rate or delay.[194]

PSV is useful to augment the V_T of a spontaneously ventilating patient during maintenance or emergence. The primary setting is the pressure-support level, which for adults may be started at 10 cm H_2O, and adjusted based on tidal volume and end-tidal carbon dioxide. Trigger window, sensitivity, maximum inspiratory flow, and apnea backup rate may also be set, depending on the particular ventilator (Figure 15-45).

Safety Features of Modern Ventilators

Flexibility. The appearance of PCV is a major advantage, allowing more challenging patients to be ventilated efficiently, such as patients with acute respiratory distress syndrome (ARDS) or morbid obesity who are difficult with VCV mode. PCV also increases safety for patients in whom excessive pressure must be strictly avoided, such as neonates and infants, and patients with emphysema. PSV and SIMV are quite valuable in supporting the patient with spontaneous respirations. Perhaps the biggest hurdle in implementation for all new modes is the education of generations of providers who are only familiar with "plain vanilla" volume control mode.

Accuracy at Lower Tidal Volumes. Factors contributing to a discrepancy between set and delivered tidal volumes are especially acute in pediatrics, and include the large compression volume of the circle system relative to the infant's lung volume, leaks around uncuffed endotracheal tubes, the augmentation of delivered V_T produced by fresh gas flow, and the difficulty of setting a small V_T using an adult bellows assembly.[15]

Modern ventilators have an unprecedented V_T range for two reasons; greatly increased accuracy in V_T delivery achieved through electronic compliance and leak testing, and V_T that is compensated for these factors, as well as changes in fresh gas flow. They are able to ventilate smaller patients much more accurately than any previous anesthesia ventilator could. This has significantly lessened the need for nonrebreathing (Mapleson) circuits and made care safer, because anesthetists will no longer have to disassemble and reconfigure a nonrebreathing circuit for a child in the middle of several adult cases. However, it is mandatory to substitute pediatric circle disposable hoses for tidal volumes less than 200 mL with the Narkomed 6000 and the Fabius.[197] Smaller filters, a pediatric D-Lite sensor, and less compliant pediatric circle breathing systems must be used on the ADU for V_T less than 150 mL.[54] The lower limit of accuracy for V_T is 10 mL (for the Narkomed 6000[66]), and 20 mL (for the Fabius,[60] Aestiva,[71] ADU,[54] Apollo,[62] Avance,[57] and Aisys[73]). When sensors or disposable breathing circuit types are changed for a pediatric case, users must repeat the leak and compliance tests of the preanesthesia check, so that maximum V_T accuracy is ensured. Likewise, these must be repeated when returning to the adult configuration.

Compliance and Leak Testing. Accuracy in delivered V_T comes with a price. An electronic leak and compliance test is part of the morning checklist, and it must be repeated every time the circuit is changed to a circuit with a different configuration (adult circle to pediatric circle, or adult to long circuit). Users must familiarize themselves with whether vaporizers and other components are included in the leak and compliance test, because what is actually checked varies between different models.

The placement of the sensor used to compensate tidal volumes for compliance losses and leaks has some interesting consequences. The Aestiva flow sensors are placed between the disposable corrugated breathing circuit limbs and the absorber head. Here they are able to compensate tidal volumes for fresh gas flow, compliance losses, and leaks internal to the machine and absorber head—but not for any of these that occur distally (in the breathing hoses). The D-Lite sensor (ADU) is placed at the Y-piece. In this position, it can compensate for all leaks and compliance losses out to the Y-piece (thus including the breathing circuit hoses). However, at this point, it adds appreciable bulk and weight close to the patient's face. This may make mask ventilation more cumbersome. Further, a sensor closer to the patient is exposed to more exhaled moisture, but the impact on monitoring integrity can be lessened with a heat and moisture exchanger between patient and sensor. Unfortunately, this adds further bulk and weight. The Narkomed 6000, Apollo, and Fabius test compliance and leaks of all components to the Y-piece via a pressure transducer within the internal circuitry near the bellows. Here the sensor is relatively protected from moisture.

Fresh Gas Decoupling Versus Tidal Volume Compensation. A final factor adding to modern ventilator accuracy is that they compensate delivered tidal volume for changes in fresh gas flow. In older

ventilators, the delivered V_T is the sum of the volume delivered from the ventilator and the fresh gas flowing during the inspiratory phase, so the actual delivered $V_T$may change as fresh gas flow is changed. For example, consider a patient with a fresh gas flow of 4 L/min, an RR of 10, an I:E ratio of 1:2, and a V_T of 700 mL. During each minute, the ventilator spends a total of 20 seconds in inspiratory time and 40 seconds in expiratory time (as a result of the 1:2 ratio). During this 20 seconds, the fresh gas flow is 1320 mL (one third of 4000 mL/min fresh gas flow). So each of the 10 breaths of 700 mL is augmented by 132 mL of fresh gas flowing while the breath is being delivered, and the actual delivered V_T is 832 mL/breath (a 19% increase).

What happens when we decrease the fresh gas flow? Assume the same parameters, but a fresh gas flow of 1000 mL/min. During each minute, the ventilator spends 20 seconds in inspiratory time and 40 seconds in expiratory time (1:2 ratio). During this 20 seconds, the fresh gas flow is 330 mL (one-third of 1000 mL/min fresh gas flow). So each of the 10 breaths of 700 mL is augmented by 33 mL of fresh gas flowing while the breath is being delivered, making the total delivered tidal volume 733 mL/breath. This means that changing fresh gas flow from 4000 mL/min to 1000 mL/min, *without changing ventilator settings*, has resulted in a 14% decrease in delivered V_T (832 to 733 mL). It would not be surprising if the end-tidal carbon dioxide rose as a result.

The situation is more acute with a child ventilated without fresh gas flow compensation. Assume a 10-kg patient with a fresh gas flow of 4 L/min, an RR of 20, I:E ratio of 1:2, and a V_T of 100 mL. During each minute, the ventilator spends 20 seconds in inspiratory time and 40 seconds in expiratory time (1:2 ratio). During this 20 seconds, the fresh gas flow is 1320 mL (one third of 4000 mL/min fresh gas flow). So each of the 20 breaths of 100 mL is augmented by 66 mL of fresh gas flowing while the breath is being delivered, making the total delivered V_T 166 mL/breath. This is a 66% increase above what is set on the ventilator. Decreasing fresh gas flow from 4 to 1 L/min, again without changing ventilator settings, decreases minute ventilation from 3320 to 2333 mL (a 30% reduction).

There are two approaches to dealing with the problem. The Apollo, Narkomed 6000, and Fabius use fresh gas decoupling (Figure 15-46). Fresh gas flow during inspiration is not added to the delivered V_T, because it is diverted (by the closed decoupling

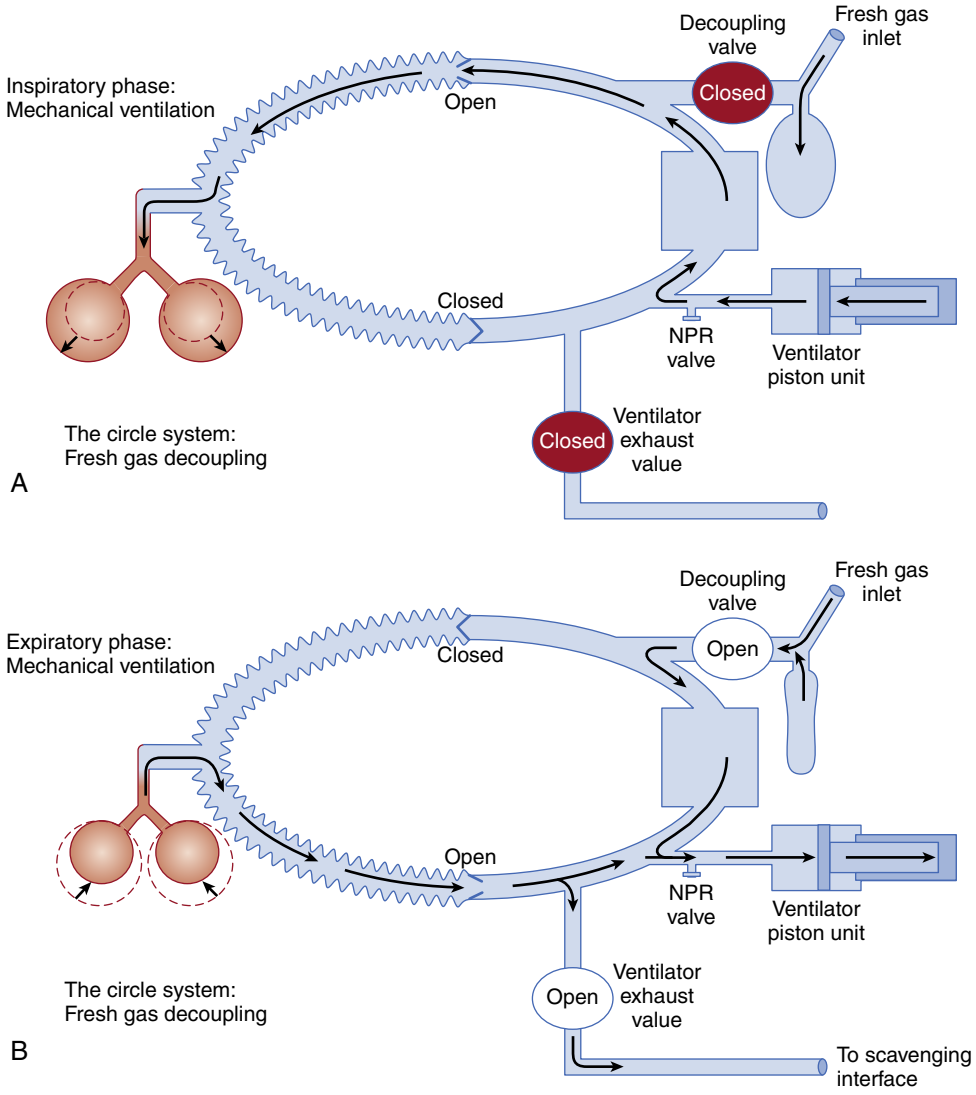

FIGURE **15-46** Circle breathing system with fresh gas decoupling. See text for explanation. *NPR*, Negative pressure relief valve. (From Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010.)

valve) to the manual breathing bag, which remains in circuit during mechanical ventilation. Thus fresh gas decoupling helps ensure that the set and delivered tidal volumes are equal. The visual appearance of the circuit during mechanical ventilation is unusual in that the manual breathing bag (normally quiescent) moves with each breath. Further, this manual breathing bag movement is opposite to the movement seen in a mechanical ventilator bellows, which empties during inspiration, and fills during expiration. With fresh gas decoupling, the manual breathing bag inflates during inspiration (due to fresh gas flow) and deflates during expiration as the contents empty into the piston. With fresh gas decoupling, if there is a disconnect, the manual breathing bag rapidly deflates because the piston retraction draws gas from it.

The same fresh-gas decoupled circuit is shown during expiration in the bottom panel of Figure 15-46. The piston refills with the patient's exhaled gas, and also fresh gas contained in the manual breathing bag (now returned to the rest of the breathing circuit by the open decoupling valve). The ventilator relief valve is now open, allowing excess gas to exit to the scavenger.

The second approach to preventing augmentation of delivered V_T by fresh gas flow is called tidal volume compensation, which is used in the Aestiva and ADU (among others). The volume and flow sensors at the Y-piece provide feedback that allows the ventilator to adjust the delivered V_T so that it matches the set V_T, in spite of changes in fresh gas flow.

Suitability for Low Flows. Low fresh gas flow is desirable to reduce pollution, reduce the cost of volatile agents and nitrous oxide, preserve tracheal heat and moisture, prevent soda lime granules from drying, and help preserve patient body temperature. Factors that enhance the safety and efficiency of low-flow anesthesia in modern ventilators are shown in Box 15-12. As you can see, a traditional-sized absorber head like the Aestiva is roughly twice the volume of some of the newer designs. All newer nondisposable portions of the breathing circuit are designed to be more leak-proof than earlier designs.

Electronic Selection of Positive End-Expiratory Pressure. Electronic selection of positive end-expiratory pressure (PEEP) is safer than previous approaches, which involved adding adapters to the breathing circuit. Add-on adapters came in different varieties, depending on how much PEEP was desired (e.g., 5 or 10 cm H_2O). They were intended to be placed between the expiratory limb of the breathing hoses and the expiratory unidirectional valve. They have been placed accidentally in the inspiratory limb, where they cause complete obstruction to flow in the breathing circuit.[198] Although it would seem easy to find this fault immediately, in the heat of the moment with a patient who is already hypoxemic, the clinician may become distracted and unable to focus effectively on the problem. This is an example of a clinical pearl: When a change in the patient's condition is noticed, think back to the last alteration made to the equipment (or to the last drug *thought* to be given), and determine whether it might have contributed to the change.

Current Ventilator Designs

GE Healthcare 7900 "SmartVent." The 7900 was designed to provide consistent delivered V_T in spite of changes in fresh gas flow, small leaks, and absorber or bellows compliance losses. It uses variable-orifice flow sensors (proximal to the inspiratory and expiratory limbs) and pressure sensors to accomplish this. Compliance losses in the corrugated hoses are not corrected for, but these are a relatively small portion of compliance losses.[199] Available modes include manual/spontaneous, volume control, pressure control, pressure support, and SIMV (in either volume or pressure mode with pressure support). PCV-VG is available on the Aisys and Avance. PEEP is integrated and electronically controlled. Spirometry loops are available. It is found on a variety of machines, including Aestiva, Aisys, and Avance. Typical Aestiva controls are shown in Figure 15-47.

GE Healthcare 7100. The 7100 is similar to the 7900, except that the selection of modes is not as extensive. The 7100, like the 7900, features tidal volume compensation. It is found on the Aespire.

GE Healthcare ADU Ventilator. The design of the ADU ventilator and gas machine system has many innovative features.[54] The ventilator (like most modern designs) is activated by a single switch (setting the "Bag/Vent" switch to "Auto"). The ventilator can use either oxygen or air as a driving gas, and will switch automatically to air if oxygen pipeline pressure is lost. Delivered V_T is adjusted to compensate for changes in fresh gas flow and total (absorber head and corrugated limbs) breathing circuit compliance losses (through the D-Lite sensor at the elbow). Entering the patient's weight will suggest appropriate ventilator settings. Volume control, pressure control, pressure support, manual/spontaneous, and SIMV modes are offered, along with integrated electronic PEEP. Flow-volume (resistance) or pressure-volume (compliance) spirometry loops may be displayed breath by breath. The controls are straightforward (Figure 15-48).

Users should exercise caution with regard to the displayed oxygen concentration. "Calc. O_2%," which is optionally displayed in the mid–lower left of the primary (left) machine status screen, is

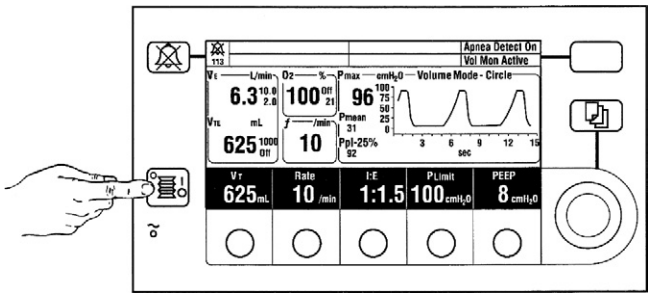

FIGURE 15-47 Display and control panel of the Datex-Ohmeda 7900 ventilator. (From *Ohmeda 7900 Ventilator Operation and Maintenance Manual*. Madison, Wis: Datex-Ohmeda; 1997.)

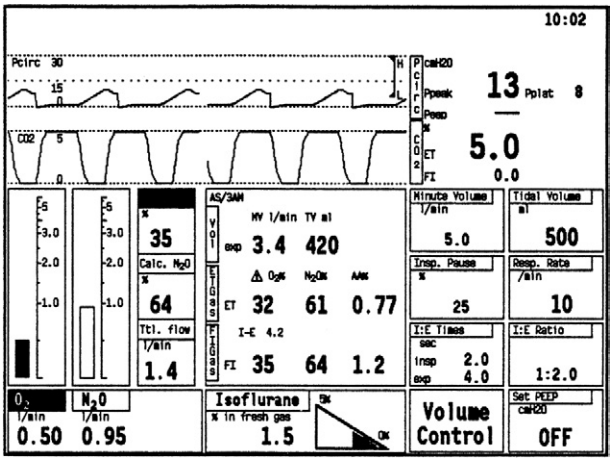

FIGURE 15-48 Machine monitors and ventilator controls are on the left display screen of the Datex-Ohmeda ADU. (From *Datex-Ohmeda AS/3 Anesthesia Delivery Unit User's Reference Manual*. Tewksbury, Mass: Datex-Ohmeda; 1998.)

based on the flowmeter settings only, unlike the oxygen analysis results displayed in the lower center area of the same screen. The danger arises in a crossover situation, in which the pipeline oxygen supply is lost and replaced with another gas (e.g., nitrogen). In this emergency, two sections of the same display may offer conflicting information. Because it is based on flowmeter settings, Calc. O_2% will indicate only the intended inspired oxygen concentration, not the actual. The oxygen analyzer display will simultaneously alarm, accurately showing a dangerous hypoxic mixture. Although the manual clearly warns of this problem, the design may confuse providers in this rare emergency situation, delaying the correct response, which might lead to patient injury.[50,54]

Dräger Divan Ventilator. The Divan ventilator is a piston ventilator found on the Narkomed 6000/6400.[66] It offers pressure control, volume control, manual/spontaneous, and SIMV modes. There is no mechanical Bag/Vent switch. Switching between modes is accomplished by electronic keypad. The Divan corrects delivered V_T for compliance losses by measuring circuit compliance, and for fresh gas flow by fresh gas decoupling. Electronic PEEP is integrated. The absorber head is warmed. The Divan is limited to a pressure of 70 cm H_2O, so like most ventilators, it cannot ventilate patients in volume-controlled mode beyond this pressure (but it is possible and perhaps preferable to ventilate the ARDS patient with pressure-controlled mode). It is accurate to very low tidal volumes (range 10 to 1400 mL). Use pediatric circle system (low compliance) hoses for tidal volumes less than 200 mL, and remember to repeat the ventilator self-test when changing circuits.

Unlike most other anesthesia ventilators, there are no visible bellows on the Divan ventilator. It is unique among current models in having a horizontal piston, which is hidden within the writing surface of the gas machine. To provide a visible indication of lung inflation, fresh gas is diverted to the manual breathing bag, which inflates during mechanical ventilator inspiration and deflates during expiration. The piston design avoids NEEP by entraining room air if pressure within the bellows is less than atmospheric pressure. The "Fresh gas low" error message warns of this condition.

Fabius GS Ventilator. The Fabius GS ventilator is another piston ventilator.[60,200] It offers pressure control, volume control, pressure support, SIMV/PSV, and manual/spontaneous modes. There is no mechanical Bag/Vent switch. Switching between modes is accomplished by electronic keypad. It corrects delivered V_T for compliance losses by measuring circuit compliance, and for fresh gas flow changes by fresh gas decoupling. Electronic PEEP is integrated. One can view measured respiratory parameters or ventilator settings (but not both simultaneously) on the monitor screen. It is accurate to very low tidal volumes (range 20 to 1400 mL). Use pediatric circle system (low compliance) hoses for tidal volumes less than 200 mL, and remember to repeat the ventilator self-test when changing circuits.

The piston movement is visible in a window to the left of the flowmeter bank. Like the Divan, it provides a visible indication of lung inflation and potential disconnects in that fresh gas is diverted to the manual breathing bag, which inflates during mechanical ventilator inspiration and deflates during expiration. The piston design avoids NEEP by entraining room air if pressure within the bellows is less than atmospheric pressure. The "Fresh gas low" error message warns of this condition.

Apollo Ventilator. The Apollo ventilator is a piston similar to the Fabius, except that spirometry is displayed. It is similar to the Narkomed 6000 in that the absorber head is heated. Modes are manual/spontaneous, volume and pressure control, pressure support, and SIMV in either volume or pressure mode.[15,62]

Traditional Anesthesia Ventilators

The Datex-Ohmeda 7000 and 7800, and the Dräger AV-2 and AV-E ventilators were covered in previous editions of this text. Departments who still retain or use these ventilators should ensure that all personnel are familiar with them and can use them safely in an emergency.[1]

Critical Incidents Related to Ventilation

Disconnects and Other Causes of Low Pressure in the Breathing Circuit. Clinical experience with anesthesia ventilators and breathing circuits has identified several situations that have led to critical incidents. Vigilance directed toward situations that have the potential to cause patient injury may contribute to the prevention of future occurrences (Box 15-19). Failure to ventilate caused by disconnection has been called the most common preventable equipment-related cause of mishaps.[25] The most common site for disconnection is between the breathing circuit and the endotracheal tube (at the Y-piece).[184] Disconnects can be

BOX 15-19

Causes of Critical Incidents

Underlying Causes of All Critical Incidents

- Improper or infrequent maintenance
- Inadequate in-service education
- Substandard equipment monitoring
- Failure to check equipment before use
- Lack of familiarity with equipment standards

Mechanisms of Critical Incidents

Failure to Ventilate

- Disconnection
- Failure to initiate ventilation or resume it after an interruption
- Misconnections of breathing circuit
- Occlusion or obstruction of breathing circuit
- Kinking or plugging of endotracheal tube
- Kinking of fresh gas delivery hose
- Mold flash or plastic emboli from wrapping material
- Leaks
- Failure or improper reassembly of bellows after cleaning
- Damage to or disconnection of pressure monitoring or other hoses
- Failure of pipeline and tank oxygen supply
- Driving a vent with cylinders (when pipeline is unavailable) causes rapid tank depletion
- Inadvertent application of suction to the breathing circuit
- Failure of scavenger interface negative-pressure relief valve
- Intubation of trachea with nasogastric tube, which is then connected to suction

Barotrauma

- Excess inflow to breathing circuit (flushing during ventilator inspiration)
- Ventilator relief valve may stick closed
- Control assembly problems

partial or complete. Recent reported causes of low pressure (leak) conditions are many: absorbent granules changed between cases by ancillary personnel but improperly reassembled or even left open[201,202]; defective absorber canister[203]; failure of the Bag/Vent switch[204,205]; leaks in corrugated hoses[206]; incompetent ventilator relief valve[207]; leaks from a hot-wire anemometer sensor[208]; the gas sampling line preventing manual ventilation by preventing closure of an APL[209-213]; and ventilator failure due to moisture in flow sensors.[70]

A proposed protocol for dealing with leaks and other causes of low pressure in the breathing circuit has been published.[214] Prevention of disconnects involves a thorough preanesthesia check of equipment, including testing the breathing circuit with a second breathing bag as an artificial lung (or breathing through the circuit). A primary monitor for disconnection is continuous auscultation of breath sounds with a precordial or esophageal stethoscope, as well as direct visual observation of chest movement (both are recommended by standard).[96,97] Electronic monitors for disconnection include capnography and pressure-based and volume-based alarms (see Box 15-18).[38,184] Because electronic monitors may have alarms disabled, either inadvertently or intentionally (because of artifacts and because of monitor failure), there is no substitute for the anesthetist's vigilance in remaining in touch with the patient through the five senses.

To manage inability to ventilate due to low pressure in the breathing circuit, first ensure ventilation is occurring by checking breath sounds. If not, and the circuit has obviously lost volume, check for leaks quickly (e.g., disconnect, suction in trachea, scavenger settings, incompetent ventilator relief valve), then try to ventilate manually using the anesthesia breathing circuit. If no volume loss is apparent, check settings of fresh gas flow, scavenger, and ventilator, as well as monitor artifact.[38] Do not interrupt ventilation for diagnosis of machine problems; proceed to manual ventilation with backup ventilation equipment (Ambu bag) without delay.[214]

Failure to Initiate or Resume Ventilation. Failure to initiate or resume ventilation may be less likely in the future because of the incorporation of modern monitoring in current gas machines. All possess common features that add to patient safety.[54,60] They have a centralized data and alarm display, as well as alarms prioritized to warnings, cautions, and advisories. They provide electronic pre-use checklists.[98,215] Furthermore, the apnea and disconnect alarms are typically placed on standby when the system's main power switch is activated, and their alarms are enabled once a breath is sensed. Therefore the anesthesia gas machine should alert the operator to a failure to turn on a mechanical ventilator after intubation, or to a failure to resume ventilation after the ventilator is shut off either temporarily (in the middle of a case for radiography) or permanently (during emergence). If turning off a mechanical ventilator temporarily mid-case, it is safest to leave one's finger on the switch until it is time to resume ventilation.

The number of different alarm conditions programmed into a modern anesthesia gas machine with integrated monitoring is staggering. It is absolutely necessary to read the manuals and participate in training for machines of such complexity.[216] Although equipment has improved dramatically, some of the underlying causes of failure to ventilate and of barotrauma will likely remain problems for the foreseeable future (e.g., lack of knowledge or training, and failure to use checklists).

Barotrauma and High Pressure in the Breathing Circuit. Although such problems as misconnections are less likely now than in the past because of improvements in design, other possible causes of failure to ventilate, or barotraumas, are still hazards: occlusion, bellows leaks, failure of gas supply, failure of the ventilator relief valve, and inadvertent application of suction or positive pressure to the airway.[138,143,153,217-224]

Unlike disconnects and other low-pressure breathing circuit problems, high pressure in the breathing circuit can evolve quickly and produce devastating consequences, allowing little time for diagnosis or correction. The causes of sustained high pressure in the breathing circuit are diverse. Obstruction to exhalation (but not inhalation) has been caused in recent times by direct connection of wall oxygen to a tracheal tube,[224] improper manufacture of a scavenger assembly,[225] failure to remove plastic wrap around a soda lime canister before installing it in the machine,[226,227] malfunctioning ventilator relief valve,[143] occlusion of the lumen of a breathing circuit extender adaptor by mold flash or other plastic debris,[150,152,153] insertion of an occluded disposable PEEP valve into the breathing circuit,[150] and an occluded expiratory unidirectional valve.[147] Most of these obstructions would have easily been detected by a preinduction high-pressure check of the breathing circuit, with release of pressure through the APL valve, using an artificial lung during checkout to ensure gas flows properly in the breathing circuit, or simply by breathing through the circuit. Consequences included high PEEP, decreased venous return, cardiovascular collapse, pneumothorax, massive subcutaneous emphysema, or death.

The algorithm for responding to sustained high pressure in the breathing circuit is as follows.[38] Assess patient-related causes such as bronchospasm. Try manually ventilating the patient with the breathing circuit (in "Bag" mode). If the high pressure is relieved, it is likely that the ventilator relief valve is at fault. The ventilator is unusable until this valve is serviced. If circuit pressure is sustained during manual ventilation with the circuit, it is likely that the scavenger is obstructed or that its relief valves have failed. In either case, attempt to disconnect the scavenger gas collection tubing from the back of the APL if possible. If the tubing cannot be disconnected, disconnect the patient from the breathing circuit and continue ventilation by Ambu bag.[38]

Fire in the Breathing Circuit. Although rare, fires in the breathing circuit have been reported in vivo[84,86,228] and in vitro.[81,86,229,230] These events are often associated with first cases on Monday, sevoflurane, and desiccated barium hydroxide lime. The most important preventive actions include (1) turning off all gas flows and vaporizers between cases and at the end of the day and (2) ensuring that carbon dioxide absorbents are changed regularly.[79,84,85] The response to breathing circuit fires is the same as for airway fires.[86]

The Anesthesia Gas Machine and Malignant Hyperthermia. When an unexpected malignant hyperthermia (MH) crisis arises, one follows a protocol including (as far as equipment is concerned) withdrawal of triggering agents. This would include stopping the administration of volatile agents, hyperventilating with oxygen 100%, increasing fresh gas flow, and (if time and help are available and can be spared from other more important tasks such as mixing dantrolene) changing the disposable breathing circuit components and granules.[77,231] When preparing the gas machine for a patient who is known to be susceptible, one changes the breathing circuit and granules, disables or removes the vaporizers, and flushes all traces of volatile agent from its internal circuitry. The old guideline for flushing was a fresh gas flow rate of 10 L/min for 20 minutes. New evidence indicates that this may be very inadequate for some machines, with the Fabius requiring as much as 104 minutes.[231-234] Keep fresh gas flows high during maintenance.[232]

DISPOSAL

The final *D* of the SPDD model is concerned with a simple but vital question: How are gases disposed of?

Disposal of Gases in Scavenging Systems

Scavenging is the collection of waste anesthetic gases from the breathing circuit and ventilator and their removal from the operating room. An amount equal to the fresh gas flow must be scavenged each minute.[89,235-237] Otherwise, the breathing circuit and the patient's lungs will either gain or lose volume, resulting in barotrauma or failure to ventilate. The components of the scavenger are listed in Box 15-20 and shown in Figure 15-49.

BOX 15-20

Components of the Scavenger System

Gas collection assembly—at adjustable pressure-limiting (APL) valve and ventilator relief valve
Transfer tubing—19 or 30 mm, sometimes color-coded yellow
Scavenging interface (most important part)
- Closed interface (all older models)
  - Communicates to atmosphere only through valves
  - If used with passive disposal system, must have positive pressure relief
  - Used with active (suction) disposal system; must have positive *and* negative pressure relief
- Open interface (most new models)
  - No valves; open to atmosphere (both negative and positive pressure relief "built in")
  - Must be used *only* with active systems
  - Reservoir required

  Safety:
  - Safer than closed interface for the patient; no barotrauma
  - Less safe than closed interface for the caregiver (if used improperly)

Gas disposal tubing
Gas disposal assembly—active disposal (common) or passive disposal

A standard for exposure to waste anesthetic gases is published by the Occupational Safety and Health Administration (OSHA).[238] OSHA directs that no worker be exposed to more than 2 ppm halogenated agents (0.5 ppm if used with nitrous oxide), and no more than 25 ppm nitrous oxide, based on a time-weighted 8-hour average concentration. Levels in unscavenged anesthetizing locations may be as high as 7000 ppm (0.7%) N_2O and 85 ppm (0.008%) halothane.[21] The highest levels are found in the anesthetist's workstation, and between the anesthesia gas machine and the wall.[20] Operating-room personnel (anesthesiologists, surgeons, and nurses) working in ear, nose, and throat operating rooms had measurable levels of exhaled sevoflurane higher than controls up to 18 hours after being on duty, although this study did not report what type of scavenging, if any, was employed.[239] The health effects of chronic exposure to volatile agents are unproved, though it is clear that occupational exposure to nitrous oxide should definitely be avoided.[171]

Several variables determine the attainable reduction in waste anesthetic gases in the operating room, including the degree of room ventilation, the condition of anesthesia equipment, the effectiveness of the scavenger, and the anesthetic techniques of the user. However, with appropriate attention to these areas, trace gas levels within the operating room can meet OSHA requirements.[21]

The most important component of the scavenger system is the interface, because it protects the patient from excessive buildup of positive pressure, and from exposure to suction. There are two types of interfaces: closed and open. The closed interface is found on older machines, though it is available as an option on new models.[240,241] A closed interface is useful where passive scavenging is used (no dedicated suction line for the scavenger, and waste gases flow passively along with room ventilation exhaust). A closed interface communicates with the atmosphere only through valves (Figure 15-50). A means for relief of positive pressure is mandatory for all closed interfaces. If the suction attached to the scavenger fails or if a hose distal to it becomes kinked, positive pressure relief

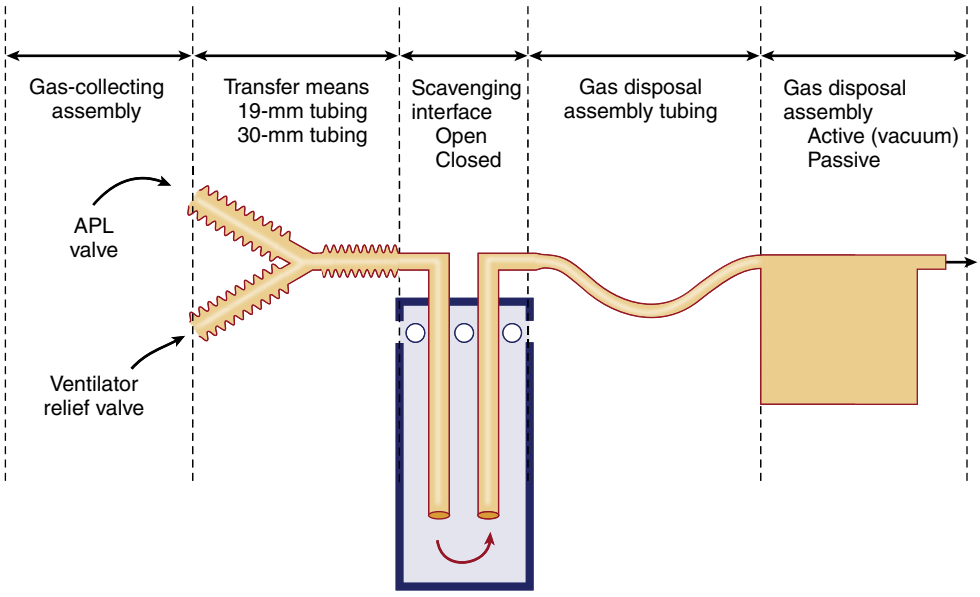

FIGURE **15-49** Components of the scavenging system. (Barash PG, ed: *Clinical Anesthesia*. 5th ed. Philadelphia: LWW; 2006:589.)

valves operate before the pressure buildup within the scavenger is transmitted to the breathing circuit and the lungs. In this case, the positive pressure relief valve opens and allows the release of waste gases into the operating-room air. If the closed interface is attached to suction, a negative pressure relief valve is also mandatory. The positive-pressure relief valve on the closed interface opens to draw in room air when suction is excessive, preventing the emptying of gas from the patient circuit. Suction should be adjusted as fresh gas flows change, so that the scavenger reservoir bag is neither flat nor overdistended.[241]

Because the closed-interface relief valves can fail,[242] an open scavenger interface is much more common on new machines (Figure 15-51). The open interface has large open holes or ports around the top. There are no valves, such as those found in closed-interface systems, to impede the flow of gases into, or out of, the reservoir. Each patient exhalation is led to the bottom of the open-interface reservoir, where a second tube withdraws it by suction before the next exhalation arrives. Use of the device with appropriate suction is critical to its proper function.[240] Yet because the device is so different from the closed interface, errors in its use have already been reported. In one report, 10 of 10 newly purchased machines equipped with open interfaces had the suction to the scavenger turned off, resulting in the release of all patient exhalations into the operating room.[242] This error in use may be related to the sounds produced by the two different interfaces. When a closed interface is leaking gas into the room through the positive pressure relief valve, one can hear a soft, intermittent hiss. The open interface, on the other hand, may hiss continuously when it has been properly adjusted.

The open interface affords patient safety advantages. With the open interface, there is no chance of relief valve failure, which can cause barotrauma or the application of suction to the breathing circuit. The device is perhaps less safe for the operator who is unfamiliar with its use; however, the only danger of this ignorance is increased occupational exposure to waste anesthetic gases. The smell of volatile agent during a case is abnormal, and its cause must be sought. The threshold for smelling volatile agents is variously stated as 5 to 300 ppm.[21,134,236] Thus if any agent is smelled, the concentration is excessive (i.e., above that described in the OSHA standard).

Many factors in addition to the scavenger affect exposure to waste anesthetic gases. Guidelines for limiting exposure are listed in Box 15-21.[21,236,237,243-245] Some may be applied generally, whereas others are applicable only to selected practice settings.

RISK MANAGEMENT

Department-Level Aspects

Risk management is defined as a detection system designed to predict failures and ensure that precautions to prevent patient harm are taken.[134] Typical anesthesia risk management components include preoperative and postoperative rounds, avoiding indifferent treatment of patients, maintaining vigilance and high standards of care, peer review, continuing education, and the commitment to delivery of high-quality and humane patient care. In terms of equipment, risk management includes cleanliness, daily performance of equipment checklists, familiarity with equipment manuals, and appropriate maintenance.[134,246]

BOX **15-21**

Means of Limiting Exposure to Waste Anesthetic Gases

- Check the scavenger before use.
- Perform regular preventive maintenance of room ventilation systems.
- Perform regular preventive maintenance of all anesthesia equipment.
- Conduct personnel monitoring and ambient trace gas monitoring.
- Seek the source of the smell of anesthetics noted during a case.
- Keep a good mask fit.
- Avoid unscavengeable techniques (open drop, insufflation).
- Prevent flow from breathing system into room air.
- Turn on anesthetic gases only after the mask is on the patient.
- Turn off anesthetic gases before suctioning.
- Wash out anesthetics into the scavenger at the end of the case.
- Do not spill liquid agent.
- Use cuffed endotracheal tubes.
- Use low fresh gas flows.
- Check the machine regularly for leaks.
- Disconnect nitrous oxide at wall outlet at end of day.
- Use total intravenous anesthesia.
- Avoid use of nitrous oxide.

The Safe Medical Device Act of 1990 requires hospitals to report instances in which medical devices cause or contribute to death, serious illness, or serious injury.[247] All medical personnel who become aware of a problem with a device must remove the equipment from contact with patients and report the problem to their supervisors. The hospital risk manager then conducts an investigation and reports the results to the FDA within 10 working days. The most common barrier to investigation of a critical incident, and the degree to which anesthesia equipment may have contributed to it, is alteration of the equipment (i.e., it has been cleaned, disassembled, or tested).[248] In the case of patient injury in which equipment may be at fault, it is most helpful if equipment (including wastebaskets and syringes in the anesthesia work area) is sequestered "as is," pending a forensic evaluation conducted by the representatives of the hospital, the manufacturer, and perhaps the patient. Equipment logs should be kept for each anesthesia machine and include reports of maintenance, critical incidents, additions or alterations, pollution control, and vaporizer calibration. Preventive maintenance should be done at intervals specified by the manufacturer (usually two to four times per year) by qualified, factory-trained technicians.[134]

Individual Risk Management

The department-level risk management plan requires the active involvement of all department members. In addition to participation in the department-level activities noted earlier, individuals play a vital role in three further aspects: performance of the machine checklist before use, limiting equipment-related disease transmission, and reducing trace and waste gas exposure through alteration of work practices (the latter two were discussed earlier in this chapter).

Anesthesia Gas Machine Checklist

Reports of equipment problems surfacing in the 1980s prompted the professional societies and government to develop a recommended anesthesia checklist.[249-251] Although equipment failures are rare, they are often the result of human error in the use of the equipment.[4,11,249] Failure to check anesthesia equipment adequately has been reported as a factor in up to 30% of critical incidents.[252,253] Users report that they often do not perform the FDA checklist, and many do not feel competent in their ability to perform it correctly.[3] When a checklist is performed, 30% of the gas machines in one study had serious faults discovered.[2] Checklists have been the focus of several studies of fault-detection ability* and much comment.[260] It is probable, but as yet unproved, that proper and consistent use of checklists will not only prevent critical incidents but also help teach and reinforce knowledge of the function and use of the anesthesia gas machine.[14] Performance of the pre-use anesthesia checkout is required by various standards.[261]

New developments in the pre-use anesthesia checkout are the publication of a new PreAnesthesia Checkout (PAC) in 2008 (see Boxes 15-22 and 15-23 at the end of the chapter).[99] It became necessary to abandon the 1990s FDA checklist because it no longer worked for different models. Considering the significant differences between models, and variations in their self-test routines, no one set of *procedures* will cover all gas machines. This new checklist is a statement of *principles* of what should be checked, and who should check it, rather than a procedures list. For example, the availability of backup ventilation equipment and backup oxygen supplies, and the calibration of the oxygen analyzer and other monitors must be checked, regardless of which machine is used. But *how* these actions are performed varies from machine to machine. If they have not done so already, anesthesia departments will need to develop specific procedures and training for the machines they use, in consultation with manufacturers and the operator's instruction manuals.

The Aestiva is a system that must be manually checked—there are no electronic aspects to the checklist.[46] At the other extreme, some gas machines checkout procedures rely almost exclusively on electronic checklists. These electronic self-check routines (like that in the ADU, Aisys, Fabius, and Apollo) may help prevent errors and omissions in the preanesthesia checklist.[262] Electronic checklists of this type are not all identical, but they do cover most essential functions, can detect leaks, and can measure breathing circuit compliance. The ADU and Fabius checklist warn if leaks greater than 150 mL/min are detected.[54] If leaks are detected, users must check the tightness of all connections—respiratory and patient circuit tubing and bellows (bellows, bellows block, ventilator relief valve, and bellows chamber). Ensure that the Y-piece is properly occluded, gas flows are closed, and the gas sampling lines in the D-Lite sensor are not still connected to the circuit. In the Apollo, these must be connected. The user performs a few manual tests at the end—suction, cylinder pressure, unidirectional valves, and gas analysis. All of these new machine checklists require that the circuit be occluded for compliance and leak testing, then reconfigured for use.

It is critical that the anesthetist can answer several questions in the affirmative at the end of a properly performed checkout. For example, is there oxygen in the oxygen line? Can the patient breathe unobstructed through the circuit? Can the patient be

*References 9, 10, 13, 14, 254-259.

BOX **15-22**

Summary of Preanesthesia Checkout Recommendations

To Be Completed Daily	TO BE REPEATED BEFORE EACH CASE
1. Verify that auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning.	
2. Verify that patient suction is adequate to clear the airway.	*
3. Turn on anesthesia delivery system and confirm that AC power is available.	
4. Verify availability of required monitors, including alarms.	*
5. Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine.	
6. Verify that the piped gas pressures are 50 or greater psi.	
7. Verify that vaporizers are adequately filled, and if applicable, that the filler ports are tightly closed.	*
8. Verify that there are no leaks in the gas supply lines between the flowmeters and the common gas outlet.	
9. Test scavenging system function.	
10. Calibrate, or verify calibration of, the oxygen monitor and check the low oxygen alarm.	
11. Verify that carbon dioxide absorbent is not exhausted.	*
12. Conduct breathing system pressure and leak testing.	*
13. Verify that gas flows properly through the breathing circuit during both inspiration and exhalation.	*
14. Document completion of checkout procedures.	*
15. Confirm ventilator settings and evaluate readiness to deliver anesthesia care. (ANESTHESIA TIME OUT)	*

From Sub-Committee of the American Society of Anesthesiologists (ASA) Committee on Equipment and Facilities: Recommendations for Pre-Anesthesia Checkout Procedures, 2008. Available at http://www.asahq.org/For-Members/Clinical-Information/2008-ASA-Recommendations-for-PreAnesthesia-Checkout.aspx.
psi, pounds per square inch.

given a positive pressure breath? Are there leaks in the breathing circuit once reassembled? Is backup ventilation equipment present in the room?

To ensure these basic requirements are met, a few activities must be part of the PAC, or be performed manually by the anesthetist after it is complete: (1) checking the oxygen analysis; (2) checking that the circuit is unobstructed and that the unidirectional valves are functioning properly; and (3) checking the reassembled breathing circuit for leaks with high pressure.[263] Check that the oxygen analyzer reads 21% when exposed to room air, and the reading increases when the sensor is exposed to gas from the oxygen pipeline. Test the unidirectional valves with an artificial lung (or by breathing through the circuit) to ensure that the circuit is not obstructed by mold flash or plastic wrapping.[150,151] To ensure that all breathing circuit connections are gas-tight, always perform a high-pressure check after the checklist is complete. While checking for backup ventilation equipment (e.g., Ambu bag) and cylinder oxygen, walk around the machine, checking for suction and an extra circuit, the location of circuit breakers, the presence of a cylinder wrench and head strap, and whether gas analysis monitors are scavenged. Because in some machines the vaporizers must be individually checked for leaks, it is possible that care of a patient could begin with the vaporizers inadvertently turned on. So the anesthetist must check that vaporizers are off during the checklist.

There is no "minimum" test other than that suggested by the operator's instruction manuals. In administering an anesthetic for an emergency surgical procedure, one should always check the suction, check for a backup means of ventilation (e.g., Ambu bag), and perform a high-pressure leak test of the breathing circuit. During preoxygenation, (whether in emergencies, or as a matter of routine in any case), observe the breathing bag for fluctuations. Respiratory effort that is visible in the breathing bag before induction begins ensures that the patient is breathing, the mask fit is good, and oxygen is flowing. A situation in which any of these conditions is absent requires immediate attention.

SUMMARY

Compared with its forebears, the anesthesia gas machine available today is a system of tremendous capability, power, safety, and complexity. The machine is a result both of improvements in design and of the integration of physiologic monitors and machine function monitors. Use of an anesthesia gas machine was more straightforward in the past because all types of anesthesia machines contained simpler, similar elements. With the introduction of new designs, this is no longer the case. The days when a few "wizards" in an anesthesia department could specialize in equipment operation and maintenance and could instruct or troubleshoot for all of his or her co-workers have likewise passed. Equipment competency must be a part of everyone's toolkit of patient-care skills. It is hoped that through study of this chapter, current equipment will be more widely understood. In this manner, our future patients may "sleep" in safety, afforded the level of care that we all wish for ourselves and our loved ones.

BOX **15-23**

Recommendations for Preanesthesia Checkout Procedures

General Considerations

The following document is intended to serve not as a preanesthesia checkout (PAC) itself, but rather as a template for developing checkout procedures that are appropriate for each individual anesthesia machine design and practice setting. When using this template to develop a checkout procedure for systems that incorporate automated checkout features, items that are not evaluated by the automated checkout need to be identified, and supplemental manual checkout procedures included as needed.

Simply because an automated checkout procedure exists does not mean it can completely replace a manual checkout procedure or that it can be performed safely without adequate training and a thorough understanding of what the automated checkout accomplishes. An automated checkout procedure can be incomplete and/or misleading. For example, the leak test performed by some current automated checkouts does not test for leaks at the vaporizers. As a result, a loose vaporizer filler cap, or a leak at the vaporizer mount, could easily be missed.

Ideally an automated checkout procedure should clearly reveal to the user the functions that are being checked, any deficient function that is found, and recommendations for correcting the problem. Documentation of the automated checkout process should preferably be done in a manner that can be recorded on the anesthesia record.

Operator's manuals, which accompany anesthesia delivery systems, include extensive recommendations for equipment checkout. Although these recommendations are quite extensive and typically not used by anesthesia providers, they are nevertheless important references for developing machine-specific and institution-specific checkout procedures.

Personnel Performing the PAC

The previously accepted *Anesthesia Apparatus Checkout Recommendation* placed all of the responsibility for pre-use checkout on the anesthesia provider. This guideline identifies those aspects of the PAC that could be completed by a qualified anesthesia and/or biomedical technician. Critical checkout steps (e.g., availability of backup ventilation equipment) will benefit from intentional redundancy (i.e., having more than one individual responsible for checking the equipment). *Regardless of the level of training and support by technicians, the anesthesia care provider is ultimately responsible for proper function of all equipment used to provide anesthesia care.*

Adaptation of the PAC to local needs, assignment of responsibility for the checkout procedures, and training are the responsibilities of the individual anesthesia department. Training procedures should be documented. Proper documentation should include records of completed coursework (e.g., a manufacturer course) or for in-house training, a listing of the competency items taught and records of successful completion by trainees.

Objectives for a New PAC

1. Outline the essential items that need to be available and functioning properly prior to delivering every anesthetic.
2. Identify the frequency with which each of the items needs to be checked.
3. Suggest which items may be checked by a qualified anesthesia technician, biomedical technician, or a manufacturer-certified service technician.

Basic Principles

The anesthesia care provider is ultimately responsible for ensuring that the anesthesia equipment is safe and ready for use. This responsibility includes adequate familiarity with the equipment, following relevant local policies for performing and documenting the PAC, and being knowledgeable about those procedures.

Depending upon the staffing resources in a particular institution, anesthesia technicians and/or biomedical technicians can participate in the PAC. Each department should decide whether or not the available technicians can or should be trained to assist with checkout procedures.

- Critical items will benefit from redundant checks to avoid errors and omissions.
- When more than one person is responsible for checking an item, all parties should perform the check if intentional redundancy is deemed important, or either party may be acceptable, depending upon the available resources.
- Whoever conducts the PAC should provide documentation of successful performance. The anesthesia provider should include this documentation on the patient chart.
- Whenever an anesthesia machine is moved to a new location, a complete beginning-of-the-day checkout should be performed.
- Automated checks should clearly distinguish the components of the delivery system that are checked automatically from those that require manual checkout.
- Ideally, the date, time, and outcome of the most recent check(s) should be recorded and the information made accessible to the user.
- Specific procedures for pre-use checkout cannot be prescribed in this document because they vary with the delivery systems. Clinicians must learn how to effectively perform the necessary pre-use check for each piece of equipment they use.
- Each department or health care facility should work with the manufacturer(s) of their equipment to develop pre-use checkout procedures that satisfy both the following guidelines and the needs of the local department.
- Default settings for ventilators, monitors, and alarms should be checked to determine whether they are appropriate.
- These checkout recommendations are intended to replace the pre-existing FDA-approved *Anesthesia Apparatus Checkout Recommendations.* They are not intended to be a replacement for required preventive maintenance.
- The PAC is essential to safe care but should not delay initiating care if the patient needs are so urgent that time taken to complete the PAC could worsen the patient's outcome.

Guidelines for Developing Institution-Specific Checkout Procedures Prior to Anesthesia Delivery

These guidelines describe a basic approach to checkout procedures and rationale that will ensure that these priorities are satisfied. They should be used to develop institution-specific checkout procedures designed for the equipment and resources available. (Examples of institution-specific procedures for current anesthesia delivery systems are published on the same website as this document.)

Requirements for Safe Delivery of Anesthesia Care

- Reliable delivery of oxygen at any appropriate concentration up to 100%
- Reliable means of positive pressure ventilation
- Backup ventilation equipment available and functioning
- Controlled release of positive pressure from the breathing circuit
- Anesthesia vapor delivery (if intended as part of the anesthetic plan)
- Adequate suction
- Means to conform to standards for patient monitoring

BOX **15-23**

Recommendations for Preanesthesia Checkout Procedures—cont'd

Specific Items

The following fifteen items need to be checked as part of a complete PAC. The intent is to identify what to check, the recommended frequency of checking and the individual(s) who could be responsible for the item. For these guidelines, the responsible party would fall into one of four categories: Provider, Technician, Technician or Provider, or Technician and Provider. The designation "Technician and Provider" means that the provider must perform the check whether or not it has been completed by a technician. It is not intended to make the use of technician checks mandatory. The intent is not to specify how an item needs to be checked, because the specific checkout procedure will depend upon the equipment being used.

1. Verify auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning.
   Frequency: Daily.
   Responsible Parties: Provider and Technician.
   Rationale: Failure to be able to ventilate is a major cause of morbidity and mortality related to anesthesia care. Because equipment failure with resulting inability to ventilate the patient can occur at any time, a self-inflating manual ventilation device (e.g., AMBU bag) should be present at every anesthetizing location for every case and should be checked for proper function. In addition, a source of oxygen separate from the anesthesia machine and pipeline supply, specifically an oxygen cylinder with regulator and a means to open the cylinder valve, should be immediately available and checked. After checking the cylinder pressure, it is recommended that the main cylinder valve be closed to avoid inadvertent emptying of the cylinder through a leaky or open regulator.
2. Verify that patient suction is adequate to clear the airway.
   Frequency: Prior to each use.
   Responsible Parties: Provider and Technician.
   Rationale: Safe anesthetic care requires the immediate availability of suction to clear the airway if needed.
3. Turn on anesthesia delivery system and confirm that AC power is available.
   Frequency: Daily.
   Responsible Parties: Provider or Technician.
   Rationale: Anesthesia delivery systems typically function with backup battery power if AC power fails. Unless the presence of AC power is confirmed, the first obvious sign of power failure can be a complete system shutdown when the batteries can no longer power the system. Many anesthesia delivery systems have visual indicators of the power source showing the presence of both AC and battery power. These indicators should be checked, and connection of the power cord to a functional AC power source should be confirmed.
   Desflurane vaporizers require electrical power and recommendations for checking power to these vaporizers should also be followed.
4. Verify availability of required monitors, including alarms.
   Frequency: Prior to each use.
   Responsible Parties: Provider or Technician.
   Rationale: Standards for patient monitoring during anesthesia are clearly defined. The ability to conform to these standards should be confirmed for every anesthetic. The first step is to visually verify that the appropriate monitoring supplies (BP cuffs, oximetry probes, etc.) are available. All monitors should be turned on and proper completion of power-up self-tests confirmed. Given the importance of pulse oximetry and capnography to patient safety, verifying proper function of these devices before anesthetizing the patient is essential. Capnometer function can be verified by exhaling through the breathing circuit or gas sensor to generate a capnogram, or verifying that the patient's breathing efforts generate a capnogram before the patient is anesthetized. Visual and audible alarm signals should be generated when this is discontinued. Pulse oximeter function, including an audible alarm, can be verified by placing the sensor on a finger and observing for a proper recording. The pulse oximeter alarm can be tested by introducing motion artifact or removing the sensor.
   Audible alarms have also been reconfirmed as essential to patient safety by ASA, AANA, APSF, and The Joint Commission. Proper monitor functioning includes visual and audible alarm signals that function as designed.
5. Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine.
   Frequency: Daily.
   Responsible Parties: Provider and Technician.
   Rationale: Anesthesia delivery systems rely on a supply of oxygen for various machine functions. At a minimum, the oxygen supply is used to provide oxygen to the patient. Pneumatically powered ventilators also rely on a gas supply. Oxygen cylinder(s) should be mounted on the anesthesia delivery system and determined to have an acceptable minimum pressure. The acceptable pressure depends on the intended use, the design of the anesthesia delivery system, and the availability of piped oxygen.
   Typically, an oxygen cylinder will be used if the central oxygen supply fails.
   If the cylinder is intended to be the primary source of oxygen (e.g., remote site anesthesia), then a cylinder supply sufficient to last for the entire anesthetic is required. If a pneumatically powered ventilator that uses oxygen as its driving gas will be used, a full "E" oxygen cylinder may provide only 30 minutes of oxygen. In that case, the maximum duration of oxygen supply can be obtained from an oxygen cylinder if it is used only to provide fresh gas to the patient in conjunction with manual or spontaneous ventilation. Mechanical ventilators will consume the oxygen supply if pneumatically powered ventilators that require oxygen to power the ventilator are used. Electrically powered ventilators do not consume oxygen, so the duration of a cylinder supply will depend only on total fresh gas flow. The oxygen cylinder valve should be closed after it has been verified that adequate pressure is present, unless the cylinder is to be the primary source of oxygen (i.e., piped oxygen is not available). If the valve remains open and the pipeline supply should fail, the oxygen cylinder can become depleted while the anesthesia provider is unaware of the oxygen supply problem.
   Other gas supply cylinders (e.g., Heliox, CO_2, Air, N_2O) need to be checked only if that gas is required to provide anesthetic care.
6. Verify that piped gas pressures are 50 or greater psi/g.
   Frequency: Daily.
   Responsible Parties: Provider and Technician.
   Rationale: A minimum gas supply pressure is required for proper function of the anesthesia delivery system. Gas supplied from a central source can fail for a variety of reasons. Therefore the pressure in the piped gas supply should be checked at least once daily.
7. Verify that vaporizers are adequately filled, and if applicable, that the filler ports are tightly closed.
   Frequency: Prior to each use.
   Responsible Parties: Provider. Technician if redundancy desired.

Continued

BOX **15-23**

Recommendations for Preanesthesia Checkout Procedures—cont'd

Rationale: If anesthetic vapor delivery is planned, an adequate supply is essential to reduce the risk of light anesthesia or recall. This is especially true if an anesthetic agent monitor with a low agent alarm is not being used. Partially open filler ports are a common cause of leaks that may not be detected if the vaporizer control dial is not open when a leak test is performed. This leak source can be minimized by tightly closing filler ports. Newer vaporizer designs have filling systems that automatically close the filler port when filling is completed.

High and low anesthetic agent alarms are useful to help prevent over- or under-dosage of anesthetic vapor. Use of these alarms is encouraged, and they should be set to the appropriate limits and enabled.

8. Verify that there are no leaks in the gas supply lines between the flowmeters and the common gas outlet.
   Frequency: Daily and whenever a vaporizer is changed.
   Responsible Parties: Provider or Technician.
   Rationale: The gas supply in this part of the anesthesia delivery system passes through the anesthetic vaporizer(s) on most anesthesia delivery systems. In order to perform a thorough leak test, each vaporizer must be turned on individually to check for leaks at the vaporizer mount(s) or inside the vaporizer. Furthermore, some machines have a check valve between the flowmeters and the common gas outlet, requiring a negative pressure test to adequately check for leaks. Automated checkout procedures typically include a leak test but may not evaluate leaks at the vaporizer especially if the vaporizer is not turned on during the leak test. When relying upon automated testing to evaluate the system for leaks, the automated leak test would need to be repeated for each vaporizer in place. This test should also be completed whenever a vaporizer is changed. The risk of a leak at the vaporizer depends upon the vaporizer design. Vaporizer designs where the filler port closes automatically after filling can reduce the risk of leaks. Technicians can provide useful assistance with this aspect of the machine checkout because it can be time consuming.
9. Test scavenging system function.
   Frequency: Daily.
   Responsible Parties: Provider or Technician.
   Rationale: A properly functioning scavenging system prevents room contamination by anesthetic gases. Proper function depends upon correct connections between the scavenging system and the anesthesia delivery system. These connections should be checked daily by a provider or technician. Depending upon the scavenging system design, proper function may also require that the vacuum level is adequate, which should also be confirmed daily. Some scavenging systems have mechanical positive and negative pressure relief valves. Positive and negative pressure relief is important to protect the patient circuit from pressure fluctuations related to the scavenging system. Proper checkout of the scavenging system should ensure that positive and negative pressure relief is functioning properly. Due to the complexity of checking for effective positive and negative pressure relief, and the variations in scavenging system design, a properly trained technician can facilitate this aspect of the checkout process.
10. Calibrate, or verify calibration of, the oxygen monitor and check the low oxygen alarm.
    Frequency: Daily.
    Responsible Parties: Provider or Technician.
    Rationale: Continuous monitoring of the inspired oxygen concentration is the last line of defense against delivering hypoxic gas concentrations to the patient. The oxygen monitor is essential for detecting adulteration of the oxygen supply. Most oxygen monitors require calibration once daily, although some are self-calibrating. For self-calibrating oxygen monitors, they should be verified to read 21% when sampling room air. This is a step that is easily completed by a trained technician. When more than one oxygen monitor is present, the primary sensor that will be relied upon for oxygen monitoring should be checked.

    The low oxygen concentration alarm should also be checked at this time by setting the alarm above the measured oxygen concentration and confirming that an audible alarm signal is generated.
11. Verify that carbon dioxide absorbent is not exhausted.
    Frequency: Prior to each use.
    Responsible Parties: Provider or Technician.
    Rationale: Proper function of a circle anesthesia system relies on the absorbent to remove carbon dioxide from rebreathed gas. Exhausted absorbent as indicated by the characteristic color change should be replaced. It is possible for absorbent material to lose the ability to absorb CO_2, yet the characteristic color change may be absent or difficult to see. Some newer absorbents do change color when desiccated. Capnography should be used for every anesthetic, and when using a circle anesthesia system, rebreathing carbon dioxide as indicated by an inspired CO_2 concentration greater than 0 can also indicate exhausted absorbent.
12. Conduct breathing system pressure and leak testing.
    Frequency: Prior to each use.
    Responsible Parties: Provider and Technician.
    Rationale: The breathing system pressure and leak test should be performed with the circuit configuration to be used during anesthetic delivery. If any components of the circuit are changed after this test is completed, the test should be performed again. Although the anesthesia provider should perform this test before each use, anesthesia technicians who replace and assemble circuits can also perform this check and add redundancy to this important checkout procedure. Proper testing will demonstrate that pressure can be developed in the breathing system during both manual and mechanical ventilation and that pressure can be relieved during manual ventilation by opening the adjustable pressure-limiting (APL) valve.

    Automated testing is often implemented in the newer anesthesia delivery systems to evaluate the system for leaks and also to determine the compliance of the breathing system. The compliance value determined during this testing will be used to automatically adjust the volume delivered by the ventilator to maintain a constant volume delivery to the patient. It is important that the circuit configuration that is to be used be in place during the test.
13. Verify that gas flows properly through the breathing circuit during both inspiration and exhalation.
    Frequency: Prior to each use.
    Responsible Parties: Provider and Technician.
    Rationale: Pressure and leak testing does not identify all obstructions in the breathing circuit or confirm proper function of the inspiratory and expiratory unidirectional valves. A test lung or second reservoir bag can be used to confirm that flow through the circuit is unimpeded. Complete testing includes both manual and mechanical ventilation. The presence of the unidirectional valves can be assessed visually during the PAC. Proper function of these valves cannot be visually assessed because subtle valve incompetence may not be detected. Checkout procedures to identify valve incompetence that may not be visually obvious can be implemented but are typically

BOX **15-23**

Recommendations for Preanesthesia Checkout Procedures—cont'd

too complex for daily testing. A trained technician can perform regular valve competence tests. Capnography should be used during every anesthetic and the presence of carbon dioxide in the inspired gases can help to detect an incompetent valve.

14. Document completion of checkout procedures.
Frequency: Prior to each use.
Responsible Parties: Provider and Technician.
Rationale: Each individual responsible for checkout procedures should document completion of these procedures. Documentation gives credit for completing the job and can be helpful if an adverse event should occur. Some automated checkout systems maintain an audit trail of completed checkout procedures that are dated and timed.
15. Confirm ventilator settings and evaluate readiness to deliver anesthesia care. (ANESTHESIA TIME OUT)
Frequency: Immediately prior to initiating the anesthetic.
Responsible Parties: Provider.
Rationale: This step is intended to avoid errors due to production pressure or other sources of haste. The goal is to confirm that appropriate checks have been completed and that essential equipment is indeed available. The concept is analogous to the "time out" used to confirm patient identity and surgical site prior to incision. Improper ventilator settings can be harmful, especially if a small patient is following a much larger patient or vice versa. Pressure limit settings (when available) should be used to prevent excessive volume delivery from improper ventilator settings.

Items to check:
- Monitors functional?
- Capnogram present?
- Oxygen saturation by pulse oximetry measured?
- Flowmeter and ventilator settings proper?
- Manual/ventilator switch set to manual?
- Vaporizer(s) adequately filled?

CHAPTER 16

Clinical Monitoring I

Cardiovascular System

◆ *Mark A. Kossick*

Monitoring of anatomic and physiologic variables during an anesthetic procedure is vital to patient safety and meeting established standards of care.[1] Many different monitors are commonly used to assist in the delivery of an anesthetic, and clinicians assimilate the data provided to make appropriate clinical judgments. Consequently, the application of critical thinking skills, thorough physical assessment, vigilance, and the appropriate selection and application of monitors are key requirements in the process of anesthesia monitoring.

Fundamental monitoring/assessment techniques include inspection, auscultation, and palpation. They provide essential objective and subjective data not available from advanced monitoring modalities and can alert the anesthetist to occult problems in select patients. *Inspection* of the patient can provide information regarding the adequacy of oxygen delivery and carbon dioxide elimination, fluid requirements, and positioning and alignment of body structures. *Auscultation* is used to verify correct placement of airway devices such as the endotracheal tube and laryngeal mask airway, to assess arterial blood pressure, and to continually monitor heart sounds and air exchange through the pulmonary system. *Palpation* can aid in assessing the quality of the pulse and degree of skeletal muscle relaxation, as well as locating major vascular structures when placing central venous lines or performing regional anesthesia techniques.

Critical thinking skills are cardinal prerequisites for successful monitoring of a patient's anesthetic. In addition, it is well known that errors in anesthesia care are minimized when clinicians remain alert and vigilant. This chapter reviews the more commonly used noninvasive and invasive cardiovascular monitors in anesthesia practice.

ECG MONITORING

The continuous monitoring of the cardiovascular status via the electrocardiogram (ECG) is a requirement for any patient receiving an anesthetic. This includes assessment of heart rate, rhythm, and in particular for some patients, ST segments. Computerized real-time ST-segment analysis continues to be incorporated in operating rooms (ORs), intensive care units (ICUs), and postanesthesia care units (PACUs) across the country. Many factors support this trend, including the development of practice guidelines by professional societies that advocate such monitoring techniques in select patient populations[2] and the demographics of the general surgical population. Approximately one third of patients scheduled for noncardiac surgery have risk factors for coronary artery disease (CAD), and postoperative myocardial infarction is three times as frequent in patients with ischemia.[3] Research has shown prolonged stress-induced ischemia (i.e., ST-segment depression) to be the major cause for cardiac morbidity (myocardial infarction) after major vascular surgery.[4] The overall incidence of perioperative ischemia in patients with CAD scheduled for cardiac or noncardiac surgery ranges from 20% to 80%.[5,6]

Because of its low cost, noninvasiveness, widespread availability, and designation as a standard of care for monitoring of all anesthetized patients,[1] the ECG remains a common and required diagnostic tool in the operating room. Compared with Holter monitors, ST-segment trending monitors have on average a sensitivity of 74% and specificity of 73% in detecting myocardial ischemia.[7] When used in high-risk cardiac patients to guide early treatment, they may reduce morbidity.[4]

Current recommendations for ST-segment deviation thresholds account for the *influence* of gender, ECG lead, age, and race on position of the ST segment.[8-11] In particular, two chest leads (V_2 and V_3) have been shown to exhibit the greatest shift of the ST junction and as such must be accounted for in applying diagnostic criteria for myocardial injury. Otherwise the proportion of false positives would increase.

The degree of elevation (or depression) is relative to an isoelectric line, which is commonly referenced as the PR segment. The PR segment extends from the end of the P wave to the start of ventricular depolarization (e.g., appearance of a Q wave) (Figure 16-1). The ST junction is defined as the point at which the QRS complex ends and the ST segment begins. It is also synonymous with the J point. In the clinical setting some biomedical engineers have eliminated the J point in their computerized ST-segment analysis software algorithms (Figure 16-2). Recommended threshold values for ST-segment changes are listed in Table 16-1.[8] When these threshold values are met, an imbalance between oxygen supply and demand *may* exist (e.g., myocardial injury).

It should be appreciated when critiquing the literature that researchers may use the J point in combination with the ST point as a means to determine the degree of ST-segment deviation. Examples would include assessing the extent of ST-segment shift by measuring 60 ms (1.5 mm) or 80 ms (2 mm) from the J point. Figure 16-2 contrasts these two means of calculating ST-segment deviation. Measuring the degree of ST-segment depression or elevation at the J point is the author's preferred method to most accurately assess ST-segment deviation values.

For anesthesia providers who use ST-segment analysis software that incorporates a J point in combination with an ST point, caution should be exercised in blindly accepting numeric ST-segment deviation values. Shortened ST segments are predictably associated with tachyarrhythmias, which can result in T waves encroaching on ST segments. Should this occur, the use of a J + 80-ms or even J + 60-ms distance could lead to an ST point intersecting a T wave instead of the ST segment. In this circumstance, the computer-derived ST-segment deviation value would reflect a *false* significant shift in the ST segment, suggesting myocardial injury (false positive) or masking a significant ST-segment depression (false negative) (Figure 16-3).

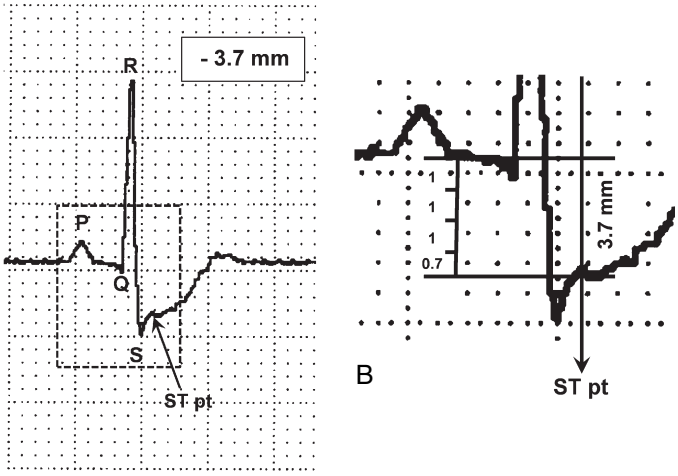

FIGURE **16-1** A single cardiac cycle (ST snippet) and enlarged section of the snippet providing greater details. The PR segment is measured from the end of the *P* wave to the beginning of the QRS complex. **A,** Depicts a depressed ST-segment that is upsloping. The junction between the *S* wave and ST segment defines the ST *point*. **B,** The PR segment is extended out via a horizontal line. This serves as an isoelectric reference (no deviation of the ECG stylus upward or downward) to determine the degree of ST-segment shift. The distance from the extended PR segment to the ST point demonstrates that the ST segment is 3.7 mm depressed (i.e., J point depression of 3.7 mm). (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical.* 3rd ed. Park Ridge, Ill: AANA Publishing. In press.)

TABLE 16-1 Threshold Values for ST-Segment Deviation

Gender and Age	ECG Leads	J-point elevation
Males > 40 years of age	I, II, III, aVR, aVL, aVF	1 mm (0.1 mV)
	V_1, V_4, V_5, V_6	
	V_2, V_3	2 mm (0.2 mV)
Males < 40 years of age	V_2, V_3	2.5 mm (0.25 mV)
Females	I, II, III, aVR, aVL, aVF	> 1 mm (0.1 mV)
	V_1, V_4, V_5, V_6	
	V_2, V_3	1.5 mm (0.15 mV)
Males and females	V_3R, V_4R*	0.5 mm (0.05 mV)
Males < 30 years of age	V_3R, V_4R*	1 mm (0.1 mV)
Males and females	V_7, V_8, V_9†	0.5 mm (0.05 mV)
Males and females of all ages	V_2, V_3	– 0.5 mm (– 0.05 mV)
	All other leads	– 1 mm (– 0.1 mV)

Endorsed by the International Society for Computerized Electrocardiology. *J Am Coll Cardiol.* 2009;53:1003-1011.
mV, Millivolt; *, right ventricular ECG leads; †, posterior chest leads.

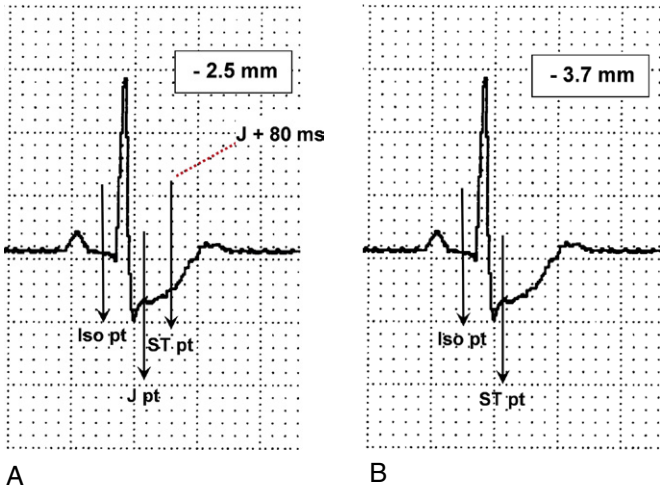

FIGURE **16-2** Two ST snippets illustrating two different techniques to calculate ST-segment depression values. ST snippet (**A**) measures ST-segment deviation 80 ms (2 mm) from the J point. ST snippet (**B**) measures ST-segment depression at the J point. The most recent American Heart Association/American College of Cardiology Foundation/Heart Rhythm Society recommendations for standardizing and interpreting the electrocardiogram advocate measuring ST-segment changes at the J point (i.e., **B**). (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical.* 3rd ed. Park Ridge, Ill: AANA Publishing. In press.)

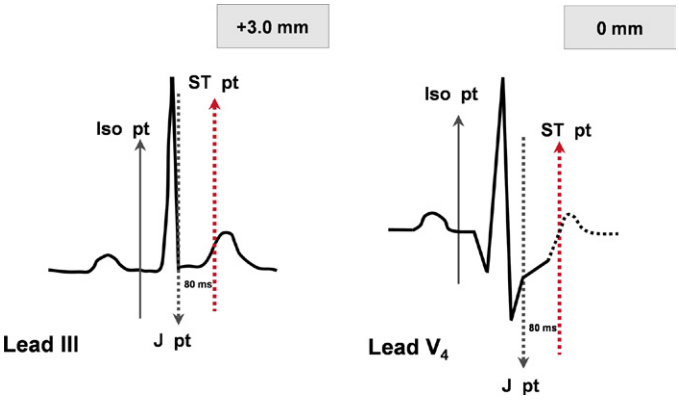

FIGURE **16-3** Two cardiac cycles from lead III and V_4 illustrating a shortened ST segment. Use of a J + 80 ms value to measure ST-segment deviation in each lead results in the ST point intersecting the T wave, thus producing inaccurate ST-segment deviation values. For lead III the misplaced ST point produces a false positive and for lead V_4 a false negative. (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical.* 3rd ed. Park Ridge, Ill: AANA Publishing. In press.)

Regarding the significance of the various forms of ST-segment depression, it is important to recall that a horizontal or downsloping depressed ST segment has greater specificity (fewer false positives) than an upsloping depressed ST segment. Adding upsloping ST-segment changes to myocardial injury diagnostic criteria does improve overall sensitivity but at a sacrifice to specificity and positive predictive value.[12,13]

Setting the ST-Segment Parameters

Most manufacturers of computerized ST-segment analysis monitors have sophisticated algorithms that allow fairly consistent and accurate placement of ST measurement points. Nevertheless, these parameters should be periodically assessed these parameters and changed as needed; responding to false trends secondary to incorrectly placed ST measurement points could lead to iatrogenic injury. In fact, manufacturers have incorporated software that permits

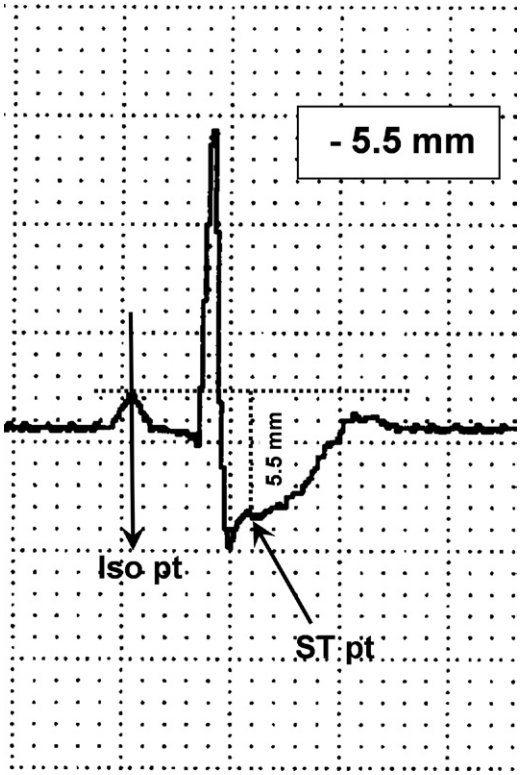

FIGURE **16-4** Iso point incorrectly placed on top of the P wave by an electrocardiogram (ECG) monitor, producing an exaggerated ST-segment deviation value. (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical*. 3rd ed. Park Ridge, Ill: AANA Publishing. In press.)

healthcare providers to override the monitor's placement of ST measurement points. A common technique for setting ST measurement points involves adjustment of two (Iso point and ST point) or three (Iso point, J point, and ST point) variables. Manipulation of a keypad or touchscreen device on the ECG monitor permits the operator to scroll each of these "points" along a horizontal axis. The "points" are depicted as vertical lines that intersect various components of a single cardiac cycle (Figure 16-2). Figure 16-4 illustrates the consequences when real-time ST-segment analysis software incorrectly places the Iso point on the apex of the P wave. The application of an ST-segment deviation algorithm can reduce the occurrence of such mishaps and improve overall management of patients at risk for ischemic changes (Figure 16-5).

Other significant variables to account for when monitoring patients at risk for ischemic events include ECG electrode placement, ECG lead selection, gain setting, and frequency bandwidth. Each of these is briefly reviewed here.

Electrocardiograph Electrode Placement

It is fairly common to see ECG electrodes placed incorrectly on a patient in an attempt to "move an operating room schedule along." Many times with a physical status (PS) I or II patient, accurate ECG electrode placement is not a critical issue. However, in patients with risk factors for CAD, such inattentiveness can lead to iatrogenic injury by producing deviated ST segments, inverted T waves, or pathologic Q waves that can be viewed as "real" problems. Proper placement of the limb lead and chest lead electrodes is described in Table 16-2. For emphasis, the precordial leads should be placed via palpation of the costae, not by gross visual estimation of an intercostal space (Figure 16-6). Understandably, some surgical procedures do not permit the use of optimal ECG lead selection and placement; ECG electrode(s) can interfere with skin preparation and surgical incision. Under these circumstances, a less than optimal ECG lead placement is acceptable and rationale should be documented.

Electrocardiographic Lead Selection

The decision regarding which ECG leads to monitor during the course of an anesthetic can be extremely important relative to the medical history of the patient. Improper selection can result in unrecognized myocardial ischemia, injury, or infarction. Research has validated that use of a single ECG lead for ischemic monitoring in patients with documented CAD is inadequate; monitoring with multiple leads enhances patient safety. In patients at risk for ischemic events, this author recommends the maximum number of ECG leads be displayed (e.g., 3, 7, 12 [derived 12-lead]) during the perioperative period to enhance continuous and comprehensive assessment of ST-segment and T-wave changes (Figures 16-7 and 16-8). Which lead(s) is/are best in detecting significant ST-segment changes remains somewhat controversial. First and foremost, if a preoperative 12-lead ECG has been done, "fingerprinting" of this tracing should serve as the primary guide for lead selection during the perioperative period. If the baseline 12-lead shows significant primary ST-segment changes in limb leads III and aVF, then this lead set should be prioritized for continuous display in the operating room. The ECG monitoring system software will dictate what lead display options can be configured. For example, with Philips software and a five-cable ECG lead system, a derived 12-lead (EASI) can be continuously displayed (see Figure 16-8). With other manufacturers and a five-cable ECG lead system, a true V lead (e.g., V_3), a modified chest lead V_5 (e.g., central subclavicular 5 [CS_5]), and a bipolar limb lead (e.g., lead II) can be configured for ECG monitoring (Figure 16-9).

In patients without a preoperative 12-lead or those who have a baseline 12-lead that is unremarkable, the literature suggests leads V_3, V_4, V_5, limb lead III, and aVF (in this order of preference) be selected for continuous monitoring for ST-segment elevation or depression.[14-18] Lead II is recommended for assessment of narrow QRS complex rhythms, particularly if the P wave is significant for diagnostic criteria (e.g., atrial flutter, atrial fibrillation, junctional rhythms).

The 1988 recommendation for V_5 and limb lead II as preferred ECG leads[19] in patients where ST-segment monitoring is desired has been mitigated by other researchers, critical care task forces, and major publications.[2,15,17,20,21] In 2002 Landesberg and colleagues studied 185 consecutive patients undergoing vascular surgery who were monitored by continuous 12-lead ST-trend analysis during the perioperative period and up to 72 hours postoperatively. Chest lead V_3 was found to detect ischemia earliest and most frequently (86.8%). Lead V_4 was the second most diagnostic lead (78.9%), and V_5 was third (65.8%). With those patients sustaining a myocardial infarction, V_4 was the most sensitive lead (83.3%), with V_3 and V_5 being the second most sensitive (75%).[17] In this study, myocardial infarction was diagnosed if cardiac troponin I levels were greater than 3.1 ng/mL and were accompanied by symptoms of ischemia or the presence of ECG criteria (i.e., ST-segment elevation, ST-segment depression, or large Q waves). Of interest was the observation that 97% of ischemic events were expressed as ST-segment depression—not elevation—and ST shifts were considered significant if their duration of change exceeded 10 minutes. As reported elsewhere in the literature, monitoring in multiple leads was advocated as a means to improve sensitivity for detecting ST-segment changes.[4,17-19]

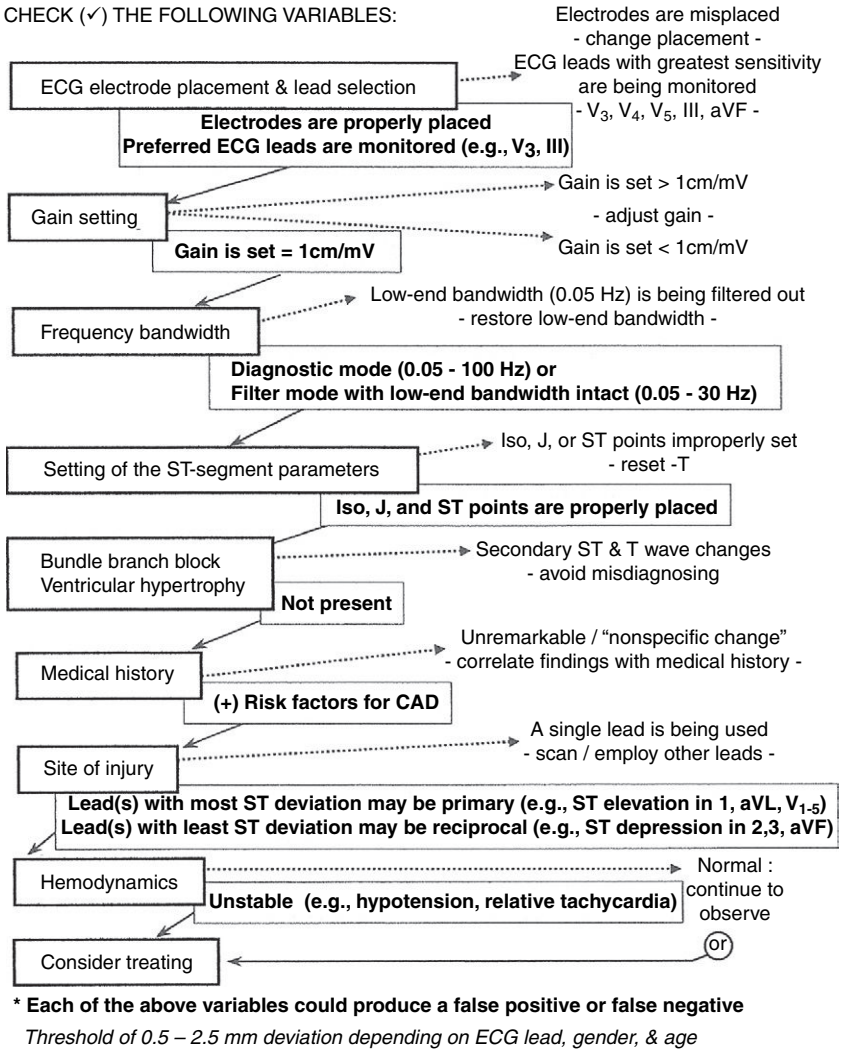

FIGURE **16-5** An ST-segment deviation assessment and treatment algorithm. (Reprinted with permission from Kossick MA. *EKG Interpretation: Simple, Thorough, Practical.* 3rd ed. Park Ridge, Ill: AANA Publishing. In press.)

Given this information, it is prudent for anesthesia providers to monitor and assess multiple ECG leads in the operating room. In the absence of an ST-segment fingerprint, this author advocates the following ECG lead combinations (for ST-segment elevation or depression) in patients with documented or identified significant risk factors for ischemic heart disease:

1. For a five-cable ECG recording system, the three-lead set of V_3, MCL_5, and aVF (the use of MCL_5 precludes the use of limb lead III) or V_3 combined with limb lead III and aVF.
2. For a three-cable ECG recording system, a two-lead set comprising MCL_5 combined with limb lead aVF.

Extended monitoring capabilities help to optimize detection of regionalized myocardial ischemia. Many times this entails nothing more than changing the lead selector switch to another ECG lead (e.g., III changed to aVF) or displaying a multilead ECG when indicated or continuously during an anesthetic (Figure 16-10). The latter produces an ECG recording of all six limb leads and a single chest lead, permitting the anesthetist to more comprehensively assess ECG data, including arrhythmias, the mean QRS axis (limb leads I and aVF), T-wave morphology, ST-segment changes, QT intervals, and the presence of right bundle branch block.

With the introduction into clinical practice of the derived 12-lead system (EASI), nurses and physicians now have a convenient method with which to globally assess the overall well-being of the myocardium (see Figure 16-8). The 12-lead is derived from modified vectorcardiographic leads and requires the use of a five-cable ECG lead system.[22] To monitor with this system, the five ECG electrodes are placed in the following locations: LA electrode over the manubrium; chest (V) electrode over the lower body of the sternum; LL electrode, left midaxillary, horizontal to the chest electrode; RA electrode, right midaxillary, also horizontal to the chest electrode; and RL electrode in any convenient location. Current and past research suggests the derived 12-lead is comparable (but not equivalent) to the standard 12-lead for multiple cardiac diagnosis in adults and children (e.g., ST-segment changes, myocardial infarction, wide QRS-complex tachycardia, QT-interval measurements).[23-25] It is possible that patients at substantial risk for CAD would benefit from global ischemic monitoring via a derived 12-lead. This software option also eliminates any need to consider "preferred" ECG leads because all six limb leads and six chest leads can be viewed during an anesthetic.

TABLE 16-2 Proper Placement of Electrocardiographic Electrodes for Monitoring Chest Leads and Limb Leads via the Mason-Likar Lead Position

Lead Name	Placement
RA	Over the outer right clavicle*
LA	Over the outer left clavicle*
LL	Near the left iliac crest or midway between the costal margin and left iliac crest, anterior axillary line*
RL	At any convenient location on the body (e.g., upper right shoulder)
V_1	Fourth intercostal space right of the sternal border
V_2	Fourth intercostal space left of the sternal border
V_3	Equal distance between V_2 and V_4
V_4	Midclavicular line at the fifth intercostal space
V_5	Horizontal to V_4 on the anterior axillary line or if difficult to identify (anterior axillary line), then midway between V_4 and V_6
V_6	Horizontal to V_5 on the midaxillary line
V_7	Horizontal to V_6 on the posterior axillary line
V_8	Horizontal to V_7 below the left scapula
V_9	Horizontal to V_8 at the left paravertebral border
V_3R	Placed right side of chest wall in mirror image to chest lead V_3
V_4R	Placed right side of chest wall in mirror image to chest lead V_4

FIGURE **16-7** Monitoring in three electrocardiogram (ECG) leads during anesthetic administration captured significant ST-segment elevation. The greatest change in ST segments occurred in limb lead III, followed by limb lead II. Noteworthy was the failure of lead V_5 to demonstrate any appreciable change in the ST segment. Postoperatively a cardiology consultation resulted in a diagnosis of Prinzmetal angina.

In contrast to a derived 12-lead or five-cable ECG electrode system, a three-cable system offers challenges to anesthesia providers concerning potential errors with ECG lead configuration. The literature documents that healthcare providers consistently struggle with modified chest lead configuration—even those who routinely monitor the ECG.[26] Modified chest leads offer an alternative to true chest leads when only a three-cable ECG recording system is available. Recently introduced into clinical practice is the modified chest lead $MAC_{1(L)}$ (modified augmented chest lead V_1). This modified chest lead is configured using limb lead aVL and has been shown to have a diagnostic accuracy similar to true chest lead V_1. The internal validity of this finding was based on His-bundle recordings, used as the gold standard for distinguishing between premature ventricular ectopy and premature aberrantly conducted beats.[27] The simplicity of this unique ECG lead has the potential to reduce modified chest lead configuration errors. Research would need be done to substantiate this theoretical advantage (e.g., ease of configuration of $MAC_{1(L)}$ versus modified chest lead V_1 [MCL_1]). Figure 16-11 illustrates the ECG configuration of $MAC_{1(L)}$, as well as the similarities in morphologic characteristics of single cardiac cycles recorded in V_1 and $MAC_{1(L)}$.

In summary, practitioners who limit ECG monitoring and assessment to a single lead or pair of leads *in patients with documented or recognized risk factors for ischemic heart disease* are potentially compromising patient safety by not using (when available) multiple-ECG-lead display configuration options.[2] In such patients, the continuous display of three-ECG leads, a multilead ECG (six limb leads and one true chest lead), or a derived 12-lead could be of clinical benefit. The literature substantiates myocardial ischemia (T-wave and/or ST-segment changes) can be regionalized and completely missed when viewing two or fewer ECG leads. Similar concerns exists when three-cable ECG lead systems are used in place of available five-cable ECG lead systems. The latter permits the viewing of a true chest lead, which is always preferable over a modified chest. Unarguably, critical assessment of all available patient data will help anesthetists exercise better judgment during an anesthetic and potentially improve anesthetic outcome.

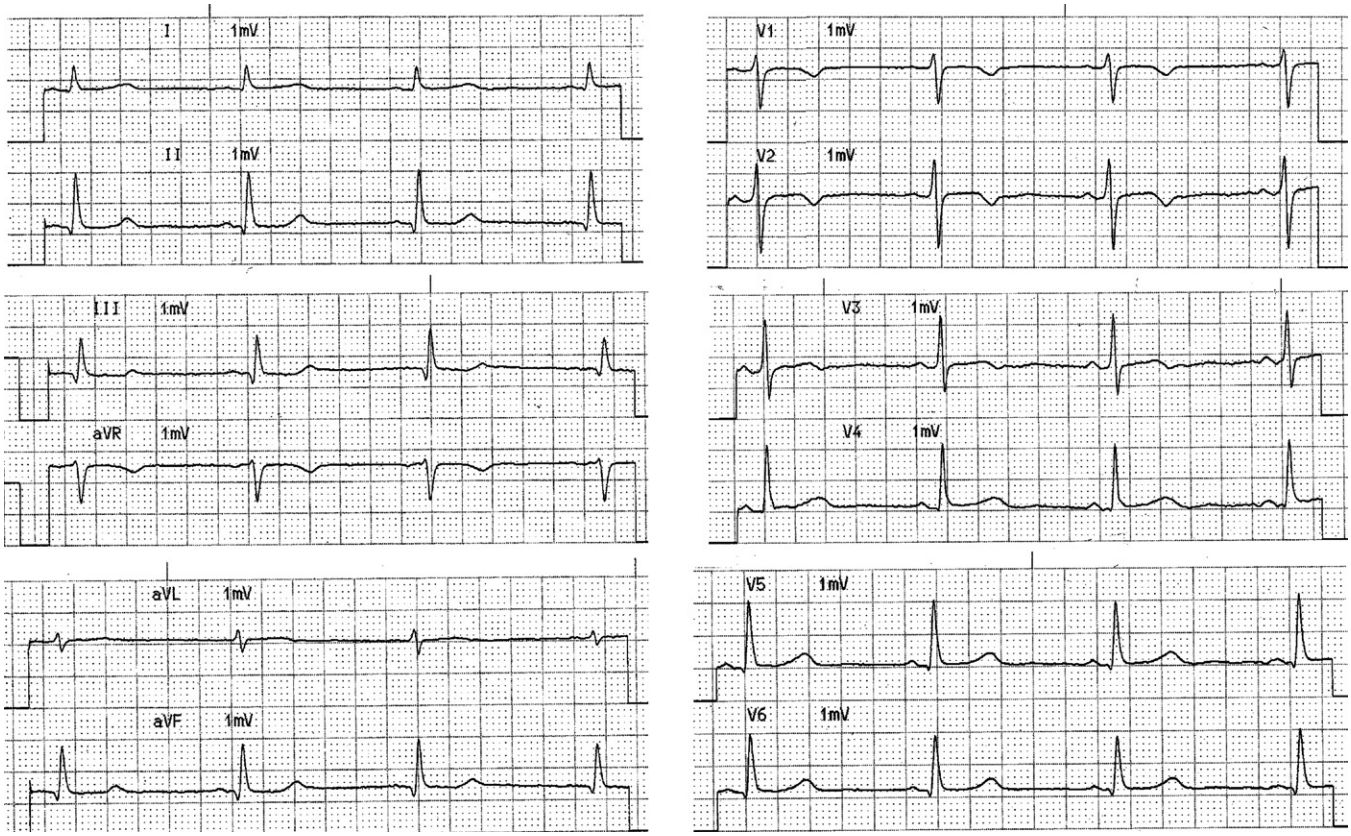

FIGURE **16-8** Derived 12-lead electrocardiogram (ECG [EASI]) recorded just prior to anesthetic induction in the operating room. The ECG monitor can be configured to continuously display all 12 leads for comprehensive assessment of ST segments and rhythm changes.

Gain Setting and Frequency Bandwidth

Two other potential problems with continuous ST-segment monitoring relate to the amplitude at which the ECG monitor has been set and whether filtering of the electrical signal is excessive. When accurate visual assessment of ST segments is a priority during an anesthetic, the gain of the ECG monitor should be set at standardization (i.e., a 1-mV signal delivered by the ECG monitor produces a 10-mm calibration pulse). This gain setting fixes the ratio of the ST-segment and QRS-complex size so that a 1-mm ST-segment change is accurately assessed (e.g., potential myocardial injury). Failure to recognize the use of other gain settings can lead to overdiagnosis or underdiagnosis of myocardial injuries (ST-segment changes). Figure 16-12 illustrates how changes in gain settings and incorrect ECG electrode and/or lead wire placement can confound ST-segment assessment.[28-30]

The filtering capacity of the ECG monitor is yet another potential source of artifact. Research has demonstrated that filtering out the low end of the frequency bandwidth (e.g., 0.05 to 0.5 to produce a new bandwidth range of 0.5 to 40 Hz) of the monitor's electrical signal can lead to distortion of the ST segment (elevation or depression) and T wave (inverted).[31,32] For this reason in many (but not all) cases, the *diagnostic mode* of an ECG monitor should be used when ST-segment analysis is a priority during an anesthetic.

Clearly, the sensitivity and specificity of computerized real-time ST-segment analysis software is dependent on the ability of the anesthetist to critically analyze the large number of factors that influence ST-segment values. Attentiveness to such variables as the patient's physical status, ECG lead placement and selection, verification of proper placement of the Iso point, ST point, type of electronic filtering used by the ECG monitor, and gain setting may affect anesthetic outcome in patients at risk for myocardial ischemia or injury.

CENTRAL VENOUS AND ARTERIAL HEMODYNAMIC MEASUREMENTS

Central venous and pulmonary artery catheters (PAC) are not commonly used in the general surgical population. In fact, since the introduction of the PAC in 1970, the frequency of its use as a monitoring tool for significant surgical procedures has significantly diminished. Even during cardiac or large invasive vascular surgical procedures, many surgeons and anesthesia providers have opted for less invasive means to assess hemodynamic measurements (e.g., Flo Trac sensor). Part of the rationale for this change in practice relates to insufficient evidence demonstrating clinical benefit from use of the PAC.[33,34] The literature is clear in regard to numerous challenges healthcare providers face in accurately interpreting data derived from PACs and central venous lines[35]; cardinal concepts that relate to critical assessment of hemodynamic data are reviewed in this section of the clinical monitoring chapter.

Practice guidelines for PAC use have been recommended and established by various professional societies.[36] It is also recognized that the competency of healthcare providers to manage central venous and arterial hemodynamic parameters can vary significantly. In one study, attending physicians from the departments of medicine, surgery, and anesthesia were unable to demonstrate the basic skill of correctly determining the pulmonary artery occlusive pressure [PAOP] from a clear tracing and applying PAC data for proper patient treatment.[37] Research with anesthesiologists who specialize in cardiovascular anesthesia care also demonstrated cognitive deficits with the use of the PAC (e.g., 39% of cardiovascular anesthesiologists could not correctly interpret a

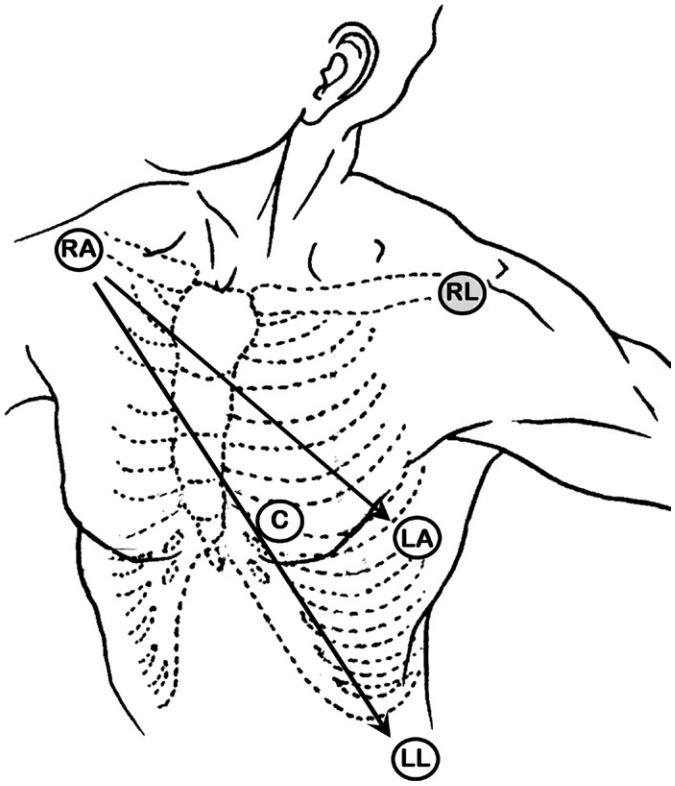

FIGURE **16-9** Preoperative electrocardiogram (ECG) configured with a five-cable ECG system to continuously display limb lead II (right arm *[RA]* negative and left leg *[LL]* positive), true V_3 chest lead (C), and modified chest lead 5 (MCL_5, i.e., central subclavicular 5 *[*CS_5*]*). V_3 electrode placement *(C)*: equal distance between V_2 and V_4. Lead selector switch set to display lead I causes the RA electrode to become negative and the left arm *(LA)* electrode (placed in the V_5 position) to become positive (CS_5). Memphis, Tenn: The University of Tennessee Health Science Center; 2003:2, 9.)

PAOP waveform).[38] Results from these two studies suggest that the understanding of PAC data among healthcare providers is extremely variable, and misinterpretation of PAC data may result in increased morbidity and mortality. It is likely that similar deficiencies in the application and interpretation of PAC data exists for advanced practice nurses (including Certified Registered Nurse Anesthetists [CRNAs]), knowing failing scores were noted on competency tests used to assess other areas of critical care.[26] Such research findings have caused several groups to develop guidelines for the indications of a PAC, along with competency requirements for interpretation of data.[36,39]

Physiology and Morphology of Hemodynamic Waveforms

Essential to accurate interpretation of hemodynamic data derived from central venous lines is a solid foundation in what constitutes "normal" distances, pressures, and waveform morphology for central venous pressure (CVP), right ventricular (RV), PA, and PAOP recordings. Table 16-3 illustrates the approximate distances for reaching the junction of the venae cavae and the right atrium (RA) from various distal anatomic sites. Table 16-4 lists the anticipated distances for reaching various cardiac and pulmonary structures from the right internal jugular vein. Advancement of a catheter 10 cm beyond these distances without the production of a characteristic waveform could indicate coiling of the central line. If this problem arises with a PAC, the balloon should be deflated and the catheter withdrawn. If any resistance is met during withdrawal, a chest radiograph should be taken to rule out knotting or entanglement with the chordae tendineae.

Right Atrial Pressure Waveform

Familiarity with the anticipated distances of relevant hemodynamic anatomy, normal intracardiac pressures, pulmonary pressures (Table 16-5), and waveform morphology facilitates accurate interpretation of PAC data and placement of central lines. For example, under normal circumstances, a CVP tracing will generate mean RA

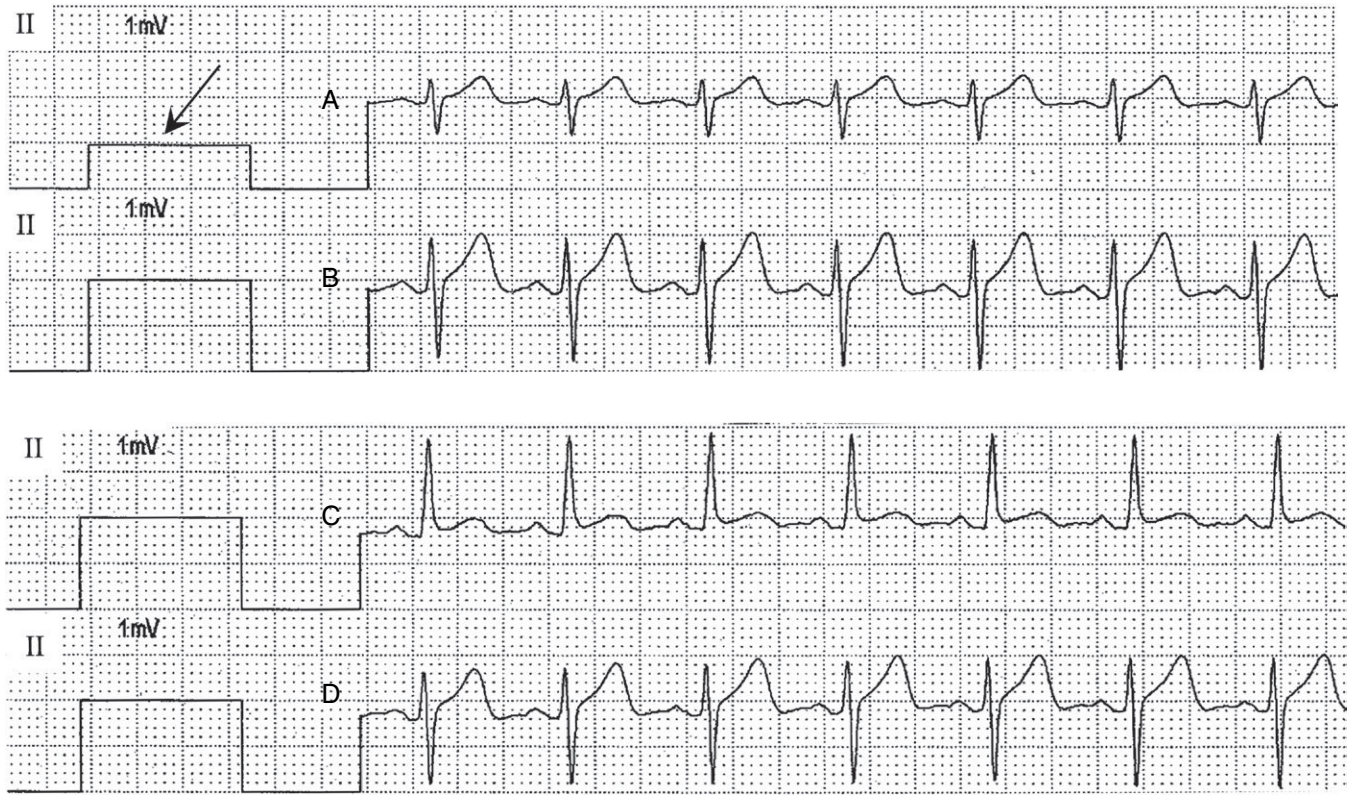

FIGURE **16-12** Series of electrocardiographic (ECG) recordings illustrating how the gain setting and incorrect ECG electrode placement can lead to misinterpretation of ST-segment changes. In strip A, the gain setting *(arrow)* on the ECG monitor has been set at half standardization (1 mV = 5 mm); it grossly gives the appearance of a minor ST-segment change. When concurrent strip *B* is compared with strip A, it becomes apparent that use of smaller gain settings can mask ST-segment deviation. Therefore if a 0.5-mm ST-segment deviation in ECG strip *A* were to occur, it would equate with a 1-mm change. A similar error in assessment of ST-segment changes can occur secondary to misplaced ECG electrodes. ECG strip recording C has all limb lead electrodes properly placed and displays an ST-segment elevation of approximately 0.75 mm. In contrast, ECG rhythm strip *D* mistakenly has the left leg electrode placed in the second intercostal space, midclavicular line, and therefore is not representative of a lead II. The end result is an ST segment that is falsely elevated (approximately 1.5 mm), suggesting inferior transmural myocardial injury. pressures in the range of 1 to 10 mmHg. The fidelity of the transducing system determines whether discernible *a*, *c*, and *v* waves will be displayed once the distal tip of a central line lies just above the junction of the venae cavae and the RA (Figure 16-13). The *a* wave is produced by contraction of the RA, the *c* wave by closure of the tricuspid valve, and the *v* wave by passive filling of the RA (which encompasses a portion of RV systole). The reason the *a* wave is commonly larger than the *c* wave is based on the position of the catheter relative to the physiologic event responsible for the pressure change. In essence, RA systole and the subsequent increase in atrial pressure is detected by a catheter positioned just above (or inappropriately within) the RA, whereas RV systole (a more distal physiologic event relative to the position of a CVP catheter) indirectly increases RA pressure by closure of the tricuspid valve.

Right Ventricular Pressure Waveform

Further advancement of a PAC (approximately 10 cm) produces dramatic changes in the morphology of the hemodynamic waveform. As shown in Figure 16-14, a brisk upstroke (isovolumetric contraction and rapid ejection [RV systole]) and steep downslope (reduced ejection and isovolumetric relaxation [RV systole and diastole]) are viewed on an oscilloscope when a PAC is advanced through the right intraventricular cavity. A PAC with the distal balloon inflated should remain in the RV for as short a time as possible to reduce the incidence of ventricular ectopy, or the development of a conduction defect such as bundle branch block. Because it is undesirable to leave the tip of a central line in the RV, pressures generated during RV systole and RV diastole are assessed indirectly via the CVP port of a PAC and distal tip of the PAC. The former is used to estimate RV end-diastolic pressure (EDP) and the latter RV systolic pressure via the PA systolic recording. Thus RVEDP is used to estimate RVED volume (RVEDV), which approximates RV preload (and less accurately left ventricular [LV] preload).

TABLE 16-5 Normal Intracardiac and Pulmonary Pressures

Location	Absolute Value (mmHg)	Range (mmHg)
MRAP	5	1-10
RV	25/5*	15-30/0-8
PA S/D	25/10*	15-30/5-15
MPAP	15	10-20
PAOP	10	5-15
MLAP	8	4-12
LVEDP	8	4-12

LVEDP, Left ventricular end-diastolic pressure; *MLAP*, mean left atrial pressure; *MPAP*, mean pulmonary artery pressure; *MRAP*, mean right atrial pressure; *PA*, pulmonary artery; *PAOP*, pulmonary artery occlusive pressure; *RV*, right ventricular; *S/D*, systolic/diastolic.
*Values are systolic pressure/diastolic pressure.

Pulmonary Artery Pressure Waveform

When a catheter enters the PA, the diastolic pressure is acutely increased with little change in systolic pressure. The upstroke of the PA tracing is produced by opening of the pulmonic valve, followed by RV ejection. The downstroke contains the dicrotic notch, which is produced by sudden closure of the pulmonic valve leaflets (the beginning of diastole).

Pulmonary Artery Occlusive Pressure Waveform

Final advancement of a PAC by 5 to 10 cm should produce a PAOP tracing. This waveform is similar to a CVP (the *a* wave is produced by left atrial [LA] systole, the *c* wave by closure of the mitral valve, and the *v* wave by filling of the LA, as well as upward displacement of the mitral valve during LV systole), except that the pressure values are somewhat greater. In addition, it is less common to detect a *c* wave on a PAOP tracing, because retrograde transmission of LA pressure (produced by closure of the mitral valve) is significantly attenuated within the pulmonary circulation. The characteristic waveform morphologies of a PAOP tracing are shown in Figure 16-14.

Negative Waveforms

The descents that follow the *a*, *c*, and *v* waves of a CVP or PAOP tracing are labeled as *x*, x^1, and *y* (see Figure 16-13). The *x* descent corresponds to the start of atrial diastole (its terminal component

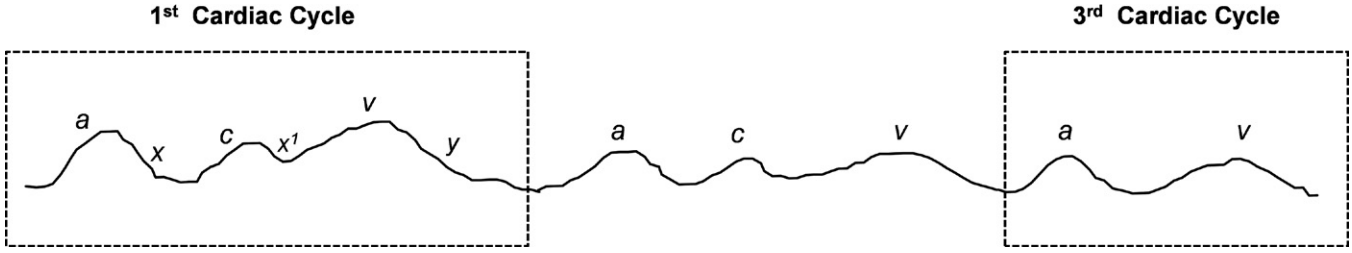

FIGURE 16-13 Positive and negative waveforms of a central venous pressure (CVP) tracing. The third cardiac cycle in this figure does not produce a *c* wave.

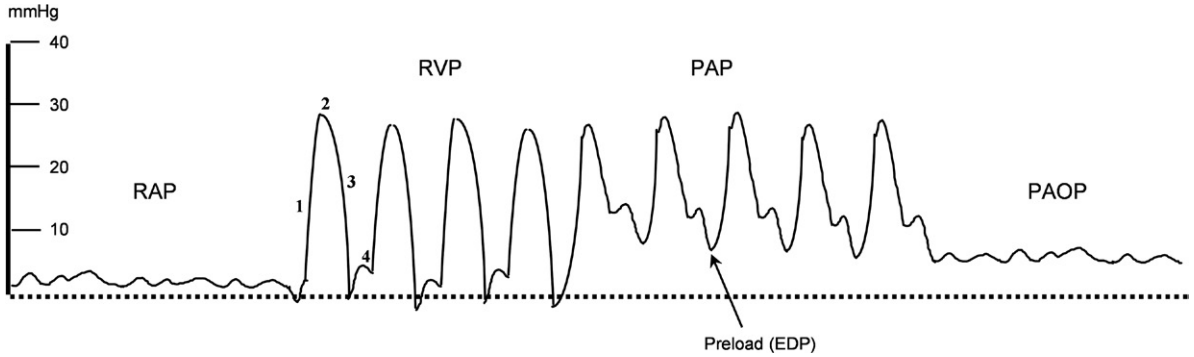

FIGURE 16-14 Pressure waveforms during positioning of a pulmonary artery catheter (PAC). *EDP*, End-diastolic pressure; *PAOP*, pulmonary artery occlusive pressure; *PAP*, pulmonary artery pressure; *RAP*, right atrial pressure; *RVP*, right ventricular pressure. *1*, Isovolumetric contraction (ascent of pressure waveform); *2*, rapid ejection; *3*, isovolumetric relaxation (mid-descent of pressure waveform); *4*, atrial systole (slight increase in pressure).

[just before the upstroke of the *c wave* (or in its absence, the *v* wave)] with RVEDP and LVEDP); the *x*[1] descent is produced by downward pulling of the septum during ventricular systole; and the *y* descent corresponds to opening of the tricuspid valve.

Correlation of Pressure Waveforms and the Electrocardiogram

The interpretation of hemodynamic waveforms can be facilitated by correlating their morphology and timeline with the ECG. The *a* wave of a CVP tracing, which is produced by atrial contraction, will follow depolarization of the atria (P wave on the ECG). The *c* and *v* waves occur after the beginning of ventricular depolarization (QRS complex), or the *v* wave may not appear until shortly after the T wave (Figures 16-15 and 16-16). When compared with the CVP tracing, the PAOP recording shows greater hysteresis between the waveforms of the ECG and the display of *a*, *c*, and *v* waves—meaning there is a greater distance between ECG activity and the subsequent pressure waveform. Identification of abnormal waveforms is greatly facilitated by the use of the ECG; for example, without an ECG recording, large positive waveforms on a PAOP tracing can be diagnosed as either cannon *a* waves or large *v* waves.

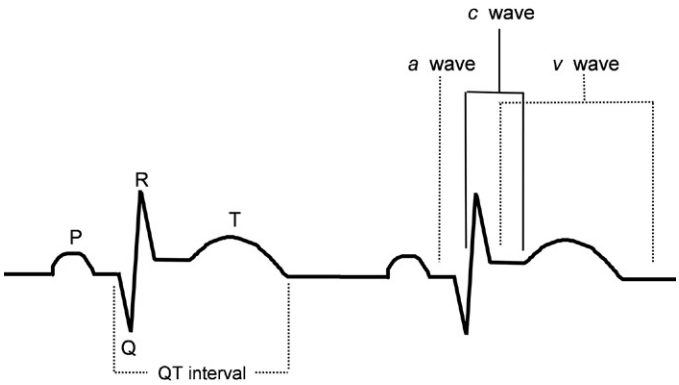

FIGURE **16-15** Temporal relationship between the electrocardiogram and hemodynamic waveforms.

Distortion of Pressure Waveforms

Arrhythmias can produce significant alterations in hemodynamic waveforms. Atrial fibrillation, junctional rhythms, and premature ventricular contractions (PVCs) can alter the shape of *a* waves. With atrial fibrillation, no synchronized atrial contraction occurs. In the CVP or PAOP tracing, this can lead to the loss of *a* waves or the appearance of small fibrillatory *a* waves. Complete atrioventricular block and some forms of junctional arrhythmias cause the atria to contract against a closed tricuspid valve, which can produce large cannon *a* waves (Figure 16-17). Ventricular pacing can be associated with both the presence of cannon *a* waves and loss of *a* waves. The former occurs if a patient does not have an atrioventricular sequential pacemaker; the latter when ventricular pacing is used in the setting of asystole (neither atrial or ventricular depolarization is occurring). Valvular defects can also produce dramatic changes in the CVP and PAOP tracings, causing an increase in the amplitude of the *v* wave secondary to regurgitation (e.g., with mitral regurgitation a portion of the stroke volume is ejected retrograde into the pulmonary circuit, owing to an incompetent mitral valve). Recognition of such abnormalities is critical for accurate recording of pressure measurements and proper placement of central lines. Significant tricuspid regurgitation can cause a CVP recording to mimic an RV tracing, and mitral regurgitation can lead to a PAOP recording to appear as a PA tracing. Specifically, large *v* waves become superimposed on *a* waves. For the indistinguishable PA and PAOP recording, analysis of an SvO_2 (venous oxygen saturation) blood sample can assist in making a differential diagnosis. The saturation will be elevated (greater than 77%) if the catheter is in a wedged position, assuming the distal tip is not in a region of the lung that is atelectatic; which in contrast would produce a false-negative result (normal or low SvO_2). As a precautionary measure, a catheter suspected of being in a wedged position should not be flushed with the fluid contained in the pressurized transducing system. Although the overall incidence of PA rupture is low (0.064%),[40] flushing of a wedged catheter (as well as balloon overinflation) can result in vascular damage ranging from minor endobronchial hemorrhage to massive hemoptysis.

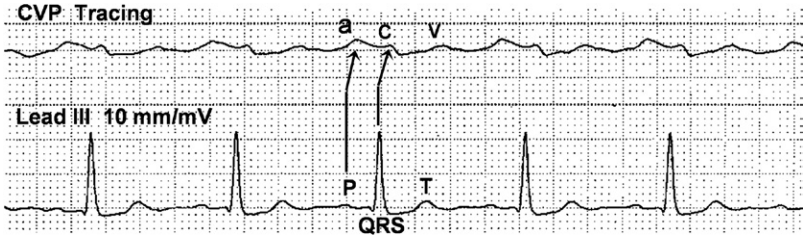

FIGURE **16-16** Electrocardiographic recording with a concurrent central venous pressure tracing that demonstrates hysteresis between atrial depolarization (P wave) and the production of an *a* wave, as well as the QRS complex and the associated *c* and *v* waves.

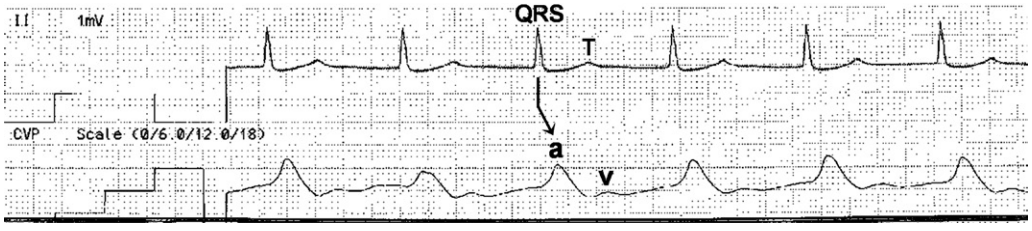

FIGURE **16-17** Electrocardiographic recording of a junctional rhythm *(top)* in which there is simultaneous retrograde atrial and antegrade ventricular depolarization (as evidenced by the lack of a P wave in each cardiac cycle). This results in the right atrium contracting against a closed tricuspid valve. As a consequence, the central venous pressure (CVP) tracing *(bottom)* has cannon *a* waves.

Significant tricuspid regurgitation and mitral regurgitation may also be associated with normal CVP and PAOP tracings.[41] These occur in patients with a low volume status and compliant atria. In addition, a poor correlation has been found between the size of the *v* wave and the degree of regurgitation. Also of interest is the finding that large *v* waves can be observed in the absence of significant regurgitation. This phenomenon can occur whenever an acute increase in preload occurs, which dynamically reduces atrial and pulmonary vascular compliance.[41]

Whenever large *v* waves are detected on a CVP or PAOP tracing, estimates of preload should be measured just before the upstroke of the *v* wave (or *c* wave when present). This point on the pressure recording equates with the EDP, the moment just before ventricular systole that ultimately produces the large *v* waves. Box 16-1 indicates how various rhythm disturbances, pacing, and valvular defects can distort the CVP tracing.

Implications of Abnormal Hemodynamic Values

The CVP serves as an estimate of right ventricular preload (RVEDP). Table 16-6 lists the causes of an elevated CVP. A low CVP correlates with hypovolemia of any cause. As stated previously, RV pressures can be assessed indirectly from the CVP and PA pressure (PAP) recordings. Right ventricular values can be elevated secondary to pulmonary hypertension, ventricular septal defect, pulmonary stenosis, RV failure, constrictive pericarditis, or cardiac tamponade.

Like the RV waveform, the PA tracing occurs within the QT interval of the ECG. LVEDP can be estimated by measuring the pressure value that exists just prior to the upstroke of the PA waveform (Figure 16-14). See Table 16-6 for a list of causes of an increase in the PAP. A false high value can also be produced by a phenomenon called *catheter whip*, which is exaggerated oscillation of the PA tracing. This can occur with excessive catheter coiling if the tip of the PA catheter is near the pulmonic valve; it also occurs in patients with dilated pulmonary arteries. The latter may occur if pulmonary hypertension exists.

When properly used, the PAOP recording has the potential to improve the clinician's ability to make a differential diagnosis in critically ill patients. Like the CVP, it indirectly assesses ventricular function and therefore has distinct limitations. To ensure that accurate pressure recordings are documented, the mean or diastolic pressure should always be determined at end-expiration (whether the patient is spontaneously breathing or receiving positive pressure ventilation). This is the time when pleural pressures are approximately equal to atmospheric pressures (except when positive end-expiratory pressure [PEEP] is being used). The rationale for this timing relates to the fact that vascular pressure recordings are calibrated relative to atmospheric pressure. As stated previously, the correct area on the pressure recording to determine preload (e.g., LVEDP) is just before the upstroke of the *v* wave (or *c* wave if present). Causes of an elevated PAOP are listed in Table 16-6.

Variables That Influence Hemodynamic Measurements

Essential for proper management of hemodynamic parameters is the recognition of how numerous variables can skew recorded pressure values. The foundation for understanding PAC data begins with the recognition that absolute numbers are generally not as important as trends. In addition, most of the data obtained from a PAC allows for only *indirect* assessment of cardiovascular function and pulmonary indices. For example, PA diastolic pressure (PADP) approximates PAOP, which approximates LA pressure, which approximates LVEDP, which provides an estimate of left ventricular end-diastolic volume (LVEDV). Table 16-7 lists clinical factors that can skew these pressure and volume relationships. Obviously, reliance on indirect pressure measurements mandates that the anesthetist understand how to interpret these data in light of such limitations. It should be assumed that for most patients who require a PAC or CVP that several, if not numerous, pathophysiologic states exist (e.g., cardiovascular disease, pulmonary dysfunction) that will skew the pressure-to-pressure and pressure-to-volume relationships.

Of the variables listed in Table 16-7, several require further discussion. Many of the factors listed can be viewed as disruptions or obstructions of the continuous column of blood that exists between the RA and LV. This is the case for valvular defects and pulmonary factors.

The goal for placement of a PAC is to have it reside in a West zone III[42] of the lung; this usually does occur, because the bulk of pulmonary blood flow lies within this region of the lung. In this

BOX 16-1

Factors That Can Distort Central Venous Pressure and Pulmonary Artery Occlusive Pressure Tracings

Loss of *a* Waves or Only *v* Waves
- Atrial fibrillation
- Ventricular pacing in the setting of asystole

Giant *a* Waves—"Cannon" *a* Waves
- Junctional rhythms
- Complete AV block
- PVCs (simultaneous atrial and ventricular contraction)
- Ventricular pacing (asynchronous)
- Tricuspid or mitral stenosis
- Diastolic dysfunction
- Myocardial ischemia
- Ventricular hypertrophy

Large *v* Waves
- Tricuspid or mitral regurgitation
- Acute ↑ in intravascular volume

↑, Increase; *AV*, atrioventricular; *PVCs*, premature ventricular contractions.

TABLE 16-6 Potential Causes of Elevated Central Venous Pressure, Pulmonary Artery Pressure, and Pulmonary Artery Occlusive Pressure

CVP	PAP	PAOP
RV failure	LV failure	LV failure
Tricuspid stenosis or regurgitation	Mitral stenosis or regurgitation	Mitral stenosis or regurgitation
Cardiac tamponade	L-to-R shunt	Cardiac tamponade
Constrictive pericarditis	ASD or VSD	Constrictive pericarditis
Volume overload	Volume overload	Volume overload
Pulmonary HTN	Pulmonary HTN	Ischemia
LV failure (chronic)	"Catheter whip"	

ASD, Atrial septal defect; *CVP*, central venous pressure; *HTN*, hypertension; *L*, left; *LV*, left ventricular; *PAOP*, pulmonary artery occlusive pressure; *PAP*, pulmonary artery pressure; *R*, right; *RV*, right ventricular; *VSD*, ventricular septal defect.

position, the PAP is greater than the pulmonary venous pressure, which is greater than the alveolar pressure. This zone corresponds to a complete circuit or conduit that allows for direct communication between right-sided heart and pulmonary pressures with left-sided intraventricular pressures (Figure 16-18). It is important to recall that each of the lung zones is physiologically—not anatomically—defined; thus a zone III can change into a zone II (PAP > alveolar pressure > pulmonary venous pressure) or zone I (alveolar pressure > PAP > pulmonary venous pressure).

TABLE 16-7 Factors That Alter the Relationships Among Central Cardiovascular Pressures and Volumes

CVP ≠ PADP	Change in RV compliance (e.g., PS) Tricuspid valve disease
PADP ≠ PAOP	Pulmonary HTN MR or AR Lung zone I or II Tachycardia ARDS RBBB
PAOP ≠ MLAP	Juxtacardiac pressure (e.g., PEEP) Lung zone I or II Mediastinal fibrosis RBBB
MLAP ≠ LVEDP	Juxtacardiac pressure (e.g., PEEP) Mitral valve disease Change in LV compliance (e.g., AS)
LVEDP ≠ LVEDV	Juxtacardiac pressure (PEEP) Ventricular interdependence Change in LV compliance (e.g., ischemia)

AR, Aortic regurgitation; *ARDS*, acute respiratory distress syndrome; *AS*, aortic stenosis; *CVP*, central venous pressure; *HTN*, hypertension; *LVEDP*, left ventricular end-diastolic pressure; *LVEDV*, left ventricular end-diastolic volume; *MLAP*, mean left atrial pressure; *MR*, mitral regurgitation; *PADP*, pulmonary artery diastolic pressure; *PAOP*, pulmonary artery occlusive pressure; *PEEP*, positive end-expiratory pressure; *PS*, pulmonic stenosis;; *RBBB*, right bundle branch block; *RV*, right ventricular.

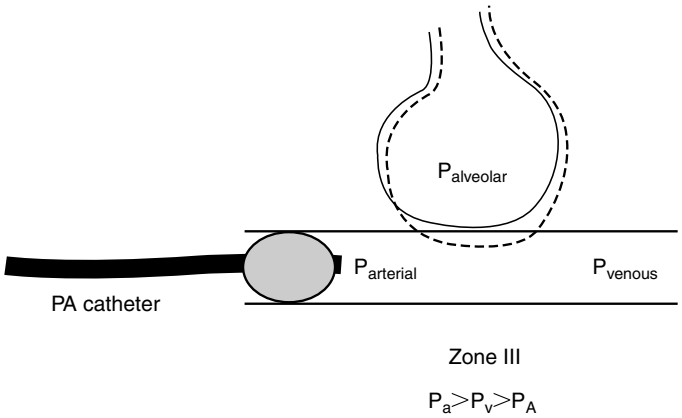

FIGURE 16-18 Pulmonary artery catheter with balloon inflated (wedging) in a West lung zone III. In this zone, pulmonary pressures equilibrate during diastole because both arterial and venous pulmonary pressures are greater than alveolar pressures. The addition of positive end-expiratory pressure *(dashed-line alveolus)* or hypovolemia can convert a zone III to a zone I or II and lead to distended alveoli and inaccurate estimates of pressures distal to the invagination. P_a, Arterial pressure; P_A, alveolar pressure; P_v, venous pressure; *PA*, pulmonary artery.

Factors that contribute to the dynamic state of zone III include the application of PEEP (Figure 16-18), significant diuresis, hemorrhage, and a change in patient position (e.g., supine to sitting). The influence of PEEP is contingent on the quantity applied, intravascular volume status, and pulmonary compliance. Normally, less than 50% of PEEP is transmitted to the microvasculature—even less if pulmonary compliance is poor (e.g., patients with adult respiratory distress syndrome).[43] In contrast, patients with decreased volume status (e.g., left atrial pressure less than 5 mmHg) who receive PEEP as low as 7.5 cm H_2O can have collapse of the pulmonary capillaries, which distorts the PAOP.[44] A PAC located in zone I or II will produce marked variations in the PAOP waveform recording during the ventilatory cycle. In addition, *a* and *v* waves (cardiac influences) are lost, and the PAOP exceeds the PADP. This is in contrast to a PAOP recording produced by a catheter located in a true wedge position. The distinguishing criteria include the development of a characteristic waveform with balloon inflation and a PAOP reading less than or equal to the PADP. The latter criterion assumes that no valvular defect is present, which could also cause the mean PAOP to exceed the PADP.

A rapid heart rate (HR) can also skew the relationship between PADP and the PAOP. Research has demonstrated that left-atrial-paced induced tachycardia (increased HR from 74 to 124 beats per minute) can produce an 11-mmHg gradient between the PADP and LVEDP. The increase in PADP and decrease in LVEDP result from the shortening of diastole, which reduces the amount of blood being transported from the pulmonary circulation to the LV.[45] Also, as HR increases, the left atrium begins to contract against a partially closed mitral valve.[46]

Another variable that significantly influences PAC data is a change in ventricular compliance. To illustrate this point, consider the fact that a high PAOP (or LVEDP) can exist in patients with an elevated preload with normal ventricular compliance, as well as in patients with a low preload with poor ventricular compliance. A patient with reduced ventricular compliance (e.g., myocardial ischemia, left ventricular hypertrophy, cardiac tamponade, ventricular interdependence) has a high PAOP or PADP that results in overestimation of LVEDV (Figure 16-19) and underestimation of LVEDP. In the setting of poor compliance, PAOP is not a reliable index for LVEDV.[47] In fact, it has been shown that during myocardial revascularization procedures, high PAOP values exist more than 50% of the time in conjunction with a low volume status (as determined by echocardiography), with patients responding favorably (despite a high PAOP) to an increase in intravascular volume.[48]

To summarize, the PADP correlates poorly (by 5 mmHg or more) with the PAOP under the following circumstances: when pulmonary vascular resistance (PVR) is elevated (e.g., chronic obstructive pulmonary disease, human papillomavirus, pulmonary embolus, adult respiratory distress syndrome, hypercarbia), when heart rates exceed 130 beats per minute, when severe mitral or aortic regurgitation is present, or when a lung zone III has changed to a zone II or I (e.g., in the presence of hypovolemia, PEEP). Increases in PVR and HR cause the PADP to exceed PAOP. Severe regurgitation and lung zone changes produce the opposite effect, with PADP being less than the PAOP; this may also hold true for right bundle branch block, based on one researcher's findings of how this conduction defect caused the PADP (in the setting of normal PVR) to be up to 7 mmHg less than the mean left atrial pressure.[49] A review of the gross interpretation of CVP and PAOP values is presented in Table 16-8.

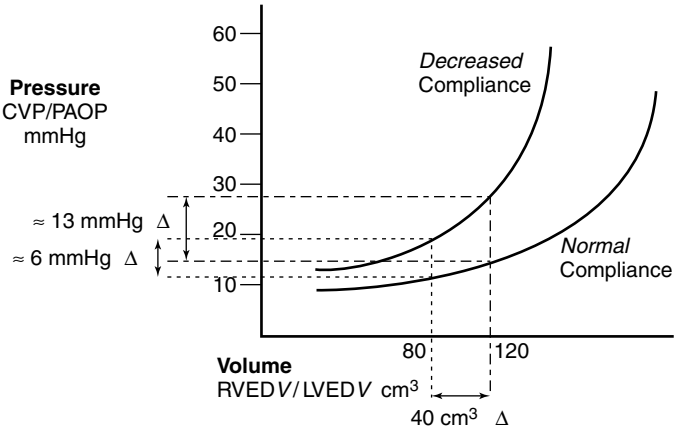

FIGURE **16-19** Effect of changes in ventricular compliance on CVP (which estimates RVEDP) and PAOP (which estimates LVEDP). The curve with *decreased compliance* distorts the relationship between pressure values and estimated ventricular volume. A preload of 80 cm^3 in a compliant versus noncompliant ventricle generates a pressure difference of ≈ 6 mmHg *(flat portion of each curve)*. On the steeper portion of both curves, the relationship between volume and pressure is skewed even more dramatically. A preload of 120 cm^3 generates a pressure difference of ≈ 13 mmHg, which can ultimately lead to a gross overestimation of ventricular preload. Δ, Change; *CVP*, central venous pressure; *LVEDP*, left ventricular end-diastolic pressure; *PAOP*, pulmonary artery occlusive pressure; *RVEDP*, right ventricular end-diastolic pressure; *RVEDV*, right ventricular end-diastolic volume; *LVEDV*, left ventricular end-diastolic volume.

TABLE 16-8 Potential Clinical Diagnosis Via the Use of Hemodynamic Values: Interpretation of Pulmonary Artery Catheter Data

CVP	PADP	PAOP	Interpretation
Low	Low	Low	Hypovolemia, transducer not at phlebostatic axis*
Normal or high	High	High	LV failure
High	Normal or low	Normal or low	RV failure, TR, or TS
High	High	Normal or low	Pulmonary embolism
High	High	Normal	Pulmonary HTN
High	High	High	Cardiac tamponade, ventricular interdependence, transducer not at phlebostatic axis*
Normal	Normal or high	High	LV myocardial ischemia or MR
Low	High	Normal	ARDS†

*Phlebostatic axis is the fourth intercostal space, midanteroposterior level (not midaxillary line); for the right lateral decubitus position, fourth intercostal space midsternum; for the left lateral decubitus position, fourth intercostal space at the left parasternal border.
†ARDS patients commonly require initial fluid administration for hemodynamic stability.
ARDS, Acute respiratory distress syndrome; *CVP*, central venous pressure; *HTN*, hypertension; *LV*, left ventricular; *MR*, mitral regurgitation; *PADP*, pulmonary artery diastolic pressure; *PAOP*, pulmonary artery occlusive pressure; *RV*, right ventricular; *TR*, tricuspid regurgitation; *TS*, tricuspid stenosis.

Other Hemodynamic Indexes

Some authors encourage the use of calculated indexes to optimize the care of critical care patients. These indexes include the pulmonary vascular resistance index (PVRI), systemic vascular resistance index (SVRI), and cardiac index (CI). The potential advantages and limitations of each index are reviewed below.

The PVRI (PVR calculated with the CI instead of the cardiac output [CO]) is equal to the difference in pressure across the pulmonary circuit (mean PAP − PAOP) divided by flow (CI) times 80. This formula is taken from Ohm's law (with the variables mathematically manipulated) for electric currents (R [Resistance] = V [Voltage] = I [Current]). A normal value is considered to be 45 to 225 dynes/sec/cm^5/m^2. Two limitations of extrapolating physiologic resistance from Ohm's law are (1) blood flow is pulsatile and not flowing continuously through a set of rigid pipes, and (2) resistance is not uniform throughout the pulmonary circuit. The electrical counterpart describes resistance not in alternating currents, but direct currents.[50]

When PVR is used clinically, it should be viewed as a gross *estimate* of RV afterload; similarly, SVR is associated with LV afterload. In the intact heart *afterload* is defined as systolic wall stress or the impedance the ventricle must overcome to eject its stroke volume. It is important to understand that vascular resistance is not synonymous with afterload but is used as an extension of the concept. Pulmonary vascular resistance, like SVR, can affect afterload, but neither formula accounts for changes in ventricular wall thickness or radius, which are components of afterload.

Systemic vascular resistance index is calculated as the difference between systemic input pressure (mean arterial pressure) minus the output pressure (right atrial pressure or CVP), divided by the CI times 80. The normal range is 1760 to 2600 dynes/sec/cm^5/m^2. Systemic vascular resistance is commonly used to offer some guidance in the use of vasoconstrictors (e.g., phenylephrine infusion) or afterload reduction (e.g., intravenous nitroglycerin or sodium nitroprusside). The limitations described previously for PVR also hold true for SVR, although perhaps to a lesser extent, because the systemic vasculature has lower compliance. In general, supporting afterload via vasoconstrictors should be deferred until maximization of preload or the use of positive inotropes has proven to be ineffective.

Determination of CO assists critical care specialists in providing rational hemodynamic therapy, evaluating the response to therapy, and determining the adequacy of tissue perfusion, which is linked to maintenance of arterial blood pressure, the delivery of oxygen, and removal of wastes. It also permits the calculation of other hemodynamic indices (e.g., PVR and SVR). A "normal" CO value can be qualified by taking into account age differences, metabolic activity (declines with anesthesia and increases with hyperthermia), and patient size. This last factor may be adjusted for by converting a CO to a CI, which attempts to normalize CO for the large number of values found in the general population. However, CI adjusts only for the variables of height and weight. It does not address the lack of uniformity of predicted basal oxygen consumption and metabolic rates resulting from differences in sex and age. In addition, the relationship between body surface area (BSA) and blood flow is indistinct.[51] CI is calculated by dividing CO by BSA. The plotting of height and weight on a body surface chart estimates the BSA in square meters (Figure 16-20). Commonly quoted "normal" values are 5 to 6 L/min for CO and 2.8 to 3.6 L/min/m^2 for CI.

The most commonly used technique for determining CO is thermodilution, whereby an analog computer calculates the CO by using the modified Stewart-Hamilton equation. This method

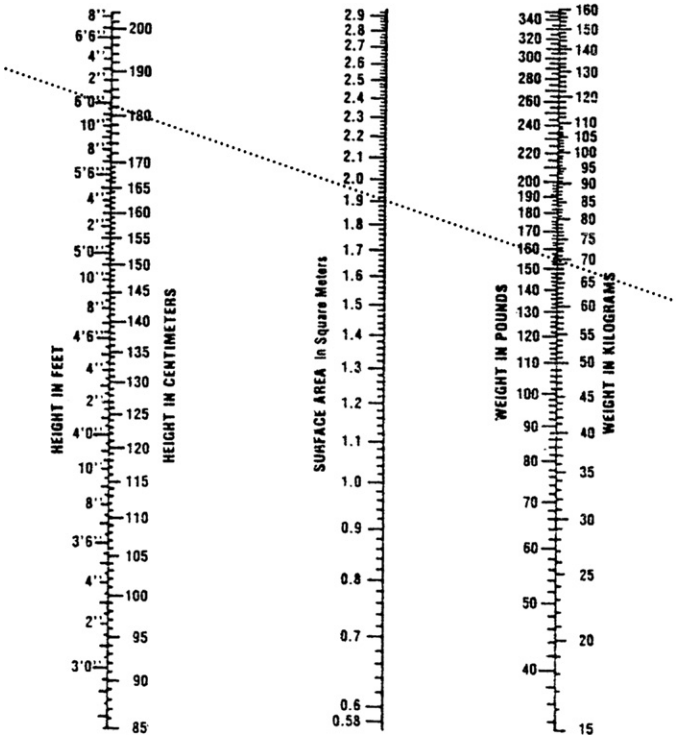

FIGURE **16-20** Chart used to calculate body surface area. In this example, a height of 6 feet and a weight of 155 lb translates into a surface area of approximately 1.9 m^2.

was first used by Fegler in 1954.[52] It entails the injection of a known quantity of an indicator solution (most commonly 5% dextrose in water, although 0.9% normal saline has a similar density factor) through the proximal port of a thermodilution PAC.[53]

The injected solution is considered a thermal indicator because it is cold relative to body temperature. It rapidly mixes with the incoming blood and is carried through the RV until it is detected by the thermistor near the end of the catheter in the PA. The computer plots a time-temperature curve, with the area under the curve being inversely proportional to the CO; therefore larger curves are not desired. Variables that can influence recorded values include the computation constant (which varies with catheter size, injectate volume, and temperature), temperature of the injectate (desired range of 0° to 24° C), volume of injection,[54] speed of injection (should be done in 4 seconds or less),[55] and the timing of injection (it should be consistent, i.e., the same time during each respiratory cycle).[56] Iced injectates have not been shown to offer any significant advantage over room-temperature injectates.[54] In fact, cold indicator solutions injected rapidly into the right atrium have been shown to produce arrhythmias[57] including sinus bradycardia.[58] Research that has examined the impact of valvular or septal defects on thermodilution CO (TDCO) values has produced conflicting results.[59-61] A list of variables that can skew CO measurements is provided in Table 16-9.

The accuracy for TDCO (including when performed in patients in the lateral position) is ±10%, and the reliability is ±5%.[62] These values are lower in the pediatric population,[63] in patients who have low CO,[64] and for measurements taken in the operating room.[65] Anesthetists should be careful not to overinterpret small changes (e.g., 5% to 10%) and should never express values beyond one decimal point. The common practice of averaging three CO output values has also been shown to improve accuracy.[66]

TABLE 16-9 Variables That May Influence Thermodilution CO Values

Overestimates	Underestimates	Unpredictable
Low injectate volume	Excessive injectate volume	Right-to-left ventricular septal defect
Injectate that is too warm	Injectate solutions that are too cold	Left-to-right ventricular septal defect
Thrombus on the thermistor of the PAC		Tricuspid regurgitation
Partially wedged PAC		

CO, Cardiac output; *PAC*, pulmonary artery catheter.

A further advancement in CO technology has been achieved via the placement of thermal filaments within the right ventricular portion of the PAC and near the tip of the thermistor (Vigilance system [Edwards Life-Sciences Corporation], OptiQue system [Abbott Laboratories]). A sophisticated computer algorithm permits for analysis of a thermal signal created by small quantities of heat being emitted from the PAC—a pulsed warm thermodilution continuous cardiac output (TDCCO) technique. This heat signal is eventually transmitted by the blood to the distal thermistor, which permits for continuous CO (CCO) assessment.[67] An adequate signal-to-noise ratio is necessary to produce accurate and *reliable* CCO measurements. Research has shown a low ratio (derived from a core body temperature greater than 38.5° C) can result in inaccurate CCO values.[68] One advantage of a CCO catheter is the elimination of the time-consuming administration of a thermal injectate through the proximal port of the PAC. It also reduces the number of discrepancies in thermodilution CO values that can occur with inconsistent injectate administration relative to the respiratory cycle.

A drawback to the CCO device is the hysteresis in recording hemodynamic information. Although the monitor displays updated CO figures every 30 seconds, they nonetheless do not represent real-time data. Instead, the CCO values depict the average CO from the prior 3 to 6 minutes.[69] This can be a significant limitation in patients who develop acute hemodynamic changes occurring in response to hemorrhage and resuscitation.[70] In this setting, a standard bolus thermodilution technique is preferable.

Manufacturers of TDCCO monitors have attempted to circumvent this limitation by developing "Fast-Filter" and "Urgent" modes to supplement the "Normal" mode of data processing. One investigation found a significant decline in the precision of CO measurements when the Fast-Filter and Urgent modes were used.[71] The reliability and accuracy of the device with intensive care and surgical patients have been established with recordings taken in the supine position[68,72] and with the backrest elevated up to 45 degrees.[73] Nevertheless, some investigators have found the TDCCO technique to be less precise than bolus thermodilution.[74-76]

Other investigators have examined a variation of the TDCCO PAC, specifically a PAC (truCATH) that measures the amount of energy required to maintain a fixed blood temperature gradient between two distal thermistors. Researchers have found the truCATH PAC and TruCCOMS monitor to overestimate low CO and underestimate high CO and suggested that an improvement in the calibration scheme may obviate this problem.[77,78] Although the truCATH provides ultrafast data, it demonstrates problems with reliability.

In spite of reports in the literature of a positive clinical outcome based on the use of TDCCO,[33,79] future studies will be required to establish whether CCO measurements (as well as other monitoring modalities such as Doppler techniques[80]) reduce the length of hospitalization and improve morbidity and mortality rates.[81]

Mixed Venous and Central Venous Oxygen Saturation

Since its introduction in 1981, SvO_2 has been described as a means to indirectly monitor oxygen delivery. This purported usefulness is based on the knowledge that SvO_2 is determined by pulmonary function, cardiac function, oxygen delivery, tissue perfusion, oxygen consumption, and hemoglobin concentration. During the course of an anesthetic (excluding cases of major trauma or hemorrhagic shock), it is not unusual for pulmonary function, hemoglobin content, and oxygen consumption to remain relatively stable. Therefore proponents of SvO_2 monitoring state that it is reasonable to assume that a decrease in SvO_2 reflects a change in oxygen delivery, presumably via a reduction in CO.[82,83] In contrast, some researchers have found a poor correlation between SvO_2 and CO.[84,85]

Continuous mixed venous oximetry is measured with the use of fiberoptic reflectance spectrophotometry through two fiberoptics housed in the PAC. One fiberoptic transmits light-emitting diodes (narrow wavebands of light) to the distal catheter. The extent of light absorption and reflection is a function of the quantity of oxyhemoglobin and deoxyhemoglobin present in the PA.[86] The receiving fiberoptic transports the reflected light to a microprocessor that interprets the signal and displays an SvO_2 value; the normal range of SvO_2 is 65% to 77%. Factors that increase SvO_2 values include left-to-right shunts, hypothermia, sepsis, cyanide toxicity, a wedged PAC, and an increase in CO. SvO_2 decreases with hyperthermia, shivering, seizures, reduced pulmonary transport of oxygen, hemorrhage, and decreased CO. Sustained low values (e.g., 50%) merit investigation followed by appropriate intervention(s). It has also been demonstrated that some SvO_2 monitoring systems adapt well to acute changes in hematocrit.[87] In addition, research with two-wavelength and three-wavelength SvO_2 oximetry catheters has shown the systems to be comparable in accuracy.[88]

Central venous oxygen saturation ($ScvO_2$) monitoring has been advocated as a surrogate for SvO_2 when a less invasive form of hemodynamic monitoring is indicated. Modified central venous catheters (CVC) that contain a fiberoptic lumen can measure $ScvO_2$ when positioned at the junction of the superior vena cava and right atrium. A major difference between SvO_2 and $ScvO_2$ measurements is the latter is considered a regional indicator of venous oxygen saturation; it measures venous O_2 saturation from the upper body and head. In contrast, SvO_2 measurements depend on blood flow from the superior vena cava, inferior vena cava, and coronary sinus (which has an O_2 content of approximately 7 mL/dL [venous O_2 saturation of 35%]). Also, the mixed venous O_2 content is greater in the inferior vena cava than the superior vena cava.[89,90] The net effect of these differences is that under normal conditions (e.g., unanesthetized subjects),[90] the $ScvO_2$ is about 2% to 3% less than the SvO_2.[89-92] However, the literature also reports the opposite relationship.[93]

From a monitoring perspective, research indicates that the use of $ScvO_2$ as a substitute for SvO_2 is both advocated[84,93-95] and discouraged.[91,96-98] Numerous clinical investigations in different practice settings with patients having diverse pathologic states have been conducted. In spite of the diverse opinions, some professional healthcare societies have established guidelines that recommend $ScvO_2$ be used as a clinical tool to guide therapy for improving morbidity and mortality. For example, the 2008 surviving sepsis campaign—international guidelines for management of severe sepsis, strongly suggested using a $ScvO_2$ goal of 70% or more (or SvO_2 65% or more) in the first 6 hours of resuscitation. Concurrent hemodynamic/clinical recommendations included achieving a CVP 8 to 12 mmHg, MAP (mean arterial blood pressure) 65 mmHg or greater, urine output 0.5 mL/kg/hr or greater, and intravenous antibiotics within the first hour of recognizing severe sepsis and septic shock.[94]

In conclusion, the cost-benefit ratio of using PACs that provide TDCO, TDCCO, SvO_2 measurements, or even CVCs with $ScvO_2$ monitoring capabilities remains controversial. As with any physiologic monitor, the potential to promote health or cause harm is determined by the clinician's ability to interpret and apply data.[99] A similar analogy can be made for computerized ST-segment analysis whereby numerous variables unaccounted for in interpretation of ST-segment shifts can potentially lead to iatrogenic injury. Therapeutic strategies should be guided by a knowledge of the patient's underlying pathophysiology and limitations of the respective hemodynamic monitoring device.

ARTERIAL PRESSURE MONITORING

As with ECG monitoring, professional societies have designated the routine assessment of arterial blood pressure (BP) to be essential for the safe conduct of any anesthetic; at minimum, BP should be recorded at least once every 5 minutes.[1] This frequency of assessment should be increased for patients noted to have any systemic disease that limits physiologic reserve, such as coronary artery disease (CAD) or valvular heart defects (e.g., aortic stenosis). This author advocates BP assessment at 1-minute intervals during the induction period of most anesthetics, the rationale being that many commonly administered induction agents are associated with cardiac depressant effects. The concomitant disruption or gross activation of homeostatic reflexes can lead to substantive changes in hemodynamics—even in relatively healthy patients. It is also known that the hemodynamic response to many drugs used during induction of anesthesia can be unpredictable, owing to differences in pharmacokinetics and pharmacodynamics among patients.

BP monitoring can be accomplished through both noninvasive and invasive techniques. Each recording modality will be reviewed with an emphasis on clinical relevance. Other resources provide a comprehensive description of the theoretic underpinnings for the calculation of noninvasive and invasive arterial BP data. In today's modern OR environment, noninvasive blood pressure (NIBP) monitoring is most often recorded by automated BP cuffs that can be configured to measure systolic blood pressure (SBP), diastolic blood pressure (DBP), and mean arterial blood pressure (MAP) in a standard mode, stat mode, at varied frequencies of assessment, and adjusted for patient age and habitus. The literature recommends BP cuffs have a bladder dimension of approximately 40% of the circumference of the extremity.[100] Bladders not properly sized and cuffs not applied firmly to the extremity can lead to inaccurate recordings. For example, cuffs that are applied loosely to the extremity, positioned below the level of the heart, or are too small can produce arterial blood pressure values that are falsely elevated.[101]

The physics associated with auscultation of BP relates to the audible discernment of Korotkoff sounds through a stethoscope. These sounds are produced by turbulent blood flow within an artery during cuff deflation. A second mechanism for BP assessment is via an oscillometric technique (Figure 16-21). NIBP devices have inflation and deflation cycles controlled by

a microprocessor. During deflation of the cuff, oscillations are sampled over the span of several cardiac cycles. Any oscillations sensed by the pressure transducer are then processed numerically. If none are sensed, a stepwise reduction in cuff pressure followed by sustained measurement for oscillations occurs. This process repeats until SBP, DBP, and MAP are derived. MAP can also be estimated by taking the sum of the SBP and DBP—the latter multiplied by two, then dividing this figure by three. Example: a BP of 120/80 has a MAP of (120 + 80 + 80) ÷ 3 = 93 mmHg). This formula accounts for diastole comprising approximately two thirds of a normal cardiac cycle.

Generally speaking, the benefits outweigh the risks of frequent NIBP recordings taken during an anesthetic. Nevertheless, injury and harm can occur with automatic NIBP measurements and may include damage to peripheral nerves (e.g., ulnar), development of a compartment syndrome, or interference with delivery of drugs through an intravenous (IV) line. For example, propofol sequestered in a forearm during BP-cuff inflation can cause intense pain. The latter can be avoided by routinely placing the BP cuff on the extremity *without* the peripheral IV. In circumstances in which the scheduled surgery involves an upper extremity, the BP cuff and IV can be placed on the contralateral arm (brachium or antebrachium), with the caveat that the NIBP be configured so BP measurements are recorded in the manual mode to prevent unexpected disruption of the delivery of IV induction drugs. Alternatively, a lower extremity (thigh or calf) can be used for BP measurements.

In morbidly obese patients, it is not unusual to have to relocate a BP cuff from the upper arm because of the cone shape of the extremity. An alternative BP monitoring site is the forearm. However, NIBP measurements taken in the forearm with the patient in supine or sitting position or the head of the bed elevated 45 degrees can *overestimate* the more proximal brachial BP.[102,103] Formulas have been proposed to correct for such discrepancies. For example, in an obese patient with a diastolic forearm pressure of 80 mmHg and arm circumference between 32 and 44 cm, the adjusted DBP would equal 72.4 mmHg. This is derived from the following equation:

$$\text{Brachial DBP} = 25.2 + 0.59 \times \text{Forearm DBP}$$

This formula was proposed relative to 129 subjects with an average body mass index of 40 ± 7 kg/m^2.[102] Discrepancies in BP measurements have also been noted between upper and lower extremities and between arms. In study participants up to 16 years of age, SBP has been shown to be *greater* in the thigh and calf than in the arm. In contrast, DBP and MAP are *lower* in the calf and thigh than in the arm.[104] Patients most likely to exhibit inter-arm BP differences are those who are obese and have a higher HR and SBP.[105] Concerns about accuracy also arise when measuring BP noninvasively versus invasively. One group of investigators found NIBP taken in the upper arm in patients with septic shock to correlate poorly with arterial-line pressure measurements, specifically causing an overestimation of MAP with the noninvasive technique.[106]

It is apparent that in the demographics of the population of the United States, a substantive change has occurred in recent years in the number of adults and children who are classified as obese. Consistent with this change are the findings that mean mid-arm circumference has increased across the country, with the greatest increase occurring in 20- to 39-year-olds. This change should cause anesthesia providers to be more attentive to the daily task of selecting properly sized BP cuffs. In fact, research has shown that up to 39% of all hypertensive patients and 47% of self-reported diabetic patients should not have their BP measured with the standard adult-size cuff.[107] Inattentiveness to this basic and essential monitoring need could cause the anesthetist to process inaccurate hemodynamic data (e.g., overestimated BP recordings) and ultimately contribute to a poor surgical outcome.

Direct measurement of arterial BP is considered by many the gold standard for recording BP. Many anatomic locations can be used for direct BP measurement, with the most common being the radial artery. Other less commonly used arteries are the ulnar, brachial, axillary, femoral, and dorsalis pedis. Risks associated with placement of an intraarterial catheter include infection (localized and systemic), thrombus formation, hematoma, vasospasm, embolization, injury to adjacent nerves and veins, ischemia to extremities or digits, loss of a limb secondary to poor collateral circulation, iatrogenic injuries (e.g., air embolization, intraarterial injection of drugs meant to be administered intravenously), and acute blood loss due to an unexpected disruption of the transducing system (e.g., cracked or disconnected stopcock). A displaced transducer (no longer level with the phlebostatic axis) can cause an "increase" in arterial blood pressure if positioned substantially below the level of the heart. Assessment of an abnormal BP recording should include an understanding of problems inherent to a fluid-pressure monitoring system. To mitigate the ongoing risks of direct arterial BP monitoring, constant vigilance on the part of the anesthetist is paramount.

Monitoring BP directly offers several distinct advantages, including beat-to-beat assessment of BP, limited hysteresis in measured values, and easy access for arterial sampling of blood for any number of laboratory tests (e.g., arterial blood gases, serum

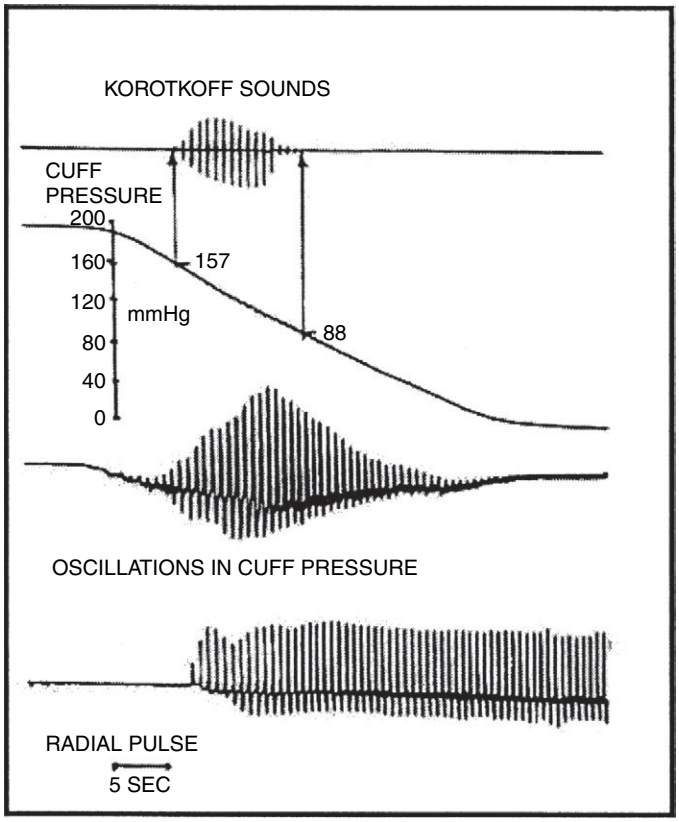

FIGURE **16-21** Arterial blood pressure, comparing Korotkoff sounds, oscillations with a blood pressure (BP) cuff, and radial artery palpation. Note correlation between onset of the first Korotkoff sound, onset of oscillations in the cuff pressure, and radial pulse wave. (From Saidman LJ, Smith NT, eds. *Monitoring in Anesthesia.* New York: Wiley & Sons; 1978.)

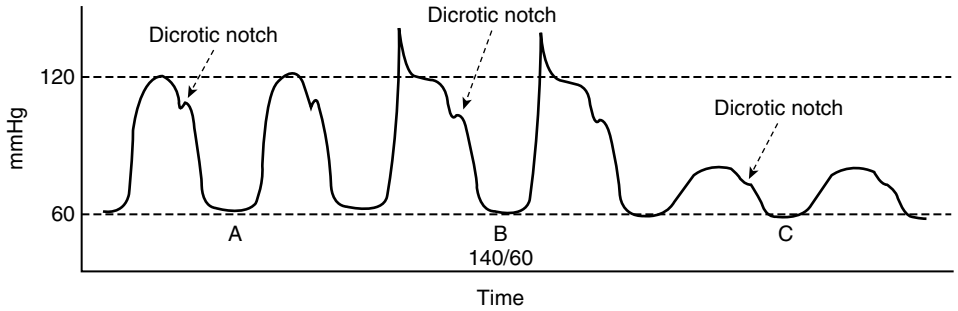

FIGURE **16-22** Radial arterial pressure waveforms. *(A)* normal morphology, *(B)* overshoot, *(C)* dampened. With waveform B, the overshoot should be ignored regarding the displayed systolic blood pressure.

electrolytes, glucose, hemoglobin levels). Indications for direct arterial BP monitoring include surgical procedures in which there is potential for acute and/or gross changes in hemodynamics. This would include operations such as repair of aortic aneurysms, carotid endarterectomy, and craniotomies. Even with lower-risk surgical procedures, direct arterial BP monitoring may be indicated, particularly if preoperative BP is poorly controlled (labile). Patients with comorbidities may be at substantial risk for a stroke or heart attack during periods of acute stress (e.g., laryngoscopy or emergence from an anesthetic) if BP is not directly monitored.

Risks associated with placement of a radial artery catheter can be minimized if precautionary measures are taken. This would include positioning of the hand and wrist on an armboard. A roll should be placed beneath the wrist, and the fingers and thumb should be taped securely across the board. This position keeps the hand from interfering with manipulation and placement of the needle-catheter system; it also facilitates palpation of the radial artery. Commonly, a 20-gauge nontapered catheter is used (a 22-gauge is optional) to penetrate an area of skin that has been prepped with antiseptic solution and infiltrated with local anesthetic. The needle, bevel pointing upward, is directed at a 45-degree angle toward the palpated pulse. If bone is encountered with the tip of the needle during advancement, the complete catheter system (catheter and needle) is slowly withdrawn while observing for the free flow of arterial blood; sometimes the artery can be pierced without a "flash back" (unintentional transfixion-withdrawal method). If during catheter withdrawal no blood is seen, the needle system is directed slightly laterally (in either direction) and readvanced. Once arterial blood is seen in the lumen of the catheter, the angle of the needle is reduced to approximately 30 degrees, then advanced slightly (a few millimeters). The catheter is subsequently threaded off the needle. "Fatigue" at a puncture site may occur, at which time a new artery may be chosen to cannulate or a "fresh set of hands" (perhaps another anesthesia provider or member of the surgical team) used to repeat the attempt at arterial puncture. After verifying correct placement of the catheter within the lumen of the artery (free flow of blood through the rigid tubing when vented to air), it is important to securely fasten the arterial catheter to the skin, preferably with suture and a sterile dressing applied on top of the puncture site.

The transducing system should be zeroed to atmospheric pressure (with the stopcock vented to air) and referenced at the level of the left atrium. In patients with poor vascular compliance, the arterial tracing can produce an "overshoot" or "ringing" phenomenon. If not recognized, BP recordings will overestimate SBP and MAP values. In contrast, a dampened waveform, which can develop with a flexed wrist or low pressure in the continuous-flush device, can lead to an underestimation of BP recordings (Figure 16-22). Direct arterial pressure measurements, although very accurate in many clinical circumstances, can still produce BP recordings that are significantly skewed and lead to inappropriate interventions (e.g., preload augmentation, indiscriminate use of vasoactive drugs).

TRANSESOPHAGEAL ECHOCARDIOGRAPHY MONITORING

Transesophageal echocardiography (TEE) has been established as a safe, noninvasive diagnostic tool for monitoring numerous cardiac parameters to guide medical and nursing care. Systolic wall motion abnormalities (SWMA), vascular aneurysms, calculation of ejection fraction, ventricular preload, and measuring blood flow within heart chambers and across valves are a few of the utilities of ultrasound imaging applied during TEE. Guidelines for indications and training proficiency have been advocated by medical professional societies.[108,109]

Sound waves used to define anatomic structures in the human body were first described by Dussik and colleagues in 1947. These investigators attempted to outline the cerebral ventricles by driving sound waves across the skull.[110] In 1971, C.D. Side and R.G. Gosling were the first to report the assessment of cardiac function via transesophageal techniques.[111] Forty years later, substantial advancements in the medical application of ultrasound have occurred, leading in some circumstances to an improvement in surgical outcomes.[112] Fundamental to the interpretation of data obtained by TEE is an understanding of the physics of ultrasound. Ultrasound waves are inaudible to the human ear, having a frequency greater than 20,000 Hz. Piezoelectric crystals are known to produce ultrasound by vibrating when exposed to an electric current. The opposite also occurs, in that they produce voltage in response to an ultrasound echo or when pressed (mechanical stress) or released. The electric current produced has been shown to be of sufficient magnitude to temporarily illuminate a small bulb. Thus they function as both generators and receivers of ultrasound waves and electric currents.

Within the esophagus, ultrasound waves emitted by piezoelectric elements are absorbed, reflected, or scattered. When reflected by an organ (e.g., heart), the ultrasound echo produced is received by the piezoelectric elements housed within the TEE probe. These elements then generate an electrical impulse that is processed, amplified, and subsequently displayed as an image on the echograph machine. Manufacturers can place as many as 32 linearly arranged elements within a probe (Figure 16-23). The frequency of the piezoelectric crystals in TEE probes ranges from 3.7 to 7 MHz. This frequency range allows for greater detail in displayed images. Unfortunately, the tradeoff for clearer images is lower tissue penetration. Thus smaller frequency values (e.g., 2.5 MHz) are required in transthoracic echocardiographic (TTE) probes because of greater distances between elements and distal anatomic structures.

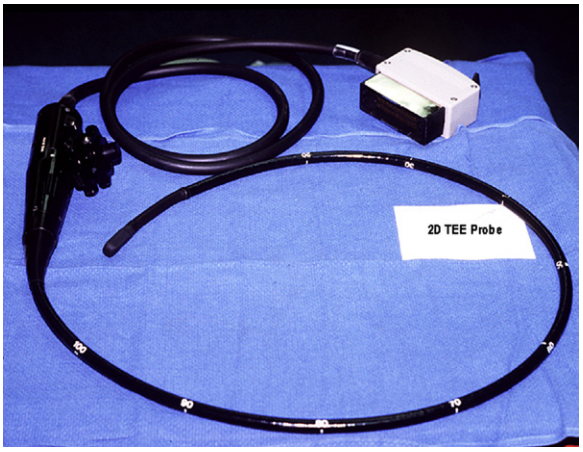

FIGURE **16-23** A 170-cm transesophageal echocardiography probe with cm markings is displayed. Examination depth is approximately 35 to 40 cm from teeth. The positioning-holding mechanisms are located on control knobs, allowing for manipulation of the probe in the anterior, posterior, and lateral planes. *2-D TEE*, Two-dimensional transesophageal echocardiography.

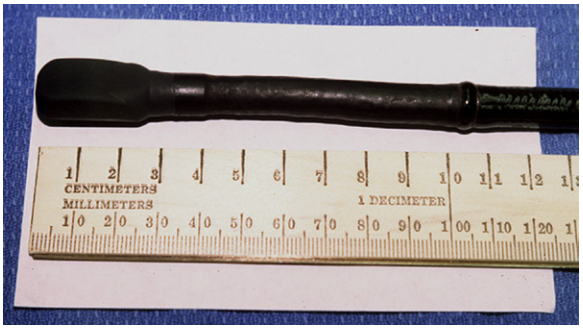

FIGURE **16-24** Transesophageal echocardiography probe. Distal tip contains thermistor and piezoelectric elements.

Clinically, three primary ultrasound imaging techniques are used: the M-mode, 2-dimensional (2-D) imaging, and the Doppler exam. The M-mode provides high picture resolution with 1000 images per second. It is commonly referenced as being unidimensional and produces a well-focused, narrow ultrasound beam. It is sometimes referred to as an *ice-pick view*. With the 2-D scan, the ultrasound beam is electronically steered across a target field. The intermittent pulses of ultrasound are produced by varying the firing sequence (phasing) of individual piezoelectric crystals. The monitor subsequently displays an image that is somewhat triangular or appears as a "slice" of pie. This produces excellent spatial orientation; however, at 30 images per second, the pictures are less well defined. The Doppler exam incorporates the concept of frequency shift, which was first described in 1842 by Austrian physicist Christian Doppler. The clinical application of this concept involves viewing red blood cells (RBCs) as moving reflectors of ultrasound. As ultrasound reflects off the moving RBCs, echos are produced, which are then recorded by the TEE transducer. With the flow of RBCs toward the TEE probe, the distance between the sound source and its reception is changing. This phenomenon is referred to as a *frequency shift*. It is analogous to the change in pitch of a train whistle as the locomotive approaches the station; sound waves are compressed, and the pitch increases (frequency shift). In contrast to RBCs, body fluids (plasma) only minimally reflect ultrasound. Spectral and color-flow Doppler exams performed with echographs incorporate this concept by assigning different colors to RBCs that move toward and away from the source of ultrasound. This permits easy visualization of retrograde flow of blood across incompetent heart valves, as may occur with mitral regurgitation (MR). For example, the retrograde flow of blood from the left ventricle into the left atria during MR is seen distinctly as a mosaic pattern of color. Doppler exams are recognized as being beneficial in determining the etiology of regurgitation and the adequacy of valve repair, as well as influencing surgical management, such as the use or nonuse of cardiopulmonary bypass.[109,112]

Fundamental elements of the TEE exam include positioning the TEE probe in the esophagus, either under sedation or after induction of the anesthetic (Figure 16-24). During the examination, cardiac anatomy can be assessed, myocardial ischemia diagnosed via the presence of SWMA, and blood flow through heart chambers and across valves seen. By convention, the posterior structures are displayed at the top of the screen (apex of the sector) and anterior structures at the bottom. The first image displayed in a standard exam is the short-axis view of the aortic valve. At a depth of approximately 35 to 40 cm from the teeth, the aortic valve leaflets and coronary arteries are seen. Rotation and angulation of the probe can allow a long-axis view of the right and left atria, tricuspid and mitral valves, pulmonic and aortic valves, and right and left ventricles. This view is useful for assessing stenotic valves, identifying masses within the atria or ventricles, and observing the overall size of each heart chamber. A short-axis view of the left ventricle can be obtained with further advancement of the probe and angling of the tip. This position is also referred to as the *standard monitoring view*, which allows the echocardiographer to assess for SWMA. Normal ventricular wall motion (which is not entirely uniform) thickens during systole, and the endocardial surface moves inward. Approximately 87% of the normal stroke volume is derived from shortening in the short axis of the ventricle—with little contribution from the long axis.

Abnormal wall motion can be described by three terms: hypokinesia, akinesia, and dyskinesia. *Hypokinesia* represents contraction that is less vigorous than normal; wall thickening is decreased. *Akinesia* depicts the absence of wall motion and can be associated with myocardial infarction. *Dyskinesia* correlates with paradoxical movement (i.e., outward motion during systole) and is a hallmark of myocardial infarction and ventricular aneurysm (Figure 16-25). Not all wall motion abnormalities are diagnostic of an imbalance between myocardial oxygen supply and demand. Abnormal loading conditions, asynchronous ventricular depolarization (e.g., left bundle branch block), echo dropout due to haphazard reflection of ultrasound off myocardial walls in lateral fields of the sector arc, or improper use of the gain controls of the TEE probe can lead to an erroneous diagnosis of SWMA. Also, the duration of SWMA can persist well after coronary reperfusion has been restored (e.g., 6 hours), indicating a stunned myocardium.[113] In canine research, a 50% decline in coronary blood flow has been shown to serve as a threshold for hypokinesia. In contrast, a 75% reduction in coronary blood flow commonly produces ST-segment deviation. Thus there is greater hysteresis and less sensitivity with ischemia-induced ECG changes than with ischemia-induced SWMA.[114,115] This finding is consistent with classic research done by Tennant and Wiggers in 1935.[116]

To summarize, the best single view for routine monitoring for SWMA (myocardial ischemia) is the short axis at the midpapillary muscle level (see Figure 16-25), followed by the apical segment in the same axis. The midpapillary muscle level includes segments of the myocardium perfused by all three coronary arteries. This level is created by dividing the long axis of the left ventricle into

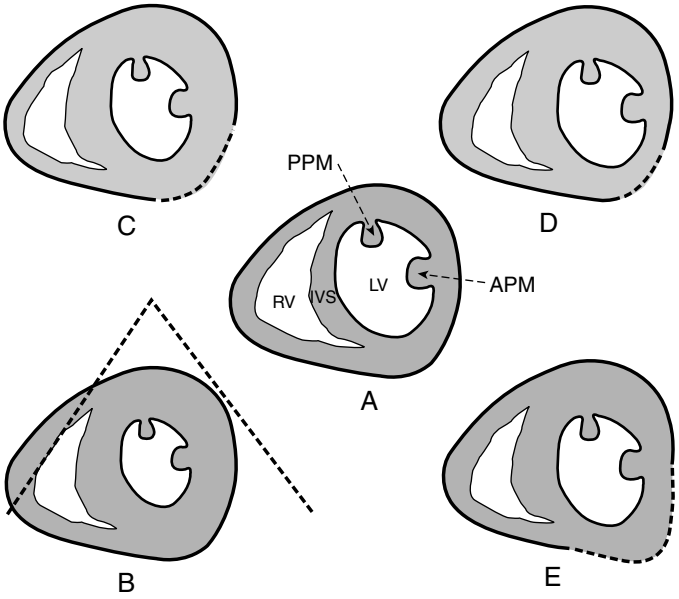

FIGURE **16-25** Midpapillary muscle level short-axis view of the heart **(A)** during diastole, **(B)** during systole with normal wall thickening and inward movement of endocardial surface, **(C)** systole with area of hypokinesia (decreased wall thickening), **(D)** systole with an area of akinesia (no change in wall thickness), and **(E)** systole with an area of dyskinesia (paradoxical movement). *APM*, Anterior papillary muscle; *IVS*, interventricular septum; *LV*, left ventricle; *PPM*, posterior papillary muscle *RV*, right ventricle.

three parts (i.e., basal, mid-, and apical regions). The mid-region extends from the tips to the bases of the papillary muscles. Interesting is the finding that the skills required of anesthesiologists, residents, and CRNAs (compared with trained observers) for recognizing gross SWMA can be acquired with little training; the study group successfully identified 95% of regional wall motion abnormalities.[117]

Newer imaging techniques introduced with TEE include contrast echocardiography, selected three-dimensional techniques, parametric imaging modes, and harmonic imaging modalities. Continued research with these echocardiographic diagnostic tools will help elucidate what patient populations may benefit most from their application. Recent investigations have shown that real-time, three-dimensional (3-D) echocardiography is a feasible way to estimate the area of the aortic valve orifice in patients with stenotic lesions and to evaluate patients with suspected CAD for myocardial wall motion and perfusion abnormalities.[118,119] Also of interest was porcine research that showed intracardiac transvenous echocardiography (ICE) to be superior to precordial Doppler and TEE techniques in diagnosing venous air embolism and retrieving as little as 0.05 to 1 mL of air.[120]

SUMMARY

With continued advancements in technology and improved clinical databases derived from research, future monitoring techniques offer promise for continued improvement in anesthesia care. The development of specialized task forces comprising multiple professional societies also contributes substantively to professional practice. Understandably, anesthesia providers should continue to maintain a healthy skepticism of reported advancements in monitoring modalities. The decision to change practice routines should occur only after critiquing the reported merits of any research findings. Ultimately, this clinical paradigm will allow patients to benefit from medical and nursing care derived from evidence-based practice.

Clinical Monitoring II

Respiratory and Metabolic Systems

◆ *Gregory Bozimowski*

CHAPTER 17

"Every breath you take, every move you make…I'll be watching you."

(Sting, 1983)[1]

The lyrics to the song, "Every Breath You Take" were written decades ago and refer to a stalking, obsession-based relationship and yet, when considered in an anesthesia monitoring context, they succinctly define the contract between the nurse anesthetist and the patient undergoing anesthesia care. Clinical monitoring in the perioperative setting is the process of observing physiologic responses to surgery and anesthesia. It is the essence of what the Certified Registered Nurse Anesthetist (CRNA) does to ensure an optimal, safe outcome.

It is important to note that the modalities chosen to obtain physiologic feedback may or may not lead to a reduction in patient morbidity and mortality.[2] Research provides rationale to support the standardization of minimal monitoring modalities. Standards are available to the anesthesia provider from both the American Association of Nurse Anesthetists (AANA) and the American Society of Anesthesiologists (ASA).[3,4] It is a matter of clinical judgment by the anesthetist that determines what modalities beyond those minimally required will provide useful information when added to the anesthetic plan of care. It is through this evidence-based approach that best practices are developed.

It is important to emphasize that despite advancements in technology, human vigilance must be maintained and considered primary in assessing patient responses to anesthesia. Human error is always possible and often associated with adverse outcomes. Monitoring alone cannot prevent adverse outcomes, but a timely response to warnings can have a positive impact.[5] It cannot be emphasized enough that reliance on technology must never be allowed to lull the clinician into complacency. Although accuracy and reliability of monitors continue to improve, the potential for machine malfunction and artifact is ever present. Timely human response to intraoperative events remains the key to predicting, avoiding, and managing untoward responses to anesthesia and surgery. The basic human senses of sight, hearing, touch, and even smell remain the primary tools in clinical monitoring. The patient is the primary source of assessment data.

This chapter reviews current monitoring standards as outlined by the AANA. In addition, a practical systems approach to monitoring is presented as it relates to the avoidance of critical incidents. Respiratory monitoring is reviewed as it relates to the ongoing assessment of airway and breathing using not only the human senses but also technologic tools used by nurse anesthetists. The modalities to be discussed in this chapter include the precordial stethoscope, carbon dioxide detection devices, and pulse oximetry. Thermoregulation is significantly altered under anesthesia, so temperature monitoring modalities are reviewed in this chapter. Finally, implications for the education of nurse anesthetists and the future of clinical monitoring are visited.

MONITORING STANDARDS

Monitoring standards are published and reviewed by anesthesia professional associations so that minimal standards in the provision and monitoring of care can be recommended. Such standards are intended to provide guidance to anesthesia providers and healthcare facilities in evaluating quality care and developing and improving the safety of practice while educating the public regarding patient rights and expectations. Standard V of the AANA *Scope and Standards for Nurse Anesthesia Practice* outlines specific monitoring requirements necessary for compliance (Table 17-1).[4] The standards acknowledge the importance of vigilant monitoring as the basis of safety in anesthesia practice. In addition, the standards point out that the CRNA must constantly be in attendance of the patient until the responsibility for care can be safely transferred to another qualified healthcare provider. They further state that these are intended to be minimum requirements and should be exceeded as deemed necessary in the judgment of the anesthetist. In most cases, when certain monitoring modalities are not used, they must be at least immediately available. The AANA interpretation specifically indicates that alarm limit parameters and audible warning systems should be used, and a specific statement is made recommending the use of variable pitch alarms. The value of variable pitch commonly used in pulse oximetry equipment has been widely appreciated for its ability to provide information regarding subtle changes in oxygen saturation using the sense of hearing, prior to visualizing the monitor. Alarms are designed to protect the patient by alerting the practitioner that the individual is at increased risk and needs immediate assistance.

An area of concern related to electronic monitoring devices is a phenomenon referred to as *alarm fatigue*. Alarm fatigue can be defined as a type of human error occurring when a practitioner is desensitized to alarms or alerts.[5,6] The ideal alarm would be easy to localize and recognize. It would be evident despite other noises and alarms, yet would allow for effective communication between care providers. The ideal monitoring device would also elicit a minimal number of false alarms. Alarms in many medical devices fall short of the ideal and as a result are subject to being ignored or even disabled by the practitioner—a very dangerous practice. Biomedical specialists continue to develop and perfect alarms to improve their usefulness in alerting the clinician to significant changes in patient status.[7]

The ever changing and developing technologic capabilities warrant that these standards also allow for consideration of new monitoring modalities as they are introduced. It is important to note that the type of anesthetic given may influence the specific monitoring needed but should not be a factor in considering the level of vigilance or accessibility of advanced monitoring and interventional equipment.

TABLE 17-1 Scope and Standards for Nurse Anesthesia Practice

Standard V	
Monitor the patient's physiologic condition as appropriate for the type of anesthesia and specific patient needs	
Parameter	**Modifier**
Monitor ventilation continuously	Verify intubation of the trachea by auscultation, chest excursion, and confirmation of carbon dioxide in the expired gas; continuously monitor end-tidal carbon dioxide during controlled or assisted ventilation including any anesthesia or sedation technique requiring artificial airway support; use spirometry and ventilatory pressure monitors as indicated
Monitor oxygenation continuously	By clinical observation, pulse oximetry, and if indicated, arterial blood gas analysis
Monitor cardiovascular status continuously	Via electrocardiogram and heart sounds; record blood pressure and heart rate at least every 5 minutes
Monitor body temperature continuously	On all pediatric patients receiving general anesthesia and when indicated, on all other patients
Monitor neuromuscular function and status	When neuromuscular blocking agents are administered
Monitor and assess the patient positioning	Assess and institute protective measures

TABLE 17-2 Crisis Management Algorithm

Algorithm	**Descriptor**
C—Circulation, Color	Determine adequacy of circulation, check pulse, blood pressure; ECG notes oxygenation through assessment and oximetry
O—Oxygen, Oxygen analyzer	Check oxygen delivery system, hypoxic guard
V—Ventilation, Vaporizer	Ventilate by hand to assess breathing circuit and airway patency, assess chest excursion and auscultation; assess $ETco_2$; check vaporizer function
E—Endotracheal tube	Systematic assessment of ETT if used, including patency, seal, etc
R—Review monitors, Review equipment	Review all monitors in use, assure appropriate calibration and maintenance, review any and all equipment in contact with the patient
A—Airway	Check patency of the unintubated airway, assess for laryngospasm, foreign body, etc
B—Breathing	Assess pattern, rate, and depth of respirations; examine, auscultate, and review $ETco_2$ and pulse oximeter monitors
C—Circulation	Repeat assessment of circulation
D—Drugs	Review drugs given; consider needed pharmacologic intervention; consider possibility of medication administration error

ECG, Electrocardiogram; *$ETco_2$*, end-tidal carbon dioxide concentration; *ETT*, endotracheal tube.

SYSTEMATIC APPROACH TO MONITORING

A systematic, evidence-based process shown to be effective in reducing anesthetic morbidity and mortality should be the goal when planning appropriate monitoring to be used. As monitoring standards guide practice by prescribing minimums to be adhered to, other processes can be helpful in defining how monitoring should occur and which modalities should be used. In the spirit of learning from previous errors or untoward events, closed-claim studies can provide valuable insight into monitoring techniques and habits that could be useful in preventing future anesthesia mishaps. Incident monitoring systems and practices can be used to collect data for practitioners to use to develop safer processes as in the often referenced analogies made to the aviation industry.[8] In a manner of speaking, clinical monitoring can be thought of as a means to avoid critical incidents.

The act of administering anesthesia results in a physiologic response to the pharmacodynamics and pharmacokinetics of each substance given. The insult of the surgical or diagnostic procedure performed also results in a physiologic response. As such, observation of the human systems response is the monitoring of the pharmacology of the agents used and the physiology of the human system. As the science and process for quality assurance and improvement have evolved, much has been learned and written about the value of a systematic approach to the analysis of critical incidents and crisis management. The concepts used in quality assurance management are therefore easily applied to anesthesia monitoring because a primary function of the nurse anesthetist is to prevent or respond to critical incidents. A systematic approach to clinical monitoring provides a means of ensuring timely responses to physiologic changes presented by the patient.

Many algorithms and protocols have been written to guide the practitioner through the monitoring process and ensure thorough, vigilant observation. Simple, systematic approaches to crisis management are often focused on or derived from the common algorithm "ABC," representing airway, breathing, and circulation. In an anesthesia context, additional foci for monitoring can include color (i.e., cyanosis), oxygen and oxygen analyzers, ventilation, vaporizer or pump settings and status, endotracheal tube patency and placement, monitors and equipment, and drug effects, thereby expanding the crises response algorithm to COVERABCD (Table 17-2).[9] There is an enormous value in developing a systematic approach to monitoring. The habit sometimes referred to as "sweeping" the anesthesia field to visualize the patient, with the eyes following a path to the anesthesia machine via the airway and breathing circuit and progressing to the monitoring modalities used, has long been taught as a means of increasing vigilance and attention to detail.

Review of critical incidents has provided insight into how clinicians can enhance safety and prevent mishaps through their use of monitors with alarms. Closed-claims review of various databases supports the notion that vigilance remains a key point, and respiratory events are of particular concern.[10] It has been suggested that in cases in which anesthesia is provided outside of the operating room, (e.g., a rapidly growing practice in which monitoring may not be as focused as in a standard anesthetizing area), the number and severity of liability claims may be increased.[11] The well

known mantra of the ABCs—observing the Airway, Breathing (respiration), and Circulation—remains foremost and critical in anesthesia clinical monitoring. Monitoring drug effects completes the basic monitoring approach. The monitoring of cardiovascular circulation is addressed in Chapter 16. The monitoring of the neurologic system can be found in Chapter 18.

Airway Monitoring

Monitoring the airway includes the observance of gas exchange from the upper to lower airways. Assessment of airway patency is performed in very subtle yet essential ways. Ventilatory movement of the chest must be observed and the presence of any sign of airway obstruction such as retractions, or seesaw motion of the chest and abdomen, is noted. Seeing the presence of condensation in an airway device or clear mask can serve to indicate the presence of gas exchange. The sense of touch can be used to perceive subtle movement of air exchange felt on the hand of the anesthetist. The sense of smell can be the first aid in detecting a disconnected circuit or airway device when volatile agents are being used. Listening for the presence of abnormal airway sounds such as stridor is crucial in noting airway obstruction. The precordial stethoscope is a valuable tool in auscultating the presence or absence of airway exchange during all phases of the anesthetic, regardless of the type administered. Ensuring adequacy of ventilation, whether an endotracheal tube or laryngeal mask airway is in use, must include verification of placement by assessing breath sounds and chest expansion, as well as verification of the presence of carbon dioxide (CO_2) in the expired gas.[3] While failure to successfully intubate is problematic, failure to recognize misplacement is catastrophic.

Respiratory Monitoring: Ventilation

Monitoring respiratory parameters is aimed at evaluating both ventilation and oxygenation. The patient must be observed for adequate minute ventilation throughout the anesthetic course. At the most basic level, this is accomplished through visualization of chest excursion and auscultation of breath sounds. The value of the precordial or esophageal stethoscope is twofold: it provides continuous assurance that ventilation is occurring and can be used to detect changes in breath sounds. Assessing the respiratory rate and tidal volume (rate alone is not adequate to determine adequacy of ventilation) is crucial to ensuring adequacy of minute ventilation, as well as interpreting patient response to pharmacologic agents and surgical stimuli.

Skin and nail bed color should be observed as part of the whole patient-assessment picture; however, skin color changes alone are not a reliable measure of whether ventilation and oxygenation are adequate. Cyanosis is a late sign of anemia or hypoxia and can be difficult to assess accurately, given such variables as differences in lighting during certain procedures and lack of controls in comparisons of patients' coloring throughout the perioperative period to name a few. Besides physical assessment skills, monitoring the adequacy of ventilation must be done throughout the perioperative period, using multiple parameters. Several themes are evident that relate to safety and vigilance in monitoring when reviewing closed-claims studies for anesthesia incidents. The most prominent of these is the value of certain specific monitors and their alarms. These include pulse oximetry, end-tidal carbon dioxide measurement, oxygen analyzers, and disconnect alarms. Of equal importance is the users' ability to assure the proper function of these prior to administering an anesthetic.[10]

Carbon Dioxide Monitoring

The measurement of arterial blood gases to determine level of carbon dioxide provides direct measurement of ventilation and metabolic status, and the necessity of this action may be indicated at times. The means of measuring the carbon dioxide tension in the blood (Pa_{CO_2}) is based on hydrogen ion concentration because CO_2 reacts with water to produce hydrogen ions through a reversible reaction. This reaction yields carbonic acid, which dissociates to yield hydrogen and bicarbonate ions,[12] as shown in the following equation:

$$CO_2 + H_2O \leftrightarrow H_2CO_3^- \leftrightarrow H^+ + HCO_3^-$$

The production of carbonic acid also allows for the qualitative—and to a limited extent, quantitative—detection of the presence of carbon dioxide through the use of disposable end-tidal carbon dioxide (ET_{CO_2}) detector devices. These colorimetric devices react to changes in pH and display it as a color change. They are widely used in emergency settings to verify proper placement of an endotracheal tube.[13] Although these devices are sensitive enough to detect carbon dioxide quickly, a minimum of six breaths has been suggested to avoid misinterpretation. False positives may result from the detection of CO_2 from air forced into the stomach during mask ventilation or the presence of carbonated beverages or antacids in the stomach.[14]

The means to measure CO_2 level must be based on the patient's condition, the type of anesthetic administered, and the complexity of the surgical procedure. The continuous measurement of carbon dioxide in expired gas provides a practical, noninvasive, and accurate reflection of arterial blood carbon dioxide and is the most common means of monitoring carbon dioxide levels in the anesthesia setting. It is also a monitoring standard of care during general anesthesia, for the patient being ventilated or whose ventilations are being assisted. In addition, the ASA monitoring standards state that "during moderate or deep sedation the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs and monitoring for the presence of exhaled carbon dioxide unless precluded or invalidated by the nature of the patient, procedure, or equipment."[3] Accuracy of ET_{CO_2} as a correlation with arterial carbon dioxide has been well documented. End-tidal CO_2 is said to be approximately 2 to 5 torr lower than arterial CO_2 in patients who have no cardiac or pulmonary abnormalities.[14] *Capnometry* is a term that encompasses all means of measuring carbon dioxide, whereas *capnography* refers to the recording of the measurement. The term *capnogram* is used to describe a continuous display of carbon dioxide during the phases of ventilation. The continuous measurement of ET_{CO_2} is accomplished through the use of infrared analysis. When a gas mixture containing more than one substance, (e.g., an exhaled gas sample) is analyzed, a quantitative measurement can be made to determine the proportional contents. Each gas in the mixture absorbs infrared radiation at a different wavelength. The amount of CO_2 is measured by detecting its absorbance at specific wavelengths and filtering the absorbance related to other component gases. Older monitors had difficulty distinguishing between nitrous oxide and CO_2, but this fault is corrected in current models.[12]

Sampling of ET_{CO_2} can be accomplished through either a nondiverting (also known as *mainstream*) or diverting (also known as *sidestream*) monitor. A nondiverting monitor measures gas directly within the breathing system. Gas passes through a wide-chambered sensor that fits over a connector between the anesthesia circuit and mask adapter. The sensor is connected to the monitor by a cable. Nondiverting monitors offer several advantages. They have

minimal sampling-time delays, use few disposable items, and do not require scavenging because gas is not removed from the system. Disadvantages include the inability to measure gases other than CO_2 and nitrous oxide, an increase in circuit deadspace by the adapter, and greater risk of interference by condensation and secretions. Also, because the sensor and cable are attached in proximity to the patient, the added weight may cause traction on the tube, increase the risk of circuit disconnect, and make sampling in a nonintubated patient difficult.

The other more commonly used CO_2 monitor type is the diverting monitor. The diverting monitor extracts gas from sample tubing attached near the patient end of the circuit and pumps it to the monitor. Disadvantages include the need for scavenging of sampled gases because they are removed from the circuit and some risk of contamination by condensation or secretions exists. Advantages of the diverting system include minimal increase in deadspace and versatility in gas analysis because the sample can also be sent to anesthetic agent monitors. In addition, the small, lightweight tubing can be adapted to sample awake, spontaneously breathing patients through the mouth, nares, or simple mask.[14]

It has become common to adapt the sampling line of a diverting $ETCO_2$ monitor to trace a capnogram in awake or sedated, spontaneously breathing patients receiving O_2 via simple mask or nasal cannula. Nasal cannula tubing already equipped with a sampling line is commercially available. It has been shown that sampling $ETCO_2$ in the spontaneously breathing patient's hypopharynx is reliable and accurate and that the exact position and use of supplemental O_2 flow will not affect reliability.[15] The use of $ETCO_2$ monitoring as a warning of hypoventilation or excess sedation has gained attention outside of the anesthesia setting. For example, $ETCO_2$ monitoring has been shown to be a more sensitive indicator of hypoventilation than clinical observation or pulse oximetry when used during sedation in the emergency department setting.[16] Other studies note the value of $ETCO_2$ monitoring during sedation as well and note the advantage over pulse oximetry alone in detecting hypoventilation in patients receiving supplemental O_2. It has been suggested that like pulse oximetry, $ETCO_2$ monitoring should be considered a standard of care for patients receiving sedation outside the operating room.[17]

End-Tidal Carbon Dioxide Capnography. Capnography can record CO_2 as a component of expired lung volume or as a measure of CO_2 alone throughout the phases of respiration plotted against time. Time capnography is most commonly used in the perioperative setting. Basic interpretation of the $ETCO_2$ capnogram is a necessary skill. The capnogram can differentiate between normal and abnormal patterns of ventilation that result from patient pathologies, anesthesia system problems, or unexpected patient responses during anesthesia.

The normal time capnogram can be recorded at varying speeds. A fast speed setting of approximately 12.5 mm/second allows interpretation of individual respiratory components and short-term changes, whereas a slow speed of approximately 25 mm/minute displays long-term changes.[18] Although no standard descriptions exist for the components of the capnogram, it is typically described as encompassing four basic phases (Figure 17-1). These phases are often displayed in a classic waveform shape best recorded during mechanical ventilation in an intubated patient. It is important to note that the basic shape of the wave form will vary depending on the mode of airway management used (endotracheal tube, laryngeal mask airway, simple mask, nasal cannula, etc.) as well as in comparison to the spontaneously breathing patient.

Although the shapes may vary, the represented phases apply universally. The first phase is the end of inspiration and very

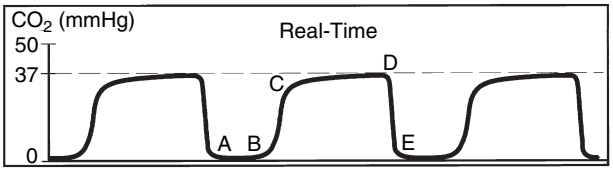

FIGURE **17-1** The four phases of a normal capnogram. *A-B* represents baseline; *B-C* represents expiratory upstroke; *C-D* represents expiratory plateau; *D* represents end-tidal concentration; and *D-E* represents descent to original baseline. (Courtesy Novametrix Medical Systems, Wallingford, Conn.)

beginning of expiration. Gas sampled at this point identifies the baseline. This sample comes from the anatomic deadspace and contains no CO_2. This portion in a normal capnogram should approximate zero. The second phase is the expiratory upstroke. Gas sampled represents a mix of deadspace and alveolar gas and thus records measurable CO_2. This phase represents the rapid passing of initial expired gas through the upper airways. The third phase represents the plateau and records alveolar emptying of CO_2. In the normal pulmonary measurement, the plateau is very nearly flat. This phase represents the longest duration of the measurement. $ETCO_2$ is measured at the end of the plateau just prior to the beginning of phase four. The fourth phase is displayed as the rapid decrease in CO_2 concentration of sampled gas as a result of inspiration of air or O_2. This downstroke returns the recorded CO_2 measurement to or very near to zero. Variations in the capnograph tracing can be very subtle and represent specific alterations in the ventilatory process. Some common deviations are worth noting. In the process of evaluating the capnogram, the anesthetist should note the respiratory rate, whether ventilation is spontaneous or mechanical, the value of measured end-expired CO_2, the shape of the recorded waveform, and the presence of additional respiratory efforts. Deviations from what is normally a close approximation of arterial CO_2 can occur. End-tidal CO_2 measurements may be inaccurate in the presence of significant ventilation and perfusion mismatching. When ventilation-to-perfusion ratio is large, the resultant increase in deadspace causes a low concentration of $ETCO_2$ overall.[19] In addition, small tidal volumes—reflecting inadequate alveolar ventilation—may produce $ETCO_2$ recordings that significantly underestimate arterial CO_2 levels. Some controversy exists as to the relative accuracy of capnography during laparoscopic procedures.[20]

After esophageal intubation, an initial, slight upstroke of carbon dioxide may be seen in those rare circumstances when carbon dioxide may be sampled from the stomach as mentioned previously in reference to disposable $ETCO_2$ detector devices. These CO_2 measurements are the result of excess air blown into the stomach during overzealous ventilation or a partially obstructed airway. Such a waveform will display for a very brief period and be followed by a measurement of zero. A waveform that fails to return to baseline during phases one and four indicates that rebreathing of carbon dioxide is occurring. This can be the result of inadequate fresh gas flow in the nonrebreathing system or a depleted or ineffective carbon dioxide absorber (Figure 17-2). Although this may be detected over time, it can be difficult to distinguish.

Sloping of the plateau phase represents a progressive prolongation of expiration. It is typically the result of either an obstruction of expired gas flow at some point along the airway or ventilation-perfusion mismatch (Figure 17-3). It also can be indicative of chronic obstructive lung disease because CO_2 is exhaled more slowly from diseased portions of the lungs (with more significant airway narrowing) than from areas with less severe narrowing.

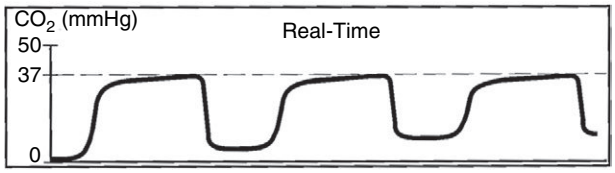

FIGURE **17-2** Elevation of the baseline indicates rebreathing. (Courtesy Novametrix Medical Systems, Wallingford, Conn.)

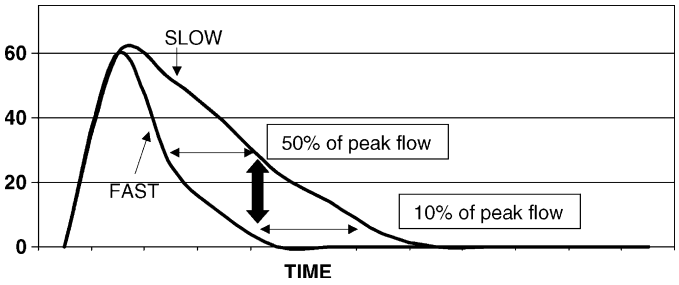

FIGURE **17-3** Inspiratory flow waveform demonstrating the effect of impedance on decay of flow. In a patient with stiff lungs (e.g., ARDS) and a fast time constant, flow decay is rapid. In the patient with normal compliance and high airway resistance (e.g., COPD), the flow decay is prolonged. In these two breaths with the same peak flow, 10% of the fast-time constant is equivalent to 50% of the slow-time constant. (From Branson RD. Functional principles of positive pressure ventilators: implications for patient-ventilator interaction. *Respir Care Clin N Am*. 11(2):2005; 119-145.)

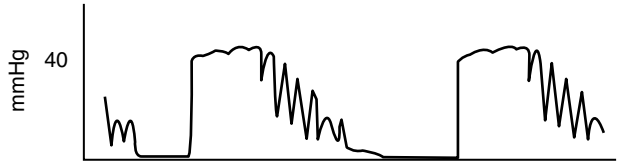

FIGURE **17-4** Cardiac oscillations occur as a result of contractions of the heart and great vessels. (From Miller RD. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010.)

Plateau-phase sloping also can occur with kinking of the endotracheal tube (ETT) or any aspect of the circuit tubing. Changes in the waveform from baseline normal should always be evaluated to determine the cause and necessary interventions.

Regular, saw-tooth waves within the expiratory phase at a rate equal to the heart are likely the result of cardiac oscillations (Figure 17-4). This is the result of the contraction of the heart and great vessels forcing gas in and out of the lungs. This is a common occurrence in pediatric patients owing to the relative size of the heart to the thorax.

During mechanical ventilation in an anesthetized and/or paralyzed patient, spontaneous respiratory effort may be seen if the anesthetic depth is insufficient to prevent respiration or when inadequate muscle relaxation is present. The resultant capnogram is often referred to as *curare cleft* (Figure 17-5). This irregular asynchronous waveform may occur within the mechanically ventilated wave or separate from it. Causes of increased or decreased end-tidal carbon dioxide levels are noted in Box 17-1.

Transcutaneous Carbon Dioxide Monitoring. As previously stated, accurate analysis of carbon dioxide reflects adequacy of ventilation. Transcutaneous CO_2 monitoring does not provide immediate, breath by breath verification of endotracheal tube placement, so its use is not common in the anesthesia care realm. Nonetheless, it is a reliable, noninvasive means of CO_2 measurement and can

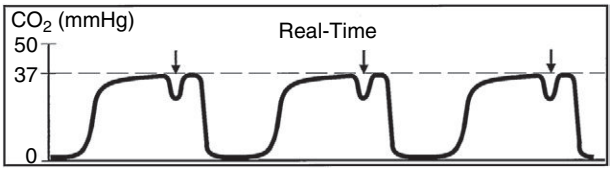

FIGURE **17-5** Clefts displayed as a spontaneous inspiration asynchronous with controlled ventilation. (Courtesy Novametrix Medical Systems, Wallingford, Conn.)

BOX 17-1

Causes of High and Low End-Tidal Carbon Dioxide

Increased PetCO2

Increased CO_2 delivery/production

Malignant hyperthermia, fever, sepsis, seizures, increased metabolic rate or skeletal muscle activity, bicarbonate administration/medication side effect, laparoscopic surgery, clamp/tourniquet release

Hypoventilation

COPD, neuromuscular paralysis or dysfunction, CNS depression, metabolic alkalosis (if spontaneously breathing), medication side effect

Equipment problems

CO_2 absorbent exhaustion, ventilator leak, rebreathing, malfunctioning inspiratory or expiratory valve

Decreased PetCO2

Decreased CO_2 delivery/production

Hypothermia, hypometabolism, pulmonary hypoperfusion, low cardiac output or arrest, pulmonary artery embolism, hemorrhage, hypotension, hypovolemia, V/Q mismatch or shunt, auto-PEEP, medication side effect

Hyperventilation

Pain/anxiety, awareness/"light" anesthesia, metabolic acidosis (if spontaneously breathing), medication side effect

Equipment problems

Ventilator disconnection, esophageal intubation, bronchial intubation, complete airway obstruction or apnea, sample line problems (kinks), endotracheal tube or laryngeal mask airway leaks

PetCO2, End-tidal carbon dioxide; CO_2, carbon dioxide; *COPD*, chronic obstructive pulmonary disease; *CNS*, central nervous system; *V/Q*, ventilation perfusion.

be useful in detecting hypoventilation. Transcutaneous CO_2 measurement is a noninvasive measure of Pa_{CO_2}. It can either estimate Pa_{CO_2} or determine trends in the measurement. Transcutaneous CO_2 monitoring can be accomplished using the same technology that is commonly used for measurement of oxygen saturation through pulse oximetry. The electrode used provides a measurement of CO_2 through measurement of H^+ ion change. Progress in the technical aspects of developing these monitors is beginning to be noted amongst researchers and clinicians.[21] Transcutaneous CO_2 monitors have gained notice for their value in analyzing analysis during circumstances in which ET_{CO_2} measurement may be inaccurate, as in the case of ventilation-perfusion mismatching. In

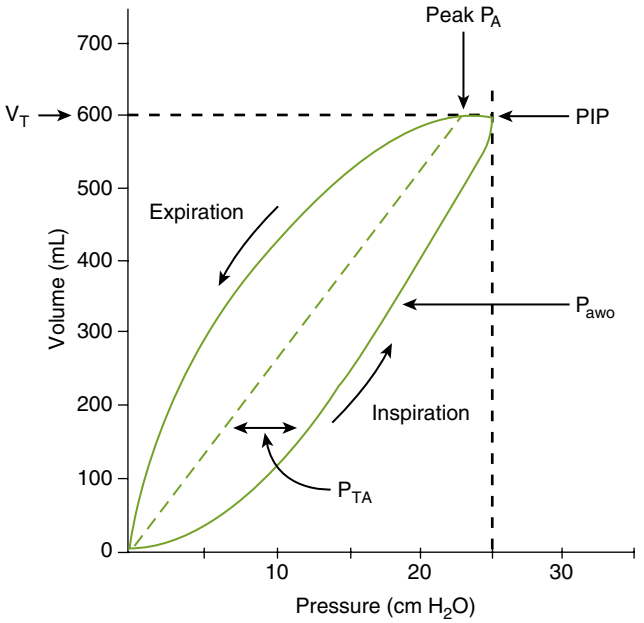

FIGURE **17-6** P-V loop showing the peak inspiratory pressure (PIP), pressure at the airway opening (Pawo), alveolar pressure (P_A), and transairway pressure (P_{TA}). (From Pilbeam SP, Cairo JM. *Mechanical Ventilation*. 4th ed. St. Louis: Mosby; 2006.)

such cases as severe obesity, which may affect ventilation-perfusion ratios as a result of reduced functional residual capacity, transcutaneous CO_2 monitoring may provide a more accurate estimate of arterial carbon dioxide than $ETCO_2$.[22] Transcutaneous carbon dioxide measurement may prove beneficial during one-lung anesthesia for thoracic surgery because it has been shown to provide a close correlation with arterial CO_2.[19] An added benefit of transcutaneous CO_2 measurement may be seen in monitoring the awake patient at risk of hypoventilation in whom $ETCO_2$ monitoring is impractical.

Flow, Volume, and Pressure Monitoring of Ventilation

Many modern anesthesia machines offer the ability to monitor spirometry loops. Observation of spirometry loops can provide rapid evaluation of changes in lung compliance and resistance. A spirometry loop is a graphic representation of a dynamic relationship between two respiratory variables: *flow and volume* or *pressure and volume*. Pressure-volume loops provide insight into lung compliance and show volume on a vertical axis and airway pressure on the horizontal axis (Figure 17-6). Flow-volume loops provide information on pulmonary resistance and show flow on the vertical axis and volume on the horizontal axis (Figure 17-7).

The forces that oppose lung expansion determine the compliance of the lung. In states of high compliance, minimal force is needed for expansion, and conversely, when compliance is low, higher force (pressure) is needed for lung expansion. Compliance is shown by a pressure-volume loop in Figure 17-6. The more upright, solid loop shows increased compliance in that greater volumes are achieved at lower pressures, as compared to the dotted loop showing decreased compliance, in that more pressure is needed to deliver the same tidal volume. Decreases in compliance will also show on a flow-volume loop as an increase in flow during exhalation and will have a higher peak and steep slope.[14] Decreases in compliance can occur as a result of pulmonary embolism, bronchoconstriction, pneumothorax, insufflation of the abdomen for laparoscopic surgery, or even inadequate muscle relaxation, to name a few causes. Compliance may be increased in emphysema, positive end-expiratory pressure (PEEP), or simply by resolving those factors that decrease compliance.[23]

Changes in resistance can also be detected by loop spirometry. An increase in resistance may occur when an endotracheal tube is kinked or blocked, when there is an airway obstruction, and when bronchoconstriction is seen. Mild bronchospasm may cause slight changes in the flow-volume loop, but as the spasm progresses, a decreased flow throughout exhalation can be seen. In a pressure-volume loop, increased resistance manifests as an increased pressure needed to deliver the same volume as that prior to the added resistance.[4]

Respiratory Monitoring: Oxygenation

While it may be a statement of the obvious, ensuring adequate oxygen delivery to the tissues is of paramount importance in the safe delivery of anesthesia. Monitoring of oxygenation follows the continuum of oxygen delivery from the source to the patient until distribution within the body. The anesthetist must evaluate the adequacy of the gas machine's delivery of O_2 and the efficiency of its delivery to the alveoli during ventilation. The anesthetist must be aware that oxygenation monitoring by itself only constitutes a part of the whole picture when considering the respiratory process. Hypoventilation, hypercapnia, and impending respiratory arrest can occur despite adequate oxygenation, particularly during the administration of supplemental O_2.[24]

Like ventilation monitoring, the means to ensure oxygenation uses multiple senses and technologies. Monitoring oxygenation starts with O_2 delivery analysis and is covered in depth elsewhere in the text. It is crucial to note that ensuring delivery of O_2 from the source does not ensure adequate uptake and distribution of O_2 on the part of the patient.

To assess the major aspects of acid-base balance and respiratory function including oxygenation, arterial blood gas (ABG) analysis is most helpful. Although the need for frequent sampling and analysis of ABG is dictated by the patient's physiologic status or surgical procedure, noninvasive, continuous monitoring of oxygenation through clinical observation and pulse oximetry is the standard of care[4] (see Table 17-1). Clinical observation parameters also include an assessment of skin color and temperature, nail-bed perfusion signs, assessment of depth and rate of respirations, auscultation of breath sounds, and assessment of upper airway patency.

Pulse Oximetry

The use of pulse oximetry has become commonplace in many healthcare settings, both inside and outside of critical care areas, and has proven valuable in detecting hypoxemia. Pulse oximetry measures heart rate and percent of oxygen saturation (SaO_2) of hemoglobin (Hgb) continuously and noninvasively. The technology involved in providing the transcutaneous measurement uses a spectrophotometer to determine SaO_2. Oxygenated Hgb absorbs infrared light at a different wavelength than unoxygenated Hgb. A light signal is emitted from one diode and transmitted through tissue, most commonly a finger, to an oppositely placed photosensitive diode that measures the amount of unabsorbed red light. Pulse oximeters can distinguish arterial from venous blood by measuring the change in transmitted light during pulsatile flow. The pulse oximeter converts the detected light to a plethysmographic signal that measures the drop in light intensity with each beat.[22,25,26]

Oxygen Saturation Physiology. To understand the measurement and significance of monitoring oxygen saturation via pulse oximetry, it is important to understand the physiology of oxygen

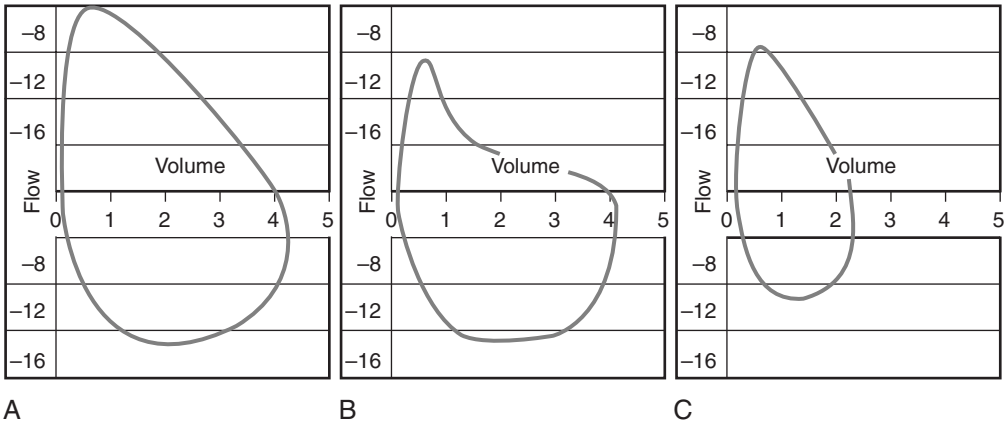

FIGURE **17-7** Flow-volume loop showing curves for normal (A), obstructive (B), and restrictive (C) lung disease. (From Rakel RE, Rakel DP. *Textbook of Family Medicine*. 8th ed. Philadelphia: Saunders; 2011.)

transport and the factors that influence its binding to and release from Hgb. This is expressed in the following equation.

$$Hgb + O_2 \leftrightarrow HgbO_2$$

The reversibility of the reaction allows for the release of O_2 to the tissues. Oxygen is transported throughout the body either physically dissolved in the blood or chemically combined with Hgb. The vast majority is carried bound to Hgb. As a result, the oxygen-carrying capacity is mainly dependent on the amount of Hgb. If varying concentrations of O_2 are added to a volume of blood, after allowing the mixture to equilibrate, the oxygen tension (P_{O_2}) of the gas can be measured. Because it is known that 0.003 mL of O_2 will dissolve in 100 mL of blood (at a P_{O_2} of 100 mmHg), the remaining O_2 bound to Hgb can be determined. In short, the P_{O_2} of the plasma determines the amount of O_2 that binds to Hgb. Like oxygen-carrying capacity, this is expressed in milliliters (mL) per 100 mL of blood.[27,28]

The proportion of Hgb bound to O_2 is expressed as percent saturation and excludes that amount dissolved in the blood. The relationship between oxygen tension and percent of oxygen saturation is illustrated in the oxyhemoglobin dissociation curve (Figure 17-8). It shows how the availability of O_2 (P_{O_2} in plasma) can affect the reversible reaction between O_2 and Hgb. The curve demonstrates that the amount of O_2 carried by Hgb (percent saturated) increases rapidly to a P_{O_2} of approximately 50 and slows thereafter, as displayed by a flattening of the curve. As blood travels to the systemic capillaries, the oxygenated Hgb releases O_2 to tissue with lower oxygen tension. In the 10 to 40 mmHg range, the curve is very steep. This demonstrates that small decreases in P_{O_2} can result in significant dissociation of O_2 for use by the tissue. For example, at a P_{O_2} of 40 mmHg, Hgb is approximately 75% saturated with O_2, whereas at 20 mmHg, only 32% is saturated. This relationship can be altered by a variety of physiologic changes. The result is a shift in the curve either to the *right*, indicating a more ready release of O_2 from Hgb at the tissue level, or to the *left*, indicating a greater attachment of O_2 to Hgb, thereby decreasing release to tissues (Table 17-3).[27,29]

Clinical Use of Pulse Oximetry. Although many studies regarding the use of pulse oximetry show conflicting impact on outcome, it should be intuitive that early detection and warning of hypoxemia, followed by appropriate interventions, will improve care. Pederson and colleagues[30] reviewed more than 21,000 perioperative patients and reported that the incidence of hypoxemia ranged from 1.5 to 3 times less in patients monitored

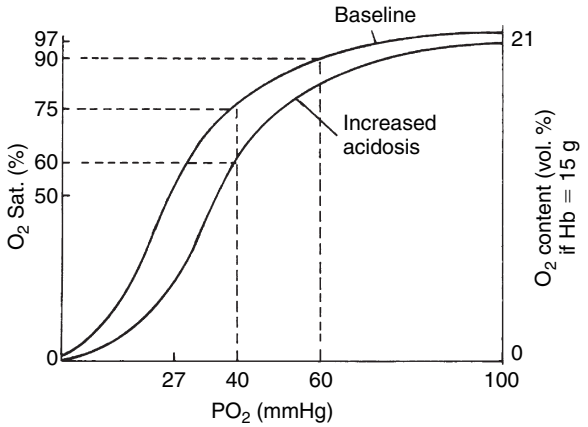

FIGURE **17-8** Oxyhemoglobin dissociation curve. (From Roberts JR, et al. *Clinical Procedures in Emergency Medicine*. 5th ed. Philadelphia: Saunders; 2009.)

with pulse oximetry. Perhaps one of the greatest benefits of pulse oximetry is in its simplicity. The pulse oximeter is calibrated by the manufacturer and needs little or no further maintenance. It is basic to apply, and ongoing product development has made the device quite portable and durable. Its efficiency in measuring O_2 saturation has been shown to be accurate within 2% when oxygen saturation is between 80% to 100% and approximately 5% when saturation falls below 80%.[5]

Despite the qualities of pulse oximetry, it is essential to understand the optimal use and limitations. Pulse oximeters can use a

variety of sensor types applied to the body. The finger probe is the most commonly used and is available as a reusable clip-on device or disposable stick-on probe. The finger probe is often used successfully on the toe as well, particularly in the pediatric population. One common problem with pulse oximeter monitoring is motion artifact.[31] Although monitors have been improved since their development, motion artifact can still be problematic. Using alternative sites can be helpful. Forehead, ear, or nose probes can be used with comparable accuracy and reliability.[14,32] The site of application of the pulse oximeter probe should be assessed at reasonable intervals during particularly long periods of use and changed as needed to avoid skin irritation or ischemia because prolonged application of a clip-on probe could potentially compromise perfusion. Another common problem associated with inaccurate measurement or sensor difficulties with pulse oximeter monitoring is the vasoconstriction state that results from cold temperatures or inadequate circulation. During such circumstances, measurement may be improved by using oximeter sites closer to the central circulation and away from the periphery, such as the forehead, nose, or ear.[32-34] Much discussion has surrounded whether the presence of nail polish affects pulse oximeter measurement. Some authors have noted that the presence of nail polish, particularly certain colors, will cause artifact and/or inaccurate measurements. More recent studies suggest that improved monitor sensitivity has virtually eliminated any effect nail polish might once have had on pulse oximetry readings.[35,36] A less commonly occurring but still problematic issue is the presence of abnormal hemoglobin. For example, methemoglobin absorbs light equally to oxyhemoglobin. As a result, pulse oximeter measurements are falsely underestimated when oxygen saturation is above 85% and overestimated when oxygen saturation is below 85%. Likewise, abnormally high levels of carboxyhemoglobin can cause the oximeter to overestimate oxygen saturation. Sickle cell anemia and other rarer forms of anemia may also impact the accuracy of pulse oximeter measurements. Injectable dyes for diagnostic use, such as methylene blue or indigo carmine, will result in a significant, but transient, decrease in the measured oxygen saturation by pulse oximetry.[14] This is because the presence of the dye alters the absorption of infrared light. Technology available on some pulse oximeters enables the monitor to distinguish between normal Hgb and carboxyhemoglobin or methemoglobin. In fact, oximetry principles in these monitors can quantitatively measure amounts of these variant forms of hemoglobin.[37]

The versatility and accuracy of pulse oximeters has sparked their use for other diagnostic purposes such as assisting in the measurement of systolic blood pressure by inflating a cuff and noting the point at which the pulse oximeter wave form is obliterated. The pulse oximeter may be useful in assisting in the location of a vessel by occluding the anatomy distal to the probe until that point is reached at which the waveform is lost.[14] Because of their sensitivity to changes in vascular supply, pulse oximeters have been used to determine the presence of vascular disease, such as in diabetic patients.[38] Changes in sympathetic tone are perceived by pulse oximetry. Vessels of the arm are subject to changes in autonomic tone and pulse oximetry has demonstrated an ability to detect the subtle changes in blood flow that occur during regional anesthesia, thereby indirectly indicating the degree of regional blockade. Research suggests that circulation to the earlobe is not greatly affected by changes in sympathetic tone but rather by changes in pulse pressure. As a result, pulse oximetry measured at the earlobe may be a sensitive indicator of systemic circulation and possibly stroke volume.[33] The degree and sensitivity to which individual monitors perform under circumstances of hypothermia or circulatory changes may vary by manufacturer.[39]

The practice of closely monitoring respiration (ventilation and oxygenation) through the measurement of carbon dioxide and oxygen saturation during the anesthetic period has proved to be priceless in ensuring safe care. As technology has advanced to allow reliable, affordable, noninvasive measurement, this practice is being adopted in other settings. Combined sensors that measure both carbon dioxide and oxygen saturation are available and may prove valuable in managing patients at risk for respiratory complications such as during the postoperative period or whenever potent opiates are administered.[24,40,41]

Temperature Monitoring

The standards of care from both the AANA and the ASA support the notion that the ability to monitor the patients' body temperature is essential.[3,4] Temperature monitoring alerts the anesthetist to hyperthermia, and as is more commonly the case, hypothermia. Despite clinical standards and the known physiology, hypothermia is an occurrence that is often underestimated in significance. The American Society of Perianesthesia Nurses (ASPN) defines hypothermia as a core temperature of less than 36° C (96.8° F). It has been reported that approximately 70% of postoperative patients experience some degree of hypothermia while other estimates reach as much as 90% of surgical patients experience some adverse effect of hypothermia.[42,43] Risks of hypothermia include wound infection and delayed healing, increased O_2 consumption through shivering, increased risk of cardiovascular incidents and myocardial infarction, and increased rate of sickling in sickle cell patients.[5,43,44] In addition, hypothermic patients have been shown to have a prolonged stay in the postanesthesia care unit, thus increasing the cost of care during the perioperative period.[42,45]

Appropriate and aggressive means of maintaining normothermia intraoperatively should be instituted, and a keystone to implementation of these interventions is temperature monitoring. National quality improvement initiatives supported by the Centers for Medicare and Medicaid Services have partnered with healthcare organizations and accrediting bodies to promote best practices aimed at improving surgical care. These initiatives have identified essential factors in preventing postoperative complications. Not the least of these identified areas of care is centered on maintenance of normothermia.[45] An understanding of the potential causes of variations in core body temperature is valuable in appreciating the importance of temperature monitoring.

Thermoregulation

Body temperature is tightly regulated through a process termed *thermoregulation*. Thermoregulation occurs through a three-phase process: afferent thermal sensing, central regulation or control, and efferent responses. Peripheral sensors send thermal information via tracts in the anterior spinal cord, such as the spinothalamic tract, to various regions of the brain including the hypothalamus. Behavioral responses to changes in temperature (i.e., layering clothing, seeking warmth) are the most important aspect of thermoregulation in persons who are awake; however, anesthesia prevents patients from responding accordingly. As a result, they must rely on autonomic efferent responses such as shivering, vasoconstriction, and sweating. General anesthetics do not have significant effects on sweating but do reduce shivering and vasoconstriction thresholds. Neuraxial anesthesia also affects thermoregulatory control, resulting in hypothermia.[46]

Normothermia can be defined as a body temperature of 37° C. It is important to note that there is typically a variance between

TABLE 17-4 Comparisons of Body Temperature Monitoring Sites

Monitoring Site	Advantages	Disadvantages
Bladder	Reflects core temperature Correlates accurately with other core sites	Invasive—requires urinary catheter placement Risk of UTI
Pulmonary artery	Reflects core temperature Correlates accurately with other core sites	Invasive—requires PA catheter Not reliable during open chest procedures
Esophageal	Considered by most authors to reflect core temperature Ease of insertion	Slight potential for oral or esophageal trauma, bleeding Not useful in awake patients Inaccurate if placed too close to the stomach
Nasopharynx	Considered by most authors to reflect core temperature Ease of insertion	Potential for nasopharyngeal trauma, bleeding Less useful in awake patients Inaccurate if breathing through nares
Tympanic	Considered by most authors to reflect core temperature Accurate if contact probe is used Ease of insertion Possible for awake patients	Slight potential for tympanic membrane trauma Possible to push ear wax from canal to membrane Infrared device less accurate
Axillary	Safe, noninvasive, ease of placement Reasonable correlation with core in adducted arm when placed close to axillary artery	Not a direct measurement of core temperature Influenced by IV fluids Easily dislodged

core and peripheral temperatures. This is key to appreciating the value of core versus peripheral temperature measurement.[42]

Hyperthermia or core temperatures exceeding 38° C, can be seen intraoperatively. The genetic predisposition to drug-induced malignant hyperthermia is well documented. Other causes of fever, such as infection or hypermetabolic states, typically are not seen in patients electively brought to surgery. Certain recreational drugs such as amphetamines, Ecstasy, or cocaine can raise the body temperature through an increased rate of metabolism.[47] Drugs such as atropine can inhibit the sweating response, resulting in impaired regulatory response and a rise in the core temperature. In the anesthesia setting these effects are typically overshadowed by the multiple factors in place that serve to lower core temperature.

Hypothermia, or core temperature below 36° C, occurs for multiple reasons. Upon entering many operating rooms, one cause of hypothermia becomes obvious to anyone, especially the patient: the ambient room temperature. Reports suggest that the greatest amount of heat loss occurs during the first hour in the perioperative setting and that patients in rooms at a temperature of 21° C will all develop hypothermia. Radiant heat loss, or that transfer of body heat into a cooler environment, accounts for the majority of heat loss in the patient undergoing surgery. This is followed by evaporative loss from liquids on the skin, such as from cleansing or perspiration or through the expiration of warm, moist air. In addition, convective heat loss (through moving cool air) and conductive heat loss (through contact with a cooler object such as an operating room table) contribute. Redistribution of lower-temperature blood from the vasodilated, anesthetized periphery to the central compartment also accounts for significant heat loss.[42,48] General and regional anesthesia inhibit thermoregulation and cause significant vasodilation such that temperature monitoring is warranted. During local anesthesia or sedation, temperature monitoring should be considered under circumstances in which the patient is at risk of hypothermia and should, at the very least, always be immediately available. It is important to note that normal core body temperature can vary between individuals as well as within individuals at different points within their circadian rhythms.[47] As a result, monitoring the patients' temperature is most beneficial when done continuously rather than intermittently and is most valuable when evaluated for trends.

Temperature Monitoring Modalities. Temperature is an important parameter in the complete monitoring of homeostasis in the perioperative period. The AANA and ASA practice standards allow for some discretion on the part of the anesthesia provider in deciding under what circumstances temperature monitoring should occur. The ASA states that body temperature monitoring should occur whenever significant changes in temperature are "intended, anticipated, or suspected." The AANA states that temperature should be monitored "on all pediatric patients receiving general anesthesia and when indicated, on all other patients."[3,4]

To ensure monitoring is done and active warming strategies employed, it is essential that the anesthetist be well aware of the factors that place patients at risk for perioperative hypothermia. Some of these risk factors include high ASA status, lengthy or involved surgical procedures, combined epidural and general anesthesia, surgery of long duration, elderly patients, and those with lean body mass. Interestingly, another identified risk factor for hypothermia is failure to monitor temperature. Protective factors of increased body weight, higher preoperative temperature, and warmer rooms were noted to help maintain normothermia.[49,50]

Technology used for temperature monitoring varies often by site measured. Thermistor, thermocouple, and platinum wire devices are frequently used with electronic monitors and have shown to be accurate and reliable. In addition, liquid crystal temperature monitors have been employed for skin temperature monitoring. Although these are noninvasive and convenient, they lack specific accuracy both in measurement and in interpretation between readings by separate observers.[14]

There has been some debate as far as how best to measure temperature, and indeed, each site has certain advantages and disadvantages (Table 17-4). The sense of touch is not reliable to

assess the patients' temperature, but the sensation of being uncomfortable in a cold operating room can serve as an alert that the patient is most likely cold as well and would benefit from temperature monitoring and warming modalities. Skin temperature measurement is convenient and noninvasive; however, its accuracy as a reflection of core body temperature is unreliable. The use of temporal artery temperature monitoring has become a popular modality. Temporal artery temperature measurements use infrared technology to measure blood temperature close to the surface with a device swiped across the forehead and down along the temporal artery. Some studies suggest this approximates oral and axillary temperatures reasonably close; however, others question their accuracy.[46,51]

Core temperature monitoring is believed to be the most reflective of thermal status in humans. This includes temperature monitoring at the tympanic membrane, distal esophagus, nasopharynx, or pulmonary artery.[46] When considering sites for core temperature monitoring, the Society for Critical Care Medicine's Fever Task Force concluded that the intravenous or bladder thermistor measures core temperature most accurately. They further state that the electronic probe measurement orally or by rectum is also reliable.[52] The type of surgery may play an important role in determining the optimal location for temperature monitoring. For example, in liver transplantation, bladder temperature has been shown to closely approximate pulmonary artery temperature measurements. Esophageal monitoring may be less reflective of core temperature during open heart surgery because of the exposed thoracic cavity. For many surgeries the tympanic membrane may be considered an ideal site, particularly because of its close proximity to the brain, therefore providing an accurate reflection of brain temperature. It should be noted, however, that tympanic membrane temperature measurement using aural probes with thermocouples provides this reliable assessment as opposed to the popular but less accurate use of infrared technology.[53]

ADDITIONAL MONITORING ISSUES

Monitoring for Procedures Outside of the Operating Room

As healthcare delivery and technology have changed, so has the role of the anesthetist. One area of change is the location in which anesthesia is delivered. It has become common administer all forms of anesthesia in areas outside of the traditional operating room setting. Multiple factors could be anticipated to increase anesthesia risk outside of an operating room. These include decreased availability of anesthesia personnel, less adjunct equipment, and unfamiliarity with supportive staff and settings. Procedures and settings often involve risk of allergic reactions to radiologic dyes, sharing of access to airway, and (in general) support staff with less experience with the anesthetized patient.

There is a growing need for studies of anesthesia morbidity and mortality as they relate to setting. A review of the ASA closed-claims database was done by Robbertze and colleagues[11] to assess for trends and look for insight into how to best provide anesthesia in these remote settings. Reviewers noted that anesthesia claims in these settings had a higher severity of injury and more often demonstrated that anesthesia was administered below the accepted standard level of care. The most common mechanism of injury was inadequate oxygenation or ventilation. Close review of these cases emphasizes that monitoring standards during anesthesia administered outside of the operating room must never be lower than what one would otherwise use. In fact, the circumstances may necessitate even closer vigilance. Frequent review and refinement of airway management skills is crucial in caring for patients in these settings. Focused attention and pressure is being applied in many areas to recognize and prevent the dangerous effects of potent opioids and other sedative drugs given for pain and procedural sedation. Emphasis should be placed on ensuring adequate ventilation and oxygenation through close visualization, monitoring of $ETCO_2$, and pulse oximetry.[24] Education, training, and certification are crucial for nonanesthesia nurses, physicians, or other providers involved in the administration of sedation in the absence of a nurse anesthetist or anesthesiologist. It behooves a healthcare facility to have strict policies in place, and such policies should be reviewed by the anesthesia providers.

ANESTHESIA EDUCATION AND PATIENT MONITORING

Teaching clinical monitoring begins in the classroom and is reinforced and emphasized in the clinical learning environment. As with all aspects of anesthesia education, teaching the art and science of clinical monitoring of the patient must be well thought out. Many educational programs and anesthesia departments use some form of simulation-based education as a supplement to clinical experience. Simulation learning is designed to give additional interactive practice and can also serve to review critical incidents and adverse events. Research offers evidence that debriefing following the simulated event is of value.[54,55] The use of simulated clinical experience can assist in developing critical decision-making skills through repetition. It is worth noting that although the simulated experience can measure response, a certain lack of realism occurs because of the sense of anticipation of the soon-to-be-designed event. As a result, a level of "hypervigilance" can occur, masking the true habits of the learner.[56]

A part of vigilance in monitoring lies in developing habits that promote frequent, almost ritualistic, patterns of assessment and visualization. Many students have a tendency to first focus on the electronic devices while forgetting the ongoing physical assessment of the patient. It is the role of the instructor to promote affective routines by explaining the underlying rationale, as well as by example. Another important part of learning to closely monitor the patient is training the senses to notice changes in the clinical picture. Every anesthetist should be able to discern when the changing audible tones of the pulsatile measurement of the pulse oximeter monitor indicate decreasing oxygen saturation. One should rapidly recognize the subtle development of abnormal airway sounds heard through a precordial stethoscope. These are only several of the basic clinical skills essential to anesthesia practice, and the anesthesia student requires time, experience, and appropriate habits to hone them.

Beyond learning the use and interpretation of monitoring methods, the student must also learn to appreciate the potential artifacts that can occur during electronic measurement. Because artifacts can result in false alarms, there exists the potential to ignore important alarms if their validity is uncertain. The student and experienced provider must learn to assimilate all data to make the right interpretation.[57]

FUTURE OF CLINICAL MONITORING

As developments in science allow for improved accuracy, reliability, portability, and ease of use of monitoring devices, undoubtedly the applications will expand. This is a prediction that has been written many times for many years. Modalities such as cardiac output monitoring were once only estimated by invasive techniques but are now frequently monitored noninvasively.

Closer monitoring of metabolic processes such as oxygen uptake or analysis of autonomic nervous system responses through noninvasive means will likely find a place in anesthesia settings as they develop.[58,59] The trend of moving toward electronic medical record keeping will impact the type of monitoring interfaces as well as the documentation of measurements. Although the accuracy and usefulness of these systems are a source of debate, it is likely that there reliability will improve. Automated anesthesia record systems have proved valuable in ways that include avoiding and defending medical malpractice claims.[60]

Advancements in monitoring alarm systems and display capabilities may prove valuable. Continuous auditory and integrated visual displays, including head mounted screens, have been tested and shown to shorten time to response; however, they may bring with them detrimental effects to visual fields and increase noise levels in the operating room.[61,62]

Although the availability of devices and advancements in monitoring capabilities may be an ever-present reality, another harsh reality is the cost associated with obtaining and using them. As healthcare delivery costs continue to increase, there will also be continued pressure to use these resources wisely. Outcome data are crucial to justifying the expense of keeping up with technology. Simply displaying patient-related data for the sake of defining physiologic or disease states without directly benefiting the patient will not justify the potential risk to the patient as well. [63]

The importance of the human factor in anesthesia delivery and monitoring does not appear to be replaceable any time soon. While new devices may prove to be useful tools, it is imperative that the anesthetist remain vigilant and well informed as to their proper use and interpretation. Although studies may be published to demonstrate the capabilities of electronic devices, practitioners continue to fall back on the value of the human senses—as is the case with the simple precordial stethoscope in perceiving apnea or other events—and emphasize the importance of learning to use and interpret them appropriately.[64]

SUMMARY

Clinical monitoring is a human skill that uses all of the senses. The importance of maintaining adequate ventilation and oxygenation has been underscored in reviews of closed-claim studies, thereby emphasizing the need for vigilant, continuous monitoring of these parameters in the patient receiving anesthesia. Of all monitoring modalities, ET_{CO_2} and pulse oximetry have been shown to be of particular value. Hypothermia is an all-too common occurrence under anesthesia, and management must center on prudent temperature monitoring. Clinical standards of care, as developed by the recognized professional anesthesia organization, must be adhered to continuously and reevaluated frequently. Outcome studies are warranted to justify the use of monitoring modalities, and the potential benefits must outweigh the potential risks.

Clinical Monitoring III

Neurologic System

◆ *Gary D. Clark and Nicholas C. Curdt*

CHAPTER 18

The practice of anesthesia requires constant vigilance and evaluation of the patient. Historically, early anesthetists such as John Snow and Arthur Guedel proposed the use of clinical and neurologic signs to evaluate and determine the depth of anesthesia. Snow described the "five stages of narcotism" for chloroform anesthesia.[1] Guedel further refined these signs of anesthesia by developing a table of "clinical signs and stages of anesthesia" the patient passes through during anesthesia.[2] Guedel used neurologic signs such as respiratory rate and rhythm, ocular movement, pupillary size, and reflexes to evaluate the depth of ether anesthesia.[1,2]

Today, the practice of anesthesia incorporates sophisticated technology for neurologic monitoring. The administration of a variety of drugs for anesthesia makes it impractical to depend solely on Snow's or Guedel's clinical signs for assessing anesthetic levels or neurologic function. Monitoring the neurologic status of a patient demands a thorough knowledge of the modern devices used and the skills needed to navigate a rapidly changing clinical environment. Goals for monitoring the neurologic system include the following:

1. Possessing a thorough knowledge of the monitors and modalities available for neurologic monitoring
2. Selecting appropriate neurologic monitor(s) for data acquisition and patient management
3. Understanding the various pathologic and anesthetic effects on patients' response with neurologic monitors
4. Managing neurologic changes during periods of surgical stimulation
5. Recognizing data changes that reflect neurologic changes and ischemia

The neurophysiologic parameters of interest that are monitored during surgery include brain function, blood flow, and metabolism. Monitoring of function is performed by measurement of electrical activity in the brain by means of electroencephalography (EEG), sensory and motor evoked potentials (EPs), and electromyography (EMG). Monitoring of blood flow/pressure is achieved by nitrous oxide wash-in, radioactive xenon clearance, laser Doppler blood flow, and transcranial Doppler sonography. Intracranial pressure can be determined by means of intraventricular catheters, fiberoptic intraparenchymal catheters, subarachnoid bolts, and epidural catheters. Lastly, brain metabolism can be measured either through invasive techniques such as placement of intracerebral Po2 electrodes or noninvasive techniques, such as transcranial cerebral oximetry and jugular venous oximetry.[3] Select methods for monitoring neurologic functions are given in Box 18-1.

This chapter examines the monitors currently used in clinical practice and managing the neurologic function of patients during the perianesthetic period. Brain monitoring methods and their indications, advantages, and disadvantages are noted in Table 18-1.

INTRACRANIAL PRESSURES AND JUGULAR VENOUS OXYGENATION

Intracranial pressure (ICP) monitoring has been successfully used for a number of years; ICP measurement reflects the pressure in the intracranial vault. The ICP changes with an increased volume of fluid as a result of edema or intravascular volume or the presence of a tissue mass, as with a tumor, in the cranium. The normal ICP ranges from 1 to 15 mm H_2O depending on position and normal cerebral vascular compliance. The ICP is directly related to the intrathoracic pressure and changes dramatically with coughing or increased intrathoracic pressures.

Recently the ICP, in conjunction with the jugular venous oxygenation ($SjvO_2$) monitoring, has been used to evaluate intracranial injury with some success. A $SjvO_2$ that ranges between 55% and 75% has been found to be a reasonable predictor of positive outcomes for traumatic brain injury (TBI) if the ICP is also maintained within a normal range. Those patients with a $SjvO_2$ less than 55% or above 75% and an elevated ICP had poor outcomes.[4,5]

ELECTROENCEPHALOGRAM

Normal EEG

The brain is an electrochemical organ generating electrical signals in a specific pattern. The electrical activity displayed through an EEG is sometimes called *electrical brainwaves*. The EEG is actually a measurement of differences in electrical potentials in groups of neurons between brain regions rather than the brain emitting electrical waves.[6] Electrodes used to produce the EEG are placed

BOX 18-1

Specialized Methods for Neurologic Monitoring

- EEG—electroencephalogram
- SSEP—somatosensory evoked potential
- MEP—motor evoked potential
- VEP—visual evoked potential
- BAEP—brainstem auditory evoked potential
- BIS—bispectral index
- PSI—patient state index
- NIRS—near-infrared spectroscopy
- EMG—electromyography
- TCD—transcranial Doppler (sonography or laser blood flow)
- ICP—intracranial pressure (intraventricular catheters, fiberoptic intraparenchymal catheters, subarachnoid bolts, and epidural catheters)
- Brain metabolism (intracerebral oxygen electrodes, transcranial cerebral oximetry and jugular venous oximetry [$Sjvo_2$])
- Bedside xenon cerebral blood flow
