Traumatic disruption of the bony, cartilaginous, and soft-tissue components of the face and upper airway require special consideration. It is imperative to create an anesthetic plan for securing the airway without promoting further damage or compromising ventilation. Possible mechanisms by which the upper or lower airway may become obstructed include edema, bleeding from the oral mucosa and palate, intraoral fracture sites, distortion of the nasal passages, injury of the pharynx and sinuses, open lacerations, and the presence of foreign bodies such as avulsed teeth, blood clots, or bony fragments.[81]

Initial management of the airway depends on the situation at hand. In the case of severe facial or neck trauma, alternative methods of tracheal intubation (e.g., fiberoptic laryngoscopy, retrograde wire placement, jet ventilation via cricothyrotomy, or emergent tracheostomy) may be necessary to secure the airway.

Injuries of the head and neck may include cervical spine or cranial injury. Although a complete evaluation of all cervical vertebrae is ideal, inspection of radiographs of the cervical spine is judicious to determine the presence or absence of dislocations and fractures. All seven cervical vertebrae must be visible in such studies. The seventh cervical vertebra is the most common site of traumatic fracture of the spine.[82] Vertebral artery injury must be suspected with a cervical injury, because these fractures can lead to vertebral artery tear or occlusion. If deteriorating respiratory function requires immediate airway management and intubation, the head should be maintained in a fixed position before any manipulation of the airway is performed. The use of manual axial in-line stabilization (MAIS) and/or a rigid cervical collar in place is recommended. The removal of the anterior segment of the collar can facilitate intubation and manipulation of the soft tissues of the neck.[82,83]

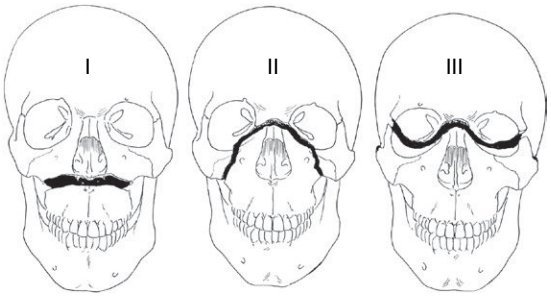

FIGURE **38-11** Examples of Le Fort I, II, and III facial fractures *(left to right)*.

Blunt trauma to the face or anterior neck may produce rapid airway occlusion secondary to soft-tissue edema or hematoma formation secondary to trauma of the vascular structures of the neck. The patient exhibiting smoke inhalation or blistering in the area of the mouth and nares or with a history of inhalation of toxic byproducts of combustion should be intubated immediately. Edema of the face and glottis, which may lack symptoms in the early stages, has the potential to produce serious airway compromise several hours after injury.

Maxillofacial Trauma and Orthognathic Surgery

Le Fort[84] determined the common fracture lines of the maxilla and face by experimentation on cadavers in 1901. The Le Fort classification is based on his finding that blunt trauma tends to cause fractures along three particular lines of the face. Fractures occurring in twenty-first–century, real-life situations (in particular, high-velocity motor vehicle accidents) often deviate from this classification system, and "pure" Le Fort fractures are rare. Nevertheless, the Le Fort classification system is widely known, and it provides a method for concise communication of fracture patterns between clinicians and radiologists. There are three types of Le Fort fractures that describe a pattern of fractures involving multiple facial bones.[85,86]

The fractures are divided into Le Fort I, II, and III (Figure 38-11). The Le Fort I fracture is a horizontal fracture of the maxilla extending from the floor of the nose and hard palate, through the nasal septum, and through the pterygoid plates posteriorly. The palate, maxillary alveolar bone, lower pterygoid plate, and part of the palatine bone are all mobilized. The Le Fort II fracture is a triangular fracture running from the bridge of the nose, through the medial and inferior wall of the orbit, beneath the zygoma, and through the lateral wall of the maxilla and the pterygoid plates. The Le Fort III fracture totally separates the midfacial skeleton from the cranial base, traversing the root of the nose, the ethmoid bone, the eye orbits, and the sphenopalatine fossa.[84,87]

A Le Fort I fracture generally causes little difficulty for the anesthesia provider. Patients may be intubated orally or nasally and the airway secured without a problem. The Le Fort II and Le Fort III fractures are of particular concern when contemplating nasal intubation. In both of these fractures, disruption of the cribriform plate may occur, opening the underside of the cranial cavity. The presence of cerebral fluid in the nose, blood behind a tympanic membrane, periorbital edema, or "raccoon-eyes" hematoma are indications that attempts to pass an endotracheal tube or nasogastric tube through the nares could lead to inadvertent intracranial placement.[87] Although the insertion of a nasal tube may aid the surgeon, an attempted nasotracheal intubation of a

patient with a basal skull fracture involves the very serious risk of introducing the tube into the skull, bringing contaminated material into the subarachnoid space and causing meningitis. The tube may also inflict damage to the brain itself.[88]

The forces required to produce facial fractures are considerable and may be associated with other trauma. It is important that cervical spine injury, subdural hematoma, pneumothorax, and intraabdominal bleeding be investigated. Soft-tissue injury to the airway and blood or debris in the oropharynx may make visualization impossible. If in doubt while in the emergency department, a tracheostomy under local anesthesia or an awake oral intubation with topical anesthesia should be considered. These patients should be treated with full stomach precautions.

As with any trauma victim, attention is first directed toward maintaining the ABCs: airway, breathing, and circulation. The repair of the facial fracture itself is not an emergency and may be carried out at a later time. Once the patient arrives in the operating room for surgery, it may be challenging to open the patient's mouth for intubation because of edema, pain, or trismus. It is necessary to differentiate the cause of the small mouth opening because it may be pain related or mechanical in nature. The administration of a short-acting narcotic or midazolam will sometimes assist the anesthesia provider in determining the cause of the restriction, which greatly influences the induction chosen. In mandibular or maxillary fractures, nasal intubation is usually best, because the patient's teeth are brought together via wires or rubber bands at the conclusion of surgery (intermaxillary fixation). Anesthesia is induced with an IV agent and maintained with narcotics, muscle relaxants, and inhalation agents. Blood loss from facial fractures can be extensive. The patient's blood should be typed and crossmatched so that blood is immediately available. The fixation process closes the teeth in proper occlusion and prevents access to the oropharynx. Masking the patient at emergence requires that the patient be awake with intact reflexes at extubation. It also requires that wire cutters or scissors be available to cut the wire or rubber bands fixing the mandible to the maxilla in case an airway emergency occurs in the recovery area.[89]

Orthopedic orthognathic procedures often require sagittal splitting of the mandible to move the lower jaw either forward or back. A Le Fort I or Le Fort II osteotomy may be purposefully performed to move the maxilla in any direction to correct anomalies. Many of these patients have anomalies of the mandible and maxilla, small mouth openings, and appliances that make intubation difficult and airway management challenging. Because many of the malocclusions are treated orally, a nasal endotracheal tube is usually preferred over an oral intubation. Securing the nasotracheal tube away from the surgical field without causing necrotic injury of the nares is vital. Because blood loss during these procedures can be extensive, the patient is typed and crossmatched. Deliberate hypotensive anesthetic techniques are often used if the patient remains stable. Rigid metal or plastic external or internal fixation devices are used to maintain stability in both the mandible and maxilla postoperatively; therefore, the proper cutting tools should be at the patient's bedside for emergency airway issues. Edema will often be extensive and progress over the first 24 hours after orthognathic surgery. To prevent postoperative respiratory problems, the patient may remain intubated for several days. If extubation is necessary, it should be done only when the patient is awake, in full command of protective reflexes, and can be carefully monitored in the postoperative period.

Radical Neck Dissection

Radical neck dissection is required when cancerous tumors have invaded the musculature and other structures of the head and neck. Neoplastic growths can occur anywhere within the upper airway and may achieve significant size with little evidence of airway penetration or obstruction. Such tumors are often friable and bleed readily. These patients are frequently heavy drinkers and smokers who have bronchitis, pulmonary emphysema, or cardiovascular disease. If the tumor interferes with eating, associated weight loss, malnutrition, anemia, dehydration, and electrolyte imbalance can be significant. Patients who have had radiation treatments of the neck and jaw prior to surgical intervention will have soft tissues that are less mobile, making intubation more difficult. Many of these patients are older and have the comorbidities associated with age.[90,91] Attempted tracheal intubation can induce significant hemorrhage and edema, causing severe compromise of the airway.

Determining the appropriate techniques for airway management entails consultation with the surgeon as to the nature, extent, and location of the tumor; therapy administered (radiation or chemotherapy); CT results; history and physical examination; and relevant preoperative laboratory values.

Head and neck reconstruction is an integral part of surgical removal of head and neck tumors. Traditional methods of reconstruction include regional pedicle flaps with microvascular reconstruction. Flaps include the pectoralis major myocutaneous flap, trapezius flap, and local rotational flaps (e.g., forehead flap). Additionally, small bowel may be harvested to reconstruct the oropharynx and esophagus. Successful anesthesia plays an important role in maximizing the overall success rate of a free flap and microvascular flow of the flap.[92] The planned donor site should be determined to plan for any limitation on the available sites to place lines necessary for monitoring and venous access. Although the choice of monitoring is largely dependent on the general condition of the patient, the placement of a central venous pressure (CVP) line, a Foley catheter, and an arterial line (beat-to-beat and arterial blood gas trends) is suggested, particularly if deliberate hypotension during anesthesia is used. The internal jugular approach should be avoided because of proximity to the surgical site. Sites commonly used for the CVP placement when the internal jugular is not accessible are the subclavian and femoral veins, respectively.

Maintenance of anesthesia is often performed with an inhalation agent and supplemental narcotics. The use of a nondepolarizing muscle relaxant must be discussed with the surgical team preoperatively because a nerve stimulator is frequently used (by the surgeon) to locate nerves distorted by the tumor during the procedure. Significant blood loss can be a problem; sometimes a controlled hypotension technique may be requested.[90,91] At least one and preferably two large-bore peripheral IV lines (16 to 14 gauge) should be in place. An arterial line, hemodynamic monitor, and central line are many times desirable. The patient's blood should be typed and crossmatched, with blood readily available. It is important to replace blood loss, but not to the point of overloading the patient. Monitoring estimated blood loss and measuring the hematocrit may provide some guidelines for replacement of blood. A positive fluid balance in the postoperative phase can result in edema and congestion of the flap, predisposing it to vascular compromise. Colloids may be used to help limit the amount of crystalloid required during the procedure. Patients undergoing a radical neck dissection are frequently hypovolemic and have electrolyte imbalances. This requires some fluid replacement and electrolyte balance intraoperatively to maintain cardiovascular stability. Cerebral blood flow can be compromised by the tumor, retractors, or blood flow; therefore it is important to maintain adequate perfusion.

In preparation for a tracheostomy or total laryngectomy to be performed during the surgical procedure, the patient should be well oxygenated. The trachea will be transected by the surgeon,

TABLE 38-9 Laryngectomy

Structures Removed	Structures Remaining	Postoperative Conditions
Total Laryngectomy		
Hyoid bone Entire larynx (epiglottis, false cords, true cords) Cricoid cartilage Two or three rings of trachea	Tongue Pharyngeal wall Lower trachea	Loses voice; breathes through tracheostomy; no problem swallowing
Supraglottic or Horizontal Laryngectomy		
Hyoid bone Epiglottis False vocal cords	True vocal cords Cricoid cartilage Trachea	Normal voice; may aspirate occasionally, especially liquids; normal airway
Vertical (or Hemi-) Laryngectomy		
One true vocal cord False cord Arytenoid One half thyroid cartilage	Epiglottis One false cord One true vocal cord Cricoid	Hoarse but serviceable voice; normal airway; no problem swallowing
Laryngofissure and Partial Laryngectomy		
One vocal cord	All other structures	Hoarse but serviceable voice; occasionally almost normal voice; no airway problem; no swallowing problem
Endoscopic Removal of Early Carcinoma		
Part of one vocal cord	All other structures	May have a normal voice; no other problems

From Odom-Forren J. *Drain's Perianesthesia Nursing: A Critical Care Approach*. 6th ed. St. Louis: Saunders; 2013:463.

which requires that the anesthesia provider suction the airway and remove the ETT only to a level above the tracheal incision. Once the tracheostomy tube has been placed by the surgeon and ventilation validated, the ETT can then be completely removed. A reinforced tube is usually placed in the distal airway by the surgeon and connected to the anesthesia machine. A reassessment of the ventilation should be performed, including the entire procedure of listening to bilateral breath sounds, observing chest excursion, and checking end-tidal CO_2 and positive inspiratory pressure (PIP) or negative inspiratory pressure (NIP). After the anesthesia provider has validated tube placement, the ETT is sutured to the chest wall for the entire surgical duration. At the end of surgery, the reinforced tube may be switched for a tracheostomy cannula.

During radical lymph node dissection of the neck for carcinoma, manipulation of the carotid sinus may elicit a vagal reflex, causing bradycardia, hypotension, or cardiac arrest. Small doses of local anesthetic injected near the carotid sinus or administration of an anticholinergic may block vagal reflexes. Owing to the long duration of the surgery and interruption of venous flow, venous thrombus is commonly seen in patients who are undergoing radical neck dissection. The head-up position and open neck veins during surgery may lead to venous air embolism. Careful monitoring with precordial Doppler sonography or transesophageal echocardiography (TEE) provides the best detection of air embolism. Immediate removal of the air through the CVP is essential. Laryngeal edema, vascular occlusion, and obstruction can also occur as a result of the venous stasis that follows major disruptions in venous flow during surgery or with trauma. Continual review of complications and follow-up treatments are necessary.[89-91,93]

Postoperative considerations consist of tracheostomy care, controlled ventilation, chest roentgenogram (to rule out pneumothorax, hemothorax, pulmonary edema), and monitoring for laryngeal edema induced by thrombosis. Postoperative characteristics of various surgical laryngectomy procedures are given in Table 38-9. It is suggested that these patients be admitted overnight in the intensive care unit because they have undergone major fluid and electrolyte shifts and altered ventilation-perfusion status and have spent an extensive time under the influence of anesthesia.[94,95]

SUMMARY

Administering anesthesia for ENT and maxillofacial procedures requires knowledge in both basic and advanced anesthesia techniques. Using these techniques demands the best skills of even a seasoned and experienced clinician. The usual tenets of safe practice must often be adhered to while remaining at a distance from the airway. Good preparation remains imperative. Cooperation and communication between the surgeon and anesthetist maintain a vital link for all concerned, especially those patients in their charge.

39 CHAPTER Anesthesia for Ophthalmic Procedures

◆ *Randolf R. Harvey*

Ophthalmic anesthesia continues to be an exciting and challenging segment of anesthesia practice. Ophthalmologists recognize the value anesthesia practitioners provide to their patients and practice. The use of topical anesthesia for cataract surgery is now routine; however, the demand for eye blocks for other procedures continues. Retrobulbar block has been progressively phased out and replaced by peribulbar block, sub-Tenon's block, or topical anaesthesia with the use of phacoemulsification for cataract surgery, Advances in retinal surgical techniques have increased the demand by surgeons for injection eye blocks for select surgeries and replaced the use of general anesthesia except in rare circumstances. This trend is also growing for corneal transplants and adult eye muscle and glaucoma procedures. This is especially true for procedures requiring deep anesthesia and akinesia.

Today more than a million ocular blocks are performed annually for surgical procedures. Thanks to ophthalmic anesthesia educational programs, safer than ever ocular blocks are being administered, and more efficient patient care is being provided. This new expertise in eye anesthesia has spurred a high demand for such services, in part because of the proliferation of ambulatory surgical centers (ASCs) to meet the increased demand for ophthalmic surgery.

OPHTHALMIC ANATOMY

Extraocular Muscles

The eye is surrounded by six extraocular muscles (Figures 39-1 through 39-3). The *superior rectus muscle*, located at the 12-o'clock position on the globe, moves the eye upward, or *supraducts* the eye. The *inferior rectus muscle*, located at the 6-o'clock position on the globe, moves the eye downward, or *infraducts* the eye. The *medial rectus muscle*, located 90 degrees medially to the 12-o'clock position on the globe, moves the eyeball nasally, or *adducts* the eye. The *lateral rectus muscle*, located 90 degrees laterally to the 12-o'clock position on the globe, moves the eyeball *laterally*, or *abducts* the eye. The *superior oblique muscle*, located on the superior aspect of the eye, rotates the eyeball on its horizontal axis toward the nose, or *intorts* the eye and depresses the eyeball. The *inferior oblique muscle*, located on the inferior aspect of the globe, rotates the eyeball on its horizontal axis temporally, or *extorts* the eye and elevates the eyeball (Table 39-1).

All the ocular muscles except the inferior oblique originate in the orbital apex around the annulus of Zinn (Figure 39-4), which is a fibrinous ring that encircles the optic foramen. The four rectus muscles move forward in a conal pattern that forms the muscle cone around the globe. These muscles, which are about 40 mm long, insert into the globe just anterior to its equator.[1] The superior oblique muscle arises just superior to the annulus of Zinn and moves forward, becoming a tendon. This tendon passes through a cartilaginous ring called the *trochlea*, which is located on the medial supranasal orbital wall. After passing through the trochlea, the tendon is redirected in a posterolateral direction and inserts on the superolateral aspect of the globe under the superior rectus muscle. The inferior oblique muscle originates from the anterior nasal orbit and moves in a posterolateral direction to the globe, inserting along the lateral aspect of the globe. The arching of both the inferior and the superior oblique muscles around the globe allows for the torsional movements of the eye.

Eyelid Muscles

The levator muscle of the upper eyelid is the primary muscle used for raising the upper eyelids. This muscle originates near the annulus of Zinn (see Figure 39-1, *B*). It moves forward just superior and slightly medial to the superior rectus muscle, inserting into the upper eyelid. Because the levator muscle only retracts and does not contract the eyelid, akinesia of this muscle is not necessary.

The *orbicular muscle* of the eye (Figure 39-5) causes the eyelids to contract. This muscle has three divisions—*orbital*, *palpebral*, and *tarsal*—which are concentrically arranged around the eyelid. Akinesia of these muscles is generally desired for ocular procedures, because if the muscles were allowed to contract around the globe, intraocular pressure would increase. However, the recent success of cataract and glaucoma procedures performed with the use of topical and subconjunctival anesthesia has demonstrated that akinesia of the orbicular muscle of the eye is not always mandatory.

Cranial Nerves

The orbital portion of the *optic nerve* (cranial nerve II) (Figure 39-6) is from 25 to 30 mm long and travels posteriorly within the muscle cone from the globe into the cranial cavity. This distance is actually longer than that from the posterior portion of the globe to the orbital apex, giving the optic nerve an S-shaped configuration. This shape allows free movement of the nerve so that the many positions of the eye are accommodated. The optic nerve is myelinated and is about 4 mm in diameter.[2] The optic nerve extends through the *optic canal* and continues until it meets the *optic chiasm* intracranially. The optic chiasm is the junction of both optic nerve tracts. Here, suspended in and surrounded by cerebrospinal fluid, the optic nerve fibers partially decussate, sending visual fibers to the contralateral eye.

The optic nerve is not a true cranial nerve but is actually an outgrowth of the brain.[1] As a result, the optic nerve is also covered by the *meninges*, the fibrous wrappings of the arachnoid, dura, and pia mater, which envelop the central nervous system (CNS). Therefore any anesthetic agent injected into the optic nerve sheath can find its way back to the midbrain through the cerebrospinal fluid and result in CNS depression and even lead to respiratory arrest. The optic nerve also carries the central retinal artery and vein into the globe. The central retinal artery and vein exit the optic nerve about 8 to 15 mm posterior to the globe.[3]

The *oculomotor nerve* (cranial nerve III) innervates the following muscles of the orbit: the superior rectus muscle, the inferior rectus muscle, the inferior oblique muscle, the medial rectus muscle, and the levator muscle of the upper eyelid. The oculomotor

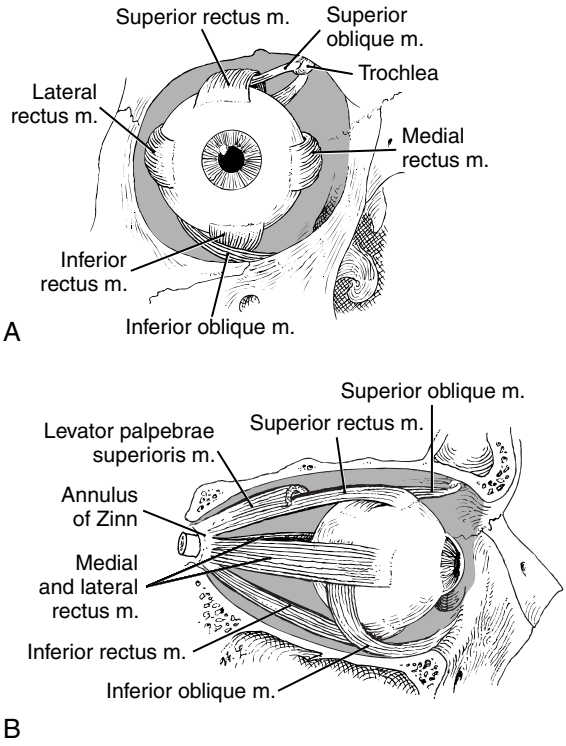

FIGURE **39-1** **A,** Frontal view of the orbit. **B,** Lateral view of the orbit. *m.*, Muscle.

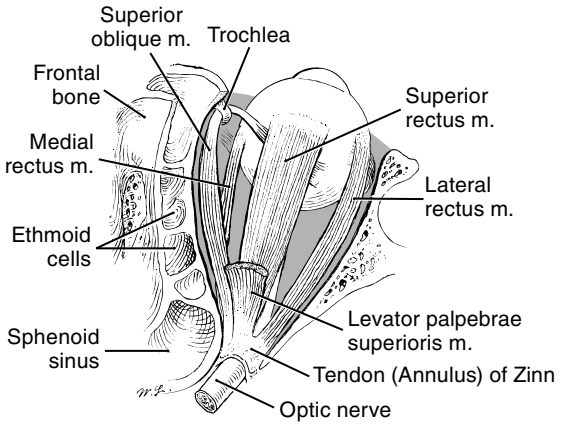

FIGURE **39-2** Superior view of the orbit. *m.*, Muscle.

nerve is the primary motor nerve to the extraocular muscles of the orbit; this nerve branches superiorly and inferiorly (Figure 39-7). The superior branch innervates the superior rectus muscle and the levator muscle of the upper eyelid. The inferior branch of the oculomotor nerve innervates the medial rectus muscle, the inferior rectus muscle, and the inferior oblique muscle. This nerve also sends parasympathetic fibers to the ciliary ganglion (Figure 39-8), which is located adjacent to the optic nerve in the posterior portion of the orbit. The ciliary ganglion receives parasympathetic fibers from the oculomotor nerve and also sympathetic fibers from the carotid artery plexus and a sensory branch from the nasociliary nerve, a branch of the ophthalmic nerve. The parasympathetic fibers move from the ciliary ganglion forward to innervate the iris sphincter muscles, which cause constriction of the pupil. The sympathetic motor fibers move forward to control the radial muscle of the iris for pupillary dilation.[1-3]

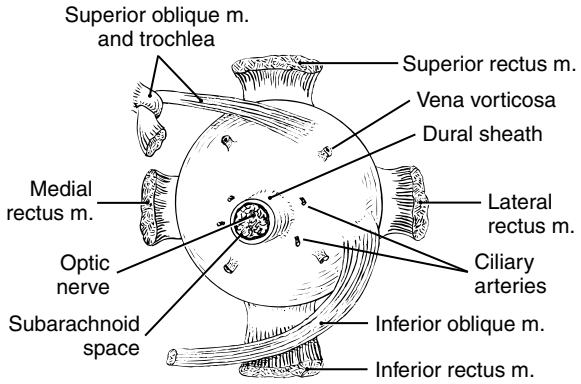

FIGURE **39-3** Posterior view of the globe. *m.*, Muscle.

TABLE **39-1** Orbital Muscles and Innervation

Muscle	Function	Cranial Nerve
Superior rectus	Supraduction	III
Inferior rectus	Infraduction	III
Medial rectus	Adduction	III
Lateral rectus	Abduction	VI
Superior oblique	Intorsion Depression	IV
Inferior oblique	Extorsion Elevation	III

The *trochlear nerve* (cranial nerve IV) (see Figure 39-7) provides the motor fibers for the superior oblique muscle. This nerve enters the orbit through the superior orbital fissure outside the muscle cone. It is the only orbital cranial motor nerve that enters the orbit from outside the muscle cone. Once inside the orbit, the nerve root moves in a medial direction to innervate the superior oblique muscle.

The *trigeminal nerve* (cranial nerve V) (see Figure 39-8) has sensory and motor components. In ocular anesthesia, the sensory component is of primary importance. The intracranial portion of the nerve forms the trigeminal ganglion, which has three main divisions: the ophthalmic, the maxillary, and the mandibular nerves. The ophthalmic branch provides for the sensation of pain, touch, and temperature to the cornea, ciliary body, iris, lacrimal gland, conjunctiva, nasal mucosa, eyelid, eyebrow, forehead, and nose. The maxillary branch provides for the sensation of pain, touch, and temperature to the upper lip, nasal mucosa, and scalp muscles.[4]

The *ophthalmic nerve* has three main branches: lacrimal, frontal, and nasociliary. The *lacrimal nerve branch* innervates the lacrimal gland in the superior lateral aspect of the orbit. The frontal branch is the largest branch of the ophthalmic nerve. This branch enters the orbit from outside the muscle cone through the superior orbital fissure and travels anteriorly outside the muscle cone superior to the levator muscle. The frontal nerve itself splits into two branches. The larger, supraorbital branch continues forward into the orbit and exits the orbit through the supraorbital notch; this branch innervates the forehead. The smaller branch is the supratrochlear nerve, which moves in a medial direction, supplying nerve roots to the forehead and the medial portion of the upper eyelid. The *nasociliary nerve branch* enters the orbit from inside the muscle cone and crosses over the optic nerve, sending nerve fibers medially and to the ciliary ganglion. The fibers to the ciliary ganglion form the short ciliary nerves, which continue anteriorly,

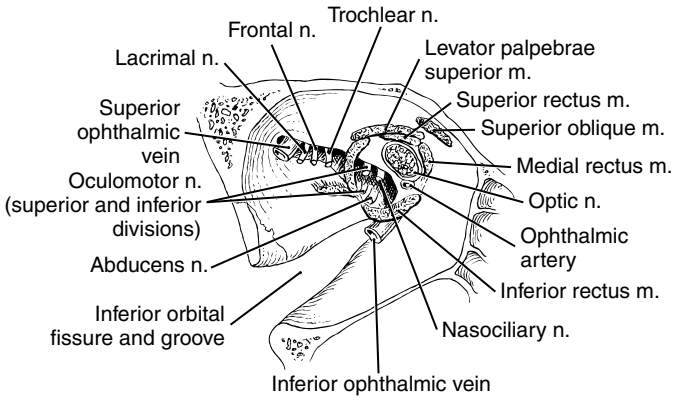

FIGURE **39-4** View of the orbital apex. *m.*, Muscle; *n.*, nerve.

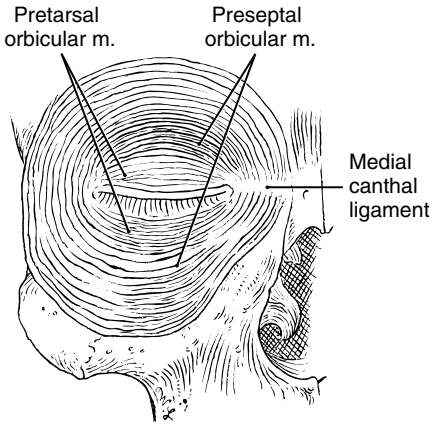

FIGURE **39-5** Orbicularis oculi muscles. *m.*, Muscle.

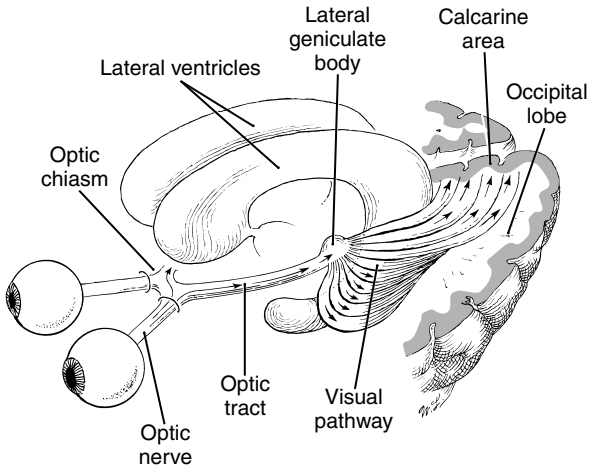

FIGURE **39-6** Intraorbital and intracranial view of the optic nerve.

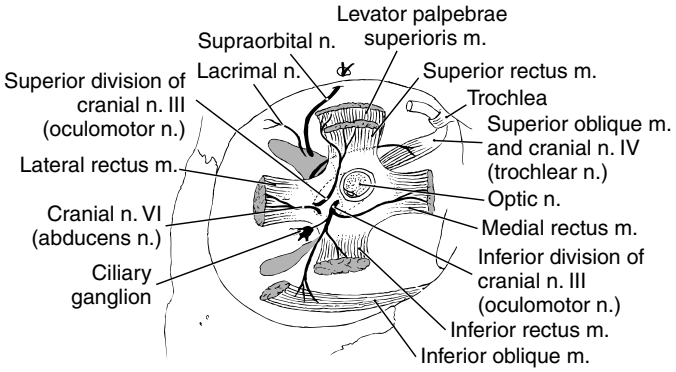

FIGURE **39-7** Frontal view of the posterior orbit with its motor nerves and the extraocular muscles. *m.*, Muscle; *n.*, nerve.

penetrating the posterior portion of the globe near the optic nerve. The nasociliary nerve also gives rise to the long ciliary nerves, which continue anteriorly and enter the posterior portion of the globe supplying the ciliary muscle, iris, and cornea. The long ciliary nerves also carry sympathetic fibers to the dilator muscle of the iris from the superior cervical ganglion. The nasociliary nerve continues along the medial aspect of the orbit just superior to the medial rectus muscle until it passes through the orbital septum to become the *infratrochlear nerve*. The infratrochlear nerve provides sensory input to the side of the nose, the medial aspect of the eyelids, the medial conjunctiva, the caruncle, and the lacrimal sac.[1-4]

The *abducens nerve* (cranial nerve VI) (see Figure 39-7) provides motor function to the lateral rectus muscle. The nerve enters through the superior orbital fissure within the muscle cone and continues along the conal surface of the lateral rectus muscle, eventually inserting in the posterior one third of that muscle.

The *facial nerve* (cranial nerve VII) (Figure 39-9) is predominantly a motor nerve for the muscles of the face. This nerve exits from the stylomastoid foramen. The facial nerve travels underneath the external auditory canal to the parotid gland, where it divides into an upper and a lower branch. Ocular anesthesia is more concerned with the upper branch of the facial nerve than with the lower. The upper branch further divides into the temporal and zygomatic branches, which innervate the orbicular muscle of the eye, the superficial facial muscles, and the scalp muscles.

The *vagus nerve* (cranial nerve X) provides motor function to the intrinsic muscles of the larynx and the heart; it provides major parasympathetic visceral innervation elsewhere. It is also the efferent pathway for the oculocardiac reflex, which can result in bradycardia and dysrhythmias.

Orbital Fossa

The *orbital fossa* has been described as pear shaped. The medial walls of the orbit extend almost straight back, whereas the lateral walls diverge at about a 90-degree angle to each other (Figure 39-10). The *superior* and *inferior orbital fissures* are in the orbital apex, which is located in the posterior orbit. These fissures are the entry portals for the orbital nerves and vessels (Figure 39-11). The *optic foramen* lies just medial to the superior orbital fissure and is the entry portal for the optic nerve and the ophthalmic artery from the intracranial to the intraorbital area. In the medial nasal aspect of the fossa, just behind the orbital rim, is the *lacrimal bone*, which is used as a landmark for the medial peribulbar block (Figure 39-12). The *ethmoid bone* is just posterior to the lacrimal bone.[4]

The *supraorbital nerve* exits the orbit in the supraorbital notch, which is in the superior nasal aspect of the orbital rim. The *infraorbital foramen*, where the infraorbital nerve and artery exit, is just below the infraorbital rim at about the 6-o'clock position. The *infraorbital nerve* is the sensory branch of the maxillary nerve. The *lacrimal*, *frontal*, and *trochlear nerves* all enter through the superior orbital fissure outside the muscle cone. The *oculomotor*, *abducens*, and *nasociliary nerves* all enter the orbit from inside the muscle cone.[4]

The *ophthalmic artery* (Figure 39-13), which is the first branch of the internal carotid artery, passes into the orbit through the optic canal. The ophthalmic artery usually lies just inferolateral to the optic nerve. The artery extends along the optic nerve for a short

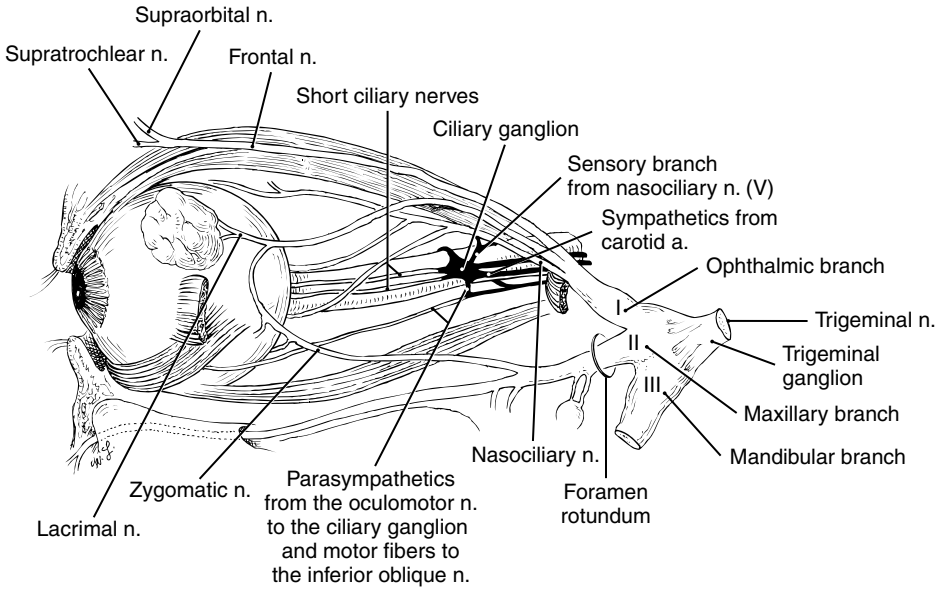

FIGURE **39-8** Lateral orbital view of sensory nerves and ciliary ganglion. *a.*, Artery; *n.*, nerve.

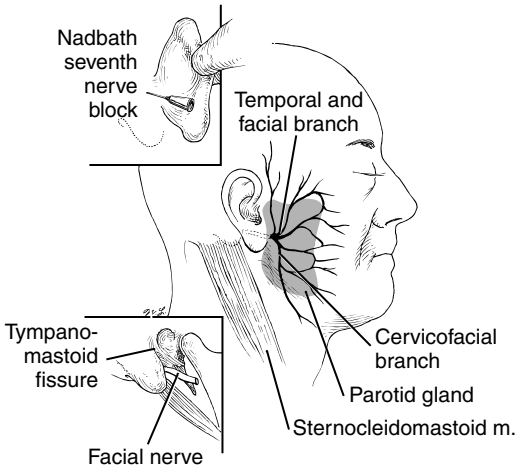

FIGURE **39-9** The origin and branches of the facial nerve. *Upper inset:* Needle placement for the Nadbath cranial nerve VII block. *m.*, Muscle.

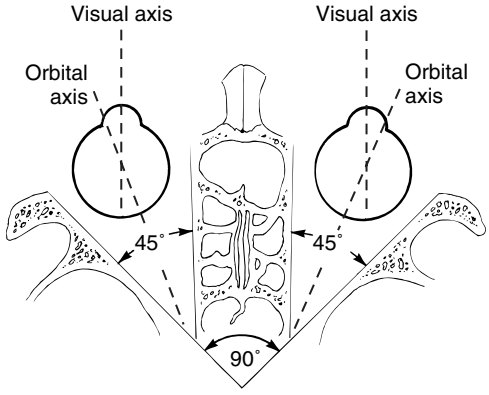

FIGURE **39-10** Superior view of the bony orbit, demonstrating the orbital and visual axes.

distance, crossing over it in most cases and continuing medially.[5] The first branch of the ophthalmic artery is usually the *central retinal artery*. The central retinal artery moves in an anterior direction underneath the optic nerve, usually entering the optic nerve on its inferomedial side 8 to 15 mm posterior to the globe.[3] The artery continues forward into the optic nerve head and branches into the retinal arteries. The ophthalmic artery gives rise to the long and short posterior ciliary arteries. The short posterior arteries move anteriorly and divide into many small branches that penetrate the globe close to the optic nerve and supply the choroid and the optic nerve head. The ophthalmic artery also provides branches to the optic nerve. The orbital branches of the ophthalmic artery include branches to the supraorbital arteries, the rectus muscles, and the lacrimal gland.[4]

The *lacrimal artery* moves anteriorly along the superior aspect of the lateral rectus muscle to the lacrimal gland. The *supraorbital artery* branches from the ophthalmic artery as it crosses over the optic nerve and extends just medial to the superior rectus and levator muscles. It continues forward on a superior nasal route and exits through the *supraorbital notch* or *foramen*.

The *dorsal nasal artery* is one of the terminal branches of the ophthalmic artery. It exits the orbital septum above the medial canthal tendon and joins with the *angular artery,* thus establishing communication between the internal and external carotid arteries.[1] The *external carotid artery* gives branches to the facial artery (the external maxillary artery). The *facial artery* originates near the angle of the mandible, extends toward the stylohyoid muscles, and then proceeds forward to the lower border of the mandible. The artery then turns upward and moves toward the nose, where it joins with the dorsal nasal artery in the medial canthal area. The inferior orbital fissure is the entrance site for the *infraorbital artery*. This artery moves anteriorly through the infraorbital canal and exits to the face through the infraorbital foramen.

The venous drainage system (see Figure 39-13) for the orbit includes the superior and inferior ophthalmic veins, which drain into the cavernous sinus that is located intracranially. Radiographic studies have demonstrated a unique characteristic of the orbital vascular system: the orbital veins are independent of the orbital arteries.[5] The venous system of the orbit is valveless, and blood flow in this area is determined by pressure gradients. The primary vein of the orbit is the *superior ophthalmic vein*. This vein travels posteriorly to the medial side of the superior rectus muscle, then beneath the superior rectus muscle inside a support hammock. The vein then emerges on the muscle's lateral aspect.

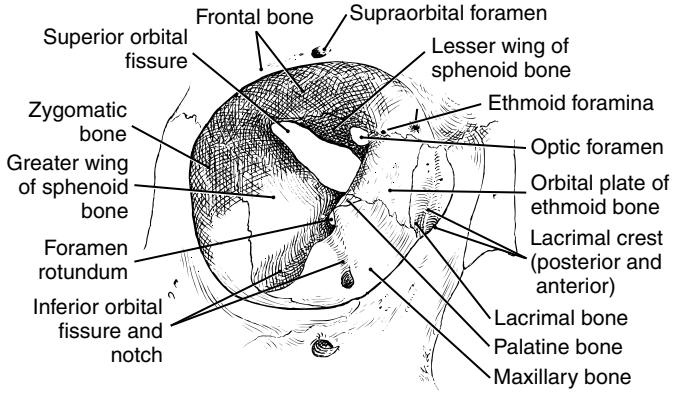

FIGURE **39-11** Frontal view of the orbital bones.

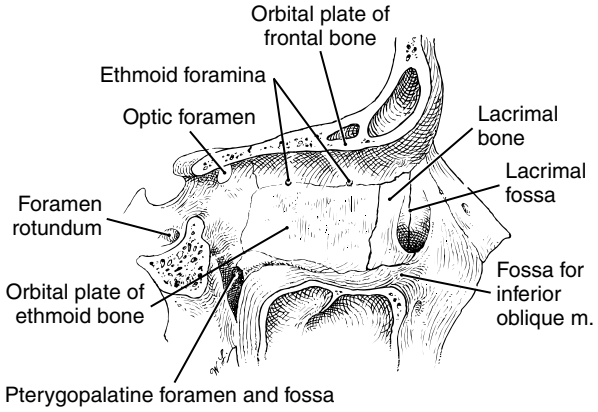

FIGURE **39-12** Lateral view of the orbital bones. *m.*, Muscle.

The vein continues its posterior direction along the lateral aspect of the superior rectus, exiting the orbit through the superior orbital fissure, and terminating in the cavernous sinus.[5]

Several veins enter into the superior ophthalmic vein: the *ciliary veins*, the *lacrimal veins*, and the *superior vortex veins*, which are located on the posterior quadrants of the globe and drain the choroid, or second layer, of the globe. The *inferior ophthalmic vein* originates from a diffuse plexus on the floor of the orbit. This vein receives several branches, including the extraocular muscles and the inferior vortex veins located on the inferoposterior quadrants of the globe. The primary branch of the inferior ophthalmic vein also drains into the *superior ophthalmic vein* before the entrance of the superior ophthalmic vein into the cavernous sinus. The *central retinal vein* exits the globe inside the optic nerve. The central retinal vein then exits the optic nerve and enters the orbit between 8 and 15 mm posterior to the globe[3] and usually passes directly to the cavernous sinus.[1]

Orbit

An evaluation of the patient's orbit and globe size is important before ocular anesthesia is conducted. The usual volume of the orbit is 30 mL (Box 39-1). The volume of a typical globe (which has a diameter of about 25 mm) is 6.5 to 7 mL.[5] The balance of the orbital volume is approximately 23 mL and is composed of muscles, vessels, nerves, and fat. Katsev et al.[6] measured 120 orbits from 60 adult skulls and found an average orbital depth of 48 mm. The distance from the middle third and lateral third of the infraorbital rim to the superior aspect of the optic foramen was also measured and ranged from 42 to 52 mm. This distance should not be confused with the depth of the orbital floor. Because of the pear shape of the orbit, the orbital floor does not extend directly to the orbital apex.

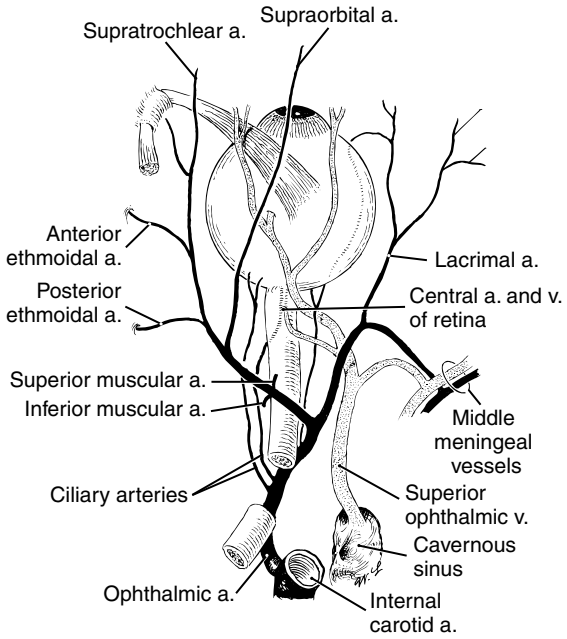

FIGURE **39-13** Superior view of the orbital arteries and veins. *a.*, Artery; *v.*, vein.

BOX **39-1**

Orbital Measurements

- Height of the orbit: 40 mm
- Width of the orbit: 35 mm
- Depth of the orbit: 42-52 mm
- Approximate orbital volume: 30 mL
- Approximate globe volume: 6.5-7.0 mL
- Balance of orbital volume: 23 mL

The orbital floor extends only to the posterior wall of the maxillary sinus, about two thirds of the depth of the orbital apex.

Orbital fat is contained in both the extraconal and the intraconal areas. The orbital fat encircles and encapsulates all these areas of the orbit.

The *orbital septum* is a fibrinous tissue that defines the anatomic anterior boundary of the orbit and keeps the adipose tissue from protruding forward. The *visual axis* (also known as the *optic axis* or the *geometric axis*) is an imaginary line from the midpoint of the cornea (anterior pole) to the midpoint of the retina or macula (posterior pole) (Figure 39-14). The horizontal (anteroposterior) diameter of the globe is an important consideration for ocular blocks. This measurement of the visual axis is referred to as the *axial length*. The axial length is measured preoperatively to determine the appropriate intraocular lens that should be placed in the eye after cataract removal. The axial length of the globe can be used *only* when measurements for intraocular lens implants are performed by the ophthalmologist. Normal axial lengths range from 23 to 23.5 mm. In the hyperopic (farsighted) eye, the globe is less than 22 mm long. This shorter eye length may allow a little more working area behind the eye during an ophthalmic block; however, this advantage may be offset by a smaller overall orbit.[4,6]

The main concern regarding ophthalmic blocks involves the longer, myopic (nearsighted) eye, whose axial length is greater than 24 mm. As the globe stretches, it is believed that the fibrinous scleral layer thins, making the globe easier to penetrate by the

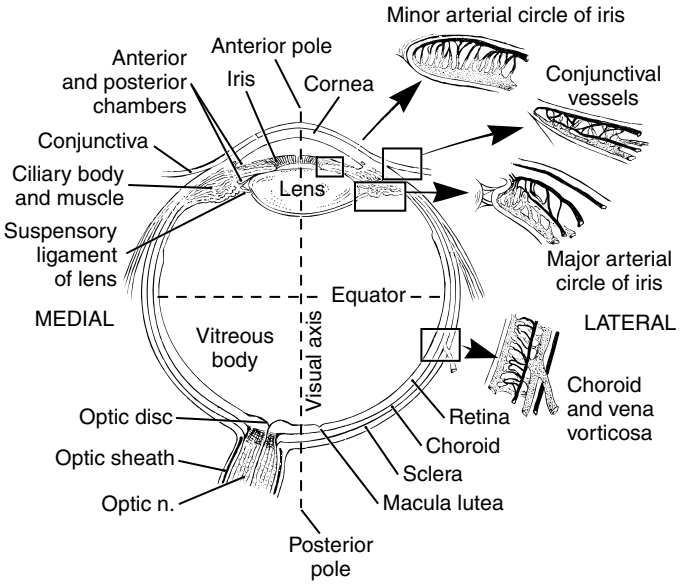

FIGURE **39-14** Cross-sectional view of the globe. *n.*, nerve.

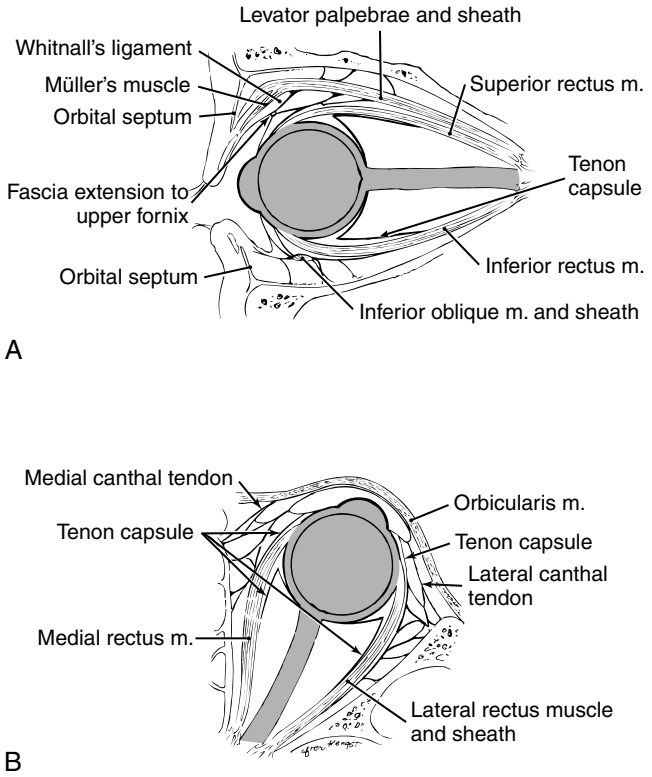

FIGURE **39-15** **A,** Lateral view of the orbital connective tissue. **B,** Superior view of the orbital connective tissue. *m.*, Muscle.

needle. This increased posterior length of the globe also increases the chance of globe puncture. Therefore, because of a greater chance of contact in the posterior aspect of the orbit, the axial length of the eye (if this measurement is available) should be considered in the planning for ocular block. If the axial length is unknown, which may be the case in glaucoma surgery, corneal transplants, retinal procedures, or muscle surgery, the practitioner's preoperative questions should include a history of nearsightedness or previous retinal procedures.

The separate *coats*, or *tunics*, of the eyeball (see Figure 39-14) start with the *sclera*, which is the outer, fibrinous protective layer. The sclera is white and opaque and lies just posterior to the cornea. The *cornea* is the outer, fibrinous protective layer located anteriorly, and it is transparent and colorless. The middle, or vascular, layer is called the *choroid*. The *retina* is the inner layer of the posterior half of the eye. The *limbal area* is defined as the area at the junction between the cornea and the sclera.[1] The *conjunctiva* is a thin, transparent mucous membrane that covers the posterior surface of the eyelids and the anterior surface of the sclera.

A *staphyloma* is a bulging of the uvea, which comprises the iris, the ciliary body, and the choroid, into a thin and stretched sclera. Staphylomas may occur in the anterior, equatorial, and posterior areas.[2]

Tissue Systems of the Orbit

Three connective tissue systems within the orbit have been defined by Koornneef.[7] They are the Tenon capsule, the orbital connective tissue, and the fascial sheaths of the extraocular muscles (Figure 39-15).

Tenon Capsule. The *Tenon capsule* (bulbar fascia) consists of fibrous connective tissue that covers the eyeball from near the corneal limbus, where it is fused to the conjunctiva, and extends behind the eye, with openings for the extraocular muscles and the optic nerve. The Tenon capsule serves primarily as a cavity in which the eye moves.

Orbital Connective Tissue. Koornneef demonstrated the presence of *connective tissue* attachments between both the globe and the periorbital area. The connective tissue begins at the orbital apex and continues anteriorly, becoming more complex and more clearly defined at the level of the globe. Koornneef[7] also noted that the tissue septa are in a 360-degree encapsulation of the globe (Figure 39-15). These connective tissue septa encircle and support the globe within the bony orbit. Connective tissue septa were also noted between the superior and inferior oblique muscles, the Tenon capsule, the rectus muscles, and the ligaments stabilizing the globe within the orbit. This connective tissue septa meshwork limits displacement of the globe.

Fascial Sheaths. The *intermuscular membrane* is a fibrous membrane that connects the four rectus muscle sheaths. Numerous extensions from these muscle sheaths form an intricate system of fibrinous attachments that interconnect the muscles into the orbit, support the globe, and check the ocular movements.

In the posterior orbit, the fascial sheaths of the extraocular muscles are not as well defined as they are immediately behind the globe.[8] Koornneef was not able to identify a common muscle cone throughout the orbit (Figure 39-16). The muscle sheaths themselves contribute fibrinous septa to the periorbit; these septa serve as ligaments for the extraocular muscles. These fascial extensions promote the efficiency of the extraocular muscle functions.[7-10]

PHARMACOLOGY: OCULAR MEDICATIONS AND ANESTHETIC AGENTS

A number of drugs are used in ophthalmology practice including mydriatics, miotics, cycloplegics, antibiotics, anti inflammatory drugs, viscoelastics, and glaucoma therapies. Ocular medications are listed in Table 39-2. The local anesthetics and hyaluronidase are covered in detail in Chapter 10.

Systemic Absorption of Eye Drops

The *lacrimal apparatus* includes the lacrimal gland, the puncta, the inferior and superior canaliculus, the common canaliculus, the lacrimal sac, and the nasolacrimal duct (Figure 39-17).

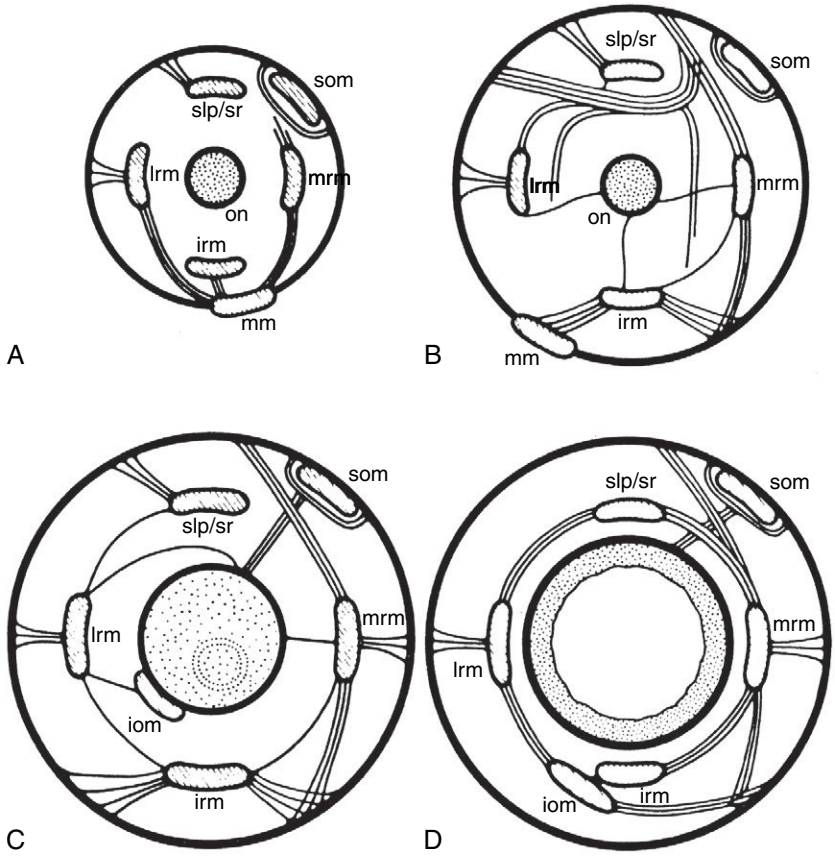

FIGURE **39-16** Extraocular muscle connective tissue system. Highly schematic representation of the connective tissue system of the extraocular muscles. **A,** Coronal section near the orbital apex. **B,** Coronal section near the posterior portion of the globe. **C,** Coronal section lying just anterior to the posterior portion of the globe. **D,** Coronal section near the equator of the globe. *iom*, Inferior oblique muscle; *irm*, inferior rectus muscle; *lrm*, lateral rectus muscle; *m*, Müller's muscle; *mrm*, medial rectus muscle; *on*, optic nerve; *slp/sr*, levator palpebrae superioris–superior rectus complex; *som*, superior oblique muscle. (From Koornneef L. Orbital septa: anatomy and function. *Ophthalmology.* 1979;86:876.)

The lacrimal gland is located in a depression of the frontal bone in the superior temporal orbit.[1-2] The gland has several ducts that lead to the conjunctival surface of the upper eyelid. Tears pass from the lacrimal gland through the ducts, over the cornea and conjunctiva, keeping the eye moist. Near the medial canthus, tears enter the puncta, travel through the canaliculus to the lacrimal sac, and drain into the nasolacrimal duct before entering the nasal mucosa.

Topical eye medications enter the bloodstream through the outer eye membrane and the lacrimal apparatus. The following measures reduce the amount of topical medications that enter the bloodstream:

- Have the patient close the eyes for 60 seconds after drops are instilled to encourage absorption by the eye and minimize drainage to the nasal mucosa.
- Have the patient avoid blinking, which rapidly moves the medication into the tear outflow canal and the systemic circulation.
- Block the tear outflow canal by placing the index finger over the medial canthus after the eye is closed.[2]

Patients may complain of a metallic taste after the administration of ocular anesthetics. This precursor to a toxic anesthetic level needs further evaluation. However, it is usually the result of the local anesthesia passing into the nasal mucosa.

SELECT OCULAR ANESTHESIA TECHNIQUES

Ophthalmic Block Techniques

Topical/Intraocular Anesthesia

Cataract and vitreoretinal surgeries are the most frequently performed intraocular surgical procedures.[11,12] Topical anesthesia for cataract surgery (e.g., 2% lidocaine) has proved to be effective in providing adequate analgesia for the surgical procedure and is commonly used with phacoemulsification. Topical anesthesia is applied as drops or gels and may be supplemented by intracameral injection by the surgeon for better intraoperative pain control. Vitreoretinal surgery usually requires at least a sub-Tenon block and more frequently injection anesthetic techniques.[12] Today's smaller-incision surgical techniques with foldable intraocular lenses provide a safer surgical experience for the patient and a more rapid recovery. Intraocular anesthesia can further enhance the analgesia for the surgical procedure; lidocaine (preservative free) has been studied and recognized as safe for intraocular administration.[13] However, topical anesthesia may not be appropriate in all cases for the surgeon or the patient, because it provides a lesser degree of analgesia and no akinesia of the ocular muscles or eyelids. There is wide variability in operative conditions, sensations, and pain relief, depending on the type of local anesthesia administered for intraocular surgery. Using data that present the strength of evidence as "strong evidence," "weak evidence," or "no evidence," the differences between local/regional

TABLE 39-2 Ocular Medications

Class	Generic Name (Trade Name)	Comments
α_2-Agonist	brimonidine tartrate (Alphagan P) apracionidine (Lopidine)	Glaucoma: Reduces aqueous humor production Contraindicated with MAO inhibitors
Cholinesterase inhibitors	ecothiophate iodide (Phospholine Iodide)	Glaucoma: Produces miosis by allowing acetylcholine to continually stimulate iris and ciliary muscles, improving uveoscleral outflow of aqueous humor May prolong effects of succinylcholine; however, rarely used
β-Blockers	timolol (Timoptic) levobunolol (Betagan Liquifilm) betaxolol (Betoptic) metipranolol (OptiPranolol) carteolol (generic)	Glaucoma: Reduces aqueous humor production Caution in patients with asthma, COPD, heart block, heart failure, and hypotension
Carbonic anhydrase inhibitors	acetazolamide (Diamox) dorzolamide (Trusopt) brinzolamide (Azopt)	Glaucoma: Reduces aqueous humor production
Cholinergic agonists	pilocarpine, topical carbachol (Miostat), intraocular acetylcholine chloride (Miochol-E), intraocular	Miotics; used to constrict pupil for surgical procedures
Cycloplegics	atropine homatropine cyclopentolate	Pupillary dilators; cause temporary paralysis of ciliary muscle and muscles of accommodation
Intraocular gases	sulfur hexafluoride perfluoropropane	Retinal detachment: Intravitreal insufflation to tamponade retina in place *Avoid nitrous oxide for up to 3 months*
Mydriatics	phenylephrine tropicamide epinephrine	Pupillary dilators; cause either a direct or indirect effect on dilator muscle of iris
Nonsteroidal antiinflammatory agents	flurbiprofen sodium (Ocufen)	Preserves pupillary dilation during surgical procedure by inhibiting prostaglandins, which cause miosis
Osmotic diuretics	glycerin (oral agent) mannitol	Reduce intraocular pressure
Prostaglandins	latanoprost (Xalatan) bimatoprost (Lumigan) travoprost (Travatan) tafluprost (Zioptan)	Glaucoma: Promotes uveoscleral outflow of aqueous humor
Viscoelastics	hyaluronate sodium (Healon, Amvisc)	Protect endothelial cells of cornea during surgical procedures

COPD, Chronic obstructive pulmonary disease; *MAO*, monoamine oxidase.

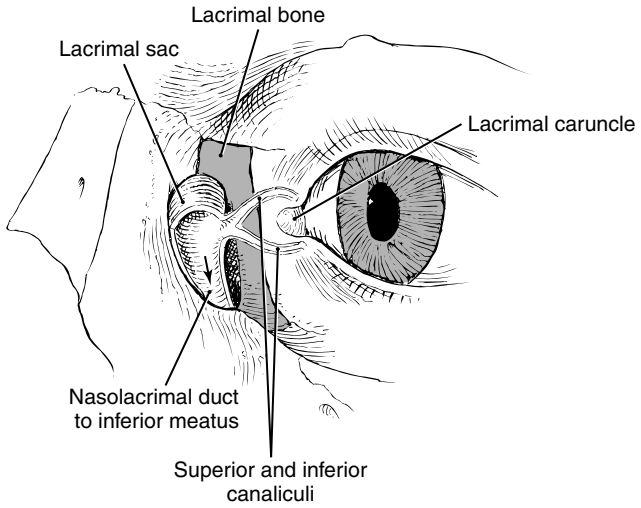

FIGURE 39-17 Frontal view of the lacrimal drainage system.

anesthetic techniques for variables such as pain (during placement of the block and during the surgery), eye akinesia, eyelid sensation, and visual sensations were quantified on a + or − scale, and the conflicts of evidence are presented as a range in Table 39-3.[12]

Sub-Tenon Block

The sub-Tenon block will produce a more profound analgesia; however, motor movement of the globe may still be present. The Tenon tissue, as described earlier, encapsulates the globe posteriorly and fuses with the conjunctiva anteriorly. Anteriorly it is inferior to the conjunctiva. The sub-Tenon block is a procedure performed between the rectus muscles of the globe. The conjunctiva is incised, the Tenon tissue is elevated and incised, and a short cannula is inserted into the sub-Tenon space. Local anesthetic is injected with the objective of a posterior spread of the agent. The dose is usually 3 to 4 mL to achieve analgesia; however, larger doses of up to 10 mL have been reported to achieve some degree of akinesia.[14]

OCULAR REGIONAL ANESTHESIA

The ocular regional needle block still remains the most common and effective way to consistently produce a profound analgesia and akinesia of the eye and eyelids.

TABLE 39-3 Comparisons of Local/Regional Anesthesia Techniques

	Topical	Sub-Tenon Block	Peribulbar Block	Retrobulbar Block
Pain on administration	0 or –	+ or ++	++ or +++	+++
Surgical pain prevented	– –	+++	++	++

FIGURE **39-18** Superior view of the parallel and oblique approach to retrobulbar anesthetic blocks. *n.*, nerve.

The term *ocular local anesthesia* has been used to refer to retrobulbar or peribulbar blocks. More correctly, local anesthesia should be defined as *superficial, topical,* or *cutaneous anesthesia,* used, for example, when skin-laceration suturing is performed that poses minimal risks both to the body as a whole and to proximate vital organs.

Retrobulbar and peribulbar injections are categorized under regional anesthesia methods. These blocks are designed to anesthetize multiple cranial nerves (III, IV, V, VI, and VII). As described earlier, the optic nerve is a continuation of the brain. The dura mater divides at the entrance of the optic nerve into the orbit. The visceral layer of the dura covers the intraorbital part of the optic nerve, and the parietal layer blends into the periosteum of the orbit.[1] Therefore, by anatomic definition, this procedure is performed in the orbital epidural space. As has been demonstrated in the anatomic reviews by Koornneef, no true muscle cone exists, especially in the posterior portion of the orbit.[7-10] Therefore, old anatomic concepts such as the image of an intact muscle cone must be set aside in favor of concepts that illustrate a communication throughout the orbit.

Techniques and Modifications

The term *retrobulbar block* refers to an ophthalmic block technique originally described by Atkinson in 1936. The patient is instructed to look up and nasally (supranasal position). A 23-gauge retrobulbar (dull) needle is inserted through the skin in the infratemporal area, just above the inferior orbital rim and advanced toward the orbital apex 35 mm (1.38 inches) deep into the muscle cone (retrobulbar space). After negative aspiration, 2 to 4 mL of anesthetic solution is injected into the muscle cone. After the injection is completed, the eyelids are closed, and digital pressure is applied over the globe to the orbit. A few minutes later, the eyelids are opened, and the globe is inspected for akinesia.[15] The popularity of the retrobulbar block for ophthalmic procedures grew, with more than 1 million blocks performed annually in the 1940s.[16] Unfortunately, so also did the complication rates.

The reported complications from retrobulbar anesthesia include trauma to the optic nerve, the blood vessels, and the globe, all of which can lead to loss of vision. Respiratory arrest may result when anesthetic agents enter the cerebrospinal fluid of the optic nerve. Seizures may occur when even small amounts of local anesthetic are injected intravascularly.

As a result of the increasing number of complications being reported, practitioners began to alter the Atkinson retrobulbar technique in an effort to increase the margin of safety for ocular anesthesia.[17] Three major problem areas in the Atkinson technique are identified in this chapter, and technique modifications are discussed (Figure 39-18).

Eye Position

The position of the eye during retrobulbar block anesthesia is an important consideration. When the patient looks upward and nasally, the optic nerve and blood vessels are placed in the path of the needle. Tension is created on the optic nerve and the surrounding vasculature, making the orbital structures more susceptible to trauma. In this position, the posterior pole of the globe also moves into the needle path. As a means of avoiding this problem, the following modification in technique has been recommended.

The primary gaze position, in which the patient is looking directly forward, allows the optic nerve to maintain its S-shaped curvature and also releases the tension on the blood vessels. The down-and-out gaze position allows the optic nerve and vessels to rotate toward the optic foramen and farther away from the needle path. Both of these eye positions have the potential disadvantage of needle visualization by the patient. The upward-gaze position should only be used as described by Gills and Lloyd.[16] Their technique allows the use of the upward-gaze position because the needle is placed lateral and parallel to both the optic nerve and the vessels.

Needle Depth

A second problem is the depth of the needle insertion. The vital structures in the ocular anatomy are more crowded in the posterior orbit. Deep needle penetration in the orbit increases the likelihood of trauma to the optic nerve and vessels. If the depth of the needle insertion is decreased to approximately 25 mm (1 inch),[17] the needle would lie just posterior to the globe, thereby reducing the risk of puncture of the vital structures. Studies have demonstrated that because of the wide variation in orbital and globe sizes, a needle depth of 19 to 31 mm (0.75 to 1.25 inches) is the safest.[6]

Needle Tip Shape

A pertinent issue debated in the literature is the use of sharp versus dull needles for ocular blocks. Dull or flat-grind needles

made specifically for retrobulbar anesthesia are touted by some clinicians as the only safe needles for use in ocular blocks. It is not so much the type of needle but where the needle is placed that increases the risk.[18] Dull retrobulbar needles may not be tolerated as well by awake patients because of the sensation of pressure they create on insertion. Other needles proposed for ocular blocks include a curved retrobulbar needle[19] and a dull pinhead needle, in which the injection port is proximal to the head of the needle.[20]

Needle Angle

The angle of the needle is a third very important area that should be considered for modification. The original Atkinson technique uses an oblique approach; that is, the needle is inserted in the infratemporal area just above the inferior orbital rim and is directed toward the orbital apex**,** a pathway that tracts the needle tip toward the posterior pole of the globe, arteries, and the optic nerve.

Gills and Lloy[16] developed a technique that takes into consideration not only the aforementioned changes but also the length and spherical shape of the globe. This technique changes the oblique approach to a parallel approach. The lateral limbic margin, corneoscleral junction, is identified, and the needle is inserted in the inferotemporal area transconjunctivally, just lateral and parallel to the lateral limbic margin. The needle is inserted to a depth of approximately 25 mm (1 inch), entering the muscle cone just behind the globe. The advantages of this technique result from the needle position, which lies lateral and parallel to the optic nerve, the vasculature, and the posterior pole of the globe. However, the technique does not address the question, When does the needle tip pass the equator of the globe? The needle tip must pass the equator of the globe before it may be safely redirected cephalad and inserted into the intraconal space.

The original retrobulbar block technique described by Atkinson can be made safer by modification of the technique. Modifications that decrease the risk of adverse effects are as follows:

- Position the globe to decrease tension on the vital orbital structures and position them farther away from the needle—for example, the primary gaze position.
- Use a depth of needle insertion of about 25 mm (1 inch), which places the needle just behind the globe itself and avoids the structures deep in the orbit.
- Consider using a more lateral to parallel approach to the orbit than was originally demonstrated by Atkinson.

Some practitioners, in an effort to further improve the safety of ocular blocks, have advocated the use of extraconal peribulbar blocks.[21-25] The literature describes these techniques as directing the needle outside the muscle cone, or *extraconal.* The anesthetic is injected, creating a positive extraconal pressure that spreads the agent inside the muscle cone to anesthetize the cranial nerves. To accomplish this, the needle is inserted parallel to, or is angled away from, the visual axis of the globe in an effort to remain outside the muscle cone. Peribulbar injections may be performed in the superior temporal, medial, and inferior temporal orbital areas. Peribulbar anesthesia requires larger volumes of anesthetic agents (8 to 12 mL). Owing to the many septal divisions of the orbit, the anesthetic flow may not adequately diffuse into the intramuscle cone. Therefore, extraconal peribulbar anesthetic injections, as described in the literature, may not consistently produce adequate akinesia and may necessitate multiple repeat injections.[22]

Patients who may benefit from the extraconal peribulbar approach are those at increased risk for globe puncture, such as those with high myopia resulting in long axial lengths, significant

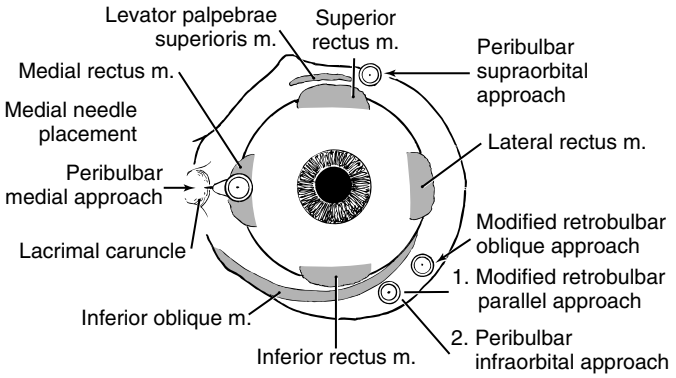

FIGURE **39-19** Frontal view of needle placement for retrobulbar and peribulbar anesthetic blocks. *m.*, Muscle.

enophthalmos, previous scleral buckling procedures, and staphylomas. However, peribulbar blocks have also been used in patients with globe punctures.[26]

The primary goal of extraconal peribulbar blocks is the avoidance of the muscle cone and its vital structures. With modified retrobulbar blocks, the goal is not only to avoid the vital structures but also to enter the muscle cone just posterior to the globe.

The least vascular areas in which ocular blocks can be performed were described by Koornneef and Kramer[9] (Figure 39-19). The inferotemporal area can be used for both the intraconal modified retrobulbar and the extraconal peribulbar technique. The superior orbital area just lateral to the 12-o'clock position through the skin and the medial orbital area through the caruncle conjunctiva may be accessed for the extraconal peribulbar technique.

The most important considerations for ocular blocks are the position of the eye and the depth and angle of the needle. Needle placement should avoid the optic nerve, arteries, veins, extraocular muscles, and the globe itself**.** At what insertion depth does the needle tip reach the equator of the globe, a spherical tangential point, beyond which it can be safely redirected into the retrobulbar space is addressed in an abstract that was accepted and presented at the 23rd annual meeting of The Ophthalmic Anesthesia Society, "A Geometrical Method Applied to an Orbital Block." The author introduces the measurement of the dynamic orbital-globe relationship and uses the measured axial length to calculate the distance to the equator of the globe, beyond which the needle may be safely redirected cephalad and inserted into the retrobulbar space. The calculation mathematically demonstrated that a 0.5-inch (12.5-mm) needle insertion was usually beyond the equator of the globe, but recommended calculating the distance to the equator on each patient for safety.[27]

Anesthesia Techniques

Gills-Lloyd Modified Retrobulbar Technique[16]

Equipment List.

- One 3-mL syringe
- One 6-mL or 10-mL syringe
- One 25-gauge 1-inch needle
- 1-inch paper tape
- One 4 × 4 gauze pad

Description. Figures 39-20 and 39-21 and Box 39-2 present valuable reference aids for the Gills-Lloyd modified retrobulbar technique.

The patient should be in a comfortable, reclining position. Anesthetic drops are placed in the conjunctiva, the eyelids are closed, and the outer eyelids are cleansed. The patient is asked to look directly overhead and to stare at a finger or other object.

The eye should not look inward but may look somewhat outward. Needle insertion through the skin is preferably avoided in this technique so that patient discomfort is minimized. The lateral limbic margin, corneoscleral junction, is identified. The lower eyelid is everted and controlled with a finger. The needle is placed with the bevel toward the globe, just above the inferior orbital rim, just lateral and parallel to the lateral limbic margin. The needle is then inserted through the conjunctiva and directed toward the orbital floor until the orbital septum is penetrated. The needle is then redirected parallel to the visual axis of the globe to a depth of 25 mm (1 inch). At this time, 1 to 1.5 mL of lidocaine, 1% to 2%, is injected after negative aspiration is performed. This initial extraconal peribulbar technique is effective in reducing the potential discomfort from the needle and the anesthetic injection of the modified retrobulbar block in the awake patient.

The eye is closed briefly in preparation for the modified retrobulbar injection. The lower eyelid is again everted and controlled with a finger. The needle is placed with the bevel toward the globe, just above the inferior orbital rim, just lateral and parallel to the lateral limbic margin. The needle is then inserted through the conjunctiva and directed toward the orbital floor until the orbital septum is penetrated. The needle is then redirected parallel to the visual axis of the globe past its equatorial plane, about 0.5-inch (12.5 mm)[27] deep. At this point, the needle is redirected cephalad between the lateral and inferior rectus muscles. Resistance may or may not be felt as the needle enters the muscle cone. The needle should be inserted about 25 mm (1 inch), depending on the size of the orbit and the globe (range, 19 to 31 mm). After negative aspiration, the anesthetic agent is injected slowly, 1 mL/10 sec, until the orbit is filled. Orbital size governs the total amount of anesthetic injected; however, about 6 mL usually suffices. Once the orbit is full of anesthesia, as indicated by orbital tension, the needle is withdrawn. The eyelids are closed, a 4 × 4 gauze is placed over the eye, and positive digital pressure is applied. The pressure helps spread the anesthetic and detect any increasing orbital pressure, which might indicate a retrobulbar hemorrhage.

The initial needle insertion is directed away from the globe so that the risk of globe puncture is decreased. Resistance may or may not be felt as the needle enters the muscle cone, depending on the presence or absence of the fibrinous connective tissue in the area behind the globe, as described by Koornneef and Kramer.[9] The sharper the needle, the less resistance felt by the practitioner and the less discomfort felt by the patient. By comparison, use of dull needles results in more resistance, potentially resulting in greater patient discomfort. Patients have described this resistance to the needle as *pressure pain*. Because a pop may or may not be felt as the needle enters the muscle cone, attention to needle depth is important for the avoidance of deep penetration into the orbit.

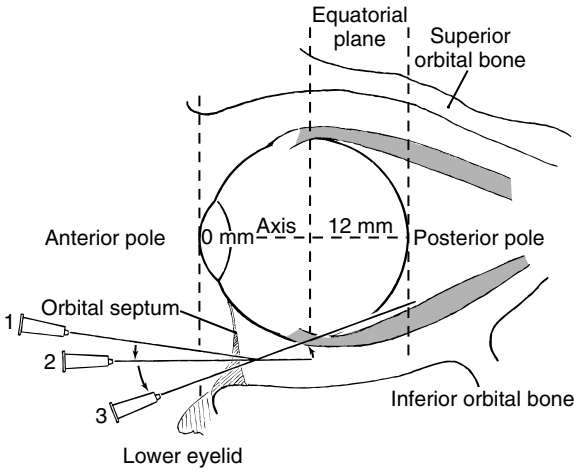

FIGURE **39-20** Lateral view of needle angles for a modified retrobulbar block.

During injection, the patient is told to inform the practitioner if any discomfort, such as stinging or a mild headache, is experienced. If this occurs, the injection should be stopped to allow the agent to take effect. The pressure sensation appears to result from the spread of the local agent throughout the orbital area. The stinging is noticed more when the agent moves into the peripheral area along the upper and lower eyelids. This slow injection process is continued until the orbit is filled with the anesthetic agent. When the anesthetic is placed into the muscle cone, the effects are seen rapidly, and the block can be evaluated for akinesia after about 2 minutes. Generous traction must be applied to the lower eyelid, because this technique is performed before the orbicular muscles of the eyelids are anesthetized (i.e., seventh nerve block). Seventh nerve blocks can be very painful and are not well tolerated by patients. These blocks generally precede retrobulbar or peribulbar blocks but may not be necessary, because the anesthetic agent from the modified retrobulbar or peribulbar block spreads randomly throughout the orbit and eyelids, providing adequate akinesia of the eyelids.[16,26]

Peribulbar Extraconal Techniques

Description. Figures 39-22 and 39-23 and Box 39-3 serve as valuable reference aids for the peribulbar technique.

Extraconal peribulbar blocks may be performed using different techniques. One is a supraorbital-only technique of injecting a large volume (10 to 12 mL) of anesthetic agent, which should distribute throughout the orbit for completion of the block. An inferotemporal-only technique also involves injection of a large volume (10 to 12 mL) of anesthesia, which should distribute throughout the orbit and anesthetize the eye. A more reproducible approach to extraconal peribulbar anesthesia is the use of both the inferior and superior approaches. Each of these injections may be performed with a 6-mL syringe for a total volume of 10 to 12 mL. The combination technique generally provides a more consistent result.

Infraorbital and Supraorbital Extraconal Peribulbar Anesthesia

Equipment List.

- One 10-mL syringe or two 6-mL syringes
- One or two 25-gauge needles
- One 4 × 4 gauze pad
- 1-inch paper tape
- One alcohol or povidone-iodine (Betadine) wipe

Description. For the *infraorbital peribulbar technique*, the lateral limbic margin is identified, and the patient is asked to look directly overhead. The lower eyelid is everted and controlled with a finger. The needle is placed, with the bevel toward the globe, just above the inferior orbital rim, lateral and parallel to the lateral limbic margin. The needle is then inserted through the anesthetized conjunctiva and directed toward the orbital floor until the orbital septum is penetrated. The needle is then redirected parallel to, or angled away from, the visual axis of the globe to a depth of about 25 mm (1 inch). After the syringe is secured and negative aspiration is performed, 6 mL of the anesthetic agent is slowly (1 mL/10 sec) injected. The rate of injection is determined by patient comfort. After the injection, the eyelids are closed, and positive pressure is applied for dispersal of the medication.

The *supraorbital peribulbar injection* is performed just inferior to the supraorbital rim, just lateral to the 12-o'clock position and superior to the globe. The needle is inserted with the bevel

toward the globe through the skin. This area is generally anesthetized from the original inferotemporal injection. The needle is inserted parallel to, or angled away from, the visual axis of the globe to a depth of about 25 mm (1 inch). After negative aspiration is performed, the anesthetist may begin a slow injection of 4 to 6 mL of anesthetic solution until a tense orbital area is observed. A more tense orbit should be expected to result from the peribulbar technique because of the increased extraconal pressure necessary to move the anesthetic intraconally.

Once this technique is completed, the eyelids are closed and taped shut. A 4 × 4 gauze pad is placed over the closed eye. A positive-pressure device is now placed over the eye to help distribute the agent throughout the orbit and achieve the desired analgesia and akinesia. The positive-pressure device also decreases intraocular pressure to an acceptable surgical level. To avoid corneal abrasion, the eyelids must completely cover the eye. It may take up to 10 minutes for satisfactory surgical anesthesia to be established from an extraconal peribulbar block. If the peribulbar block fails

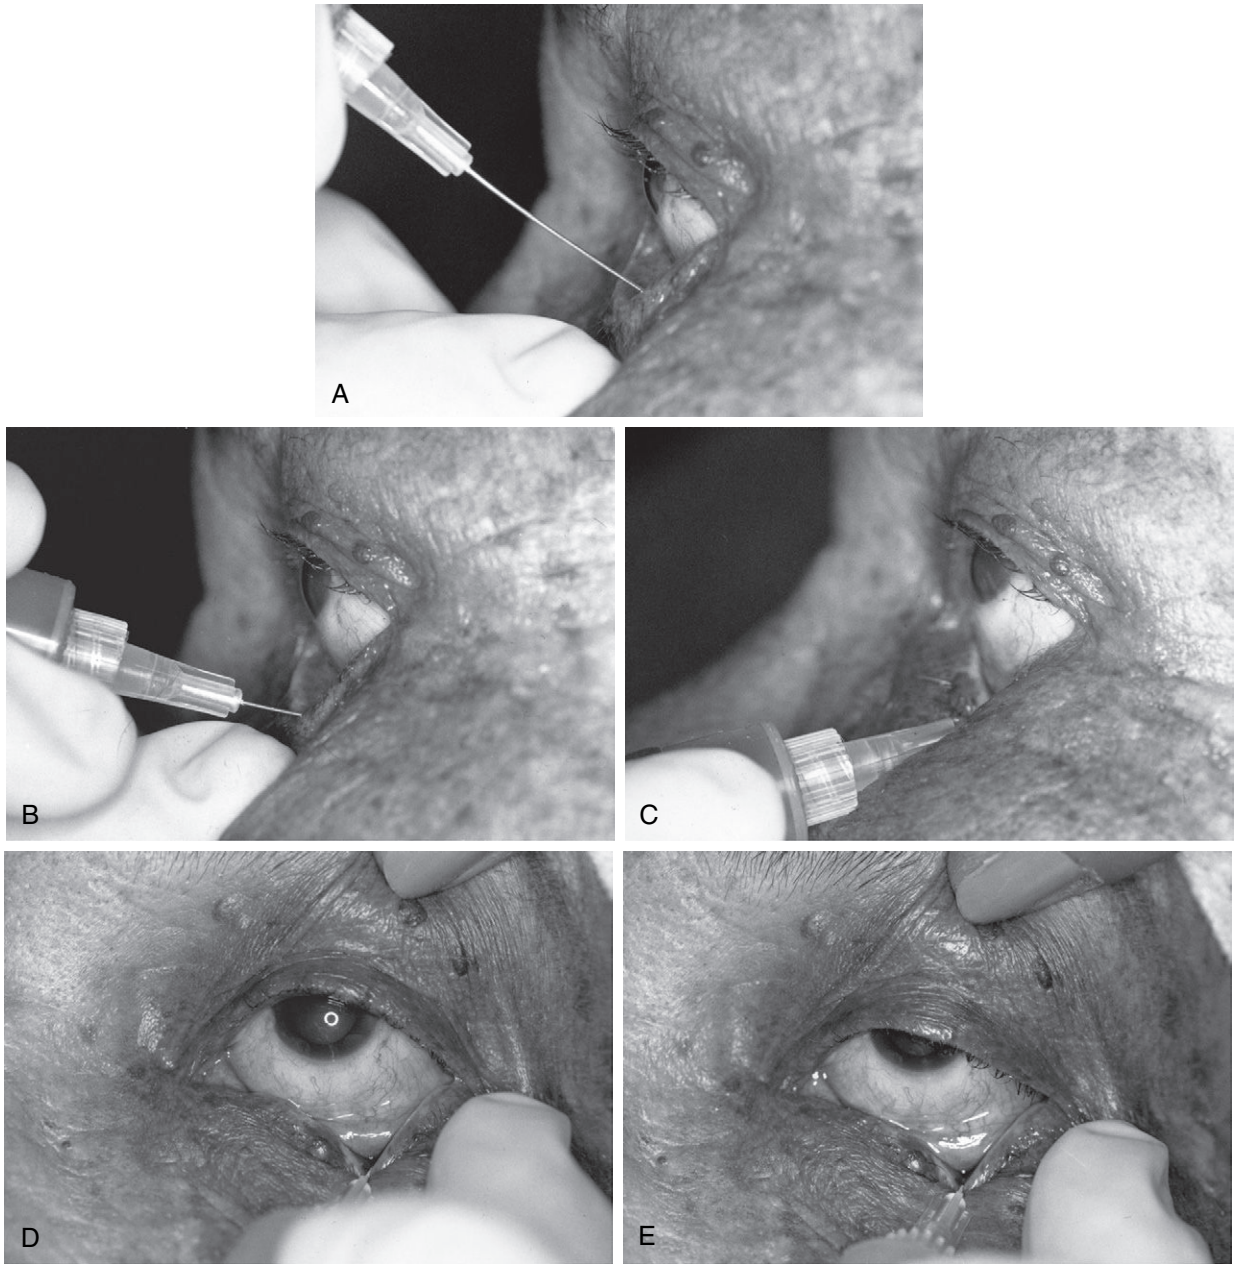

FIGURE **39-21** **A,** In the Gills-Lloyd modified retrobulbar technique, the needle should be inserted transconjunctivally or transcutaneously, angled away from the visual axis of the globe toward the orbital floor until the orbital septum is penetrated. **B,** After penetrating the orbital septum, the needle should be redirected parallel to the visual axis to a depth of about 12 mm (0.5 inch) passing the equatorial plane of the globe. **C,** After passing the equatorial plane of the globe, the needle should be redirected cephalad to a depth of about 25 mm (1 inch). At this point, the needle enters the muscle cone, and the medication is injected. **D,** Needle placement, which is lateral and parallel to the lateral limbic margin. **E,** Completion of the modified retrobulbar block. Some degree of globe proptosis and drooping of the upper eyelid should be expected.

to attain adequate akinesia within 10 minutes, the appropriate muscles must be reblocked by use of the inferior technique for the inferior rectus, inferior oblique, and lateral rectus muscles. The superior technique is used for the superior rectus, superior oblique, and medial rectus muscles. The supraorbital approach should not be attempted through the conjunctiva because of the potential for damage to the levator muscle of the upper eyelid; such damage may result in upper eyelid ptosis.

BOX **39-2**

The Gills-Lloyd Modified Retrobulbar Technique: Parallel Approach

- Insert the needle transconjunctivally or transcutaneously, with the bevel toward the globe, lateral to the lateral limbic margin and angled away from the visual axis of the globe toward the orbital floor, until the orbital septum is penetrated (see Figure 39-21, *A*).
- After penetrating the orbital septum, redirect the needle parallel to the visual axis to a depth of about 12 mm (0.5 inch) past the equatorial plane of the globe (see Figure 39-21, *B*).
- Past the equatorial plane of the globe, redirect the needle cephalad to a depth of about 25 mm (1 inch), entering the muscle cone while remaining lateral to the lateral limbic margin, and inject the medications (see Figure 39-21, *C*).

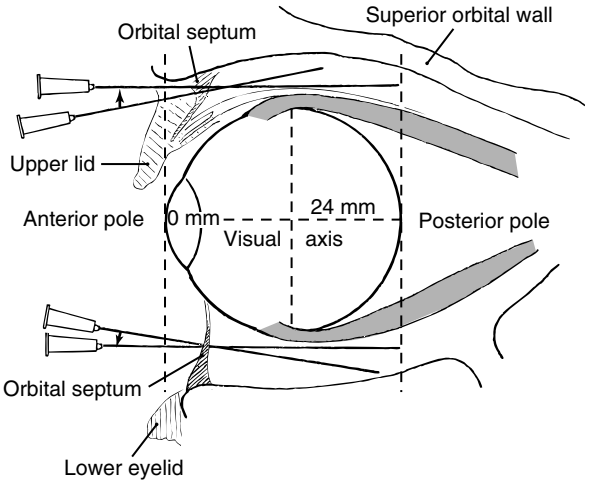

FIGURE **39-22** Lateral view of needle angles for peribulbar block.

Medial Extraconal Peribulbar Block

Equipment List.

- One 3-mL syringe
- One 30-gauge, ½-inch needle

Description. Figures 39-24 and 39-25 and Box 39-4 serve as valuable reference aids for medial peribulbar anesthesia.

The *medial peribulbar area* is a rather avascular fatty compartment that lies just medial to the medial rectus muscle. This area narrows significantly as it approaches the posterior surface of the globe, with the medial rectus muscle lying next to the bony orbit. Superior to the medial peribulbar area is the supranasal area. This area contains a portion of the superior ophthalmic vein and branches of the ophthalmic artery and should be avoided when ophthalmic blocks are performed.

The medial area also has herniated orifices within the connective tissue that communicate anteriorly to the posterior surface of the orbicular muscle of the eye. Therefore, the anterior spread of the anesthetic agent blocks cranial nerve VII, resulting in satisfactory akinesia of the eyelids for surgery. The medial peribulbar technique also can be used with minimal discomfort to provide eyelid akinesia before a modified retrobulbar block is performed; in this case, proparacaine drops are applied to the caruncle before the block is administered. The anesthetic agent is injected into the periorbital space that exists between the medial wall of the bony orbit and the medial rectus muscle. The technique is very effective as a secondary block both for incomplete akinesia of the medial rectus muscle and the superior oblique muscle and as a primary block for the orbicular muscles of the eyelid.

To avoid needle injuries to the medial rectus muscle, a modified insertion site, needle length, and angle may enhance the ease of needle placement and safety. The landmark for the modified technique is the *caruncle*, a small mound at the inner canthus of the eye formed by a conjunctival fold at its junction with the skin. The needle is inserted through the caruncle conjunctiva, tangential to the globe, and is directed medially and posteriorly toward the lacrimal bone, which is just posterior to the lacrimal sulcus. Care must be taken to avoid trauma to the puncta, the lacrimal cuniculi, and the lacrimal sac. To avoid contact with the medial

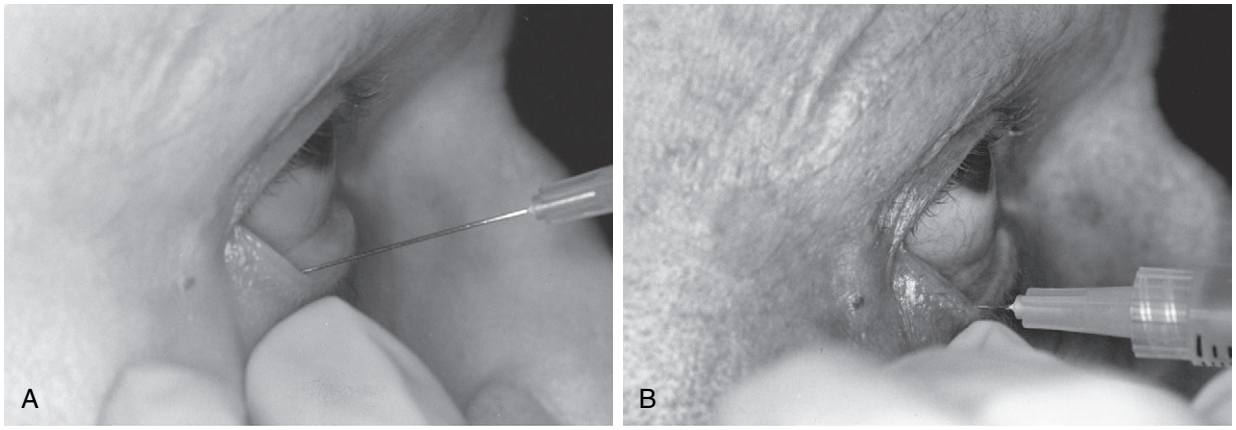

FIGURE **39-23** **A,** In the infraorbital approach, the needle is inserted transconjunctivally or transcutaneously and angled away from the visual axis of the globe toward the orbital floor to a depth of about 25 mm (1 inch), and the medications are injected. **B,** After penetration of the orbital septum, as shown in **A,** the needle is redirected parallel to the visual axis to a depth of about 25 mm (1 inch), and the medications are injected.

rectus muscle, it is important to keep the needle angled toward the lacrimal bone and away from the visual axis. Insert the needle, bevel toward the globe, to a depth of about 12 mm (0.5 inch). After negative aspiration is performed, 3 mL or more of anesthetic agent may be injected for facilitation of the desired effect. After the block is completed, the eyelid should be closed and light pressure applied to reduce the incidence of bleeding.

Ocular Block Evaluation

After an ophthalmic block is performed, partial movement of one or more of the ocular muscles may occur. Residual movement should be assessed to determine which muscles are involved and whether additional anesthesia is required. Analgesia of the globe generally precedes akinesia of the eye muscles. Therefore, analgesia of the globe may be assumed, but not guaranteed, in the presence of an akinetic muscle. The effectiveness of a modified retrobulbar block may be evaluated 2 minutes after it is administered, and an extraconal peribulbar block 10 minutes after it is administered, by observing for eye movement in all four quadrants.

BOX 39-3

Peribulbar Techniques

Infraorbital Approach

- Insert the needle transconjunctivally or transcutaneously, with the bevel toward the globe, lateral to the lateral limbic margin and angled away from the visual axis of the globe toward the orbital floor, to a depth of about 25 mm (1 inch), and inject the medications (see Figure 39-23, *A*).

  or
- After penetrating the orbital septum, as described above, redirect the needle parallel to the visual axis to a depth of about 25 mm (1 inch), and inject the medications (see Figure 39-23, *B*).

Supraorbital Approach

- Insert the needle only transcutaneously, with the bevel toward the globe, just inferior to the supraorbital rim, just lateral to the 12-o'clock position and superior to the globe. Angle away from the visual axis of the globe toward the orbital ceiling, to a depth of about 25 mm (1 inch), and inject the medications.

  or
- After penetrating the orbital septum, as described above, redirect the needle parallel to the visual axis to a depth of about 25 mm (1 inch), and inject the medications.

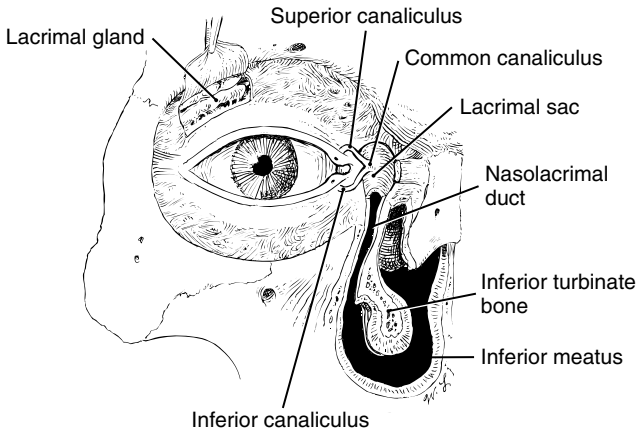

FIGURE **39-24** Frontal view of the lacrimal drainage system.

Eyelid Block

Once satisfactory akinesia of the globe is established, evaluation for movement of the eyelids is necessary. Partial to complete akinesia of the orbicular muscle is generally found after the ocular block. If incomplete akinesia of the orbicular muscle persists, perform a medial peribulbar to complete the block of nerve VII. Several blocks of nerve VII are described in the literature, including those by Van Lint, O'Brien, Nadbath, and Hustead.[24,28,29]

The O'Brien and Nadbath techniques block cranial nerve VII proximally, resulting in unilateral facial paralysis. The O'Brien and Nadbath techniques are still used; however, their popularity is decreasing because of their systemic side effects and patient discomfort. The Van Lint technique more appropriately addresses the need for eyelid akinesia, with less potential for adverse effects, by blocking the temporal and zygomatic branches of the facial nerve to the orbicular muscles. However, it is very painful. A variation of these techniques may be used for *orbicularis oculi block*. This technique has the advantage of being safer, less painful, and better accepted by the awake patient than the Van Lint block, but it requires injections through the skin and has the potential for causing patient discomfort and eyelid ecchymosis. The preferred technique for eyelid akinesia remains the medial peribulbar block.

Orbicularis Oculi Block

Equipment List.

- One 6-mL syringe
- One 30-gauge, ½-inch needle
- One alcohol wipe

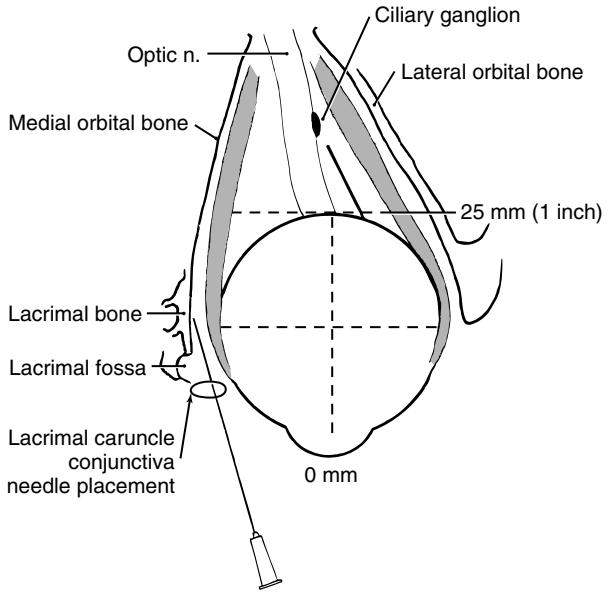

FIGURE **39-25** Superior view of the needle angle for a medial peribulbar block. *n.*, Nerve.

BOX 39-4

Medial Peribulbar Block

- Penetrate the caruncle conjunctiva with the bevel of the needle toward the globe and the needle angled toward the lacrimal bone, to a depth of approximately 12 mm (0.5 inch), and inject the medications.

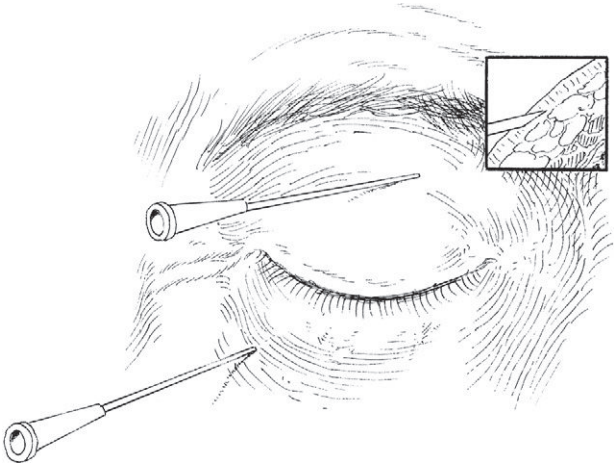

FIGURE **39-26** Frontal view of the needle placement for an orbicularis oculi block.

Description. Figure 39-26 and Box 39-5 serve as valuable reference aids for the orbicularis oculi block.

This technique is performed after a modified retrobulbar or peribulbar block in which residual eyelid movement remains. The first injection is made inferotemporally in the lower eyelid. The needle is inserted bevel down, subcutaneously and tangentially to the lower eyelid, and 1 to 2 mL of the anesthetic agent is injected just under the skin of the eyelid. After the needle is removed, the local anesthesia should be digitally spread to the medial and the lateral canthi; this measure avoids running the needle across the lower eyelid. The second injection is made supranasally in the upper eyelid. A finger should be placed over the closed eyelid, slightly depressing the globe. The needle is again inserted, bevel down, subcutaneously and tangentially to the eyelid, and 1 to 2 mL of the agent is injected just under the skin of the eyelid. After the needle is removed, the local anesthetic is digitally spread to the medial and lateral canthi. Once the anesthetic is spread throughout the eyelids, light to moderate pressure is applied over the eyelids for prevention or reduction of superficial bleeding.

Van Lint Technique

Equipment List.

- One 6-mL syringe
- One 25- or 27-gauge, 1.5-inch needle
- One alcohol or povidone-iodine wipe
- One 4 × 4 gauze pad

Description. A 37.5-mm (1.5-inch) needle is inserted inferotemporally into the subcutaneous tissue of the lateral canthus. The first injection of 1 to 2 mL of anesthetic agent is directed nasally along the lower margin of the orbit and then withdrawn to its origination point. The second injection of 1 to 2 mL of anesthetic agent is directed upward along the supratemporal margin of the orbit. After the block is completed, light pressure is applied over the closed eyelids to disperse the medication and decrease ecchymosis.

POSITIVE ORBITAL PRESSURE

The increased volume of local anesthetic required for both modified retrobulbar and peribulbar anesthetics causes an increase in orbital and intraocular pressures. The anesthetic agent not only tracks along and penetrates the fascial sheaths behind the globe, it also moves anteriorly underneath the conjunctiva, producing chemosis (i.e., subconjunctival edema) of the eye. These events may make the surgical procedure more difficult to perform. However, the random diffusion of the orbital anesthetic cannot be controlled. The agent merely tracks along the path of least resistance. Clinically, chemosis can begin with the injection of as little as 1 to 2 mL of anesthetic. In other instances, chemosis has not been seen even after the injection of as much as 12 mL of anesthetic agent.

Positive-pressure devices are used to reduce increased intraocular/intraorbital pressures and chemosis. Such devices are placed directly over the globe and orbit to enhance the orbital spread of anesthetic agent and return the orbital anatomy to a softer, more normal state for surgery. Positive-pressure devices deepen the anterior chamber by further reducing the intraocular pressure, thus allowing greater room for surgical intervention.

BOX **39-5**

Orbicularis Oculi Block

- *Lower lid:* Insert the needle subcutaneously, bevel down and tangential to the lid in the infratemporal area, and inject the medications.
- *Upper lid:* While slightly depressing the globe, insert the needle subcutaneously, bevel down and tangential to the lid in the supranasal area, and inject the medications.

Positive-Pressure Device

Honan Intraocular Pressure Reducer

The Honan intraocular pressure reducer, or Honan balloon, is an inflatable pneumatic device used to apply ocular compression after retrobulbar or peribulbar anesthetic injection. A rubber head strap is placed behind the head. The eye is taped closed, and a folded 4 × 4 gauze pad is placed over the eye. The Honan cuff is placed over the gauze pad and secured with the Velcro head strap. The pressure gauge is inflated to 30 mmHg, a value marked in yellow on the gauge.

ANESTHESIA MANAGEMENT

Preoperative Preparation

Ophthalmic procedures are most commonly performed on young children and elderly persons. Each age group has a unique set of physical problems. For the young child, the questions regarding the patient's history should include any congenital, metabolic, and musculoskeletal abnormalities, such as malignant hyperthermia, that may affect anesthesia care. In the elderly patient, multisystem medical problems may be present, and drug interactions from multiple medication regimens may exist. A thorough patient history is therefore paramount.

Admissions on the Day of Surgery

Anesthesia practitioners must not forget how stressful a surgical procedure on the eye can be for patients. A kind and professional attitude on the part of all those providing care will help patients deal more effectively with personal stress. The proper use of progressive relaxation and hypnotic techniques further helps alleviate their anxiety. Establishing a good patient-provider relationship works synergistically with pharmacologic agents in promoting the best possible surgical environment. On admission, the patient's mental and physical status, vital signs, and electrocardiogram (ECG) should be reviewed for any changes that may require postponement.

Regional Versus General Anesthesia

Patients undergoing regional block, in which they are awake for the procedure, must be evaluated for claustrophobia, severe

arthritis, tremors, and any other physical derangements that may make it difficult for them to lie supine. Patients' mental status also must be evaluated so that their degree of cooperation and ability to follow commands can be determined.

Elderly patients often take multiple medications and may not remember all of them. Patients should be instructed to bring their medications to the surgery center the day of surgery. A preoperative visit to the primary care physician is advised to confirm that the patient's overall medical condition is optimized for the planned surgical procedure.

The attending surgeon, in collaboration with the anesthesia practitioner, will make the final evaluation as to the patient's fitness on the day of surgery. An ECG performed within the past year should augment medical evaluation. The preoperative ECG assessment furnishes a baseline of what is optimal for the individual patient. Comparing the baseline ECG against the patient's ECG on the day of surgery helps determine whether any further preoperative testing is warranted.[30] For patients receiving regional anesthesia, routine laboratory tests are not ordered unless they are medically necessary. Appropriate laboratory data may be necessary when general anesthesia is planned.[31,32]

After the patient history and physical examination are completed, the appropriate anesthesia plan can be formulated. General anesthesia should be used for infants and young children. General anesthesia is also indicated for patients with severe claustrophobia, a history of uncontrolled acute anxiety attacks, or inability to cooperate, communicate, or lie flat (Box 39-6). It is also a consideration for procedures of greater than 2 hours' duration.[33] Most adults tolerate ophthalmic procedures well when regional anesthesia is used. Given the potential risks associated with general anesthesia (Box 39-7), regional anesthesia should be considered the anesthetic of choice in adults, especially the elderly, for ophthalmic procedures.

BOX 39-6

Indications for General Anesthesia

- Pediatric patient
- Patient's lack of cooperation
- Severe claustrophobia
- Inability to communicate
- Inability to lie flat
- Open-eye injuries
- Procedures with durations greater than 2 hours

BOX 39-7

Disadvantages of General Anesthesia

- Nausea/vomiting
- Retching/bucking
- Increased intraocular pressure
- Aspiration
- Complications secondary to other medical problems (e.g., cardiovascular disease)
- Time and expense

Regional Anesthesia

Regional Block with Minimal Sedation

Nothing-per-Mouth Status. The views of anesthesia practitioners vary on the advisability of nothing-per-mouth (*nil per os*; NPO) status prior to ocular procedures, especially cataracts. Some practices allow patients undergoing surgery in the morning to eat a light breakfast the day of surgery. Those undergoing surgery in the afternoon may be told to eat a light lunch.[34] Patients also may be encouraged to consume clear fluids until they are admitted to the facility.[35] However, practitioners also may mandate a strict NPO protocol.

Patients are requested to take their medications as usual on the day of surgery. An exception may be patients who complain of a frequent need to urinate after taking diuretic medications. Antiglycemic agents may be reduced or withheld when patients are NPO according to usual practice.[36] Evaluation and management of any anticoagulant medications are required for certain eye procedures to decrease the likelihood of bleeding. A medical consult with discontinuation several days prior to surgery may be necessary for certain anticoagulants. An increase in bleeding has been reported following vitreoretinal surgery in patients taking antiplatelet drugs.[37] Others note discontinuation is not necessary.[38] It is generally not required that antiplatelet drugs (e.g., aspirin, Clopidogrel) and anticoagulants (e.g., warfarin [Coumadin]) be discontinued. The risk of systemic complications, such as cardiovascular accidents and myocardial infarctions, is potentially greater if administration of these products is discontinued. Continuing anticoagulant administration, however, requires consultation and agreement between the anesthesia practitioner and the surgeon.[17,39] If bleeding occurs, it may be more severe; therefore, patients also need to be made aware of the risk and benefits of continuing their anticoagulants. Patients who are receiving or have previously been treated with chemotherapy also may have prolonged bleeding times.

Regional Block Environment

Ocular blocks are commonly performed outside the operating room. This method facilitates a more efficient case flow and a more comfortable environment for the patient. The potentially life-threatening effects of orbital epidural blocks require that appropriate resuscitative equipment and trained personnel are available to monitor the patient. The area used for performing ocular blocks should have the following:

- Oxygen
- Bag-valve mask
- Suction
- Airways
- ECG equipment
- Blood pressure cuff
- Oxygen saturation monitor
- Intravenous access tubing
- Canthotomy set
- Ammonia capsules
- Nitroglycerin tablets
- Atropine
- Glycopyrrolate

Additional resuscitative equipment and medications as recommended by advanced cardiac life support guidelines should be available.

Sedation for Regional Blocks and Ophthalmic Procedures

The goal of conscious sedation is to help patients gain and maintain control by reducing their heightened state of anxiety. This enhances their cooperation and ability to tolerate the awake surgical procedure.

Many techniques have been advocated to relax the patient prior to the ocular block and during the surgical procedure.[40,41] Conscious sedation techniques have included the use of benzodiazepines,

BOX 39-8

Sedation Techniques

- Good rapport between patient and clinician—minimizes medications necessary
- Intravenous benzodiazepine administration
- Intravenous narcotic administration
- Intravenous propofol or narcotic administration

BOX 39-9

Causes of Discomfort Resulting from Regional Blocks

- Needle injection through the skin
- Needle penetration of the conjunctiva
- Needle penetration of the intermuscular membrane
- Rapid injection of anesthetic
- Stinging from peripheral spread of anesthetic

narcotics, and nonbarbiturates. When these medications are properly tailored they are tolerated well by the elderly patient. Sedation techniques should be designed to decrease anxiety (Box 39-8) and reduce the discomfort of the block (Box 39-9). When the block is less painful, patients require less sedation for comfort. The surgeon's preference for an awake, relaxed, or sleeping patient during the procedure also should be considered. Sleeping patients often snore and may have sudden head movements on awakening.

If the patient is to be asleep during the block, fasting before the procedure consistent with the facility's criteria for general anesthesia should be followed (Box 39-10). Propofol is an excellent choice for this technique because of its short duration of action.[42]

Sedation is typically effective and safe for ocular blocks and intraoperative use but necessitates provider vigilance and monitoring to recognize and treat any of the adverse medical events that may occur.[43]

Monitoring for Regional Anesthesia

Communication is the cornerstone of interacting with the patient who is awake. Informing the patient regarding what to expect and what to do if he or she experiences any problems is mandatory. Questions and instructions must be clear and specific, especially if the patient is hearing impaired or if a language barrier exists.

The positioning of the patient is very important. Pillows may be used under the knees to decrease back strain. The patient with severe arthritis must be carefully padded and positioned. The patient's head and neck should be placed in a satisfactory surgical position. The practitioner should ensure that the patient is warm and as comfortable as possible. Nasally administered oxygen may be considered. Monitoring equipment should consist of the standard monitors used for all procedures. Observing the surgical procedure on a television monitor is preferable to not seeing the surgery. This allows the anesthetist to follow the surgical progress and visualize critical points in the procedure at which patient movement would be most detrimental.

The surgical draping placed over the patient's face should be tented, and high-flow air may be used to dissipate expired carbon dioxide more quickly. Claustrophobia can be a problem for awake patients, and some patients experience it for the first time during this procedure. Techniques for dealing with claustrophobia include

BOX 39-10

Procedure for Patient Who Is Asleep During Regional Block

- Tilt head to maintain patent airway
- Open patient's eye in primary gaze position
- Administer regional block
- Administer incremental sedation as required

taping the nonsurgical eye or adjusting the drape so that the patient can see the room with the nonsurgical eye. If a patient experiences a claustrophobic attack, the surgical drapes should be tented away from the face immediately, while the sterile field is maintained, and verbal control of the patient is gained. At this point, the anesthetist must determine whether the patient can proceed with surgery under regional block. Rarely, the patient may experience incomplete ocular analgesia, even in the presence of muscle akinesia. This problem responds well to 2% lidocaine MPF (methylparaben-free) drops or subconjunctival anesthetic injection.

Acute increased intraocular pressure during the surgical procedure can be catastrophic and cause loss of ocular contents. This problem can be created by coughing or a choroidal hemorrhage. The increased intrathoracic pressure created during coughing is reflected through the valveless orbital veins, resulting in an acutely increased intraocular pressure of 40 mmHg or greater.[44] A choroidal hemorrhage occurs when a vessel in the vascular choroidal layer of the eye ruptures, bleeding into the closed cavity and creating an acute rise in intraocular pressure with potential expulsion of eye contents unless the eye is closed quickly. In the acute phase, medications that lower intraocular pressure may be of minimum benefit.

If the patient has a history of postnasal drip, vasoconstrictive nose drops may be given preoperatively. If the patient complains of a dry throat, small amounts of water may be given. These two remedies are helpful in reducing the incidence of coughing intraoperatively. The patient must also be instructed to give notice before he or she coughs. Instructing the patient to clear his or her throat effectively reduces the forcefulness of the cough. Quick, shallow breaths have been reported to help suppress the cough reflex.[44] Sedating the patient or using intravenous lidocaine to prevent further coughing can help but has minimal effect during an active coughing episode.[45]

After the surgery is completed, the patient is transported from the operating room to postanesthesia recovery (PAR). Postoperative recovery time should be in accordance with the individual patient's physical and mental status and the amount of medication administered.

In a meta-analysis of regional verses general anesthesia for ambulatory anesthesia, patients who received peripheral nerve blocks, such as orbital regional eye blocks, experienced less postoperative pain, nausea, and a decreased postanesthesia care time.[46] If postoperative nausea is noted immediately after surgery, it may result from the sedative medications, increased intraocular pressure, or ocular pain.[47] On the afternoon or evening after their surgery, patients are generally called at home to evaluate their status. A sudden onset of nausea at home after the procedure is more likely associated with increased intraocular pressure than anesthetic medications. Patients are usually examined the following day by the surgeon and are requested to fill out questionnaires regarding their experience on the day of surgery.

General Anesthesia

For general anesthesia, preoperative patient preparation should include the appropriate fasting guidelines for the patient's age and physical condition (e.g., diabetes). The patient should be reminded that the surgical eye will be patched when he or she awakens. Sedation should be administered as needed to help the patient relax. Benzodiazepines such as midazolam are effective in low doses. For reduction in the incidence of postoperative nausea, the use of 5-HT3-receptor antagonists, histamine-2 antagonists, metoclopramide, and other antiemetics should be considered. Induction of general anesthesia with propofol or etomidate is recommended because they decrease intraocular pressure. In infants and children, inhalation induction also decreases intraocular pressure. Because of their emetic effect, narcotics should be used in low doses. Other than during examinations under anesthesia, endotracheal intubation is indicated for maintenance of the airway.

Succinylcholine causes a transient increase in intraocular pressure; however, it can be used safely for ocular procedures. Some caveats include the following:

- The sustained contracture of the extraocular muscles after succinylcholine could cause an expulsion of the intraocular contents. This assumption is theoretic, and it is now felt that succinylcholine may be safely used in eye surgery. See full discussion later.
- In eye muscle surgery, the sustained contraction may interfere with the forced duction test used by the surgeon for the treatment plan.

Nondepolarizing muscle relaxants are satisfactory for induction and have the advantage of decreasing intraocular pressure.[48] Laryngoscopy, especially with light anesthesia, increases intraocular pressure, but intravenous lidocaine (1.5 to 2 mg/kg), given 1 to 1.5 minutes before laryngoscopy, helps attenuate this response. Inhalation anesthetics, which also decrease intraocular pressure, are commonly used for the maintenance of general anesthesia.

For intraocular procedures, the continued use of nondepolarizing muscle relaxants is recommended for the maintenance of an akinetic eye and a satisfactory intraocular pressure. The anesthetist must be aware of the adverse ECG changes that may result from the oculocardiac reflex, which may be elicited when traction is exerted on the extraocular muscles and orbital structures. Patients undergoing eye-muscle surgery have an increased incidence of malignant hyperthermia and postoperative nausea. In retinal procedures in which sulfur hexafluoride or perfluoropropane is used as an intraocular gas, the use of nitrous oxide should be discontinued 15 minutes before injection.

When spontaneous ventilation returns after neuromuscular blockade is reversed, the patient may be extubated while receiving deep anesthesia with 100% oxygen and placed in the lateral position until he or she awakens. In the patient with a difficult airway, full stomach, or incompetent esophageal sphincter, gastric suction and intravenous lidocaine (1.5 to 2 mg/kg) may be given before the patient is extubated awake. This method helps reduce the incidence of coughing and vomiting, along with their deleterious effects.

The laryngeal mask airways (LMAs) also have their respective place in ophthalmic procedures. They may be inserted without muscle relaxants and removed with less risk of coughing in the awake patient. Along with the usual risk assessment for gastric aspiration, the practitioner should also consider that the lack of access to the airway during the procedure, intraoperative malposition of the LMA, and light anesthesia in the absence of muscle relaxants may result in laryngospasm or coughing. The LMA is gaining popularity in extraocular procedures such as strabismus and scleral buckles.[42]

Postoperative care, with attention paid to the alleviation of pain and control of nausea, will help maintain a satisfactory intraocular pressure. The ophthalmologist should be made aware of continued postoperative nausea, because it may be the result of acute increased intraocular pressure.[47]

Open-Eye Injury and the Use of Succinylcholine

Traumatic eye injuries can be categorized as either open- or closed-globe injuries. Open-eye injury in a patient with a full stomach is at best a difficult situation for the anesthesia provider. These injuries are commonly considered emergencies requiring general anesthesia. The clinician must protect the patient from aspiration and yet avoid increased intraocular pressure that could result in expulsion of intraocular contents. Authors have traditionally debated the risks and advantages of using succinylcholine for this procedure.[49,50] Normal intraocular pressure (IOP) is 10 to 22 mmHg, with slight diurnal and positional changes of 1 to 6 mmHg. It is physiologically determined by aqueous humor dynamics, changes in choroidal blood volume, central venous pressure, and extraocular muscle tone. The most important determinant of IOP is the balance between production and elimination of aqueous humor, maintaining an average volume of 250 mL. Aqueous humor is formed in the ciliary process from capillaries by diffusion, filtration, and active secretion. It flows through the posterior chamber, around the iris, and into the anterior chamber. It is eliminated through the spaces of Fontana and canal of Schlemm at the iridocorneal angle, where it flows into the episcleral venous system. Any increase in venous pressure (e.g., cough, strain, head-down position) will increase IOP. Additionally, any decrease in cross-sectional area of the spaces of Fontana (e.g., mydriatic drugs) will increase IOP.[51-55] Administration of succinylcholine increases IOP within 1 minute and peaks at an increase of 9 mmHg within 6 minutes after succinylcholine administration. The exact mechanism of this increase is unknown. Some feel that tonic contractions of the extraocular muscles may explain this IOP increase. It is now thought, however, that succinylcholine-induced IOP increase is a vascular event, with choroidal vascular dilation or a decrease in drainage secondary to elevated central venous pressure, temporarily inhibiting the flow of aqueous humor through the canal of Schlemm.[52]

It is clear that succinylcholine raises IOP. However, at induction of general anesthesia, there are many activities that raise IOP to a much greater degree than succinylcholine, including crying, Valsalva maneuver, forceful blinking, rubbing of the eyes, and coughing or bucking during poor intubating technique. Therefore, the increase in IOP due to succinylcholine may be inconsequential if optimal intubating conditions are not provided.

Moreno wrote: "This observation, coupled with the lack of any documented cases of extrusion of intraocular contents in open globes of humans when succinylcholine is used, causes us to question the traditional teaching that succinylcholine should be avoided in all cases when open globe is suspected or known."[51]

Chidiac and Raiskin[52] have stated that two questions need to be asked before the decision about the use or avoidance of succinylcholine in open-globe surgeries is made: Is this an easy airway; and is the eye viable? If the airway assessment shows that intubation should be easy, then regardless of the patient's aspiration risk, and regardless of the viability of the eye, succinylcholine can be avoided and replaced with rocuronium. If the airway assessment shows that this could be a difficult intubation, regardless of the patient's aspiration risk, then the second question becomes important: Is the eye viable? If the ophthalmologist feels that the eye is viable, use of succinylcholine is recommended. Pretreatment with drugs that attenuate the intraocular pressure effect of

succinylcholine, such as a small dose of nondepolarizing agent and lidocaine, should be used.

Choosing or avoiding succinylcholine is a matter of balance of risk. To control IOP at induction, there must be adequate dosing of drugs timed appropriately to coincide with the three potent stimuli: the administration of succinylcholine, the laryngoscopy, and the endotracheal intubation. It is clear that succinylcholine increases IOP, but this increase can be attenuated with various pretreatments, is less than increases seen with inadequate paralysis at the time of laryngoscopy and intubation, and is unimportant when weighed against the risk of loss of the airway. Therefore, in the situation of "difficult airway, eye viable," one should use succinylcholine.

Closed-globe injuries require significant planning and preparation to prevent further damage to the eye by an increase in IOP. They also require smooth induction and emergence because patient coughing or bucking will cause a detrimental increase in IOP.[53]

OPHTHALMIC ANESTHESIA COMPLICATIONS

Anxiety coupled with underlying cardiovascular disease may promote marked hypertension, cardiac dysrhythmias, or angina in the patient before surgery. Vasovagal responses (e.g., fainting) secondary to anxiety are not unusual. Ammonia capsules are effective in preventing and treating fainting episodes.

Chronic coughing secondary to chronic obstructive pulmonary disease, asthma, or postnasal drip must be evaluated. Vasoconstrictive nose drops effectively decrease postnasal drip. Coughing and deep breathing before surgery help clear the lungs of excess mucus in patients with chronic pulmonary disease. Proper evaluation and treatment help reduce undesired perioperative systemic and ocular sequelae.

Most complications of regional ocular anesthetics can be attributed to direct traumatization of the orbital vessels, the globe, and the optic nerve. Trauma to these structures can result whenever a needle is placed near the eye. Frequently, the cause of complications during general anesthesia is patient movement.

Retrobulbar Hemorrhage

Retrobulbar hemorrhage results from trauma to an orbital vessel. The retrobulbar bleeding moves the eyeball forward (proptosis), and a subconjunctival hemorrhage is usually present. Venous hemorrhages are typically slow in onset, but arterial hemorrhage has a rapid onset and more pronounced proptosis and subconjunctival hemorrhage. Ecchymosis of the eyelids and orbit is usually present. The pressure caused by the bleeding in the bony orbital cavity produces increased orbital pressure on the optic nerve, vessels, and globe. This pressure usually resolves without problems but may result in an occlusion or spasm of the central retinal artery or vein, resulting in partial to complete loss of vision.[56] One may detect a progressively increasing orbital pressure when digital pressure is applied over the eye after an ocular block. Continuous digital pressure may be all that is required for stopping a venous hemorrhage.[17] If the orbital pressure continues to increase in the presence of digital pressure, a lateral canthotomy is indicated and may be performed by the ophthalmologist or the anesthesia practitioner, who should then notify the ophthalmologist. *Canthotomy* is a procedure performed to increase the orbital space by cutting the lateral canthus and reducing the orbital pressure that results from a retrobulbar hemorrhage.

Anesthesia practitioners who perform ocular blocks should consider being instructed in the performance of a canthotomy, and a canthotomy set should be readily available (Box 39-11). The ophthalmologist should examine the central retinal artery and vein for patency. Occlusion of these vessels may warrant further surgical intervention for reduction of elevated orbital pressure.

BOX 39-11

Canthotomy Procedure

Equipment

1 straight hemostat
1 plastic scissors

Procedure

1. If possible, inject lidocaine along the lateral canthus.
2. Place the hemostat in a temporal direction along the lateral canthus 4-6 mm, and clamp the hemostat.
3. Remove the hemostat.
4. Use the plastic scissors to incise only in the crush marks left by the hemostat.
5. Control local bleeding with the hemostat or with digital pressure.

A localized episcleral hemorrhage also causes subconjunctival bleeding. In this situation, however, no proptosis of the globe or increase in orbital pressure is noted. These episcleral vessels are the same ones the ophthalmologist cauterizes after a conjunctival incision. The vessels break as a result of the spread of local anesthesia through the subconjunctival area and are of no consequence. However, the ophthalmologist should be notified of their presence before the procedure begins.

Retrobulbar hemorrhage remains the most common sequela for ocular blocks (Box 39-12). Peribulbar injections also can cause orbital hemorrhages.[26] Retrobulbar hemorrhages have been reported to occur in 1% to 3% of cases.[57]

Intravascular Injection

Grand mal seizures have been reported to occur after retrobulbar injections with lidocaine and lidocaine-bupivacaine combinations.[58,59] Seizures may result from a less-than-toxic dose of local anesthesia by direct intraarterial injection, resulting in retrograde flow to the cerebral circulation (Box 39-13). Mathers[60] surveyed 200 ophthalmologists. Sixty-six responded and reported three seizures occurring after retrobulbar injections. From these data, it appears that seizures after retrobulbar anesthesia may occur more frequently than reported in the literature. A reaction after an orbital vein injection also has been reported: the patient experienced uncontrolled shivering and rigor approximately 15 seconds after the retrobulbar injection. These symptoms resolved within 2 minutes of onset.[61]

Globe Puncture

Multiple reports have been published regarding globe perforations. Both sharp and dull needles have either penetrated or perforated the eye during retrobulbar and peribulbar injections. Although rare, globe punctures have occurred in the hands of experienced practitioners who have performed many thousands of ophthalmic blocks. The literature also notes that patients may or may not exhibit signs and symptoms of a puncture immediately, and the diagnosis has been made anywhere from 1 to 14 days after the event.[18,62-65] The most devastating globe injury reported, fortunately rare, is an ocular explosion. The globe can literally burst apart from the intraocular pressure exerted by the local anesthesia injection.[66,67]

The myopic eye has an increased axial length of greater than 24 mm. Scleral thinning may result from this increased

BOX 39-12

Measures for Preventing Retrobulbar Hemorrhage

- Choose least vascular areas for needle placement.
- Avoid deep orbital injections.
- Avoid supranasal position of gaze.
- Use primary gaze position.
- Use upward-gaze position (Gills-Lloyd technique only).
- Insert needle slowly.

BOX 39-13

Measures for Preventing Seizures Resulting from Intravascular Injection

- Choose least vascular areas for needle placement.
- Avoid deep orbital injections.
- Avoid supranasal position of gaze.
- Insert needle slowly.
- Aspirate gently before injection; negative aspiration is no guarantee that you are not in a blood vessel.
- Avoid injection against resistance.
- Avoid forceful rapid injections.

BOX 39-14

Measures for Preventing Globe Puncture

- Use caution in patients with increased axial length.
- Avoid supranasal position of gaze.
- Direct needle away from axis of globe during insertion through the orbital septum.
- Observe globe movement with needle insertion.
- Insert needle slowly, with the bevel toward the globe.
- Never forcefully inject anesthetic.
- Use modified retrobulbar and peribulbar techniques (although globe punctures have also been reported with these).

BOX 39-15

Signs and Symptoms of Globe Puncture*

- Increased resistance to injection
- Immediate dilation and paralysis of the pupil
- Rapid increase in intraocular pressure with edematous cornea
- Pain and agitation
- Hypotony of the globe
- Intraocular hemorrhage

*Patient may or may not exhibit signs and symptoms of a puncture immediately.

anteroposterior diameter. A previous scleral buckling procedure also increases the anteroposterior diameter of the eye. *Staphyloma*, a bulging of the sclera, also may predispose the patient to globe puncture. The risk of puncture increases when this abnormality is located inferoposteriorly on the globe. *Enophthalmos* is a recession of the eyeball into the orbit. This condition decreases the distance between the posterior pole of the globe and the posterior orbital wall. The supranasal gaze position rotates the posterior pole of the globe in line and closer to the retrobulbar needle path. Multiple orbital injections also have been cited as a factor in globe punctures, along with unexpected patient movement (Box 39-14).

The choice of sharp versus dull retrobulbar needles is highly debated. The literature reviewed appears to draw conclusions based more on opinion than on fact. A review of the literature confirmed a lack of safety with the use of blunt needles. Optic nerve penetration, ocular perforation, and CNS complications result from the use of blunt needles.[18] The surgeon should be notified if a globe puncture is suspected (Box 39-15).

Optic Nerve Sheath Trauma

To review, the *optic nerve sheaths* surround the optic nerve and are composed of the meninges of the brain. The outer sheath contains the *dura mater* and the inner sheath consists of the *arachnoid mater* and *pia mater*. The subarachnoid space contains cerebrospinal fluid and is continuous with the optic chiasm. The dura splits into two layers at the optic foramen. The outer dural layer becomes continuous with the orbital periosteum. The inner layer forms the dural covering of the optic nerve, creating the orbital epidural space.[1] Anesthetic agents injected into the subdural or subarachnoid space may track back to the optic chiasm. Here, the anesthetic can affect the contralateral eye by blocking cranial nerves II and III as they proceed through the subdural or subarachnoid space; this block can result in contralateral amaurosis.[68-70] The condition can be a precursor to the continued migration of the anesthetic to the respiratory centers of the midbrain, resulting in respiratory arrest.[56,71,72]

The anesthetist should observe the contralateral pupil before an ocular block is performed. The pupil may be dilated from accidental administration of preoperative eye drops, a preoperative examination, or existing pathology. If the contralateral pupil is constricted before the ocular block and dilates after the ocular block (contralateral amaurosis), one must assume that subarachnoid or subdural injection has occurred and be prepared to treat a respiratory arrest.

The onset of *respiratory arrest* is usually within 2 to 5 minutes after injection; however, it may occur as late as 10 to 17 minutes after injection. Spontaneous ventilation usually returns in 15 to 20 minutes but may take up to 55 minutes for complete recovery. Treatment includes appropriate ventilatory and cardiovascular support, supplemental oxygen with oxygen saturation monitoring, ECG monitoring for cardiac dysrhythmias, and blood pressure monitoring. The surgeon should be notified immediately so the eye can be examined for any optic nerve trauma that may require surgical intervention.

A retrobulbar hemorrhage resulting in increased extravascular pressure may result in occlusion of the central retinal artery or vein, or both. Also, direct trauma to the ophthalmic artery or the optic nerve by the retrobulbar needle may cause artery or vein occlusion without causing retrobulbar hemorrhage[73] (Box 39-16).

Ocular Ischemia

Retinal vascular occlusion or thrombosis has been reported after ocular blocks.[74,75] Studies have also reported a decrease in the pulsatile ocular blood flow after ocular blocks, secondary to the pressure exerted by the volume of local anesthesia injected into the orbit. However, the same orbital injection volume did not cause a significant rise in the intraocular pressure. Even though not contraindicated, caution should be exercised in patients with preexisting compromised ocular circulation.[76-79] Some authors have advocated not using epinephrine in the local anesthetic solution.[80,81]

BOX 39-16

Measures for Preventing Optic Nerve Sheath Trauma

- Avoid supranasal eye position.
- Choose least vascular area for needle insertion.
- Avoid deep orbital injection.
- Insert needle slowly.
- Avoid forceful injection of anesthetics.
- Use modified retrobulbar or peribulbar techniques.

Optic nerve atrophy has been reported after intraocular surgery with either *regional block* or *general anesthesia*.[56] Direct trauma to the optic nerve may result in transient symptoms, such as contralateral amaurosis or respiratory arrest, or it may result in vascular occlusion or thrombosis, or both, with partial to complete loss of vision.

Extraocular Muscle Palsy and Ptosis

Inferior muscle palsy has been reported after retrobulbar anesthesia. Segmental inferior rectus muscle enlargement was noted posterior to the globe deep in the orbit.[82] The complication has not been reported to occur after general anesthesia.[83] The initial signs and symptoms of this problem manifest after surgery as persistent vertical diplopia. Surgical intervention is indicated for correction of this condition. Trauma to the superior oblique tendon–trochlea complex also has been reported to occur with peribulbar anesthesia[84] (Box 39-17).

Carlson et al.[85] performed experiments on the rectus muscle of monkeys and humans and demonstrated minimal myotoxic damage to ocular muscles after retrobulbar administration of local anesthetics. Typically after the injection of local anesthesia, the surface muscle fibers degenerate, then regenerate. However, direct injections of local anesthesia into the rectus muscle resulted in massive internal muscle lesions that were large enough to produce noticeable functional deficit. The myotoxicity of local anesthetics also may play a role in postoperative ptosis, especially in the elderly, because regeneration of their muscle fibers may not be as complete as that in younger patients. However, ptosis is also associated with the superior rectus stay suture and the eyelid speculum. Postoperative ptosis may take as long as 6 months to resolve.

Facial Nerve Blocks

Patients commonly experience discomfort as a result of blocks of cranial nerve VII. Prolonged Bell's palsy has been seen after Nadbath and O'Brien blocks, probably secondary to direct nerve trauma.[86] Several authors have reported cases of dysphagia, hoarseness, coughing, and respiratory distress after Nadbath blocks (Box 39-18). They noted that these symptoms were consistent with paresis of the vagus, glossopharyngeal, and spinal accessory nerves. These nerves exit the skull about 10 mm medial to cranial nerve VII. Therefore, anesthesia injected for a cranial nerve VII block could also reach these nerves and result in unilateral vocal cord paralysis.[87,88]

Patients have also complained of jaw ache with movement for several weeks after a cranial nerve VII block. Grand mal seizure has rarely occurred (1 report) when 3 mL of 2% lidocaine with epinephrine (1:200,000) was injected using the Nadbath technique.

Zaturansky and Hyams[89] reported an ocular perforation that occurred when a modified Van Lint procedure was performed after a retrobulbar block. The needle penetrated the proposed eye just under the insertion of the lateral rectus muscle.

BOX 39-17

Measures for Preventing Extraocular Muscle Trauma

- Avoid needle contact with extraocular muscles.
- Avoid deep orbital penetration.
- Avoid angling needle toward visual axis of the globe when parallel to an extraocular muscle.

BOX 39-18

Prevention and Treatment of Complications from the Nadbath Block

- Avoid using the Nadbath technique in patients weighing less than 45 kg.
- Avoid using large volumes of anesthesia and hyaluronidase.
- Avoid using the Nadbath technique when patients have a preexisting unilateral vocal cord dysfunction.
- Place the patient in seated or lateral position to maintain a patent airway and patient comfort.
- The patient with an unsatisfactory airway should be intubated.

Oculocardiac Reflex

The *oculocardiac reflex* is a trigeminal-vagal reflex that was first described in 1908 by Aschner. The stimulus for this reflex is generated by pressure on the globe, the orbital structures (e.g., the optic nerve), or the conjunctiva, or by traction on the extraocular muscles (particularly the medial rectus muscle). The afferent pathway for the stimulus is via the long and short ciliary nerves to the ciliary ganglion and then through the gasserian ganglion along the ophthalmic division of the trigeminal nerve terminating in the main trigeminal sensory nucleus in the floor of the fourth ventricle. The efferent pathway consists of the vagus nerve to the cardio-inhibitory center.

The reflex may be elicited during local infiltration anesthesia, retrobulbar or peribulbar blockade, and general anesthesia. The occurrence of the reflex in ocular procedures is variable, but it is commonly seen in muscle procedures performed in children. The oculocardiac reflex reveals itself most often as an acute sinus bradycardia. However, it also may cause a wide variety of other cardiac dysrhythmias, such as nodal rhythms, atrioventricular block, ventricular ectopy, idioventricular rhythm, and asystole. Continuous ECG monitoring is essential for the diagnosis of dysrhythmias that result from the oculocardiac reflex. If cardiac dysrhythmias are observed, the surgeon must be instructed to immediately cease all pressure or traction on the orbit. Simultaneously, the patient should be assessed for adequate oxygenation and ventilation and for adequate anesthetic depth because one or more of these may be an underlying cause for the dysrhythmia. The aberrant rhythm usually resolves without intervention within a few seconds.

However, if the aforementioned measures are taken and the dysrhythmia continues, thus threatening to cause hemodynamic instability, intravenous atropine should be administered. Atropine, 2 to 3 mg, may be required for complete vagal blockade. Caution should be exercised with the administration of atropine, because atropine itself may induce cardiac dysrhythmias. Glycopyrrolate may be given for less severe bradycardic episodes. The surgeon may proceed only after the dysrhythmia is resolved. If the reflex recurs, the aforementioned process should be repeated. The oculocardiac reflex, however, appears to fatigue with continued manipulations.

The use of intravenous atropine or intravenous glycopyrrolate just before surgery may help reduce the incidence of the reflex, especially in children.[90,91]

Other Complications

Corneal abrasion is the most common injury occurring after general anesthesia. It is believed to result from the drying of the exposed cornea or from direct trauma, such as an anesthesia-mask injury. Ensuring that the eyelids are closed and secured with tape should provide satisfactory protection of the cornea. *Movement during ocular surgery was identified as the single most common mechanism of injury*. Movement was described as coughing and bucking, which resulted in poor visual outcome. In these reported cases, muscle relaxants were used less than 50% of the time, and nerve stimulators were omitted. Chemical injury can result from spillage of cleaning materials or preparatory solutions into the eye. In these cases, the eye should be flushed immediately with saline.[92]

Central retinal artery occlusion may result from prolonged pressure on the eye.[93] This type of injury may result with the patient in the prone position. Careful attention to padding and periodic checks of the eyes are necessary, especially for long procedures. Eye protectors, along with foam headrests or gel donuts for the face, may help prevent eye trauma. It is prudent to request an ophthalmic examination immediately after surgery if the patient complains of any eye problems or if the anesthesia provider suspects a problem. Ocular positioning injuries are discussed in detail in Chapter 21.

SUMMARY

Anesthesia management for ophthalmic procedures has changed rapidly in the last few years. As an anesthesia practitioner you will be challenged with the increasingly complex comorbidities and multiple pharmacologic agents used in the care of the elderly patient. The pediatric patient also presents anesthetic challenges, many associated with the preterm infants and chronic upper respiratory infections**.** Newer surgical techniques for cataract surgery have increased the popularity of topical anesthesia for such procedures; however, the advances in retinal surgical techniques, corneal transplants, and adult eye muscle and glaucoma procedures are fueling an increased demand by surgeons for anesthesia practitioners to perform ophthalmic eye blocks versus general anesthesia. Orbital regional blocks have the further advantage of minimizing postoperative pain, requiring minimal to no opioid administration, with significant reductions in postoperative nausea and vomiting. General anesthesia will continue to be the technique of choice for the pediatric patient, patients with ocular trauma, and patients who are not candidates for topical or orbital regional blocks.

Anesthesia for Orthopedics and Podiatry

CHAPTER 40

◆ *Patricia Tuttle*

The Merriam-Webster dictionary defines orthopedics as "a branch of medicine concerned with the correction or prevention of deformities, disorders, or injuries of the skeleton and associated structures (as tendons and ligaments)".[1] Evidence of such "corrections" dates back many centuries. Egyptian artifacts have been found that demonstrate the use of splints for patients, and some of the earliest documented orthopedic interventions came from the battlefields of the gladiators. Jean-Andre Venel established the first orthopedic institute in 1780. Much progress in orthopedics has been made in recent decades including the development of better arthroscopic techniques, total hip and knee replacements, ligament repairs using minimally invasive techniques, spine surgeries, and more. As the baby boomers born after World War II reach retirement age, the demand for orthopedic repair and the incidence of degenerative joint disease are expected to increase.[2]

Anesthesia and orthopedics are described time and again in historical accounts, the earliest being events usually occurring on battlefields throughout history. Although the initial encounters involved anesthetic techniques that were rather primitive, anesthesia for orthopedics has evolved into a highly specific set of choices that are deemed to be safe for patients . Modern techniques must account for complicated, sometimes lengthy procedures requiring significant postoperative pain control.

The anesthetic plan can vary greatly; the administered anesthetic can be regional, general, a combined technique, or involve intravenous sedation. The anesthetic choice is based upon many factors: What type of surgery is the patient having? How long will the procedure take? Does the patient have preferences? Does the patient's airway present any challenges? In what position will the patient be placed for surgery? What comorbidities are present? Answers to all of these questions and others carry weight in the decision-making process when determining care of orthopedic patients.

Preoperative assessment for orthopedic patients follows much the same guidelines used for any other surgical candidate. A thorough review of systems, review of home medications and the last date taken, current anticoagulant status, and baseline laboratory values are only some of the components of a preoperative assessment of these patients. Often for patients scheduled for total joint replacement, a baseline complete blood count (CBC), a pregnancy test (for females of childbearing age), and a urinalysis may be completed. Also, most orthopedic surgeons prefer to evaluate their patients for the presence of infection before committing to joint replacement surgery.[3] Surgical site wound infection is a serious and potentially catastrophic complication after joint arthroplasty.[4] Pathogens in the urinary tract are common, and their presence can create a potential reservoir of resistant pathogens and increase patient morbidity.

One of the ways all surgeons attempt to decrease the chance for surgical site infection includes the administration of appropriate preoperative antibiotics in a timely fashion. For cefazoline (a first-generation cephalosporin), the preoperative time allotment is within 1 hour of incision time; for vancomycin, within 2 hours of incision time. In 2006 the Centers for Medicaid and Medicare Services (CMS) introduced a program called the Surgical Care Improvement Project, often abbreviated SCIP. The goal of the group was to find common opportunities for improving surgical care and to provide definitions of these measures and the appropriate guidelines that would decrease risks to patients when instituted. These risks may include surgical site infection, postoperative thromboembolism, intraoperative and postoperative glucose management, and most recently, maintenance of core body temperature. The list of inclusions is fluid, based upon research findings and performance related to the measures.

Many institutions require their health care providers to be responsible for implementing appropriate interventions under the SCIP guidelines and, just as important, require them to document these interventions. These data are abstracted at hospitals across the country, and the data are then fed into a website called *Hospital Compare*. The *Hospital Compare* website allows patients and their families to view how a particular hospital participates in the guidelines and how the outcomes of that hospital compare to other hospitals in the area, specific to those guidelines. In addition to creating a best practice environment, and better patient outcomes, compliance with these measures are often incentivized financially through private insurers as well as the CMS. All anesthetists should familiarize themselves with the guidelines their institution has in place and should strive to fulfill their responsibilities accordingly.[5] The most up-to-date guidelines related to SCIP can be found at *www.jointcommission.org/surgical_care_improvement_project*.

Advances in technology are yielding a much higher rate of arthroscopic procedures. Outpatient surgery is now the routine for many orthopedic procedures. Outpatient surgery is being used for everything from shoulder repair to orthopedic repair in the knee, ankle, wrist, and elbow. The advantages of today's surgical techniques are readily apparent. Smaller incisions mean less pain. Patients who have arthroscopic procedures experience faster recovery from anesthesia, have shorter lengths of stay, use fewer narcotics for pain relief, and return to work more quickly than those undergoing open procedures.[6] From an anesthesia standpoint, it means more patients are being managed on an outpatient basis.

PNEUMATIC TOURNIQUET

One of the ways blood loss can be diminished in the operating theater is through the application of the pneumatic tourniquet. The advantages of a bloodless field are important for the surgeon. Pneumatic tourniquets maintain a relatively bloodless field during extremity surgery, minimize blood loss, aid identification of vital

structures, and expedite the procedure.[7,8] The components of the pneumatic tourniquet consist of the inflatable cuff, connective tubing, a pressure device, and usually, a timer. Specialized training and understanding of the application and management of the pneumatic tourniquet is required for proper management of the device intraoperatively. Safety considerations for use of a tourniquet are noted in Box 40-1.

Tourniquets are generally applied after the initiation of anesthesia. The time of inflation should be documented in the anesthesia record and should be in parallel with the time documented in the operating room (OR) record. Interruption of blood supply leads to tissue hypoxia and acidosis.[9] The degree of hypoxia and acidosis is partially influenced by the duration of insufflation. For this reason, the inflation device also comes with a built-in timer, generally set for 60-minute increments, with an alarm that will sound as a warning when the allotted time has been exhausted. A maximum of 2 hours is generally considered safe.[10] The pressure to which the tourniquet should be inflated depends on the patient's blood pressure and the shape and size of the extremity.

Deflation of the tourniquet results in the release of metabolic waste into the systemic circulation. The release of these substances can cause metabolic acidosis, hyperkalemia, myoglobinemia, myoglobinuria, and renal failure.[11,12] The deflation of the tourniquet may be marked by transient changes in the hemodynamics or pulse oximetry readings for the patient. Most of these resolve quickly, except in those patients with extreme conditions related to their cardiac or vascular status. Box 40-2 lists common physiologic changes that occur with pneumatic tourniquet.

Tourniquet Pain

One of the greatest concerns when the tourniquet is in use is the patient perception of tourniquet pain. In 1944 Denny-Brown and Brenner[13] reported the first investigation into the cause of tourniquet discomfort. They listed characteristic anatomic changes associated with tourniquet ischemia that were due to acute compression of the nerves under the inflated cuff. Compression of the intraneural blood vessels caused a secondary ischemia of the nerve fibers. Similar reports of "tourniquet discomfort" or "aching" despite adequate spinal anesthesia prompted considerable attention being directed toward discovering ways to minimizing subjective discomfort. Based on their discoveries and subsequent measurements of "occlusive pressure" in 1979, Klenerman and Hulands[14] suggested using tourniquet pressures of two times the patient's systolic blood pressure to minimize the subjective discomfort and destruction of tissues. Klenerman[15] modified this

BOX 40-1

Safety Measures for Preventing Tourniquet Complications

- The tourniquet should be applied where the nerves are best protected in the underlying musculature.
- Proper functioning of the equipment should be tested before it is operated.
- The tourniquet should be used for no longer than 2 hours.
- The widest cuff possible should be chosen (wide bladders can occlude the blood flow with the use of a lower cuff pressure).
- A minimum of two layers of padding should be placed around the extremity of loose fibers/lint that can become embedded in the contact closures. The best results for the protection of the skin occurs with the use of an elastic stockinette.
- The tourniquet size should be half of the limb diameter. The cuff should overlap between 3 to 6 inches. Large areas of overlap result in rolling and wrinkling of the underlying skin and increased pressure in that area.
- The tourniquet choice size should allow placement of two fingers between the cast padding and the cuff.
- When possible, the extremity should be exsanguinated prior to the inflation of the cuff. An Esmarch bandage is most commonly used.
- Only the minimally effective pressure should be used for occluding blood flow to the extremity. For the upper extremity, 70 to 90 mmHg more than the patient's systolic blood pressure should be used. For the lower extremity, twice the patient's systolic pressure should be used. For Bier block anesthesia, a minimum standard tourniquet pressure of 300 mmHg should be used unless the tourniquet is on the upper leg. In that case, twice the patient's systolic pressure should be used unless that amount is less than 300 mmHg.
- The pressure display must accurately reflect the pressure in the tourniquet bladder.

BOX 40-2

Physiologic Changes Caused by Limb Tourniquets

Neurologic Effects
- Abolition of somatosensory evoked potentials and nerve conduction occurs within 30 minutes.
- Application for more than 60 minutes causes tourniquet pain and hypertension.
- Application for more than 2 hours may result in postoperative neuropraxia.
- Evidence of nerve injury may occur at the skin level underlying the edge of the tourniquet.

Muscle Changes
- Cellular hypoxia develops within 2 minutes.
- Cellular creatinine value declines.
- Progressive cellular acidosis occurs.
- Endothelial capillary leak develops after 2 hours.

Systemic Effects of Tourniquet Inflation
- Elevation in arterial and pulmonary artery pressures develops. This is usually slight to moderate if only one limb is occluded. The response is more severe in patients undergoing balanced anesthesia that does not include a potent anesthetic vapor.

Systemic Effects of Tourniquet Release
- Transient fall in core temperature occurs.
- Transient metabolic acidosis occurs.
- Transient fall in central venous oxygen tension occurs, but systemic hypoxemia is unusual.
- Acid metabolites (e.g., thromboxane) are released into the central circulation.
- Transient fall in pulmonary and systemic arterial pressures occurs.
- Transient increase in end-tidal carbon dioxide occurs.

recommendation a year later to between 50 and 75 mmHg more than the patient's systolic pressure.

The ischemic pain associated with tourniquet application is similar to that of thrombotic vascular occlusion and peripheral vascular disease.[16] At about 45 to 60 minutes after tourniquet pressurization, patients report various symptoms associated with dull aching that progress to burning and excruciating pain that may require general anesthesia. Once the pain begins, it is often resistant to analgesics and anesthetic agents, despite the anesthetic technique. Even with a well-controlled general anesthetic at the time of tourniquet inflation, ischemic pain may begin during this same time interval and may cause increasing heart rate and blood pressure that require pharmacologic intervention.[17]

Although specific neural and metabolic factors responsible for tourniquet pain are still unknown, several researchers have identified the nerve fibers responsible for transmission of the impulses. The burning and aching pain corresponds to the activation of the small, slow-conducting, unmyelinated C fibers. The pinprick, tingling, and buzzing sensations that frequently accompany tourniquet application, often even after deflation, correspond to activation of the larger and faster myelinated A-delta fibers.

Myelinated A-delta and unmyelinated C fibers differ in their sensitivity to local anesthetics. As the concentration of local anesthetic decreases, the activation of C fibers increases, but the A-delta fiber activation is still suppressed. This means that C fibers may be more difficult to anesthetize than A-delta fibers, and tourniquet pain therefore seems more consistent with pain sensation carried by C fibers.[16] Other research has shown that certain local anesthetics enhance the effect of the blockade in the presence of increased stimulation of the isolated nerve fiber. For example, the potency of bupivacaine is enhanced by an increase in the rate of nerve stimulation and may offer an advantage by lowering the incidence of tourniquet pain.[18]

Regardless of the sensory level achieved in these patients, they still experience tourniquet pain. It is apparent that a high-quality blockade of the sacral roots is more important than the thoracic sensory level in reducing the incidence of tourniquet pain, because the intensity of pain may be due to ischemia of the entire leg, as well as under the cuff.[19] The addition of opioids, ketorolac, and melatonin to local anesthesia solutions have all shown some efficacy in reducing the incidence of tourniquet pain.[20-22] Sedation with dexmedetomidine is also effective.[23]

Postoperative Tourniquet Paresthesias

Properly placed tourniquets inflated to appropriate pressures rarely cause injury. The use of excessive tourniquet pressure for a prolonged time may cause postoperative paresthesias that are frustrating to treat and very painful for the patient. Excessive tourniquet pressure causes deformation of the underlying nerves—the myelin may be stretched on one side of the node and invaginated on the other. Nerve damage due to rupture of the Schwann cell membranes may also be present. Use of proper padding, appropriate choice of tourniquet size, and adherence to recommendations of appropriate pressure and time minimize the incidence of this complication.

PATIENT POSITIONING

Chapter 21 provides an excellent overview of proper positioning during surgery. It is important to have a thorough understanding of the physiologic changes that occur in various positions. Appropriate patient positioning must allow optimal exposure of the surgical site, allow for appropriate monitoring throughout the procedure, provide good access to the patient's airway, allow for comfort and warmth, minimize or prevent physiologic functioning compromise, protect all body systems, and maintain patient dignity.[24] Positions chosen may include supine, lateral decubitus, prone, and even beach chair/sitting. Neutral alignment and proper padding of exposed neural pathways can help diminish injuries sustained intraoperatively related to positioning. Communication between the entire team (i.e., anesthesia, OR nurse, and surgeon) will yield the best outcomes for the patient.

Over the millennia, human physiology has adapted to being in an upright or erect position for the majority of the wakeful hours. For example, in the upright position there are three zones of ventilation-perfusion within the lungs: (1) areas where alveolar pressure is greater than arterial pressure, (2) areas of complex, variable pressure gradients between alveolar and arterial components, and (3) areas where arterial pressure is greater than alveolar pressure. Figure 40-1 illustrates lung zones 1, 2, and 3. Other examples of physiologic adaptation are the valves found in dependent areas of the venous system, such as the extremities, and the absence of valves in nondependent areas, such as the cranium. Changes from the upright position produce corresponding physiologic changes[24,25] (Figure 40-2).

ARTHROSCOPY

Arthroscopy is a minimally invasive surgical procedure performed to examine and sometimes repair damage of the interior of a joint using an arthroscope.[26] The concept was introduced in the United States in 1926.[27] However, without the availability of practical sources of illumination, arthroscopy languished. The development of fiber-optic light sources in the 1970s brought a resurgence of interest in the use of arthroscopy. Initially, arthroscopy was used to obtain a diagnosis of a patient's orthopedic malady so a definitive, corrective surgical procedure could be performed. As interest in the procedure and technique increased, coupled with development of the necessary smaller surgical instrumentation, previously open surgical procedures on the knee, such as partial or complete meniscectomy, loose-body removal, or ligament repair or reconstruction, were attempted and refined solely via the arthroscope.

Successful performance of arthroscopic procedures on the knee produce several benefits for the patient, including reduced blood loss, less postoperative discomfort, and reduced length of rehabilitation. The success achieved with arthroscopic procedures on the knee led to application of the principles and techniques to other

joints (e.g., the shoulder, elbow, wrist, hip, ankle, and phalangeal joints of the foot).[28,29] Many of these surgeries have become routine outpatient procedures. Through the middle portion of the 1990s, application of arthroscopic procedures focused on the shoulder. Accordingly, shoulder arthroscopy use ranges from simple debridements to more complex rotator cuff repairs.[27] The development and refinement of shoulder arthroscopic procedures mirrors that of knee arthroscopic procedures; that is, as more skill and comfort are obtained with initial procedures, more traditionally open surgical treatments are attempted solely via the arthroscope.

Anesthetic Management

Arthroscopic procedures may be managed by almost any of the available anesthesia techniques (e.g., general anesthesia, regional anesthesia, combined regional and general anesthesia, and local blockade with sedation). Patient selection for a given anesthetic technique is crucial with arthroscopic procedures, as with all operative procedures. As previously mentioned, for some patients there is absolutely no substitute for receiving general anesthesia. Critical factors in the selection and presentation of the available anesthesia techniques appropriate for arthroscopic procedures are the patient positioning necessary to facilitate the proposed arthroscopic procedure and the overall state of health of the patient. For example, shoulder arthroscopy uses one of two positions to accomplish the surgery, either lateral decubitus or modified Fowler's ("beach chair") position.[30] The choice of position is determined in part by the nature and extent of the malady being surgically addressed. For some shoulder arthroscopy procedures, supplemental traction with weights and abduction may be necessary to provide optimum operative visualization (Figure 40-3); for others, the modified Fowler's position may be used with the force of gravity or manual traction providing sufficient operative visibility. Reviewing the patient's chart and more importantly, personally interviewing the patient, along with understanding the physiologic changes associated with various positions, assist in choosing the best care for each patient.

Patient positioning for arthroscopic procedures can encompass virtually the entire gamut of possible operative positions. Most often, arthroscopic procedures for lower extremity joints use the supine position, as do most arthroscopic procedures on the upper extremities. Arthroscopy on the knee requires the supine position with the foot of the OR bed lowered (Figure 40-4). The nonoperative leg should either be wrapped with an elastic bandage or have some form of compression stocking in place to reduce pooling of blood and the potential for thrombus formation. At times, patients undergoing elbow arthroscopy may be placed in the supine, lateral decubitus, or prone position; the position is dictated by operative necessity and surgeon preference (Figures 40-5 and 40-6). The prone position is advantageous primarily because of the better limb stability during the procedure.[31] Shoulder arthroscopy is usually accomplished via either the modified Fowler's position or the lateral decubitus position, based on optimal access to the injury and surgeon preference (see Figure 40-3).[30] Hip arthroscopy is also typically accomplished via the lateral decubitus or the supine position, with the patient on a fracture table (Figure 40-7). The fracture table is used to provide greater stability while traction is applied, using either weights and counterweights (lateral decubitus position) or mechanical traction attached to the leg-holding device of the fracture table (supine position).[32]

Complications from arthroscopic procedures represent a small percentage of the total number of procedures performed.[33-36]

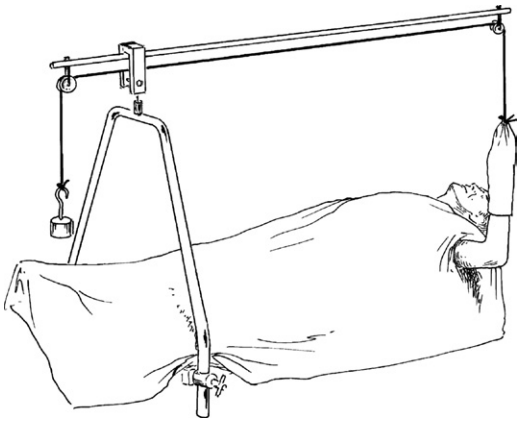

FIGURE **40-5** Supine position for elbow surgery.

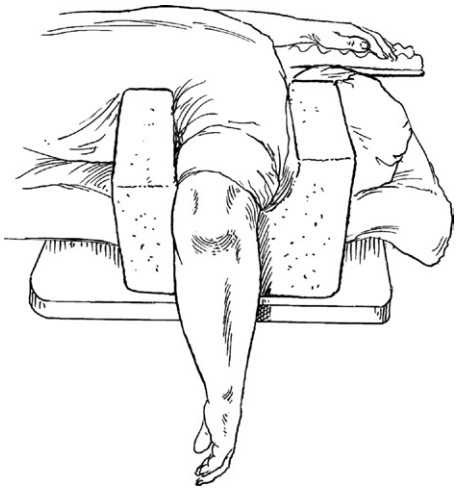

FIGURE **40-6** Prone position for elbow surgery.

Complications that may occur include subcutaneous emphysema, pneumomediastinum, and potentially life-threatening tension pneumothorax. Accordingly, complications resulting from arthroscopic procedures that particularly concern the nurse anesthetist are relatively few. The full range of potential anesthetic complications associated with patient positioning apply (e.g., inadvertent extubation, eye or corneal injury, visual loss from the prone position, and nerve injury from improper patient positioning). Blood loss is not generally a concern, but significant and sustained hypotension warrants immediate and thorough investigation. The pneumatic tourniquet may be used to provide a clear, bloodless surgical field. Trocar insertion sometimes results in inadvertent vessel puncture that may go undetected because of the tourniquet. In cases that are located proximally (i.e., hip or shoulder) and therefore done without a tourniquet, vascular damage is discovered much earlier.

To provide optimal visualization of joint structures during arthroscopic procedures, the irrigating fluid used to distend the operative joint is instilled under pressure. This is achieved through gravity or mechanical pressurization. The typical irrigation setup uses large bags of irrigating solution, 3 to 5 L in volume. The nurse anesthetist should be aware of the fluid being infused in comparison with the outflow. Even small differences can add up to a large volume for the patient, especially in the case of an extended procedure. This absorption could potentially lead to fluid volume overload, congestive heart failure (CHF), pulmonary edema, or even hyponatremia if sterile water is used.[33-36]

BOX **40-3**

Signs and Symptoms of Tension Pneumothorax

- Sudden, inexplicable hypoxemia
- Elevated central venous pressure
- Tachycardia
- Absent breath sounds on the affected side
- Cyanosis
- Diaphoresis
- Decreasing oxygenation
- Tracheal shift
- Agitation (may be observed in patients receiving regional anesthesia)
- Hypotension
- Jugular vein distention
- Increased airway pressure
- Asymmetric chest wall movement
- Percussive hyperresonance over the affected side
- Extreme anxiety (may be observed in patients receiving regional anesthesia)

During subacromial decompression, subcutaneous emphysema, tension pneumothorax, and pneumomediastinum have been reported during shoulder arthroscopy.[35] These complications appear to be associated at least in part with the use of mechanical irrigation pumps and power-saver suction. Careful assessment during this irrigation period is important. Box 40-3 lists the signs and symptoms of tension pneumothorax. Because tension pneumothorax is a potentially life-threatening event, early recognition and treatment are paramount. Ideally, placement of a chest tube is most desirable to relieve the increased intrathoracic pressure. An immediate and very effective treatment is needle decompression with a 14- to 18-gauge intravenous angiocatheter placed into either the second or third intercostal space anteriorly or the fourth or fifth intercostal space laterally. Successful decompression is accompanied by a sudden rush of air, as well as readjustment of physical symptoms and vital signs back toward the patient's normal parameters. After successful decompression, the intravenous catheter stylet should remain in place and be covered or capped to prevent air from being sucked

back into the chest cavity until a chest tube can be properly inserted.[37,38]

ARTHROPLASTY

Arthroplasty is the surgical replacement of all (total arthroplasty) or part (hemiarthroplasty) of a joint to achieve a return of natural motion and function of the joint, as well as restoration of the controlling function of the surrounding soft tissues (i.e., muscles, ligaments, and tendons). The goals of arthroplasty are pain relief, stability of joint motion, and deformity correction. The original hip prosthesis was fabricated from stainless steel. Prostheses currently in use are stronger metal alloys, based on nonferrous metals, generally cobalt or titanium. These alloys demonstrate greater tensile strength and are more resistant to fatigue than the original stainless steel. The search for stronger metals that can withstand greater amounts of abuse is persistent because of the increasing demand for these components to last longer. And in fact, even younger groups of patients are lining up for joint replacements as people have become more active and athletic. The rigors of activities such as running and skiing are leading to the need for increased numbers of joint replacements in patients that are younger than ever before.[39]

Joint Arthroplasty

Hip Surgery

Several hundred thousand patients in the United States undergo some form of hip arthroplasty each year. The majority of patients are over age 65 and more than 75% have at least one comorbidity when they present for surgery.[40] Women are twice as likely as men to require the surgery. Hip arthroplasty is most often indicated for patients experiencing degenerative joint disease or arthritic damage. A report on outcomes noted that, in patients having total joint arthroplasty, younger age and male sex are associated with an increased risk of revision. Older age and male sex are associated with increased risk of mortality and older age is related to worse function, particularly among women. Age and sex do not influence the outcome of pain. Despite these differences, all subgroups derived benefit from total joint arthroplasty.[41]

It is classified as a major surgical undertaking. This procedure requires a large incision, extending from near the iliac crest across the joint to the midthigh level. Several large muscle groups must be incised and dissected through to gain access to the joint, after which the joint is disarticulated. The muscle relaxation provided by a subarachnoid block makes it ideal to facilitate the surgical process. The anesthetic plan for patients undergoing hip surgery frequently involves the use of some sort of regional technique. In the event of patient refusal, or contraindication for spinal anesthetic, general anesthesia may be selected. Nitrous oxide should be avoided due to the risk of air entrapment. The duration of the surgery, level of narcotic required to maintain patient comfort, and required positioning make it less desirable to perform these surgeries utilizing an laryngeal mask airway (LMA).

Once anesthesia induction is complete, the patient is positioned, prepped, and draped for incision. After a final timeout, skin incision is made. The femoral head and neck are excised, leaving the femoral canal open. The femur is highly vascular, as is the acetabulum, and the reaming required to prepare them for receipt of orthopedic components often opens venous sinuses, which can result in significant blood loss. For these patients, intraoperative blood loss ranges from 500 to 1000 mL per case.[42]

The hemoglobin threshold at which red-cell transfusion is warranted is controversial. A recent study compared a liberal strategy of transfusion at a hemoglobin below 10 g/dL after hip fracture with a more restrictive strategy of transfusion at a hemoglobin below 8 g/dL. The liberal and restrictive strategy groups were similar with regard to rates of death, inability to walk independently on 60-day follow-up, and in-hospital morbidity in elderly patients at high cardiovascular risk.[43]

BOX 40-4

Significant Risk Factors for Developing Bone Cement Implantation Syndrome

- Preexisting cardiovascular disease
- Preexisting pulmonary hypertension
- American Society of Anesthesiologists class 3 or higher
- New York Heart Association class 3 or 4
- Canadian Heart Association class 3 or 4
- Surgical technique
- Pathologic fracture
- Intertrochanteric fracture
- Long-stem arthroplasty

Adapted from Donaldson A, et al. Bone cement implantation syndrome. *Br J Anaesth.* 2009;102(1):12-22.

The canal is further cleaned with a sponge to prepare the surface for receipt of adhesive, after which methyl methacrylate (MMA) cement may be instilled into the femoral canal. For some procedures, usually in younger or very physically active patients, MMA is not used to secure the femoral prosthesis, and the prosthesis is referred to as being *press-fit*. The femoral prosthesis is inserted into the canal and forcibly "seated" with a mallet. Physiologic changes are common with the instillation of the MMA. These changes are termed *bone cement implantation syndrome* (BCIS).

BCIS has no agreed-upon definition, although it is characterized by a number of clinical features that may include hypoxia, hypotension, cardiac arrhythmias, increased pulmonary vascular resistance (PVR), unexpected loss of consciousness when regional anesthesia is administered, and cardiac arrest. The etiology of these effects is poorly understood and only suggested. Some theories involve the role of emboli formed during cementing and prosthesis insertion. Several mechanisms such as histamine release, complement activation, and endogenous cannabinoid-mediated vasodilation have been proposed. It is most commonly associated with hip arthroplasty but may also occur during other cemented procedures including knee arthroplasty and vertebroplasty. Although definitive studies are lacking, it is estimated to occur in 2% to 17% of surgeries. It usually occurs at the following stages in the surgical procedure: femoral reaming, acetabular or femoral cement implantation, insertion of the prosthesis or joint reduction, or occasionally after limb tourniquet deflation. Numerous patient-related risk factors have been implicated and are given in Box 40-4.

A fall in end-tidal carbon dioxide concentration may be the first indication of clinically significant BCIS under general anesthesia. Early signs of BCIS in the awake patient undergoing regional anesthesia include dyspnea and altered sensorium. If BCIS is suspected, the inspired oxygen concentration should be increased to 100% and supplementary oxygen should be continued into the postoperative period. It has been suggested that cardiovascular collapse in the context of BCIS be treated as right-sided heart failure. Aggressive fluid resuscitation is recommended and hypotension should be treated with α-agonists.

Communication between the surgical team and the anesthesia team is imperative at the time of cementing. Prior to cementing, the patient's blood pressure should be optimized, the patient

should be placed on 100% Fi_{O_2}, pressure bags should be available for rapid IV fluid administration, and IV fluid bags should be full or near so. It is also important to document the cement time on the anesthesia record. The acetabular component is secured in place with screws and bone grafting.[44]

Positioning. Patients being prepared for hip arthroplasty are generally positioned in the lateral decubitus fashion. Placing the patient in a lateral decubitus position produces physiologic changes similar to those found in the supine patient. Although the majority of organ systems are unaffected, the physiologic alterations of most concern revolve around pulmonary and cardiovascular functioning.[45] Upright positioning contains three zones of ventilation-perfusion distribution. Placing the patient in the lateral decubitus position results in a significantly greater proportion of the uppermost lung being classified as *zone 1*, where ventilation is more abundant than pulmonary blood flow, as well as a large portion of the dependent lung being classified as *zone 3*, where pulmonary blood flow exceeds alveolar ventilation (see Figure 40-2). In addition, the percentage of the *zone 2* areas of the lung fields is reduced and split between the lungs, with the larger amount being in the dependent lung.

The alteration in ventilation-perfusion distribution is accompanied by reductions in vital capacity and tidal volume. On assuming the lateral decubitus position, healthy, conscious individuals experience about a 10% reduction in vital capacity as a result of reduced anterior, as well as lateral, movement of the dependent rib cage along with restriction of the dependent hemidiaphragm. Ventilation-perfusion distribution may be further altered by the shift in the mediastinum toward the dependent side, which rotates the heart on its axis. This cardiac rotation can impede venous return, reducing cardiac output. The reduced cardiac output can produce hypotension, which must be judiciously treated with either fluid challenges or small doses of vasoactive medication. Judicious attention to padding and warming and continuous assessment are required.[45,46]

Thromboprophylaxis. Patients undergoing total hip and total knee arthroplasty as well as other orthopedic patients are at risk for venous thromboembolism. These include deep vein thrombosis and pulmonary embolism. Most deep vein thromboses are asymptomatic, but they can lead to long-term morbidity to the same extent as symptomatic events. Unique coagulation factors may be associated with orthopedic surgery patients that differentiate them from patients undergoing other types of surgery.[47] Many different guidelines exist.[48] The American College of Chest Physicians evidence-based guidelines for preventing thromboembolism in orthopedic surgery have recently been updated. They recommend that patients undergoing major orthopedic surgery receive either low-molecular-weight heparin; fondaparinux; dabigatran, apixaban, and rivaroxaban (total hip or total knee arthroplasty but not hip fracture surgery); low-dose unfractionated heparin; adjusted-dose vitamin K antagonist; aspirin; or an intermittent pneumatic compression device (IPCD) for a minimum of 10 to 14 days. Thromboprophylaxis for up to 35 days is preferred. They recommend the use of low-molecular-weight heparin in preference to the other agents and suggest adding an IPCD during the hospital stay. In patients at increased bleeding risk, the use of an IPCD alone with no pharmacologic prophylaxis is recommended.[49]

Knee Arthroplasty

Total knee arthroplasty is the other frequently performed joint replacement procedure. The pneumatic tourniquet is placed circumferentially over the thigh to decrease blood loss and maintain full view of the joint for the surgeon. Nevertheless, blood loss as a result of total knee arthroplasty can be up to 2 units. During the procedure, the articulating surfaces of the femur and tibia are excised via precise angular cuts, and the patellar articulating surface is shaved, all to conform the bones to surfaces of the prostheses. Both the femoral and tibial surfaces are covered with MMA cement, and the individual prosthesis components are forcibly seated with a mallet. The high-density polyethylene patellar component is cemented and seated with a viselike clamp. The medial and lateral menisci are replaced with a conforming wedge of high-density polyethylene. The same considerations related to MMA as discussed in hip arthroplasty apply here as well.[50]

Ankle Arthroplasty

Ankle arthroplasty is performed for a number of orthopedic problems. The most common intraarticular procedures are osteochondral lesion, ankle or subtalar debridement, subtalar fusion (thirty-three), and partial talectomy. The most common extraarticular procedures are os trigonum excision, tenolysis of the flexor hallucis longus tendon, and endoscopic partial calcanectomy. End-stage osteoarthritis of the ankle is a major cause of pain and disability.[51] **A**rthroscopy is used not only to evaluate and treat intraarticular abnormalities but also for endoscopic and tendoscopic procedures.[52] A tourniquet may be used to facilitate a bloodless field. Deep vein thrombosis (DVT), pulmonary embolism (PE), and fat embolism are all associated with total hip arthroplasty. Thromboprophylaxis is discussed previously.

Anesthetic Management

These procedures can be performed with either a regional or general anesthetic technique. Ankle procedures that require a tourniquet are commonly performed under spinal or epidural anesthesia. A combination of regional techniques such as spinal anesthesia for the surgical procedure with a popliteal, femoral, or a combination of leg blocks for postoperative analgesia.[53,54] Regional anesthesia that combines sciatic and femoral nerve blocks is sufficient for all surgical procedures below the knee that do not require a thigh tourniquet. The femoral nerve innervates the medial leg to the medial malleolus, and the remainder of the leg below the knee, including the foot, is innervated by the common peroneal nerve and tibial nerve, both branches of the sciatic nerve. The sciatic nerve is usually blocked high in the popliteal fossa to ensure anesthesia to the tibial and peroneal nerves.[55]

Upper Extremity Arthroplasty

The number of shoulder arthroplasties, particularly total shoulder arthroplasties, performed is rapidly increasing. The use of reverse total arthroplasty, which was approved by the Food and Drug Administration in 2003, may be part of the reason for this increase.[56]

The goals of shoulder arthroplasty include pain reduction and increasing range of motion. Indications for shoulder arthroplasty include posttraumatic brachial plexus injuries, paralysis of the deltoid muscle and rotator cuff, chronic infection, failed revision arthroplasty, severe refractory instability, and bone deficiency after resection of a tumor in the proximal aspect of the humerus.[57] Shoulder arthroplasty is performed with the patient in either the lateral decubitus or modified Fowler ("beach chair") position (see Figure 40-3). Because a pneumatic tourniquet cannot be used, shoulder arthroplasty is associated with higher amounts of blood loss.

Elbow arthroplasty is performed with less frequency than shoulder arthroplasty. The goals for elbow arthroplasty are much the same as for shoulder arthroplasty: pain relief and improvement

in joint function. The indications for elbow arthroplasty include rheumatoid arthritis, traumatic arthritis, and ankylosis of the joint.

Anesthetic Management

Patients undergoing total shoulder arthroplasty can be managed by general anesthesia, interscalene blockade, or supraclavicular blockade. Combined regional and general anesthesia is also a choice. It is important to be mindful of the ongoing potential for inadvertent extubation. This is a result of the surgical manipulations and desired patient positioning necessary while in close proximity to the patient's head and neck. The patient's neck may be subjected to excessive stretch during the surgical manipulations, and if the patient's head becomes dislodged from the supportive device used, there is the potential for cervical spine injury. Special attention to the head supports avoids pressure on the patient's eyes.

For the patient undergoing shoulder arthroscopy, pulmonary function will more closely resemble "normal" function as a result of being in the modified Fowler's position. The potential for venous air embolism is somewhat increased in this position. The risk of fat or bone marrow embolism and thromboembolism is incumbent with the required reaming of the shaft of one of the body's long bones. The potential cardiovascular effects of MMA cement also must be considered if the humeral component is cemented in place. The sitting position may result in detrimental cerebral damage to patients experiencing hypotension.[58] Complications during shoulder arthroscopy in the beach chair and lateral decubitus positions are compared in Table 40-1. Prevention of position-related complications during shoulder arthroscopy are shown in Table 40-2.

Visual loss may be especially problematic in patients having arthroscopic procedures using deliberate hypotensive techniques. When intraoperative hypotensive techniques are used, cerebral perfusion and blood supply to the cranial nerves, including the optic nerve, is diminished. Intraoperative cerebral ischemia has been reported, resulting from hypoperfusion. The decreased cerebral perfusion is likely due to several factors, including the decrease in blood pressure associated with anesthesia and upright position. Other factors include failure to correct for cerebral pressure being lower than the point of blood pressure measurement, and vascular compromise related to malpositioning of the head and neck, probably through changes in cerebral blood flow from a combination of postural hypotension and excessive head and neck manipulation. Pressure measurements must be assessed at the level of the brain because autoregulation occurs in the intracranial arterioles and capillaries. When the patient is seated upright, there is a significant hydrostatic gradient between the brain and the site of blood pressure measurement. The magnitude of the gradient is approximately 2 mmHg per inch of height differential. When the cuff is on the upper arm, this difference can easily be 25 mmHg. Failure to properly measure the blood pressure may lead to inaccurate assessment of the patient's true cerebral perfusion.[59]

Hypotensive bradycardic episodes (HBEs) are a relatively common adverse effect of shoulder arthroscopy and may lead to potentially devastating complications. HBEs have been defined as a decrease in heart rate of at least 30 beats/min within a 5-minute interval, any heart rate less than 50 beats/min, and/or a decrease in systolic blood pressure of more than 30 mmHg within a 5-minute interval or any systolic pressure below 90 mmHg. These transient but profound hypotensive and/or bradycardic events have been reported in patients undergoing shoulder surgery in a semiupright position under an isolated interscalene block anesthetic with a reported incidence approaching 30%. The etiology of these HBEs is unknown, but the most common proposed mechanism is activation of the Bezold-Jarisch reflex.

TABLE 40-1 Position-Related Complications During Shoulder Arthroscopy

Beach Chair	Lateral Decubitus
Hypotensive bradycardic events with interscalene block (4%-29%)	Temporary paresthesia (10%)
Cervical neurapraxia (rare)	Permanent neurapraxia (2.5%)
Air embolism/pneumothorax	Risk of musculotendinous nerve injury (5-o'clock portal) (rare)
Cerebral hypoperfusion event	Fluid-related obstructive airway compromise

HBE, Hypotensive bradycardic episodes.

The Bezold-Jarisch reflex is an inhibitory reflex mediated through cardiac sensory receptors with a vagal efferent limb. In the case of surgical positioning with the patient in the beach-chair position, enhanced venous pooling occurs due to dependent extremities, leading to a subsequent increase in sympathetic tone and ultimately a low-volume, hypercontractile ventricle. Cardiac hypercontractions lead to activation of the Bezold-Jarisch reflex with an abrupt autonomic withdrawal of sympathetic response and activation of increased vagal tone. The combination of venous pooling and paradoxical increased vagal tone results in sudden, profound bradycardia and hypotension that can be difficult to rapidly reverse.

The first descriptions of HBE, historically, were in patients receiving spinal anesthesia for a variety of surgeries. The mechanism clearly involves sympathetic blockade; however, decreased sympathetic tone to the heart with decreased cardiac filling is an important contributor. It has been proposed that epinephrine used with the local anesthetics for interscalene block may actually contribute to HBE by increasing cardiac hypercontractility, as well as exacerbating the position-related hypovolemic state.

It is possible that when administered in a regional block, epinephrine is absorbed slowly and may be physiologically equivalent

to a low-dose intravenous administration. At such concentrations, epinephrine could predispose to HBE by increasing cardiac contractility, resulting in ventricular emptying, increasing heart rate (which reduces cardiac filling), and peripheral vasodilation and pooling (decreased afterload); these factors ultimately create ventricular hypovolemia with hypercontractions.

Prophylaxis to prevent HBE includes aggressive treatment of fluid deficits and blood loss. Minimize venous pooling in the upright position with support stockings. Avoid the use of local anesthetics containing epinephrine and consider the use of intraoperative β-blockade in select patients.[59]

Elbow arthroplasty can be performed in any of three positions: supine, lateral decubitus, or prone. The deciding factors on which position to use for this procedure are surgeon preference and the health of the patient. Elbow arthroplasty can be managed by general anesthesia or supraclavicular, intraclavicular, interscalene, or brachial plexus blockade. During elbow arthroplasty, the pneumatic tourniquet is generally used to minimize blood loss and provide a clear surgical field. It is necessary to be prepared to treat the patient's tourniquet pain whenever regional anesthesia is used. Any time a pneumatic tourniquet is used, the risk of thromboembolism exists. This risk is increased in those patients with a history of venous thromboembolism (VTE).[60]

SPINAL SURGERY

Minimally invasive techniques are being used for noncomplex spinal procedures. Percutaneous endoscopic lumbar discectomy (PELD) is the technique of choice for minimally invasive spine surgery (MISS).[61] Other procedures that may be treated with minimally invasive techniques include vertebroplasty and kyphoplasty, cervical discectomy and foraminectomy, and intradiscal electrothermal therapy. The procedures are performed in an interventional radiology suite and usually require local anesthesia with intravenous sedation. General anesthesia is occasionally used for difficult procedures, and low-dose propofol, remifentanil, or dexmedetomidine infusions have all been used successfully. The greatest anesthetic challenge may be positioning because these patients often have severe osteoporosis and other spinal deformities. They are often elderly and have significant comorbidities, so a thorough preoperative workup and preparation is essential.[62] Attention to postoperative analgesia improves recovery.[63]

Back injuries account for a large percentage of work-related injuries and are a leading cause of work absences. Occupational factors suspected of accelerating spinal degeneration include accident-related trauma; heavy physical loading, lifting, bending, and twisting; prolonged sitting; and sustained nonneutral work postures and long periods of sitting while driving.

Complex spinal surgery presents several anesthetic challenges including airway control, positioning, fluid and blood transfusion management, hemodynamic control, and postoperative analgesia. The majority of spine patients will be placed in the prone position for surgery.

Patients in this position for prolonged periods present significant challenges. It is important to maintain adequate venous return to maintain the hemodynamics of the patient.[64] If the increased intraabdominal or intrathoracic pressures resulting from being prone reduce venous return, it will reduce cardiac output. In addition, placing a patient in the prone position produces significant increases in both systemic and pulmonary vascular resistance. These increases lead to significant decreases in stroke volume and cardiac index.[65]

Respiratory dynamics are greatly affected by placing the patient in the prone position. The three-zone model discussed earlier is rearranged. The proportion of zone 2 reduces, whereas that of zone 3 increases.[66] Care is taken to prevent barotraumas through appropriate changes in ventilatory settings to maintain oxygenation and positive pressures within acceptable limits.

Finally, the prone position can alter central nervous system (CNS) dynamics more than the supine position, which is of particular concern if head injury or closed head pathology is present or suspected. The anterior neck is particularly supple and lacks considerably bony structural and protective support. With the unconscious patient or one under general anesthesia, head rotation during positioning must be done with great care. If the patient's head is rotated 60 degrees, compression of the contralateral vertebral artery begins to constrain blood flow; if rotated 80 degrees, the contralateral vertebral artery becomes completely occluded.[67] The carotid artery and jugular vein on the upper side of the neck can become compressed by extreme degrees of head rotation, and those on the down side of the neck may become compressed by inappropriate head support.[64]

Under general anesthesia or with a patient whose level of consciousness is already altered, the alteration in arterial blood supply to the brain may not be easily recognized. Therefore, patients in whom any aberration in carotid blood flow is suspected or who have head injury should probably have the head maintained in a neutral anatomic alignment while in the prone position. In addition, even if no arterial or venous compression occurs, if the patient's head rests below the level of the heart, he or she is at an increased risk for postoperative visual loss, which is discussed below. Whether the head is rotated to the side or placed in a neutral sagittal position, careful attention must be directed to the avoidance of pressure on the orbit. This can be accomplished with soft surgical pillows or one of several commercially available foam supports. Mayfield tongs provide an additional level of stability and eliminate pressure on the face or the eyes.[65]

In the past, laminectomies required large incisions to afford the surgeon optimal visualization of the affected area of the spinal column. Currently less invasive techniques that make use of the microscope afford the surgeon better visualization while eliminating the need for the large incisions that were commonplace in the recent past, even for straightforward, "simple" lumbar laminectomies. In addition, the smaller incision results in reduced blood loss, faster wound healing, less trauma to surrounding soft tissues, shorter recovery, shorter length of hospitalization, and quicker return to a preinjury level of activity.

The most common reasons for spinal surgery are intervertebral disc herniation and spinal stenosis. These maladies can occur anywhere along the spinal column from C2 to C3 through the L5 to S1 vertebrae. Surgical intervention via the posterior approach consists of a midline incision and tissue dissection to expose the disc herniation or stenotic areas. Surgery is undertaken to relieve the pressure on the nerve root that is causing the pain. Certain conditions require the fusion of two or more vertebrae together. This fusion can provide increased stability.

Several agents can be used to accomplish this fusion, whether via bone grafting, plates and screws, or with the use of cage devices. The goal is to prevent further degeneration and loss of the surgical correction achieved. Interbody cage devices facilitate fusion of the specific vertebral joint.[68] Interbody cage procedures, done by experienced surgeons, are more quickly accomplished than the previously standard bone-grafting procedure, are less costly, provide greater stability, and afford faster recovery and rehabilitation times.[69]

In contrast to interbody cage devices and procedures, total disc replacement procedures are accomplished most commonly via an

anterior approach. Anterior approaches to spinal surgery often require the assistance of a general surgeon to aid in displacement of organs and vasculature.[70-73] A double-lumen tube may be used for lung isolation to facilitate surgical exposure. Fusion within the cervical spine is most often accomplished by initial discectomy followed by a wedge of bone graft, often cadaveric, or by fusion of the joint with a plate and screws.

Scoliosis is lateral curvature of the spinal column. The majority (75% to 80%) of scoliosis cases are idiopathic. The remaining 20% to 25% can be identified as resulting from such conditions as congenital skeletal abnormalities, neuromuscular disease, neurofibromatosis, trauma, or irritative phenomena resulting from spinal cord compression from a tumor. Untreated, scoliosis can lead to complex deformity in two planes (sagittal and coronal), chronic pain, neurologic and cardiopulmonary compromise, and cosmetic concerns.[74] Treatment pathways are determined by the severity and cause of the deformity and may be nonsurgical or surgical.

Surgical intervention consists primarily of fusion of multiple joint spaces, with or without anterior release, and may include extensive instrumentation (e.g., Harrington rods or other instrumentation). Scoliosis repair may require anterior or posterior approaches for repair. Either approach is a major surgical intervention, but the anterior approach is more technically involved. The anterior approach to the thoracic spine requires performing a thoracotomy.

In conjunction with the development of "cage" technology, the principles of laparoscopy/endoscopy are being adapted and applied to spinal surgery. The first use of laparoscope for lumbar discectomy was documented by Obenchain[75] in 1991. Laparoscopic techniques were first used by Mack et al.[76] for thoracic spinal surgery in 1993. Application of laparoscopic principles and techniques offers numerous advantages to anterior vertebral joint fusion (Box 40-5), the most important being better respiratory functioning, diminished blood loss, and shorter length of stay, resulting in decreased medical costs. The major disadvantage of using laparoscopic techniques in spinal surgery is the time it takes for the user to become proficient at the technique to avoid prolonged time in the operating room.

Not all patients are good candidates for the laparoscopic approach. It is contraindicated for lumbar repair in patients with abdominal adhesions from inflammatory processes, laparotomy, or abdominal trauma patients. In addition, those patients with marked cardiac or pulmonary disease processes may not be able to tolerate the hypercarbia that can result from abdominal insufflation of carbon dioxide. For thoracic spinal surgery candidates, laparoscopy is currently contraindicated for patients unable to tolerate one-lung ventilation and those with severe or acute respiratory insufficiency, high positive airway pressures, and pleural symphysis. Patients who have required previous thoracotomy or chest-tube placement must be more extensively evaluated preoperatively to determine whether thoracoscopic spinal surgery should be used. Also, at present, patients in need of internal fixation with extensive instrumentation of the anterior spine are not considered candidates for thorascopic spinal surgery.[77]

BOX 40-5

Advantages of Laparoscopy for Anterior Spinal Surgery

- Enhanced visualization
- Decreased potential for infection
- Reduced trauma to surrounding soft tissues
- Shorter hospitalization
- Shorter rehabilitation period
- Decreased blood loss
- Improved intraoperative and postoperative ventilation
- Reduced intensive care unit time
- Better cosmetic appearance
- Reduced overall costs

Anesthetic Management

General anesthesia provides the safest approach for spinal surgery. Not only is the airway secure, but muscle relaxants can be used, preventing movement at critical times during surgery. Aspirin, antiplatelet drugs, and anticoagulants should be appropriately managed and discontinued as possible. Preoperative testing should include a complete blood count, platelet count, and coagulation studies. A preoperative chest x-ray, pulmonary function tests, electrocardiogram (ECG), and echocardiogram should be obtained as appropriate. Evoked potentials will likely be monitored along with other neurologic testing as indicated (see Chapters 18 and 28).

A major anesthesia concern during spinal surgery centers on patient positioning. For spinal surgery involving the posterior approach, to facilitate the surgery, the patient will almost always be placed prone. While turning the patient, special attention must be given to the head and the endotracheal tube. Foam, gel pads, or head supports should be in place prior to the turning. Once turned, the first goal is to reconnect the breathing circuit and recheck the breath sounds to ascertain whether the tube is still in the correct place and has not migrated into the bronchus. The potential for eye or corneal injury is high in the prone position. Care must be taken to pad the extremities and to prevent neural injury.

When positioned prone, the patient's abdomen should not be compressed, because compression of the abdominal cavity will displace the organs, and therefore the diaphragm, in the cephalad direction, producing reduced functional residual capacity, reduced tidal volume, and increased airway pressures. Abdominal compression also contributes to engorgement of the epidural venous network and can be a contributing factor to greater blood loss during the surgical procedure. To avoid abdominal compression, the abdomen must be elevated from the surface of the OR bed.

Numerous methods and devices can be used to greatly reduce or eliminate abdominal compression. The simplest method is the use of bilateral "prone or chest rolls," which are firm but compressible pads that extend from the shoulder to the iliac crest (Figure 40-8). Other devices include the Wilson frame (Figure 40-9), the Relton adjustable pedestal frame (Figure 40-10), and the Andrews frame, or spinal-surgery table (Figure 40-11). Each of these positioning devices is designed to allow the abdomen to "hang" freely and reduce the possibility of compressing major vascular structures.

The Andrews spinal-surgery table is the most complex of the positioning devices. With the Andrews table, as with the other positioning devices, the patient is induced and intubated on the transport stretcher, after which he or she is lifted onto the table.

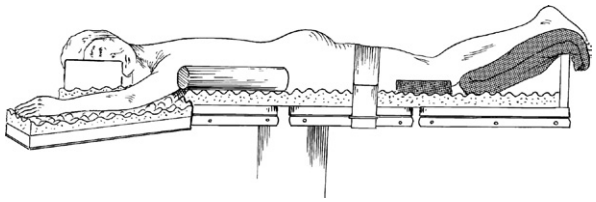

FIGURE **40-8** Prone position using chest rolls.

On initial positioning on the Andrews table, the patient lies flat with the legs resting perpendicular to the plane of the table. A buttock support is securely attached to the framework of the table and the bony prominences of the hips and, particularly, the knees are adequately padded. The leg portion of the table is then lowered until the weight of the lower body rests on the knees, resulting in the patient's hips and knees being flexed at 90 degrees. This table produces a modified knee-chest position, allows the abdomen to "hang" freely, and greatly reduces the potential for compression of the major vascular structures of the lower abdomen and pelvic region (femoral arteries and veins). This position also maximizes the surgeon's visualization of the surgical site. Blood loss is decreased by using the Andrews spinal-surgery table.[78] However, hypotension occurs frequently when using this table as a result of blood pooling in the dependent lower extremities. Antiembolic stockings may help counteract the tendency for blood to pool in the lower extremities, and any hypotensive event must be treated.

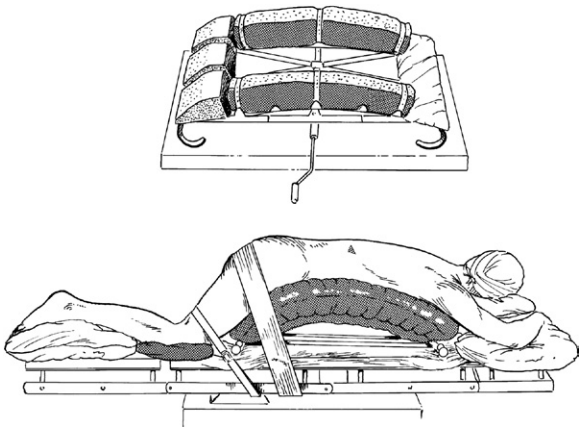

FIGURE **40-9** Spinal operations using a convex saddle frame (Wilson frame).

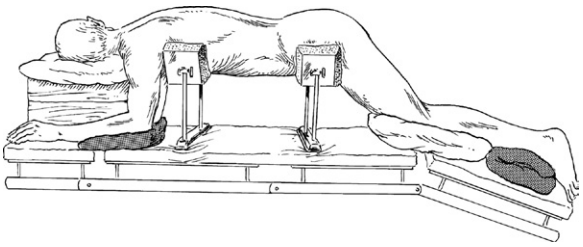

FIGURE **40-10** The Relton adjustable pedestal frame.

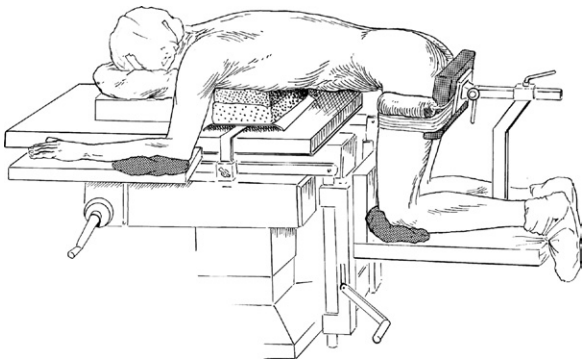

FIGURE **40-11** The Andrews frame.

Scoliosis correction with large-scale instrumentation (e.g., Harrington instrumentation) is a major surgical intervention. The surgeon may choose a posterior, anterior, or thoracoabdominal approach to accomplish the procedure, depending on the location and severity of the defect. The posterior approach requires the patient to be in the prone position. Scoliosis of the lower thoracic to upper lumbar spine may necessitate a thoracoabdominal incision and require the patient to be placed in a semilateral position. Scoliosis exclusively of the thoracic spine requires the patient to be placed in the lateral decubitus position.

Entry into the thoracic cavity necessitates placement of a double-lumen endobronchial tube so the ipsilateral lung can be deflated to facilitate visualization of the thoracic spine. Intubation may be difficult at best if the patient has a severe deformity For surgical correction of scoliosis by spinal fusion with anterior release, the patient is placed in the lateral decubitus position for the thoracotomy incision and requires endobronchial intubation. Depending on the direction of curvature of the thoracic spine, the heart may necessarily be manipulated, which may produce cardiac dysrhythmias. In patients who are myelopathic or have cervical spine instability, a fiberoptic or other assisted device intubation, either awake or after the induction of general anesthesia, may be indicated. This also may be necessary in patients who have undergone previous spinal fusion with limitation of neck extension. In the anesthetized patient, evoked potentials can be measured before and after intubation as well as before, during, and after positioning.[65]

With the large incision and complex dissection required for the multilevel spinal fusions and instrumentation needed to surgically correct the scoliosis, significant blood loss may occur. Blood transfusion is virtually ensured during the course of the procedure. Procedures more likely to be associated with major blood loss are those involving the thoracic spine, particularly for malignancy or trauma. Autologous blood donation, the use of cell salvage devices, and serial hemoglobin and hematocrit determinations and urine output are all used to manage fluid and transfusion therapy. The choice of anesthetic drugs is standard with consideration for evoked potential monitoring and postoperative analgesia as part of the plan.

As described, laparoscopic principles and techniques are beginning to be applied more frequently to spinal-fusion surgery. Spinal fusion via laparoscopy provides the surgeon with enhanced visualization of the surgical site, reduces operative time once the surgeon and staff have acquired and are comfortable with the necessary skills, results in greatly reduced trauma to the surrounding soft tissues, produces dramatically less blood loss, reduces recovery and rehabilitation time, greatly reduces medical costs, contributes to an earlier return to preinjury level of activity, and is aesthetically more pleasing to the patient. It is important to compensate for any hypercarbia that may accompany insufflation of carbon dioxide, particularly during long procedures.

Sudden, dramatic, unanticipated, sustained hypotension requires rapid intervention and assessment of cause. The surgeon should be informed, and together a plan to rapidly determine the cause and initiate appropriate effective treatment measures may be instituted. Because of the close proximity to the spinal column, injury to the aorta can occur during surgery on the thoracic or lumbar spine. In addition to aortic injury, the inferior vena cava, iliac vessels, and common femoral vessels may be damaged as a result of traction during laparoscopic spinal procedures.[77] Injury to these vascular structures can be a truly emergent situation. If the patient is in the prone position, rapid closure of the surgical wound is imperative so the patient can be repositioned to facilitate repair

BOX **40-6**

Recommendations of the ASA Task Force on Perioperative Blindness

- The consensus of the Task Force is that a high-risk patient's vision should be assessed when the patient becomes alert (e.g., in the recovery room, intensive care unit, or nursing floor). If there is concern regarding potential visual loss, an urgent ophthalmologic consultation should be obtained to determine its cause. Additional management may include optimizing hemoglobin or hematocrit levels, hemodynamic status, and arterial oxygenation. To rule out intracranial causes of visual loss, consider magnetic resonance imaging. The Task Force believes that there is no role for antiplatelet agents, steroids, or intraocular pressure–lowering agents in the treatment of perioperative ischemic optic neuropathy.
- There is a subset of patients who undergo spinal procedures while they are positioned prone and receiving general anesthesia who have an increased risk for the development of perioperative visual loss. This subset includes patients who are anticipated before operation to undergo procedures that are prolonged, have substantial blood loss, or both (high-risk patients).
- Consider informing high-risk patients that there is a small, unpredictable risk of perioperative visual loss.
- The use of deliberate hypotensive techniques during spinal surgery has not been shown to be associated with the development of perioperative visual loss.
- Colloids should be used along with crystalloids to maintain intravascular volume in patients who have substantial blood loss.
- At this time, there is no apparent transfusion threshold that would eliminate the risk of perioperative visual loss related to anemia.
- High-risk patients should be positioned with the head level with or higher than the heart when possible. In addition, the head should be maintained in a neutral forward position (e.g., without significant neck flexion, extension, lateral flexion, or rotation) when possible.
- Consideration should be given to the use of staged spinal procedures in high-risk patients.

Adapted from Lee LA, et al. The American Society of Anesthesiologists Postoperative Visual Loss Registry: analysis of 93 spine surgery cases with postoperative visual loss. *Anesthesiology*. 2006;105(4):652-659; Lee LA, et al. Postoperative Visual Loss Study Group. Risk factors associated with ischemic optic neuropathy after spinal fusion surgery. *Anesthesiology*. 2012;116(1):15-24. ASA, American Society of Anesthesiologists.

to the damaged vessel. Volume resuscitation may be required in the event of an injury to a blood vessel. For this reason, it is imperative to have two large-bore IV access sites in addition to verifying the availability of blood. Venous air embolism can occur in certain procedures, and appropriate monitoring and vigilance is required (see Chapter 28).

Postoperative Visual Loss

Postoperative vision loss (POVL) associated with general anesthesia and prone positioning in spinal surgery have been increasing in incidence over the past several decades. The American Society of Anesthesiologists (ASA) developed a Postoperative Visual Loss Registry in an effort to better understand and evaluate this devastating operative complication. Over 93 incidents have been reported between 1999 and 2005.[79] The main causes of visual loss after nonocular surgery are retinal vascular occlusion and ischemic optic neuropathy. Direct pressure to the periorbital region of the eye can cause increased intraocular pressure and blindness as the result of central retinal artery occlusion. The cause of ischemic optic neuropathy (ION) is still unclear. Although it can strike patients of any age, there is an increased incidence in patients less than 18 and more than 65 years of age. The Postoperative Visual Loss Study Group has reported that obese and male patients have an increased risk of developing ION after major spinal surgery in the prone position. Increased intraabdominal, intrathoracic, and intraocular pressure in the prone position may lead to venous congestion and therefore contribute to the problem. Obesity, male sex, Wilson frame use, longer anesthetic duration, greater estimated blood loss, and decreased percent colloid administration were significantly and independently associated with ION after spinal fusion surgery.[80,81] Other researchers have also noted that significant risk factors include male sex, anemia from blood loss greater than 1 liter, surgery lasting over 5 hours, and intraoperative hypotension. Unlike corneal abrasion, the most common eye injury, which is usually self-limiting, the prognosis for visual recovery from POVL is poor.[82]

Most cases of POVL occurring after spinal surgery are bilateral. Visual loss was typically within the first 24 to 48 hours postoperatively. There is usually painless visual loss, an afferent pupil defect or nonreactive pupil, and no light perception, or visual field deficit. Color vision is decreased or absent. Elevated intraocular pressures greater than 40 mmHg from prolonged prone positioning and fluids may be a factor. It is advisable to position a patient's head level with or above the heart, where possible, and in a neutral position.

A foam headrest should be used. Placing the head in pins is also used but is more invasive. For most procedures in which the patient is prone, it is reasonable to use any of the commercially available square foam headrests. It is not advisable to cover the eyes with goggles when the head is positioned prone in a square foam headrest. With a transparent surgical table headpiece, a mirror can enable indirect viewing of the eyes. A foam headrest with a mirror attachment allows eyes to be viewed easily during surgery. Ensure that the eyes are properly positioned and checked intermittently by palpation and visualization. Document eye checks at least every 20 minutes. A horseshoe headrest should not be used because of the greater risk of head movement caused by the surgeon, along with the resulting compression of the eye.[83-87] The ASA Task Force recommendations for the prevention of visual loss are given in Box 40-6.[79,87] A complete discussion of postoperative visual loss can be found in Chapter 21.

FOOT AND ANKLE SURGERY

Each of us is acutely aware of any problems with our ankles or feet. They carry the weight of our bodies around, and we can feel any compromise in their integrity almost immediately. Patients may seek the care of an orthopedic surgeon for problems with their feet, or they may see a doctor of podiatric medicine (DPM). Both of these specialists are highly skilled in the surgical correction of the multitude of problems that occur with the feet and ankles.

The most commonly performed procedures on the ankle involve surgical repair of ankle fractures and fusion of the ankle joint. The Achilles tendon is also a frequent focus of surgery, particularly on more physically active individuals. The most widely known surgical procedures on the feet are bunionectomy

(with or without fusion), correction of hammertoe deformities (with or without fusion), and plantar fasciotomy (either open or endoscopic).

Open repair of ankle fractures is usually accomplished using plates and screws to hold the bone fragment in proper alignment until the fragments grow back together. Ankle fusion (arthrodesis) is performed for a multitude of medical reasons and may involve two or three bones being fused together to provide pain relief and greater joint stability. Incisions are usually made on both the medial and lateral aspects of the ankle joint to allow for optimal surgical access to the involved bones. The fracture is reduced, after which a plate is placed across the fracture site or sites. Holes are drilled with the plate acting as the template, and screws are placed into these holes. For ankle fusions, incisions are typically made across the medial and lateral aspects of the joint, and wires or screws are used to fuse the appropriate bones in place. The incisions are closed, and some type of inflexible stabilizing device is applied (e.g., cast or plaster splints or ambulatory boot) while the patient is under anesthesia. Pneumatic tourniquets are almost always used to keep blood loss at a minimum and provide a clear surgical field.

Bunion deformity usually involves the first, or great, toe. Incision is made along the anterior surface from about midtoe across the metatarsophalangeal joint. The bony deformity is excised. Depending on the variation of the bunionectomy procedure chosen, excision of the bony deformity may be the totality of the procedure, or the angular deformity may be corrected with a screw or wire fusion.

Hammertoe deformity correction involves incision of the anterior surface of the malformed toe or toes. The incision crosses the joint containing the bony deformity. The surgeon dissects down to the joint and excises the bony deformity. Depending on the severity of the deformity, the interphalangeal joint may be fused by inserting a wire.

Plantar fasciotomy is indicated for severe foot pain during or after ambulating or on arising after sleep. Pain results from chronic plantar fasciitis that has not responded to conservative therapy. Open fasciotomy is accomplished via a small incision along the posterior surface of the calcaneus. The plantar fascia is incised to relieve the tension across the plantar arch. Endoscopic plantar fasciotomy is accomplished via two "miniature" incisions, one medial and one lateral, at the beginning of the plantar arch. A small trocar is inserted through these incisions. The sheath of the trocar is slotted to allow visualization of the plantar fascia with the endoscope. The full thickness of the plantar fascia is incised, and the skin incisions are closed.

Anesthetic Management

Patients scheduled for foot or ankle surgery are excellent candidates for regional anesthesia. Most surgical procedures on the foot or ankle can be accomplished within a 2-hour timeframe, often on an outpatient basis. Spinal anesthesia provides sufficient surgical anesthesia to allow completion of most procedures. However, the postanesthesia recovery phase may be unacceptably long and require an overnight stay in the hospital or outpatient facility, which may be unacceptable to the patient.

Nerve blocks are especially effective for surgical procedures on the foot or ankle. Intravenous sedation by either continuous infusion or intermittent bolus can provide amnesia and minimize or eliminate any anxiety the patient may have. The surgeon can inject the surgical site with long-acting local anesthetic (e.g., bupivacaine) to maintain the patient's comfort immediately and for several hours postoperatively.

FOREARM AND HAND SURGERY

Surgical procedures on the hand or forearm may be precipitated by trauma resulting in complex or dislocated fractures to the bones of the forearm, hand, or fingers, or may be performed to alleviate numbness of the hand resulting from compression of the nerves of the forearm or wrist, as in carpal tunnel syndrome. Procedures on the fingers and hand are often relatively quick, requiring 1 hour or less to complete, whereas surgical correction of complex or dislocated fractures of the forearm may require considerable instrumentation and time to complete. For virtually all surgical procedures of the hand and forearm, the pneumatic tourniquet is used.

Anesthetic Management

Patients scheduled for surgical procedures on the forearm or hand are well-suited candidates for regional anesthesia. Ultrasound-guided brachial plexus blockade or an intravenous regional block provide excellent surgical anesthesia for most surgical procedures of the forearm and hand anticipated to require 1 hour or less to accomplish.

For procedures that may require considerable amounts of time to accomplish—those precipitated by traumatic injury, such as complex, comminuted fractures or reconstruction of the vascular and nerve structures of the hand or forearm, for example—the better anesthetic choice may be general anesthesia. Tourniquet pain becomes an issue with longer procedures if regional anesthesia is chosen. Also, for the patient requiring surgery as the result of traumatic injury, the issue of the patient's nothing-by-mouth (NPO) status becomes important. Frequently, trauma patients have eaten or ingested liquids close to the time of the injury. Alcohol ingestion may be involved as well. For these reasons, rapid-sequence induction of general anesthesia may be a more appropriate anesthetic course.

ARTHRITIC SYNDROMES

Of the many arthritic syndromes, two are especially disconcerting: rheumatoid arthritis (RA) and ankylosing spondylitis (AS). Both of these arthritic conditions extend beyond the primary affliction to the skeletal system and orthopedic medicine. They are both also associated with specific concerns related to the airway and should be indicators for a thorough airway assessment in the preoperative period.

In 2010 the American College of Rheumatology and the European League Against Rheumatism revised the classification criteria for RA. It is listed in Box 40-7.[88]

Of particular concern are the effects of RA on the cervical spine, temporomandibular joint, larynx, and pulmonary system. Deposition of rheumatoid nodules causes inflammation of the intervertebral discs and dura, which is expressed as atlantoaxial joint subluxation. The synovium of the temporomandibular joint is also affected by RA and can result in severe limitation of joint range of motion. The cricoarytenoid joints are common sites for rheumatoid nodule deposition. The resultant chronic synovitis may cause fixation of the vocal cords in adduction and airway obstruction. Finally, RA is associated with several forms of pulmonary disease, including pleural effusion, interstitial lung disease, obliterative bronchiolitis, and vasculitis (Box 40-8).

Ankylosing spondylitis is also a chronic inflammatory process. The primary target is the spinal column and surrounding soft tissues. The progressive nature of AS means the spine can be injured by seemingly inconsequential trauma. Patients with AS also may experience cardiac valvular dysfunction, conduction delays, bundle branch blocks, and restrictive lung disease.

BOX **40-7**

The 2010 American College of Rheumatology/ European League Against Rheumatism Classification Criteria for Rheumatoid Arthritis

Who should be tested? The target population includes patients who:
1) Have at least one joint with definite clinical synovitis (swelling)
2) Have synovitis that is not better explained by another disease

Classification Criteria for RA

Add score of categories A-D below. A score of ≥ 6 to 10 is needed for classification of a patient as having definite RA.

	Score
A. Joint involvement	
1 large joint	0
2 to 10 large joints	1
1 to 3 small joints (with or without involvement of large joints)	2
4 to 10 small joints (with or without involvement of large joints)	3
More than 10 joints (at least 1 small joint)	5
B. Serology (at least one test result is needed for classification)	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute-phase reactants (at least one test result is needed for classification)	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of symptoms	
Less than 6 weeks	0
6 weeks or more	1

ACPA, Anticitrullinated protein antibody; *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *RA*, rheumatoid arthritis; *RF*, rheumatoid factor.

Anesthetic Management

The primary concern when caring for a patient with either RA or AS is the patient's airway. The mobility of the patient's cervical spine must be meticulously evaluated during the preoperative interview. Any neurologic symptoms that occur during movement of the cervical spine must be thoroughly documented at that time. As a result of RA or AS, cervical mobility may be severely restricted; therefore, the patient may prove to be extremely difficult to intubate. Because of the high risk to these patients from cervical-spine manipulation during direct laryngoscopy for tracheal intubation, awake fiberoptic or other intubation techniques may be the safer course of action. The prudent anesthetic course also may include positioning the patient such that neurologic symptoms remain absent before induction of general anesthesia. The cervical spine must be neutrally positioned throughout any surgical procedure, during emergence, and during transfer to the postanesthesia care unit. Regional anesthesia is a safe approach to extremity surgery in these patients.[71,72]

BOX **40-8**

Types of Pulmonary Diseases Commonly Found in Rheumatoid Arthritis Patients

- Pleural effusion
- Intrapulmonary nodules
- Rheumatoid pneumoconiosis (Caplan syndrome)
- Interstitial lung disease
- Vasculitis
- Obliterative bronchiolitis
- Upper lobe fibrosis
- Pulmonary infections
- Bronchogenic carcinoma

SUMMARY

Orthopedic surgical procedures are varied and require a wide variety of anesthetic plans. The patient's health history and acceptability of various anesthetic techniques, the proposed surgery and its duration, the patient's intraoperative position, and the need for postoperative pain management are important considerations in the planning and preparation for a safe and comfortable outcome. In addition, many of these procedures carry high risk for blood loss, so preoperative type and screen are indicated in nearly all of these cases. The anesthetic plan must adapt to the needs of the patient and the proposed surgery rather than expect the patient to adapt to one anesthetic technique.

Growth in orthopedics over the last few decades has increased not only options and techniques but also a linear increase in patient outcomes. The invention of the arthroscope has diminished some of the severity of certain repairs and has provided a diagnostic tool for surgeons. Coupled with this is a decreased length of stay and fewer side effects from anesthesia. Trauma and high-profile surgeries corresponding to the increasing geriatric population are challenging and require techniques that reduce complications and provide postoperative pain management.

The Immune System and Anesthesia

CHAPTER 41

◆ *Michael P. O'Donnell*

The field of immunology addresses the body's defense mechanisms against pathogens, such as bacteria and viruses that have the potential to trigger tissue injury and disease. Protection from infection and disease depends on the functions of particular leukocytes, the phagocytes and lymphocytes, with the assistance of auxiliary cells such as mast cells, basophils, and platelets (Table 41-1).[1-3] Immune responses involve not only these various cell types, but also soluble mediator molecules secreted by the cells. These soluble mediators include *cytokines*, a superfamily of peptide molecules that regulate the actions of immune system cells (Box 41-1).

Two components of immunity provide defense against invading pathogens: the innate immune system and the adaptive (acquired) immune system. This chapter highlights immune system physiology and pathology, including the effects of human immunodeficiency virus (HIV) on the immune system, with particular consideration of the effects of anesthesia on immune function.

THE IMMUNE SYSTEM

Innate Immune System

Innate immunity is nonspecific, that is, it provides defense against a very large number of pathogens, rather than being directed at one specific microorganism or type of microorganism. Components of innate immunity include physical barriers such as the skin and lung alveoli, the pathogen-hostile environment of the gastrointestinal tract, leukocytes whose primary function is phagocytosis and destruction of invading pathogens, and soluble molecules such as interferons and the complement system.[1-3]

Phagocytes

Polymorphonuclear neutrophils (PMNs) and macrophages are the primary phagocytes of the immune system. Polymorphonuclear neutrophils and monocytes, the cellular precursors of tissue macrophages, are generated from pluripotent hematopoietic stem cells in the bone marrow (Figure 41-1). Both cell types are continually released to the blood, and many are stored in the marrow until mobilized for defense. Chemical substances known as *colony-stimulating factors* that enter the circulation from an area of infection are transported to the marrow to stimulate production and release of PMNs and monocytes. Colony-stimulating factors are members of the cytokine superfamily (see Box 41-1).

After release from bone marrow, PMNs and monocytes circulate for a short time (less than 24 hours) in the blood before moving either directly across, or through pores between, venule endothelial cells to enter tissues. This process is known as *diapedesis*. Transendothelial movement of PMNs and monocytes and their subsequent movement within tissue to a site of inflammation are not random events, but rather are orchestrated by numerous chemotactic substances that include chemokines produced by endothelial cells, bacterial and viral components, and products C3a and C5a of the blood complement system (Figure 41-2). Production of endothelial-cell chemokines and adhesion molecules, which permit leukocytes to "stick" to the endothelium prior to diapedesis, is stimulated by proinflammatory cytokines, in particular, tumor necrosis factor-alpha (TNF-α) produced by activated macrophages (Figure 41-3).

The primary function of PMNs and macrophages is phagocytosis of pathogens such as bacteria and viruses. In this process, the phagocyte engulfs and destroys the foreign agent. Of critical importance is the ability of the phagocyte to distinguish between what is foreign and what is self. To this end, phagocytes have receptors that recognize carbohydrate and lipid moieties, known as *pathogen-associated molecular patterns* (PAMPs), present on cell surfaces of many pathogens but typically not on cells of the host. An example of a microbial PAMP is lipopolysaccharide in the cell walls of gram-negative bacteria. Phagocyte recognition of PAMPs permits the phagocyte to bind directly to the pathogen.

Phagocyte selectivity also can be provided by the process of opsonization, in which serum components bind to the pathogen and permit indirect recognition by phagocytes. Antibodies directed against a pathogen (and produced as part of acquired immunity) act as opsonins by binding to the pathogen and subsequently to antibody receptors on the phagocyte cell membrane (Figure 41-4). Alternatively, the complement product C3b may act as an opsonin, with subsequent binding of C3b to its receptors on phagocyte cell membranes. Phagocyte binding to a pathogen is followed by endocytosis of the pathogen and its intracellular destruction by lysosomal enzymes and products of the phagocyte respiratory burst, which include superoxide ion, hydrogen peroxide, and nitric oxide (Figure 41-5).

Although some macrophages are mobile and migrate through tissues in response to chemotactic signals, many are fixed within tissues for long periods of time (resident macrophages) as part of the mononuclear phagocyte system (also called the *reticuloendothelial system;* Figure 41-6). This system includes the network of monocytes, mobile macrophages, and fixed macrophages that provides phagocytic function in body tissues. The resident macrophages are particularly important in those tissues potentially exposed to large amounts of pathogens, that is, skin, lymph nodes, lung alveoli, liver sinusoids, and the spleen. When these macrophages encounter a pathogen, a number of responses are rapidly set into play: (1) phagocytosis of the pathogen, which provides a first line of defense against infection, (2) secretion of chemotactic mediators that promote infiltration of leukocytes to the site of infection, (3) secretion of colony-stimulating factors that mobilize PMNs and monocytes from the bone marrow, and (4) secretion of proinflammatory cytokines such as TNF-α and interleukin-1 (IL-1). Neutrophil infiltration provides a rapid second line of defense against the pathogen, while a delayed but potent third line of defense occurs as infiltrating monocytes mature into macrophages, and lymphocytes migrate to the area of infection.

TABLE 41-1 Cellular Components of Immunity

Components	Functions
Phagocytes	
Polymorphonuclear neutrophils (PMNs)	Phagocytosis and destruction of microorganisms; contain bactericidal substances and produce bactericidal reactive oxygen molecules
Monocytes	Circulating cells of the mononuclear phagocyte system; after entering tissues, monocytes mature into macrophages
Macrophages	Mobile and fixed tissue cells of the mononuclear phagocyte system; perform phagocytosis and destruction of microorganisms, present antigen to helper T (T_H) cells and secrete cytokines
Eosinophils	Provide defense against parasitic infections and perform phagocytosis of allergen-antibody complexes formed in an allergic response
Lymphocytes	
Natural killer (NK) cells (also called *large granular lymphocytes* [LGLs])	Destruction of virus-infected "self" cells and tumor cells; secrete cytokines
B lymphocytes	Differentiate into plasma cells that secrete antibodies; present antigen to T_H cells
Helper T lymphocytes (T_H cells)	Secrete cytokines that stimulate T_H cell proliferation and activation of B lymphocytes, cytotoxic T lymphocytes, and macrophages
Cytotoxic T lymphocytes (CTLs)	Engage antigen and secrete pore-forming proteins known as *perforins* into foreign cell membrane; secrete granzymes that destroy the targeted cell
Auxiliary Cells	
Mast cells and basophils	Release histamine and other proinflammatory mediators responsible for hyperemia, increased vascular permeability, and pain
Dendritic cells	Present antigen to T_H cells
Platelets	Participate in coagulation and "walling off" areas of inflammation; secrete proinflammatory mediators

BOX 41-1

Cytokines

- Cytokines are peptide molecules that regulate the actions of immune system cells.
- The cytokine superfamily includes interferons (IFNs), interleukins (ILs), tumor necrosis factor-alpha (TNF-α), colony-stimulating factors (CSFs), and chemokines (chemotactic cytokines).
- IFNs have antiviral activity and act to suppress spread of viral infection; IFN-α and IFN-β are produced by cells already infected by virus, and IFN-γ is produced by activated NK cells and T_H1 lymphocytes.
- IL-1 and IL-6 are produced by several cell types, including lymphocytes and macrophages.
- IL-2 is produced by T_H1 lymphocytes and promotes proliferation and function of T lymphocytes, B lymphocytes, and natural killer (NK) cells.
- IL-4 and IL-10 are produced by T_H2 lymphocytes; IL-4 activates B lymphocytes.
- IL-6 stimulates hepatocytes to release acute phase proteins such as C-reactive protein (CRP).
- IL-12 is produced by antigen-presenting cells (APCs) and promotes differentiation of T_H0 lymphocytes into T_H1 lymphocytes.
- TNF-α is released from activated macrophages and T_H1 lymphocytes.
- IFN-γ, IL-1, IL-6, IL-12, and TNF-α are important proinflammatory cytokines.
- IL-4 and IL-10 are important antiinflammatory cytokines.
- Granulocyte, monocyte, and granulocyte-monocyte CSFs are released from activated macrophages and vascular endothelial cells and stimulate bone marrow to release PMNs and monocytes into the circulation.
- Chemokines are produced by venule endothelial cells and activated macrophages and act to attract leukocytes to an area of infection.

Adapted from Rang HP, et al. *Rang and Dale's Pharmacology*. 7th ed. Edinburgh: Churchill Livingstone; 2012.

Phagocytosis and breakdown of pathogens also permits macrophages to present chemical components (e.g., peptide fragments) of pathogens to cells of the acquired immune system. In this way, macrophages behave as "antigen-presenting cells" to recruit the acquired immune system and greatly augment the body's defense responses to pathogens.

Natural Killer Cells

Another cellular component of the innate immune system is the natural killer (NK) cell. These cells have some morphologic resemblance to lymphocytes, and hence are also referred to as *large granular lymphocytes* (see Table 41-1). NK cells develop in the bone marrow (see Figure 41-1), though the exact mechanism of their differentiation from precursor cells is not well understood. NK cells are potent killers of virus-infected "self" cells. Although leukocytes known as *cytotoxic T lymphocytes* (CTLs; discussed later) destroy many virus-infected cells, some viruses (e.g., herpes simplex virus [HSV]) evade detection by these lymphocytes. Fortunately, NK cells can recognize and kill HSV-infected cells. The mechanism by which NK cells kill virus-infected cells is the same as that by which CTLs destroy infected self-cells and foreign cells. The NK cell binds to the infected cell, secretes a pore-producing protein known as *perforin* into the infected cell membrane, and then releases cytotoxic proteolytic enzymes into the infected cell.

Natural killer cells have other key functions. They are the main immune cells of the pregnant uterus, where they act to protect the uterus and the fetus from viral infections during pregnancy. NK cells are very important in the surveillance of tumor cells (i.e., transformed self-cells) and can destroy some tumor cells. They also release cytokines that influence the immune response to pathogens. One key cytokine released by NK cells is interferon-gamma (IFN-γ).

Interferons

As noted in Box 41-1, the interferons (IFNs) are cytokines with antiviral activity. Indeed, the name *interferon* derives from the ability of these substances to "interfere" with viral replication. There are two main IFN families: type I and type II. Type I IFNs include IFN-α and IFN-β, which are released from many cell types within hours after initiation of viral infection. These cytokines act on neighboring

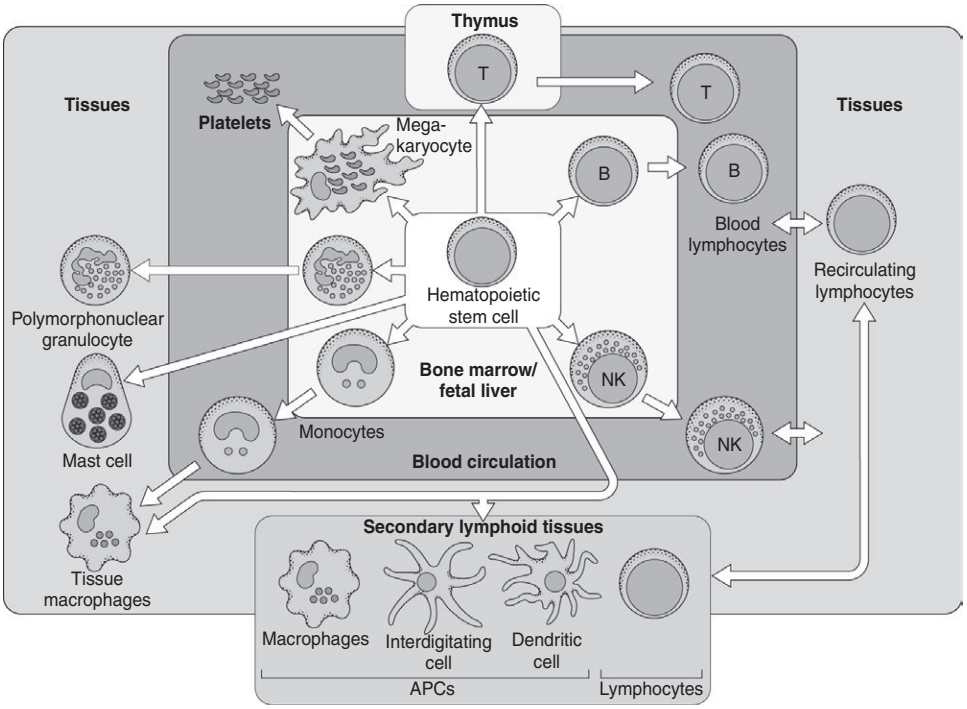

FIGURE **41-1** All immune cells originate from hematopoietic stem cells. Polymorphonuclear cells and monocytes are released from bone marrow to the circulation and then pass into tissues. B cells mature in the fetal liver and postnatal bone marrow, and T cells mature in the thymus gland. These lymphocytes are released into the circulation and pass into tissues. Other cells that originate from hematopoietic stem cells include mast cells, platelets, antigen-presenting cells (APCs), and natural killer (NK) cells. (From Male D, et al. *Immunology*. 8th ed. Philadelphia: Saunders; 2013:18.)

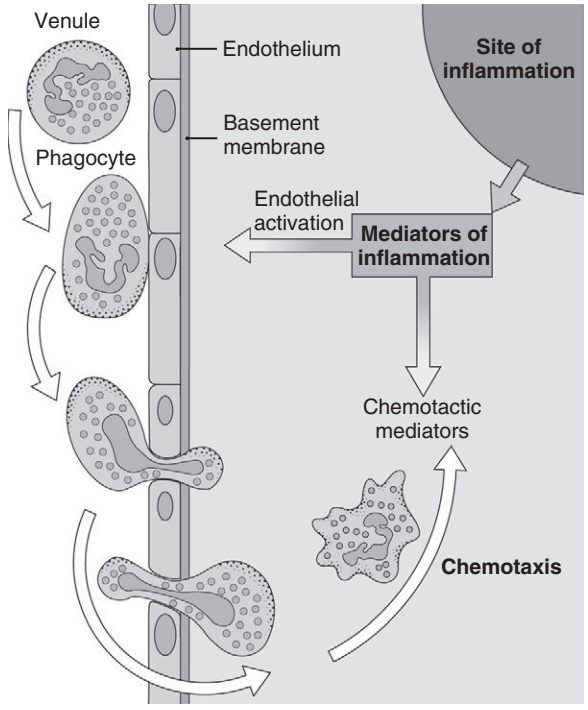

FIGURE **41-2** Infection or tissue injury causes inflammation and release of inflammatory mediators, some of which stimulate chemotaxis of phagocytes to the site of inflammation. Chemokines stimulate phagocytes to stick to the venular endothelium and undergo migration across the vessel wall (diapedesis). Phagocytes then move to the site of inflammation in response to a concentration gradient of chemotactic molecules such as complement product C5a. (From Male D, et al. *Immunology*. 8th ed. Philadelphia: Saunders; 2013:14.)

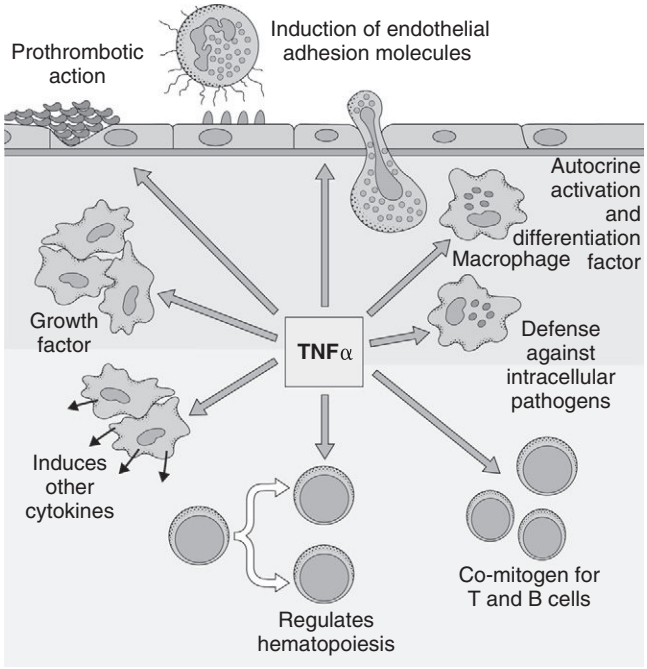

FIGURE **41-3** The cytokine TNF-α plays a central role in inflammation. Among its proinflammatory actions, it promotes clotting, leukocyte adhesion and diapedesis, macrophage activation, and cytokine production by other cells. (From Male D, et al. *Immunology*. 8th ed. Philadelphia: Saunders; 2013:112.)

Phagocyte	Opsonin	Binding
1 	–	±
2 	Complement C3b	++
3 	Antibody	++
4 	Antibody and complement C3b	++++

FIGURE **41-4** Phagocytes have some intrinsic ability to bind and phagocytize pathogens *(1)*. Phagocytosis is enhanced if the pathogen has been opsonized by complement product C3b *(2)* or antibody *(3)*. Phagocytes have C3b and Fc receptors that bind opsonized pathogens. Phagocytosis is greatly enhanced if both C3b and antibody opsonize the pathogen *(4)*. (From Male D, et al. *Immunology*. 8th ed. Philadelphia: Saunders; 2013:10.)

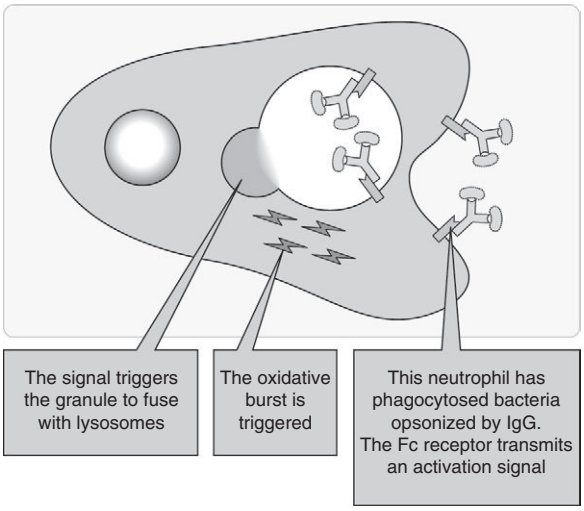

FIGURE **41-5** Mechanism of phagocyte killing of pathogen. Opsonized pathogen undergoes phagocytosis, triggering the respiratory (oxidative) burst and fusion of the phagocytic granule with intracellular lysosomes, which digest the pathogen. (From Nairn R, Helbert M. *Immunology for Medical Students*. 2nd ed. Philadelphia: Mosby; 2007.)

noninfected cells in a paracrine fashion to prevent spread of the viral infection. In addition, type I IFNs promote proliferation and activation of NK cells, which can bind to and destroy virus-infected cells. Synthetic IFN-α produced by recombinant technology is used to treat hepatitis B infection and some neoplasms. Recombinant IFN-β has been used successfully to reduce nervous system inflammation in some patients with multiple sclerosis.

Type II IFN is IFN-γ released from activated NK and T lymphocytes. Like the type I IFNs, IFN-γ can exert protective antiviral activity in noninfected cells, but more importantly it serves to activate macrophages, promote further NK-cell activity, and stimulate differentiation of T lymphocytes. Synthetic IFN-γ is used for treatment of chronic granulomatous disease (discussed later).

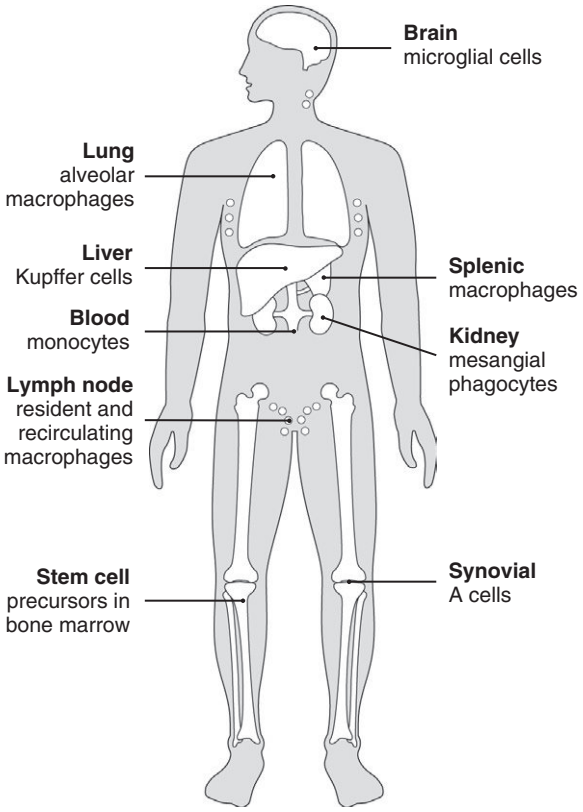

FIGURE **41-6** Cells of the mononuclear phagocyte system are located in many tissues and organs. These cells all derive from blood monocytes that originate from hematopoietic stem cells in the bone marrow. (From Male D, et al. *Immunology*. 8th ed. Philadelphia: Saunders; 2013:5.)

Complement

The complement system is a collection of plasma proteins produced mainly by the liver; it plays a key role in both innate and acquired immunity. When the complement system is activated, a cascade of reactions occurs in which a particular complement component catalyzes the production of the next component in the cascade and so on until the final product is produced. The main proteins of the complement system are labeled C1 through C9. The complement cascade can be triggered by an antigen-antibody reaction that activates C1 (the classical pathway) or by direct microorganism interaction with C3 (the alternative and lectin pathways). In either case, activation of the complement cascade generates products that cause opsonization, chemotaxis, and activation of mast cells and basophils. The final product of the cascade is a complex of five complement factors—C5b6789—that acts as a membrane attack complex by inserting cytolytic pores into pathogen cell membranes (Figure 41-7).

Acquired Immune System

Acquired, or adaptive, immunity is specific, that is, the immune responses are directed against a particular antigen, which is usually a component of a microorganism or foreign tissue.[1-3] In some cases, though, a "self" antigen may generate an autoimmune response that results in tissue injury. By one definition, an antigen is a chemical substance with a molecular weight greater than or equal to 8000 Da, and thus antigens are typically polypeptides or large polysaccharides.[3] Acquired immunity directed against a particular antigen is usually directed at one or more small regions, known as *epitopes*, within the antigen structure.[1-3]

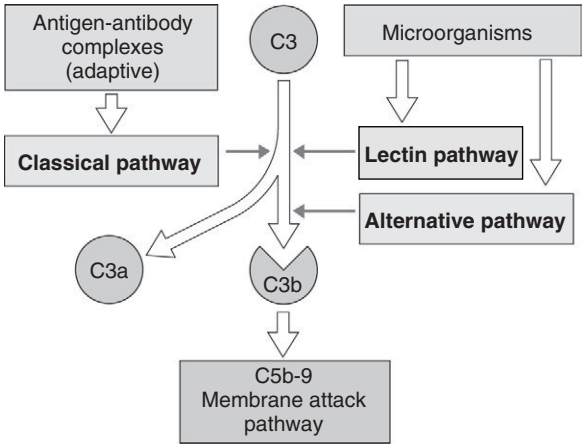

FIGURE **41-7** Three pathways can serve to activate the complement cascade. Antigen-antibody reaction typically activates the classical pathway. The alternative and lectin pathways do not require antibody and are directly activated by chemical groups on the pathogen surface. Thus the alternative and lectin pathways serve innate immunity, whereas the classical pathway is linked to the adaptive immune system. All three pathways convert C3 to C3b as the central event of the complement cascade. C3b can then promote the formation of the membrane attack complex. (From Male D, et al. *Immunology*. 8th ed. Philadelphia: Saunders; 2013:72.)

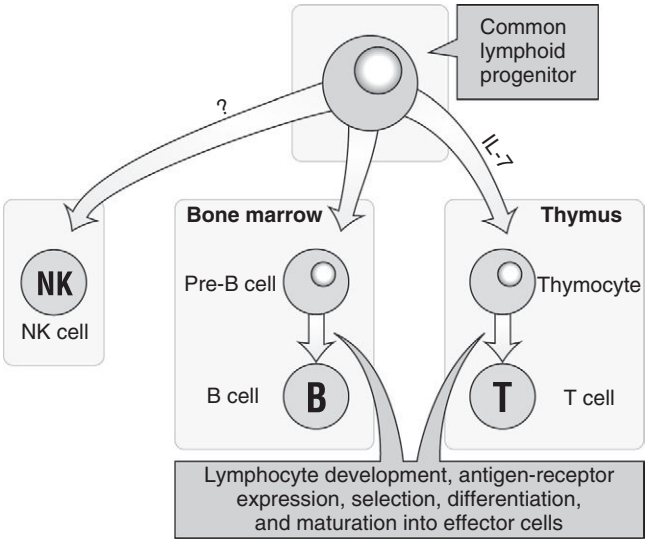

FIGURE **41-8** Development of B cells, T cells, and natural killer (NK) cells from a common lymphoid progenitor. B cells begin maturation in the bone marrow, and T cells mature in the thymus gland. NK cells develop in the bone marrow, although the mechanism of their differentiation is unclear. (From Nairn R, Helbert M. *Immunology for Medical Students*. 2nd ed. Philadelphia: Mosby; 2007.)

Acquired immunity depends fundamentally on lymphocytes, which comprise approximately 30% of circulating leukocytes. There are two main families of lymphocytes: B lymphocytes (B cells) and T lymphocytes (T cells). B lymphocytes are responsible for humoral immunity, which is provided by soluble antibodies directed against a particular antigen. T lymphocytes are responsible for cell-mediated immunity directed against a particular antigen.

Maturation of lymphocytes occurs in primary lymphoid tissues: the thymus gland, fetal liver, and bone marrow. Initially, some pluripotent hematopoietic stem cells differentiate to become lymphoid progenitor cells, which in turn differentiate to become either pre-T cells (thymocytes) or pre-B cells (Figures 41-1 and 41-8). Pre-T cells migrate from the marrow to the thymus gland, where they are processed to become mature T cells directed against specific antigens. T-cell maturation is characterized in part by the appearance of T-cell receptors (TCRs) on the cell membranes. Specificity of a particular T cell for an antigen reflects the specificity of its TCRs to recognize and bind that antigen. As a critical part of thymic processing, T cells that recognize and bind self-antigens undergo programmed cell death, known as *apoptosis*, whereas T cells that recognize foreign antigens expand and migrate to secondary lymphoid tissues—lymph nodes, adenoids, and tonsils; submucosal lymph tissue; and the spleen. Literally thousands of different T-cell clones develop in the thymus gland, each clone having TCRs directed against a particular antigen.

Distinct populations of T cells are produced during thymic maturation. The two main populations are $CD4^+$ T cells, also known as *helper T (Th) cells*, and $CD8^+$ T cells, also known as *cytotoxic T lymphocytes* (CTLs). (The abbreviation *CD* refers to "cluster of differentiation" and indicates a particular cell-membrane marker molecule that can be used to identify the hematopoietic cell type.) Naive helper T cells (Th0 cells) have not been exposed to antigen and can differentiate into several subsets, including Th1 and Th2 cells, based on the nature of an ongoing immune response and cytokines present in the local environment (Figure 41-9).

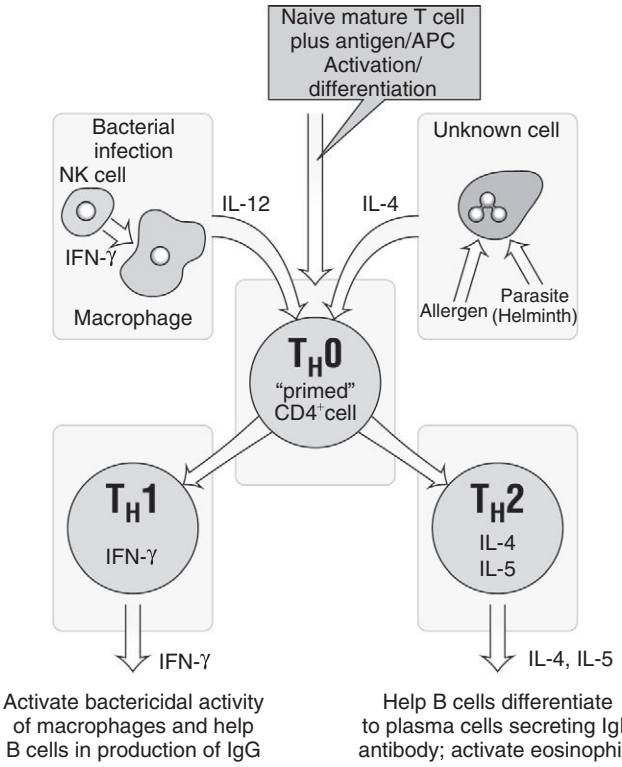

FIGURE **41-9** Differentiation of T helper subsets. When a naive, mature T helper cell is presented antigen by an antigen-presenting cell (APC), it becomes "primed" to differentiate into either a Th1 or Th2 cell. Preference of differentiation is driven by the nature of the infection and the local cytokine environment. After differentiation, Th1 cells secrete interferon-gamma (IFN-γ) and promote cellular immunity, and Th2 cells secrete interleukin (IL)-4 and -5 and promote humoral immunity. Th1 = T_H1 and Th2 = T_H2. (From Nairn R, Helbert M. *Immunology for Medical Students*. 2nd ed. Philadelphia: Mosby; 2007.)

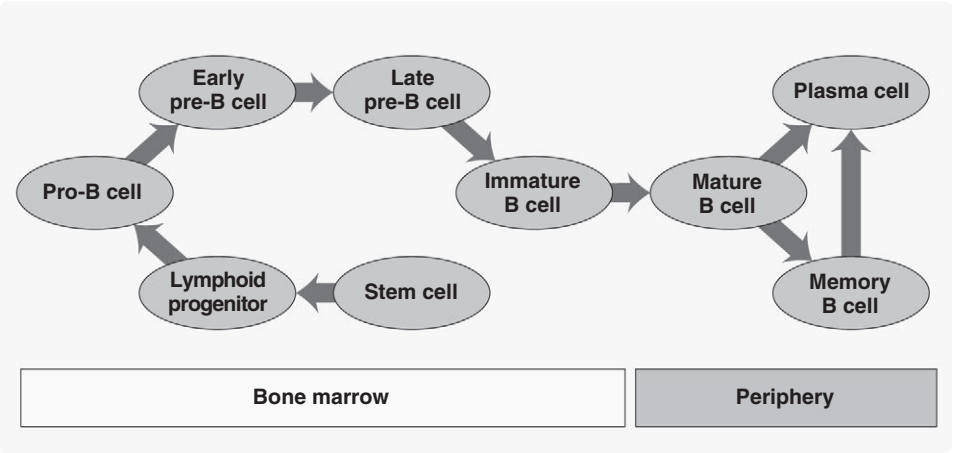

FIGURE **41-10** Stages of B-cell development. After B-cell release from the bone marrow, maturation is completed in the periphery. When activated by exposure to antigen, mature B cells differentiate into antibody-secreting plasma cells and proliferate to form memory B cells that provide for clonal expansion. (From Nairn R, Helbert M. *Immunology for Medical Students*. 2nd ed. Philadelphia: Mosby; 2007.)

Th1 cells promote the function of the mononuclear phagocytes, whereas Th2 cells promote the function of B lymphocytes.

Development of B cells begins in the fetal and postnatal bone marrow and is completed in secondary lymphoid tissues such as the spleen and lymph nodes (Figure 41-10). As maturation proceeds, B cells that recognize self-antigens undergo apoptosis and are not released into the blood. Those B cells that do leave the bone marrow and migrate to secondary lymphoid tissue acquire two types of immunoglobulin (Ig) molecules on the cell surface, IgM and IgD. These surface-bound Ig molecules are functionally analogous to the TCRs on surfaces of mature T cells, that is, they recognize and bind specific antigens. Other Ig molecules that may be expressed on B-cell surfaces include IgA, IgG, and IgE. Similar to the situation for T cells, thousands of different B-cell clones are produced, each clone having surface Ig molecules directed against a particular antigen.

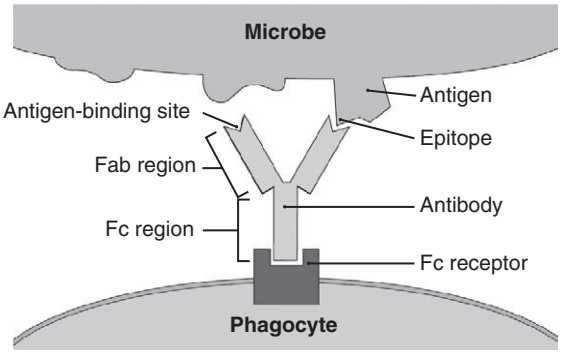

FIGURE **41-11** The Fab region of an antibody binds to a small portion (epitope) of an antigen on the pathogen surface. The "stem" of the antibody is its Fc region, which binds to phagocyte Fc receptors to promote phagocytosis. (From Male D, et al. *Immunology*, 8th ed. Philadelphia: Saunders; 2013:10.)

Humoral Response to Antigen

When a mature B cell encounters and binds antigen, it proliferates and differentiates into plasma cells that secrete soluble antibodies directed against the antigen. In addition, memory B cells are produced that expand the clone of B cells directed against that antigen. The secreted antibodies are Ig molecules and are members of the gamma globulin fraction of serum proteins. Five main classes of Ig molecules exist, which differ substantially in molecular size and charge: IgA, IgD, IgE, IgG, and IgM. Immunoglobulin G comprises approximately 70% of serum immunoglobulins, whereas IgA and IgM comprise approximately 20% and 10%, respectively. Normally, serum levels of IgD and IgE are very low. Rather, IgD is located primarily on B-cell surfaces, where it serves to bind antigen, whereas IgE is found primarily on the surfaces of tissue mast cells and circulating basophils and plays a role in hypersensitivity reactions.

An Ig molecule consists of two or more pairs of light chain–heavy chain polypeptide combinations. The variable, or Fab, regions of an Ig molecule are regions in which the amino acid sequence permits specific, high-affinity binding to antigen (hence, the variable regions "vary" in amino acid sequence among antibody molecules). The constant, or Fc, portion of Ig molecules has a relatively "constant" amino acid sequence that can bind to Fc receptors on phagocyte cell membranes (Figure 41-11).

Antibodies promote antigen removal by different mechanisms, including activation of the classical complement pathway, opsonization of a pathogen for phagocytosis, and binding to a pathogen to permit recognition by NK cells. Recently, monoclonal antibodies (mAbs) (i.e., antibodies with very high specificity for antigen) have been developed by recombinant technology for treatment of diseases such as rheumatoid arthritis, Crohn's disease, and breast cancer, as well as for other applications (Box 41-2). Adalimumab and infliximab are mAbs directed against the proinflammatory mediator TNF-α.

Antibodies can provide effective defense against toxins or pathogens in the extracellular compartment. However, many pathogens exist within cells of the host, and defense against these pathogens requires a second component of the adaptive immune response—cell-mediated immunity provided by T lymphocytes.

T-Lymphocyte Response to Antigen

Cell-mediated immunity requires "presentation" of antigen to T lymphocytes by infected cells or antigen-presenting cells (APCs) such as dendritic cells, macrophages, and B lymphocytes. What is actually presented to the T cell is a small portion of the parent antigen that has been processed, or degraded, by the presenting cell. The antigen fragment is presented bound to a major histocompatibility (MHC) molecule on the presenting cell surface. T-cell receptors on T cells directed against the antigen then recognize and bind the antigen-MHC complex (Figure 41-12).

BOX **41-2**

Monoclonal Antibodies

The monoclonal antibodies (mAbs) are genetically engineered immunoglobulins (IgGs) that react with specific molecular targets. They may be part mouse/part human (termed *chimeric* or *humanized*, depending on the degree of mouse Ig sequences) or fully human. In chimeric and humanized mAbs, antigen-recognizing portions of mouse antibodies are joined to the framework of a human IgG molecule.

- **Abciximab:** Chimeric mAb against the clotting receptor GpIIb-IIIa on platelets; used to prevent clotting in patients undergoing coronary angioplasty.
- **Adalimumab:** Humanized mAb against the cytokine TNF-α; used for rheumatoid arthritis.
- **Alemtuzumab:** Humanized mAb against an antigen on T and B lymphocytes; used to treat B-cell leukemia.
- **Basiliximab:** Chimeric mAb against the receptor for the cytokine interleukin-2 on activated T cells; used in acute rejection of kidney transplants.
- **Daclizumab:** Humanized mAb against the receptor for the cytokine interleukin-2 on activated T cells; used in acute rejection of kidney transplants.
- **Etanercept:** Fusion protein for the tumor necrosis factor used in therapy for rheumatoid arthritis.
- **Infliximab:** Chimeric mAb against the cytokine TNF-α; used for rheumatoid arthritis and Crohn's disease.
- **Omalizumab:** Humanized mAb against the binding of IgE to the high-affinity IgE receptor on the surface of mast cells and basophils; used for the treatment of asthma.
- **Palivizumab:** Humanized mAb against a protein of respiratory syncytial virus (RSV); used to treat RSV infection in children.
- **Rituximab:** Humanized mAb against the cytokine CD20 receptor on B cells; used in non-Hodgkin lymphoma.
- **Trastuzumab:** mAb against HER2; used for breast cancer treatment.

FIGURE **41-12** General mechanism of antigen presentation to T cells. A surface major histocompatibility complex (MHC) molecule presents a peptide portion of pathogen in an infected cell. The T-cell receptor recognizes and binds the MHC molecule/peptide combination. (From Male D, et al. *Immunology*. 8th ed. Philadelphia: Saunders; 2013:10.)

The MHC is a collection of genes that serve immune recognition in all mammals. There are two types of MHC molecules that function in immune recognition. Class I molecules are present on the surfaces of all nucleated cells, and class II molecules are present on the surfaces of APCs. In humans, the MHC is known as the *human leukocyte antigen* (HLA). Three regions, or loci, on the HLA encode for MHC class I molecules found on nucleated cell surfaces. Collectively, these three regions comprise more than 100 genes and are known as *HLA-A*, *HLA-B*, and *HLA-C*. A separate region on the HLA, known as *HLA-D*, encodes for MHC class II molecules found on APCs. Within this region are three loci, known as *HLA-DP*, *HLA-DQ*, and *HLA-DR*. A key characteristic of the HLA is the high degree of polymorphism of the MHC molecules for which it encodes. An individual's HLA type (haplotype) is determined by the MHC molecules expressed on that person's cell membranes. Genetic variability in HLA type influences susceptibility to infection and autoimmune disease and rejection of transplanted tissue. Tissue typing prior to organ transplantation involves characterization of the HLA types of donor and recipient to determine whether an acceptable "match" is present.

MHC class I molecules present antigen derived from an intracellular pathogen, such as a virus, that has infected the cell. The antigen-MHC class I complex is presented to CTLs, which bind the complex and destroy the infected cell. MHC class II molecules present antigen derived from pathogens that have undergone phagocytosis and subsequent processing. The antigen-class II complex is presented to Th0 cells, which can then differentiate into several subsets of Th cells, two of which are Th1 and Th2 cells (see Figure 41-9). The Th1/Th2 ratio is determined by the nature of the immune response and the local cytokine environment. Interleukin-12 produced by APCs favors Th1 differentiation. Th1 cells secrete IFN-γ, which activates mononuclear phagocytes. Th2 cells secrete IL-4 and IL-5, which promote conversion of B lymphocytes to antibody-secreting plasma cells and stimulate mast cells to release inflammatory mediators. Activation of T cells in response to antigen also promotes T-cell production of IL-2, which acts locally to promote T-cell proliferation and augment the immune response to the antigen.

Vaccination

A key characteristic of the immune response to antigen is clonal expansion of specific B and T lymphocytes directed at the antigen. Clonal expansion allows a more rapid and vigorous immune response on subsequent exposure to the antigen. Vaccination is a process that produces acquired immunity against specific diseases by deliberate exposure of an individual to particular antigens. Vaccination against diseases such as typhoid, cholera, pertussis, and influenza is accomplished by administration of dead organisms that have retained their chemical antigens (epitopes), yet cannot cause an actual disease state. Toxoid vaccines are chemical modifications of toxins produced by pathogens such as tetanus and diphtheria. Attenuated microorganisms are mutated pathogens that themselves do not readily produce disease, but may be used to produce immunity against diseases such as poliomyelitis, measles, rubella, and smallpox.

Passive immunity is produced by administering preformed antibody to provide protection against an invasive pathogen or toxin,

often as a lifesaving maneuver. For example, passive immunity may be a maneuver used to treat botulism, diphtheria, or snakebite. Preformed antibodies are obtained from human or animal blood after immunization against a particular antigen.

Inflammation

Inflammation is the collective response to tissue injury, which can be caused by invasion of infectious microorganisms, toxins, or trauma. The inflammatory response consists of several components: localized vasodilation and increased blood flow; increased capillary permeability and extravasation of plasma proteins, including complement and coagulation factors; and chemotactic movement of leukocytes to the site of injury. The clinical manifestations of inflammation include erythema, localized edema, and pain.[1,2]

Both the innate and acquired immune systems participate in the production of inflammation. Communication between the two immune systems is provided by a network of peptide mediators known as cytokines (see Box 41-1). Normally these substances act locally to regulate the immune response and may exert synergistic or inhibitory interactions in the regulation of immune cell activity. If produced in high amounts during an exuberant inflammatory response, though, some cytokines may demonstrate measurable blood levels and exert adverse systemic effects.

When resident macrophages encounter a pathogen, they become activated to phagocytize the pathogen and secrete proinflammatory cytokines such as TNF-α, IL-1, IL-6, and IL-12. Among its various actions, TNF-α stimulates the production of endothelial-cell adhesion molecules and chemokines, which are necessary for leukocyte infiltration to the site of infection (see Figure 41-3). Overproduction of TNF-α can have deleterious local and systemic effects. Indeed, high circulating levels of TNF-α are characteristic of chronic major illness and systemic inflammatory response syndrome.

Like TNF-α, IL-1 stimulates endothelial-cell adhesion molecule production. It also has other actions, one of which is to alter the hypothalamic core temperature set-point and produce fever. One important consequence of increased body temperature is more rapid lymphocyte proliferation to combat infectious microorganisms. IL-1 also activates T lymphocytes, thereby recruiting those cell types against the infection. IL-12 promotes preferential differentiation of Th0 cells to the Th1 subtype and activates NK cells. Both Th1 cells and NK cells release IFN-γ, which enhances NK-cell activity and inhibits Th2 cell function. IL-6 stimulates B lymphocytes and may play a role in wound healing. In addition, a recent study in mice has provided evidence that IL-6 can directly stimulate adrenocortical secretion of glucocorticoids, providing a unique mechanism by which the inflammatory response can provoke stress hormone secretion.[4]

TNF-α, IL-1, and IL-6 stimulate production of acute-phase proteins.[1,2] These serum proteins are produced by hepatocytes, and their serum levels increase rapidly with the onset of infection. One acute-phase protein of particular importance is C-reactive protein (CRP), which derives its name from its affinity for the C protein of pneumococci. Indeed, CRP serves to opsonize pneumococci and promote their phagocytosis by macrophages. The serum CRP level is often used as a clinical measure of inflammation and may have particular prognostic significance. A number of large, prospective studies have demonstrated the serum CRP level to be an independent predictor of cardiovascular risk.[5,6] It has also been suggested that elevated serum CRP levels might be predictive of perioperative morbidity. One recent study found an association between elevated CRP level and increased length of hospital stay in patients with medium cardiovascular risk undergoing orthopedic procedures.[7]

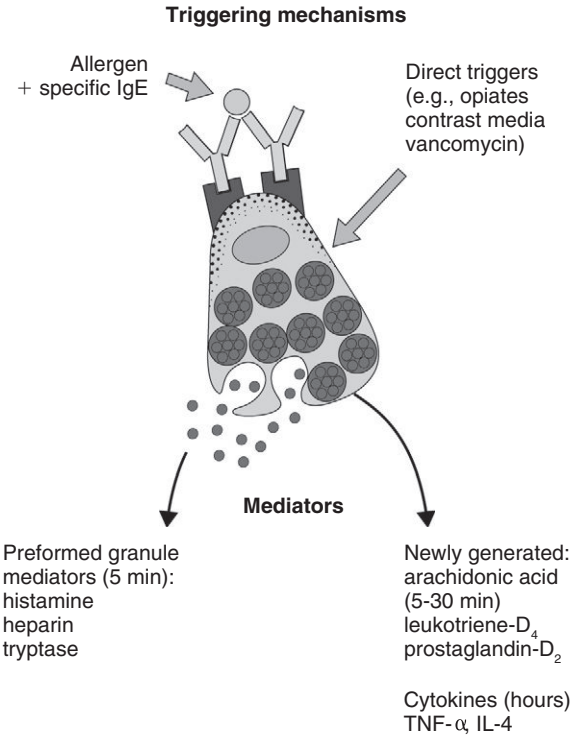

FIGURE **41-13** Release of proinflammatory mediators after binding of antigen to IgE molecules on mast cell membranes. Preformed mediators such as histamine are rapidly released, whereas de novo synthesis delays release of other mediators such as leukotrienes and cytokines. Mast cells can also be directly activated by agents such as opioids, vancomycin, radiocontrast media, and complement products C3a and C5a. Similar events occur in response to activation of circulating basophils. (From Male D, et al. *Immunology*. 8th ed. Philadelphia: Saunders; 2013:381.)

If the immune response is successful in clearing the pathogen and allowing recovery of tissue function, the inflammatory response is termed *acute inflammation*.[1,2] In some situations, though, the initial immune response does not completely remove the pathogen, and infection persists, causing chronic inflammation to develop. Chronic inflammation is characterized by greater numbers of macrophages and CTLs, compared with the leukocyte population seen with acute inflammation. One concern with chronic inflammation is that it can cause significant injury to host tissues. Chronic bacterial infection, such as occurs with tuberculosis, can lead to the formation of granulomas. These structures are composed of a central core of macrophages and epithelioid cells (produced from activated macrophages) surrounded by infiltrating T lymphocytes. TNF-α is a key cytokine responsible for granuloma formation. Chronic viral infections can also cause tissue injury, such as occurs with chronic hepatitis B virus infection.

Auxiliary cells, such as tissue mast cells, circulating basophils, and platelets, play a key role in inflammation and mobilization of immune responses (see Table 41-1). Mast cells and basophils can be activated by allergens that cross-link antibody molecules bound to the cell surface (to be discussed), by complement products C3a and C5a, by particular drugs such as codeine, morphine, and vancomycin, and by radiocontrast media. Once activated, mast cells and basophils undergo rapid release of proinflammatory substances such as histamine and serotonin and slower de novo production and release of leukotriene D_4 (a powerful bronchoconstrictor) and cytokines TNF-α and IL-4 (Figure 41-13).

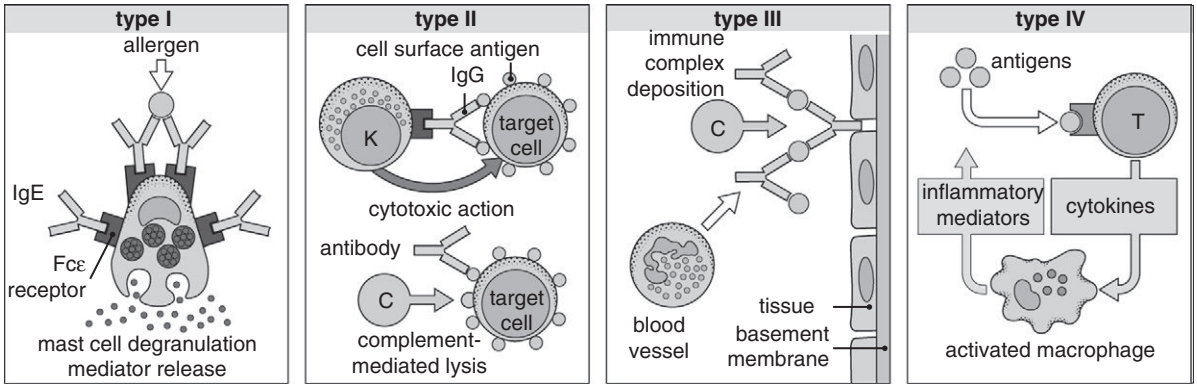

FIGURE **41-14** The Coombs and Gell classifications of the four types of hypersensitivity reactions. Type I reactions are immediate hypersensitivity reactions, and type IV reactions are delayed-type hypersensitivity reactions. See discussion in text for characteristics of each type of reaction. (From Male D, et al. *Immunology*. 8th ed. Philadelphia: Saunders; 2013:372.)

Blood platelets can be activated in several ways, including contact with damaged endothelial cells, by IgG immune complexes, and by platelet-activating factor released from activated macrophages. Activated platelets can aggregate and help to "wall off" an area of inflammation. In addition, activated platelets release serotonin, which acts to increase capillary permeability.

IMMUNE SYSTEM PATHOLOGY

Hypersensitivity and Allergic Reactions

In some cases, the immune response to antigen is greatly exaggerated, a situation referred to as *hypersensitivity*.[1,2] In 1963, Coombs and Gell classified hypersensitivity reactions into types I, II, III, and IV (Figure 41-14). Recently, however, it has been recognized that this classification system is somewhat artificial, as there are overlapping mechanisms of action in types I, II, and III.

Type I Hypersensitivity

Type I hypersensitivity is a rapidly developing reaction that results from antigen-antibody interaction in an individual who has been previously exposed and sensitized to the antigen. The responsible antigen, referred to as an *allergen*, reacts with specific IgE antibodies on tissue mast cells and circulating basophils to trigger mediator release (see Figure 41-13) and an allergic response. A key mediator of allergic symptoms is histamine (Box 41-3). Chemically, allergens are usually proteins, and a multitude of environmental factors, including grass, pollen, dust, mites, molds, and animal dander, can generate type I hypersensitivity reactions.

Allergic reactions present with symptoms such as rhinitis, conjunctivitis, urticaria, pruritus, and possibly anaphylaxis. The term *anaphylaxis* refers to a severe, generalized, immediate hypersensitivity reaction that includes pruritus, urticaria, angioedema (especially laryngeal edema), hypotension, wheezing and bronchospasm, and direct cardiac effects, including arrhythmias. A shocklike state can develop from hypotension secondary to systemic vasodilation and extravasation of protein and fluid. Clinical manifestations of an allergic reaction can present in various combinations and usually occur within minutes of exposure to the precipitating antigen(s). In some cases, though, the onset of signs and symptoms may be delayed for an hour or longer. Signs and symptoms can be protracted and variably responsive to treatment. Biphasic anaphylaxis also can occur, in which early signs and symptoms clear, either spontaneously or after acute therapy, and then symptoms recur several or many hours later. Generally, the severity of an anaphylactic event relates to the suddenness of its onset and to the magnitude of the challenge, that is, the bigger the provocative stimulus, the more severe the reaction. However, anaphylaxis can occur after exposure to minute amounts of allergen in highly sensitive individuals.

BOX 41-3

Histamine

- Histamine is a basic amine stored in granules within mast cells and basophils and secreted when allergen interacts with membrane-bound IgE or when complement components C3a and C5a interact with specific membrane receptors.
- Histamine produces symptoms of allergic reactions by acting on H_1 or H_2 receptors on target cells.
- The main actions of histamine in humans (via the receptors involved) are:
  - Vasodilation (H_1)
  - Increased vascular permeability (H_1)
  - Contraction of most smooth muscle other than that of blood vessels (H_1)
  - Cardiac stimulation (H_2)
  - Stimulation of gastric secretion (H_2)
- Intradermal injection of histamine causes the cutaneous "triple response": erythema from local vasodilation, wheal from increased vascular permeability and protein and fluid extravasation, and flare from an "axon" reflex in sensory nerves that releases a peptide mediator.
- The pathophysiologic effects of histamine can be blocked by H_1-receptor antagonists (diphenhydramine, hydroxyzine, cyclizine, loratadine) and H_2-receptor antagonists (cimetidine, ranitidine, famotidine)

Adapted from Rang HP, et al. *Rang and Dale's Pharmacology*. 7th ed. Edinburgh: Churchill Livingstone; 2012.

Anaphylactoid reactions are caused by mediator release from basophils and mast cells in response to a non–IgE-mediated triggering event. Such reactions present with similar clinical manifestations as those with anaphylaxis, though symptoms may be less severe than those associated with IgE-mediated reactions.[8]

Tryptase is a marker for mechanistic delineation of an allergic response. It is an enzyme released from mast cells, along with histamine and other inflammatory mediators, during an allergic response. Tryptase has a half-life of several hours and is stable at room temperature. It demonstrates a positive predictive value of 92.6% and a negative predictive value of 54.6% as an indicator of

an immunologically mediated event. Thus a significantly elevated tryptase level (greater than 25 mcg/L) strongly suggests an allergic mechanism. The presence of a normal tryptase level, however, does not exclude an immunologic reaction because elevated tryptase levels are not found in almost one third of anaphylactic cases. Although diagnosis of anaphylaxis should not rely on a single test, the high positive predictive value of tryptase makes it useful medicolegally and for subsequent patient management.[8,9]

Type II Hypersensitivity

Type II hypersensitivity reactions result from IgG and IgM antibodies binding to antigens on cell surfaces or extracellular tissue components such as basement membrane (see Figure 41-14).[1,2] The antigen-antibody reaction activates the complement cascade, causing production of C3a and C5a, which attract PMNs and macrophages, and production of the C5b5789 membrane attack complex that inserts into target cell membranes. Examples of type II hypersensitivity reactions include transfusion reactions, autoimmune hemolytic anemia, myasthenia gravis, and Goodpasture syndrome.

Type III Hypersensitivity

Type III hypersensitivity represents immune complex disease, in which antigen-antibody complexes deposit in tissues and cause injury (see Figure 41-14). Normally, immune complexes are cleared by the mononuclear phagocyte system shortly after their formation. In some situations, however, immune complexes persist and deposit in tissues. Protracted infections or autoimmune processes can lead to type III reactions. The mechanism of tissue injury is similar to that in type II reactions, involving activation of complement and recruitment of phagocytes. Systemic lupus erythematosus, rheumatoid arthritis, and glomerulonephritis are examples of immune complex diseases.

Type IV Hypersensitivity

Type IV hypersensitivity is also referred to as *delayed-type hypersensitivity* (see Figure 41-14). By the strict Coombs and Gell definition, type IV reactions require at least 12 hours after contact with antigen. Migration of antigen-specific $CD4^+$ lymphocytes to the reaction site is followed by cytokine release and a local inflammatory response. Contact hypersensitivity is one form of type IV reaction and occurs where skin has come into contact with antigen. Contact dermatitis and the response to poison ivy are examples of contact hypersensitivity. Another form of type IV hypersensitivity is granulomatous hypersensitivity, in which chronic infection leads to the formation of granulomas in tissues. Granulomatous diseases include tuberculosis, sarcoidosis, and Crohn's disease.

Drug Reactions

Predicting who will react adversely to a drug or combination of drugs is difficult. Fortunately, life-threatening adverse reactions to drugs and products used during anesthesia and surgery are very uncommon, with the overall incidence estimated to be 1 in every 5000 to 10,000 anesthetics.[8] Much of the information regarding the epidemiology of adverse reactions to anesthetic agents derives from a series of European studies, and there may be limitations in extrapolating the results of such studies to anesthesia in the United States. Indeed, there appears to be geographic differences in the relative risk of allergic drug reactions.[10]

Dong and Mertes et al.[8] have reported that immune-mediated reactions account for approximately 63% of all perioperative hypersensitivity events. Of the perioperative agents that triggered anaphylactic reactions, neuromuscular blocking agents (NMBAs) did so most often, followed by latex and antibiotics (Table 41-2). Moreover, of the NMBAs that caused allergic reactions, succinylcholine was most frequently cited, followed by atracurium, cisatracurium, vecuronium, and rocuronium and in that order. Anaphylactoid (nonimmune-mediated) reactions may account for as much as 37% of adverse reactions to NMBAs.

TABLE 41-2 Agents Responsible for Perioperative Allergic Reactions in France: 2005-2007

Causal Agent	Percentage
Neuromuscular blocking agents	47.4
Latex	20
Antibiotics	18.1
Hypnotics	1.1
Opioids	2.2
Colloids	2.3
Other agents (contrast media, protamine, others)	8.8
Local anesthetics	0.6

From Dong SW. Hypersensitivity reactions during anesthesia: Results from the ninth French survey (2005-2007). *Minerva Anestesiol.* 2012;78(8):868-78.

Although anaphylactic reactions to local anesthetics are rare, ester local anesthetics are more likely than amide agents to elicit an allergic response.[8,11] Ester local anesthetic metabolites, such as para-aminobenzoic acid, have been identified to be responsible for this higher incidence of allergic response. Local anesthetic solutions containing methylparaben and propylparaben as preservatives may induce allergic responses in susceptible individuals. Thus administration of preservative-free local anesthetic solutions may reduce the likelihood of an allergic response. Recent theories suggest that allergies to various antioxidants and certain sulfite components may be responsible for some degree of allergic reactions to local anesthetic preparations. Adverse reactions to local anesthetics are much more likely to result from accidental intravascular injection of the local anesthetic or absorption of epinephrine coadministered with the anesthetic.

Persons who have an increased allergic tendency are termed *atopic* and exhibit a genetic predisposition to such events. Atopic patients frequently present with some history of hay fever, rhinitis, asthma, or food or drug allergy. There has been long-standing concern as to whether such patients are at increased risk for an anaphylactic or anaphylactoid reaction during anesthesia. Such a relationship does appear to exist for latex allergy, in which a history of generalized atopy or specific allergy to certain fruits, such as kiwi, avocado, or figs, is recognized as a significant risk factor for latex reactions.[8,9] By contrast, a generalized history of allergy does not necessarily predispose a patient to anaphylactic or anaphylactoid reactions to anesthetic drugs. However, if a patient has a history of sensitivity to a particular anesthetic drug, such as a muscle relaxant, that individual may well be at increased risk for allergic responses to other agents in that class. Indeed, Mertes et al.[8] found cross-sensitization in 60% to 70% of patients allergic to NMBAs.

Avoiding known causal agents (particularly those that induce histamine release), combined with careful selection and application of additional drugs, can reduce risk of adverse reactions. A thorough history and discussion with the patient or the patient's guardian can usually reveal the potential for untoward drug effects and alert the anesthesia provider to avoid suspicious agents. Patients frequently mistake drug sensitivity or an unpleasant

response for an allergy. This is especially true with local anesthetic solutions containing epinephrine or administered with opioids. Careful investigation and cautious interviewing techniques are usually beneficial in clarifying these questionable areas. Reviewing past procedural notes and anesthesia records, and possible consultation with an allergist when appropriate, can further help in determining situational specifics and facilitate appropriate planning. The administration of H_1- and H_2-receptor antagonists preemptively may prevent allergic reactions in many cases when a known or suspected sensitivity is present.

Treatment of Intraoperative Allergic Reactions

There is considerable variability in the severity of hypersensitivity reactions as well as in patient responses to treatment. Unfortunately there are no randomized controlled trials of anaphylaxis treatment regimens in patients. Thus the clinician must formulate a treatment scheme based on the clinical presentation and the availability of treatment options. Fortunately during anesthesia, the patient is monitored and intravenous access is usually available, both of which facilitate successful treatment. If possible, all drugs and surgery should be interrupted. Airway patency must be maintained, and 100% oxygen should be administered. Intravenous epinephrine and fluid administration are key interventions. The rate and amount of epinephrine administration are dictated by the severity of symptoms, which can be stratified as grades 1 to 4 (Box 41-4).

Antihistamines also may be useful in the treatment of anaphylaxis, particularly for symptoms of urticaria and angioedema (see Box 41-4). An H_1-receptor antagonist, alone or in combination with an H_2-receptor antagonist, may be useful in reversing hypotension refractory to epinephrine and intravascular fluid replacement. Glucocorticoids, such as intravenous hydrocortisone, may reduce the risk of recurring or protracted anaphylaxis (see Box 41-4).

BOX 41-4

Treatment of Intraoperative Allergic Reactions

Epinephrine

Titrate dose according to severity of symptoms[1] and patient response; repeat dose every 1 to 2 min as necessary; use IV infusion for larger doses.

Adults

- Grade 2: 10-20 mcg
- Grade 3: 100-200 mcg
- Grade 4: 1 mg
- IV infusion starting dose: 0.05-0.1 mcg/min

Children

- Grade 2-3: 1-5 mcg/kg
- Grade 4: 10 mcg/kg

Fluid Therapy

- Normal saline: 10-25 mL/kg for 20 min (repeat if necessary), *or* Colloid: 10 mL/kg

Anaphylaxis Refractory to Epinephrine

- Vasopressin: IV doses of 2-10 international units until response
- Norepinephrine: Initial dose of 0.05-0.1 mg/kg/min

Antihistamines

- H_1-receptor antagonist (e.g., diphenhydramine): 0.5-1.0 mg/kg IV
- H_2-receptor antagonist (e.g., ranitidine): 50 mg IV

Corticosteroids

Hydrocortisone

- Adults: 250 mg IV
- Children: 50-100 mg IV

Classifications of Immediate Hypersensitivity Reactions According to Grade of Severity

- Grade 1: Erythema, urticaria, with or without angioedema; epinephrine is not administered
- Grade 2: Moderate severity; cutaneous signs, hypotension and tachycardia; cough, difficult to ventilate
- Grade 3: Life-threatening severity; cardiovascular collapse, tachycardia or bradycardia, dysrhythmias, bronchospasm
- Grade 4: Cardiac and/or respiratory arrest

From Mertes PM, et al. Perioperative anaphylaxis. *Med Clin North Am*. 2010;94(4):761-789.

Transfusion Reactions

Because of advances in technologic capabilities and quality-control practices, blood transfusion reactions are fortunately not a common occurrence. The relative risk of an allergic transfusion reaction of mild severity (i.e., urticaria and pruritus) is approximately 1:500, whereas a fatal hemolytic reaction occurs in approximately 1 in 250,000 to 600,000 transfusions administered nationally. The mechanism responsible for most transfusion reactions involves ABO incompatibility. Transfusion of incompatible blood type causes recipient antibodies to react with donor red blood cells, causing their destruction and the potential for significant consequences. Disseminated intravascular coagulation, renal failure, and death are not uncommon after this type of reaction. Because the most common cause for a major hemolytic transfusion reaction is human error, it should never be assumed that another person is solely responsible for checking blood that one is preparing to administer to a patient.

Transfusion reactions are frequently masked, or at least delayed appreciably, during anesthesia. Hallmark symptoms of cardiovascular instability such as hypotension, as well as fever, hemoglobinuria, and bleeding diathesis, are indicative of a transfusion incompatibility and should be immediately treated.[12]

Latex Allergy

It has been estimated that approximately 1% to 2% of the general population has allergy to latex.[13] Allergies to latex-containing products continue to be a source of significant problems for specific populations. Health-care workers who experience frequent exposure to devices and products that contain latex are at increased risk of developing latex allergy.[13] Certain patients, particularly those with congenital neural tube deficits and those who have undergone multiple surgical procedures, have an increased rate of latex sensitivity. Moreover, individuals with particular food allergies (Box 41-5) are at increased risk for latex allergy.

The most frequent clinical manifestations of latex reactions include some form of contact dermatitis, type I hypersensitivity reaction with the potential for anaphylaxis, or type IV hypersensitivity reaction. Dong et al.[8] found latex reactions to be the second most common cause of anaphylactic reactions during anesthesia and surgery. Box 41-6 lists clinical manifestations of latex reactions in both awake and anesthetized patients.

Preventive procedures and recommended protocols have been established for the management of latex allergies that can have significant anaphylactic consequences. The incidence of latex allergies increased proportionately with the 10-fold increase in

BOX 41-5

Food Allergies That Increase Risk of Latex Allergy

- Avocado
- Banana
- Figs
- Cherimoya
- Chestnut
- Eggplant
- Kiwi
- Mango
- Melon
- Papaya
- Passion Fruit
- Pineapple
- Potato
- Tomato
- Wheat

BOX 41-6

Latex Reactions

Awake Patient	Anesthetized Patient
Itchy eyes	Tachycardia
Generalized pruritus	Hypertension
Shortness of breath	Wheezing
Feeling of faintness	Bronchospasm
Feeling of impending doom	Cardiorespiratory arrest
Nausea	Flushing
Vomiting	Facial edema
Abdominal cramping	Laryngeal edema
Diarrhea	Urticaria
Wheezing	

BOX 41-7

Immunosuppressant Drugs

Most immunosuppressant drugs act in the induction phase of the immunologic response to reduce lymphocyte proliferation; some also inhibit components of the effector phase. The drugs used for immunosuppression can be roughly divided into agents that:

- Inhibit cytokine gene expression, e.g., glucocorticoids
- Inhibit purine or pyrimidine synthesis, e.g., azathioprine, mycophenolate mofetil
- Inhibit IL-2 production or action, e.g., cyclosporine, tacrolimus, rapamycin
- Block T-cell IL-2 receptors, e.g., basiliximab, daclizumab

Immunosuppressant drugs are used to:

- Suppress rejection of transplanted organs
- Suppress graft-versus-host disease in bone marrow transplants
- Treat autoimmune diseases, including idiopathic thrombocytopenic purpura and some types of hemolytic anemia, glomerulonephritis, and myasthenia gravis
- Treat arthritic diseases such as rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis
- Treat severe inflammatory bowel disease such as ulcerative colitis and Crohn's disease

medical glove usage to accommodate universal precautions and barrier protection during anesthesia, surgery, and obstetric care. Using gloves that do not contain latex (e.g., gloves processed from polyvinyl or neoprene) can prevent this source of latex exposure. Although skin prick, patch testing, and radioallergosorbent tests for latex allergy are available, all present various challenges in qualifying a conclusive diagnosis. The American Latex Allergy Association provides protocols and detailed plans for avoiding and treating latex allergic responses.[14]

DISEASES OF THE IMMUNE SYSTEM

Autoimmune Disease

In the process of lymphocyte maturation, there normally occurs negative selection (apoptosis) of most cells that react against self-antigens.[1,2] Despite the efficiency of this self-tolerance mechanism, however, individuals normally display detectable levels of autoreactive B cells and T cells, which are usually not activated, owing to inadequate presentation of self-antigen or other factors that prevent autoreactivity. Impairment in the mechanisms that act to prevent autoreactivity can lead to production of excess amounts of autoreactive antibodies and T cells and autoimmune disease. Examples of such diseases are Hashimoto thyroiditis, insulin-dependent diabetes mellitus (IDDM), myasthenia gravis, rheumatoid arthritis, and systemic lupus erythematosus (SLE).

There is much evidence that certain HLA haplotypes predispose a patient to autoimmune disease. Rheumatoid arthritis, for example, associates with certain HLA-DR haplotypes, and the risk of IDDM is greatly increased in persons with certain HLA-DQ haplotypes. The majority of autoimmune diseases affect women more often than men; in particular, they affect women of childbearing and working age. Moreover, it is not uncommon for an individual to have more than one autoimmune disease.

In some cases, autoimmune disease may result secondarily from an infection in which microbial antigens contain epitopes that are shared with self-antigens. Presentation of microbial antigen to Th cells as part of the normal response to infection then triggers activation and proliferation of lymphocytes directed against not only the microbe but also self-antigens in tissues. This process of microbial cross-reactivity is the basis of rheumatic heart disease that develops in some individuals after a streptococcal infection. In this case, antibodies produced against streptococcal antigens cross-react with certain heart valve antigens. Microbial cross-reactivity also may play a role in the development of rheumatoid arthritis and ankylosing spondylitis.

Treatment of autoimmune disease depends in part on whether the disease is organ-specific (e.g., hypothyroidism, myasthenia gravis, IDDM) or systemic (e.g., rheumatoid arthritis, SLE). Organ-specific disease may be treated with discrete strategies, for example, cholinesterase inhibitors used to treat myasthenia gravis and exogenous insulin used to treat IDDM. Systemic disease may be treated with antiinflammatory and/or immunosuppressive regimens. Antiinflammatory agents that may be used include cyclooxygenase inhibitors, corticosteroids (see Box 41-4), and more recently monoclonal antibodies directed against the inflammatory mediator TNF-α (see Box 41-2). Treatment with immunosuppressant drugs (Box 41-7) may reduce the immune response but carries significant risk of opportunistic infections.

Immunodeficiency

Primary immunodeficiency is caused by deficient function of lymphocytes, the complement system, or phagocytes.[1,2] Deficient B-cell and antibody function can predispose to pyogenic infections, in which bacterial infection causes pus accumulation. IgA deficiency is a primary disorder and is the most common immunodeficiency syndrome. It occurs almost exclusively in Caucasians, with a prevalence of 1 in 700, and affected individuals are prone to develop type III hypersensitivity reactions. Approximately one

fifth of patients with IgA deficiency also have deficient production of two IgG subclasses, IgG2 and IgG4, which makes them susceptible to pyogenic infections. Individuals with deficient antibody responses are prone to recurring respiratory infections with encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. Such recurrent infections can result in bronchiectasis and chronic obstructive pulmonary disease.

Individuals who lack T cells or who have deficient T-cell function are prone to opportunistic infections by environmental pathogens such as yeast and chickenpox, microorganisms to which normal individuals develop prompt immunity. Because T cells support (in part) B-cell function, T-cell defects also may be accompanied by deficient humoral immunity. Individuals born with severe combined immunodeficiency (SCID) have low levels of circulating lymphocytes, lymphoid tissue that is virtually devoid of lymphocytes, and an immature thymus gland. A number of genetic mutations, including X-linked and autosomal recessive genes, can cause SCID. Affected infants are prone to develop diarrhea and pneumonia and usually do not survive more than 2 years unless treated with a bone-marrow transplant. T-cell deficiency also accompanies the DiGeorge syndrome, which results from abnormal development of the thymus and parathyroid glands, structures that originate from the same embryonic tissue. The syndrome is characterized by an "elfin-like appearance," with eyes set widely apart and a shortened infranasal depression. Structural micrognathia is frequently associated with this syndrome and can hinder laryngoscopy and airway management efforts. Congenital cardiac abnormalities and tetany secondary to deficient parathyroid gland function are also characteristic of DiGeorge syndrome.

Genetic abnormalities in complement proteins may cause primary immunodeficiency syndromes. Hereditary angioneurotic edema (HAE) is caused by absent or defective C1 inhibitor, a protein that normally acts to control complement activation and coagulation mechanisms. Deficient C1 inhibitor activity can lead to kinin accumulation, angioedema, and upper airway obstruction. Exogenous C1 inhibitor can be administered to treat acute angioedema.

Deficiencies in PMNs or the mononuclear phagocyte system can result in severe, life-threatening infections. Neutropenia represents a variable reduction in PMNs, which can predispose the affected individual to severe bacterial infections. Chronic granulomatous disease (CGD) results when defective PMNs are unable to generate a bactericidal respiratory burst after bacterial phagocytosis. Ingested pathogens that survive within the phagocytes trigger a cell-mediated immune response against the phagocytes and formation of granulomas. Symptoms of CGD in pediatric patients include pneumonia and abscesses in various tissues.

Secondary immunodeficiency can result as an adverse effect of immunosuppressive drugs administered to prevent graft rejection or to treat autoimmune disease (see Box 41-7). Glucocorticoids have potent immunosuppressive effects. These steroid agents markedly reduce circulating levels of lymphocytes and monocytes, inhibit immune cell cytokine production, and inhibit T-cell activation. Lymphocytopenia and monocytopenia result within hours after a single dose of glucocorticoid and resolve within 24 hours. Azathioprine is a cytostatic immunosuppressive agent that is effective only on dividing lymphocytes, reducing levels of both B and T lymphocytes. Mycophenolate mofetil inhibits lymphocyte proliferation by blocking the last step of purine synthesis necessary for DNA replication. Cyclosporine, tacrolimus (formerly known as *FK-506*), and rapamycin bind to cytoplasmic proteins known as *immunophilins*, causing blockade of signal transduction pathways from the cell membrane and inhibition of T-cell proliferation.

BOX 41-8

Routes of HIV Transmission

Absolute
- Blood
- Body fluids containing blood

Possible
- Cerebrospinal fluid
- Pericardial fluids
- Amniotic fluids
- Semen, vaginal secretions
- Synovial fluid
- Pleural fluid

Remote
- Feces
- Saliva
- Sputum
- Sweat
- Tears
- Urine
- Wound drainage
- Nasal secretions

Not Implicated in Health-Care Settings
- Human breast milk

Human Immunodeficiency Virus

Secondary immunosuppression also can result from infection that causes depletion of immune cells. In this regard, infection with HIV is the most significant etiology. The virus exists as two main types, HIV-1 and HIV-2. Of the two, HIV-1 is more prevalent and more pathogenic. The primary targets of HIV infection are $CD4^+$ lymphocytes. A glycoprotein on the viral envelope binds to the CD4 antigen to allow the virus to enter the T cell. HIV is a retrovirus, that is, its genome contains two strands of single-stranded RNA. After the virus enters the host cell, its RNA undergoes reverse transcription to produce complementary DNA that is incorporated into the host-cell DNA. Synthesis of new viral RNA then occurs in the host cell, followed by formation of new virus particles and their release to infect other $CD4^+$ cells. Infection with HIV alters T-cell function and causes cytotoxicity, leading to the characteristic decline in $CD4^+$ cells. Exactly how HIV infection kills T cells, though, is not known and may involve several mechanisms. Ultimately, with a sufficient fall in $CD4^+$ cells, individuals become susceptible to life-threatening opportunistic infections.

Epidemiology

The epidemiologic basis for HIV infection begins with transmission of the virus through certain body fluids. Box 41-8 lists the potential sources of transmission of HIV, which can enter the body through blood contact, sexual transmission, and perinatal exposure. In 2009 the Centers for Disease Control and Prevention estimated that approximately 1.7 million individuals 13 years of age and older in the United States were living with HIV/AIDS. Moreover, the annual incidence of HIV infection in the United States was estimated to be nearly 50,000.[15] Infection with HIV can progress to acquired immune deficiency syndrome (AIDS) and fatal disease. Although there is no cure for HIV infection, early diagnosis and pharmacologic intervention have become very successful in controlling HIV infection in many individuals while preserving immune system integrity.

Acute infection with HIV is characterized by a mononucleosis-like illness, in which release of inflammatory mediators, including IL-1 and TNF-α, causes symptoms such as malaise, fever, myalgias, and rash. At the same time, a transient decline in circulating $CD4^+$ cells occurs. Over several weeks after the primary infection, antibodies directed against virus envelope proteins are produced, and CTLs begin to kill infected T cells that display HIV peptides. These immune responses permit resolution of the symptoms of acute infection; however, anti-HIV antibodies and CTLs become

overwhelmed by viral replication and mutation, and progression of HIV infection occurs.

Spontaneous resolution of the acute symptoms of HIV infection is followed by a variable period of asymptomatic infection. If the infection is not treated, a gradual, progressive fall in $CD4^+$ cells occurs in conjunction with a gradual increase in the plasma viral load. Progression to AIDS in untreated individuals occurs in an average time of 10 years, although in some individuals progression may occur much more rapidly or perhaps not at all. With respect to the latter possibility, there are reports of individuals who have not developed AIDS despite multiple exposures to HIV, suggesting that the adaptive immune system in some individuals may provide chronic protection by an as yet undefined mechanism. Clinically, AIDS is defined as a $CD4^+$ cell count less than 200 cells/μL or by the presence of an AIDS-indicator condition (discussed later).

Treatment Modalities

Antiretroviral agents from several classes of drugs are currently available to treat HIV infection. These drug classes include the nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), entry inhibitors, and integrase inhibitors. Most current therapies involve a "cocktail" of antiretroviral agents. A combination of three or four agents, known as *combined antiretroviral therapy,* is now the usual therapeutic approach.

Nucleoside/Nucleotide Reverse Transcriptase Inhibitors. The NRTIs bind to and inhibit the viral reverse transcriptase enzyme responsible for production of HIV RNA. The prototype agent in this class is zidovudine, also known as *ZDV,* which was the first antiretroviral drug to be approved by the U.S. Food and Drug Administration for treatment of HIV infection. Resistance to zidovudine may occur with certain HIV strains, and the most significant side effect of AZT therapy is bone-marrow suppression, which causes anemia and neutropenia. Other NRTIs include abacavir, didanosine, lamivudine (3TC), and stavudine (d4T).

Nonnucleoside Reverse Transcriptase Inhibitors. Like the NRTIs, the NNRTIs bind to and inhibit the viral reverse transcriptase enzyme but at a different molecular site. Resistance to NNRTI monotherapy can readily occur, and adverse effects include skin rash and (uncommonly) Stevens-Johnson syndrome. NNRTIs are metabolized by hepatic CYP3A4, and agents can either induce or inhibit this cytochrome P-450 isoform. Thus the practitioner should be prepared for possible interactions with other drugs, including some anesthetic agents that are metabolized by CYP3A4. The prototype NNRTI is nevirapine; other NNRTIS include delavirdine and efavirenz.

Protease Inhibitors. The viral enzyme protease catalyzes production of viral core structural proteins from immature polypeptide precursors. By inhibiting this enzyme, the PIs cause production of altered, noninfectious virions. Drugs in this class include amprenavir, indinavir, ritonavir, saquinavir, and tipranavir. Adverse effects of the PIs include Cushing-like signs and symptoms (e.g., central obesity, buffalo hump, glucose intolerance). Like the NNRTIs, the PIs can either induce or inhibit CYP3A4, and drug interactions should be anticipated. Of note, ritonavir can reduce fentanyl clearance and increase its plasma half-life.[16]

Entry Inhibitors. Entry inhibitors prevent viral adherence to and entry into the host cell. Enfuvirtide is an entry inhibitor that binds to the gp41protein on the virus surface, thereby interfering with virus attachment to the $CD4^+$ cell. It is injected subcutaneously, and clearance does not involve cytochrome P-450 enzymes. Another agent, maraviroc, binds to the CCR5 receptor on the $CD4^+$ cell to prevent virus entry.

Integrase Inhibitors. Integrase inhibitors, agents in this newest class of antiretroviral agents, inhibit HIV DNA integrase, which is the enzyme responsible for splicing HIV DNA into the host cell genome. The only integrase inhibitor currently available is ratelgravir.[17]

Therapeutic modalities may fail owing to patient nonadherence, inadequate potency of antiretroviral agents, or viral resistance. Ongoing research continues to address resistance and investigate multiple strains of the virus that may not respond to current therapeutic approaches. Ultimately, of course, the goal is to develop a cure for HIV. In this regard, numerous clinical trials of HIV vaccines have been conducted over the past decade in locations around the world and have produced mixed results. The STEP study, an international HIV vaccine clinical trial conducted in part by the National Institute of Allergy and Infectious Diseases, included 3000 participants in nine countries including the United States. Unfortunately, the study was discontinued after an independent monitoring board determined that the vaccine did not prevent HIV infection or affect the course of the disease in those who became infected with HIV. Numerous organizations, including the National Institute of Allergy and Infectious Diseases Center for HIV/AIDS Vaccine Immunology (http://www.niaid.nih.gov/topics/hivaids/Pages), The Collaboration for AIDS Vaccine Discovery (http://www.cavd.org), The Global HIV Vaccine Enterprise (http://www.hivvaccineenterprise.org), and the International AIDS Vaccine Initiative (http://www.iavi.org) are currently pursuing trials of potential HIV vaccines.

Anesthesia Management

The perioperative care of HIV patients should take into account several underlying conditions. Frequent complications include: espiratory impairment and alteration in neuronal functions related to viral factors, host response, and environmental factors such as alcohol, drug addiction, and hepatitis C co-infections. Cognitive dysfunction or a peripheral neuropathy are common. Lipodystrophy, dyslipidemia, and insulin resistance are the main metabolic-related side effects of combined antiretroviral therapy. Atherosclerosis, coronary artery disease, and major nutritional impairment are also common.[18] Patients with HIV infection may require a variety of surgical interventions. Although several studies have evaluated the effects of surgery and anesthesia in patients with HIV infection, to date there is no conclusive evidence to support any particular set of recommendations. The protease inhibitors decrease the metabolic pathways of opioids, nonsteroidal antiinflammatory drugs (NSAIDs), and benzodiazepines, increasing the risk of overdose.[18] Midazolam's effects may be enhanced when administered to patients taking certain protease inhibitors that inhibit cytochrome dependant drug metabolism. This enzyme inhibition prevents the breakdown of midazolam. Careful titration of reduced doses should be adapted until individual patient responses can be gauged. Most alterations caused by various anesthetic agents and techniques are transient and have not been shown to contribute to any adverse outcome. Many clinicians avoid regional anesthesia to reduce needle-induced spread of infectious materials.

Preoperative evaluation should consider the patient's medical management and adherence to antiretroviral therapy and other treatments. Consultation with and participation of the patient's primary care provider in the planning process may be beneficial. Other factors that may be important in the preoperative risk stratification include the patient's CD4 count and viral load.

When anesthesia care is planned, attention should focus on possible end-organ and systemic dysfunction. Clinically significant alterations occur in many organ systems, particularly in the advanced disease stages of HIV infection, when vigilant

monitoring and at times intensive intervention may be necessary. The patient (or his or her legal representative or caregiver) should be included in the planning and evaluation of potential care options. Informed consent may be the responsibility of a legal guardian or durable power of attorney designee for the patient who may be mentally incompetent.

The immunocompromised patient may have combined deficiencies that predispose to significant or fatal outcomes. It is important to remember that microorganisms that are not routinely pathogenic can cause the demise of these patients. Meticulous implementation of infection control measures throughout the perioperative period should be a primary focus in the care of these vulnerable patients. Respiratory isolation should be used when it is either known or suspected that airborne pathogens may be transmitted. Examples of such pathogens include the causative agents of tuberculosis and varicella. The immune-system compromise resulting from HIV infection markedly increases the susceptibility to tuberculosis, and recurrent or newly acquired tuberculosis is frequently the cause of death for persons infected with HIV. A striking clinical feature of tuberculosis in patients with HIV infection is a high incidence of extrapulmonary involvement, usually with concomitant pulmonary presentation.[18-20]

Although equipment preparedness is important for every patient to whom anesthesia is administered, it is of particular significance with the immunocompromised patient. Meticulous attention to behaviors and adherence to strict aseptic technique in providing care to these most vulnerable patients is paramount to safe practice and quality patient care. The anesthesia machine and its multitude of components should be adequately maintained, cleaned, and disinfected. It is advisable to use a new disposable circuit, including a new carbon dioxide sampling port and a 22-micron heat and moisture exchanger (HME) filter, on all patients.

A multitude of clinical presentations have the potential to affect anesthesia management in the patient infected with HIV. Oxygenation and metabolic functions are often impaired during progressive HIV infection. Pulmonary infections can alter both gas exchange and lung perfusion and create ventilation-perfusion mismatch. Dehydration and hypovolemia secondary to gastrointestinal disturbances can further complicate the patient's clinical course. Patients with HIV infection also may present with pain-related syndromes,[21] neuropathies, and muscle weakness.[22] A thorough preoperative assessment, including current physical examination, laboratory results, and radiographic examination, combined with other studies as indicated by patient presentation and current disease state, is critical prior to anesthesia.

Complications from HIV

Wasting syndrome may be seen in patients with HIV infection and results from disturbances in food absorption and metabolism. This syndrome is defined as profound, involuntary weight loss greater than 10% of baseline body weight. Chronic diarrhea frequently contributes to this scenario. Parenteral nutrition and appetite stimulation are usually required when this syndrome is persistent. Preoperative assessment should include evaluation of volume status and related physiologic studies to plan appropriate management.

Neurologic evaluation is essential for patients with HIV infection. Both the central and peripheral nervous systems can be impaired due to direct disease effects, concomitant opportunistic infections, or adverse effects of therapeutic agents used to combat viral insult. Peripheral neuropathies may result in considerable discomfort or physical limitations, and autonomic neuropathy may result in some degree of cardiovascular instability requiring immediate or continuous intervention. AIDS-related dementia can influence both motor and cognitive states, particularly in advanced disease states.

Non-Hodgkin lymphoma, manifesting as a space-occupying lesion within the central nervous system, may require surgical or chemotherapeutic intervention. Kaposi sarcoma, a cancer that invades endothelial tissues, can attack both skin and internal organs. Women infected with HIV may develop cervical dysplasia and cancers.

As HIV infection progresses to AIDS, advanced disease combinations emerge that would otherwise be resisted in the immunocompetent host. These opportunistic disease processes increase in both manifestation and severity as the immune system fails. Both acute and chronic bacterial infections tend to plague HIV-infected individuals. *Mycobacterium avium-intracellulare* (MAI) infection is characterized by intractable diarrhea and resultant wasting states. Splenic and pulmonary infections with MAI lead to severe thrombocytopenia and tuberculosis. MAI attacks the immunosuppressed host easily and is transmissible.

Several viral infections can occur or recur from previously dormant states as HIV disease progresses. Herpes simplex and varicella infections can invade oral and esophageal tissues and the central nervous system. Cytomegalovirus can affect the gastrointestinal and pulmonary systems, resulting in colitis and pneumonia. Retinal invasion may lead to marked visual disturbances and blindness. Ganciclovir is used to treat cytomegalovirus infection.

Opportunistic protozoal infections can develop in persons with advanced HIV infection. *Pneumocystis jiroveci* pneumonia is responsible for the majority of deaths secondary to opportunistic infection in persons with HIV infection. Fever and impaired gas exchange frequently result in hypoxemia, and pneumothorax is not uncommon. Toxoplasmosis encephalitis can affect both central nervous system function and the sensorium. Cryptosporidiosis can trigger considerable diarrhea, resulting in significant dehydration and related electrolyte imbalance. Volume status must be judiciously evaluated and monitored.

Fungal infection is responsible for histoplasmosis and aspergillosis pneumonia in the patients with HIV infection. Such insults can result in significant febrile and hypoxic states, with impairment of gas exchange and overall sensorium. Disseminated candidiasis infections are responsible for oropharyngeal and esophageal pathology that includes stomatitis, dysphagia, and esophagitis. Patients with cryptococcal meningitis can experience increased intracranial pressure.

Childbearing women constitute a significant portion of reported cases of HIV and AIDS. This observation is of considerable significance in that perinatal transmission accounts for greater than 80% of all pediatric AIDS cases that have been reported in the United States. The Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission recommends antepartum combination therapy in pregnant women to reduce the risk of perinatal transmission. If the parturient with HIV infection has not received antepartum antiretroviral therapy, then antiretroviral drugs should be administered intrapartum along with antiretroviral prophylaxis in the neonate to reduce the risk of transmission. A 6-week treatment with zidovudine is recommended for all neonates of women with HIV infection.[23] Moreover, neonates of women who did not receive antepartum antiretroviral drugs should receive a combination drug regimen, such as zidovudine, for 6 weeks combined with three doses of nevirapine in the first week after birth.

The pregnant patient with HIV presents unique challenges for health maintenance. Anemia can be particularly significant in advanced states of HIV infection, frequently necessitating transfusion therapy. Elective cesarean section in the HIV-positive parturient appears to reduce the risk of HIV transmission from mother to neonate.[24] However, complications of cesarean section, including blood loss and wound infection, may be exaggerated in parturients with HIV infection as a result of immunosuppression.[25] Avidan et al.[26] reported no increase in intra- or postoperative complications associated with spinal anesthesia and cesarean section in parturients with HIV infection who were receiving effective antiretroviral therapy and who received preoperative broad-spectrum antibiotics. Such an approach may be effective in reducing risk of perinatal HIV transmission in parturients in whom antiretroviral therapy is effective and spinal anesthesia is not contraindicated.

Perioperative pain management can be a particular challenge in patients with advanced HIV infection. Indeed, patients with HIV infection frequently present with pain-related syndromes and thus may be taking prescription or over-the-counter analgesic medications and are frequently opioid dependent.[21] Both routine analgesic modalities and analgesic agents combined with the use of various chemotherapies, nerve blocks, and complementary therapies have been beneficial in treating acute postoperative and obstetric pain in patients with HIV infection.[27]

Managing HIV Infection

Occupational Safety. The primary emphasis in managing HIV infection during anesthesia and other aspects of patient care is an effective prevention program. Because the routes of HIV transmission are well known, an appropriate infection control program, with consistent application of proven blood and body substance precautions, can prevent disease transmission. Universal precautions were developed after known modes of transmission of both HIV and hepatitis B virus (both blood-borne pathogens) were clarified. More recent efforts to apply this practice throughout all patient care areas have resulted in the consistent application of standard precautions during patient care. The basic premise on which these guidelines are based is the prevention of parenteral, mucous membrane, and nonintact skin exposure to blood and certain body fluids from all patients. Guidelines include the following:

- Gloves must be worn when contact with body substances is suspected or possible.
- A plastic gown or apron must be worn when soiling with body substances is likely.
- Protective masks and eyewear must be worn in the presence of airborne disease or for preventing splash or aerosolization of body substances to eyes or mucous membranes.
- Hands must be thoroughly washed before and after body substances or articles possibly covered with body substances have been handled and after gloves have been removed at the completion of each task or procedure.
- Uncapped needles and syringes must be discarded in puncture-resistant receptacles placed as close to their point of use as is practical.
- Trash and linens must be discarded in impervious, sealed plastic bags that are labeled as infectious and transported according to standard precautions.

Self-protection against HIV and all other infectious blood-borne pathogens such as hepatitis B and C viruses is an essential element of safe practice. The Occupational Safety and Health Administration (OSHA) Act, which became effective in 1992, mandates that employers minimize occupational exposure to all blood-borne pathogens in workplaces where a potential for such exposures exists. Known or suspected exposure to blood-borne pathogens should be responded to immediately with appropriate action, as recommended by OSHA and institutional infection control standards. The AANA infection control guide details recommended practices for managing blood-borne pathogens during anesthesia care.[28] Current HIV/AIDS treatment guidelines and protocols may be obtained from the National HIV/AIDS Clinicians' Consultation website at http://www.nccc.ucsf.edu/.

HIV Postexposure Prophylaxis. As of December 2001, the Centers for Disease Control and Prevention (CDC) had received voluntary reports of 57 documented cases of HIV seroconversion temporally associated with occupational exposure to HIV among U.S. healthcare personnel. Because there is no cure or effective vaccine for HIV, optimal postexposure care, including the administration of antiretroviral drugs, remains a high priority for protecting healthcare personnel.[29,30]

Percutaneous injury with a hollow-bore needle is the most common mechanism of occupational HIV transmission. Pooled data from several prospective studies of healthcare personnel suggest that the average risk of HIV transmission is approximately 0.3% after a percutaneous exposure to HIV-infected blood and approximately 0.09% after a mucous membrane exposure.[29] The average risk associated with exposure of nonintact skin and exposure to HIV-infected fluids and tissues other than blood or bloody fluids is too low to be estimated in prospective studies.

In a retrospective study, the CDC found that the risk of HIV transmission to healthcare workers was increased when the device causing the injury was visibly contaminated with blood or was used for insertion into a vein or artery, when a deep injury occurred, or when the source patient died within 2 months after the exposure.[29] A low-plasma HIV RNA titer does not exclude the possibility of transmission, especially because this measurement does not account for cell-associated HIV. Transmission from source patients with undetectable HIV RNA has been documented.

Suture needles have not been implicated as a source of infection in prospective studies, but occupational HIV infection has been reported among surgical personnel, and suture needles are one potential source of such infection. Exposure of intact skin to contaminated blood has not been identified as a risk for HIV transmission.

Evidence suggests that postexposure prophylaxis (PEP) with antiretroviral drugs soon after occupational exposure to HIV decreases risk of infection. The CDC recommends that PEP be initiated within hours of exposure and that the regimen be administered for 4 weeks. In most cases, individuals exposed to HIV will receive a two-drug regimen (basic regimen). A third, and even a fourth, drug (expanded regimen) may be considered for individuals at increased risk for infection, although there are no data that demonstrate increased efficacy of a three- or four-drug regimen. Indeed, it is clear that protection afforded by PEP is not absolute. Of six healthcare workers known to have acquired HIV infection despite PEP, three individuals received three drugs and one received four drugs.[29]

ANESTHESIA AND THE IMMUNE SYSTEM

The effects of anesthesia on the immune system have been investigated for more than 30 years. For two reasons, however, no clear picture regarding how anesthetic agents alter immune function has emerged. First, anesthesia is administered in the context of surgery, which itself has significant effects on immune function. Second, many in vitro studies have been performed to examine the effects of anesthetic agents on immune components in controlled, experimental situations. Results of these in vitro studies,

although possibly yielding mechanistic insights, do not always agree with in vivo observations. The focus of this final section of the chapter is to describe the relationship between stress and the immune system and to summarize the results of in vitro and in vivo studies of the effects of individual anesthetic agents on the principal components of the immune system, that is, phagocytes, lymphocytes, and soluble mediators.

Effects of Surgery on the Immune System

The immune response to surgery is variable and involves both the innate and the adaptive immune systems. Tissue injury caused by surgery induces an immediate, localized response by cells, particularly macrophages, of the innate immune system.[31,32] Cytokines such as IL-1 and TNF-α are released from resident macrophages and promote a local inflammatory response in the injured tissue. Among their effects, IL-1 and TNF-α stimulate production of IL-6, which in turn acts on hepatocytes to stimulate the synthesis and release of acute-phase proteins such as CRP. The magnitude of the inflammatory response and the perioperative plasma IL-6 levels appear to correlate with the severity of the surgical procedure.[33] In this regard, higher IL-6 levels have been found in patients undergoing open cholecystectomy than in patients undergoing laparoscopic cholecystectomy.[34] Of potential clinical importance, the plasma IL-6 level may predict the likelihood of postoperative morbidity and mortality.[32] Moreover, as previously discussed, plasma CRP levels may be predictive of perioperative morbidity.[7]

In addition to the inflammatory response at the site of surgical tissue injury, surgery strongly stimulates the body's neurohumoral stress response, which in turn can produce immunosuppression by several mechanisms.[32,35,36] First, a variety of stressors associated with surgery, including hypotension, hypothermia, activation of pain pathways, and proinflammatory cytokines (e.g., IL-1, IL-6, and TNF-α) released from the site of surgical injury, can stimulate the hypothalamic-pituitary-adrenal (HPA) axis and cause release of the glucocorticoid cortisol from the adrenal cortex. Glucocorticoids such as cortisol have potent antiinflammatory and immunomodulatory effects. Among its effects, cortisol shifts the Th1/Th2 cell balance, suppressing APC production of IL-12 and Th1-mediated cellular immunity and stimulating Th2 cell production of antiinflammatory cytokines such as IL-4 and IL-10. Although this cortisol-mediated effect functions to prevent exaggerated inflammation at the surgical site, diminished Th1 cell activity and increased production of Th2 cytokines effectively produces immunosuppression characterized by depressed cell-mediated immunity (via phagocytes, CTLs, and NK cells) and susceptibility to infectious pathogens and metastasis of tumor cells.

In addition to stimulating the HPA axis, surgical stress strongly activates the sympathetic nervous system activation, increasing secretion of catecholamines from the adrenal medulla.[32,35,36] Catecholamines may promote immunosuppression through activation of β-adrenergic receptors on immune cells. In this regard, activation of β-adrenergic receptors has been found to suppress in vitro monocyte production of TNF-α and IL-1 and PMN production of reactive oxygen molecules.[37,38] Moreover, like cortisol, catecholamines may facilitate a stress-induced shift in the Th1/Th2 cell balance. Elenkov et al.[39] treated whole blood with bacterial lipopolysaccharide (endotoxin) to stimulate monocyte cytokine production.[39] Dexamethasone, used to mimic the in vivo effects of cortisol, inhibited monocyte IL-12 production. The catecholamines epinephrine and norepinephrine also inhibited IL-12 production and increased IL-10 production. The effects of the catecholamines were blocked by the β-adrenergic antagonist propranolol. As discussed, IL-12 induces Th0 cell differentiation to Th1 cells and promotes cellular immunity. By contrast, IL-10 inhibits Th1 cell function and promotes Th2 cell responses and humoral immunity. The authors suggested that stress hormones, that is, glucocorticoids and catecholamines, can shift the Th1/Th2 cytokine balance to a pattern that predisposes to infections by pathogens that would normally be intercepted by cellular immunity.

Evidence from animal and human studies indicates that the extent of surgery-induced immunosuppression correlates with the invasiveness of the surgical procedure. Anesthetized animals that underwent experimental laparoscopy had preserved postoperative cellular immunity compared with animals that underwent more invasive laparotomy.[40,41] Similarly, in humans, laparoscopic cholecystectomy caused less postoperative suppression of T-cell proliferation than did open cholecystectomy,[42] and minimally invasive thoracic surgery caused less postoperative suppression of circulating lymphocytes than did conventional thoracotomy.[43]

Anesthesia may attenuate the stress response to surgically induced tissue injury, and thus influence the perioperative immune response to surgery. Moreover, attenuation of the stress response may be of greater significance with regional versus general anesthesia. However, anesthetic agents themselves may have immunomodulatory activity, which must be considered in formulating an overall picture of how anesthesia affects perioperative immune function.

Effects of Anesthesia and Anesthetic Agents on Immune Function

Lymphocyte Number and Function

Several studies have found that anesthesia and surgery together can alter the levels of circulating lymphocytes. In patients undergoing elective abdominal surgery with isoflurane general anesthesia, arterial blood lymphocytes were increased at 5 minutes after induction of anesthesia, 5 minutes after skin incision, and 5 minutes after peritoneal incision.[44] Unfortunately, the authors did not measure lymphocyte levels later in the surgical procedure or in the postoperative period.

An early rise in circulating lymphocytes might be transient. Indeed, several studies indicate that perioperative lymphopenia can occur in patients undergoing inhalational anesthesia and surgery.[45] Rem et al.[46] reported decreased blood lymphocytes at 6 and 9 hours after skin incision in women undergoing hysterectomy with halothane anesthesia. Similarly, Corsi et al.[47] found reduced number of T lymphocytes at 10 minutes after the initiation of hysterectomy surgery in patients anesthetized with isoflurane. In these studies, the lymphopenia resolved by 48 hours after surgery. In patients undergoing craniotomy, the postoperative Th1/Th2 cell ratio was reduced in patients anesthetized with isoflurane.[48] A trend toward reductions in both the Th1 cell count and the postoperative Th1/Th2 cell ratio was observed in patients undergoing isoflurane general anesthesia for transurethral resection of the prostate (TURP), although the reductions did not achieve statistical significance.[49]

Perioperative lymphopenia in patients undergoing surgery with isoflurane anesthesia is consistent with data showing reduced plasma levels of IL-2, a key cytokine responsible for T-cell proliferation, in patients undergoing isoflurane anesthesia.[50] Plasma IL-2 was reduced at the end of surgery and had returned to the preinduction level at 24 hours postoperatively. Moreover, because IL-2 promotes T-cell differentiation to Th1 cells, a perioperative reduction in the Th1/Th2 cell ratio is consistent with isoflurane anesthesia suppression of IL-2 production.

One or more circulating factors associated with general anesthesia and surgery may contribute to perioperative lymphopenia.

Such factors might include cortisol and catecholamines released as components of the stress response to surgery, as discussed earlier, as well as intravenous and inhalation anesthetic agents themselves. Indeed, there is evidence that induction agents may suppress lymphocyte proliferation. Devlin et al.[51] treated blood obtained from healthy volunteers with phytohemagglutinin (PHA), an agent commonly used to provoke in vitro T-cell proliferation. Intravenous induction agents such as etomidate inhibit T-cell proliferation at concentrations representative of those achieved in the blood during anesthesia. By contrast, propofol did not impair in vitro T-cell proliferation. In a follow-up study by the same group, blood was collected from healthy volunteers who received intravenous injections of either thiopental or etomidate but did not undergo surgery.[52] In contrast to results of the in vitro studies, the authors found no alteration of PHA-stimulated in vitro T-cell proliferation, although they did find depression of delayed-type hypersensitivity (DTH) reactions to allergens, suggesting that in vivo T-cell *function* was impaired by administration of the induction agents. These latter results are of potential clinical significance because there has been reported an association between depressed DTH reactions and increased postoperative mortality.[53]

In vitro studies suggest that inhalational agents might contribute to perioperative lymphopenia by suppressing lymphocyte proliferation[54] and production of IL-1 and TNF-α[55] and by inducing lymphocyte apoptosis.[56] However, PHA-induced proliferation of lymphocytes obtained from volunteers administered inhalation anesthesia with enflurane or halothane, but who did not undergo surgery, was not impaired.[57]

Studies of B-cell function, although limited, suggest that postoperative reduction of B-cell numbers[45] and suppression of B-cell function[58] can occur in surgical patients. Such responses, however, may result primarily from the stress response to the surgical procedure. In anesthetized patients, B-cell function was not altered until after the surgical procedure was initiated. Recently investigators reported on immune suppression that happens from the effects of anesthesia. Neurosurgical patients were anesthetized using a propofol, sevoflurane, and vecuronium technique. Immune cell numbers of neutrophils, monocytes, lymphocytes, and lymphocyte subsets including T cells, inducer and helper T cells, suppressor and cytotoxic T cells, NK cells, and B cells were measured. Thirty minutes after induction neutrophils, monocytes, and lymphocytes decreased compared with their levels before anesthesia. At extubation the neutrophils returned to the base level. Natural killer cells decreased significantly during anesthesia. The concentration of cytokines in peripheral blood did not change significantly. They concluded that a transient but significant alteration in the distribution of white blood cell populations and lymphocyte subsets was induced by anesthesia.[59] Procopio et al. reported no change in antibody responses to antigen in healthy volunteers who received either isoflurane anesthesia or lumbar epidural anesthesia (lidocaine) but did not undergo surgery.[60]

Anesthesia and surgery may suppress NK-cell number and function and predispose cancer patients to tumor cell metastases.[36,61,62] Activation of the neuroendocrine stress response may be responsible, at least in part, for suppression of NK-cell activity in surgical patients. The intrinsic function to fight cancer cells is competent immune cells, particularly $CD4^+$ T helper 1-type cells, $CD8^+$ cytotoxic T cells, and natural killer cells. However, surgical inflammation, some anesthetics, and inadvertent anesthesia management suppress these effector cells and induce suppressive immune cells, which render cancer patients susceptible to tumor recurrence and metastasis after surgery. Accumulated basic and clinical data suggest that total intravenous anesthesia with propofol, cyclooxygenase antagonists, and regional anesthesia can decrease negative consequences associated with perioperative immunosuppression. Volatile anesthesia, systemic morphine administration, unnecessary blood transfusions, intraoperative hypoxia, hypotension, hypothermia, and hyperglycemia should be avoided.[61] In this regard, NK-cell activity was reduced after hysterectomy[63,64] or upper abdominal surgery.[65] However, Procopio et al.[60] reported *increased* NK-cell cytotoxicity in healthy volunteers who received either isoflurane anesthesia or lumbar epidural anesthesia (lidocaine) but did not undergo surgery. Catecholamine release may be particularly important in surgery-induced NK-cell suppression, because β-adrenergic blockade has been shown to attenuate stress-induced NK-cell suppression in humans.[65]

Some agents used for anesthesia and analgesia may cause suppression of NK cells. In vitro studies have shown inhalational agents to cause dose-dependent suppression of NK-cell activity.[66] Moreover, Melamed et al.[67] demonstrated that administration of halothane, ketamine, or thiopental for 1 hour suppressed NK-cell activity and promoted tumor metastases in a nonsurgical rat model of breast cancer metastasis. By contrast, propofol did not affect NK-cell function nor did it promote tumor metastasis.

Opioids may have effects on NK cells, which express μ and δ opioid receptors. Morphine can decrease the effectiveness of several functions of both natural and adaptive immunity, and significantly reduce cellular immunity.[68] By contrast, intravenous fentanyl administered at clinically relevant doses *augmented* NK-cell cytotoxicity in healthy volunteers who did not undergo surgery.[69] The relevance of this latter finding to surgical patients, though, is unclear. Indeed, patients who received either low- or high-dose fentanyl during surgery demonstrated postoperative suppression of NK-cell cytotoxic activity, the duration of which was greater in those patients who received high-dose fentanyl.[70] Tramadol, a weak opioid agonist that also inhibits norepinephrine and serotonin reuptake, has been found to provide postoperative analgesia comparable to that of morphine without suppressing NK-cell activity.[71]

Of agents used for anesthesia, propofol may have the least effect on lymphocyte function. PHA-stimulated proliferation of T cells isolated from healthy volunteers was not altered by propofol,[51] and propofol increased the in vitro Th1/Th2 cell ratio.[72] In patients undergoing craniotomy, the postoperative Th1/Th2 cell ratio was reduced in patients anesthetized with isoflurane but not in patients anesthetized with propofol.[48] Propofol anesthesia might therefore be beneficial in patients with depressed immune function in whom a decrease in the Th1/Th2 cell ratio could exaggerate the condition.[36]

Phagocyte Function

Numerous studies indicate that anesthesia and surgery can impair phagocyte function and that this effect may result in part from a direct effect of anesthetic agents on PMNs and monocytes/macrophages. Inhalational agents may have suppressive effects on PMN function. Halothane, isoflurane, and sevoflurane were found to inhibit in vitro adhesion of PMNs to endothelial cells,[73] and halothane and isoflurane inhibited in vitro PMN superoxide ion production, that is, the "respiratory burst" important for killing pathogens.[74,75] Heine et al.[76] studied PMNs isolated from surgical patients and found in vitro phagocytosis and respiratory burst to be suppressed after 4 hours of isoflurane anesthesia. Inhalational agents also impair in vitro monocyte chemotaxis,[45] and Kotani et al.[77] found decreased phagocytic activity of alveolar macrophages isolated from patients undergoing orthopedic surgery with isoflurane anesthesia.

Intravenous agents used in anesthesia may alter PMN function. Propofol, etomidate, ketamine, and thiopental were found to suppress in vitro PMN phagocytosis and superoxide production.[78-81] Neutrophils isolated from surgical patients displayed reduced in vitro phagocytosis and respiratory burst after 4 hours of propofol anesthesia.[76] The effects of propofol on PMN function might depend on its lipid carrier. Propofol dissolved in long-chain triglycerides (LCTs) suppressed in vitro PMN superoxide formation and phagocytosis. By contrast, propofol dissolved in a mixture of LCTs and medium-chain triglycerides (MCTs) enhanced PMN production of reactive oxygen molecules.[79] Similarly, etomidate dissolved in a LCT/MCT mixture enhanced PMN function, whereas etomidate dissolved in conventional propylene glycol solvent modestly suppressed PMN function. Interestingly, and of potential clinical significance, the α_2-agonist sedative agents clonidine and dexmedetomidine do not suppress in vitro PMN phagocytosis or superoxide ion formation, despite the fact that PMNs do display α_2 adrenoceptors.[82]

Intravenous anesthetic agents may also impair monocyte/macrophage function. Ketamine and midazolam reduced in vitro monocyte chemotaxis and proliferation, and thiopental, etomidate, and propofol inhibited proliferation of cultured monocytes.[83,84] Kotani et al.[77] found decreased phagocytic activity of alveolar macrophages isolated from patients undergoing orthopedic surgery with propofol anesthesia.

Among the opioids commonly used in anesthesia and surgery, morphine may be the only agent that suppresses phagocyte function. Welters et al.[85] demonstrated dose-dependent reduction of PMN phagocytosis and respiratory burst in vitro by morphine action on μ-3 opioid receptors on PMN cell membranes. The inhibitory effects of morphine were linked to nitric oxide production and were blocked by the μ-receptor antagonist naloxone. By contrast, alfentanil, fentanyl, and remifentanil had no effect on PMN respiratory burst or phagocytosis.[80,86] These latter results are consistent with reports that fentanyl does not bind to the μ-3 receptor.[87] Morphine also inhibits macrophage phagocytosis[88] and release of IL-10 and IL-12.[89]

Regional Anesthesia and Analgesia

It is generally agreed that the stress response to surgery is less with neuraxial anesthesia than with general anesthesia. Neuraxial anesthesia can be very effective in attenuating postoperative pain, which is a potent activator of the stress response and probable contributor to postoperative immunosuppression. Not unexpectedly, a number of studies have shown that neuraxial anesthesia can prevent, or reduce the degree of, perioperative immune dysfunction.

In a study of women undergoing elective hysterectomy, Rem et al.[46] demonstrated that epidural anesthesia prevented postoperative lymphopenia that occurred in patients who underwent general anesthesia. In another study of patients undergoing hysterectomy, epidural anesthesia prevented lymphopenia and reduced NK-cell activity that occurred in patients undergoing neuroleptanesthesia. In addition, epidural anesthesia attenuated the perioperative increase in cortisol level.[63]

Hole and Unsgaard[90] isolated lymphocytes from patients undergoing total hip replacement under either general or epidural anesthesia. Lymphocytes were then treated with PHA to provoke in vitro T-cell proliferation. PHA-induced T-cell proliferation was depressed during and after surgery in patients receiving general anesthesia but not in patients receiving epidural anesthesia. In a separate study by Hole[91], serum obtained from patients undergoing general anesthesia, but not that from patients undergoing epidural anesthesia, showed suppressed proliferation of T cells when compared with cells obtained from healthy, nonsurgical volunteers. In a recent meta-analysis, researchers compared the effect of central neuraxial (spinal or epidural) anesthesia with general anesthesia on postoperative NK-T lymphocyte function. Anesthetic technique did not appear to significantly affect postoperative NK-T lymphocyte function. [92]

In patients undergoing TURP, significant reductions in lymphocyte number and in vitro response to mitogens were observed in patients who received general anesthesia, but not in patients who received spinal anesthesia.[93] Le Cras et al.[49] found the postoperative Th1/Th2 cell ratio to be increased in TURP patients who received spinal anesthesia, compared with a trend for reduced Th1/Th2 cell ratio in patients who received isoflurane general anesthesia. The combination of spinal block with sevoflurane general anesthesia preserved the Th1/Th2 cell ratio and attenuated tumor cell metastases after experimental laparotomy in mice.

SUMMARY

Two components of immunity provide defense against invading pathogens: the innate immune system and the adaptive immune system. Innate immunity is nonspecific, and adaptive, or acquired, immunity is specifically directed against a particular antigen.

Both the innate and acquired immune systems participate in the production of inflammation, which is the collective response to tissue injury caused by infectious microorganisms, toxins, or trauma. In some cases, the immune response can be greatly exaggerated, a situation referred to as *hypersensitivity*. Anaphylaxis is a severe and potentially life-threatening type I hypersensitivity reaction.

Immune system dysfunction can manifest as autoimmune disease or immunosuppression. Impairment in mechanisms that normally act to prevent autoreactivity of the immune system can lead to autoimmune disease. Primary immunodeficiency is caused by deficient function of lymphocytes, the complement system, or phagocytes.

Secondary immunodeficiency can result as an adverse effect of immunosuppressive drugs administered to prevent graft rejection or treat autoimmune disease or from infection that causes depletion of immune cells, such as occurs with human immunodeficiency virus-1 (HIV-1) infection. Numerous clinical presentations have the potential to affect anesthesia management in the patient infected with HIV. Percutaneous injury with a hollow-bore needle is the most common mechanism of occupational HIV transmission.

Surgery strongly stimulates the body's stress response, which can produce immunosuppression by release of cortisol from the adrenal cortex and catecholamine secretion from the adrenal medulla. Perioperative lymphopenia commonly occurs in patients undergoing general anesthesia and surgery, and surgical stress may reduce the Th1/Th2 cell ratio and predispose to certain infections. Impaired lymphocyte proliferation has been reported in surgical patients and may be caused by circulating factors such as stress hormones and intravenous and inhalation anesthetic agents. Opioids, in particular morphine, may suppress NK cell activity.

Neuraxial anesthesia may prevent, or reduce the degree of, perioperative immune dysfunction. Spinal and epidural anesthesia have been found to prevent postoperative lymphopenia and adverse changes in lymphocyte subpopulations and NK-cell activity that occur in patients who undergo general anesthesia. Thus one potential advantage of neuraxial anesthesia over general anesthesia may be less postoperative immunosuppression.

42 CHAPTER Anesthesia and Laser Surgery

◆ *Bernadette T. Higgins Roche*

The term *laser* is an acronym for *l*ight *a*mplification by the *s*timulated *e*mission of *r*adiation. Stimulated emission of radiation was first proposed by Albert Einstein in 1917, and the first laser was developed by Arthur Schawlow and Charles Townes in the late 1950s; Townes went on to win the Nobel Prize in physics for his work on masers and lasers. The first laser, a 694-nanometer (nm) ruby laser, was built by Theodore Maiman in 1960. Lasers now have widespread use in a variety of unrelated fields, including construction, communications, the military, energy production, and the entertainment industry. Lasers are also used in spas and beauty salons for laser hair removal (LHR) by cosmetologists and estheticians.

Medical lasers were introduced in the mid-1960s when the ruby and the argon-ion lasers were first used in retinal surgery. With the development of smaller and more powerful lasers, the use of lasers expanded to all surgical specialties and are frequently used in laparoscopic procedures, surgery of the upper and lower airways, endoscopic arthroscopic procedures, and transmyocardial and transluminal revascularization. Capable of making incisions as small as 0.5 microns, the laser scalpel offers definite advantages over traditional surgery, including improved access to operative sites, greater precision in tissue destruction and removal, increased anatomic preservation, and controlled hemostasis. Surgical lasers have revolutionized the field of dermatology and esthetic surgery.[1] In dentistry, lasers are used for gum reshaping, drilling, and whitening of teeth. Lasers continue to play a major role in ophthalmology, in large part because of the introduction of the excimer laser in the 1980s. In 1995 and 1999, the Food and Drug Administration (FDA) approved excimer lasers for photorefractive keratectomy (PRK) and laser-in-situ keratomileusis (LASIK), respectively. LASIK is now one of the most common surgical procedures in the United States. Medical lasers have other therapeutic applications, including photodynamic therapy (PDT) in which laser-activated drugs are used to destroy cancer cells. Medical lasers are commonly used even in private medical offices.

BASIC PRINCIPLES OF LASERS

Light

Electromagnetic radiation is a broad spectrum of heat energy composed of radio waves, microwaves, infrared waves, visible light waves, ultraviolet waves, x-rays, and gamma rays (Figure 42-1). A wavelength is the distance between two successive points on a periodic wave that has the same phase. The wavelength decreases and the frequency increases as the electromagnetic spectrum moves from radio waves to gamma waves. Ultraviolet, visible, and infrared waves with a wavelength range of 200 to 1000 nm make up the optical portion of the electromagnetic spectrum. Visible light includes a rainbow of colors—red, orange, yellow, green, blue, indigo, and violet—with a very narrow range of wavelengths of 400 nm (violet) to 700 nm (red). The ultraviolet and infrared portions of the optical spectrum are invisible to humans. Infrared radiation is perceived as heat, and ultraviolet radiation causes a chemical reaction in human skin with little heat production.

Light can be described as both a wavelength and a particle of energy called a *photon*. The energy of an electromagnetic wave is proportional to its frequency and inversely proportional to its wavelength. Because of its short wavelength and high frequency, ultraviolet radiation contains a lot of energy that can damage the skin. The energy of a photon is defined as the energy emitted when an electron falls from an excited orbit to one of lower energy; the energy between the two orbits defines the wavelength of the emitted photon. The following equation describes the relationship between the energy and the wavelength of light.

$$E = hc / \lambda$$

(E = energy in joules, h = Planck's constant (6.63×10^{-34} J-s), c = the speed of light (2.998×10^{-8} m/s), and λ = wavelength in meters).

Spontaneous and Stimulated Absorption and Emission of Energy

In an atom, electrons exist in specific locations called orbits or orbitals. A specific level of energy is associated with each orbital. The ground state or orbital closest to the nucleus has the lowest energy state; the higher orbitals have the greatest energy. If an electron is to move to a higher orbital, it must gain the difference in energy between the two orbitals; conversely, it will lose energy if it falls to a lower orbit. Electrons have a tendency to return to the ground state spontaneously, releasing a photon of light energy in the process. This is called *spontaneous emission of radiation*. The energy of the photon and therefore its wavelength is dependent on the energy difference between the two orbits. Light produced by fluorescent lights or incandescent bulbs is a result of electrons changing orbits and returning to ground state. Both the energy of the released photon and the wavelength of the light are proportional to the energy difference between the excited state and the ground state of the atom. Light produced by spontaneous emission is composed of different wavelengths and frequencies; consequently, the photons oscillate randomly (noncoherence), and the light disperses as it travels.

An atom can be "pumped" up to a higher energy level by a stimulating photon if its energy is the same as the energy difference between the two orbitals. A stimulating photon can also cause an atom in an excited state to undergo decay and release energy. When an atom is struck by a stimulating photon, it decays back to its ground state and emits a second photon. If the energy of the stimulating photon is equal to the energy difference between the excited and ground states of the atom, the emitted photon will have the same wavelength, energy, frequency, and direction as the stimulating photon. This process is known as *stimulated emission of radiation* (Figure 42-2). The two photons can strike other excited

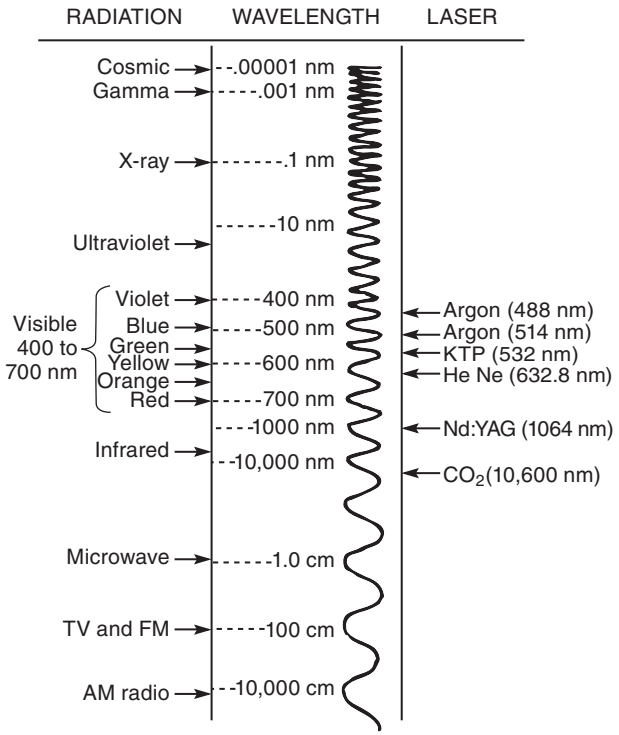

FIGURE **42-1** Electromagnetic spectrum. (Modified from Arndt KA, et al., eds. *Lasers in Cutaneous and Aesthetic Surgery*. Philadelphia: Lippincott-Raven; 1997:4.)

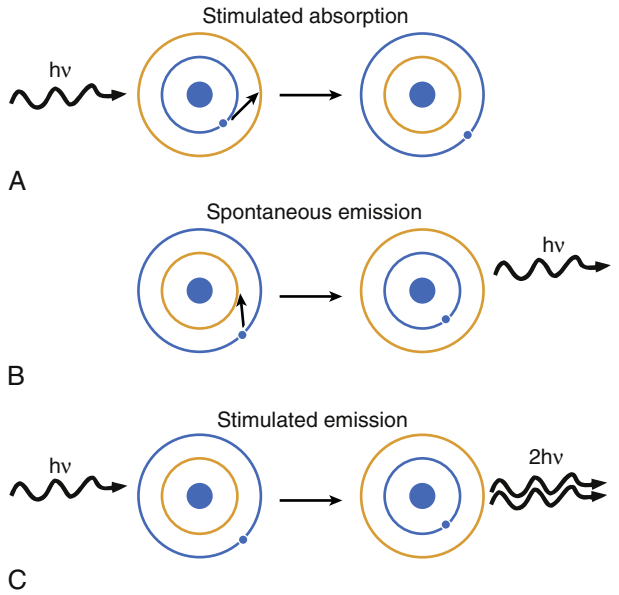

FIGURE **42-2** Absorption, emission, and stimulated emission. Photons may interact with orbital electrons in three ways. **A,** A photon striking an electron may transfer its energy to the electron, pushing the electron into a higher-energy orbit. This interaction is known as *absorption*. **B,** An electron in an orbit higher than the ground (i.e., minimal energy) state may spontaneously lose energy in the form of an emitted photon. **C,** An incoming photon may interact with an electron that is already in a high-energy orbit, with the result that two perfectly coherent, collimated photons leave the electron; this is known as *stimulated emission*. (From Miller RD, et al. *Miller's Anesthesia*. ed 7. Philadelphia: Churchill Livingstone; 2010:2408.)

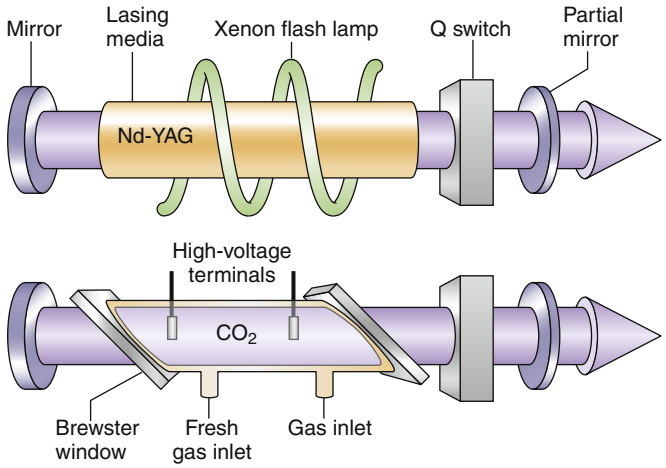

FIGURE **42-3** Generic laser hardware. A laser system consists of several components, regardless of whether the laser is a solid-based, liquid-based, or gas-based device. The central component is the laser medium itself, which may be a solid crystal of yttrium-aluminum-garnet (YAG) with a small concentration of neodymium as dopant, or may be a tube containing carbon dioxide (CO_2). The energy pump provides the means of obtaining a population inversion of orbital electrons; it may consist of a xenon flash lamp or an electric spark generator. A pair of axial mirrors permits repeated passes of collimated photons through the medium, allowing maximum amplification by stimulated emission. The mirror on the right is not 100% reflective, allowing the beam to escape eventually. The optional Q switch increases the efficiency of pulsed lasers by allowing a small delay to increase the pumping. (From Miller RD, et al. *Miller's Anesthesia*. ed 7. Philadelphia: Churchill Livingstone; 2010:2408.)

atoms and stimulate additional emission of photons, resulting in a sudden burst of coherent radiation as all the atoms return to ground state in a rapid chain reaction.

Properties of laser light that differentiate it from fluorescent or incandescent light include coherence, directionality, and monochromaticity. Laser beam photons have the same wavelength and oscillate synchronously in identical phase with one another (coherence). Laser light moves in a parallel, narrow beam (spatial coherence) over long distances and displays minimal dispersion. This spatial coherence, known as *collimation*, allows the laser light to be focused on a very small area (Figure 42-3).

Reflectors placed on the moon allow calculation of the distance to the moon by the length of time it takes for a laser light to return to earth. Reflection of a laser beam can reduce the collimation and increase the dispersion, especially if the reflecting surface has a matte or dull finish; however, the reduction in collimation and increased dispersion of a reflected laser beam is insignificant if the reflecting surface is smooth and shiny.

Laser light is composed of specific and discrete wavelengths; consequently, the light emitted is monochromatic and specific for each laser. Just as white light is composed of multiple colors, some lasers are tunable and can emit light at several different wavelengths. However, tunable lasers can only emit one color or wavelength at a time. A typical light bulb is more powerful than a laser, but its light is not collimated, and the dispersion of the light reduces its intensity. In contrast, the intensity of a 1-milliwatt (mW) laser can be six times that of a 100-watt (W) incandescent bulb. Although a typical laser emits only a few milliwatts of power, from a distance of 100 feet lasers can produce a highly intense beam of 1 to 2 mm that can be 1 million times more concentrated than light from an incandescent source.

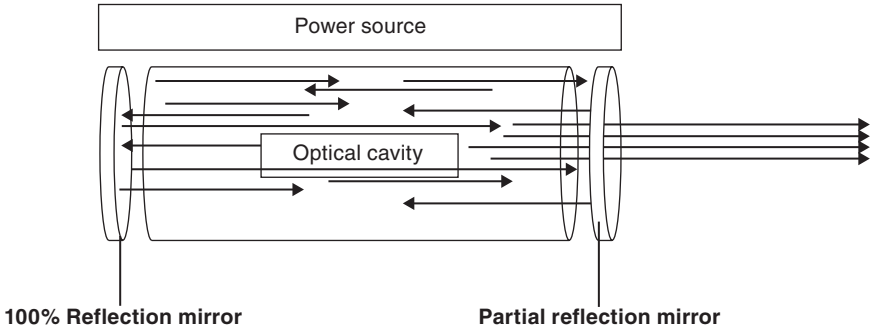

FIGURE **42-4** Basic components of a laser. The optical cavity contains the lasing medium (e.g., solid, liquid, gas). The power source (e.g., flash lamp, electric current, other laser) pumps up the electrons in the lasing medium to a higher energy state. Two mirrors reflect the photons back into the cavity, where they stimulate other excited atoms to emit identical photons. One mirror is partially transparent and allows a portion of the laser beam to exit the cavity in a narrow beam.

Components of a Laser

A laser is a device that creates and amplifies a narrow, intense beam of coherent light. It consists of an energy source, an optical resonating cavity, and a laser medium to create the laser light (Figure 42-4). Lasers require an external energy source to transfer or pump up the energy of the laser medium. The electrons in the lasing medium absorb the energy and move to a higher energy state. Flash lamps, continuous light, high-voltage discharge, diodes, or another laser can be used as the energy source. Electric current is used to excite gas lasers, such as carbon dioxide (CO_2) and argon (Ar) lasers. Liquid and solid state lasers, such as the potassium-titanyl-phosphate (KTP) laser, require activation by a flash lamp or another laser.

The optical resonating cavity, a tubelike structure, provides optimal amplification of the laser beam. It contains the lasing medium and a mirror at each end of the tube. When the lasing medium is excited by the outside energy source (e.g., flash lamp, electric current), the atoms are "pumped" to a higher energy level, increasing the number of atoms in the excited state. Population inversion is necessary for stimulated emission of radiation, and it occurs when more atoms are in an unstable excited state than the resting state. When one of the atoms spontaneously decays back to its ground state, it releases a photon that "stimulates" another excited atom to decay back to its ground state, releasing another photon. The wavelength, frequency, phase, and direction of the second photon are identical to those of the first photon. The mirrors reflect the excited photons back into the resonating cavity at approximately 186,000 miles per second, where they travel back and forth in a parallel fashion, stimulating the release of more photons from other excited atoms and amplifying the resultant laser light. One of the mirrors is partially transparent and allows a very thin beam of the coherent, collimated, and monochromatic laser light to exit and focus on the target tissue.

The laser medium can be a solid, gas, liquid, or semiconductor that is stimulated to a metastable state when pumped with an external energy source. Lasers are commonly named after the laser medium that determines the wavelength output of the laser. Solid-state lasers such as the neodymium: yttrium-aluminum-garnet (Nd:YAG) laser use a solid matrix that is doped with a small amount of impurity (dopant). It is the impurity, that is, Nd, that provides the energy source for the laser. Solid-state lasers are more powerful than gas lasers and require optical pumping. Gas lasers use a variety of gases as lasing media, including argon, CO_2, helium, helium-neon, and krypton and require an electrical source of energy for pumping. Complex dyes, dissolved in a liquid such as alcohol, constitute the lasing media in liquid lasers. Optically pumped, liquid lasers are tunable over a broad range of wavelengths, mostly in the visible spectrum. Excimer lasers use electrical stimulation to produce a dimer of a halogen such as chlorine and fluorine and an inert gas such as argon, krypton, or xenon. The dimer is unstable and quickly breaks down into its constituent atoms, releasing energy in the form of light. Semiconductor lasers, also called *diode lasers*, are composed of semiconductor crystals that are pumped by a high-intensity current. They are commonly used in compact disc players, laser printers, and laser pointers. The gallium-arsenide laser is an example of a semiconductor laser.

Modes of Operation

The majority of medical lasers deliver only one wavelength, and laser selection is dependent on the desired effect on the targeted tissue. The wavelength or color of the laser light is dependent on the laser medium, and the effect on tissue is dependent on the wavelength. In addition to selecting the appropriate wavelength, the surgeon must use the appropriate exposure time and energy density (power setting) to achieve the intended photomechanical, photothermolytic, or photochemical effect.

A laser beam can be delivered in a continuous wave (CW), pulsed-wave, or Q-switched mode. In the CW mode, the laser continues to emit a steady beam as long as the laser medium is excited. Output is measured in watts and can vary significantly among lasers. For example, the power of the helium-neon laser is measured in milliwatts, whereas the output of the more powerful CO_2 laser is measured in kilowatts. Power density of the beam (irradiance or flux) varies from a few watts per square centimeter to hundreds of watts per square centimeter.

Collateral tissue damage can be expected if the laser beam is held on tissue longer than the thermal relaxation time (i.e., time it takes for 50% of the laser energy to be thermally conducted to surrounding tissue). Pulsing the laser beam or scanning a continuous beam allows time for concentration of the energy, limits the exposure time, and minimizes thermal damage. In the pulsed mode, the laser emits peak energy levels in individual pulses from femtoseconds (quadrillionths of a second) to seconds. The power of a pulsed laser is measured in joules, and energy intensity is expressed as joules per square centimeter.

The duration of the laser beam is limited by computerized scanning of the laser beam in a preset pattern before delivery of the beam to the tissue. In the Q-switched mode, the laser emits high-energy, ultrashort pulses (approximately 10 to 250 nanoseconds [nsec]). A shutter is placed in the optical path to allow the buildup

of a large population inversion. After release of the shutter, the electrons fall rapidly to ground state, releasing a large amount of energy that is measured in megawatts.

Laser effects on tissue can be controlled by the mode of delivery. The Nd:YAG laser is used in the CW mode for coagulation of tumors, in the pulsed mode for hair removal, and in the Q-switched mode for tattoo removal. In the CW mode, the CO_2 laser can be focused very tightly and used for incision, much like a scalpel, whereas the defocused CO_2 laser can be used to vaporize a larger area of tissue. When delivered through a scanning device, the laser beam can remove a predetermined thickness of skin.

Fiberoptic cables are used for delivery of laser beams with visible and near-infrared wavelengths. Articulated arms with reflecting mirrors mounted in tubes are used to direct the beam of a far-infrared laser (CO_2). Additional devices may be attached to the fiberoptic cables or articulated arms, including slit lamps for use on the eye, operating microscopes, and insulated fibers for use with endoscopes. Contact laser probes (sapphire) attached to the distal end of a fiberoptic bundle transform the light energy into heat for precise cutting and reduced penetration.

EFFECTS OF LASERS ON BIOLOGIC TISSUES

Lasers are associated with rapid and precise vaporization or coagulation of tissues and are commonly used in a variety of unrelated diagnostic and therapeutic procedures. Laser light is monochromatic and has very selective effects on biologic tissues. The degree of laser light transmission, scattering, reflection, or absorption is dependent on the tissue and the wavelength of the light. Absorption of the light is necessary for the laser to be effective; if the tissue transmits, reflects, or scatters the light, the laser will have little or no effect on the tissue. A specific wavelength may be absorbed by one type of tissue and transmitted by another. Biologic tissues can be thought of as an aqueous solution of light-absorbing molecules. Chromophores, such as hemoglobin and melanin, and water are the main absorbing components, and they determine the reaction of the tissue to the laser light. To be effective, the laser light must match the absorptive property of the tissue. If light absorption occurs, the laser light is converted to heat; vaporization or ablation of the tissue occurs when the temperature reaches 100° C. As the tissue is vaporized, the thermal energy of the laser beam cauterizes capillaries and provides immediate hemostasis. A lower temperature would produce tissue coagulation or denaturation rather than ablation.

A tissue's reaction to light absorption depends on the wavelength, intensity, and exposure time of the light. Powerful, short pulses of laser light cause an explosive tissue expansion (photomechanical reaction), whereas low-power, long pulses cause a rapid increase in temperature (photothermal reaction) that results in tissue vaporization and coagulation. When applied for longer durations, low-power lasers can cause a chemical reaction or change in specific molecules (photochemical reaction). Laser light is also used to activate photosensitizing medications that are selectively absorbed by a specific tissue (photodynamic reaction). The effectiveness of nonthermal laser-assisted techniques is dependent on the ability of special drugs (photosynthesizers) to produce cytotoxicity in the presence of oxygen (O_2) after stimulation with light of an appropriate wavelength.

Tissue absorption is greatest with longer wavelengths such as the far-infrared wavelength of the CO_2 laser (10,600 nm). The CO_2 laser beam is completely absorbed by water in the first few cellular layers, resulting in explosive vaporization of the top layer but little or no damage to the underlying tissues. Excimer lasers (ultraviolet) are associated with an even more superficial effect because of their strong absorption by water. The light from lasers with visible wavelengths, such as the ruby, argon, and krypton lasers, is transmitted by water and absorbed by cells that contain dark pigment. It can penetrate the skin and the cornea to coagulate pigmented or vascular lesions. The light from near-infrared lasers, such as the Nd:YAG, is transmitted rather than absorbed by water. Because they have a greater tissue penetration, near-infrared lasers are better suited for deeper procedures such as tumor debulking. Advantages of lasers include precision, access to remote sites in the body, reduced blood loss, reduced damage to adjacent tissue, and improved patient satisfaction. A disadvantage of laser therapy may be delayed wound healing.

MEDICAL LASERS

The major types of lasers used in medicine are far-infrared (CO_2), mid-infrared (erbium [Er]:YAG, holmium [Ho]:YAG, Nd:YAG), near-infrared (diode), visible (ruby, krypton, argon, copper, and gold vapor), and ultraviolet (excimer). Commonly used surgical lasers are listed in Table 42-1.

Carbon Dioxide Laser

The CO_2 laser has wide application and is the most commonly used surgical laser. The infrared light produced by the CO_2 laser (10,600 nm) is invisible to the human eye, and a low-power helium-neon (He-Ne) laser (633 nm) is incorporated to provide a visible red beam for surgical aim. Because it emits light in the infrared region of the electromagnetic spectrum, the CO_2 laser is a powerful but dangerous laser. Infrared radiation is heat, and this laser basically melts through whatever its beam is focused on, including steel. It is a very precise laser; with the lateral zone of damage less than 0.5 *nanometer* (nm) from the area of incision. The CO_2 laser beam is not transmitted by quartz, glass, or other transparent material and must be delivered as a free beam or through a rigid endoscope with a mirrored, articulated arm. The CO_2 laser light is strongly absorbed by water, and vaporization of cells occurs within the first 100 to 200 μm of the irradiated surface. It can be used in both the CW and pulsed-wave mode. Focused into a tight beam, the CO_2 laser can be used for cutting. Defocusing the beam decreases the power density, and the tissue will be vaporized, or *ablated*. The CO_2 laser is used extensively in general surgery, orthopedics, gynecology, urology, and otolaryngology and is associated with minimal blood loss. When used with a scanning device, thin layers of the skin are ablated for skin resurfacing during cosmetic surgery. Because of its high power, the CO_2 laser is widely used in industry for cutting, drilling, and welding.

Yttrium-Aluminum-Garnet Lasers

The lasing medium of the YAG laser is a YAG crystal rod doped with atoms of rare earth minerals, which accounts for the different properties of the YAG lasers. YAG lasers can be used in the CW, pulsed-wave, or Q-switched mode.

Neodymium: Yttrium-Aluminum-Garnet Laser

The Nd:YAG laser emits a near-infrared invisible light at 1064 nm and requires the addition of a visible aiming beam. It has a penetration of 5 to 7 mm and can be used to cut or coagulate tissue. In the Q-switched mode, the laser removes black tattoo ink and hair. The Nd:YAG laser has important applications in internal debulking and is used to treat gastrointestinal and tracheobronchial tumors and genitourinary lesions. The pulsed and Q-switched Nd:YAG laser is used in ophthalmology. The energy of the Nd:YAG beam is more widely dispersed, and damage to adjacent tissues may not be evident for hours after the laser treatment.

Holmium: Yttrium-Aluminum-Garnet Laser

When doped with holmium (Ho), the YAG laser emits a mid-infrared beam at 2070 nm that is strongly absorbed by water. Output in the mid-infrared spectrum requires a coincident aiming beam. The Ho:YAG laser is used to vaporize, cut, coagulate, and sculpt avascular tissue with a minimal amount of thermal necrosis. The primary applications of the Ho:YAG laser are in endoscopic orthopedic procedures (bone and cartilage ablation) and urology (stone removal and transurethral resection of the prostate [TURP]).

Erbium: Yttrium-Aluminum-Garnet Laser

When a YAG laser is doped with erbium (Er), it emits a mid-infrared beam at 2940 nm (peak absorption of water). Because the infrared beam is not transmitted by quartz or glass, the Er:YAG can be used only as a free beam or through a rigid endoscope. It has limited penetration and excellent precision. It is used extensively in laser resurfacing of the skin and vaporization of fibrous tissue, cartilage, and bone. Because of its ability to penetrate dental tissue, the Er:YAG laser is also used in microdentistry for cavity fillings, root canals, and treatment of gum disease.

TABLE 42-1 Common Surgical Lasers

Laser	Wavelength	Applications
Far-Infrared		
CO_2	10,600 nm	Multiple uses: general surgery, orthopedics, gynecology, urology, otolaryngology, plastic surgery
Mid-Infrared		
Nd:YAG	1064 nm	Multiple uses: gastroenterology, pulmonology, urology, ophthalmology, dermatology
Ho:YAG	2070 nm	Orthopedics, urology
Er:YAG	2940 nm	Dermatology
Near-Infrared		
Diode	800-900 nm	Multiples uses: ophthalmology, otolaryngology, periodontics, cosmetic surgery, pain management Multiple nonmedical applications
Visible		
Argon	488 and 514 nm	Multiple uses: ophthalmology, plastic surgery, dermatology, gynecology, otolaryngology
Krypton	476, 521, 568 nm	Dermatology
Copper bromide	511 and 577 nm	Dermatology, photosynthesizer
KTP	532 nm	Dermatology
Pulsed dye	577-585 nm	Dermatology
Gold	578-628 nm	Oncology
Ruby	694 nm	Dermatology
Alexandrite	755 nm	Dermatology
Ultraviolet (Excimer)		
Argon-fluoride	193 nm	Multiple uses: ophthalmology, dermatology
Krypton-fluoride	249 nm	Dermatology
Xenon-chloride	308 nm	Multiple uses: dermatology, ophthalmology, dermatology
Xenon-fluoride	351 nm	Multiple uses: angioplasty, ophthalmology, dermatology

Er:YAG, Erbium: yttrium-aluminum-garnet; Ho:YAG, holmium:YAG; *KTP*, potassium-titanyl-phosphate; *Nd:YAG*, neodymium:YAG.

Diode Lasers

Diode lasers are semiconductors that emit a near-infrared light (800 to 900 nm) when pumped with a high-intensity electric current. Medical uses include ophthalmology, dermatology (hair removal), and periodontal surgery. Diode lasers are also used to "pump" other laser media such as YAG rods. They have multiple nonmedical applications and are used in laser printers, laser pointers, the entertainment industries, and fiberoptic communication systems.

Visible Lasers

Argon Laser

In an argon laser, the argon gas has lost one or more of its electrons, and the positive ions are excited by a large electrical discharge. The argon ion laser emits visible blue-green light with wavelengths of 488 nm and 514 nm simultaneously. The laser light is transmitted by water and absorbed by hemoglobin and melanin, where the main effect is photocoagulation. Penetration is approximately 1 to 2 millimeters (mm), but this can vary depending on the degree of pigmentation. The beam passes through quartz optical fibers, allowing the laser to be used with a microscope or endoscope. The argon laser is used in ophthalmology, plastic surgery, dermatology, gynecology, and otolaryngology.

Krypton Laser

The active medium krypton is also a rare gas with one or more electrons removed, and the krypton ions are excited by an electrical discharge. The laser produces visible green and blue light at 476, 521, and 568 nm. It is absorbed by hemoglobin and used for photocoagulation of vascular or pigmented lesions.

Ruby Laser

The ruby laser uses a synthetic ruby crystal of aluminum oxide doped with chromium. It emits a red light with a wavelength of 694 nm and has a penetration greater than 1 mm. The ruby laser light is absorbed by melanin and blue, green, and black pigment. It is very effective for tattoo removal, hair removal, and treatment of pigmented lesions such as freckles, liver spots, and nevi (Q-switched mode). Although the ruby laser was one of the first medical lasers, its use in surgery has declined in favor of newer and more powerful lasers.

Alexandrite Laser

Named after Czar Alexander II, the solid-state alexandrite laser contains a rod of synthetic chrysoberyl doped with chromium. It emits a deep red light at 755 nm, and frequency doubling of the alexandrite laser produces a tunable laser output of 360 to 400 nm. Blue and black pigments absorb the beam, with a lesser degree of absorption by melanin. It is used for tattoo removal, and treatment of some pigmented lesions.

Metal Vapor Lasers

The active medium of metal vapor lasers is a neutral metal heated beyond its vapor point. A pulsed electrical discharge is used for excitation of the vapor. Vaporized copper bromide emits green light at 511 nm and yellow light at 577 nm that is used to treat vascular lesions. It also has applications for facial resurfacing. The gold vapor laser (578 to 628 nm) is used in photodynamic therapy for cancer.

Potassium-Titanyl-Phosphate Laser

The wavelength of the Nd:YAG laser is halved when it is passed through a potassium-titanyl-phosphate (KTP) crystal. A solid-state laser, the KTP laser is similar to the argon gas laser. The beam is transmitted by water and absorbed within 1 to 2 mm of vascular or pigmented tissue. A bright green light (532 nm) delivered through fiberoptics, scanners, or microscopes is used to cut tissue (CW mode) and remove vascular lesions (pulsed mode) and red-orange and black tattoo ink (Q-switched mode). Although the power density of the KTP laser is sufficient to cut vascular tissue, it does not provide effective hemostasis.

Dye Lasers

Organic fluorescent materials are dissolved in a solvent such as methanol and are typically pumped with a flashlamp or another laser. The energy levels of the dyes are very close to one another and allow the lasers to release a wide range of wavelengths. In the CW and pulsed mode, dye lasers have wavelengths of 400 to 1000 nm. They can produce extremely short pulses (measured in trillionths of a second [picoseconds]). The major advantage of the dye laser is the ability to tune the wavelength to maximize the laser-tissue interaction. Dye lasers are used in dermatology for excision of vascular and pigmented lesions, in urology for treatment of urinary calculi, and in oncology for photodynamic therapy. The pulsed dye laser (PDL) uses a rhodamine dye to emit a yellow laser beam at 577 to 585 nm (peak absorption of hemoglobin). It is the laser of choice for treatment of port-wine stains and thick, red scars.

Excimer Lasers

Derived from the terms *excited* and *dimer,* excimer lasers use a medium composed of a reactive noble gas (chlorine or fluorine) and an inert halogen gas (argon, krypton, or xenon). When the medium is electrically stimulated, an unstable pseudomolecule (dimer) is produced. As the dimer breaks down to its constituent atoms, it releases light in the ultraviolet range that is strongly absorbed by water. Excimer lasers have a photochemical effect on targeted tissues (pulsed mode), with minimal thermal effect on the underlying tissue. The very short wavelength (ultraviolet) is capable of high resolution and has applications in microscopic surgery. Examples of excimer lasers include the argon-fluoride (193 nm), krypton-fluoride (249 nm), xenon-chloride (308 nm), and xenon-fluoride (351 nm) lasers. They are currently used in ophthalmology for photorefractive keratectomy (PRK) and laser-in-situ keratomileusis (LASIK). Other uses include removal of arterial plaques and treatment of psoriasis.

Cold Lasers

Cold lasers, also known as *low-level laser therapy (LLLT)* and *soft lasers,* use diodes to produce visible to infrared light. The laser beam can penetrate up to 2 inches without damaging tissues or producing a significant amount of heat. Through biostimulation of cellular metabolism, cold lasers speed up the healing process. They are used for treatment of carpal tunnel syndrome and other soft-tissue injuries.

Photodynamic Therapy

Photodynamic therapy (PDT) involves administration of photosensitizers, chemical entities that absorb light and induce a change in another chemical. They are used in the diagnosis of cancer because of their tendency to accumulate in cancer cells. They are also used to treat cancer. Approximately 72 hours after an intravenous administration, when the photosensitizer has left normal cells but remains in cancer cells, the tumor is exposed to laser light with a red wavelength. The photosensitizer absorbs the light and reacts with oxygen to produce free oxygen radicals that destroy cancer cells. Currently PDT is used to treat bladder, esophageal, and pulmonary tumors. It is also used in dermatology (local application) for treatment of acne, psoriasis, and skin cancer. New research supports the use of PDT in antimicrobial therapy because of its ability to target many viral and bacterial pathogens.

LASER SAFETY

Lasers are divided into four classes according to their potential for causing biologic damage (Table 42-2). Class I lasers are incapable of producing damaging radiation and are exempt from radiation hazard controls. This classification includes CD players and laser printers; supermarket laser scanners are classified as IA. Class II lasers emit radiation in the visible portion of the electromagnetic spectrum, but their radiant power is less than 1 mW. The human aversion reaction to bright light will protect the eyes, but injury

TABLE 42-2 Laser Classification

Class	Laser Description
Class I	Do not emit hazardous radiation and are exempt from radiation hazard controls. Typically continuous wave of 0.4 μW at visible wavelengths. *Examples:* CD players and laser printers, CD-ROM devices, geologic survey equipment, and laboratory analytical equipment.
Class IA	Includes lasers that are not intended for viewing. Maximum power is 4.0 mW. *Example:* supermarket laser scanners.
Class II	Do not cause ocular injury unless viewed directly for an extended period. The normal aversion response to bright light protects the eye from a brief exposure. Class II lasers only operate in the visible range (400-700 nm). Maximum power is 1 mW or less. *Examples:* helium-neon lasers and some laser pointers.
Class IIA	Special-purpose lasers not intended for viewing. Power output is less than 1 mW. Ocular injury can occur if viewed directly for more than 1000 seconds over an 8-hour day, not continuous exposure. *Examples:* scanners and bar-code readers.
Class IIIA	Do not pose a serious eye hazard unless viewed through optical instruments (e.g., microscopes). Power outputs for CW lasers operating in the visible range are between 1 and 5 mW. *Examples:* solid-state laser pointers.
Class IIIB	Direct beam viewing or specular reflections result in ocular injury. Power output is between 5 and 500 mW for CW lasers and less than 0.125 J within 0.25 second for a pulsed laser. Do not produce a hazardous diffuse reflection and are not considered fire hazards. *Examples:* spectroscopy, stereolithography, and entertainment light shows.
Class IV	Significant ocular injury can result from direct beam viewing, specular reflections, and diffuse reflections. These lasers require significant controls. Power output is greater than 500 mW for a CW laser and greater than 0.125 J within 0.25 second for a pulsed laser. Skin and fire hazards are also present with Class IV lasers. *Examples:* medical lasers and industrial lasers (drilling, cutting, and welding).

FIGURE **42-5** Danger sign indicating laser procedure in progress.

can occur if the beam is viewed directly for an extended period of time. Class II lasers include laser pointers and scanners. Class III lasers, which include spectroscopy and light shows, can cause eye injury if viewed directly. The direct beam and reflected beam of Class IV lasers are hazardous to the eye and are potential fire and skin hazards. Reflected laser beams are specular and maintain the beam coherence; diffuse beams are scattered when they are reflected from a rough or matte surface. Most medical lasers are Class IV; these lasers also create hazardous airborne contaminants and require a high-voltage power supply.

The U.S. Food and Drug Administration (FDA) regulates the manufacturing and marketing of lasers used in medicine; however, it does not regulate laser safety.[2] The American National Standards Institute's (ANSI) Z136.1–2007 standard addresses medical laser safety and defines control measures for the four laser classifications, which are applicable to medical, industrial, military, and educational laser safety programs.[3] The ANSI requires a laser safety officer (LSO) at institutions that use Class IIIB or Class IV lasers. The LSO is responsible for overseeing education, operation, maintenance, safety, and servicing of medical lasers. Compliance with the ANSI guidelines is voluntary. The Occupational Safety and Health Administration (OSHA) does not have specific regulations governing the safe operation and use of lasers but has identified the hazards associated with the use of medical lasers and developed safety standards to protect patients and operating room personnel.[4] The Association of periOperative Registered Nurses (AORN) and other professional organizations have also developed standards and recommendations for laser safety.[5,6]

When not in use, the laser should be disabled and stored in a secure location. Physicians and other licensed healthcare providers who use lasers should have appropriate training and institutional privileges for laser use. An aiming beam should be used for lasers that do not produce a visible light. Warning signs posted on the inside and outside of all entrances should include the type and wavelength of the laser in use, as well as the specific laser safety eyewear (LSE) required for everyone entering the laser area (Figure 42-5).

Restricted access is ensured through the use of a safety interlock system that will prevent unexpected entry or trigger a shut-off device for the laser if the door is unexpectedly opened. All other optical paths (windows) should be covered to prevent the transmission of a misdirected laser beam. A variety of laser-absorbing glass, plastics, laser safety curtains, and screens are available that attenuate the laser energy. If only CO_2 lasers are used, window coverings are not necessary, because glass absorbs laser energy at 10,600 nm. If a Nd:YAG or a laser with a similar wavelength is used, a laser-blocking shield is necessary to stop accidental exit of the laser beam. A windowless room provides the maximum protection. Surgical cabinets and large surgical instruments should have a matte or dull surface to avoid reflection of a misdirected laser beam. Surfaces of instruments can be made laser safe by sandblasting, ebonization, and anodization.[8] Lasers require high power and carry the potential for electrical injury.

The majority of laser-related accidents and injuries can be attributed to inappropriate use or intentional use of malfunctioning equipment. The most common hazards of medical lasers include thermal trauma, eye injury, perforation of organs or vessels, gas embolization, electrical shock, air contamination, and fire. Beam injuries are due to the direct effects of the laser on the eye and skin; nonbeam injuries are secondary and caused by laser-generated air contaminants (LGACs), fire, electrical shock, and noise.[7]

Thermal Trauma

The most common cause of laser-induced tissue damage is thermal in nature and usually requires exposure to high-energy beams for an extended period of time, resulting in a photochemical change or thermal burn. Tissue proteins are denatured after absorption of the laser energy, and tissue damage can range from mild reddening of the skin to blistering and charring. Skin trauma is dependent on the energy and wavelength of the laser. Longer wavelengths have a deeper skin penetration than shorter wavelengths; shorter wavelengths (400 to 700 nm) are nearly completely absorbed in the first 4 mm of the skin. Burns occur with exposure times greater than 10 μsec and wavelengths ranging from the near-ultraviolet to the far-infrared (315 to 10,300 nm). Ultraviolet-A (315 to 400 nm) exposure causes hyperpigmentation and erythema, but the greatest skin damage is caused by ultraviolet-B (UV-B) radiation (280 to 315 nm). In addition to thermal trauma, carcinogenesis is a potential risk of UV-B exposure. Exposure to ultraviolet-C (UV-C) waves (200 to 280 nm) is less harmful to the skin because they are predominantly absorbed in the outer dead layers of the epidermis. The CO_2 and other infrared lasers penetrate deeper and are associated with first-degree (reddening), second-degree (blistering), or third-degree (charring) burns. Lasers also may precipitate the development of or exaggerate existing skin lesions, including reactivation of viral infections.

Safety interventions to prevent thermal trauma include restricted access to the lasing area; restricted use of the laser system by qualified personnel; application of saline-soaked towels to the area of the patient's skin that surrounds the path of the laser beam, and use of long-sleeved jackets, gloves, and face shields by operating room personnel. Topical sunblock cream will protect against ultraviolet radiation for patients undergoing repeat laser treatments. In addition, liquid gases used for cooling of the laser medium, especially liquid nitrogen, are hazardous if accidentally spilled on the skin. Some of the chemicals used in dye lasers are toxic and hazardous to handle.

Eye Trauma

Because incandescent and fluorescent light are *not* coherent, only a small portion of the energy is spread out over the retina, and these light sources do not harm the human eye. In contrast, the human eye is extremely vulnerable to laser radiation because it *is* coherent, and all of its energy can be focused on a very small portion of the cornea or retina. Eye trauma from laser light is dependent on the power and wavelength of the laser beam, exposure duration, pupil size, retinal pigmentation, and location of the injury. Pulsed-mode lasers present an additional hazard to the eye; laser pulses of

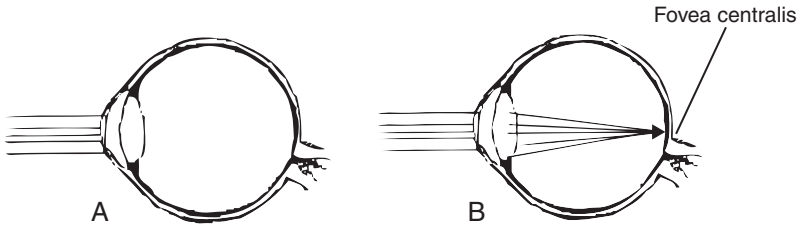

FIGURE **42-6** Laser-associated eye injury. **A,** Mid- and far-infrared wavelengths (less than 400 nm and greater than 1400 nm) are absorbed by the cornea and associated with corneal injury. **B,** Retinal injury is associated with visible and near-infrared (400-1400 nm) wavelengths.

less than 10 microseconds induce shock waves that rupture tissue, resulting in a larger area of permanent retinal damage.

Ultraviolet (200 to 400 nm) and mid-infrared (1400 to 3000 nm) radiation are absorbed by the cornea and can cause corneal photokeratitis (Figure 42-6). Visible lasers and near-infrared lasers (400-1400 nm) are associated with retinal injury. Mid-infrared wavelengths greater than 1400 nm are absorbed by water and cause damage to the cornea and increase the opacity of the lens, resulting in traumatic cataracts; they are also associated with aqueous flare, an increased turbidity of the aqueous humor. Far-infrared radiation (3000 to 10,000 nm) is absorbed by the cornea and can result in corneal burns and potential loss of vision. Inadvertent exposure to the invisible CO_2 laser beam (10,600 nm) causes burning pain of the cornea or sclera. There are no immediate signs of exposure to ultraviolet radiation, but severe eye pain and a sensation of sand in the eye may be present later. After minor injury, regeneration of the epithelium occurs without any permanent abnormality, but corneal scarring and cataract formation may result with more extensive injury. Table 42-3 lists the effect of lasers on eyes and skin.

TABLE **42-3** Effect of Lasers on Eyes and Skin

Laser	Eye Effect	Skin Effect
Ultraviolet C (200-280 nm)	Photokeratitis	Erythema (sunburn)
Ultraviolet B (280-315 nm)	Photokeratitis	Increased pigmentation
Ultraviolet A (315-400 nm)	Photochemical cataract	Darkening/burn
Visible (400-700 nm)	Photochemical and thermal retinal injury	Darkening/burn
Infrared A (700-1400 nm)	Cataract, retinal burn	Burn
Infrared B (1400-3000 nm)	Cataract, corneal burn, aqueous flare	Burn
Infrared C (3000-10,000 nm)	Corneal burn	Burn

The retina is composed of two types of photoreceptors, rods and cones. Rods make up over 95% of the retina; they are sensitive to light but not color. Cones make up less than 5% of the total retinal area and are responsible for detecting color and fine detail. They are heavily concentrated in the fovea centralis, an area associated with the sharpest and most brilliantly colored vision. Retinal damage is associated with visible and near-infrared (400 to 1400 nm) lasers. The beam is transmitted by the cornea and focused by the lens to produce an intense concentration of light energy on a small portion of the pigmented retina. Focusing of the laser by the lens amplifies the irradiance on the retina 100,000 times (see Figure 42-6). The conversion of the light energy to heat can cause retinal burns, visual loss, or total blindness. One milliwatt of visible laser radiation entering the eye deposits 100 W/cm^2 at the retina. Wavelengths less than 400 nm and greater than 1400 nm are not associated with retinal damage.

A visible laser beam produces a bright color flash of the emitted wavelength followed by an afterimage of its complementary color (e.g., a green, 532-nm laser light would produce a green flash followed immediately by a red afterimage). If the individual's cones are damaged by a green laser light, he or she may have difficulty discriminating between blue and green colors thereafter. The Q-switched Nd:YAG laser beam (1064 nm) is especially hazardous to the eye because the beam is invisible, and the retina lacks sensory innervation. Visual disorientation resulting from retinal damage may not be apparent until considerable thermal damage has occurred. Unlike corneal injuries, laser damage to the retina is permanent.

Acute and chronic loss of color sensitivity has been reported in ophthalmologists who frequently use surgical lasers. The Rockwell Laser Industries maintain a voluntary reporting database of laser accidents; in recent years the majority of the reports have involved temporary blindness of in-flight aircraft pilots by the accidental or intentional use of laser pointers from the ground.

All medical lasers are Class IV lasers, and laser safety eyewear (LSE) is required to prevent injury from the direct laser beam or reflected laser light from surgical instruments, cabinets, lights, watches, jewelry, and other smooth reflective surfaces in the operating room.[8] Although LSE will protect against accidental exposure to a laser beam, they will not protect against intrabeam or direct viewing of a laser beam. The eye aversion or blink response of 0.25 second is triggered by bright, visible light only. It will not prevent the trauma of invisible laser beams and provides no protection against lasers with a wavelength of 700 to 1400 nm. In addition, the aversion response is absent or sluggish under general anesthesia and deep sedation. In operating rooms darkened for video and microscope use, the pupils of the eyes will dilate and increase the risk for laser exposure for both surgical personnel and awake patients. During laser procedures, operating room personnel and awake patients must wear LSEs specific for the type of laser in use. An anesthetized patient's eyes should be covered with saline-moistened eye pads and laser shields. Petroleum-based eye ointments should not be used during laser procedures because they may cause severe burns if ignited by a misdirected laser beam.

The maximum permissible exposure (MPE) is the level of laser radiation exposure not associated with biologic changes in the eye. It is directly related to the wavelength and inversely related to the exposure time and expressed as radiant exposure (J/cm^2) or irradiance (W/cm^2). The ANSI Z136.1–2007 standard identifies acceptable MPE levels for medical lasers.[3] The nominal hazard zone (NHZ) refers to the physical space in which the direct,

reflected, or scattered laser radiation exceeds the MPE. During laser procedures, the entire operating room is considered to be within the NHZ; however, it may extend beyond transparent windows for certain lasers.

During laser procedures, LSE must be worn by everyone in the room. The LSE must have the appropriate optical density (OD) and reflective properties for the laser wavelength, the beam intensity, and the expected exposure conditions; it must also have side shields. Optical density (OD) refers to the ability of a material to attenuate or absorb energy of a specific wavelength to a safe level below the MPE while allowing transmission of sufficient ambient light for safe visibility. OD = $\log_{10}$ (E_i /E_t) where E_1 is the incident beam irradiance (W/cm^2) or worst-case scenario, and E_2 is the transmitted beam irradiance (MPE limit in W/cm^2).[3] A LSE with an OD of 2 will allow transmission of 1/100 of the laser energy; in contrast, LSE with an OD of 4 will allow transmission of only 1/10,000 of the laser energy. The OD is rated for a specific wavelength or range of wavelengths; use with a different wavelength will result in a completely different OD value. Because LSE are laser specific, the wavelength and OD are imprinted on the LSE, and users must ensure they are wearing the appropriate LSE for the laser in use. For example, LSE for the ND-YAG laser has an OD of 6 at 1064 nm, whereas LSE for the CO_2 laser has an OD of 7^+ at 10,600 nm. In addition, LSE with an OD of 4 and a wavelength of 755 nm will not protect against a laser beam that requires LSE with an OD of 6 and a wavelength of 755 nm. Lasers also may operate at different wavelengths, for example, doubled Nd:YAG lasers, and tunable lasers, such as the titanium-doped sapphire laser, require different levels of protection at each wavelength and may require the use of two different LSE. Certain lasers require amber-, green-, or red-colored filters, but the color of the LSE lens should not be used for LSE identification. Vision correction glasses may attenuate the effect of the CO_2 laser beam but do not completely protect the eye from direct or reflected laser beams because they lack protective side shields. Medical lasers generally require a LSE of 4 to 7 OD. There are no laser glasses available that protect against all types of laser beams; LSE that cover several wavelengths would require very dark filters, which would interfere with visual acuity.

Perforation

Operator error, such as a misdirected laser beam or failure to check for proper laser function before use, accounts for the majority of laser perforations of a viscus or vessel. A pneumothorax can be a life-threatening complication of a misdirected laser beam, especially during the administration of nitrous oxide (N_2O). Lasers cannot photocoagulate blood vessels larger than 5 mm, and unexpected or excessive bleeding may accompany an accidental perforation with a misdirected beam. Because of greater tissue penetration and dissemination, perforation with the laser beam of the Nd:YAG laser is associated with delayed tissue damage. Perforation, bleeding, or edema may not be apparent for hours to days. Patients undergoing Nd:YAG laser surgery of the airway should be monitored for 24 to 48 hours after the procedure.

Embolism

Some lasers require a coolant to protect the tip of the quartz fibers from overheating. The coolant may be air, CO_2, or a liquid. Although it is a rare event, venous gas embolism is a potential fatal hazard of laser procedures, especially with the gas-cooled Nd:YAG laser.[9] Coronary and cerebral embolisms have occurred during endobronchial Nd:YAG therapy, and transmyocardial laser revascularization is also associated with cerebral microembolization. Fatal venous air embolism has been reported during Nd:YAG hysteroscopies. A liquid coolant will reduce the risk of air embolism. CO_2 emboli appear to be less damaging than air or nitrogen emboli.

Laser-Generated Air Contaminants

Thermal destruction of tissue with a laser or electrosurgical unit (ESU) creates a smoke plume that may contain toxic gases and vapors, including benzene, hydrogen cyanide, formaldehyde, dead and live cellular material, carcinogens, and viruses.[7,10,11,12] It is estimated that approximately 500,000 healthcare workers are exposed to laser or electrosurgical smoke every year.[13] Contaminants in the surgical smoke plume have the potential to cause respiratory, ocular, dermatologic, and other diseases, including cancer, in patients and operating room personnel.

The CO_2 laser produces the greatest amount of smoke. During the use of the CO_2 laser, the amount of smoke produced from 1 gram of tissue is equivalent to the smoke from three to six cigarettes. The smoke plume may contain fine particulates (0.3 μm) that can be deposited in the lower airways. In addition to ocular and respiratory irritation, the smoke plume has the potential for causing cellular mutations. Because lasers are commonly used to vaporize tumors and viral lesions, concern exists that the laser plume may contain infectious material and viral DNA. There are no specific OSHA standards addressing the hazards of the surgical smoke plumes, other than expecting employers to advise employees of the hazards of surgical smoke.[13]

The National Institute for Occupational Safety and Health (NIOSH) recommends the use of a local exhaust ventilation system—for example, a portable smoke evacuator—as the most efficient method to control laser-generated smoke. It should contain a high-efficiency particulate air (HEPA) filter or equivalent for trapping particulates, and the suction nozzle should be kept within 2 inches of the surgical site to effectively capture airborne contaminants.[14] Evacuation tubing, filters, and absorbers should be considered infectious waste, and new filters and tubing should be installed before each procedure.

A triple filtration smoke evacuator is indicated for evacuation of a large smoke plume. Three-stage disposable filter systems include a HEPA filter that can filter 0.3-μm particulate matter, a layer of activated charcoal for odor absorption, and an ultra–low-penetration air (ULPA) filter that can filter particulate matter as small as 0.01 μm. High-filtration masks (0.3 μm) should be worn by operating room personnel to filter out particulate matter and noxious odors. A close-fitting surgical mask can filter particulate matter as small as 5 μm but is ineffective when moist. In addition to high-efficiency mask, AORN recommends the use of protective eyewear and gloves.[10] Despite the support from professional organizations for active smoke evacuation during all laser procedures, the lack of a regulatory OSHA mandate continues to place many operating room personnel at risk for exposure to the laser-generated air contaminants.[11,13]

Reasons for noncompliance with smoke evacuation recommendations include lack of smoke evacuation equipment or supplies, surgeon's refusal to use the devices, increased noise of the smoke evacuators, and lack of training regarding the health risks of surgical smoke.[15,16] Use of an evacuator is less likely to occur during laser procedures in an outpatient or office practice setting. Laser safety precautions can be found in Box 42-1.

Electrical Hazards

Lasers require high-voltage circuits and present a risk for electrical shock and electrocution. Contributing factors include damaged electrical cords, inadequate grounding, inadequate safeguards,

BOX **42-1**

Laser Safety Precautions

- Restrict laser use to qualified personnel.
- Restrict access to laser area during laser operation.
- Close all doors and cover windows.
- Post Laser Warning signs inside and outside the laser area.
- Use appropriate laser safety eyewear (LSE) for personnel and awake patients
- Provide eye protection for anesthetized patients.
- Provide skin protection for patients and operating room personnel
- Minimize the potential for specular reflections by removal of unnecessary shiny surfaces form from the room.
- Maintain room lights as bright as possible to constrict the pupils.
- Adjust brightness of patient monitors to ensure appropriate degree of visibility with LSE.
- Require surgeon to warn of activation of laser and to keep the beam path above or below normal eye level (less than 4.5 feet or greater than 6.5 feet).
- Use an aiming beam or operational warning devices for lasers with invisible beams.
- Avoid looking into the primary beam at all times.
- Place laser in standby mode when it is not in active use.
- Do not leave an active laser unattended.
- Restrict maintenance of laser to authorized individuals who are trained in laser maintenance.

lack of compliance with safety procedures, and use by unqualified personnel. Older laser models that use an external water cooling system present a great electrical hazard. Electrocution is the leading cause of laser-related injury and death in all industries. Laser repair technicians appear to have the highest risk in the healthcare community.[7]

Fire

According to the Emergency Care Research Institute (ECRI), an independent, nonprofit organization that researches the safety, quality, and cost-effectiveness of patient care, there are approximately 600 surgical fires annually in the United States. The ECRI has ranked surgical fires as the ninth-highest technology hazard of 2011.[17] Historically, surgical fires were associated with the use of explosive or flammable anesthetics. When the use of these anesthetics was discontinued in the 1970s, sensitivity of the operating room staff to the possibility of a fire decreased. However, the risk of a surgical fire is still a very real but preventable hazard of modern surgery.[18,19] The number of surgical fires has increased and is primarily associated with the use of electrocautery units (ESUs) and surgical lasers. Unlike ESUs, lasers do not require direct contact to ignite a fuel source.

Electrocautery units and lasers account for 68% and 13% respectively of airway fires. The most common site of surgical fires is the airway (34%) and head or face (28%). In 74% of the cases, an oxygen-enriched environment was a contributing factor. In a survey of otolaryngologists, 25% of respondents had personally witnessed at least one fire in the operating room.[20] Immediate recognition and management of a surgical fire can limit patient injury, whereas delayed recognition and response can be fatal for the patient. In addition to burns, patient injuries include inhalation of toxic products of combustion, namely, carbon monoxide, ammonia, hydrogen chloride, and cyanide, that can cause significant airway and pulmonary damage. In 2003 the Joint Commission issued a Sentinel Event Alter for preventing surgical fires. In 2008 it listed reduction of surgical fires as the 11th National Patient Safety Goal, which addressed the need for education of operating room personnel, control of heat sources and fuels, and minimization of oxygen concentrations under the surgical drapes.[21]

For a fire to occur, three components of the fire triangle must be present: a fuel source, an ignition source, and an oxidizer. All three components are frequently present in the operating room, and a fire can occur any time the three components are allowed to interact. Everyone in the operating room must understand the fire hazards presented by all three sides of the fire triangle, including those not under their direct control.[22-24] Vigilance is key, and communication among all members of the surgical team is mandatory. It is imperative that all surgical personnel are aware of the hazards of fire during laser procedures and know how to prevent and respond to operating room fires.

Fuel Sources

Fuel sources are abundant in the operating room and are predominantly under the control of the nursing staff. They include surgical preparation solutions, petroleum-based ointments, facial hair, surgical drapes, gloves, ointments, sponges, dressings, endotracheal tubes, laryngeal mask airways, breathing circuits, nasogastric tubes, suction catheters, pneumatic tourniquet cuffs, Silastic stents, suction catheters, and tracheostomy tubes. Bowel gas, which contains methane and hydrogen, also provides a fuel source during intraabdominal laser procedures. Volatile organic chemicals such as alcohol, acetone, and ether are common components of skin preparations, tinctures, degreasers, suture pack solutions, and liquid wound dressings. Alcohol and alcohol-based solutions are very volatile and pose a significant fire hazard in the operating room. If adequate drying time is not provided, the laser can ignite the alcohol vapor. This is more likely to occur in a confined space (e.g., tented drapes) and an oxygen-enriched environment. Care must be taken to ensure that the surgical preparation solution does not pool under the patient or saturate the drapes. Alcohol-based hand sanitizers also may release alcohol vapor, which is flammable, and poses a new fire hazard in operating rooms. Although they will resist ignition and slow the spread of a flame in room air, fire-retardant drapes and materials are not fireproof. Materials considered nonflammable may ignite easily and burn more quickly and at a higher temperature when exposed to an oxidizer-enriched environment.

Endotracheal tubes are a fuel source during airway surgery, if the laser beam or reflected laser light comes into direct contact with it. Localized thermal trauma occurs if the fire is contained to the outside of the endotracheal tube. Rupture of the endotracheal-tube cuff allows leakage of anesthetics gases into the path of the laser beam, increasing the risk of an ignition. If the fire burns through to the inner side of the tube, an intraluminal fire occurs, fed by both the anesthetic gases and the volatile products of combustion of the endotracheal-tube wall. The intraluminal flame will travel toward the source of the oxidizer. A secondary flame can shoot out of the distal end of the endotracheal tube like a blowtorch and cause extensive lower airway damage.

During surgical procedures that involve lasers or ESUs, careful attention to possible fuel sources is paramount. A basin of water or normal saline should be available during laser procedures to extinguish a burning endotracheal tube or other material. Two syringes filled with normal saline should be readily available to extinguish an airway fire. Use of excessive tape to secure the endotracheal tube should be avoided to allow easier removal of the tube in the event of an airway fire. Emergency supplies, including

BOX **42-2**

Prevention of Surgical Fires

- Educate surgical personnel on the fire triad and common sources of fuels, ignition, and oxidizers in the operating room (OR).
- Schedule annual mandatory fire drills for the entire OR team and include evacuation of anesthetized patients in the event of an uncontrolled surgical fire.
- Identify location of fire alarms and extinguishers and shut-off valves for pipeline gases.
- Avoid open air administration of supplemental oxygen.
- Administer supplemental oxygen through an ETT or LMA.
- Limit supplemental O_2 to 30%.
- Alert surgical team members to potential sources of fire: oxidizers, fuels, and source of ignition.
- Avoid pooling of preparation solutions and allow adequate drying time before draping patient.
- Coat facial hair with a water-soluble surgical lubricant during head and neck surgery.
- Use flame-retardant drapes and moistened sponges and towels in the area of the laser.
- Use laser-resistant endotracheal tubes during laser surgery of the upper airway. Inflate the cuff with saline and dye to allow early recognition of tube rupture.
- Use moistened sponges to prevent air leaks, especially when using uncuffed tubes during airway surgery. Sponges and pledgets should also be moistened to resist ignition.
- Use a properly applied incise drape to help isolate head, neck, and upper-chest incisions from oxygen-enriched atmospheres and flammable vapors.
- Use continuous suction to minimize the buildup of O_2 in the oropharynx during airway surgery and beneath the drapes during monitored anesthesia care for head and neck surgery.
- Have immediately available a container of water to extinguish burning materials. Two syringes of sterile saline should be available during laser surgery of the airway.
- Have fire extinguishers available in the room or immediately accessible.
- If possible, discontinue supplemental oxygen at least 1 minute before and during laser use for head and neck surgery, and especially surgery of the airway.

ETT, Endotracheal tube; *LMA*, laryngeal mask airway; O_2, oxygen.

a rigid bronchoscope and forceps, should also be readily available. A carbon dioxide fire extinguisher (Class BC) is appropriate for extinguishing surgical fires. The BC fire extinguisher leaves no residue and will not damage human tissue. Dry powder extinguishers (Class ABC) are inappropriate as the first response because the powder (ammonium phosphate) contaminates all surfaces, is a respiratory irritant, and may interfere with visibility. Recommendations for prevention of surgical fires are listed in Box 42-2.

Oxidizers

Oxidizers present in the operating room include air, O_2, and N_2O, and are under control of the anesthetist. Oxygen is heavier than air and tends to accumulate in low-lying areas such as around surgical drapes. In an oxygen-rich environment, materials ignite faster, burn quickly with greater intensity, release more heat, and are more difficult to extinguish.

Ignition Source

The surgeon generally controls the sources of ignition; these include ESUs, fiberoptic light sources or cables, high-speed drills, and lasers. However, electrical sparks from malfunctioning equipment not under the surgeon's control, including monitors and defibrillators, also can result in a fire. Desiccated soda lime is another possible source of ignition in the breathing circuit.

Prevention of a Surgical Fire

Operating room personnel must be educated on the prevention of surgical fires. They need to understand the fire triangle, be able to identify the procedures that present a risk of fire, understand their role in preventing a surgical fire, and know how to respond to a surgical fire. A number of professional organizations have developed practice guidelines and educational resources to assist healthcare institutions develop policies and procedures that address fire prevention and effective response strategies to a surgical fire.[25] In collaboration with the Anesthesia Patient Safety Foundation (APSF), the ECRI developed a clinical guide to surgical fire prevention.[26] The American Society of Anesthesiologists (ASA) have an operating room fire algorithm for both airway and nonairway fires.[27] Fire posters are available on the ECRI website, and a free video on the prevention and management of operating room fires is available on the APSF website.[28,29]

Surgical personnel must be familiar with the location and function of fire alarms, fire extinguishers, and emergency exits and should know how to shut off electrical and medical gas supplies. They should be aware of the fire hazards present in the laser area, such as anesthetic gases, skin preparation solutions, adhesive plastic tape, and surgical drapes. Every operating room should have a fire safety plan in place that includes mandatory fire drills for all operating room personnel including anesthesia providers and surgeons.[26,27] Simulation of a surgical fire scenario in a high-fidelity simulation center provides an excellent opportunity for team training in the prevention and management of a surgical fire.[30]

Anesthetic Gases

Administering an oxygen concentration of less than 30% will reduce the risk of a rapid and widespread propagation of fire, that is, a flash fire. The new clinical guidelines developed by the ASA, ECRI, and the APSF advise against the use of 100% oxygen during head, face, neck, and upper chest surgery.[26 27,29] Air, not oxygen, should be used for open delivery for patients who can maintain a safe oxygen saturation. For patients with normal pulmonary function, low-dose sedatives and narcotics can be administered without supplemental oxygen. Pulse oximetry will identify the patient who may require supplemental O_2, as well as the patient who can tolerate short periods of ventilation with room air. Mild drug-induced respiratory depression that results in a stable decrease in saturation as low as 92% does not require supplemental oxygen. Saturation of 90% or less is undesirable. If supplemental oxygen is necessary, the airway should be secured with a laryngeal mask airway (LMA) or endotracheal tube, and oxygen concentration should be the lowest possible to support acceptable patient oxygenation and should not exceed 30%.[26,27,29,31] Buildup of oxygen should be minimized by scavenging the operative site with suction. During airway surgery, the oropharynx should be suctioned throughout the procedure.

If supplemental O_2 via a mask or nasal cannula is necessary, it should be discontinued at least 1 minute before and during laser use; this will close communication between the anesthetist and the surgeon who must give adequate notice of his intent to activate the laser. Nitrous oxide readily supports combustion and should be avoided in cases with potential for fire. Suitable gases include O_2 and air, O_2 and nitrogen, and O_2 and helium. Helium has a high thermal conductivity and is more resistant to ignition. In addition, its lower viscosity can help overcome the increased resistance resulting from smaller internal diameter (ID) tubes or airway obstruction.

TABLE 42-4 Gas Mixtures That Deliver 30% Oxygen or Less

Air (L/min)	Oxygen (L/min)	Total Gas Flow (L/min)	O_2 Concentration
0.89	0.11	1	29.7%
1.78	0.22	2	29.7%
2.7	0.30	3	28.9%
3.60	0.40	4	28.9%
4.45	0.55	5	29.7%

Volatile anesthetics are nonflammable, but their use is not recommended during airway laser procedures because they may deteriorate to potentially toxic compounds in the presence of a fire.[3] Gas mixtures that deliver 30% oxygen or less are listed in Table 42-4.

Endotracheal Tubes

Polyvinyl chloride (PVC) tubes ignite easily and produce toxic materials that can increase the amount of damage to the airway. PVC tubes appear to be more susceptible to damage by the CO_2 laser; however, the presence of blood on the tube makes a PVC tube also susceptible to damage by the Nd:YAG laser. The radiopaque barium sulfate strip found on most PVC tubes has a faster ignition rate than the PVC. Red rubber tubes appear to be more resistant to initial ignition, have a slower rate of burn, and produce less toxic smoke. However, they tend to melt and can produce carbon monoxide. Although silicone tubes are also less combustible, inhalation of silica ash may produce pulmonary damage.

Laser-resistant endotracheal tubes should be used during laser surgery of the airway.[32] The Laser-Flex tracheal tube (Nellcor) is a flexible stainless steel tube with a matte finish that is resistant to the CO_2 and KTP lasers. In the event of a proximal-cuff rupture with a laser beam, the distal cuff will maintain a tracheal seal and prevent anesthetic gases from leaking into the path of the laser beam. The Lasertubus (Rüsch) is a soft, white rubber tube that is resistant to the argon, Nd:YAG, and CO_2 lasers. The lower 17 cm of the tube is covered with a Merocel Laser Guard wrap that dissipates the laser light and prevents backscatter. Soaking the tube in water will reduce ignition potential. The Lasertubus has two high-volume cuffs, one inside the other. The Bivona Fome-Cuf (Portex), a silicone and aluminum spiral tube, is designed for use with the CO_2 laser. It has a polyurethane self-inflating foam cuff covered with silicone that is designed to maintain a tracheal seal in the event of a cuff rupture. Inability to deflate the foam after cuff rupture is a recognized problem with this tube. The Laser Shield II (Medtronic), a reflective aluminum-wrapped silicone tube with a smooth fluoroplastic covering, is specific for use with CO_2 and KTP lasers. The cuff is designed to be inflated with saline, and methylene blue is present in the inflation valve for immediate detection of cuff rupture. The Laser-Trach (Kendall/Sheridan) is a red rubber tube with an embossed copper foil for use with CO_2 and KTP lasers.

Application of a metallic foil wrap (aluminum or copper) or a thin metal-coated plastic tape has been used to protect PVC and red rubber endotracheal tubes during laser surgery of the airway, but this practice should be discouraged. Recognized problems with foil wrappings include laser reflection damage, potential areas of exposed tube, unprotected cuff, the need to use a smaller ID tube, and airway damage from the sharp edges of the foil wrap. Only the Merocel Laser-Guard endotracheal tube wrap (Medtronic) has FDA approval for endotracheal-tube protection.

Laser-resistant endotracheal tubes are not laser-proof and carry the inherent risk of ignition. Cuff rupture is often the prelude to an airway fire. The cuffs should be inflated with normal saline; addition of methylene blue may alert the surgeon to cuff rupture.[27] The endotracheal-tube cuff should be fully inflated and a stethoscope used to confirm the absence of a leak before the laser is used. Saline-moistened cotton gauze should be placed proximal to the endotracheal-tube cuff. The gauze and the attached cotton strings should be constantly remoistened. At least 1 minute should elapse before a laser is used after reinflation of an endotracheal-tube cuff or repositioning of the endotracheal tube for correction of a leak.

LMAs have been tested with the KTP and Nd:YAG lasers. The tube of the standard silicone mask is more resistant to the laser beams than the disposable PVC tube, but the PVC cuff is more resistant than the silicone cuff. The intubating LMA (silicone and steel) is more sensitive to the KTP laser. The presence of blood increases the vulnerability of all the LMAs, especially with the KTP laser. Additional precautions for use of an LMA during laser procedures include inflation of the cuff with saline and methylene blue and protection of the cuff with moistened gauze. The use of 5 to 10 cm H_2O positive end-expiratory pressure (PEEP) has been advocated during laser surgery of the airway to prevent the hot, toxic gases from reaching the lower airways.

Management of a Surgical Fire

Fire must be anticipated during any laser procedure. Communication among all members of the surgical team is vital for the prevention of and coordinated response to a surgical fire. Fire management includes early recognition, halting of procedure, extinguishing the fire, evacuation if appropriate, and postoperative care of the patient.[26,27] For a nonairway fire, all gases should be discontinued and all drapes and burning material removed from the patient and extinguished with saline, water, or by smothering. The patient should be immediately assessed for thermal trauma or smoke inhalation. In the event the fire spreads, the acronym *RACE* is applicable: ***R***escue the patient, ***A***lert other staff and ***a***ctivate the fire alarm systems, ***C***onfine the fire by shutting doors, closing off gas supplies and electrical power, and using fire extinguishers, and ***E***vacuate the room.

In the event of an airway fire, the anesthetist has approximately 6 seconds for recognition and removal of an endotracheal tube that has ignited. Signs of an airway fire include darkening of the endotracheal tube or breathing circuit with soot, an orange or red glow to the endotracheal tube, and the presence of flames in or around the endotracheal tube. The endotracheal tube acts like a blowtorch, with high concentrations of O_2 adding to the intensity of the fire. Within seconds the flames can reach a height of 5 to 10 inches. Intraluminal fires will spread toward the proximal end of the tube—the source of the O_2. Severe thermal or chemical trauma is unlikely to occur if the flame is vented through the tube or oropharynx. Downstream gases contain the products of oxidation and little O_2, but a free-end fire can occur if the products of oxidation ignite in the O_2-rich alveoli.

In rapid succession, the endotracheal tube should be removed, all flammable and burning material removed from the airway, all gases discontinued, and saline poured into the patient's airway to extinguish any residual smoldering material and cool the tissues.[26,27] Ventilation should be resumed, but an oxygen-enriched gas mixture should be avoided until all risk of re-ignition is eliminated. The endotracheal tube should be examined for intactness, and direct visualization of the tracheobronchial tree with a rigid bronchoscope is recommended for assessment of thermal injury and removal of foreign material including endotracheal tube fragments. A flexible bronchoscope may be necessary for evaluation

BOX **42-3**

Management of Airway Fires

- Discontinue use of laser.
- In rapid succession, remove ETT, turn off all gases, remove sponges and any flammable material, and pour saline into airway.
- Extinguish burning ETT/LMA in basin of water.
- Resume ventilation with air. Ventilate with 100% O_2 only when the fire is extinguished.
- Examine airway and remove residual debris with rigid bronchoscope. Consider lavage with normal saline. Examine small and distal airways with flexible fiberoptic bronchoscope.
- Administer humidified O_2 by mask if airway damage is minimal and risk of laryngeal edema is low.
- If indicated, reintubate with a smaller ETT.
- Assess extent of thermal trauma with ABG, carboxyhemoglobin levels, and CXR.
- Keep patient intubated and administer 40% to 60% humidified O_2 if airway burn is present or suspected.
- Consider tracheostomy and mechanical ventilation for postoperative management.
- Consider administration of steroids.
- Admit patient to ICU for a minimum 24-hour observation.
- Retain all equipment and materials involved in the fire for further inspection.
- Reassemble surgical team to identify the sequence of events that led to the surgical fire.
- Report fire as a sentinel event to The Joint Commission, ECRI, and the FDA.

ABG, Arterial blood gas; *CXR*, chest x-ray; *ECRI*, Emergency Care Research Institute; *ETT*, endotracheal tube; *FDA*, Food and Drug Administration; *ICU*, intensive care unit; *LMA*, laryngeal mask airway; O_2, oxygen.

of distal airways, and tracheobronchial lavage with saline solution should be considered. If reintubation is indicated, a smaller endotracheal tube should be used; a chest x-ray (CXR) and arterial blood gases (ABGs) are indicated to guide postoperative management. Carboxyhemoglobin (CoHgb) levels are needed for assessment of smoke inhalation.

After an airway fire, 24-hour observation of the patient is indicated. For minor burns, the patient should be monitored for development of laryngeal-tracheal edema. A patient with severe burns should remain intubated and receive 30% to 60% humidified O_2. A tracheostomy and mechanical ventilation with PEEP should be a definite consideration. Corticosteroids have been recommended for the treatment of both smoke inhalation and the bronchospasm that may be precipitated in patients with irritable airways. Additional treatment is dependent on the extent of the injury and the response of the patient. Complications may be delayed, and tracheal stenosis can occur months after an airway fire. A monthly laryngoscopy or bronchoscopy may be indicated for up to 6 months. All equipment and materials involved in a surgical fire should be retained for further inspection; surgical fires should be reported to The Joint Commission as sentinel events. Recommendations for management of an airway fire are listed in Box 42-3.

ANESTHESIA FOR LASER PROCEDURES

Anesthesia is frequently required for laser procedures, and most anesthetic techniques are suitable for laser procedures. Although they may appear to be less invasive, laser procedures have complications similar to those of traditional surgery. Continuous use of LSE is mandatory during laser surgery. The lenses of CO_2 LSE are usually clear and do not affect color perception, but tinted or colored LSE are required for other lasers and can affect color perception. Some Nd:YAG LSE can significantly dim the green color on monochrome monitors, tempting the anesthesia provider to remove the LSE while the laser is in use. Prior to anesthetizing a patient for a laser procedure, the anesthetist should observe the monitors through the LSE to ascertain the effect of the tinted LSE on the visibility of the displayed parameters. Display lights and alarms of patient monitors should be set to maximum brightness or otherwise adjusted to compensate for the color restriction. Audible alarms should be adjusted to the loudest setting.

Major anesthetic concerns exist when the airway is shared between the anesthetist and the surgeon during a laser procedure. The proximity of the endotracheal tube and anesthetic gases to the laser beam creates a very real hazard of airway fire.[25,27,33] Communication between the surgeon and the anesthetist is paramount to ensure patient safety, maximize surgical access, and avoid complications. Ventilation techniques during laser procedures of the airway depend on the surgeon preference and the site of the laser application.

For the patient receiving supplemental O_2 during monitored anesthesia care (MAC), good communication between the surgeon and anesthetist is mandatory. To reduce the risk of fire, buildup of oxygen should be minimized during head and neck surgery by continuous scavenging of the operative site with suction. Supplemental O_2 should be discontinued 1 minute before and during laser use. Pulse oximetry will allow monitoring of the patient's response to the decrease in O_2 concentration. To maximize surgical view and access, small-sized endotracheal tubes are necessary, and the anesthetist must be prepared to deal with the associated increase in resistance to ventilation. During airway surgery, the oropharynx should be continually suctioned throughout the procedure. Some surgeons may prefer an apneic technique, in which case the airway is alternately shared between the surgeon and the anesthetist. After induction of general anesthesia and the administration of a muscle relaxant, the patient is hyperventilated by mask after brief periods of laser application. The pulse oximeter must be monitored closely and ventilation immediately resumed if oxygenation decreases 2% to 3% below the patient's initial saturation or when 1.5 to 2 minutes have elapsed. However, this technique is to be discouraged; during periods of apnea there are still high O_2 concentrations in the upper and lower airways that are susceptible to ignition by the laser beam. Because of their potential to deteriorate toxic compounds in the presence of a fire, volatile anesthetics are best avoided during laser surgery of the airway.[3]

SUMMARY

Because of their ability to cut, coagulate, vaporize, and selectively destroy abnormal tissue, medical lasers have numerous applications in all medical and surgical specialties. They are an integral part of a surgeon's armamentarium, and newer and more powerful lasers are finding expanded use in surgery. Anesthetists are involved on a daily basis with patients undergoing laser procedures in the hospital operating rooms and off-site locations, ambulatory surgeries and clinics, and private practice offices. Safe provision of anesthetic care requires knowledge of laser physics, as well as the potential hazards associated with the use of medical lasers. Continuous use of eye and skin protection for both the patient and the operating room personnel and continuous use of a smoke evacuator is mandatory. The anesthetist must be acutely aware of the risk of fire during laser procedures, especially laser surgery of the airway, and must be prepared to both prevent and respond to a surgical fire. This can be accomplished by fire safety education and participation in annual fire drills with the other members of the operating room team.

43 CHAPTER Obesity and Anesthesia Practice

◆ *John J. Nagelhout*

OVERVIEW

Obesity is a complex, multifactorial, chronic disease that develops from an interaction between the genotype and the environment.[1-6] It is the second leading cause of preventable death in the United States.[1] The prevalence of overweight and obesity has increased significantly during the last three decades. Obesity is associated with an increased incidence of a wide spectrum of medical and surgical conditions and morbidity. As a result, anesthetists can expect to encounter overweight and obese patients frequently in their practices. These patients may present a considerable challenge due to the multiple pathophysiologic changes associated with obesity. A thorough understanding of the pathophysiology, pharmacology, and specific anesthetic considerations associated with obesity will promote optimal anesthesia care.

Statistics

The prevalence of obesity around the world continues to rise, and in the United States, millions of Americans are considered to be severely obese. Current estimates are that 200 million or 66% of U.S. adults are classified as overweight or obese, and more than 34% of adults are classified as obese. In nationwide data from 2004, 7% of women and 3% of men were extremely obese.[7] There are an estimated 26 million people in the United States with a body mass index (BMI) of no less than 35 kg/m^2, and 15 million with a BMI of 40 kg/m^2 or higher.[1,4]

For persons ages 20 years and older, there has been an increase in the proportion of obese adults from a previous level of 23% in 1994 to a new level of approximately 35% (Figure 43-1).

Obesity is not confined to the United States; it is a health problem that is increasing at an alarming rate throughout the world. Globally there are approximately 2 billion individuals documented as overweight (BMI of 25 kg/m^2 to 29.9 kg/m^2), which approximates the number of individuals who are starving worldwide.[8,9] It is estimated that there are more than 300 million obese people worldwide,[10] and three countries report that more than 50% of their population is obese. The World Health Organization (WHO) has predicted that the number of severely overweight adults is expected to double by 2025. Concerns about the global obesity crisis are growing, and WHO reports that obesity accounts for more than 400,000 deaths annually, second only to tobacco-related disease as a cause of preventable and premature death.[11]

In the United States, individuals who are obese have a 10% to 50% percent greater risk of death from all causes, compared with healthy-weight individuals (BMI 18.5 to 24.9). Obesity is associated with about 112,000 excess deaths per year.[12] Most of the increased risk is due to cardiovascular causes.[13]

Cost of Obesity

Public awareness of the problems that arise from obesity is corroborated by the $147 billion spent annually on medical treatment, weight-reduction programs, exercise equipment, low-fat diet products, pharmacologic agents, advertising, and marketing.[4] Obesity is a major health concern, and obese patients admitted for surgery may exhibit one or more medical conditions in addition to the primary underlying problem.[14] Clearly, identification of obesity-related conditions is vital to the safe administration of an anesthetic.

Definitions

BMI is the accepted measure of body habitus that normalizes adiposity for height.[1] BMI can be calculated according to the following formulas:

- BMI = Weight (in kilograms)/height (in meters)^2
- BMI = (Body weight [in pounds]/height [in inches]^2) × 703

Overweight is defined as a BMI of 25 to 29 kg/m^2, and *obesity* as a BMI of 30 kg/m^2.[1-3] The rationale for these definitions is based on epidemiologic data that reveal increasing mortality with BMIs over 25 kg/m^2.[6] For individuals with a BMI greater than 30 kg/m^2, mortality rates for a number of conditions, especially those associated with cardiovascular disease, are increased 50% to 100% above rates in individuals of normal weight. A person's degree of obesity is commonly defined using the body mass index, as classified in Table 43-1. A BMI greater than or equal to 25 is considered "overweight," a BMI of greater than or equal to 30 is considered "obese," and a BMI greater than or equal to 40 is classified as "morbidly obese." We are now seeing references to "super-obese" (BMI greater than 50) and "super-super-obese" (BMI greater than 60).[15]

Ideal body weight (IBW) is a term used interchangeably with the terms *normal weight* and *desirable weight*.[1-3] IBW is a measurement of height and body mass that exhibits the lowest morbidity and mortality for a given population.[2] Determination of IBW is especially useful in calculating drug and intravenous infusion doses in morbidly obese patients. Certain drugs, if administered according to actual body weight, can produce toxicity, renal damage, or hemodynamic instability. Conversely, some drugs must be given according to actual body weight if therapeutic effects are to be achieved. Simplified weight calculations for ideal and lean body weight (LBW) are as follows:

- For men: IBW = Height (in centimeters) − 100
- For women: IBW = Height (in centimeters) − 105
- LBW = IBW × 1.3

Risk Factors

Obesity is associated with an increase in the incidence of many medical conditions (Box 43-1). The risk for cardiovascular disease, certain cancers, diabetes, and overall mortality is linearly related to weight gain. Type 2 diabetes, coronary heart disease, hypertension, and hypercholesterolemia are prominent conditions in overweight and obese patients.[1-3] With increasing weight gain and increased adiposity, glucose tolerance deteriorates, blood pressure rises, and

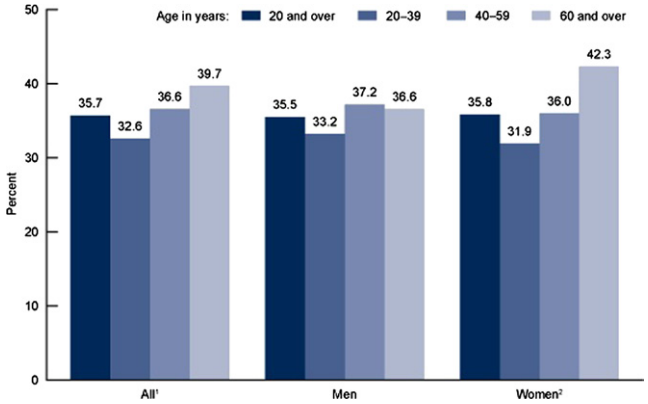

FIGURE **43-1** Prevalence of obesity among adults aged 20 and over by sex and age in 2009-2010. (From Ogden CL, et al. *Prevalence of Obesity in the United States, 2009-2010. NCHS Data Brief, No 82.* Hyattsville, Md: National Center for Health Statistics; 2012.)
[1]Significant increasing linear trend by age (ρ<0.01).
[2]Significant increasing linear trend by age (ρ<0.001).
NOTE: Estimates were age adjusted by the direct method to the 2000 U.S. Census population using the age groups 20–39, 40–59, and 60 and over.

TABLE 43-1 Classification of Overweight and Obesity by Body Mass Index

	Obesity Class	Body Mass Index (kg/m²)
Underweight	—	Less than 18.5
Normal	—	18.5-24.9
Overweight	—	25-29.9
Obesity	I	30-34.9
	II	35-39.9
Morbid obesity	III	Greater than 40

the lipid profile becomes more atherogenic.[2] Using BMI, age, and gender as independent variables, a multiple logistic regression model established that males (P = 0.021), those with higher BMI (P <0.0001), and those of older age (P <0.0001) tended to have more comorbid illness. These data suggest that age, male gender, and extent of obesity are risk factors because they are markers for sicker patients.[16] Hormonal and nonhormonal mechanisms contribute to the greater risk of breast, gastrointestinal, endometrial, and renal cell cancers.[6] Psychological health risks often stem from social ostracism, discrimination, and impaired ability to participate fully in activities of daily living. Coexistent feelings of worthlessness and low self-esteem can lead to depression that not only magnifies anesthetic morbidity, but also contributes to an increased incidence of suicide among morbidly obese persons.

ADIPOSE TISSUE

Adipose tissue has major integrative physiologic functions, secretes numerous proteins, and is considered an endocrine organ.[2] Its major functions as an organ are to provide a reservoir of readily convertible and usable energy and to maintain heat insulation.[2,3,17] Functions associated with liver fat metabolism include degradation of fatty acids into usable units of energy, synthesis of triglycerides from carbohydrates and proteins, and synthesis of other lipids from fatty acids, particularly cholesterol and phospholipids.[17] The ability of the liver to desaturate fatty acids is tremendously important because all cells contain some unsaturated fats synthesized by the liver.

BOX 43-1
Conditions Associated with Obesity

Cardiovascular System
- Coronary heart disease
- Hypertension
- Dyslipidemia
- Cerebrovascular disease
- Thromboembolic disease
- Cardiomegaly
- Congestive heart failure
- Pulmonary hypertension

Endocrine System
- Type 2 diabetes
- Thyroid disorders

Respiratory System
- Restrictive lung disease
- Obesity hypoventilation syndrome
- Obstructive sleep apnea

Gastrointestinal System
- Hiatal or inguinal hernia
- Gallbladder disease
- Nonalcoholic fatty liver disease: steatosis, cirrhosis, hepatomegaly
- Gastroesophageal reflux disease (GERD)

Other Systems
- Gout
- Infertility
- Impaired immune response
- Wound infections
- Osteoarthritis
- Malignancy: esophageal, gallbladder, colon, breast, uterine, cervical, prostate, renal
- Urinary incontinence
- Pancreatitis
- Low back pain
- Obstetric complications

Body fat is also important in heat regulation and insulation. Fat cells, which arise from modified fibroblasts, enlarge and fill with liquid triglycerides to nearly 95% of their storage capacity.[17,18] During exposure of the skin to cold (several weeks), the fatty acid chains of the triglycerides shorten, or become more unsaturated.[3] This phenomenon lowers their melting point, which allows the fat in the fat cells to maintain a liquid state. Metabolically, this is significant. Only liquid fat can be hydrolyzed and transported from the cells to be used for energy.[3]

Body Fat Distribution

In early childhood, fat-cell formation occurs rapidly.[2] Overfeeding during this time accelerates fat storage and triggers hyperproliferation of fat cells. During adolescence, the number of fat cells stabilizes and remains constant throughout adult life. Children become obese through an increase in fat-cell numbers, whereas adults become obese through hypertrophy of existing fat cells.[2,3] The distribution of body fat, however, is a clearer indicator of increased health risk.[18]

Central, android, or abdominal visceral obesity ("apple" shape), with a waist/hip ratio greater than 0.85 in men and 0.92 in women, is perceived as a malignant form of fat accumulation[2,19]

FIGURE **43-2** Obesity. **A,** Central android, or abdominal visceral. **B,** Peripheral gynecoid, or gluteal.

(Figure 43-2, *A*). Waist/hip ratio is calculated by dividing the narrowest waist measurement by the broadest hip measurement while the patient is standing.[2] Waist circumference is the newly established standard used as a marker for abdominal obesity. In men a waist circumference greater than 102 cm (40 inches) and in women a waist circumference of 88 cm (35 inches) denote increased risk for certain diseases and conditions.[2,17] These include ischemic heart disease, diabetes mellitus, hypertension, dyslipidemia, and death.[1-3]

Peripheral gynecoid, or gluteal femoral obesity ("pear" shape), with a waist/hip ratio below 0.76 is associated with varicose vein development, joint disease, and reduced incidence of non–insulin-dependent diabetes mellitus (Figure 43-2, *B*). Medical risks accompanying gynecoid fat deposition are less perilous than those associated with the android pattern.[1,20]

Differences in morbidity between android and gynecoid fat distribution are caused by metabolic attributes of the adipose and tissues adjacent to it. Gynecoid repositories of fat, found primarily in women, are metabolically static and are proposed to function as energy depots for pregnancy and lactation.[3,20] Android fat distribution, typically seen in males, is metabolically active with regard to free fatty acid (FFA) release.[2] When elevated levels of FFAs are mobilized from adipose tissue, portal venous drainage delivers high concentrations of FFAs to the liver. Continual delivery of excessive FFAs stimulates hepatic synthesis of very-low-density lipoproteins (VLDLs) and circulation of low-density lipoproteins (LDLs). Hepatic exposure to high concentrations of FFAs also increases gluconeogenesis and inhibition of insulin uptake, which induces non–insulin-dependent diabetes mellitus. Although VLDLs, LDLs, and hyperglycemia are catalysts for the formation of associated cardiovascular and cerebrovascular disease, some studies support the possibility that hyperinsulinemia alone may cause hypertension.[2,3]

CAUSES OF OBESITY

Body size is dependent on genetic and environmental factors. Genetic predisposition, believed to be a primary factor in the development of obesity, explains only 40% of the variance in body mass.[6] The significant increase in the prevalence of obesity has resulted from environmental factors that result in increased calorie intake and reduced physical activity.[6,17] Other factors such as socialization, age, sex, race, and economic status affect its progression. In the United States, food consumption has risen as a result of the "super-sizing" of portions and the availability of high-fat fast food and snacks. Physical activity has been reduced as a result of modernization (e.g., television and computers) and sedentary lifestyle and work activities. Cultural and lifestyle variations play an important role in the development of obesity.[6] For example, some ethnic foods contain high levels of fats and carbohydrates, whereas others (e.g., Asian) focus on low-fat foods such as fish and vegetables.

There is increased interest in the role of inflammation in obesity. Several inflammatory mediators such as angiotensinogen (AGT), transforming growth factor beta (TGF-β), tumor necrosis factor alpha (TNF-α), and interleukin 6 (IL-6) are elevated in morbidly obese patients. Weight loss results in a reduction in both the inflammatory mediators and comorbidities associated with obesity.[21] Continued investigation into genetic-environmental interactions may provide further understanding and treatment of obesity.[19,20]

PATHOPHYSIOLOGY OF OBESITY

A number of pathophysiologic changes occur as a result of overweight and obesity.[22] These changes involve all of the major body organ systems, leading to an increase in morbidity and premature death. The risk of many of the medical conditions associated with obesity increases linearly with BMI.[2-4]

Cardiovascular Considerations

Cardiovascular considerations are predominantly a reflection of the progressive compensatory processes that evolve to meet the increased metabolic demands of the fat organ.[23,24] Cardiovascular disease dominates the morbidity and mortality in obesity and manifests in the form of ischemic heart disease, hypertension, and cardiac failure.[14] Development and sustenance of the fat mass necessitates formation of extra blood vessels and increased circulatory, pulmonary, central, and peripheral blood volume.[2-4] For every 13.5 kg of fat gained, an estimated 25 miles of neovascularization occurs to provide blood flow at a rate of 2 to 3 mL/100 g of tissue per minute. This represents an increased cardiac output of 0.1 L/min for each kilogram of fat acquired.[3] Expansion of blood volume, stimulated by hypoxia-induced chronic respiratory insufficiency, is seen in severe obesity. Accelerated renin-angiotensin activity and the perfusion requirements of the fat organ further increase the vascular fluid compartment.[2-4,23,24]

Movement of the expanded blood volume through extensive vascular tissue, under compression by adipose tissue, places greater demand on the myocardium. Increased workload caused by elevation of the basal metabolic rate is reflected in increased cardiac output, increased oxygen (O_2) consumption, increased carbon dioxide production, and normal or slightly abnormal arteriovenous O_2 difference.[2,25] Chronically elevated cardiac output precedes increased left-sided heart pressures and left ventricular hypertrophy. Because heart rate usually remains the same, cardiac output must be augmented by an increase in stroke volume. Therefore, cardiomegaly, atrial and biventricular dilation, and biventricular hypertrophy ensue. These contribute to the development of hypertension and eventual congestive heart failure.[2-4,26]

Hypertension is defined as a systolic pressure greater than 140 mmHg, a diastolic pressure greater than 90 mmHg, or both.[3] The prevalence rates of hypertension in obese patients are more than twice as high as those in lean men and women.[26,27] Blood pressure has been shown to increase 6.5 mmHg for every 10% increase in body weight.[28] In the nonhypertensive remainder of the severely obese, decreased systemic vascular resistance may serve to facilitate forward blood flow through the doubled body habitus.[2,4] Hypertension is precipitated by increased blood viscosity, catecholamine kinetics, and possibly increased estrogen

concentrations. Hyperinsulinemia, elevated mineralocorticoids, and abnormal sodium reabsorption are also implicated as causes of hypertension. Hypercholesterolemia (i.e., cholesterol levels greater than 240 mg/dL) often coexists with hypertension, thereby predisposing obese patients to atherosclerosis and cerebrovascular accident.[25,27] Arrhythmias may occur as a result of hypoxemia, hypercapnia, electrolyte disorders, sleep apnea, ventricular hypertrophy, hypertension, and coronary artery disease.[23,24]

Coronary artery disease in the obese is a frequently associated but independent risk factor. It appears with or without hypertension, hypercholesterolemia, diabetes mellitus, hyperlipidemia, or sedentary lifestyle.[2-4,29] Obesity coincident with coronary artery disease results in frequent angina, congestive heart failure, acute myocardial infarction, and sudden death.[14,25,26] Ischemic heart disease is more common in those obese individuals with a central distribution of fat.[25]

Respiratory Considerations

Compromise of respiratory function results from the compression of fat on abdominal, diaphragmatic, and thoracic structures. Over time, thoracic kyphosis and lumbar lordosis develop, resulting in impaired rib movement and fixation of the thorax in an inspiratory position.[1,3] As a result, chest wall, lung, parenchyma, and pulmonary compliance is reduced to 35% of predicted values.[29,30] Metabolic needs of the fat organ and the greater mechanical work of breathing stimulate increased myocardial O_2 consumption. Increases in carbon dioxide production and retention, coupled with decreased ventilation, coincide with reduced respiratory muscle efficiency.[2] Lung inflation is inhibited, which causes declinations in functional residual capacity (FRC) to less than closing capacity. Premature airway closure increases dead space and causes carbon dioxide retention, ventilation-perfusion mismatch, shunting, and hypoxemia.[1,19] Morbid obesity is associated with reductions in FRC, expiratory reserve volume (ERV), and total lung capacity.[29-31] FRC declines exponentially with increasing BMI.[2] A recent study of pulmonary function in morbidly obese patients indicates that forced vital capacity varies inversely with BMI, and patients with a very high BMI, even when asymptomatic, will have major reductions in lung function.[32]

Concomitant diminution of vital capacity, total lung capacity, ERV, and inspiratory capacity are demonstrated by rapid, shallow breathing. These ventilation patterns are characteristic of restrictive lung disease.[2,30,31] Eventual hypoventilation, hypercarbia, and acidosis result from depression of central nervous system responsiveness to chronic hypoxia.[3] Recurrent hypoxemia leads to secondary polycythemia and is associated with an increased risk of coronary artery disease and cerebrovascular disease.[18] Respiratory muscle dysfunction also has been reported with obesity[33] and may result from an inefficiency secondary to changes in chest-wall compliance or the lower lung volumes found in obesity. These abnormalities predispose obese patients to respiratory failure in the setting of even mild pulmonary or systematic insults.[34]

Obstructive Sleep Apnea

Obesity is a well-established risk factor for sleep apnea, with the incidence of obstructive sleep apnea (OSA) increasing in direct proportion with the level of obesity. Patients characterized with OSA have a BMI greater than 30 kg/m^2, abdominal fat distribution, and a large neck girth (greater than 17 inches in men and greater than 16 inches in women).[2] For patients with clinically severe obesity (BMI 35 kg/m^2 or greater) who present for bariatric surgery, the incidence of sleep apnea ranges from 71% to 77%.[35-57]

OSA is characterized by excessive episodes of apnea (10 seconds) and hypopnea during sleep that are caused by complete or partial upper airway obstruction.[38] Up to 25% of all surgical patients are at risk of OSA.[39] Obstructive sleep apnea is characterized by intermittent closure or narrowing of the upper airway during sleep, which leads to episodes of apnea-hypopnea, arousal, and oxygen desaturation.[40] This disorder is pervasive and affects nearly 18 million Americans.[41] As many as 80% to 95% of persons with OSA are undiagnosed.[42]

Apnea is the cessation of airflow at the nose and mouth for more than 10 seconds.[43] Apnea is considered obstructive if there is continued respiratory effort despite airflow cessation. Hypopnea is defined as a 50% reduction in airflow for 10 seconds for 15 or more times per hour of sleep associated with snoring and a 4% decrease in oxygen saturation. It connotes a transient reduction in airflow caused by increased upper airway resistance.[42] OSA syndrome is diagnosed by polysomnography using an apnea-hypopnea index (AHI).[44] There are different definitions of OSA. The AHI is the number of abnormal respiratory events per hour of sleep. Classically, the accepted minimal clinical diagnostic criteria for OSA are an AHI of 10 plus symptoms of excessive daytime sleepiness. The American Academy of Sleep Medicine defines mild OSA as AHI between 5 and 15, moderate OSA as AHI between 15 and 30, and severe OSA as AHI more than 30. The Medicare guidelines diagnose OSA with an AHI of 15, or an AHI of 5 with 2 comorbidities.[35]

The pathogenesis of OSA is likely multifactorial.[45] Contributing factors include airway anatomy, the state-dependent control of the upper airway dilator muscles, and ventilatory stability. The site of upper airway obstruction typically lies in the pharynx. The pharyngeal luminal area during inspiration reflects a balance between collapsing intrapharyngeal negative suction pressure and dilating forces provided by the pharyngeal muscles.[46] In awake human subjects, the patency is maintained by the central nervous system's continually mediated contraction of the tensor muscles. These dilator muscles oppose the negative collapsing force developed during inspiration.[42] This activation of muscle tone is typically reduced during sleep and in many individuals leads to compromised patency of the upper airway with turbulent airflow and snoring. In obese patients, more adipose tissues in the pharyngeal structures increase the likelihood that relaxation of the upper airway muscles will cause collapse of the soft-walled oropharynx between the uvula and the epiglottis. Extraluminal pressure is increased by superficially located masses, and the upper airway is compressed externally.[40,42,47,48]

While sleeping, any and all of these mechanical, neural, and structural factors may contribute to upper airway collapse that either interferes with or eliminates ventilation, which results in a surge of pharyngeal dilator muscle activity that subsequently opens the airway. A period of hyperventilation then follows, which reverses hypercarbia, and then correspondingly the central respiratory drive is reduced. The process can repeat itself continually throughout the night, causing intermittent hypoxia and hypercarbia, fragmenting sleep, and triggering adrenergic surges with each cycle.[42,43,46] Clinically significant episodes of 5 or more per hour or more than 30 per night result in hypoxia, hypercapnia, systemic and pulmonary hypertension, and cardiac arrhythmias.[20,30,31,38]

Patients undergoing electrocardiogram (ECG) Holter monitoring showed that nocturnal paroxysmal asystole, episodic bradycardia, and sinus node dysfunction were more prevalent in patients with OSA.[49] Study of OSA patients with permanent atrial pacemakers demonstrated that subjects had fewer episodes of OSA if their pacemakers were set to increase their heart rate during the

BOX 43-2

STOP-Bang Scoring Model for Screening for Obstructive Sleep Apnea

1. Snoring: Do you snore loudly (loud enough to be heard through closed doors)?	Yes	No
2. Tired: Do you often feel tired, fatigued, or sleepy during daytime?	Yes	No
3. Observed: Has anyone observed you stop breathing during your sleep?	Yes	No
4. Blood Pressure: Do you have or are you being treated for high blood pressure?	Yes	No
BMI: BMI more than 35 kg/m^2?	Yes	No
Age: Age more than 50 years old?	Yes	No
Neck circumference: Neck circumference greater than 40 cm?	Yes	No
Gender: Male?	Yes	No

High risk of OSA: Answering yes to 3 or more items.
Low risk of OSA: Answering yes to fewer than 3 items.

Adapted from Seet E, Chung F. Obstructive sleep apnea: preoperative assessment. *Anesthesiol Clin*. 2010;28(2):199-215.
BMI, Body mass index; *OSA*, obstructive sleep apnea.

night. It is hypothesized that the increased vagal tone accompanying bradycardia also affects airway patency.[50]

Patients with OSA also have a higher incidence of comorbidities. Approximately 50% to 60% of patients with OSA are hypertensive, and an estimated 50% of hypertensive patients have sleep apnea.[51]

Because 80% to 95% of all patients with OSA are undiagnosed and untreated, many patients who present for surgery will not be diagnosed. During preanesthetic evaluation, patients should be asked about their sleeping patterns, and anesthesia providers should have a high index of suspicion for OSA in all obese patients.[52] Some advocate that all obese patients, or those who observe them while they sleep, be routinely asked about nocturnal snoring or apnea, arousals, and diurnal sleepiness.[53] Several screening tools have been developed for preoperative use. The STOP-Bang screening tool (Box 43-2) is easy to use and has a sensitivity of up to 93%.[39,54,55]

Suggestions for the management of obstructive sleep apnea patients are listed in Table 43-2.

Obesity Hypoventilation (Pickwickian) Syndrome

Obesity hypoventilation syndrome (OHS), or pickwickian syndrome, is a complication of extreme obesity characterized by OSA,

TABLE 43-2 Perioperative Anesthetic Management of the Patient with Obstructive Sleep Apnea

Phase	Anesthetic Concern	Principles of Management
Preoperative period	Cardiac arrhythmias and unstable hemodynamic profile	Indirect evidence advocating the usefulness of PAP to reduce cardiac arrhythmias, stabilize variable blood pressure, and decrease myocardial oxygen consumption
	Multisystem comorbidities	Preoperative risk stratification and patient optimization Individualized intraoperative anesthetic management tailored to comorbidities
	Sedative premedication	α_2-Adrenergic agonist (dexmedetomidine) premedication may reduce intraoperative anesthetic requirements and have an opioid-sparing effect
	OSA risk stratification, evaluation, and optimization	Preoperative anesthesia consults for symptom evaluation, airway assessment, polysomnography if indicated, and formulation of anesthesia management
Intraoperative period	Difficult intubation	Ramp from scapula to head Adequate preoxygenation ASA difficult airway algorithm
	Opioid-related respiratory depression	Opioid avoidance or minimization Use of short-acting agents Regional and multimodal analgesia (e.g., nonsteroidal antiinflammatory drugs, acetaminophen, tramadol, ketamine, gabapentin, pregabalin, dexamethasone)
	Carry-over sedation effects from longer-acting intravenous sedatives and inhaled anesthetic agents	Use of propofol for maintenance of anesthesia Use of insoluble potent anesthetic agents (sevoflurane and desflurane)
	Excessive sedation in monitored anesthetic care	Use of capnography for intraoperative monitoring
Reversal of anesthesia	Postextubation airway obstruction and desaturations	Verification of full reversal of neuromuscular blockade Ensure patient fully conscious and cooperative before extubation Semiupright posture for recovery
Immediate postoperative period	Suitability for outpatient surgery	Lithotripsy, superficial, or minor orthopedic surgeries using local or regional techniques may be considered for outpatient surgery No requirement for high-dose postoperative opioids Transfer arrangement to inpatient facility should be available
	Postoperative respiratory event in known and suspected high-risk patients with OSA	Longer monitoring in the PACU Continuous oximetry monitoring and PAP therapy may be necessary if recurrent PACU respiratory events occur (e.g., desaturation, apnea, bradycardia)

hypercapnia, daytime hypersomnolence, arterial hypoxemia, cyanosis-induced polycythemia, respiratory acidosis, pulmonary hypertension, and right-sided heart failure. At its extreme, there is evidence of nocturnal episodes of central apnea, apnea without respiratory efforts, reflecting progressive desensitization of the respiratory centers to nocturnal hypercarbia.[30,31,38,47]

OHS is defined as obesity (body mass index greater than 30 kg/m2), daytime hypoventilation with awake P_{CO_2} greater than 45 mmHg, and sleep-disordered breathing in the absence of other causes of hypoventilation. About 90% of patients with OHS also have OSA. The prevalence of OHS in patients with OSA is uncertain but is estimated to be between 4% and 20%.[56]

OHS, which occurs in 8% of the obese population, is clinically distinct from simple obesity.[31] With simple obesity, the partial pressure of arterial carbon dioxide, pH, and pulmonary compliance are within normal ranges.[29] Hypoxia may be present, but no evidence of cardiac failure or arterioalveolar O_2 difference exists. In contrast, OHS is diagnosed when the morbidly obese patient exhibits inappropriate and sudden somnolence, sleep apnea, hypoxia, and hypercapnia.[3] A P_{CO_2} greater than 45 during wakefulness on arterial blood gas testing with compensatory metabolic compensation and hypoxemia (P_{O_2} less than 70) is suggestive of OHS.[56] Alveolar ventilation is reduced because of shallow and inefficient ventilation related to decreased tidal volume, inadequate inspiratory strength, and inadequate elevation of the diaphragm. Cardiac enlargement, cyanosis, polycythemia, and twitching also are evident on physical examination.[4] Activities of daily living are altered by the somnolent episodes. Operating machinery or driving a vehicle may cause injury or death.

Gastrointestinal Disease

The incidence of gastroesophageal reflux disease, gallstones, and pancreatitis increases with obesity. Obesity is associated with a number of liver abnormalities referred to as *nonalcoholic fatty liver disease* (NAFLD).[57] NAFLD includes steatosis, steatohepatitis, fibrosis, cirrhosis, hepatomegaly, and abnormal liver biochemistry. Patients with NAFLD are at risk for developing cirrhosis, hepatic decompensation, and hepatocellular carcinoma. The pathogenesis of NAFLD is not fully understood, although researchers have found that a combination of environmental, genetic, and metabolic factors lead to advanced disease. There have been improvements in noninvasive radiographic methods to diagnose NAFLD—especially for advanced disease. However, liver biopsy is still the standard method of diagnosis for NAFLD.[58]

The prevalence of NAFLD is up to 30% in developed countries and nearly 10% in developing nations, making NAFLD the most common liver condition in the world. The pathogenesis of NAFLD is related to insulin resistance and it is frequently found in individuals who have central obesity or diabetes. Insulin resistance and excess adiposity are associated with increased lipid influx into the liver and increased hepatic triglyceride accumulation. Defects in lipid use via mitochondrial oxidation and lipid export also may contribute to hepatic lipid build-up. Clinically, NAFLD is commonly asymptomatic and usually detected incidentally by liver function tests or imaging performed for other reasons. Subjects with NAFLD have a higher mortality rate than the general population and are at increased risk of developing cardiovascular disease and diabetes in the future.[57] In obese patients, the mortality rate from liver cirrhosis is 1.5 to 2.5 times higher than in nonobese persons.[18]

Gallstones

Gallstones are 30% more prevalent in obese than nonobese women, and this prevalence increases linearly with BMI.[4] Higher concentrations of cholesterol in the bile and an increased ratio of bile salts to lecithin are responsible for the development of gallstones.[59] Jaundice also may accompany bile duct obstruction. Laparoscopic and open cholecystectomies are commonly performed in this group of patients because of the increased incidence of gallbladder disease in the obese. Although technically more difficult for both surgical and anesthesia teams, the benefits of laparoscopic gallbladder removal (e.g., reduced postoperative pain, shorter hospitalization, earlier return to activities of daily living) outweigh the risks.

Endocrine and Metabolic Disease

Obesity is seldom the result of primary endocrine dysfunction. Thyroid, adrenocortical, and pituitary function should be investigated with obesity that manifests atypical symptoms.[3] Menstrual problems such as oligomenorrhea, amenorrhea, menorrhagia, and the presence of hirsutism may herald hypothalamic-pituitary abnormalities. Obese men may experience decreased libido or impotence indicative of hypogonadism. Low serum follicle-stimulating hormone and testosterone levels are frequently evident.[20]

Within groups of individuals demonstrating non–insulin-dependent diabetes mellitus, 80% are obese. The risk of type 2 diabetes increases linearly with BMI.[20]

There is a 35% to 40% prevalence of the metabolic syndrome in the U.S. population. Patients with obesity and metabolic syndrome may have complicated medical histories including diabetes, heart disease, and OSA. Metabolic syndrome comprises an array of conditions including glucose intolerance and/or type 2 diabetes mellitus, hypertension, dyslipidemia, and cardiovascular diseases. Patients with the metabolic syndrome have increased risks for developing coronary artery disease, stroke, peripheral vascular disease, and type 2 diabetes mellitus, and greater mortality from coronary disease and other causes. These patients also have a proinflammatory and prothrombotic state. Whether this syndrome is a disease itself or is composed of discrete disorders is the subject of much investigation and controversy. Individuals with the metabolic syndrome have a cardiovascular risk 50% to 60% higher than normal. The definition and characteristics of metabolic syndrome is noted in Box 43-3.[60]

BOX 43-3

Metabolic Syndrome Definition

The American Heart Association and the National Heart, Lung, and Blood Institute defines metabolic syndrome as the presence of three or more of the following criteria:

1. Elevated waist circumference
   - Men: 40 inches (102 cm) or greater
   - Women: 35 inches (88 cm) or greater
2. Elevated triglycerides
   - 150 mg/dL or greater
3. Reduced HDL cholesterol
   - Men: less than 40 mg/dL
   - Women: less than 50 mg/dL
4. Elevated blood pressure
   - 130/85 mmHg or greater
5. Elevated fasting glucose
   - 100 mg/dL or greater

Adapted from Levin PD, Weissman C. Obesity, metabolic syndrome, and the surgical patient. *Anesthesiol Clin*. 2009;27(4):705-719.

Orthopedic and Joint Disease

Obese persons often develop osteoarthritis from continued mechanical stress on weight-bearing joints. A linear relationship between degree of arthritis and weight exists.[2-4] Ankles, hips, knees, and lumbar spine are frequently burdened. Bone resorption secondary to limited physical activity also may reduce bone density and contribute to stress fractures. Reduction of weight can curb orthopedic injury and lessen the discomfort in the back and lower extremities.

PEDIATRIC OBESITY

Obesity is a growing problem among U.S. children. In 1994, one in five children between the ages of 6 and 17 was overweight, tripling the rate of 30 years ago.[61] The 2004 National Center of Health Statistics (NCHS) report shows 20% of children and adolescents 2 to 19 years of age are overweight, and that 4% of adolescents have BMIs greater than 40. Adolescents are more overweight than preschool children.[62,63] These adverse trends in obesity have potentially profound effects on children's health now and for their long-term health outlook.

Obesity is clinically diagnosed as a weight-for-height greater than the 90th percentile or a BMI greater than or equal to the 95th percentile, age and sex specific. Pediatric obesity is recognized by BMI greater than the 95th percentile on the Centers for Disease Control and Prevention (CDC) growth chart. Evidence-based guidelines and expert committee recommendations have repeatedly stressed that the BMI for age should be the basis of our definitions of pediatric overweight and obesity.

Studies document links between early childhood and adolescent obesity and adult obesity:

- Obese adolescents have a 70% to 80% chance of being obese adults.[64]
- Childhood obesity is associated with a higher chance of premature death and disability in adulthood, particularly in urban areas.[65]
- Childhood and adolescent overweight and obesity are linked with adult cardiovascular and endocrine problems.[66]
- Obese children are three to five times more likely to suffer a heart attack or stroke before they reach the adult age of 65.[66]
- Being overweight as young as age 18 could be the strongest predictor of future hip replacement because of osteoarthritis.[67]

Determinants of obesity are multifactorial and include genetics, biology, and social and environmental behaviors that may begin in early childhood. The escalating national and global epidemics of obesity and sedentary lifestyle warrant increased attention by physicians and other healthcare professionals. The health goals for obese children and adolescents should be to develop healthy eating habits, maintain weight or reduce the rate of gain, and to be active rather than sedentary.[68]

Some specific problems obese children face related to the healthcare community are the following:

- Pediatric obesity is more common than diabetes, human immunodeficiency virus (HIV), cystic fibrosis, and all childhood cancers combined.
- Primary hypertension in children has become increasingly common in association with obesity and risk factors such as a family history of hypertension and an ethnic predisposition to hypertensive disease. Obese children are at approximately a threefold higher risk for hypertension than nonobese children.[69]
- Most children with type 2 diabetes are overweight or obese at diagnosis and usually have a family history of type 2 diabetes. Americans of African, Hispanic, Asian, and American Indian descent are disproportionately represented.[70]
- OSA sleep disorder was very common in a clinical sample of overweight children. OSA is not associated with abdominal obesity. On the contrary, higher levels of abdominal obesity and fat mass are associated with central sleep apnea.
- Bariatric surgery may be useful but only with carefully selected obese children with serious comorbidities and unresponsiveness to interventions. The biggest barrier seems to be the psychosocial aspect, although complications from child bariatric surgery may include leaks, deep vein thrombi, micronutrient deficiency, bleeding, and infection.[71]
- Psychosocial disorders may result when obese children are treated differently. This may be the most devastating effect of obesity on children. They may feel isolated and lonely and have self-esteem and identity problems. It is important for the healthcare professional to be sensitive to this issue and understand that an individual's confidence, especially a child's, is affected by self-image and perceptions of peers.[72]

Unfortunately, children with long-standing obesity (especially morbidly obese) develop medical problems previously seen only in adulthood. Medical effects of obesity such as hypertension, insulin resistance, coronary artery disease, and metabolic syndrome previously reserved for adults are on the rise in children and adolescents.[73,74]

The prevalence of the metabolic syndrome is high among obese children and adolescents and increases with worsening obesity. Diagnosis of metabolic syndrome in children and adolescents is only now receiving greater attention, and there does not seem to be consensus on precise standards of treatment. As with adults, the dominant underlying risk factors for this syndrome appear to be abdominal obesity, insulin resistance, hypertriglyceridemia, hypertension, and proinflammatory and prothrombotic states.[74]

Studies show that obesity increases the burden of disease for children and adolescents, and special attention has been given to clinical complications for that population. These include cardiovascular disease (dyslipidemia and hypertension), respiratory disease (sleep apnea, snoring, asthma), orthopedic conditions (Blount's disease, slipped capital femoral epiphysis), gastrointestinal disease (gallbladder, steatohepatitis), and endocrine disease (insulin resistance, hyperinsulinism, impaired glucose tolerance, and type 2 diabetes that is normally reserved for adults). Other conditions in adolescent females include polycystic ovarian syndrome and menstrual irregularity. Studies also include psychosocial conditions such as depression, eating disorders, and social isolation.[75]

MATERNAL OBESITY

Obstetric complications of maternal obesity correlate more to pregravid obesity rather than excessive weight gain during gestation. Maternal obesity, not diabetes, seems to be the most important link to the nation's increase in mean birth weight. Mean increase in birth weight in the past 30 years was 116% at 37 to 41 weeks' gestation.[76] Prepregnancy obesity significantly increases the parturient risk for cesarean delivery.

Both first and second stages of labor are longer in obese women. Obesity is a risk factor for developing gestational hypertension, insulin-treated gestational diabetes, and hydramnios. However, neonatal outcome of obese women is comparable to women with normal prepregnancy body mass index.[77]

The National Institutes of Health (NIH) recognizes many risk factors associated with maternal obesity. Outcomes in pregnancy complicated by obesity include gestational diabetes, preeclampsia, preterm labor, cesarean delivery, postpartum hemorrhage, infection, pregnancy-induced hypertension (PIH), and macrosomic

infants. The American College of Obstetricians and Gynecologists (ACOG) reports increased risk for spontaneous abortion and miscarriage rates of almost double that of nonobese women in the first 6 weeks of pregnancy.[76] Metabolic syndrome in pregnancy manifests as preeclampsia, gestational hypertension, insulin resistance, and diabetes. Preeclampsia increases further in obese women with gestational diabetes mellitus (GDM) that is poorly controlled, a previous history of GDM, family history of type 2 diabetes, and history of a macrosomic fetus.[73]

Newborns considered large for gestational age (LGA), or macrosomic, are at long-term risk for adolescent and adult obesity. Weiss et al.[78] defined *fetal macrosomia* as birth weight greater than 4000 g. The study found the rate of macrosomia to be 8.3% in nonobese parturients, 13.3% in those who were obese, and 14.6% in the morbidly obese. These increased birth weights have been linked to increased adolescent metabolic syndrome and type 2 diabetes. By age 4, 25% of these children have impaired glucose tolerance. Children born to mothers with BMIs greater than 30 in the first trimester are more likely to show fetal overgrowth and adiposity beginning in utero and continuing into the first years of life. The results of one study demonstrated that at ages 2, 3, and 4, growth was increased by 15.1%, 20.6%, and 24.1%, respectively.[79]

Peripartum risks associated with maternal obesity include the following:

- Cesarean delivery and associated morbidity (approaches 40% in severely obese)
- Difficult placement of epidural and spinals, requiring multiple attempts
- Difficult intubation risk, usually in an emergent setting (twice the risk of nonobese women)
- Decreased ability of ultrasound to detect cardiac and craniospinal abnormalities
- Increased postoperative complications, longer surgery times, wound infection and breakdown, endometritis, antepartum venous thrombi/emboli (VTE), and excessive blood loss during surgery but no increased risk of postpartum hemorrhage

Bariatric Surgery for Obese Women: Gestational Considerations

Owing to limited success with lifestyle changes, more obese women of reproductive age are seeking bariatric surgery as an alternative. Previous reports showed complications during pregnancy after these malabsorptive procedures, including increase in premature rupture of membranes, small bowel ischemia, nutrient deficiencies, and fetal abnormalities.[76] Cesarean deliveries increased in women who had previous bariatric surgery. Gestational diabetes and PIH disorders were significantly reduced in women having laparoscopic adjustable gastric banding procedures. There were no significant differences in placental abruption and previa, labor dystocia, or perinatal complications with bariatric surgery prior to conception.

Recommendations by ACOG[80] include weight screening annually, especially for women of childbearing age with a family history of cardiovascular disease and diabetes mellitus. They recommend physical activity, proper diet, behavioral therapy, and bariatric surgery for women with BMIs greater than 40 with comorbidities prior to pregnancy. After delivery, continued exercise and diet, as well as breastfeeding the infant, are beneficial. During pregnancy, weight gain should be limited following the Institute of Medicine (IOM) suggestions: 25- to 35-lb increase in nonobese women, 15 to 25 lb in overweight women, and 15 lb in obese women.

Genetic predisposition, physiology, and mechanisms related to maternal and fetal-placental interaction are important to the growth and development of children. Maternal obesity is shown to be a significant risk factor in adverse outcomes in pregnancy. Higher birth weights have a definite connection to overgrowth in children and obesity in adolescents.

TREATMENT OF OBESITY

A multimodal approach in the treatment of obesity includes dietary intervention, increased exercise, behavior modification, drug therapy, and surgery. Weight-loss programs are individualized to each patient based on the degree of obesity and coexisting conditions. Drug therapy is initiated in patients with a BMI greater than 30 kg/m^2 or a BMI between 27 and 29.9 kg/m^2 with a coexisting medical condition.[2-4] Medications that promote weight loss have limited efficacy. Despite the enormous potential market, efforts to develop effective drug therapies have been disappointing. The FDA guidance for long-term weight loss drugs recommends that a 5% weight reduction be maintained for 12 months after treatment initiation. Orlistat (Xenical; Alli) is the only over-the-counter medication currently approved for obesity treatment. Orlistat is a lipase inhibitor that decreases the absorption of fat in the gastrointestinal tract. Side effects are minor and mostly related to gastrointestinal discomfort. It may inhibit the absorption of fat-soluble vitamins A, D, E, and K, requiring supplementation. Occasionally monoamine oxidase inhibitors are used off label.[81] The Food and Drug Administration (FDA) has recently approved one new drug and a new combination of two old drugs for chronic weight management. Lorcaserin (Belviq) is a selective serotonin 2_C receptor agonist. Activation of the serotonin 2_C receptor, found mainly in the central nervous system, is thought to suppress appetite. Qsymia (Vivus) is a fixed-dose combination of the weight-loss drug phentermine and an extended-release formulation of topiramate. The new products are approved for use in obese patients (body mass index [BMI] of ≥30 kg/m^2) and for patients who are overweight (BMI ≥27 kg/m^2) and have one weight-related risk factor such as hypertension, dyslipidemia, or type 2 diabetes. Both drugs have some success taken as adjuncts to diet and exercise and may be effective in increasing weight loss in the first year of use.[82]

Surgical Treatment

Besides common surgeries performed within the general population, obese persons undergo additional procedures to ameliorate obesity-related diseases (Box 43-4). The four most common bariatric procedures at present are the Roux-en-Y gastric bypass (RYGB), laparoscopic adjustable gastric bypass (AGB), sleeve gastrectomy (LSG), and the biliopancreatic diversion with duodenal switch (BPD with DS). All are safe, effective, minimally invasive, and relatively cost-effective. Surgical approaches

BOX 43-4

Obesity-Related Diseases Requiring Surgery

- Cholelithiasis
- Thromboembolism
- Peripheral vascular disease
- Urolithiasis and urinary incontinence
- Osteoarthritis-related orthopedic procedures
- Varicose veins
- Hiatal and abdominal wall hernias
- Cancer (endometrial, breast, prostate, colorectal, renal)
- Uterine fibroma
- Ovarian cysts
- Cesarean section

designed to treat obesity can be classified as malabsorptive or restrictive.[81] Malabsorptive procedures are not commonly used. Restrictive procedures include the largely historic vertical banded gastroplasty (VBG) and the increasingly common gastric banding, including laparoscopic adjustable gastric banding and laparoscopic sleeve gastrectomy The mechanisms of various bariatric procedures are shown in Box 43-5. Despite the technically demanding nature of the Roux-en-Y gastric bypass procedure, it has become the procedure of choice for clinically severe obesity. Laparoscopic adjustable gastric banding is greatly increasing in frequency in the United States.[81,83-87]

Advances in laparoscopic surgery have significantly improved surgical procedure times, morbidity, and mortality related to bariatric surgery. If the operation is performed using the "closed" method, the negative impact of pneumoperitoneum on respiratory system mechanics and oxygenation during laparoscopy can be seen. Ezri [88] demonstrated that the endotracheal tube moves more often in obese patients undergoing laparoscopy compared with those having open abdominal surgery. Patients appreciate laparoscopic bariatric surgery because it reduces postoperative pain and the duration of convalescence.[89] Many studies show reductions in overall morbidity when a laparoscopic technique is used.[90-93]

Indications for bariatric surgery are noted in Box 43-6. Postoperatively, patients must stay in close contact with multidisciplinary team members. Rehabilitation of previous lifestyle patterns is achieved through counseling and support provided by psychologists, dietitians, physical therapists, and internists.[84-86] Most patients who are monitored for as long as 5 years postoperatively achieve losses from their original weight of as much as 30% to 60%.[98]

BOX 43-5

Mechanism of Action of Select Bariatric Operations

Restrictive
- Vertical banded gastroplasty (VBG; historic purposes only)
- Laparoscopic adjustable gastric banding (AGB)
- Laparoscopic sleeve gastrectomy (LSG)

Largely Restrictive, Mildly Malabsorptive
- Roux-en-Y gastric bypass (RYGB)

Largely Malabsorptive, Mildly Restrictive
- Biliopancreatic diversion (BPD)

BOX 43-6

Indications for Bariatric Surgery

Patients must meet the following criteria for consideration for bariatric surgery:
- BMI greater than 40 kg/m^2 or BMI less than 35 kg/m^2 with an associated medical comorbidity worsened by obesity
- Failed dietary therapy
- Psychiatrically stable without alcohol dependence or illegal drug use
- Knowledgeable about the operation and its sequelae
- Motivated individual
- Medical problems not precluding probable survival from surgery

BMI, Body mass index.

PHARMACOLOGIC CONSIDERATIONS

Obesity causes physiologic changes that can affect the pharmacokinetics and pharmacodynamics of anesthetic agents. An overview of these changes are listed in Box 43-7. The common approach to anesthetic drug administration is to give water-soluble drugs according to ideal body weight (IBW) and lipid-soluble drugs according to total body weight (TBW). Lean body mass increases approximately 20% to 40% in obesity, so adding 30% to the ideal body weight is a convenient dose adjustment. Contradictory results from individual drug studies in small patient groups are common; therefore specific recommendations are frequently conflicting. A few general observations can be made. Postoperative respiratory depression is especially problematic in obese patients; therefore most clinicians favor short-acting drugs, which allow for fast recovery. The newer inhalation agents desflurane and sevoflurane produce excellent recovery profiles in obese patients. Although desflurane is less soluble than sevoflurane, clinical differences are minimal. Nitrous oxide can be safely used in patients where a requirement for high oxygen concentrations does not preclude its administration. Succinylcholine doses for intubation are given according to TBW to ensure excellent intubating conditions, whereas the nondepolarizing muscle relaxants used for operative maintenance are given according to IBW. Use of a nerve stimulator to guide relaxant administration assists in minimizing residual paralysis and reversal concerns. Remifentanil infusion is an especially popular analgesic due to titratability and rapid offset and is administered according to IBW. Dexmedetomidine is also a useful adjunct for sedation, amnesia, and analgesia. Specific dosing recommendations for some common anesthetic agents in obesity are listed in Table 43-3.[81,94,95]

ANESTHETIC MANAGEMENT: PREANESTHETIC EVALUATION

The goals of the preanesthetic evaluation are to obtain pertinent data regarding the patient's medical or surgical history, to optimize current physiologic functioning, and to determine an appropriate anesthetic plan (see Chapter 19). Of paramount importance is the need to establish a nonjudgmental and trusting relationship with the patient. Explanations of anticipated events during preoperative preparation (e.g., multiple venipunctures, central and arterial line insertions, awake intubation, pain management) and protection of the patient's privacy will allay anxiety.

BOX 43-7

Pharmacokinetic Changes Associated with Obesity

- Increased fat mass
- Increased cardiac output
- Increased blood volume
- Increased lean body weight
- Changes in plasma protein binding
- Reduced total body water
- Increased renal clearance
- Increased volume of distribution of lipid-soluble drugs
- Abnormal liver function
- Decreased pulmonary function

Medications

Obese persons must be queried for concurrent use of weight-reducing substances, herbal supplements, and anorexiant drugs. Patients who take over-the-counter drugs, including herbal medications, often forget or are afraid to reveal that they are taking these preparations, which can have deleterious consequences on induction. Patients' usual medications should be continued until the time of surgery, with the exception of insulin and oral hypoglycemics.[96] Recommendations for preoperative management of antidiabetic drugs are given in Chapters 19 and 33. Antibiotic prophylaxis is important because of an increased incidence of wound infections in the obese.[97]

Laboratory Tests

Given the current climate of cost-consciousness and cost-efficiency, only the laboratory tests appropriate in light of the patient's history, physical examination, and planned surgery should be ordered.[14] In morbidly obese patients, baseline studies that may be directly affected by associated medical conditions are performed. Routine testing includes assessment of a complete blood count, electrolyte panel, glucose and hemoglobin A_{1c}, coagulation profile, liver and renal function tests, and a lipid profile. Complete blood cell counts may reveal a hematocrit as high as 65%, which can result from contracted blood volume or polycythemia associated with cardiopulmonary disease.[14,29] Leukocytosis (greater than 11,000 µL) is a strong predictor of risk for acute myocardial infarction independent of tobacco smoking.[17]

Arterial blood gas analysis that compares samples taken with the patient lying supine and sitting while breathing room air provides baseline values and can distinguish simple obesity from OHS. The renal panel may reflect abnormal glucose and potassium levels, which are indicators of insulin resistance and potentiation of myocardial irritability. Concomitant use of diuretics and certain cardiac medications can exacerbate electrolyte disturbances.[14] Blood urea nitrogen (BUN) and creatinine levels may be elevated in response to dehydration or renal dysfunction. Liver function tests are typically elevated in obese patients. This is generally not the result of hepatic disease but of infiltration of the hepatocytes with triglycerides (e.g., fatty liver, liver steatosis). The severity of fatty infiltration may alter pharmacologic effects of many anesthetic drugs, thereby requiring dose reductions.

Coagulation studies are necessary, especially if regional anesthesia is planned or if coagulopathy exists. Patients taking anticoagulants for treatment of deep vein thrombosis or atrial fibrillation may exhibit elevated prothrombin and partial thromboplastin times. Use of nonsteroidal antiinflammatory drugs (NSAIDs) may prolong bleeding times and affect surgical hemostasis.

In obese patients undergoing abdominal or thoracic surgery, pulmonary function tests are invaluable and essential for anesthetic planning; for selected procedures, the tests may be waived.[18] Chest radiography is necessary to determine the presence of cardiomegaly, pulmonary infiltrates, and evidence of chronic obstructive pulmonary disease.

Cardiac Assessment

Evaluation of cardiac function is essential in overweight and obese patients undergoing surgery. Investigation of prior myocardial infarction and the presence of hypertension, angina, or peripheral vascular disease is crucial. Limitations in exercise tolerance, history of orthopnea, and paroxysmal nocturnal dyspnea may indicate left ventricular dysfunction.[94] A careful elicitation of drug history is invaluable in garnering clues about the patient's coexistent diseases. When possible, cardiac medications should be continued up to and including the morning of surgery.

An electrocardiogram (ECG) is essential for determination of resting rate, rhythm, and ventricular hypertrophy or strain. Because of the increased incidence of coronary artery disease (CAD) and myocardial infarction in this population, the preoperative ECG is also helpful in providing a reference for comparison in the event that myocardial ischemia is suspected in the perioperative period. Beyond this, there is no reason to believe that extensive preoperative testing to detect CAD is indicated based solely on a patient being obese.[98] The ECG may be of low voltage because of the excess overlying tissue and therefore might result in underestimation of the severity of ventricular hypertrophy. Axis deviation and atrial tachyarrhythmias are relatively common.[4]

QT-interval prolongation, discovered retrospectively in severely obese patients who died from refractory dysrhythmias, is a marker for sudden cardiac arrest.[3] In cases of fatal and nonfatal dieting, prolonged QT intervals were also exhibited on patient ECGs.[4] In addition, sudden cardiac death is more prevalent in morbidly obese patients with left ventricular hypertrophy and

TABLE 43-3 Guidelines for Dosages of Intravenous Anesthetics in Obese Patients

Drug	Dose Recommendation	Comments
Propofol	Induction dose based on LBW Maintenance dose based on TBW	Increased fat mass does not affect initial distribution/redistribution during induction; cardiac depression at high doses is a concern
Succinylcholine	Intubating dose based on TBW	Increased fluid compartment and pseudocholinesterase levels require higher doses to ensure adequate paralysis
Rocuronium Vecuronium Cisatracurium	All doses based on IBW	Hydrophilic drugs given according to IBW will ensure shorter duration and a more predictable recovery in this respiratory-challenged population
Fentanyl Sufentanil	Loading dose based on TBW Maintenance doses based on LBW and response	Increased distribution volume and elimination time correlate with degree of obesity
Remifentanil	Infusion rates based on IBW	Distribution volumes and elimination rates are similar to normal-sized individuals; fast offset requires planning for postoperative analgesia
Dexmedetomidine	Infusion rates of 0.2 mcg/kg/min	Useful as an adjunct; lower than usual infusion rates are recommended to minimize adverse cardiac side effects

IBW, Ideal body weight; *LBW*, lean body weight; *TBW*, total body weight.

ventricular ectopy.[5] If ventricular hypertrophy or cardiomyopathy is suspected, echocardiography is useful. Tricuspid regurgitation on echocardiography is the most confirmatory test of pulmonary hypertension when combined with clinical evaluation.[99]

Exercise testing may elicit valuable information about myocardial function in morbidly obese patients. Most are physically unable, however, to achieve adequate levels of exercise stress to make the studies worthwhile.[14] In addition, echocardiography is useful for determining whether akinesis or wall-motion abnormalities are present in the obese myocardium.

Cardiomegaly, pulmonary congestion, elevated diaphragm, and a tortuous aorta can be identified by use of chest radiography. Results of radiographic studies serve to guide preoperative pharmacologic and medical management (e.g., diuretics, β_1-agonists, antibiotics). Repeated radiographs may be required to obtain adequate penetration and visualization of all lung fields. Unfortunately, standard stationary and portable x-ray machines cannot accommodate massively obese persons. As a result, diagnostic x-ray examinations or evaluation of central line placement may be impossible. Under these circumstances, clinical expertise and management of subtle symptoms are invaluable. If it is indicated, the patient should be referred to a cardiologist for further investigation and optimization of his or her condition (e.g., control of blood pressure, treatment of heart failure, or treatment of coronary pathology).[100]

Respiratory Evaluation

Careful preoperative evaluation of the patient's respiratory function identifies potential problems. A patient who becomes dyspneic and desaturates when recumbent experiences the same symptoms during induction in the supine position. Questions must elicit information regarding the presence or absence of OSA, orthopnea, wheezing, sputum production, or smoking history. Pulmonary function tests are valuable for assessing the presence of respiratory impairment. Recent upper respiratory infection, snoring, or sleep disturbances may indicate obstructive processes. The potential for difficult mask ventilation also should be considered during the preoperative visit. Obesity has been identified as an independent risk factor for difficult facemask ventilation. Increasing this risk would be findings such as presence of a beard, lack of teeth, and history of snoring.[101] Room air pulse oximetry saturations and blood gases obtained in supine and upright positions may reflect disturbances in cardiac compensation.[102]

Airway Evaluation

A thorough airway evaluation is warranted for determination of the optimal airway management technique in overweight and obese patients.[103] A variety of assessment criteria have been evaluated for prediction of difficult intubation in obese patients. Most practitioners use evaluation of multiple patient physical characteristics to identify potential airway problems indicative of the unanticipated difficult airway. These include measurement of interincisor distance, thyromental distance, head and neck extension, Mallampati classification, body weight, and, most importantly, a history of difficult airway.[104-106] Inspection of the oropharynx is necessary to determine Mallampati classification for intubation difficulty.[104] The value of oropharyngeal Mallampati classification alone is low. Evaluation of the length of upper incisors, visibility of the uvula, shape of the palate, compliance of the mandibular space, and length and thickness of the neck provide further criteria for assessment.

Opinions differ about the use of a patient's weight (BMI) as an independent predictor of difficulty in intubation. Some have demonstrated that difficult intubation is more common in obese patients.[107] Others have demonstrated that increased BMI per se is not a predictor of difficult intubation.[108] Variables determined likely to predict difficulty in intubation of the obese patient include increased neck circumference, Mallampati classification greater than 3, increased age, male sex, temporomandibular joint (TMJ) pathology, a history of OSA, and abnormal upper teeth.[108,109] Of these, a high Mallampati score (3 or greater) with a large neck circumference and a history of sleep apnea were in the aggregate found to be good predictors of difficulty in intubation.[104]

Fat rolls around the neck (restricting neck motion) and fat in the airway (decreasing glottic opening) together increase the difficulty of successfully intubating the trachea. The larger the neck circumference, the more difficult the laryngoscopy and intubation. Neck circumference of 40 cm was associated with a 5% probability of difficult intubation, and neck circumference of 60 cm was associated with a 35% probability of difficult intubation. A normal neck circumference in a 70-kg man is about 35 cm. Other researchers, using ultrasound to quantify the amount of anterior neck soft tissue, produced data that support these findings.[110]

Anatomic aberrations of the upper airway induced by severe obesity include reduced temporomandibular and atlanto-occipital joint movement. Unsatisfactory mouth opening, presence of neck or arm pain, or inability to place the head and neck into "sniffing position" may indicate the need for awake fiberoptic intubation. Extreme airway narrowing in conjunction with shortened mandibular-hyoid distance (less than three fingerbreadths) can complicate mask ventilation and intubation. Presence of a short, thick neck, pendulous breasts, hypertrophied tonsils and adenoids, or a beard can contribute to a difficult airway. Marginal room air pulse oximeter saturations, abnormal arterial blood gases, and history of complicated airway management also indicate a potentially difficult intubation.[104-106] (Refer to Chapter 22 for a full description of the assessment and management of a difficult airway.) Airway management techniques should be explained to the patient, with emphasis on awake intubation and the need for postoperative ventilation.[111,112]

Vascular Access

Venipuncture can be challenging in overweight and obese patients with excessive fat that obscures blood vessels from visualization and palpation.[14] Central cannulation of vessels is impeded by distortions of the underlying anatomy by adipose tissue.[113] Hemorrhage, hypothermia, and trauma further reduce the likelihood of accessing vessels with ease. Use of a portable ultrasound machine may improve central venous catheter placement. As in all patients, iatrogenic pneumothorax must be avoided. Morbidly obese patients are less able than nonobese patients to tolerate the ensuing respiratory impairment.

ANESTHETIC MANAGEMENT: PREPARATION

Operating Room Equipment

In preparation for either emergent operating room procedures or nonemergent hospital admission, appropriate equipment must be readied. Newer-model operating room tables can accommodate up to 600 lb of weight. Older-model standard operating room tables could hydraulically elevate 300 to 350 lb of weight. In cases of extreme morbid obesity, "big boy" hydraulic beds are obtained and used in the operating room. Heavy-duty stirrups, extra-large retractors, elongated instruments, arm sleds, doubled armboards, and extremity tourniquets must be obtained. Sometimes a sanitized engine crane or other hoisting device must be used to suspend the panniculus adiposus for optimal surgical exposure.

Extra-large thigh cuffs can be used on the upper arm or the lower leg (over the posterior tibial artery). A regular-size or large blood pressure cuff can be used on the forearm over the radial artery until arterial cannulation for blood pressure monitoring can be performed. Bed-warming devices, fluid warmers, and warm airflow blankets should be used to prevent hypothermia, which can occur rapidly when large areas of body surface are exposed.

Airway Equipment

An equally important part of airway assessment is the preparation of equipment and personnel necessary to ventilate and intubate the morbidly obese patient. An assortment of blades, laryngoscopy handles, endotracheal tubes, masks, oral and nasopharyngeal airways, and stylets should be assembled. Laryngeal mask airways (LMAs), intubating laryngeal mask airways (ILMA), GlideScope, fiberoptic and bronchoscopic devices, Eschmann introducers, a jet ventilator (or Venturi apparatus), and emergency tracheotomy and cricothyrotomy kits must be available in the event that ventilation by mask or endotracheal tube is unsuccessful. Most departments have a difficult-airway cart that has all of the available equipment that should be placed in the operating room. Recently the ILMA and LMA CTrach (a modified version of the intubating LMA that allows continuous videoendoscopy of the tracheal intubation procedure) have been advocated as particularly useful tools for ventilating and intubating morbidly obese patients.[114,115]

Monitoring

Intraoperative monitoring, both basic and advanced, should address the specific needs of the patient. Selection of electrocardiographic leads, when possible, should enhance detection of myocardial ischemia and pathology (leads II and V_5). Needle electrodes may be useful for obtaining a better tracing. Cuffs with bladders that encircle a minimum of 75% of the upper arm circumference, but preferably the entire arm, should be used. Forearm measurements with a standard cuff overestimate both systolic and diastolic blood pressures in obese patients.[116] Placement of an arterial catheter is appropriate for monitoring hemodynamic status and is advocated for all but the most minor procedures in the morbidly obese.[18] Use of central venous and pulmonary artery catheters are not standard but should be considered in patients undergoing extensive surgery or those with serious cardiorespiratory disease.[94,113]

Aspiration Prophylaxis

Anesthesia providers have traditionally considered obese patients to be "full-stomach" patients and at risk for regurgitation and subsequent pulmonary aspiration.[117-119] It is known that gastroesophageal reflux and hiatal hernia are more prevalent in the obese, and this may predispose them to esophagitis and pulmonary aspiration. More recent data, however, have demonstrated that obese patients (BMI greater than 30 kg/m^2) may have a lower incidence of "at-risk" stomach contents compared with lean patients.[120] The actual incidence of clinically significant aspiration in these patients has not been conclusively determined, but is likely quite low. The airway should be secured expeditiously, but use of a "rapid-sequence induction" should be individualized and not routinely performed.[94] In one study, researchers evaluated gastric contents of 232 surgical patients. Only 20 of 75 obese patients (27%) had high-volume, low-pH stomach contents, compared with 66 of 157 (42%) of lean patients. More recent studies have also demonstrated that obese patients who are fasting may not have gastric pH and volumes that would put them at risk for pulmonary aspiration.[121,122]

There is no consensus on whether obese patients have delayed, normal, or accelerated gastric emptying.[123] Current recommendations are that obese patients should follow the same fasting guidelines as nonobese patients. All patients should be allowed to drink as much as 300 mL of clear liquids until up to 2 hours before elective surgery; that volume has been demonstrated to not adversely affect the pH and volume of gastric contents at induction of anesthesia.[124]

Obesity is significantly related to gastroesophageal reflux disease (GERD).[125,126] Although increased body mass has been shown by some researchers to correlate directly with an increased incidence of reflux symptoms,[127] others have demonstrated the opposite and question the routine use of rapid-sequence induction on all patients who present with a diagnosis of GERD.[128]

Owing to the more recent and favorable data, some advocate the avoidance of rapid-sequence induction technique on obese patients as standard protocol, citing that it is a common misperception that all obese patients should be viewed as "full-stomach" patients, and in the event of failed intubation, obese patients may have poorer outcomes.[129,130] Although obese patients and patients with sleep apnea syndrome are prone to GERD, and both groups may also have an increased risk of difficult intubation, in the case of elective surgery in a fasted patient with no risk factors other than obesity or sleep apnea syndrome, the requirement for rapid-sequence induction is debatable.[131]

However, if symptoms are present in obese patients with GERD disease, the potential increased risk of aspiration should be discussed with the patient, and prophylactic measures (e.g., cricoid pressure, H_2 blockers, and proton-pump inhibitors) should be considered.[132] Although rapid-sequence induction may be safe for some obese patients, its safety in superobese patients has been questioned. For patients with a BMI greater than 50 kg/m^2, or lower but with risk factors such as OSA or large neck circumference, either an awake intubation (with local anesthesia) on spontaneous respiration of the patient or intubation without relaxants (after only propofol administration) is suggested.[133]

Patient Positioning for Induction

Obese patients are more difficult to intubate in the "sniffing" position, but placed in the "ramped" position there is no evidence that this risk is greater than in the general population.[134] It is essential that optimal patient positioning for laryngoscopy is ensured prior to induction of anesthesia. This includes the placement of towels under the patient's shoulders and head and putting the operating room table in reverse Trendelenburg position to increase the patient's FRC. The term *HELP* (*h*ead *e*levated *l*aryngoscopy *p*osition) reminds clinicians of the importance of patient positioning for successful laryngoscopy.[135] This position generally improves the view during laryngoscopy and contributes to increasing the safety period until patients demonstrate signs of oxygen desaturation. This position is also a better patient position for using rescue ventilation techniques, such as bag-valve mask ventilation or insertion of an LMA, should they be required.

One study described positioning morbidly obese patients with the head, upper body, and shoulders significantly elevated above the chest, such that an imaginary horizontal line could connect the patient's sternal notch with the external auditory meatus. Positioning patients in this manner resulted in successful intubation in 99 of 100 morbidly obese patients, with all having a Cormack grade I view.[136]

Others have also concluded that the "ramped" position (with blankets used to elevate both the upper body and head of the patient) improves laryngeal view in obese patients when compared

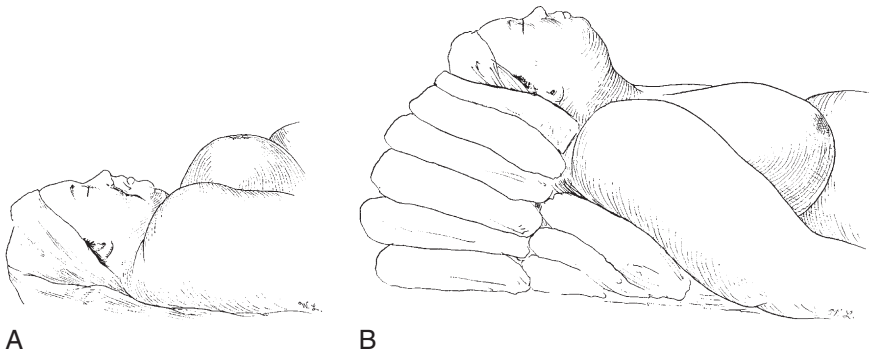

FIGURE **43-3** **A,** Supine position. **B,** Sniffing position.

with a conventional 7-cm cushion under the patient's head (sniffing position), which should result in fewer failed intubations[137] (Figure 43-3). Without proper support and alignment of the oropharynx and trachea (see Figure 22-13), ventilation may be obstructed, and visualization of the laryngeal structures may be obscured.

The importance of proper positioning and the difficulty of repositioning morbidly obese patients during failed intubation can be underestimated by practitioners who are not experienced in airway management in obese patients. If direct laryngoscopy is unsuccessful, LMAs can be effective for establishing ventilation and should be immediately available.[111,124] In one study, the use of an intubating laryngeal mask resulted in better patient oxygenation compared with intubation through direct laryngoscopy in morbidly obese patients.[115]

During a rapid-sequence induction, cricoid pressure is applied while the patient's trachea is intubated. There is much discussion regarding the effectiveness of cricoid pressure and the advantages and risks associated with the technique.[138]

In theory, when pressure is applied to the cricoid cartilage, it causes an occlusion in the esophagus between the cricoid cartilage and the vertebral body. However, it has been demonstrated that the application of cricoid pressure results in a reduction in lower esophageal sphincter pressure in anesthetized patients, but gastric pressure is reportedly less than the esophageal pressure, and the barrier to reflux remains intact.[139]

Researchers have determined that during rapid-sequence induction, gastric pressure is about 14 mmHg or less and that gastric barrier pressure is less than 15 mmHg. These researchers concluded that the amount of cricoid pressure that is adequate to protect most anesthetized patients from regurgitation is 20 Newtons (N), increasing the force to 30 N as loss of consciousness occurs.[140]

The theory, however, has been challenged. In a recent study of awake patients using magnetic resonance imaging (MRI), it was demonstrated that when applying cricoid pressure, the esophagus may actually be displaced laterally. The lateral laryngeal displacement was noted in 67% of the subjects with cricoid pressure, and airway compression of at least 1 mm was demonstrated in 81% of the subjects as a result of cricoid pressure.[141]

ANESTHETIC MANAGEMENT: MAINTENANCE

Intubation

For airway management to be facilitated, the obese patient should be positioned with the head elevated (reverse Trendelenburg position) on the operating room table. This position promotes patient comfort, reduces gastric reflux, provides easier mask ventilation, improves respiratory mechanics, and helps maintain FRC. The reduced FRC in obese patients contributes to the rapid desaturation that occurs with induction of general anesthesia.[142] To attenuate the desaturation and maximize O_2 content in the lungs, patients are preoxygenated with 100% mask O_2 for at least 3 to 5 minutes.[143] Adequate preoxygenation is vital in obese patients because of rapid desaturation after loss of consciousness secondary to increased oxygen consumption and decreased FRC. Application of positive-pressure ventilation during preoxygenation decreases atelectasis and improves oxygenation in morbidly obese patients. A study in morbidly obese individuals (limited to 160 kg by the weight limit of the computed tomography [CT] scanner) has demonstrated that the administration of continuous positive airway pressure (CPAP) during the preoxygenation period and gentle ventilation with positive end-expiratory pressure (PEEP) during anesthetic induction significantly reduce atelectasis, as documented by chest CT scans.[144] An associated benefit to the reduced atelectasis was a significantly increased average Pa_{O_2} (457 ± 130 pascals [Pa] versus 315 ± 100 Pa, P = 0.035) in those subjects who received CPAP-PEEP versus the control subjects. Theoretically, the increase in Pa_{O_2} would increase the apneic time to oxygen desaturation if an airway event were to occur.[145]

Some practitioners advocate the use of an "awake look" to visualize the difficulty of the airway.[104-106,111,112] Careful administration of sedative drugs and application of topical anesthesia to the oropharyngeal structures, possibly including transtracheal and superior laryngeal nerve blocks, are performed. Nasal O_2 is used as a supplement during awake laryngoscopy. If the epiglottic and laryngeal architecture is easily visualized, successful asleep intubation can be done. If the airway structures cannot be visualized, an intubating LMA, awake fiberoptic, or other type of intubation should be used.[111,146,147] Many clinicians advocate the use of a modified rapid-sequence induction when aspiration is a consideration.[148] This is a technique with preoxygenation and cricoid pressure as usual, but the lungs are lightly ventilated prior to securing the airway. This avoids the rapid desaturation that frequently occurs in the obese patient with no or a minimal increased risk of aspiration. The endotracheal tube must be safely secured to prevent movement during positioning and surgery.[88]

The surgeon and another skilled anesthesia provider also must be in attendance during the induction. Muscle hypotonus in the floor of the mouth, followed by rapid occurrence of soft-tissue obstruction and hypoxia, requires one person to support the mask and airway while another person bag-ventilates the patient. In the case of inability to ventilate or intubate, the American Society of Anesthesiologists' difficult airway algorithm should be followed (see Chapter 22). Intubation of the obese patient can be safely accomplished with careful assessment and planning and use of modern airway techniques.

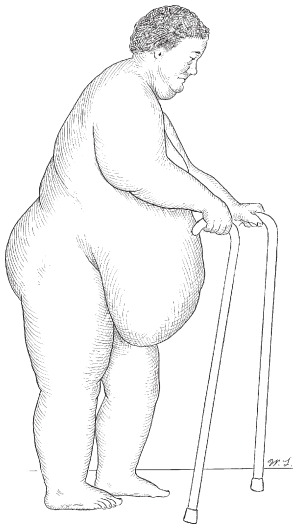

FIGURE **43-4** Panniculus in a standing patient.

Effects of General Anesthesia on Respiration

General anesthesia depresses respiration in normal subjects, so any preexisting pulmonary dysfunction is exaggerated by anesthesia.[18] The type of surgery, positioning, and underlying disease pathology further compound the undesirable respiratory responses caused by obesity and anesthesia.[149-154] General anesthesia causes a 50% reduction in FRC in the obese anesthetized patient, as compared with a 20% reduction in anesthetized nonobese patients.[88] Airway collapsibility is likely due to the decreased lung volume associated with deeper anesthesia as the end-expiratory esophageal pressure is reduced with lighter planes of anesthesia.[155] FRC can be increased by ventilating with large tidal volumes (15 to 20 mL/kg), although this has been shown to improve arterial O_2 tension only minimally.[83,149] In contrast, the addition of PEEP achieves an improvement in both FRC and arterial O_2 tension, but only at the expense of cardiac output and O_2 delivery.[151,152] Current ventilation recommendations include using tidal volumes of 10 to 12 mL/kg to avoid barotrauma.[83] During laparoscopic surgeries, the respiratory rate should be 12 to 14 breaths per minute.[80]

Prolonged (longer than 2 to 3 hours) and extensive procedures (those involving the abdomen, thorax, and spine) negatively influence respiratory function. Subdiaphragmatic packing, cephalad displacement of organs, and surgical retraction cause decreased alveolar ventilation, atelectasis, and pulmonary congestion.[149,150] Recumbent or Trendelenburg positioning further reduces diaphragmatic excursion, which is already impaired by the weight of the panniculus (which can be very large) (Figure 43-4). Trendelenburg positioning also causes elevated filling pressures, which then increase right ventricular preload. Subsequently, myocardial O_2 consumption, cardiac output, pulmonary artery occluding pressures, peak inspiratory pressures, and venous admixtures are increased above upright-sitting values.[151]

In a normal-weight person, cardiac output increases in response to supine posturing to maintain hemodynamic stability. By increasing left ventricular output, the centrally located circulating volume is propelled forward, thereby minimizing pulmonary congestion and hypoxia. In a severely obese patient, positive-pressure ventilation (which impedes venous return) and inability to increase cardiac output may result in cardiopulmonary decompensation.[152,153] This is exhibited intraoperatively by hypoxia, rales, ventricular ectopy, congestive heart failure, and hypotension.[154] Bag ventilation by hand may be useful to attenuate hypotension resulting from positive pressure.

Use of ventilators powerful enough to inflate the morbidly obese thorax is critical to minimizing hypoxia. Pressure- or volume-controlled ventilators can be used to maintain adequate oxygenation and normocapnia. Avoidance of prolonged prone, Trendelenburg, or supine positioning also decreases ventilation-perfusion mismatch. Optimization of oxygenation by using no less than 50% flow of inspired O_2 is emphatically recommended.[18,31,83] Intermittent manual "sighs" of large volume can also augment the FRC.

Application of PEEP can reduce venous admixture and support adequate arterial oxygenation. PEEP, however, can impair arterial oxygenation in some patients when it is superimposed on large tidal volumes.[153] For these reasons, PEEP that exceeds 15 cm H_2O is not recommended.

Other intraoperative events, such as hemorrhage or hypotension, further impair ventilatory homeostasis and result in hypoxemia that extends into the postoperative period.[30] A vertical abdominal incision, compared with a horizontal (transverse) incision, also prolongs postoperative hypoxia.[103] Pain causes further reductions in diaphragmatic excursion and vital capacity, leading to atelectasis and ventilation-perfusion mismatch.[18,83] For these reasons, 24-hour postoperative admission to a monitored bed is prudent for severely obese patients, who already exhibit higher morbidity and mortality apart from anesthesia and surgery.

Some suggested ventilatory strategies are listed in Table 43-4.

Choice of Anesthetic Technique

Selection of the anesthetic technique is dependent on the patient, coexisting history, planned surgical procedure, and anesthetist and patient preference. Diverse anesthetic techniques have been described for use with obese patients undergoing surgical and diagnostic procedures.[94,134,156-161] Anesthetic management of obese patients can include local or monitored anesthesia, general (e.g., narcotic, inhalation) anesthesia, regional blocks, or a combination of techniques.

No demonstrable difference in emergence from inhalation versus narcotic technique has been discerned in the obese patient.[18] The use of short-acting anesthetics facilitates smooth anesthetic induction, maintenance, and emergence from anesthesia. Objectives for maintenance of anesthesia in the obese patient include strict maintenance of airway, adequate skeletal muscle relaxation, optimum oxygenation, avoidance of the residual effects of muscle relaxants, provision of appropriate intraoperative and postoperative tidal volume, and effective postoperative analgesia. Depending on the patient's condition and the type of surgery, these can be achieved by either general or regional anesthesia. An epidural anesthetic with concomitant "light" general anesthesia is frequently chosen. A light general anesthetic can facilitate management of the airway, ventilation, and the patient's level of consciousness, whereas the epidural provides surgical analgesia and anesthesia. The epidural catheter can be used for postoperative analgesic administration and will enhance earlier resumption of deep breathing and coughing maneuvers.

Volume Replacement

Despite the augmentation of circulatory fluid that accompanies morbid obesity, the estimated blood volume is actually diminished.[22] Fat, which contains only 8% to 10% water, contributes less fluid to total body water than equivalent amounts of muscle. The normal adult percentage of total body water is 60% to 65%.[18] In the severely obese, it is reduced to 40%. Therefore, calculation

TABLE 43-4 Ventilatory Management of the Morbidly Obese Patient

Goal/Recommendation	Rationale/Additional Information
Prevent Hypoxemia During Induction	
HOB elevated (back-up Fowler or reverse Trendelenburg) 30 degrees Use of CPAP during induction Preoxygenate with 100% O_2	May increase the safe apnea period during induction
Prevent/Reverse Atelectasis	
Restrict the use of Fio_2 to less than 0.8 during maintenance of anesthesia	Use of a high Fio_2 concentration during anesthesia accelerates the onset and the amount of atelectasis
Recruitment ("vital capacity") maneuver after intubation by using sustained (8-10 seconds) pressure of 40 cm H_2O or greater	Monitor for adverse effects (bradycardia, hypotension)
Maintain Lung Recruitment	
Use PEEP (10-12 cm H_2O)	Monitor for hypotension or decreasing arterial oxygenation (PEEP-induced increase in pulmonary shunt fraction)
Prevent Reoccurrence of Atelectasis	
Intermittent intraoperative re-recruitment	Monitor highest oxygenation and respiratory system compliance achieved after recruitment: a decline may be a sign of redeveloping atelectasis
Avoid Lung Overdistension	
Use tidal volume 6-10 mL/kg of ideal body weight Keep end-inspiratory pressure below 30 cm H_2O Consider mild permissive hypercapnia if necessary	Increase the ventilation rate to control excessive hypercapnia instead of using large tidal volumes or high ventilatory pressures
Maintain Postoperative Lung Expansion	
Use CPAP or BiPAP immediately after tracheal extubation Keep the upper body elevated Maintain good pain control Use incentive spirometry Encourage early ambulation	

Adapted from Thompson J, et al. Anesthesia case management for bariatric surgery. *AANA J*. 2011;79:2:147-160.
BiPAP, Bi-level positive airway pressure; *CPAP*, continuous positive airway pressure; *Fio_2*, fractional inspired oxygen concentration; *HOB*, Head of bed; *PEEP*, positive end-expiratory pressure.

of estimated blood volume should be 45 to 55 mL/kg of actual body weight rather than the 70 mL/kg apportioned in nonobese adults.[17] Use of reduced parameters for volume replacement and avoidance of rapid rehydration lessen cardiopulmonary compromise. Fluid management is guided by the usual clinical parameters such as blood pressure, heart rate, and urine output measurements. Fluid requirements for bariatric procedures may be greater than anticipated to maintain renal perfusion. Although rare, acute renal failure occurs in approximately 2% of bariatric procedures. Predisposing factors include hypovolemia, a BMI greater than 50 kg/m^2, prolonged surgery time, intraoperative hypotension, and preexisting renal disease.[162] Adequate intraoperative fluid replacement also helps reduce postoperative nausea and vomiting after bariatric procedures.[163] Volume expanders, such as hetastarch (Hespan), should not be administered at greater than recommended volumes per kilogram of IBW (20 mL/kg). Dilutional coagulopathy, factor VIII inhibition, and decreased platelet aggregation can result from excessive administration. Albumin may be used as indicated to support circulatory volume and oncotic pressure. No difference in the criteria between the administration of blood products in normal-weight patients versus severely obese patients has been identified.

Intraoperative Positioning

Surgical positioning of morbidly obese patients necessitates extra precautions for the prevention of nerve, integumentary, and cardiorespiratory compromise. The type of surgery, combined with inordinate stretching or compression of nerve plexuses and prolonged immobility, cause local tissue ischemia and damage, which begins at the cellular level. Hypothermia, hypotension, table positioning, and the pressure effect the adipose tissue places on orthopedic or cardiopulmonary structures potentiate impairment.[165]

Although many peripheral nerves are subjected to possible ischemia or necrosis, the ulnar, brachial plexus, radial, peroneal, and sphenoid nerves are the most vulnerable to injury in any anesthetized patient. In morbidly obese patients, the incidence may be increased because of excessive weight on the anatomic structures.[164] Care is necessary when one is positioning obese extremities in slings, draping them on Mayo stands, or securing them in lithotomy stirrups. Excess weight and loose skin may "strangle" or macerate tissues on the dangling ankle or wrist. Draping of heavy upper extremities atop poorly secured Mayo stands can cause cuts, bruises, or abrasions of the arm, breast, or abdomen, as well as obscure early signs of skin breakdown or circulatory compromise.

Prolonged hyperextension, external rotation, or abduction greater than 90 degrees overstretches the brachial plexus and can cause postoperative muscle pain, nerve palsies, or paralysis. Often obese patients do not have the range of motion that nonobese individuals possess. Therefore, less flexion or abduction and rotation of hips, legs, and arms may be necessary. Frequent palpation of pulses, generous padding, correct alignment, and repeated inspection of extremities for color and temperature can help diminish the incidence of positioning-related injuries.[165,166]

Lower back pain can be aggravated by both spinal and general anesthesia because of ligamentous relaxation that results in loss of lumbar curvature. Surgical towels placed under the lumbar spine before induction will enhance lordosis and reduce postoperative discomfort.[164]

Treatment of the panniculus is often a major concern for both anesthetist and surgeon. Extra-long straps and wide adhesive tape can secure the panniculus and reduce shifting when the operating table is changed. If Trendelenburg positioning is anticipated, some means to prevent the panniculus from sliding cephalad must be devised. The head-down position, coupled with the crushing weight of the thorax and panniculus, compresses the brachial neurovascular bundle between the clavicle and first rib. If the patient requires a fracture table, ensure that sufficient padding encircles the pole adjacent to the patient's vulva or penis.[166] Genital and pudendal nerve injury can be profound if adipose tissue surrounding the thigh is not carefully distracted to reveal proper placement of the padding.

Integumentary Concerns

Decubitus ulcers, skin infection, and wound dehiscence are exceedingly common in the severely obese. Decubitus ulcers arise

from prolonged immobility and compression of the fat on bony prominences and vessels. Traction, external fixation devices, and straps may cause certain types of injury. Creases of the skin are subject to erosion and ulceration from sweat and constant friction of opposing skin surfaces. Inability to perform hygiene under the breasts, between neck folds, or beneath the abdominal pannus accommodates organism proliferation. Concomitant diabetes further accelerates the growth of bacterial or fungal infections. As a result, wound dehiscence, particularly in the abdomen, can occur after suboptimal surgical closure in compromised skin. A poorly vascularized panniculus and torsion on the wound by the weight of the fat apron also contribute to malunion of the tissue.[166] Although atelectasis and hypoxia are less frequent with a horizontal laparotomy, a vertical laparotomy approach is often preferred by the surgical team. Compression of abdominal contents on superficial wound layers is lessened during ambulation and therefore may reduce the occurrence of dehiscence.[85]

Extubation

The risk of airway obstruction after extubation is increased in obese patients.[167] A decision to extubate depends on evaluation of the ease of mask ventilation and tracheal intubation, the length and type of surgery, and the presence of preexisting medical conditions, including OSA. Criteria for extubation must include all of the standard objective and subjective criteria used by every clinician. Patients are usually placed with the head up or in a sitting position prior to extubation. If doubt exists regarding the ability of the patient to breathe adequately, the endotracheal tube is left in place and extubation over an airway exchange catheter or via a fiberoptic bronchoscope may be performed.[167,168]

Regional Anesthesia

Regional anesthesia can be used as the primary anesthetic in selected cases or as an accompaniment to postoperative pain and mobility management.[18,25,166] Difficulties are frequently encountered, though, in severely obese patients. Anatomic landmarks used to guide conduction blockade are not easily visualized, palpable, or identifiable with ultrasound. Brachial plexus anesthesia can be hampered by adipose tissue in the axillary region, inability to position the arm, and an undetectable pulse. Full-term pregnancy, obesity, and the coincident discomfort of active labor further inhibit the discernment of spinous processes and posterior iliac crests. Redundant rolls of fat, unsatisfactory ventilation, and inability of the patient to sustain optimal positioning make neuraxial anesthesia even more challenging.

For subarachnoid or epidural anesthesia, it is recommended that the patient sit upright so that landmarks such as C7 or L3 to L4 can be more easily identified.[86] In addition, skin-fat folds will fall toward the operating table, and respiratory ventilation will be enhanced. A selection of longer needles (7 inches) should also be available before anesthetic administration is begun. Generous infiltration with local anesthetic will provide greater patient comfort during insertion of the "finder," Tuohy, or spinal needle. The importance of generous administration of local anesthetic cannot be overemphasized because repeated insertions and repositioning of the needle or introducer may be required before access to the epidural (or subarachnoid) space is achieved.

Another consideration regarding subarachnoid or epidural anesthesia in severely obese pregnant or surgical patients is the lack of predictability of spread of local anesthetic. Obese patients will also experience greater respiratory embarrassment from a high regional block than normal-weight patients.[169] Successful laparotomy procedures have been described after epidural anesthesia.[170]

In obese parturients, a cesarean section can be performed under spinal or epidural anesthesia. A significant correlation exists with increased body mass and rostral spread of epidural subarachnoid anesthetics when a patient is positioned supine. Undesirable cephalad spread of local anesthetics can be obviated by reducing the volume and increasing the patient's upright sitting time.

ANESTHETIC MANAGEMENT: POSTOPERATIVE CARE

Pain Management

Optimal postoperative pain management is facilitated by the use of oral analgesics, NSAIDs, patient-controlled analgesia, local infiltration of the surgical site, and epidural anesthesia. Obese patients are more sensitive to the respiratory-depressant effects of opioid analgesics; therefore caution and close monitoring are warranted.[171] Supplemental O_2 and pulse oximetry monitoring are mandated. If the patient was on CPAP (nasal or facemask) preoperatively, CPAP should be applied at all rest times in the early post–general anesthetic period. The CPAP protects the patient with OSA against airway obstruction during sleep by pneumatically splinting the oropharynx.[43,172,173] Postoperative opioids must be used judiciously.

Postoperative Complications

Morbidity and mortality rates are higher in obese patients than in normal-weight patients. Various studies have reported that the mortality rate during the perioperative period has decreased among morbidly obese patients.[174] Older age, a high BMI, and male gender have been confirmed as proven surgical risk factors for obese patients undergoing gastric bypass surgery.[175,176] Other factors that have been shown to increase mortality risk include hypertension, diabetes, postoperative leak with bariatric procedures, and thromboembolism.[177] Those with major comorbid diseases had a higher BMI, a higher mortality, a greater leak rate, and a higher rate of surgical site infections.[178] Ventilation abnormalities are exacerbated in obese patients with OSA and OHS and may last for several days. The maximum decrease in partial pressure of arterial oxygen occurs 2 to 3 days postoperatively.[29] In one study, morbidly obese subjects had a mean maximal oxygen uptake that was similar to patients with severe heart failure (mean ejection fraction 21.5 ± 8%).[179] The same investigators studied cardiorespiratory fitness in 109 patients prior to laparoscopic gastric bypass. They found that severe complications and mortality were more common in patients whose maximum oxygen uptake was less than 15.8 mL/kg/min than in those whose maximum oxygen uptake was more than 15.8 mL/kg/min ($P = 0.02$).[180] This may be a promising way to identify high-risk patients and perhaps monitor their preoperative progress. Blouw et al.[181] tried to identify factors influencing the frequency of respiratory failure in patients with morbid obesity. They found that a higher rate of respiratory failure is associated with BMI greater than 43 kg/m^2.

Rhabdomyolysis is a complication in about 1.4% of bariatric surgeries, owing to high pressures exerted on deep tissues. Serum creatinine phosphokinase (CPK) measured pre- and postoperatively aids in early diagnosis and treatment, which helps reduce further complications such as myoglobinuric acute renal failure that can be as high as 30% with serum CPK greater than 5000 units/L.[182] A recent report[183] describes rhabdomyolysis of the gluteal muscles leading to renal failure in several morbidly obese patients who were supine for 5-hour gastric bypass operations. Another case report[184] describes rhabdomyolysis leading to renal failure and death after bariatric surgery.

The risk of thromboembolism, wound infections, and atelectasis is amplified in patients with increased BMI.[29,168]

Thromboembolism is facilitated by immobility (venous stasis), increased blood viscosity (polycythemia, hypovolemia), increased abdominal pressure, and abnormalities in serum procoagulants and anticoagulants.[6] Obesity is an independent risk factor for development of venous thromboembolism (VTE).[185] Thromboembolism is reported to be the most common cause of postoperative mortality after bariatric surgery, accounting for as many as 50% of all deaths.[186]

Four important risk factors, namely, venous stasis disease, BMI of 60 or more, truncal obesity, and obesity hypoventilation syndrome (OHS) or sleep apnea syndrome (SAS) are significant in the development of postoperative venous thromboembolism, and if present, preoperative prophylactic placement of an inferior vena cava (IVC) filter should be considered. Venous stasis disease, BMI greater than 60, truncal obesity, OHS, OSA, a previous incidence of pulmonary embolism, and hypercoagulable states have been suggested as factors that increase the baseline risk of perioperative pulmonary embolism in obese patients after bariatric surgery.[187] Administration of minidose heparin (5000 units administered subcutaneously twice per day), low-molecular-weight heparin, antiembolic stockings, and correctly fitting pneumatic compression boots can lessen the occurrence of deep vein thrombosis in the early postoperative period. Early ambulation and maintenance of vascular volume further attenuate the likelihood that clots will develop. Wound infections and pulmonary embolism are 50% higher in obese patients than in normal-weight patients.[188-190]

Post–Gastric Bypass Anastomotic Leaks

In a recent series of more than 3000 gastric bypass patients from four centers, the anastomotic leak rate was 2.1%.[191] The most common signs and symptoms of a leak were tachycardia (72%), fever (63%), and abdominal pain (54%). An upper gastrointestinal series was positive in 17 of 56 patients. Tachycardia is the most sensitive sign of an anastomotic leak, and a heart rate greater than 120 beats per minute should prompt an investigation, even if the patient looks and feels well. Tachypnea or decreasing oxygen saturations can also signal early sepsis from a leak and may be clinically indistinguishable from pulmonary embolism. Signs and symptoms of an anastomotic leak are shown in Box 43-8.[81,192,193]

In general, morbidly obese patients have higher rates of postoperative and intensive care unit (ICU) complications and may require more intensive care and increased staffing requirements.[194] Investigations in surgical/trauma ICU patients universally report an adverse effect of obesity on outcomes. In a surgical ICU, investigators reported that morbid obesity conferred elevated odds of death after 4 days of ICU stay,[195] and among blunt-trauma patients, obese patients suffered more frequent complications (e.g., multiple-system organ failure, acute respiratory distress syndrome, myocardial infarction, and renal failure), including the need for more vasopressors, additional days of ventilator support, and more often failed extubation. Among survivors, obese patients had a higher ICU and hospital length of stay.[196]

BOX 43-8

Signs and Symptoms of Anastomotic Leak

- Unexplained tachycardia (sustained heart rate greater than 120 bpm)
- Shoulder pain (usually left)
- Abdominal pain
- Pelvic pain
- Substernal pressure
- Shortness of breath
- Fever
- Increased thirst
- Hypotension
- Unexplained oliguria
- Hiccups
- Restlessness

SUMMARY

Obesity is a complex and multifactorial disease, and its incidence is continuing to increase in the U.S. patient population. Through an understanding of the implications of associated conditions in obesity, the anesthetist can promote more favorable anesthetic outcomes. Consideration of the physiologic and pharmacologic changes and their implications for optimal anesthetic management guides clinical practice.

44 CHAPTER Regional Anesthesia

Spinal and Epidural Anesthesia

◆ *R. Lee Olson, Joseph E. Pellegrini, and Beth Ann Movinsky*

Spinal and epidural blocks are known collectively as *central neuraxial blockade* (CNB) because they involve the placement of local anesthetic solution onto or adjacent to the spinal cord. Both spinal and epidural blocks share much of the same anatomy and physiology but are distinct from one another due to their unique anatomic, physiologic, and clinical features.

The person most credited with introducing spinal anesthesia is Augustus Bier, who in 1898 described the injection of cocaine into the spinal column and its potential for use as a surgical anesthetic technique. When cocaine was introduced into the subarachnoid space, anesthesia lasted approximately an hour. With the development of newer and safer anesthetic drugs, needles, and techniques, regional anesthesia expanded to include many neural blocks for the enhancement of surgery and obstetrics and the management of pain.[1,2] Modern procedures have simplified, refined, and increased the safety and success of regional anesthesia techniques.[2]

APPLIED ANATOMY AND PHYSIOLOGY OF THE CENTRAL NEURAXIS

Knowledge of anatomic landmarks and underlying structures aids the anesthetist in forming a three-dimensional "mind's-eye" picture. This picture, coordinated with the "feel" of the structures and tissues against the needle and a steady, sensitive hand, facilitates accurate placement of the needle tip and administration of appropriate techniques and medications. Although anatomy is the oldest of medical sciences (with detailed descriptions of the spinal column dating from the nineteenth century), modern imaging methods such as computed tomography (CT), magnetic resonance imagining (MRI), and endoscopic examination have permitted in vivo investigations that further our understanding of spinal anatomy. The following is therefore a current review of applied anatomy of the central neuraxis.

The sequential interconnectivity of the 33 bones called *vertebrae* form the spinal, or vertebral, column, which anesthetists use as a bony reference during the placement of various anesthetics or analgesics. This column is located in the posterior midline of the trunk and allows for truncal flexibility because movable joint surfaces and cartilaginous vertebral bodies exist between 24 of the 33 vertebrae (Figure 44-1). The vertebral column extends from the base of the skull and the foramen magnum to the tip of the coccyx. The vertebral bodies are stacked on top of one another, separated by fibrocartilaginous intervertebral disks that provide support for the cranium and trunk. In general, each vertebra can be visualized as having two parts. The anterior, cylindric portion of the vertebra is solid and called the *body*. This heavier portion of the vertebra forms the anterior portion of the vertebral arch. The body of each vertebra is contiguous with two pedicles that stretch in a posterior and slightly lateral direction, joining to two laminae that stretch posteriorly and medially to complete an arch, creating an oval-triangular foramen. This foramen, known as the *vertebral foramen*, allows for the passage and protection of the spinal cord. Transverse processes on both sides of the pedicles allow for muscular attachments and the control of movement. A spinous process projects along the median plane from the union of the laminae in a posteroinferior direction. The spinous process is the long, slender, bony prominence that can often be seen and felt along the midline of the back. The spinous process also provides a place for muscular attachment and movement control. In addition, the inferior angle of the bone creates an overlap that further protects the spinal cord (Figure 44-2).[3]

The pedicles and processes of each vertebra have superior and inferior articular surfaces and lateral notches. The superior notch is shallow when compared with the deeper inferior notch. When the vertebrae are stacked, the notches and the articulating surfaces, known as *zygapophyseal* or *facet joints*, form the intervertebral foramina. The intervertebral foramina provide safe passage for spinal nerves passing from the spinal cord to the rest of the body. The articular surfaces of the facet joints are covered with hyaline cartilage, which permits a gliding motion between the vertebrae. Because the facet joints are innervated by branches from closely associated spinal nerves, these joints often become clinically important. When the joint is injured, the associated spinal nerves also may be affected, leading to pain along associated dermatomes or muscle spasm along associated myotomes.[3]

The size and shape of vertebral lamina and spinous processes differ among the thoracic, lumbar, and sacral regions, and variation exists within each region. Knowledge of these variations is important in the practice of regional anesthesia and in selection and administration of spinal and epidural anesthesia. For instance, cervical and thoracic vertebrae have spinous processes that angle acutely in a caudad direction such that the process of the superior vertebra overlaps the inferior vertebra and its process. This construction adds protection to the spinal cord when an individual stands erect. When attempts are made to insert a needle into the cervical or thoracic regions, the tight construction and angles of the vertebral column must be considered.

In the lumbar region the vertebrae are larger, and the spinous processes become shorter and broader and have a posterior orientation with less overlap than in other vertebrae. Relatively large gaps, bridged by ligaments, exist between the spinous processes in the lumbar area. This provides the anesthesia practitioner easier access for needle placement, catheter passage, and the instillation of anesthetic into the epidural or subarachnoid space for surgical or obstetric procedures.

The sacrum is a triangle-shaped section of fused bodies of vertebrae. The broader portion is the base, which tapers as it approaches the coccyx. The sacrum is shaped so the weight of the body forces the base of the sacrum downward and forward. It is wedged tightly between the two iliac crests by the downward forces exerted on the spinal column. The lamina of the last sacral vertebra is incomplete

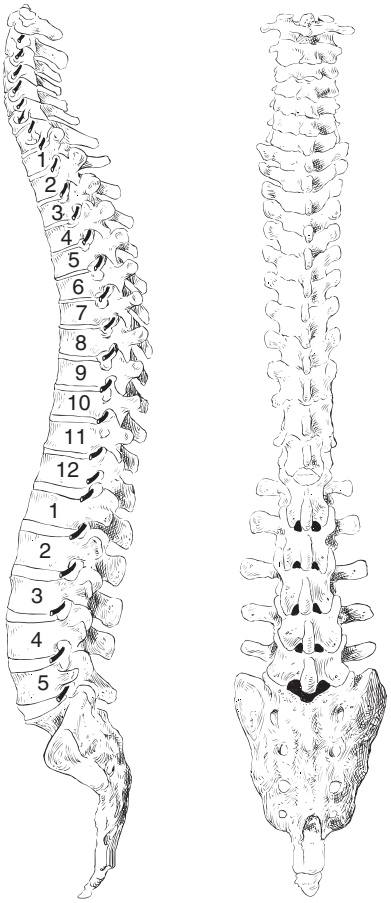

FIGURE **44-1** The spinal, or vertebral, column with its 33 vertebrae.

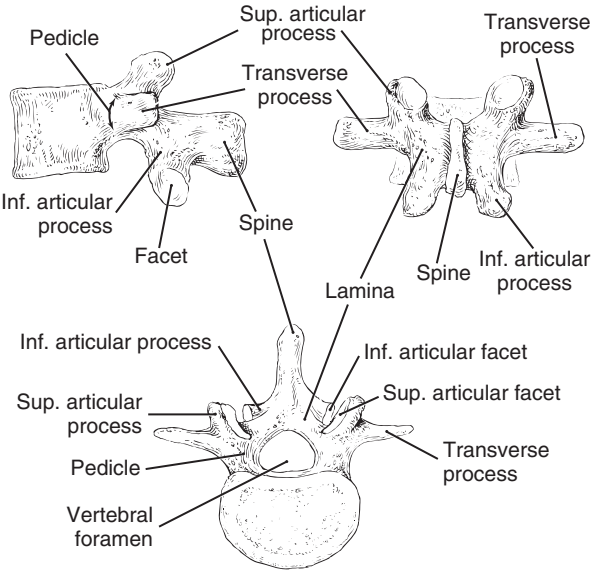

FIGURE **44-2** Articular surfaces, transverse processes, and spinous process. *Inf*, Inferior; *Sup*, superior.

and bridged only by ligaments. This area is known as the *sacral hiatus* (Figure 44-3). The coccyx is composed of four small segments of bone that become fused into two bones as an individual ages; between the ages of 25 and 30 years, fusion is complete. The bodies of the vertebrae can be identified with the transverse processes and articular processes. No pedicles or spinous processes are present. The last, or fourth, bone is small and is similar to a nodule.

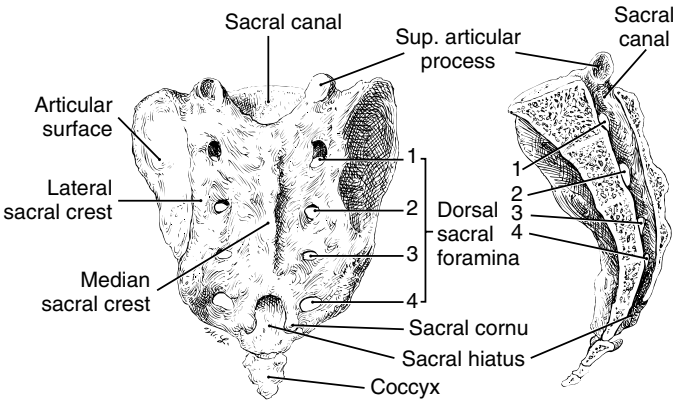

FIGURE **44-3** Sacrum and coccyx.

The changing size of the bone from the first to the fourth vertebra gives the coccyx the appearance of a triangle. The projections of the rudimentary articular processes are known as the *cornua*, and the superior pair is the most pronounced. These sacral cornua are the "horns" or bony protuberances that guard the area of the sacral hiatus.[3] Because they can be easily palpated in children and in most adults, they are important surface anatomic landmarks for the performance of a caudal anesthetic procedure.

Of the more than 35 pairs of muscles and ligaments in the back, the supraspinous ligaments, the interspinous ligaments, and the ligamentum flavum (yellow ligaments) are of special significance to the anesthesia practitioner. These three structures act as landmarks that help in identification of and access to the epidural and subarachnoid spaces. The supraspinous ligament is a strong cordlike ligament that connects the apices of the spinous processes; it is thick and serves as the major ligament in the cervical and upper thoracic regions. The supraspinous ligament consists of three layers: the superficial layer extends over several vertebral spinous processes, the middle layer connects two or three spinous processes, and the inner layer connects only the neighboring spinous processes. The ligament blends at all levels with the thin interspinous ligaments that run between adjacent spinous processes. The interspinous ligaments are usually absent or of poor quality in the cervical region and can be exceptionally thin in the lumbar area, even in young people. The ligamenta flava are the strongest of the posterior ligaments. These broad elastic bands join the vertebral arches through vertical extensions from adjacent lamina. The ligamenta flava are paired flat ligaments that run caudad from the inferior border of one lamina to the upper border of the lower lamina on both sides of the midline. The two ligaments almost fill the space, leaving only a separation in the midline and thereby creating a V or wedge that points posteriorly to align with the interspinous and supraspinous ligaments. The V is thin on the lateral edge and thickest midline—in an adult approximately 3 to 5 mm at the L2-L3 interspace. The ligaments extend from each lamina with an overlapping of fibers that creates the appearance of a contiguous ligament from one vertebral body to the next. The ligament is thicker in the lumbar area than in the cervical area and is responsible for maintenance of upright posture. The ligaments' color comes from their high content of yellow elastic tissue.[4]

The spinal cord itself is a cylindrical structure extending from the medulla oblongata through the spinal foramen to the level of the L2 vertebra in most adults and ranges from 42 to 45 cm in length (Figure 44-4). Because the vertebral column grows more rapidly than the spinal cord, the spinal cord in children extends

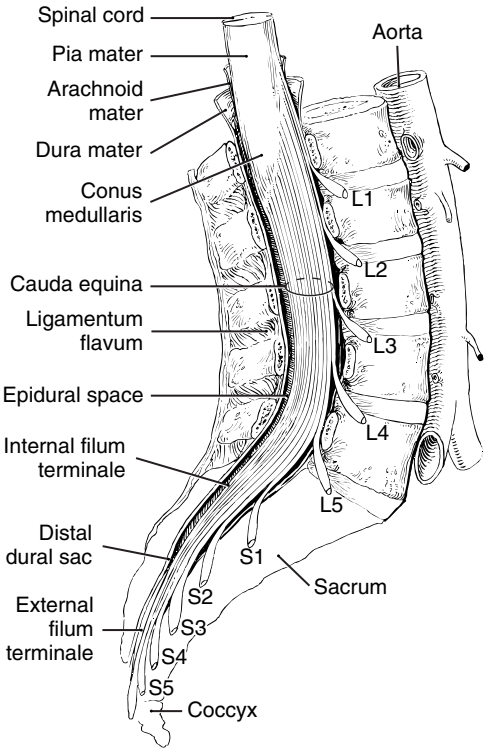

FIGURE **44-4** Extension of the spinal cord to the second lumbar vertebra.

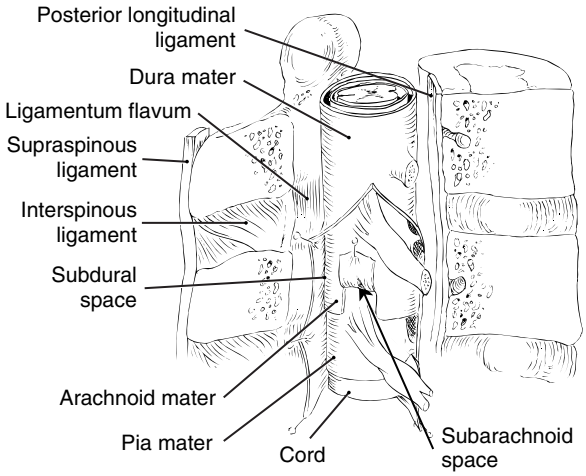

FIGURE **44-5** The linings of the spinal cord and the posterior ligaments of the spinal column.

initially to the level of the third lumbar vertebra. In approximately 1% of adults, the spinal cord may extend below L2 and rarely to the level of L3. The spinal cord tapers to the conus medullaris, and nerve pathways continue in a collection of rootlets called the *cauda equina* or *horse's tail*, which extends from L1 to S5. The spinal cord is enlarged in two regions. The first, called the *cervical enlargement*, extends from the spinal segments C4 to T1. The ventral rami of the spinal nerves in this enlargement form the brachial plexus of nerves that innervates the upper limbs. The second enlargement stretches from segments L2 to S3. This lumbosacral enlargement contributes corresponding nerves to create the lumbar and sacral plexuses. It is important to note that the spinal cord levels do not directly correspond with vertebral levels. For example, in adults the lumbosacral enlargement (L2 to S3) usually extends from the body of the T11 vertebra to the body of the L1 vertebra.[3]

The spinal cord is enveloped by the same three membranes that line the cranium, and they are collectively called the *meninges*. The meninges are nonnervous support tissues that provide a protective covering for the cord and nerve roots from the foramen magnum to the base of the cauda equina. The linings are identified as the *dura mater*, the *arachnoid mater*, and the *pia mater*. The dura mater is the outermost layer. It is a thick, tough membrane that provides most of the protection for the central cord structures. The nerve roots are covered with dura mater while inside the spinal canal. As the roots exit the canal via the intervertebral foramen, the dura blends into the root at a junction referred to as a *dural cuff* or *root sleeve*. The arachnoid mater is a thin, spiderweb-like covering that forms the middle layer. Beneath the arachnoid mater is a space that is continuous with the central canal of the cord and the ventricles. This space, which is filled with cerebrospinal fluid (CSF), is known as the *subarachnoid space*. This mater and the fluid protect the spinal cord from shock injuries and are the medium for the interaction with local anesthetics and opioids that occurs during the administration of regional anesthesia. The innermost layer, the pia mater, is thin and is in direct contact with the outer surface of the spinal cord (Figure 44-5).[3]

The epidural space is a potential space outside the dural sac but inside the vertebral canal and is continuous from the base of the cranium to the base of the sacrum at the sacrococcygeal membrane. The epidural space contains epidural veins, fat, lymphatics, segmental arteries, and nerve roots. Fat in the epidural spaces is physiologically fluid, acting as a pad and lubricant for the movement of neural structures within the canal. The posterior epidural space, as it is approached by the anesthetist's advancing needle, is protected by the ligamenta flava, the lamina, and the spinous processes. It is easy but inaccurate to depict the epidural space as a uniform column surrounding an equally uniform and tapering spinal cord. A better mental picture is provided by a "look" along the longitudinal axes. The epidural space can be envisioned as a series of lateral, posterior, and anterior compartments existing among the vertebral body, lamina, and pedicles. The compartments, occupied mostly by fat but also by nerves and fibrous tissue, repeat at each segment in a metameric fashion. Of greatest interest to the anesthetist, the posterior epidural space is a series of fat-filled tripodial pads, shaped like a three-sided sand dune. The pad stretches and narrows in a caudad direction as it approaches the next inferior lamina. In areas of the vertebral canal surrounded by bone, the dura actually contacts bone, leaving only a potential epidural space that physically separates the epidural fat-containing compartments. The posterior epidural space, therefore, is a discontinuous group of tapering fat pads that repeat throughout the length of the spinal canal and are separated by a potential space that allows the passage of fluids or small catheters.[4-7]

The distance from the skin to the epidural space and the depth of the epidural space, or the distance to the dura, is of interest to one wishing to avoid needle injury of neural and vascular tissues. The distance to the epidural space varies with vertebral level and is loosely correlated with patient weight. The distance from skin to the lumbar epidural space using a midline approach varies from 2.5 cm to 8 cm, with an average of 5 cm. Because the space itself is not uniform in shape, the depth of the epidural space from the ligamenta flava to the dura varies considerably. Given the tripodial, dunelike shape of the epidural space, expect the space to narrow considerably when approaching laterally to the midline and in more caudad areas in the space. The depth of the epidural space is also relative to the vertebral level of approach and angle of needle entry, but some clinical generalizations can be made. The epidural

space is largest (posterior to anterior) in the midline of the midlumbar region, at 5 to 6 mm. The midline thoracic region epidural space may be 3 to 5 mm deep and is narrower there (lateral width). Caution must be exercised when one approaches the lower cervical region because the epidural space is very small (only 1.5 to 2 mm), leaving little room for error.[5]

In addition to a larger epidural space, another anatomic reason to stay midline with an approaching anesthetic needle is the presence of the epidural veins. The epidural veins are valveless veins that form a plexus draining the blood from the spinal cord and the linings of the cord. The plexus is most prominent in the lateral portion of the epidural space. In pregnant or obese patients, the epidural veins become engorged and swollen as increased intraabdominal pressure results in venous congestion of the lumbar and sacral vessels. The potential for injury or accidental cannulation of these vessels is increased because of this physiologic compensation.[3,4,6]

A final anatomic consideration for neuraxial anesthesia is the existence of normal and abnormal curvatures of the spinal column. A median-plane longitudinal view of the vertebral column reveals four curvatures in the normal adult. The thoracic and sacral curvatures have posterior curvatures (concave anteriorly), whereas the cervical and lumbar regions have anterior curvatures (concave posteriorly). In a supine patient, the apex of the lumbar curve is usually at L3 to L4, and the trough of the thoracic curve is at T4.[8] *Scoliosis*, the most common abnormal curvature, is a lateral curvature of the spine, and *kyphosis* is an excessive posterior curvature or hump, usually of the thoracic region. Excessive *lordosis*, or hollowing of the back, may occur as a result of obesity as the body attempts to restore the center of gravity. A temporary lordosis may also occur during pregnancy. Changes in these anatomic curves will challenge the anesthesia practitioner during the performance of epidural or spinal anesthetic techniques. Clear knowledge of the curves is also important when anticipating the spread of local anesthetics in the subarachnoid space relative to the site of injection and the patient's position.[9]

Neuroanatomic Mapping and Evaluation of Neuraxial Anesthesia

The goal of neuraxial anesthesia is to block pain transmission from areas of injury, disease, or surgical intervention. Therefore, it is clinically useful to have knowledge of the innervations of body structures being operated on in relation to spinal nerve location within the vertebral column. Anatomic maps have been generated based on cutaneous sensation alone. These sensation maps are referred to as *dermatomal maps*, *charts*, or *levels*. A *dermatome* is defined as the area of cutaneous sensation supplied by a spinal nerve that is anatomically identified as it passes through an intervertebral foramen. For example, the umbilical area is directly anterior to the L3 vertebra but receives cutaneous innervations from T7 to T11, depending on the dermatomal map consulted (Figure 44-6).

For the practical clinician, use of accepted anatomic landmarks and test methods is perhaps the best method for documenting the functional level of blockade—the level of the loss of sensation achieved. The level of anesthetic can be evaluated in many ways, and tests can be used to evaluate several components of the neuraxial anesthetic. For motor function, a straight leg raise or a request to "step on the gas" works well as a clinical measure. Cutaneous sensation can be evaluated through use of a Wartenberg pinwheel, a Semmes-Weinstein monofilament aesthesiometer, or (more practically and simply) with the stylet from the spinal or epidural needle, a portion of a broken wooden tongue blade, or

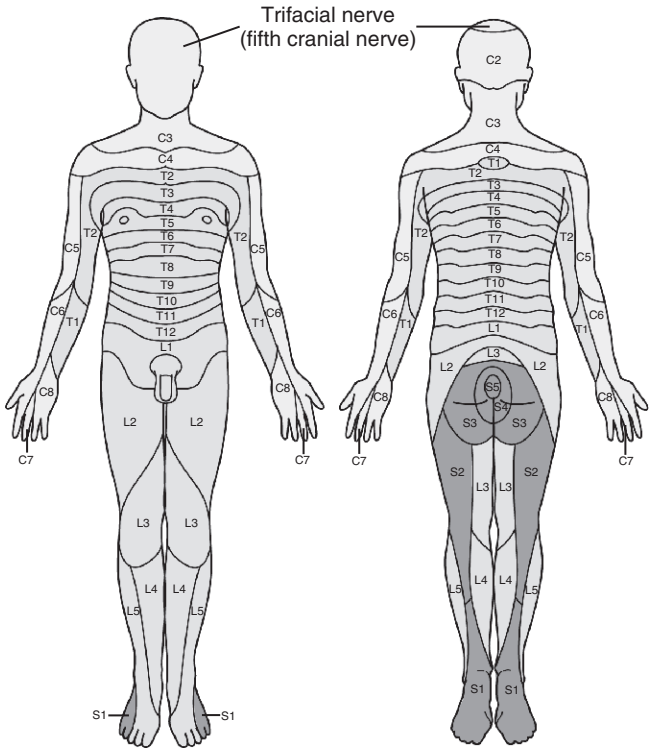

FIGURE **44-6** Dermatomes.

even a peripheral nerve stimulator. Such "pressure" or "scratch" tests are done using two surface-anatomy points for comparison. Inform the patient that the sensation on a normal area, such as the skin surface of the shoulder, is scratchy or sharp. Next, scratch or press an area expected to be numb, such as the lateral thigh. Gradually work cephalad in 2- or 3-inch bands until the patient notices a change in sensation. Note the level of the change in sensation relative to a dermatomal map. This approximates the upper level of sensory loss. Skin refrigerant, ice cubes, and alcohol pads can be used in a similar manner to identify changes in temperature sensation.

Physiology and Mechanisms of Action

Despite more than 90 years of research and experience with spinal and epidural anesthesia, much speculation remains regarding the exact cellular locations and molecular mechanisms involved when local anesthetics, opioids, and other pharmacologically active agents bind to produce spinal analgesia and anesthesia.[10,11] For a thorough review of local anesthetics and details on mechanism of action please see Chapter 10. What is known and clinically important about spinal and epidural anesthesia is that the primary site of action for local anesthetics is on the nerve roots within the spinal cord. When a drug is injected directly into the CSF, the drug distributes through the subarachnoid space based on the physical and chemical properties of that injectant and the characteristics of the space in which it must spread. When the drug concentration reaches a minimal effective concentration, neuronal transmission is altered in a manner that clinically provides anesthesia. Neurons—some myelinated, others not; some relatively large, others smaller—differ in susceptibility to drugs such as local anesthetics, and these pharmacodynamic relationships are not easily explained (Table 44-1). The processes involved at the cellular level are complex, and *blockade* is perhaps a confusing term. It is more accurate to say that anesthetic drugs alter nerve transmission, predominantly by affecting sodium ion channels and

TABLE 44-1 Classification of Nerve Fibers

		CONDUCTION		
Nerve Fiber	Myelination	Diameter (μm)	Velocity (m/sec)	Function
A-α	Heavy	15-20	70-120	Motor
A-β	Moderate	5-12	30-70	Touch and pressure
A-γ	Moderate	5-10	30-70	Proprioception
A-δ	Light	2-5	12-30	Pain and temperature
B	Light	1-4	3-15	Preganglionic, autonomic
C	None	0.5-1	0.5-2	Pain and temperature

inhibiting the units of information that are transferred along the spinal cord. Complete blockade or a "chemical transection" of the cord is an oversimplification. For example, somatosensory evoked potentials have been recorded in individuals made functionally insensate from lidocaine epidural anesthesia. This suggests that neural transmissions are reaching the brain without causing sensory perceptions.[4,12]

When a local anesthetic interrupts nerve transmission of autonomic nerves but not sensory nerves or motor nerves (because of a variation in susceptibility), a "differential block" is said to have occurred. A differential block is seen in the more rostral spinal segments of a spinal anesthetic. As the spinal anesthetic spreads from the epicenter of injection, the distal reaches of drug distribution are presumably of lesser concentrations. A differential block is clinically important when sensory anesthesia is desired at a specific level; however, sympathetic blockade could be deleterious in a patient with coexisting disease. The level of sympathetic blockade could be as high as six or more dermatomal levels above the level of sensory blockade and therefore contribute to hypotension and bradycardia.[11]

Drug injected into the epidural space is distributed to the same sites of action as a spinal anesthetic but in a slightly different manner. The drug must first distribute along the epidural space then diffuse through the meninges and dural cuffs to reach the nerve roots or reach the spinal cord through absorption into the radicular arteries.[13] Data exist to support the clinical impression that spinal anesthesia is generally more effective or complete from the patient's perspective than epidural anesthesia and therefore referred to as a more "dense" anesthetic. Epidural local anesthetics first act at sites such as the dural cuffs, at which spinal nerves pass through the peridural spaces. This is consistent with the segmental onset often associated with epidural anesthesia. If the concentration and volume of the anesthetic agent are increased, or if time is allowed for the drug to diffuse into the CSF or pass via radicular arteries into the spinal cord, the epidural anesthetic can become more dense.[4,8]

Central Neuraxial Blockade: Indications and Preoperative Considerations

Spinal and epidural anesthesia (central neuraxial blocks) can be used successfully for a variety of inpatient or ambulatory surgical procedures involving the lower extremities, perineum, and abdomen. In addition, spinal and epidural anesthesia or analgesia is used for the treatment of acute and chronic pain syndromes, for obstetric procedures and labor analgesia, and can be applied in patients at the extremes of age.[14] Spinal anesthesia techniques also may be used in combination with other techniques, such as epidural catheter techniques, general or intravenous anesthetic techniques, and with the use of a laryngeal mask airway, to provide anesthesia during surgery. Such combinations, or balanced techniques, minimize the side effects of any one anesthetic technique, maximize the benefits, and offer options in the selection of anesthesia or analgesia for surgical or obstetric procedures.[15]

As with any anesthetic plan, proper preparation, patient selection, education, and collaboration with surgeons and nurses are the keys to success. Often the best time to obtain a truly informed consent is during the preoperative visit. It is important to establish rapport with patients to gain their trust and cooperation. Patients eager to be involved in their own care often have the emotional maturity to understand the benefits of their anesthetic options and make rational choices. Anticipate patients' fears and anxieties; they are often easily dealt with through education and the reassurance provided by the calm voice of a confident and competent anesthetist.

Before presenting the option of a regional anesthetic to the patient, the anesthesia practitioner should answer the following three important questions about the procedure:

1. Will the patient be comfortable having this surgical procedure performed with the proposed regional anesthetic technique?
2. Will the patient be able to remain in the required position without difficulty for the length of the procedure?
3. Does this regional anesthetic technique outweigh the risks of performing this procedure using an alternate anesthetic technique?

The answers to these questions directly affect the choice of anesthetic techniques offered to the patient. When recommending any anesthetic technique to the patient, the practitioner has a responsibility to educate the patient, the patient's family, and other interested parties about the anesthesia procedure and the potential outcomes. One can then obtain an informed consent and garner the trust of the patient before performing any technique. Without this trust, even the best anesthetic technique may be a failure.

Potential advantages of neuraxial anesthesia include less nausea, vomiting, and urinary retention; a reduced total opioid requirement; and greater mental alertness compared with patients who have received general anesthesia alone. After regional anesthesia, patients are quick to eat, void, and ambulate. Ambulatory surgical patients may or may not be discharged any sooner after spinal anesthesia when compared with those who have undergone general anesthesia, but they can avoid unnecessary overnight admissions resulting from complications of general anesthesia. A growing body of evidence also supports improved outcomes for selected patients and situations. Spinal and epidural anesthesia blunt the body's stress response to surgery and may offer preemptive analgesia. In addition, studies have shown neuraxial anesthetics to decrease intraoperative blood loss, lower the incidence of postoperative thromboembolic events and postoperative ileus, increase patency of vascular grafts, improve respiratory function and cardiac stability, and improve outcome in high-risk surgical patients.[16-20] "Walk-in, walk-out" spinals with a low dose of lidocaine and opioids for ambulatory surgery created the concept of selective spinal anesthesia. Because lidocaine spinals are no longer used, single lower limb anesthesia can be produced with a low dose of hyperbaric bupivacaine. Spinal techniques produce a reliable block, with low incidence of side effects and rapid home-readiness. Reintroduction of chloroprocaine may provide a solution for bilateral, short-acting spinal anesthesia in the future.[21] Although headache remains a small concern, this risk is greatly reduced.[22,23]

Another group of patients well known to benefit from the use of CNB techniques are patients who require anesthesia for obstetric procedures. One primary example is the administration of an epidural anesthetic to the patient in labor. No other modality can

provide the parturient with relative relief from the most severe discomfort and still permit the baby and mother to interact immediately after delivery, all with minimal possibility of respiratory distress or depression. Also, epidural techniques in labor allow a safe conversion of the analgesia to a surgical anesthetic if a cesarean section becomes necessary.[24,25]

Patient safety also may be increased with spinal or epidural anesthesia. Urologic procedures such as cystoscopic examinations and transurethral resections of the prostate (TURP) are most often performed with the use of spinal anesthesia. When awake and anesthetized to the level of the dome of the bladder (T10), the patient may verbally respond to bladder overdistention, thereby helping the urologist minimize the potential for bladder rupture. In addition, the mental status and sensorium of a responsive patient can easily be monitored and the development of conditions associated with TURP syndrome such as hypervolemia, hyponatremia, and ammonium toxicity are more readily detected.[19,26]

Safety is also an issue when the patient is placed in the prone or jackknifed position as for perianal procedures. A patient in such a position under general anesthesia is at risk for inadvertent extubation and positioning injury. A hypobaric spinal anesthesia technique offers several advantages. The anesthetic procedure can be performed after the patient is positioned and has verbalized that he or she is comfortably padded. With hypobaric spinal anesthesia, the spread of the local anesthetic is controlled, and spontaneous ventilation is maintained.

Additionally, patients often fear postoperative discomfort.[27] Therefore, another advantage of spinal anesthesia is the ability to administer long-acting opioid analgesics or clonidine. Epidural catheter placement allows for opioids, low concentrations of local anesthetics, or mixtures containing both solutions to be continuously infused or administered by patient-controlled devices, thereby keeping patients comfortable well into the postoperative period. Because the total doses of opioids and local anesthetics are small, the patient remains alert and possibly ambulatory while receiving analgesia with minimal side effects.[4,8] The patient's right to be fully informed also necessitates a discussion of the disadvantages of CNB. Consider the patient's perspective, and keep in mind that the disadvantages and risks inherent in any anesthetic plan are relative only to those of another anesthetic option. For example, patients with a history of headaches or backaches are at increased risk for experiencing these problems after spinal and epidural analgesia but also may have exacerbations of these problems after a general anesthetic. Such patients should be evaluated and counseled regarding this potential problem before the administration of any anesthetic. A thorough history of the patient's previous pattern of headaches or backaches is essential when faced with the challenge of evaluating similar symptoms in the postoperative period.

To many patients, the risk of paralysis is the most important concern, despite the extreme rarity of any neurologic sequela. The incidence rate of persistent paresthesia and sensory or motor dysfunction is less than 0.1%.[4,28-30] Common patient questions also may include the following:

- "Will the injections hurt?"
- "How long will I be numb?"
- "I am afraid of hearing (or smelling or feeling) the surgery. Can I be asleep?"

Patient perceptions can be corrected with thoughtful explanation and discussion of the clinician's expectations regarding the patient's case. Additional discussion should include the topic of intraoperative risks, such as the inability to obtain adequate anesthesia, paresthesia, hypotension, dyspnea, high or total spinal anesthesia, nausea and vomiting, use of additional sedation, and allergic reactions. Postoperative complications may include backache, postdural puncture headache (PDPH), hearing loss, transient neurologic symptoms, infection, and peridural abscess or hematoma formation.[5,22,31-34]

Before administration of any anesthetic, a thorough preoperative history and physical examination must be conducted. During this part of the preoperative patient visit, any concerns regarding administration of spinal anesthesia can be identified. Often the terms *absolute* and *relative contraindications* are used; the definition of these categories varies, and their use is therefore controversial. It is more important to think of the anesthetic risks and associated complications relative to the possible benefits of the proposed anesthetic technique. An obvious example is patient refusal or lack of cooperation. Other preoperative concerns include increased intracranial pressure, significant preexisting or therapeutic coagulopathy, skin infection at the site of injection, hypovolemia, spinal cord disease, patients with a fixed-volume cardiac state such as hypertrophic cardiomyopathy or severe atrial stenosis, and an anticipated lengthy surgical time. Finally, if a difficult airway is anticipated, the plan of care must be discussed with both patient and surgeon.

Neurologic diseases are often listed as potential, absolute, or relative contraindications for neuraxial anesthesia, but data are often mixed. A dural puncture by a spinal needle or a larger epidural needle creates a rent in dural tissue that may or may not leak CSF. In patients with a preexisting increase in intracranial pressure, the risk of brain herniation is increased. In the case of epidural catheter placement or epidural blood patch, the addition of large volumes of fluid into the epidural or subarachnoid spaces could increase already elevated intracranial pressures.[4,8]

Musculoskeletal deformities such as severe kyphoscoliosis, arthritis, osteoporosis, and fusion and scarring of the vertebrae are considered relative contraindications to neuraxial anesthesia. The location of the epidural or subarachnoid spaces by needle tip may be technically difficult, and spread of anesthetic agents may be limited by anatomic alterations.[28] However, a large retrospective study surmises that osteoporosis may be an important risk factor for CNB complications.[35]

Peripheral neuropathies can be the result of metabolic, autoimmune, infectious, or hereditary etiologies. A presumption is that patients with preexisting neural compromise are more susceptible to and less able to recover from injury when exposed to a secondary insult, compared with patients with healthy tissues. Also, abnormal tissues may not respond to pharmacologic agents in predictable ways. Secondary insults might stem from needle or catheter trauma, ischemic injury from the use of vasoconstrictors, or direct local anesthetic neurotoxicity. For example, diabetes mellitus (DM) is the most prevalent cause of peripheral polyneuropathy, with most patients having some abnormalities in nerve conduction. A study by Hebl et al.[36] supports the increased risk of the "double-crush" phenomenon, finding that 0.4% of patients with diabetic polyneuropathy experience new or progressive changes in their neurologic deficits. This suggests that spinal or epidural anesthesia may worsen or exacerbate conditions such as a gradually progressive diabetic neuropathy. However, the same group of investigators also took a retrospective look at central nervous system (CNS) diagnoses such as post-poliomyelitis, multiple sclerosis, traumatic spinal cord injury, and amyotrophic lateral sclerosis. The nature of their study did not permit definitive recommendations, yet they found no patients with exacerbations or deterioration of symptoms. Additionally, they note that their results suggest the safety of CNB in these patients and that their

findings were supported by other studies. Until further prospective study can support definitive conclusions, the decision to perform a CNB technique must be made by weighing the relative risks to the individual patient's neurologic disease against the potential benefits of minimizing the anesthetic effects on their coexisting diseases.[36] Because few objective data are available, use of CNB in such patients becomes a medicolegal risk, especially if blame is incorrectly placed on the anesthetic. If a neuraxial block is the appropriate anesthetic choice, then precise documentation of the patient's preexisting disease state and existing neurologic compromise is a mandatory precaution, as is attentive follow-up care.[4,8,28,31,37]

The existence of a significant preexisting or therapeutic coagulopathy increases the risk of spinal or epidural hematoma formation in a patient receiving a CNB. Spinal or epidural hematoma is a rare but devastating complication, possibly resulting in permanent neurologic injury. Therefore, central neuraxial anesthesia should be avoided in any patient with a known coagulopathy. Insufficient data are available to quiet the controversy surrounding absolute laboratory values below which the practitioner should avoid CNB. To determine whether a CNB technique should be avoided, it has been suggested that the following arbitrary values be used as a guide: platelet counts of less than 100,000 and prothrombin time (PT), activated partial thromboplastin time (aPTT), and bleeding times that are greater than two times normal values. For a spinal anesthetic, this is perhaps an overly conservative guide.[38] However, severe bleeding with or without symptomatic hypovolemia or the potential for severe bleeding is a possible contraindication to the administration of a regional anesthetic because the sympathectomy caused by CNB further aggravates severely contracted volume states.

Much discussion has arisen regarding the use of spinal and epidural anesthesia when coagulopathy for thromboprophylaxis or for therapeutic treatment of coexisting disease has been initiated, planned, or is ongoing because the therapies, timing, and the effects on coagulation are highly varied. For example, the use of platelet inhibitors, such as aspirin or nonsteroidal antiinflammatory drugs (NSAIDs), is not a contraindication to spinal and epidural anesthesia. Even planned intraoperative anticoagulation with heparin is reasonably safe after atraumatic dural puncture if the patient presents with a normal coagulation profile. Traditionally, a patient's bleeding time was obtained prior to administration of neuraxial anesthesia, but the predictive value of bleeding time has not been established in patients taking aspirin and NSAIDs.[39,40] Also, with the increased use of natural and herbal medicines, anesthetists must be alert to the possibility of drug interactions. Alone, herbal supplements appear not to increase the risk of spinal hematoma; however, data on combinations of herbal and other anticoagulants are not available. Herbal medications that effect hemostasis and some perioperative concerns are listed in Table 44-2. If basic precautions are followed, many thromboprophylaxis strategies have had an extensive safety record when co-administered with neuraxial anesthetics. The surgeon and anesthesia practitioner should consider the potential benefit versus risk before neuraxial intervention for patients who have been or will be anticoagulated for thromboprophylaxis. The number, variety, and indications for the use of anticoagulants and thrombolytics continue to increase.

The incidence of neurologic dysfunction resulting from hemorrhagic complications resulting from neuraxial blockade is unknown. Although the incidence cited in the literature is estimated to be less than 1 in 150,000 epidural and less than 1 in 220,000 spinal anesthetics, recent epidemiologic surveys suggest that the frequency is increasing and may be as high as 1 in 3000 in some patient populations. Overall, the risk of clinically significant bleeding increases with age, associated abnormalities of the spinal cord or vertebral column, the presence of an underlying coagulopathy, difficulty during needle placement, and an indwelling neuraxial catheter during sustained anticoagulation, particularly with standard heparin or low-molecular-weight heparin. The American Society of Regional Anesthesia and Pain Medicine (ASRA) convened its Third Consensus Conference on Regional Anesthesia and Anticoagulation. Practice guidelines were formulated. Many international anesthesia societies have also issued guidelines.[41-43] Guidelines for the use of regional blocks in patients receiving thromboprophylaxis are given in Table 44-3.

By following evidence and consensus-based precautions, the low incidence of permanent neurologic complications can be decreased. A meta-analysis by Brull et al.[44] identified the risk of permanent neurologic injury after spinal anesthesia at 1 to 4.2:10,000 and after epidural anesthesia at 0 to 7.6:10,000. Because complications are very infrequent, risk factor identification is difficult, and vigilant care must be maintained for all patients.

TABLE 44-2 Herbal Medications Affecting Hemostasis*

Herb	Important Effects	Perioperative Concerns	Time to Normal Hemostasis After Discontinuation
Garlic	Inhibition of platelet aggregation (may be irreversible) Increased fibrinolysis Equivocal antihypertensive activity	Potential to increase bleeding, especially when combined with other medications that inhibit platelet aggregation	7 days
Ginkgo	Inhibition of platelet-activating factor	Potential to increase bleeding, especially when combined with other medications that inhibit platelet aggregation	36 hrs
Ginseng	Lowers blood glucose Increased prothrombin (PT) and activated partial PTs in animals Other diverse effects	Hypoglycemia Potential to increase risk of bleeding Potential to decrease anticoagulant effect of warfarin	34 hrs

Adapted from Horlocker TT, et al. Regional anesthesia in the anticoagulated patient: defining the risks (the second ASRA Consensus Conference on Neuraxial Anesthesia and Anticoagulation). *Reg Anesth Pain Med.* 2003;28:172-197.
*At this time, it is not deemed necessary to discontinue herbal medications and allow resolution of their effects on hemostasis before surgery or anesthesia.

Analysis of known case reports found the median time to onset of neurologic dysfunction after initiation of low-molecular-weight heparin (LMWH) therapy to be 3 days. Scrupulous postoperative nursing surveillance is also required to support patient safety. The initial complaint may be of new-onset weakness to the lower limbs and sensory deficit, although bowel and bladder dysfunction and new-onset back pain may occur. If emergent neurosurgical care is required, recovery is unlikely if surgical decompression of the hematoma is delayed more than 8 hours.[30,35,44]

The etiology of neuraxial infection is based on the theory that needle placement disrupts the body's physiologic protective mechanisms and deposits infectious or noxious agents beyond the skin into underlying tissues and the peridural space and past the blood-brain barrier into subarachnoid spaces. Indeed, skin infection at the site of injection increases the risk of meningitis or epidural abscess formation. Infectious complications include, but are not limited to, epidural, spinal, or subdural abscess; paravertebral, paraspinous, or psoas abscess; meningitis; encephalitis; sepsis; bacteremia; viremia; fungemia; osteomyelitis; or discitis. Although colonization of the catheter may be considered a precursor to infection, colonization per se is not considered an infection. A recent advisory committee published guidelines noting several factors to consider to minimize infections. They included conducting a history, physical examination, and preprocedure laboratory evaluations, use of prophylactic antibiotic therapy as indicated, and use of strict aseptic techniques including the use of proper antiseptic solution. The use of sterile occlusive dressings at the catheter insertion site, a bacterial filter during continuous epidural infusion, limiting disconnection and reconnection of neuraxial delivery systems, and limiting the duration of catheterization were also encouraged.[34]

Although infectious complications of CNB are rare, the practitioner must maintain aseptic technique during the preparation and administration of any regional anesthetic to minimize the potential for infection. Septic meningitis or epidural abscess due to bacterial contamination, and the consequences of persistent neurologic deficits such as loss of bowel and bladder control, chronic pain, and lower extremity weakness or paraplegia, can be devastating. Other factors that increase the risk of infection include dermatologic conditions such as psoriasis that prevent aseptic skin preparation, underlying sepsis, diabetes, immunologic compromise, steroid therapy, and the preexistence of chronic infections such as human immunodeficiency virus (HIV) or herpes simplex virus (HSV). Because meningitis after spinal or epidural anesthesia is so rare, it has been difficult to directly attribute causality to the anesthetic or to identify significant risk factors. In fact, based on the limited data available, it would appear that regional anesthesia is safe in cases of secondary HSV infection and reasonable for patients in the early stages of HIV infection. Again, vigilance must be emphasized. Known predisposing factors include advanced age, diabetes, alcoholism, cancer, and AIDS. Patients are monitored for signs of meningeal irritation, fever, increasing back pain, neurologic changes, and local tenderness to injection sites. Although classic symptoms such as high fever, nuchal rigidity, and severe headache may be present, less alarming symptoms can occur, resulting in misdiagnosis. Although α-hemolytic streptococci is commonly seen in spinal block meningitis, *Staphylococcus aureus* is the most common causative organism in epidural abscesses, and

TABLE 44-3 Regional Anesthesia in the Patient Receiving Thromboprophylaxis

Medication	Clinical Management
Antiplatelet medications	No contraindication with aspirin or NSAIDs; discontinue ticlopidine (generic) 14 days, clopidogrel (Plavix) and prasugrel (Effient) 7 days prior to block; GP 11b/111a inhibitors tirofiban (Aggrastat) and eptifibatide (Integrilin) 8 hours, abciximab (ReoPro) 24-48 hours to allow return of normal platelet function
Unfractionated heparin	
Subcutaneous	No contraindication with twice daily dosing of less than 10,000 units; consider delay until after block if technical difficulty anticipated Safety of doses greater than 10,000 units or more than twice daily dosing has not been established
Intravenous	Heparinize 1 hour after block; remove catheter 2-4 hours after last heparin dose; document normal aPTT; sustained heparinization with an indwelling catheter associated with an increased risk; monitor neurologic status aggressively
LMWH	Delay procedures at least 12-24 hours after last dose of LMWH; regardless of technique, remove all catheters 2 hours before first LMWH dose; no additional hemostasis-altering drugs to be administered
Warfarin	Normal INR before neuraxial technique (usually requires 4-5 days); remove catheter when INR is 1.5 or less
Thrombolytics	Absolute contraindication
Thrombin inhibitors	Bivalirudin (Angiomax); desirudin (Iprivask) Avoid regional block, insufficient information
Fondaparinux (Arixtra)	Until additional clinical information is obtained, neuraxial techniques should involve only single needle pass, atraumatic needle placement, no indwelling catheters; if this is not feasible, an alternate method of prophylaxis should be used
Dabigatran (Pradaxa)	Discontinue 7 days prior to regional block; for shorter time periods, document normal thrombin time (TT) or ecarin clotting time (ECT); first postoperative dose 24 hours after needle placement and 6 hours post catheter removal, whichever is later
Herbal medicine	No evidence for discontinuation; be aware of potential drug interactions

iatrogenic methicillin-resistant. *S. aureus* is a growing concern. Epidural abscess, like epidural hematomas with evidence of neurologic deficit, can best be diagnosed by MRI. Early, aggressive surgical intervention and antibiotic administration are vital.[4,28,35,45-47]

Arachnoiditis and aseptic meningitis are rare but can occur when foreign substances irritate the meninges. As the needle is inserted, precautions must be taken to avoid introduction of glass or metal particles, highly concentrated local anesthetics or dextrose solutions, detergents or antiseptics, and a core of epidermis. Indwelling catheters, previous myelography, and hemorrhages into the subarachnoid or epidural space also have been associated with meningeal irritation and scarring. Modern technology and techniques incorporate the use of disposable equipment, needles with matched stylets, filter needles, and improved pharmacologic agents that make this complication rare.[48]

Shock and severe uncorrected hypovolemia are contraindications to spinal or epidural anesthesia, because both techniques cause sympathetic blockade. The resulting vasodilation prevents physiologic compensation and may worsen hypotension. In addition, management of shock and hypovolemia often requires aggressive fluid therapy and multisystem treatments that are often physiologically and psychologically uncomfortable for the aware patient.[4,8,28]

Patients with a fixed-volume cardiac state such as hypertrophic cardiomyopathy or severe atrial stenosis do not tolerate bradycardia, decreases in systemic vascular resistance, or decreases in venous return and left ventricular filling—all physiologic changes that can be anticipated with neuraxial block by local anesthetics. In these patients, even transient episodes of hypotension can cause serious coronary hypoperfusion and cardiac arrest. Therefore spinal, and usually epidural, anesthesia, are avoided; however, few things in anesthesia are truly absolute. For example, epidural administration of opioids has been used to provide obstetric analgesia and may provide cardiac benefit for these patients. Precautions in such a scenario might include close hemodynamic monitoring with an arterial line and pulmonary artery catheter, careful titration of the anesthetic, intravascular volume expansion, and use of ephedrine or phenylephrine to treat hypotension.[30]

Spinal anesthesia is typically a singular deposit of local anesthetic and therefore provides anesthesia for a fixed duration. If uncertainty exists about the anticipated length of surgery, epidural catheter placement is more appropriate to allow for the additional administration, or continuous infusions, of anesthetic agents. If the extent of the surgery is unknown, a neuraxial anesthetic may be initiated only to be converted at a later time to a general anesthetic when the surgeon exceeds the limits of the anesthetic block. This is rarely an ideal situation; the patient may experience discomfort, albeit brief, and the anesthesia practitioner must contend with less-than-ideal intubating conditions. Despite the advantages of neuraxial anesthesia, many patients such as the elderly and those with arthritis or musculoskeletal limitations of the neck and upper extremities poorly tolerate prolonged immobility. The judicious use of conscious sedation can quickly devolve into a "room air general," placing the patient at risk for hypoventilation, hypoxia, and hypercarbia. To avoid such circumstances, combined neuraxial and general anesthetic techniques are advocated and offer advantages by minimizing the total dose of general anesthetic used. Such techniques lower the risk of secondary effects of general anesthesia (e.g., nausea and vomiting) while gaining the advantages associated with neuraxial anesthesia, such as attenuation of the stress hormone response and improved postoperative pain relief.[8]

The administration of spinal or any regional anesthesia to patients with a difficult airway or full stomach requires careful consideration. The use of spinal anesthesia permits the patient to retain upper airway and pharyngeal reflexes that block the sympathetic nervous system. This theoretically results in increased gastric and intestinal motility, causing the stomach to empty. However, such benefits may be negated by the perception of pain and anxiety that accompanies illness or injury. If sedation is used to counter such perceptions, the airway may again become compromised. Furthermore, if hypotension develops from the resulting sympathectomy, the patient may experience nausea and vomiting. When an injury has occurred after the ingestion of alcohol or if the patient received opioid analgesics, the pain caused by the injury may be the only stimulus for consciousness.

When spinal or other regional anesthesia is instituted, the reticular activating centers in the brain receive less input. This often results in somnolence in a normal patient but can result in unconsciousness in the overly sedated or inebriated patient. In addition, spinal or epidural anesthesia may reach an undesirably high level that is physically and psychologically intolerable for the patient and can even become a "total spinal." A total spinal is characterized by unresponsiveness accompanied by cardiac and respiratory compromise. In such situations, airway support is required, and the emergent management of any airway can severely compromise patient safety. Therefore, regional anesthesia is not an alternative to a secure airway. For patients identified as potentially difficult to intubate, equipment should be immediately available to secure the airway in a safe manner. Advances in airway management such as the laryngeal mask airway, improved fiberoptics, laryngoscopes, and adjunct airway equipment may tip the risk-benefit scale in favor of regional anesthesia.[8,11,48]

SPINAL ANESTHESIA

Spinal anesthesia became popular after the discovery of the local anesthetic properties of cocaine, the invention of the hollow needle and syringe, and the written descriptions of the first lumbar puncture. The first clinical application of the technique was reportedly performed in the late 1890s. However, spinal anesthesia's prominence was short lived. The introduction of specific, reversible, neuromuscular blocking drugs and concurrent improvements in inhalation agents for general anesthesia soon displaced its popularity. It has regained popularity, in large part because of the introduction of newer agents, equipment, and techniques to employ it safely in the ambulatory setting.

Equipment and Techniques

Preparation for spinal anesthetic procedures, like that for any other regional technique, requires the immediate availability of emergency equipment and supplies should emergent resuscitation be required. Usually spinal anesthetics are administered in the operating room where the minimal requirements—functional laryngoscopes, endotracheal tubes, induction agents, cardiovascular drugs including atropine and ephedrine or phenylephrine, suction, oxygen and ventilation equipment, a noninvasive blood pressure monitor, and pulse oximetry and electrocardiographic monitoring equipment—are readily available.

The original spinal technique, performed by August Bier in 1898, has been continually examined and modified in hope of reducing the incidence of complications—primarily that of PDPH. The goal of needle design has been to create a needle that minimally rends, tears, or cuts dural tissues. As technology has improved, the use of sterile, disposable procedure trays containing needles, syringes, catheters, and drugs has virtually eliminated problems previously associated with dull needles or contaminated equipment and has allowed for the development of innovative needles. Currently, two

main types of needles are available for use in spinal anesthesia. Needles such as the Quincke-Babcock or Pitkin have a *cutting bevel tip*. These needles have matching stylets, which minimizes tissue coring, and the tip's cutting angle is blunter than that of a standard needle. The newer *noncutting-tip needles* are either pencil-point shaped with lateral openings (e.g., Sprotte, Whitacre, or Pencan needles) or have the rounded bevel tip of the Greene-type needle and an opening at the needle's end. Several of the more popular types of spinal needles are shown in Figure 44-7. Spinal needles also have matched stylets and are marketed for spinal anesthesia use in sizes ranging from 22- to 29-gauge and in lengths of approximately 3.5 inches (88 mm) and 5 inches (120 mm). Most blocks are performed using 25- to 27-gauge, 3.5-inch (88-mm) needles.[28,48]

Recent data support the use of noncutting-tip needles over cutting needles for several reasons. Cadaver lumbar punctures performed with sharp cutting needles show piercing of the cauda equina roots without resistance appreciated by the practitioner. This does not occur with pencil-point needles. The bevel of cutting-tip needles encourages tip deviation on insertion, whereas symmetric noncutting needles stay midline. The use of a beveled needle requires holding the bevel direction parallel to longitudinal dural tissue fibers to minimize the risk of PDPH. Noncutting needles may drag fewer skin contaminants into subdermal tissue than cutting needles. Pencil-point needles pierce the dura with a clearly perceptible "click" or "pop" not as easily noticed with cutting needles. Newer, thin-walled noncutting needles have improved CSF flow rates without compromise to strength. This allows for their use for CSF diagnostic procedures and helps simplify the identification of the intrathecal space by permitting quick return of CSF after stylet removal. Finally, unless prohibitively small cutting needles are used, the incidence of PDPH is clearly reduced with the use of noncutting needles. Pencil-point needles are associated with less than a 1% risk of PDPH and a failure rate of approximately 5%.[8,28,49,50]

After the patient arrives in the surgical or obstetric preoperative area, the consents for surgery and anesthesia should be checked, and any further patient questions or concerns should be addressed.

Review of the anesthetic preoperative history and physical examination should include the addition of any last-minute changes in patient status and notation of recently obtained diagnostic results. Intravenous access is achieved, and a continuous crystalloid infusion is begun. Preoperatively, most patients benefit from low-dose anxiolysis. With the increased emphasis on same-day admission, surgery, and discharge, long-acting agents are avoided. A rapid-acting benzodiazepine with a relatively short duration, such as midazolam, is highly titratable in 0.5- to 1-mg increments given intravenously and minimally alters the patient's hemodynamic status when used in low doses. The drug's effects can be reversed with flumazenil.

Monitors appropriate to the patient's physical status should be applied and at minimum include blood pressure monitoring, a continuous electrocardiogram, and pulse oximetry. For the purpose of baseline comparisons, vital signs must be assessed with the patient in both the supine position and the position in which the block will be administered.

The surgical or obstetric procedure to be performed helps determine the patient's position for the administration of the block. For example, if vaginal or urologic surgery is planned, a "saddle" block with the patient in a sitting position may be indicated. The prone position is useful for rectal surgery, because the patient can be placed in position before the block is implemented. This reduces the time required for positioning by permitting the patient to move with minimal assistance and to personally verify comfort and adequacy of padding. A lateral position favors spinal drug spread for right- or left-sided extremity or abdominal procedures. When the patient is in the lateral position, a pillow placed under the head and perhaps shoulders helps maintain neutral alignment of the spinal column. Surgical table height or patient position may need to be adjusted to compensate for variations in anatomic structure or physiologic limitations and to maximize anesthetist ergonomics. To maximize the space between spinous processes, the patient should arch the back (with assistance from the clinician) into a C shape or "like a Halloween cat." Once the patient is positioned, anatomic surface landmarks are used to identify the lumbar region of the back to be used for dural puncture, a point below the end of the spinal cord (L2). The line formed between the tops of the iliac crests, called the *intercristal line* or *Tuffier's line*, crosses the vertebral column as high as the L3 to L4 disk or as low as the L5 to S1 disk (Figure 44-8). The accuracy of predicting the precise

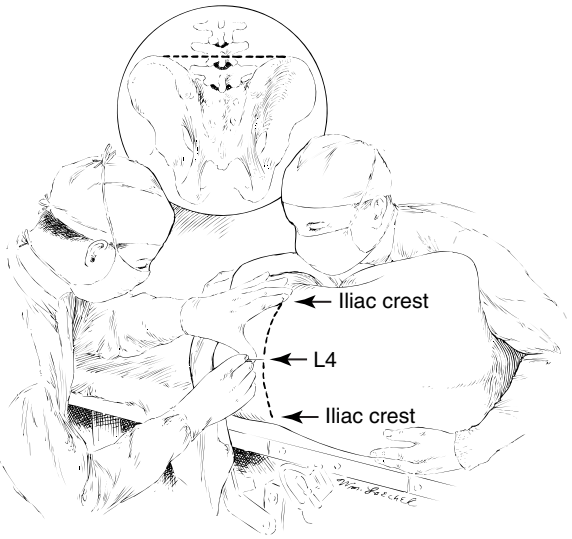

FIGURE **44-8** Patient positioning and identification of landmarks in the lumbar region of the back.

level of needle insertion is at best 50%. This fact may account for variability in the spinal anesthesia level ultimately achieved, yet this landmark has been clinically useful since the advent of spinal anesthesia.[7] The skin overlying a prominent spinous process at this level is marked for easy identification after the skin is prepared and draped. A surgical skin-marking pen is useful for this purpose, with caution exercised to avoid scratching the skin surface and predisposing the patient to infection.

Next, the spinal anesthesia tray is opened, and sterile gloves are donned. The patient is prepared with an antiseptic solution such as Betadine, a povidone-iodine solution that releases a concentration of 1% free iodine as it dries on a surface. The solution must remain in contact with the skin for at least 1 minute to be effective, and then the dry residue can be wiped away with sterile gauze to help prevent a chemical arachnoiditis. Do not use alcohol to remove residue because alcohol neutralizes the iodine solution and minimizes its antiseptic effect. Maintain aseptic technique, and apply the sterile drape to the back. Many spinal and epidural drapes have a circular window that is placed over the area of anticipated injection and adhesive strips to simplify application to the patient's back. Avoid touching the adhesive, because this has been shown to create small holes in gloves, which increases the risk of infection in both the patient and anesthesia practitioner.[51]

A rapid-acting local anesthetic such as 1% lidocaine is used for local infiltration of the area just caudad to the identified spinous process. Approach the skin of the back with the bevel of the needle facing away from the skin and at a 15- to 30-degree angle from the skin. Start injecting before the bevel of the needle is completely through the skin, and raise a skin wheal to place local anesthetic into subdermal tissues most likely to contain nociceptors. Deep tissues, including the supraspinous ligament, can be anesthetized by spreading 3 to 5 mL of local anesthetic through the tissues in a fan pattern.[8,28]

Larger 22- to 25-gauge spinal needles and epidural needles (used for continuous spinal anesthetic techniques) have tensile strength sufficient to permit introduction of the needle without additional support. However, spinal needles smaller than 25 gauge often require an "introducer" needle to help stabilize the needle during insertion and minimize infection in the surrounding dermis. The introducer is typically an 18- or 20-gauge needle with a "B" or blunt bevel. Introducer needles are approximately 3.8 cm long and matched to the spinal needles. The introducer is inserted through the skin and supraspinous ligament and into the interspinous ligament. Care must be taken, especially in thin individuals, not to enter the subarachnoid space with the introducer needle; the dura may be only 2.5 cm beneath the skin. Depth to the epidural space and the nearby dura correlates with weight but typically averages approximately 4 to 5 cm and rarely exceeds 9 cm. An introducer needle placed into the subarachnoid space would be likely to cause a PDPH.[4,8,15,28]

Several common spinal anesthesia techniques can be used, including a straight midline approach. With this easy-to-learn technique, the anesthesia practitioner inserts the needle directly midline between the spinous processes and toward the umbilicus perpendicularly to all planes or at the lumbar level with a slight cephalad angle (Figures 44-9 and 44-10). If bone is encountered early, the needle is withdrawn into the introducer and subcutaneous tissue. The introducer is then redirected in small angular increments in a cephalad direction. If bone is encountered when the needle is deeply inserted, the needle should be withdrawn and redirected caudad. As the tip of the spinal needle passes through the ligamenta flava, the sensation is similar to that felt when a needle is passed through a pencil eraser. As the needle tip passes through the dura, the anesthesia practitioner may sense a "pop" or "click." The stylet is removed, and several seconds are given for CSF to return through the small-gauge needle. Once CSF return is confirmed, some authors recommend rotating the needle 360 degrees in 90-degree increments to ensure that the needle tip is seated well within the subarachnoid space (see Figure 44-10). Other authors suggest that such needle manipulation risks a larger dural rent or needle dislodgement. Whichever method is used, secure needle handling is important. As shown in Figure 44-11, firmly place the dorsum of one's nondominant hand against the patient's back and below the spinal needle. Grasp the needle hub between the thumb and index finger. With this *Bromage* type of grip, the patient's body then acts as a firm support for the needle-stabilizing hand and helps prevent advancement or withdrawal of the needle tip from the subarachnoid space when the syringe is applied to inject the anesthetic agent.

A second technique is called the *paramedian approach*. With this technique, the needle is inserted 1 cm or approximately one fingerbreadth lateral to the caudad aspect of the interspace. The needle is directed toward the spinal canal and angled slightly cephalad and then medially approximately 10 to 15 degrees (see Figure 44-10). Elderly and arthritic patients may have decreased back flexibility and degenerating, calcified ligaments. For such

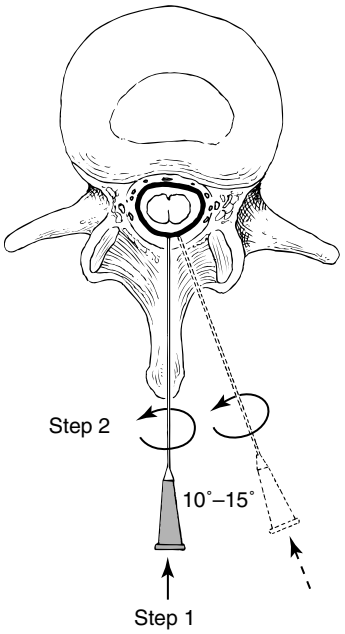

FIGURE **44-9** Insertion of the needle between the spinous processes and toward the umbilicus.

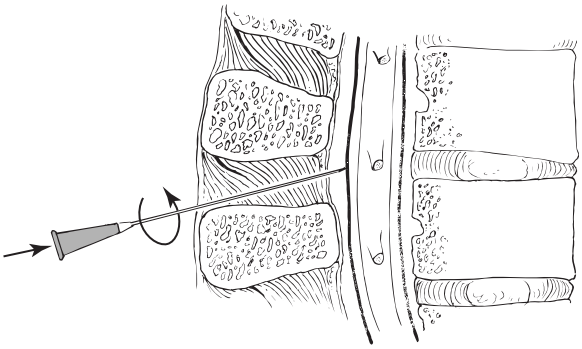

FIGURE **44-10** Spinal needle rotated 360 degrees to aid evaluation of tip location within the subarachnoid space.

patients, this approach may be the only possible means of entering the subarachnoid space because it aims for the largest area between processes and avoids calcified interspinous ligaments. A third approach to the subarachnoid space, known as the *Taylor approach*, takes advantage of the L5 interspace, which is the largest interlaminar space. A point 1 cm medial and 1 cm caudad to the posterior superior iliac spine is located, and the needle is angled medially and cephalad at a 55-degree angle toward the fifth lumbar interspace. The Taylor approach is best used for pelvic and perineal surgical procedures.[4,7,8,15,28]

Intrathecal Drugs, Spread, and Block Levels

Once the anesthetic solution is delivered into the CSF, the distribution of its active molecules through the subarachnoid space is dependent on the chemical and physical characteristics of the solution in relation to the chemical and physical characteristics of the patient's CSF and the subarachnoid space. In adults, approximately 500 mL of CSF is produced each day, predominantly by the choroid plexuses of the cerebral ventricles. Much of the CSF is reabsorbed by arachnoid granulations along the sagittal sinus to regulate CSF pressure to 10 to 20 cm H_2O. At any given time, a total of approximately 140 mL of CSF flows by bulk flow through the subarachnoid spaces, the central canal of the cord, and the ventricles of the brain. It is estimated that only 30 to 80 mL of the total CSF is present in the spinal canal. However, this quantity is difficult to measure, variable among individuals, and uncontrollable by the clinical anesthetist.[3,4,52]

The density of a substance compared with the density of water is a ratio known as *specific gravity*. The specific gravity of CSF is 1.004 to 1.009 and can vary depending on variations in temperature and location of the fluid within the subarachnoid space. For example, the specific gravity of CSF sampled from the lumbar area is slightly greater than that of CSF from the ventricles. This difference is directly dependent on the protein in the CSF, as well as on the effects of gravity and the position of the patient. The specific gravity of CSF also tends to increase as patient age increases, correlating to increases in glucose and protein. Hyperglycemia and uremia increase specific gravity of CSF, whereas jaundice and related liver problems may decrease specific gravity. The change in specific gravity is related to the presence of bilirubin within the CSF. An increase in a solution's temperature decreases its specific gravity. This decrease averages 0.001 point for each degree rise in Celsius temperature. Although all of these factors have been thought to influence the distribution of an anesthetic solution injected into the CSF, they are usually beyond the control of the anesthetist.[4,8,15,28,52]

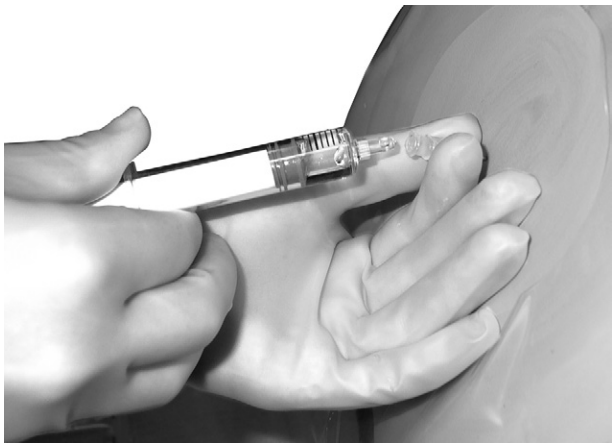

FIGURE **44-11** The Bromage grip, showing needle control and syringe connection.

A closely related concept, *baricity*, refers to the resting position of two fluids with differing specific gravities when the fluids are mixed in a single container, such as CSF and an anesthetic agent in the subarachnoid space. The baricity of the injected solution is compared with that of the CSF. Knowledge about the baricity of an injected solution provides the practitioner with information that helps determine the potential spread of the anesthetic mixture in the subarachnoid space. Therefore, when several medications are combined, the specific gravity of the combined solution at body temperature should be considered when the spread of the medication is anticipated. Unfortunately these bedside mixtures are rarely controlled or measured, and use becomes reliant on practical experience. When baricity (i.e., the ratio of specific gravity of local anesthetic to patient CSF) equals 1, the solution is referred to as being *isobaric*. Because the specific gravity of CSF is variable, it is not possible to prepare a solution that is precisely isobaric. Near-isobaric solutions remain and act in approximately the same location in which they are injected. A *hyperbaric* solution has a specific gravity that is greater than that of CSF. The solution would fall, or sink to the lowest anatomic point at which CSF is contained within the subarachnoid space in relation to gravity and the patient's position (presuming that, as previously mentioned, drug preparations are corrected for body temperature). *Hypobaric* solutions that are less dense than CSF rise or float to the highest anatomic position possible when injected into the subarachnoid space.

Because the normal range for the specific gravity of CSF is variable, local anesthetics, opioids, or other solutions injected into the CSF must be predictably hypobaric or hyperbaric. By tradition, hypobaric solutions are defined as having a baricity of less than 0.999, and hyperbaric solutions have a baricity of greater than 1.0015. Clinically this is accomplished by dissolving the drug in either sterile water to create a hypobaric solution or 5% to 8% dextrose solutions to create a hyperbaric solution. If CSF or normal saline is added to the medications, the specific gravity of the solution is similar to that of CSF, and the drugs remain approximately where injected.[4,8,15,28,52]

More than 23 factors, including CSF density and local anesthetic baricity, have been thought to affect the spread of local anesthetics in CSF and therefore affect the level and quality of the anesthesia achieved. Less than half of these factors have been found to have clinical significance, and an even smaller number are controllable by the anesthetist performing the anesthetic procedure.[28] Clinically the most important factors are those that can be manipulated by the anesthesia practitioner. These are the total dose of the local anesthetic, the site of injection, the baricity of the drug (drug choice), and (when nonisobaric solutions are used) the position or posture of the patient during and after injection.[52]

The duration of a spinal anesthetic is based primarily on local anesthetic choice and total dose. Highly protein-bound drugs, such as tetracaine, bupivacaine, and ropivacaine, have long durations of action compared with less protein-bound drugs such as lidocaine and mepivacaine. Vasoconstrictors such as 0.1 to 0.2 mL of 1:1000 (1 mg/mL) epinephrine solution are sometimes added to the local anesthetic solution to prolong the duration of action. Epinephrine is thought to prolong the duration of spinal anesthesia by causing vasoconstriction, thereby delaying normal uptake of local anesthetics, by direct antinociceptor action, or by a combination of these effects. The effect of added epinephrine on the prolongation of anesthesia is greatest with tetracaine, less with lidocaine, and minimal with bupivacaine. In addition, local

TABLE 44-4 Choice of Medication for Spinal Anesthesia Used for Surgical Procedures

Procedure	Medication*	Dosage	Duration Without Epinephrine	Duration With Epinephrine
Vaginal delivery	Tetracaine	5 mg	1-1.5 hr	2.5-3 hr
	Bupivacaine	5-7 mg	1 hr	1.5 hr
	Lidocaine	25 mg	15-25 min	45 min-1 hr
Cesarean section	Tetracaine	8 mg	1-1.5 hr	2.5-3 hr
	Bupivacaine	10 mg	1-1.25 hr	1.5-2 hr
	Lidocaine	50-75 mg	30-45 min	1-1.25 hr
Anorectal surgery	Tetracaine (hyperbaric)	6 mg	1-1.5 hr	3 hr
	Tetracaine (hypobaric)	6 mg	1 hr	3 hr
	Bupivacaine	8 mg	1 hr	1.5-2 hr
	Lidocaine	25-50 mg	15-30 min	45 min
Genital or lower-extremity procedure	Tetracaine	6-10 mg	1.5 hr	2-3 hr
	Bupivacaine	8-12 mg	1.5 hr	2 hr
	Lidocaine	75-100 mg	45-60 min	1.25-1.5 hr
Hernia, pelvic procedure	Tetracaine	10-12 mg	1.5 hr	2-3 hr
	Bupivacaine	12-15 mg	1.5 hr	2 hr
	Lidocaine	100 mg	45-60 min	1.25-1.5 hr
Intraabdominal surgery	Tetracaine (by patient height)	5 ft to 5 ft, 5 in = 12 mg 5 ft, 6 in to 6 ft = 15 mg >6 ft = 18 mg	1.5 hr	2-3 hr
	Bupivacaine (by patient height)	5 ft to 5 ft, 5 in = 15 mg 5 ft, 6 in to 6 ft = 18 mg >6 ft = 20 mg	1.5 hr	2 hr
Back and spine surgery	Tetracaine	10-15 mg	1-1.5 hr	2-2.5 hr
	Bupivacaine	15-20 mg	1-1.5 hr	1.5-2 hr

*Local anesthetic solutions administered to intrathecal or epidural spaces must be sterile and preservative free.

anesthetic solutions may include opioids (10 to 25 mcg fentanyl, 2.5 to 10 mcg sufentanil, or 250 mcg preservative-free morphine) or the α-agonist clonidine, 150 mcg, to prolong duration. These agents act at opioid and α_2-adrenergic receptors, respectively. The exact nature of the synergistic effect among opioids, α_2-agonists, and the local anesthetics is not clear, but the result is again prolonged spinal anesthesia. Volume in the tested range of 1 to 14 mL, and therefore concentration, minimally affects the duration of anesthesia or the final sensory level achieved. Increasing the total dose of a spinal local anesthetic will increase its duration of action and affect the sensory level achieved. Duration of sensory and motor blockade for local anesthetics has been shown to be predictable. For example, increasing the dose of hyperbaric bupivacaine from 10 mg to 15 mg prolongs the duration of sensory block by 50% and increases the maximum sensory level achieved. Based on these principles, Table 44-4 offers medication administration suggestions to achieve an approximate sensory level and duration of spinal anesthesia in a typical clinical setting.[52,53]

Selecting the precise site of injection, as mentioned, is technically inaccurate at the clinical level.[7] The higher the site of injection, obviously, the higher the level of sensory block, but this is limited by the anatomy of the spinal cord and the anesthetist's desire to approach the subarachnoid space below the termination of the spinal cord. Theoretically, if a patient is administered a hyperbaric solution at the L3 level and placed supine, the local anesthetic would flow both cephalad and caudad from the relative peak of the lumbar lordosis to the troughs of the thoracic kyphosis and sacral regions. If a hyperbaric drug is placed below L3 with the patient in a sitting position, and the patient is left sitting for 5 minutes, a lumbar and sacral-root anesthetic known as a *saddle block* will occur. However, even under experimental conditions using the second to fifth lumbar interspace, the data on the ability to control the maximum sensory block level achieved are inconsistent. Therefore, the site of injection can be a poor predictor of the final level of sensory anesthesia achieved.[52]

Several authors suggest that the level of the anesthetic can be adjusted or modified by use of position changes within the first few minutes after injection or until the medication becomes fixed on the nerve roots and the spinal cord. Some have even found that changes in position as late as 60 minutes after injection can alter the level of block achieved. For example, one of the suggested methods used to modify the level of the anesthetic is to raise a supine patient's legs 45 degrees. This position is thought to increase blood flow through the epidural venous plexus, indirectly altering CSF pressures. Such a position also flattens the lumbar lordosis, altering flow of hyperbaric local anesthetic within the subarachnoid space. The combined effects result in further cephalad spread of local anesthetic solutions. If one uses a similar line of thought, morbid obesity and third-trimester pregnancy also are associated with epidural venous engorgement when the patient is supine, and a slightly higher level of spinal anesthesia is found when compared with controls. With traditional hyperbaric solutions, the block achieved may range from T3 to T6. Therefore, the anesthetist's ability to precisely control the level of sensory anesthesia through baricity and changes in posture is associated with great variability and low predictability from patient to patient.[28,52,54] Once achieved, the final level of sensory blockade should be determined as discussed previously, then documented.

Continuous spinal anesthetics are administered with the same techniques used to establish a spinal or epidural anesthetic. A

small epidural needle is used for the procedure, with the bevel turned parallel to dural fibers to help minimize the risk of PDPH. After the needle is inserted into the subarachnoid space, the bevel of the needle is turned either caudad or cephalad to facilitate passage of an epidural catheter into the subarachnoid space. The catheter is inserted only 2 to 3 cm into the subarachnoid space. Further insertion could result in advancement of the catheter along a nerve root or in curling of the catheter. The incidence of headache is minimal in elderly patients or when the catheter can remain in the subarachnoid space for at least 40 hours. Because of reports of cauda equina syndrome, in 1992 the Food and Drug Administration (FDA) removed from the U.S. market small needles and microcatheters designed to further reduce the risk of PDPH. *Cauda equina syndrome*, or persistent paralysis of the nerves of the cauda equina with resultant lower extremity weakness and bowel and bladder dysfunction, has subsequently been attributed to the deposition pooling and possibly repeat dosing of neurotoxic concentrations of hyperbaric local anesthetics, particularly 5% lidocaine.[4,8,148,53,55]

This same solution of lidocaine in varying concentrations has been associated with *transient neurologic symptoms* (TNS). Symptoms are usually described as pain originating in the gluteal region that radiates to both lower extremities. Symptoms appear within a few hours up to 24 hours after recovery and spontaneously disappear in virtually all cases in 10 days. The symptoms range from mild to severe radicular back pain in up to 30% of patients, and although NSAIDs are the usual treatment, opioids may be required. No permanent problems occur. Symptoms include a burning, aching, cramplike, and radiating pain in the anterior and posterior aspect of the thighs. Pain radiates to the lower extremities, and lower back pain is common. Other anesthetics have been implicated, but it is much more prevalent after spinal lidocaine.[56] Surgical positioning may be a factor as well.[57] The exact mechanism is unclear. Newer techniques and agents other than lidocaine are being used now, and that has diminished this problem as a clinical issue. Treatment is supportive and should include NSAID agents when possible.[58,59]

Physiologic Alterations and Their Management

Spinal anesthesia causes several physiologic changes that are predictable and can usually be readily managed through anticipation and prevention or with minimal intervention. Physiologic changes include effects on the central nervous system, cardiovascular system, respiratory system, and gastrointestinal (GI) system. In addition, physiologic alterations caused by central neural blockade affecting neuroendocrine, renal, and hepatic function are mentioned.

The obvious central nervous system effect of spinal anesthesia is the inhibition of nerve impulse conduction, resulting in spinal anesthesia. This occurs when the local anesthetic concentration exceeds the minimal blocking concentration of the particular nerve exposed to the drug. Neurons have different levels of susceptibility to local anesthetics, and this partially explains the differential block seen with spinal and epidural anesthesia. As a local anesthetic spreads from the epicenter of its injection site, the concentration of molecules decreases. As the local anesthetic spreads rostral and the concentration gradient lessens, only the most susceptible neurons will be blocked, and a differential block occurs. With spinal anesthesia, typically kinesthetic sense is inhibited at a dermatomal level higher than light touch or cold sensation, which in turn is inhibited at a more rostral dermatomal level than pinprick anesthesia. Therefore, a differential blockade among the levels of sympathetic, somatic sensory, and somatic motor fibers can be identified. Attempts to demonstrate the numbers of segments between areas of differential blockade have found that sympathetic fibers are blocked a mean of six or seven segments higher than somatic sensory fibers.[10,11]

The reticular excitatory area in the brainstem is responsible for the brain's overall state of alertness or arousal. The primary determinant of the activity of the reticular excitatory area is the amount of sensory input from the body. Because spinal anesthesia greatly decreases the number of sensory impulses to the reticular excitatory area, normal patients often experience somnolence. Caution must be taken during administration of spinal anesthesia to a patient in pain and already under the influence of central depressants such as alcohol or opioids. The pain caused by the injury may be the only stimulus for consciousness, and when spinal or other regional anesthesia is instituted, unconsciousness may ensue.[11]

Spinal or epidural techniques using local anesthetics block sympathetic nerve transmission in addition to blocking sensory and motor fibers. Therefore, the sum effect of neuraxial anesthesia on the cardiovascular system depends primarily on the overall degree of sympathetic blockade in terms of the rostral spread of the anesthetic and partially on the degree of patient sedation and central sympathetic inhibition. Blockade of the sympathetic nervous system causes arterial vasodilation, decreased systemic vascular resistance, venous pooling, and a reduction in venous return. These changes cause a redistribution of blood that often results in hypotension. If the block is high enough, the sympathetic nerve fibers that innervate the heart, known as the *cardiac accelerators* (T1 to T4), become anesthetized. An imbalance occurs between vagal fibers, and the heart rate often slows, further contributing to hypotension. Baroreceptor reflexes, volume receptor reflexes, and decreased central sympathetic outflow all contribute to the complexity of the cardiovascular response to neuraxial anesthesia. The overall result is loss of normal cardiovascular homeostatic reflexes and the ability to compensate for minor cardiovascular stresses.[60,61] Rapid changes in position, changes in skeletal muscle tone caused by relaxation, decreased venous return, low preoperative volume status, reflex surgical stimulation, preoperative medications (especially opioid- and sedative-hypnotics), and concurrent conditions such as pulmonary embolism, pregnancy, and systemic reactions to medications have all been implicated in increased severity of perioperative hypotension.[11,60]

Hypotension is immediately relevant to the perfusion of critical organs such as the heart and brain and is important to all organs in maintaining near homeostasis. Although normotensive patients have been shown to maintain cerebral blood flow despite a moderate decrease in blood pressure, hypertensive subjects may have altered cerebral blood flow autoregulation and are less tolerant of changes in mean arterial pressures.[11] A similar situation exists with elderly patients and patients with known coronary disease. With these caveats in mind, most clinicians allow a decrease in blood pressure of 20% from a patient's baseline before initiating treatment.

Clinicians continue to debate the optimal treatment of spinal anesthesia–induced hypotension and bradycardia. The treatment is often dependent on coexisting disease, but some general recommendations can be made. Preventive management of hypotension includes the administration of glucose-free crystalloid or colloid solutions in volumes of approximately 15 mL/kg, 15 minutes before the start of the anesthetic procedure to maintain preload to the heart. This initial infusion should include replacement of any fluid deficit caused by restricted oral intake and has been shown to help prevent immediate cardiovascular side effects. Infusions of

α-adrenergic vasoconstrictors and sympathomimetic agents have been shown to help reduce the incidence of cardiovascular side effects requiring treatment. Should the treatment of hypotension become necessary, the ongoing administration of intravenous solution is often the first response; however, excessive fluid therapy can lead to fluid overload and urinary retention, especially in the elderly.[60]

Continued treatment is guided by the patient's presenting symptoms and coexisting disease. The heart rate can be used to help guide pharmacologic intervention. Ephedrine (a mixed α- and β-agonist) in 5 to 10 mg intravenous boluses is the agent of choice in patients with symptomatic bradycardia. Ephedrine's indirect effects cause an increase in peripheral vascular resistance and heart rate. If the heart rate is normal or elevated, incremental injections of an α-agonist, such as 50 to 100 mcg of intravenous phenylephrine, causes increased systemic vascular resistance without further increasing the heart rate. The use of phenylephrine may therefore be more efficacious in the elderly. Bradycardia is treated with intravenous atropine 0.4 to 0.8 mg.

Severe hypotensive events should be treated vigorously with medication and fluids, because mortality from rare cardiac arrests increases when treatment is delayed.[4,10,15,60]

Most studies demonstrate that midthoracic levels of either spinal or epidural anesthesia have minimal effects on tidal volume, respiratory rate, minute ventilation, and arterial blood gas tensions in otherwise healthy individuals. The phrenic nerve is rarely paralyzed, even when sensory levels reach the cervical dermatomes. However, the accessory abdominal and intercostal muscles for ventilation are impaired, and the ability to cough and clear secretions is inhibited. With the loss of perception of intercostal and abdominal wall muscle movement and the inability to cough, the patient may begin to feel dyspneic. Caution must be exercised if the accompanying anxiety is treated with large doses of sedatives or opioids. They may worsen ventilation and result in hypoxia. Although regional techniques have been shown to have minimal effects, adequate ventilatory ability during surgery is dependent on multiple factors, and improved pulmonary outcomes have not been clearly demonstrated. Some of the factors that affect ventilatory ability under spinal or epidural anesthesia include the presence of coexisting disease, depressant medications, patient position, type and location of the surgery and incision, and presence of hypotension and hemorrhage. The anesthetic plan must be adapted to the patient and the operation.[10,11]

The GI tract is regulated by the parasympathetic and sympathetic nervous systems. The parasympathetic innervation of the GI tract is primarily via the vagus nerves and is composed of both afferent and efferent fibers. Parasympathetic afferent nerves transmit sensations of satiety, distention, and nausea, whereas efferent outflow generally increases GI activities such as tonic contractions, sphincter relaxation, peristalsis, and secretion. Sympathetic innervation of the GI tract stems from the T5 to L2 spinal cord segments and via prevertebral ganglia. Sympathetic afferent nerves are responsible for transmitting pain information; efferent nerves inhibit peristalsis and gastric secretion and cause sphincter contraction and vasoconstriction. When spinal and epidural anesthesia cause a sympathetic blockade, the result is unopposed or dominant parasympathetic activity. The neuraxial sympatholysis results in a generalized constriction of the bowel, normal to increased peristalsis, increased intraluminal pressure, and increased GI blood flow.[10,11,15] The combination of abdominal muscle relaxation and a contracted bowel offers improved operating conditions for intraabdominal procedures, but because gastric motility can be increased, some clinicians have questioned the risk of wound disruption. Several studies have reported that the intraoperative and postoperative use of neuraxial anesthesia does not increase the risk of wound breakdown. Steinbrook[62] and other researchers suggest that continued postoperative analgesia, especially with a thoracic epidural and local anesthetic infusion, has beneficial effects on the recovery of bowel function after major abdominal surgery.[10,11]

Nausea and vomiting are associated with neuraxial block in up to 20% of patients. Nausea and vomiting are primarily related to the GI hyperperistalsis of parasympathetic dominance, although other contributing factors may include hypoxemia, hypotension, systemic medications (opioids or rapidly infused antibiotics), and psychological stimuli. A cardiac mechanism associated with spinal anesthesia, as proposed by some authors, also may lead to nausea and vomiting. Theoretically, cardiac vagal afferent nerves can be activated in response to a decrease in venous return via ventricular mechanoreceptors, especially with high block levels. Therefore, the vagolytic properties of atropine provide indirect-acting antiemetic effects in the treatment of the nausea and vomiting associated with high spinal anesthesia.[11,15]

The neuroendocrine stress response is a combination of responses of the body to tissue trauma (such as surgery) or critical illness. The response includes components of neural, immune, endocrine, metabolic, and inflammatory systems that are closely integrated through a complex mechanism of hormones, neurotransmitters, and receptors that affect cells throughout the body. These systems are activated in proportion to the level of critical illness or tissue injury experienced by the body.[11] The stress response is usually associated with increases in blood concentrations of adrenocorticotropins, cortisol, insulin, growth hormone, aldosterone, and glucose. Initially a protective response—the stress response—can lead to tachycardia, hypertension, catabolism, immunosuppression, and hypercoagulability.[10] Regional blocks such as spinal and epidural techniques moderate the stress response to surgery. Although spinal anesthesia blocks this response only for the duration of the anesthetic administration, the use of continuous epidural analgesia well into the postoperative period has the potential to improve perioperative outcome.

Renal blood flow and function are well preserved during spinal anesthesia when blood pressure is maintained. Hepatic blood flow is directly proportional to the mean arterial pressure and therefore depends on the treatment of any hypotension associated with the spinal or epidural anesthetic.[10] Spinal and epidural anesthetics block sympathetic fibers, thereby increasing the tone of the internal urethral sphincter; in addition, neuraxial opioids cause a decrease in detrusor contraction and an increase in bladder capacity. These changes in the genitourinary system can result in the rare complication of urinary retention.

Complications of Spinal Anesthesia

Postdural Puncture Headache

PDPH is perhaps the most commonly discussed and managed complication of neuraxial anesthesia, with a documented incidence that has varied over the years from 0.2% to 24%. Theoretically PDPH is caused by a decrease in the CSF available in the subarachnoid space through a leak created by the dural puncture with an intruding needle. The medulla and brainstem, having lost their hydraulic support, drop into the foramen magnum, stretch the meninges and pull on the tentorium. This pulling, further irritated by movement and the upright position, causes a characteristic headache.[4,22,28,63] A contributing theory suggests that cerebrovasodilation may result from low CSF pressure. This theory is supported by the beneficial effects of vasoconstrictor drugs such as caffeine and theophylline.[63]

Several factors are known to increase the incidence of PDPH. The use of large, non–pencil-point needles or a cutting-needle bevel direction that is perpendicular to the long axis of the body will make larger holes in the dural fibers and create larger CSF leaks. Multiple punctures also increase CSF leak and the risk of headache. In addition, female patients are more likely than male patients to get a PDPH, and the young are more likely than the elderly to experience this complication. Most studies also demonstrate a higher incidence of PDPH in the pregnant population. Postpartum women in their 30s are most often affected. Patients with a history of PDPHs are predisposed to another headache after a subsequent spinal anesthetic procedure. However, one should keep in mind that not all headaches that follow spinal anesthetic procedures are PDPHs. It is common for patients to experience headaches after surgery and even after general anesthetics. Factors that contribute to headaches may include anxiety, interrupted sleep, dehydration, hypoglycemia, and even simply the lack of normal morning caffeine intake. A differential-diagnosis approach should be taken to identify serious complications such as subdural hematoma, subarachnoid hemorrhage, meningitis, sinusitis, or subarachnoid hemorrhage.[15,22,28,50,63]

Fortunately, PDPHs have several characteristic features that aid in diagnosis. Usually PDPHs occur within several hours to the first or second postoperative day. Historically, bed rest was thought to help prevent PDPH, but subsequent studies found that avoiding early ambulation simply postponed the onset of PDPH. The headache is typically described as a mild to incapacitating bilateral frontal headache that radiates from behind the eyes and across the head toward the occiput and often into the neck and shoulders. The headache is considered positional, because it subsides when the patient is lying down. The only other form of headache that has this positional component is caused by pneumocephalus. Other symptoms that may be associated with PDPH include nausea and vomiting, appetite loss, blurred vision or photophobia, a sensation of a plugging of the ears and loss of hearing acuity, tinnitus, vertigo, and depression.[8,22,28,63]

Although PDPHs are self-limiting and often resolve in less than 10 days, early identification and prompt treatment are essential if complications of immobility, depression, and patient dissatisfaction (a potential reason for litigation) are to be avoided. Conservative management includes a horizontal position, adequate hydration, oral analgesics, and the administration of 500 mg intravenous caffeine benzoate, 300 mg of oral caffeine, or theophylline. Caffeine has shown effectiveness for treating PDPH, decreasing the proportion of participants with PDPH persistence and those requiring supplementary interventions. Gabapentin, theophylline, and hydrocortisone also have shown a decrease in pain severity scores when compared with placebo or conventional care. There is a lack of conclusive evidence for the other drugs such as sumatriptan.[64,65] The horizontal position is impractical for most patients, especially mothers of newborns, and encourages further complications of immobility.[63] Abdominal binders, thought to increase epidural venous plexus blood flow and therefore CSF pressure, are also uncomfortable and often impractical. Increasing fluids during the evaluation and early management period was thought to increase the central volume and increase the secretion of CSF from the choroid plexus, but this is not well supported in the literature. However, adequate hydration should be maintained in all patients.[28] Caffeine and theophylline are both methylxanthine derivatives that cause cerebral vasoconstriction and central nervous system stimulation. Caffeine therapy, both oral and parenteral, is the most commonly used pharmacologic treatment modality. Caffeine has been shown to eliminate headache in up to 70% of patients, but this effect may be transient. Still, Baysinger et al.[66] suggested that prophylactic intravenous caffeine administration may safely minimize PDPHs.

An epidural blood patch is considered the definitive treatment for PDPH. Thought to work via clot formation that seals the dural rent and increases CSF pressure, the epidural blood patch is associated with a greater than 90% cure rate. Clinically an epidural blood patch is performed in a manner similar to that of placing an epidural catheter. First, the availability of intravenous access is identified, usually in the antecubital fossa, and informed consent is obtained. Both the patient's back and intravenous access site are prepared and draped in an aseptic manner. An insertion site at or below the level of the lowest initial needle insertion is chosen, because blood has been shown to spread in a predominantly cephalad direction within the epidural space. The epidural space is identified by use of either loss-of-resistance or hanging-drop technique (discussed in the section on epidural anesthesia). Autologous venous blood (approximately 20 mL) is withdrawn from the vein and then slowly injected through the epidural needle into the epidural space. The injection proceeds until the patient senses pressure in the back, buttocks, or legs. Typically, this occurs at a volume of 12 to 15 mL, which is sufficient blood to patch most patients. A supine position should be maintained for $^1/_2$ to 1 hour before the patient ambulates. Relief of the headache is often instantaneous. In the rare case in which an epidural blood patch fails, a repeat blood patch may be attempted in 24 hours, with a similar success rate.[22,28,63]

The success rate and excellent safety record of the epidural blood patch encourages the use of this therapeutic option early in the treatment of PDPH. However, some risks, although minor or rare, are associated with this more invasive procedure. Backache, often associated with the administration of general, spinal, or epidural anesthetic techniques, occurs in up to 35% of patients after an epidural blood patch. Although rarely as debilitating as a PDPH, backache risk should be explained to the patient. The most common cause of backache is relaxation of the muscles of the back and flattening of the normal lordotic curve. As the muscles stretch, injury to tendons and ligaments can occur. The position of the patient might increase the severity of the problem. An exaggerated lithotomy position or a completely supine position can further increase tension on tendons, resulting in increased trauma to both the muscles and the tendons. Trauma from multiple punctures; hemorrhage; infections; use of large needles, retractors, and forceps; extremes of positions; preexisting diseases such as arthritis and osteoporosis; and prolonged labor can contribute to backaches that may persist well into the postoperative period.[28,63]

Management of backache includes the use of antispasmodics and NSAIDs to reduce discomfort, permit ambulation, and promote a more rapid recovery. In addition, authors have reported a 5% incidence of transient (24- to 48-hour) temperature elevation, a 1% incidence of neck ache, radicular pain, nerve root irritation, cranial nerve palsy, and meningitis, although the cause of meningitis was unproven.[23,28,63]

Several caveats regarding the treatment of PDPH are worth mentioning. Systemic infection, perhaps indicated by fever, presents a relative contraindication to epidural blood patch and warrants a trial of pharmacologic intervention. The risk of neurologic sequelae after epidural blood patch in the presence of HIV infection or sepsis is controversial, because few data are available, leading some authors to suggest alternative therapies such as epidural 0.9% sodium chloride or dextran.[15,46,63] Prophylactic epidural blood patch placement has not been shown to be consistently successful.[22] In light of the relatively low incidence of PDPH and the

effectiveness of the epidural blood patch, treatment should not begin until the problem exists. Finally, an alternative diagnosis should be sought if two epidural blood patches fail to resolve the patient's symptoms.[28,63]

Nausea

As with general anesthesia, intraoperative and postoperative nausea and vomiting (PONV) associated with CNB is a complex issue. Although it is believed that PONV is less common with regional anesthesia techniques than general anesthesia techniques, agents such as propofol have considerably narrowed the incidence gap. Although not life threatening, PONV remains a significant concern for patients and clinicians. General strategies can be implemented to help reduce the incidence of this unpleasantness.

Nausea immediately after the initiation of CNB is often considered a sign of significant hypotension and a climbing block level. Resulting cerebral ischemia affects the vomiting centers of the medulla, possibly triggering nausea. Others posit that gut ischemia leads to the release of emetogenic substances such as serotonin. Fluid and sympathomimetic administration treats the hypotension, and the nausea resolves. Another contributing element may result from the sympathectomy caused by the onset of CNB. The resulting unopposed parasympathetic activity in the gastrointestinal tract results in hyperactivity, possibly contributing to nausea. Evidence that this may be the case is that vagolytic agents such as atropine are efficacious in treating this nausea.[67]

Avoiding hypotension, providing adequate hydration, and supporting perfusion with supplemental oxygen are the basis of an antiemetic plan for CNB. Premedication and intraoperative sedation can significantly affect the incidence of intraoperative nausea and PONV. Clonidine does not influence the incidence of PONV, and evidence supports that propofol has antiemetic effects. The addition of epinephrine to local anesthetics administered intrathecally for spinal anesthesia increases the incidence of nausea. Also, a dose-dependent increase in PONV occurs when intrathecal morphine is used. However, the addition of 20 mcg fentanyl or 2.5 to 5 mcg of sufentanil to spinal bupivacaine results in less intraoperative nausea compared with placebo. Similar strategies apply to epidural anesthesia, although opioid use must be matched to patient and case type to maximize analgesia while minimizing secondary effects.[67] Multimodal approaches that have been widely adapted should be applied to PONV after regional anesthesia as well.[68]

Urinary Retention

Urinary retention is common after anesthesia and surgery with a reported incidence of between 5% and 70%. Spinal or epidural anesthetics block sympathetic fibers and increase the tone of the internal urethral sphincter. However, other factors often contribute to the risk of urinary retention after surgery and anesthesia. These include the type of surgical procedure, bladder distention from the administration of large volumes of intravenous fluids, bladder trauma, prolonged hypotension, incision pain, urethral edema caused by prolonged labor, benign prostatic hypertrophy, and the use of neuraxial or intraoperative opioids, anticholinergics, sympatholytics, and other drugs. Comorbidities, type of surgery, and type of anesthesia influence the development of postoperative urinary retention (POUR). The risk of retention is especially high after anorectal surgery, hernia repair, and orthopedic surgery and increases with advancing age. Certain anesthetic and analgesic modalities, particularly spinal anesthesia with long-acting local anesthetics, adding epinephrine and epidural analgesia, promote the development of urinary retention. Reasonable fluid administration with less than 1000 mL helps avoid bladder overdistention. Portable bladder ultrasound provides rapid and accurate assessment of bladder volume and aids in the diagnosis and management of POUR. Catheterization is recommended when bladder volume exceeds 600 mL to prevent the negative sequelae of prolonged bladder overdistention. Urinary retention and subsequent catheterization can lead to complications such as urinary tract infections and urethral strictures. Low-risk patients with less than 600 mL bladder volume may be sent home with instruction to return if they cannot void.[67-71]

Neurologic Risk

Patients greatly fear the perceived risk of paraplegia resulting from neuraxial anesthetics, and the seriousness of such complications warrants concern. However, several very large series have shown that the incidence of persistent motor paralysis is exceedingly rare (less than 1 per 10,000). Because neurologic sequelae are rare, the knowledge base of complications comes from case studies, and often the cause is not proved but rather inferred by association. Direct needle or catheter nerve injury, drug-related neurotoxicity, anterior spinal artery syndrome, undiagnosed neurologic disease, intraneural or intramedullary injections, the presence of blood in the CSF, patient positioning, hematomas, and abscesses are associated with permanent neurologic deficits. Therefore, good clinical practice depends on (1) the use of appropriate anesthetic techniques that minimize risk and (2) the conduct of postoperative assessments in a manner that promotes early detection, diagnosis, and treatment—especially because reversibility of complications is often time dependent.[15,28,30,72,73] Transient neurologic symptoms are discussed in Chapter 10.

Unexpected Cardiac Arrest

Cardiac arrest associated with neuraxial anesthesia is often sudden and unexpected and can result in severe neurologic injury and death. Additionally, this undesired complication occurs in a significant number of young, previously healthy patients. Estimates of occurrence have ranged from 7:10,000 for spinal anesthesia and 1:10,000 for epidural anesthesia. This suggests that cardiac arrest is not such a rare event in neuraxial anesthesia. How then might it be differentiated from arrests under general anesthesia (3:10,000)?[74]

Because unexpected cardiac arrest with spinal anesthesia has been reported in previously healthy patients, some authors consider this a physiologic response to neuraxial blocks. Other authors suggest a pattern of presentation with a gradual downward trend in heart rate followed by an abrupt onset of severe bradycardia or asystole.[11] Spinal anesthesia cardiac arrest can occur well after the onset of spinal blockade. Large and recent retrospective studies note that arrests can occur 20 to 60 minutes after the onset of spinal blockade and are frequently associated with intraoperative events such as significant blood loss and orthopedic cement placement.

The etiology of cardiac arrest during spinal block anesthesia is related to cardiocirculatory factors, mainly a reduction of preload resulting from sympathetic blockade. These decreases in preload may initiate reflexes that cause severe bradycardia. Three reflex responses have been suggested. The first involves the pacemaker stretch. The rate of firing of these cells within the myocardium is proportional to the degree of stretch. Decreased venous return results in decreased stretch and a slower heart rate. The second reflex may be attributable to the firing of low-pressure baroreceptors in the right atrium and vena cava. The third is a paradoxical Bezold-Jarisch reflex, in which mechanoreceptors in the left ventricle are stimulated and cause bradycardia. Other factors that

increase the risk of developing cardiac arrest include changes in patient positioning and hypovolemia.

Maintaining preload should be a priority, and prophylactic preloading with a bolus of IV fluid should not be omitted before initiating spinal anesthesia. It is important to institute treatment as soon as possible. Standard regimens for volume preloading may not be sufficient to maintain adequate preload, so a low threshold for administering additional fluid boluses, using vasopressors or repositioning the patient to augment venous return, may be appropriate. For patients with bradycardia during spinal anesthesia, the stepwise escalation of treatment of bradycardia with atropine (0.4-0.6 mg), ephedrine (25-50 mg), and, if necessary, epinephrine (0.2-0.3 mg) may be appropriate. For severe bradycardia or cardiac arrest, full resuscitation doses of epinephrine should be promptly administered.[74-77]

Auditory, Ocular, and Facial Complications

Unexpected complications or complications that a patient may not ascribe to anesthesia may be unreported or underreported, especially if they are transient in nature and not life threatening. The complications of transient hypoacusis or hearing loss and retinal hemorrhage are thought to be caused by changes in CSF pressure, either from postdural puncture leaks or increases in pressure from the epidural administration of a large volume of solution. Epidural injection of 8 to 16 mL of fluid can increase CSF pressure by 85 cm H_2O for several minutes before compensation occurs. Horner syndrome (i.e., ptosis, miosis, anhidrosis, and enophthalmos) and trigeminal nerve palsy probably result from a high spread of local anesthetic to the sympathetic fibers of the head and neck and to cranial nerve V, respectively. These problems are usually self-limiting; however, knowledge of their previous occurrence enables the compassionate anesthetist to provide counsel and reassurance to anxious patients.[32,78]

EPIDURAL ANESTHESIA

Epidural anesthesia is a central neuraxial block that can be used for a wide variety of procedures. Unlike spinal anesthesia that results in an all-or-none block, epidural anesthesia can be titrated to deliver either analgesia or anesthesia for a wide variety of surgical and analgesic procedures. Epidural anesthesia allows the anesthesia practitioner better control of the extent of sensory and motor blockade than is offered by spinal anesthesia. The luxury of placing an epidural catheter that can be used before, during, and for an extended period after any surgical procedure is another advantage. The general indications for epidural anesthesia are the same as those outlined for spinal anesthesia, with the distinct difference that epidural anesthesia allows for continuous anesthesia secondary to placement of an epidural catheter. This makes epidural anesthesia more suitable for procedures of long duration and for extended use in the postoperative period to deliver long-term, titratable analgesia.

Local anesthetics or other analgesic solutions injected into the epidural space spread anatomically. Horizontally, medication spreads to the regions of the dural cuffs, where it is able to diffuse into the CSF and leak into the intravertebral foramen and paravertebral spaces to achieve analgesia/anesthesia. Longitudinally, medication spreads in a cephalad direction, with possible sites of anesthetic action along the paravertebral nerve trunks, intradural spinal roots, dorsal and ventral spinal roots, the dorsal root ganglia, the spinal cord, and the brain. Initial blockade is probably a result of anesthetic blockade at the spinal roots within the dural sleeves.[4] The dural cuffs or sleeves have a proliferation of arachnoid villi and granulations that effectively reduce the thickness of the dura mater, permitting rapid diffusion of anesthetics from the epidural space through the dura and into the CSF. Differences in physicochemical properties of anesthetics (e.g., lipid solubility) may account for the differences in diffusion rates across the dura, which contributes to the variances seen in sensory, motor, and sympathetic blockade.[5] Because epidural anesthesia is diffusion dependent, relatively large volumes (20 mL) of local anesthetics must be used to achieve anesthesia as compared with spinal anesthesia, which routinely only requires 1 to 2 mL. In addition, because epidural anesthesia requires that the medication be delivered to the subarachnoid space by the process of diffusion and spread, anesthesia takes significantly longer to achieve than spinal anesthesia. Given these caveats, any procedure that can be done with the patient under spinal anesthesia can also be done under epidural anesthesia.[4] However, epidural techniques allow for the placement of a continuous catheter, which is especially useful in cases of unpredictable duration, for prolonged postoperative analgesia, and for chronic pain control. In addition, labor epidural analgesia is the only method currently available that can relieve most of the discomfort of labor while minimally affecting maternal or fetal physiology. Labor epidural analgesia is highly satisfactory in these patients because it permits their participation in a comfortable delivery and allows maternal-infant bonding after delivery. Labor analgesia also satisfies obstetricians and anesthesia practitioners in that its flexibility allows quick conversion from an analgesic technique to a surgical anesthetic technique for cesarean section.

Equipment and Techniques

Patient preparation and positioning and the availability of emergency equipment and monitors are similar to the preparation for a spinal anesthetic. With a spinal anesthetic, the practitioner seeks CSF by piercing the dura, while the tip of the epidural needle seeks the fat-filled space deep to the ligamentum flavum and shallow to the dura. The standard epidural needle is typically 16 to 18 gauge and 3 inches long, with a blunted bevel and gentle curve of 15 to 30 degrees at the tip. This blunt bevel and curve allow the needle to pass through the skin and ligamentum flavum and abut against the dura, rather than penetrate through the dura. The two most common epidural needles used in clinical practice with a curvature at the blunt bevel are the Tuohy and Hustead needle designs. The Tuohy needle has the most pronounced curvature (30 degrees) at the tip and is often cited as the easiest for beginning practitioners to place because it allows directional placement of the epidural catheter into the space and the curved, blunt tip is less likely to penetrate into the subarachnoid space. However, it also has been noted that placement of the Tuohy needle can be more difficult because the tip's exaggerated curvature is too blunt, inhibiting penetration through the skin and ligamentum flavum as compared with other needle tips. The Hustead needle is an intermediate needle with a less-pronounced 15-degree curvature that can more easily pass though skin and ligamentum flavum.

A third epidural needle is the Crawford needle. It is a thin-walled epidural needle that does not have the curvature of the Tuohy or Hustead needle. The straight tip may allow easier access through the skin into the epidural space. The Crawford needle is preferred by practitioners when catheter advancement into the epidural space is difficult or the angle of approach is steep, as encountered with thoracic epidural catheter placement. Because the Crawford needle lacks the curvature at the bevel end, it also has been implicated in a higher ratio of accidental dural punctures and is typically not used by beginning practitioners. These three common epidural needles are shown in Figure 44-12.

Smaller-gauge (20- to 22-gauge) epidural needles are available in each needle design for pediatric catheter techniques, regional blocks, and specialty use. Many needle designs incorporate wings near the base or hub. The wings provide a grip for the practitioner that permits distribution of pressure equally over the needle during insertion. The wings and notches in the hub also align with the stylet and needle tip to indicate the direction of the needle tip's bevel and lumen. Needles also may have clear hubs to allow early detection of blood or CSF, plastic stylets to prevent coring, and 0.5- or 1-cm depth markings along the needle shaft.

Epidural catheters also come in a variety of materials and designs. Typically, catheter diameter is 2 gauges smaller than the needle. For example, a 20-gauge catheter would be used with an 18-gauge Tuohy needle. Catheters are constructed of physiologically inert materials designed to resist kinking, compression, and stretching and should be radiopaque. The two most common epidural catheters used in clinical practice are the single-holed, open-ended (uniport) and lateral-holed, closed tip (multiport) epidural catheters. Each catheter design is reported to offer several advantages and disadvantages. Studies that have compared the differences in catheter designs show a significantly lower incidence of inadequate analgesia with multiport catheters but a higher incidence of inadvertent intravenous cannulation.[79] Catheters have markings that identify the tip of the catheter to help verify removal of the catheter and identify when the catheter is at the tip of the needle, with 1-cm markings to measure depth of catheter placement. The depth that a catheter should be threaded beyond the needle tip and into the epidural space is often a controversial topic. Manufacturers of epidural catheters recommend that a catheter should be threaded 1 to 3 cm into the epidural space to avoid possible migration into an epidural vein or through an intravertebral foramen.[15,80] However, in clinical practice practitioners noted that when an epidural catheter was only threaded 1 to 3 cm, a higher incidence of epidural catheter failure could result. Many practitioners reported anecdotally that when the catheter was threaded 3 to 5 cm into the epidural space, a higher success rate without a resultant increase in migration into an epidural vein or intravertebral foramen occurred. This routine clinical practice was validated by Beilin et al.[80] They reported that a catheter insertion of less than 3 cm resulted in a higher incidence of inadequate analgesia, and an insertion depth of more than 5 cm resulted in an increase in inadvertent intravenous cannulation. They recommended that optimal catheter insertion should be 3 to 5 cm into the epidural space.

Proper patient positioning is important to ensure successful catheter placement. Epidural anesthesia is most often instituted with the patient in the sitting or lateral decubitus position and the landmarks, aseptic preparation, draping, and localization are similar to those for a spinal anesthetic. The spine should be in proper alignment, using pillows or pads if necessary, and intervertebral spaces should be identified and marked prior to preparation of the patient's back (see Figure 44-8). In contrast to thin, flexible spinal needles, epidural needles are larger and more rigid. Therefore, placement of the epidural needle does not require an introducer needle and offers better directional control; however, all needle-handling techniques must anticipate patient movement. Whether inserting a spinal or epidural needle into a patient, a similar controlled grip is used to accommodate for potential patient movement. This grip, described earlier as the *Bromage grip* (see Figure 44-11), allows the patient's body to act as a firm support for the needle-stabilizing hand and helps prevent advancement or withdrawal of the needle tip from its position (1) if the patient should move, (2) when the syringe is applied, and (3) as a catheter is passed into the epidural space. The needle is placed bevel tip cephalad through the supraspinous ligament and seated in the interspinous ligament before the stylet is removed. After the stylet is removed, the needle is slowly advanced by use of either the hanging-drop technique or the loss-of-resistance technique into the epidural space.[5]

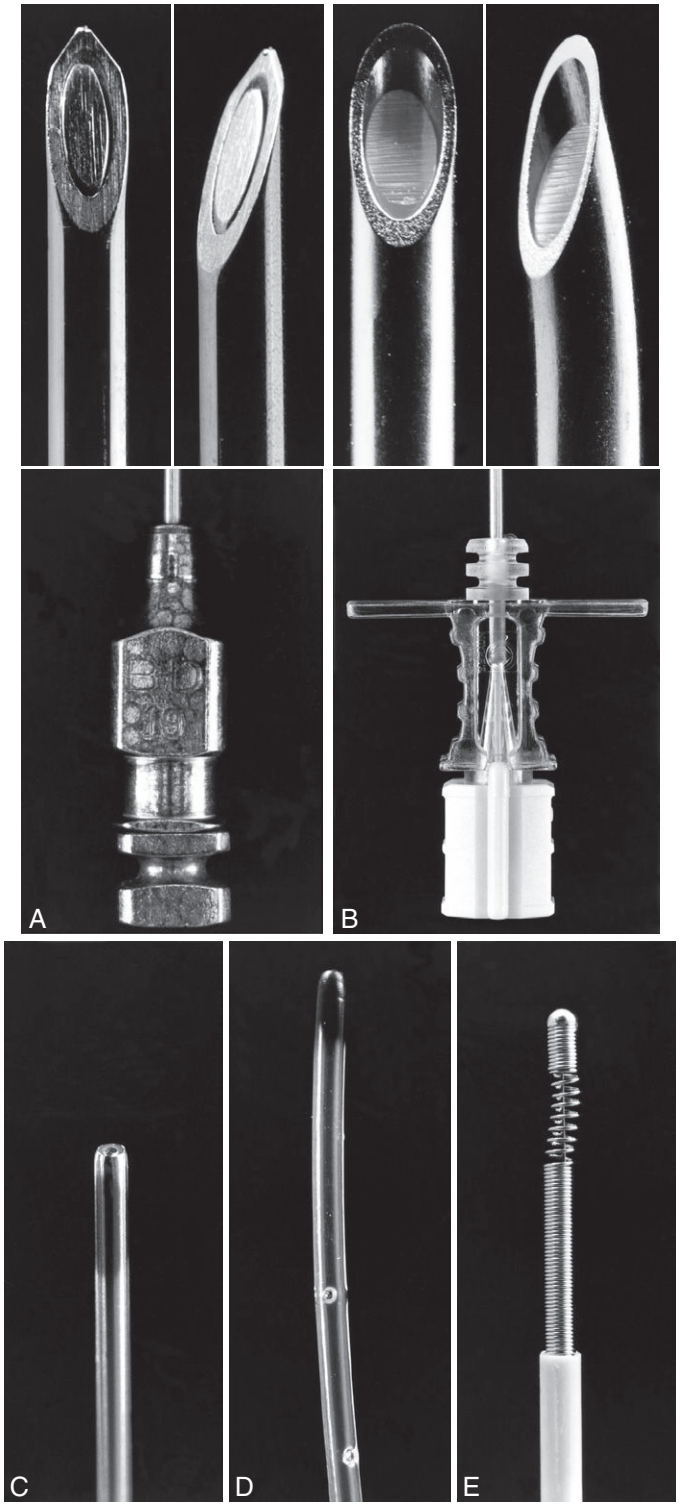

FIGURE **44-12** Epidural needles with catheter assortment. **A,** A 19-gauge, reusable Crawford epidural needle. **B,** A 19-gauge, disposable Tuohy needle. **C,** Single–end-hole epidural catheter. **D,** Closed-tip, multiple–side-hole catheter. **E,** Spring wire–reinforced, polymer-coated epidural catheter. (From Miller RD, et al. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010;1628-1629.)

After the needle is seated in the interspinous ligament, the hanging-drop technique is accomplished by filling the hub of the needle with saline. The surface tension of the saline creates a droplet hanging on the needle hub. The needle is then advanced slowly in a slight cephalad orientation toward the epidural space. As the needle is advanced through the ligamentous structures, the drop should not move; however, as the tip of the needle enters into the epidural space, the negative pressure within the space will cause the drop of fluid to be drawn into the needle. This aspiration of the hanging drop into the needle signifies that the needle has successfully entered the epidural space. It should be noted that if the needle becomes plugged or the negative pressure in the epidural space is very low, the drop will not be drawn into the hub of the needle and passage into the epidural space will not be recognized. A dural puncture could result. Therefore, the hanging-drop technique is not recommended for the novice practitioner.[5]

The loss-of-resistance technique is the most common method used to enter the epidural space. The epidural needle is placed through the dermis into the interspinous ligament or ligamenta flava, at which time the stylet of the epidural needle is removed. Once the needle has been firmly seated into the ligament, a loss-of-resistance syringe (plastic or glass) containing 2 to 3 mL of normal saline or air and a freely movable plunger is attached. If the needle is properly seated in the ligament, it should be difficult to inject the normal saline or air, and slight pressure on the syringe plunger should result in the plunger springing back to its original position. Some practitioners use a combination of saline and air in the syringe during the loss-of-resistance technique, using approximately 3 mL of normal saline and a small air bubble (0.1 to 0.3 mL). They report that this provides them with a more compressible feel for entry into the ligamentum flavum. If the air bubble cannot be compressed without injecting the normal saline, the needle is most likely not seated into the ligamentum flavum and may still be in the interspinous ligament or off midline into the paraspinous muscles. The needle is advanced toward the epidural space by application of pressure to the needle, not the syringe or syringe plunger. If normal saline is used, constant pressure may be applied to the syringe plunger. Contact with the needle or needle wings is maintained to control needle advancement. As the needle passes through the ligamentum flavum, resistance increases, and it is very difficult to inject either saline or air. Once the bevel of the needle completes the passage through the ligamenta flava and enters the epidural space, an immediate loss of resistance occurs. The contents of the syringe can then be injected gently and without resistance. After the syringe is removed from the needle, an outward rush of a small amount of air or fluid may occur. Penetration of the dura with a large epidural needle usually results in profuse return of CSF; the needle should be removed immediately to minimize CSF loss.

The loss of resistance experienced by a beginning practitioner, or by the experienced practitioner in a patient with difficult anatomy, may not be easily discerned. Sometimes it may be necessary to further evaluate the needle tip's location. For example, several milliliters of air can be injected through the needle while the soft tissue lateral to the spinous process is palpated. If crepitus is felt, the needle is most likely located in the tissues adjacent and shallow to the spinous process. If fluid returns from either the needle or catheter, CSF can be distinguished from normal saline (NS) or local anesthetic. CSF is warm to the forearm, compared with recently administered room-temperature fluids. Glucose test paper will detect the glucose in CSF. Local anesthetics mixed with a similar volume of thiopental will immediately form a precipitate. Multiple tests should be used to achieve the most accurate confirmation of fluid type.

Once the practitioner is reassured of the needle tip's position, an epidural catheter is threaded through the needle and into the epidural space to a depth of 3 to 5 cm. As the catheter is passed into the epidural space, it is important to warn the patient that a "funny bone" sensation may be experienced down one or both legs. This is a paresthesia that may indicate that the catheter has brushed by a nerve root as it was passing into the epidural space or perhaps even lodged into the nerve root. If the paresthesia is persistent prior to or after needle removal, the catheter must be withdrawn and replaced. Injection of medication into a patient complaining of persistent paresthesias can result in nerve-root damage or even nerve-root death and cause long-term morbidities. If the catheter is being replaced secondary to a persistent paresthesia, it is best to move to a new interspace to avoid oversensitized nerve roots. It is important that the needle remain stabilized during catheter advancement. Often if a patient does experience a paresthesia during threading of the catheter, the patient will move reflexively. Unanticipated movement and an uncontrolled needle could result in inadvertent subarachnoid puncture. Once the catheter is threaded approximately 3 to 5 cm, the needle is withdrawn slowly over the catheter. It is common practice to note the depth of the catheter at the level of the skin (by noting the cm-depth mark on the catheter) both prior to and after removal of the epidural needle. Once the epidural needle is removed, the catheter depth should be noted and documented. If the catheter was inadvertently threaded deeper than desired into the epidural space, it should be slightly withdrawn to the desired depth as noted at the level of the skin. If the catheter migrated out of the epidural space, again the depth should be observed and recorded. Finally, if the depth into the epidural space is less than 1 cm, replacement of the catheter should be considered before any attempts are made to inject through the catheter. Never attempt to withdraw the catheter through the needle! This can shear the catheter and embed foreign material in the patient's back. Surgical intervention may be required for catheter remnant removal.

Once a catheter is placed and the needle removed safely, a catheter-to-syringe adapter is placed on the free catheter end. Observe the clear catheter as it enters the back. Look for backflow of CSF or blood. Owing to the greater resistance of a long and narrow catheter compared with a needle, gravity flow alone may not reveal the presence of blood or CSF. Therefore, gentle syringe aspiration is applied to the catheter via the adapter. Because tissue at the catheter tip may create a ball-valve effect, CSF or blood may not flow out; therefore, a negative aspiration test does not guarantee that the catheter tip is in the epidural space. Only if fluids do return does this test confirm that the catheter tip is placed either into an epidural vein or the subarachnoid space. The return of CSF or blood indicates that the catheter should be removed and replaced at a different interspace. To avoid this ball-valve effect or to dislodge any skin or tissue that may have lodged at the catheter tip, some practitioners advocate injection of 1 to 2 mL of normal saline solution through the catheter to confirm catheter patency before injection of medications. After needle removal, the catheter should be taped away from the midline of the back to avoid spinous processes and minimize the risks of catheter displacement from the epidural space or pressure injuries over bony prominences.

Prior to injection of a large amount of medication into an epidural space, a test dose of a small amount of medication is administered to determine whether the catheter or needle has inadvertently entered the subarachnoid space or possibly threaded into an epidural vein. A test dose of 3 mL of a rapid-acting, low-toxicity local anesthetic agent with or without a small

concentration of epinephrine is most typically used. A lidocaine 1.5% with 1:200,000 epinephrine solution provides 45 mg of lidocaine with 15 mcg of epinephrine per 3 mL dose. If the needle or catheter tip is in the subarachnoid space, this dose will result in spinal anesthesia within 3 minutes. If the same test dose is injected into a blood vessel, the 15 mcg of epinephrine will result in a 20% rise in heart rate and systolic blood pressure within 30 seconds. The patient also may experience sensations from the intravascular lidocaine, describing symptoms such as tinnitus, a metallic taste, circumoral numbness, or a rushing sound in the ears. The duration of these test-dose effects is less than 5 minutes. After the test dose is injected, vital signs are reassessed. Additionally, 100 mcg of undiluted fentanyl can be injected as a test dose to avoid potential complications caused by even low doses of epinephrine. If the needle or catheter is intravascular, the patient will experience immediate dizziness and sleepiness from the opioid. Despite all efforts to avoid them, systemic toxic reactions can still occur. Be vigilant, be cautious, and be prepared to handle emergencies.[81-83]

Epidural anesthesia also can be administered by direct injection through the needle once it has been placed into the epidural space. This is called a "single-shot" epidural anesthesia technique, and the same contraindications and safety precautions apply as those already reported for catheter insertion. Once the needle is placed into the epidural space, the end of the open needle is observed for the presence of blood or CSF. Allow a few seconds for gravity flow of fluids to detect blood or CSF when the single-shot technique is used, then attach a syringe for medication administration using needle control techniques previously discussed.

Epidural anesthesia can be performed at any of the four segments of the spine but is most typically performed at the lumbar level. As with spinal anesthesia, there are two approaches, the midline and paramedian approach, that are used to facilitate placement of the epidural needle into the epidural space. The most common approach is the midline approach because it is the easiest to perform and helps place the catheter in the medial region of the epidural space. The paramedian approach is usually selected when surgery or degenerative joint disease contraindicate the midline approach. Using the paramedian approach is more difficult for the beginner because advancement into the interspinous ligament does not occur. The needle advances primarily through paraspinous muscle mass, and resistance is only felt when entering the ligamentum flavum. The technique for paramedian placement involves identification of the desired interspace and the spinous process. The skin surface area approximately 3 cm lateral to the lowest aspect of the spinous process is prepped and anesthetized. The epidural needle is then placed through the anesthetized region and directed toward the midline using a slight cephalad orientation. Once the dermal levels are penetrated and the paraspinous muscle mass encountered, the needle stylet is removed and attached to a syringe containing either air or normal saline (or both) and advanced. The midline of the spine should be encountered approximately 3 to 5 cm from the entry point. The needle is advanced slowly using the incremental approach described earlier through ligamenta flava and then into the epidural space. When a paramedian approach is required by difficult surface anatomy or a steep approach to the thoracic levels is anticipated, the Crawford needle may be preferred. The Crawford needle's straight, blunt bevel allows the catheter to pass directly through the end of the needle, thus facilitating threading of the catheter.

Ultrasound Epidural Placement

The loss of resistance technique using air, normal saline, or a combination of air/normal saline is the gold standard method used by anesthesia practitioners to identify the entry into the epidural space. Traditionally epidural needle placement at a desired interspinous level is determined by palpation of anatomic landmarks; however, appreciating these landmarks can be extremely difficult in some patients. This difficulty could be secondary to obesity and/or scoliosis of the spine, which often require multiple passes with the epidural needle before proper placement or completely abandoning placement attempt secondary to inability to find the epidural space. Despite considerable improvement in the quality of needles and epidural catheters within the last 30 years, the techniques for identification of the epidural space have remained the same, and as described previously, using these techniques to identify the epidural space can be impossible in some individuals.

To facilitate placement of spinal and epidural analgesia/anesthesia, ultrasound has been introduced into clinical anesthesia, and it has been found to be particularly useful in determining the spinous and transverse processes, thereby facilitating easier placement.[84] In addition, ultrasonography also allows the Certified Registered Nurse Anesthetist (CRNA) to adequately determine the distance from the skin to the epidural space, which may result in a lower incidence of accidental dural punctures. There are two useful acoustic windows used to assess lumbar spine anatomy. One of these windows is assessed using a transverse midline approach, whereas the other is assessed using a paramedian longitudinal approach (Figure 44-13). The midline approach allows the anesthetist to adequately identify the midline, whereas the transverse approach allows for assessment of the interspace. In addition, the depth to the epidural space can be determined using ultrasound equipment.

In contrast to the ultrasound machines used for peripheral nerve blocks, which operate using a high-frequency linear probe (10-15 MHz), the ultrasound probe used for spinal and epidural placement needs to be low frequency (2-5 MHz). These low-frequency probes are traditionally curved linear probes of the same type used routinely on pregnant women in labor and delivery to assess fetal function. The ultrasound can be used to identify the epidural space depth and position, or it can be used to facilitate real-time viewing of epidural needle placement into the epidural space. The technique of using one or two operators is well described in the literature.

Technique

An ultrasound (US) machine that is capable of deep scans and equipped with a low-frequency (2-5 MHz) curvilinear probe should be used to facilitate the scan. Two different approaches (longitudinal paramedian and transverse midline) are used to help identify spinous processes, articular processes, ligamentum flavum, anterior dura mater, posterior dura mater, and depth to epidural and subarachnoid space.[85] The patient is placed in a lateral position with flexed knees and hips or in a sitting position with the back curved out to present the spines. After proper positioning of the patient, the low-frequency US probe is placed over the sacral area, 3 cm left of midline and slightly angled toward the center of the spine. The hyperechoic (white) line of the sacrum is identified and then the probe is moved slowly cephalad until hyperechoic sawlike images are seen (see Figure 44-13). These sawlike projections are the articular processes, and between the sawlike images are the vertebral interspaces. Next the ligamentum flavum, posterior dura mater, and vertebral body are identified, and the exact level of each interspace and the spinous process is marked. The probe is then placed horizontal along the midline of the spine at the marked levels of the interspaces and spinous processes. The hyperechoic spinous process is identified using the long triangular

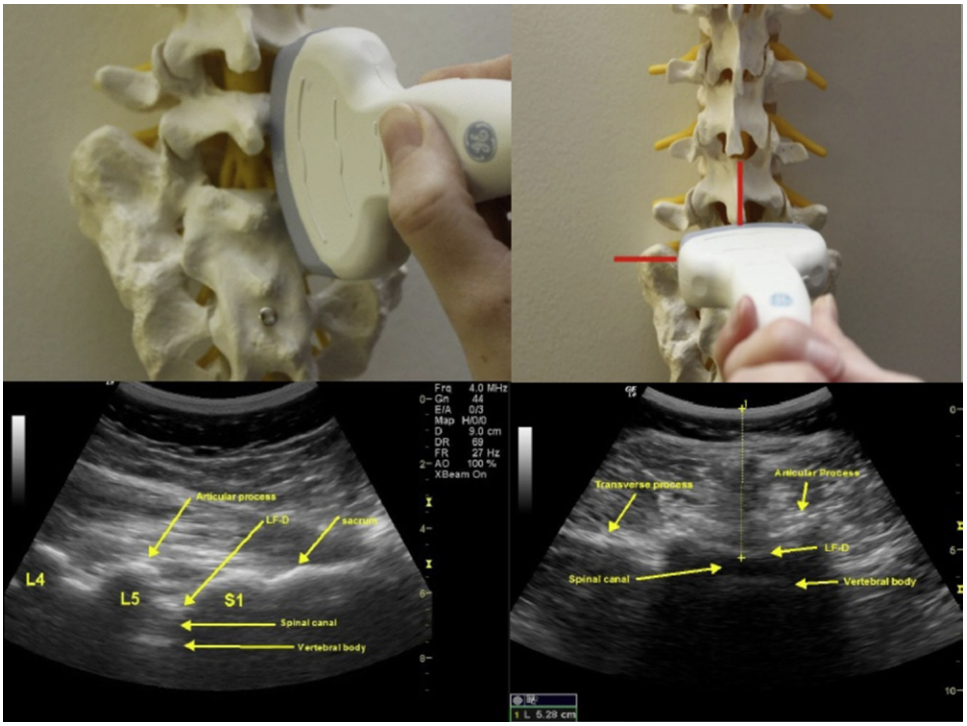

FIGURE **44-13** Orientation of ultrasound probe and identification of underlying structures.

hypoechoic shadow. The probe is moved caudad or cephalad to capture the best view of the interspace, ligamentum flavum, and dorsal dura mater. Once a clear image is obtained, the screen is frozen and the midline is marked along the right lateral surface of the probe. The insertion point is determined by the intersection of the extensions of the two marks on the skin in the vertical and horizontal planes. One mark identifies the midline and the other identifies the interspace (see Figure 44-13). The depth to the epidural or subarachnoid space is obtained from the "frozen screen" of the transverse view using the US machine calipers; one prong of the calipers is placed at the skin and the other at the inner side of the ligamentum flavum.[86]

Epidural Drugs, Spread, and Block Levels

As with any anesthetic technique, the clinical success of epidural anesthesia is often dependent on experience because multiple factors must be managed and balanced to provide safe patient care. Two of these factors, dose and the site of injection, are the most important factors in determining the extent of dermatomal blockade. It should be remembered that the size of the segmental epidural spaces increases down the spinal cord as the spinal cord occupies less and less space. For example, when a very small volume of local anesthetic is injected into the cervical region, it will spread across a larger number of segments as compared with when the same volume is injected into the thoracic region. This is also true when comparing the dermatomal spread between the thoracic and lumbar or caudal regions. The suggested dose of local anesthetic is dependent on the location of the catheter tip as it lies in the epidural space. Common clinical practice is to insert the epidural needle at a vertebral interspace such that the catheter tip falls near the middle of the spinal dermatomes of the proposed surgical incision. For example, an epidural catheter placed for labor or lower abdominal anesthesia would be placed at the L2 or L3 interspace. Placement would be at T8 to T10 for upper abdominal surgery; T4 to T5 for thoracic surgery; and C7 to T1 for chronic pain treatments or surgeries of the arms, shoulders, or upper chest. This has several advantages. The catheter tip, being at the relative center of the spread of the local anesthetic, creates an area of high concentration at the spinal nerves specific to the site of the operation with the least amount of local anesthetic. This high concentration at a specific location results in rapid block onset and greater block density, which often creates a differential blockade that can be controlled by dose.

Dose is described as volume multiplied by concentration. The concentration of the local anesthetic generally affects the density of the block, whereas the volume, within limits, affects the spread from the needle or catheter tip throughout the epidural space. Successful analgesia can be achieved with relatively small volumes and high concentrations of local anesthetics. Clinically useful doses are based on volumes that permit an even filling of the anterior and posterior epidural spaces at the level of insertion. For example, the suggested volumes per segment at the cervical and thoracic levels are 0.7 to 1 mL per segment, remembering that the spread will occur in both a cephalad and caudad fashion. Therefore, an initial total dose, usually less than 10 mL, will achieve a 10- to 14-dermatomal spread of local anesthetic. In contrast, when the local anesthetic is injected at the lumbar level, the volume of local anesthetic required is 1.25 to 1.5 mL per segment. A typical initial volume of 15 to 20 mL is required to ensure adequate anesthesia by blocking a total of 12 to 16 segments (6 to 8 segments above and below the catheter tip). Also, it should be remembered that spread of blockade tends to occur faster in the cephalad direction from the catheter tip, possibly because thoracic nerve roots are smaller in diameter than large lumbar and sacral nerve roots.[4,5,8]

Other factors thought to affect the level of blockade achieved with epidural anesthesia include height, weight, age, patient position during injection, pregnancy, and the speed or mode of injection. However, the clinical significance of these factors has been challenged. Correlations between patient height and weight and the spread of the epidural block are clinically insignificant, except perhaps, in the extremely tall, short, or morbidly obese patient. Studies have examined patients in the sitting and lateral positions

during administration of epidural anesthetics and found small differences in spread and onset that favor the dependent portion of the patient's body. Therefore, provision of anesthesia to the sacral roots might be facilitated by having the patient sit up during the injection. In addition, leaving the patient on the operative side after the solution is injected may speed onset. However, these are clinically small differences and may not always be effective.

Drugs should be injected slowly into the epidural space to avoid rapid increases in CSF pressure, headache, and increased intracranial pressure. A rapid speed of injection has not been shown to increase the spread of anesthetic. Also, incremental or bolus injection modes appear to have no influence on spread. The spread of epidural anesthetics may be three or four dermatomes greater in elderly patients, because age-related tissue changes create a less compliant and less leaky epidural space. Although conflicting data exist, some studies suggest that the epidural spread of anesthetics is greater in pregnant patients.[4,5,8] Therefore, it is recommended that the volume of anesthetic solution administered to pregnant patients and elderly patients should initially be limited to 0.5 to 1 mL per segment when injected at lumbar levels.

The density of block is also more dependent on the concentration of local anesthetic used. The lower the concentration, the lower the effect the local anesthetic will have on the degree of sensory and motor blockade. Routinely a lower concentration of local anesthetic is used to facilitate analgesia (as in laboring analgesia) or to provide a sympathectomy. If the primary purpose of the epidural is to provide complete surgical anesthesia, higher concentrations must be used. Table 44-5 lists recommended volumes of local anesthetic based on the position of the catheter and the location of the intended surgical intervention.

All solutions should be injected in increments of 3 to 5 mL every 3 minutes and titrated to the desired anesthetic level. With loading doses and intermittent injections, aspiration of the catheter should occur before any injection. This gradual administration of the medication slows the rate of onset of the anesthetic level and controls the development of the sympathetic blockade. After a loading dose is given, the anesthetic is maintained with either intermittent dosing or a continuous infusion technique.

Intermittent injections are most often used when high concentrations of local anesthetic (2% lidocaine or 0.5% ropivacaine) are administered. A continuous infusion is more appropriate when the goal of the epidural is to provide a consistent level of analgesia. Continuous infusions typically use a lower concentration of local anesthetic solution (0.0625% to 0.125% bupivacaine or 0.1% to 0.2% ropivacaine), and the level of block is monitored on a regular interval basis. A continuous opioid infusion also may be used either as a sole agent or as an admixture with low concentrations of local anesthetic. Typical infusion rates range from as low as 2 mL/hr for concentrated hydrophilic opioid solutions, such as preservative-free morphine, up to 20 mL/hr for dilute solutions of local anesthesia (0.125% bupivacaine or 0.1% ropivacaine) used for postoperative or labor analgesia. Often continuous infusions will contain a dilute concentration of local anesthetic solution with an admixture of a low-dose lipophilic opioid such as fentanyl, 1 to 5 mcg/mL, or sufentanil, 1 to 1.5 mcg/mL. Epidural infusions of these mixtures augment the quality and duration of analgesia while limiting the side effects of any one drug.

Epidural Opioids

Opioids placed into the epidural space may undergo uptake into the epidural fat, systemic absorption, or diffusion across the dura into the CSF.[87] When administered via the epidural route, opioids produce considerable CSF concentrations of drug. Penetration of the dura from the epidural space into the subarachnoid space is influenced by lipid solubility and molecular weight. The administration of an epidural opioid by either an intermittent or continuous infusion has become common in many anesthesia practices. When an opioid is administered epidurally, it needs to cross from the epidural space through the dura to reach the opioid receptors located in the substantia gelatinosa in the spinal cord. Besides the physical barrier of the dura, epidural opioids also may be deposited in the fat and connective tissues in the epidural space, which may significantly increase the opioid dose required to achieve analgesia. In fact, in order to achieve adequate analgesia from epidurally administered opioids, the dose is increased by approximately 10 times the opioid dose administered intrathecally. Also, the epidural space is highly vascularized, and there is significant absorption of the opioids into the systemic circulation; however, the rate of absorption is dependent on individual pharmacokinetics and lipid solubility of the opioid. For example, epidural administration of fentanyl and sufentanil (highly lipid-soluble opioids) results in a serologic level of opioid similar to that produced when the drugs are administered intravenously. When an opioid is administered by the epidural route, the onset of action and duration are dependent on the type of drug used. A faster onset and analgesic peak effect is achieved when a more lipophilic opioid is used versus an opioid that is more lipophobic. Epidural opioids can be administered by either a single bolus dose or a continuous infusion. A continuous infusion provides easier analgesic titration to patient requirements, which is especially important when a shorter-acting opioid such as fentanyl is used. Epidural opioids also

TABLE 44-5 Recommended Doses for Epidural Analgesia

Procedure	Position of Catheter	Dose (mL)
Chest	T12-L2	8-12
Upper Abdomen		
Cholecystectomy	L2	12-16
Gastric resection	L2	12-16
Incisional pain	L2	7-10
Lower Abdomen		
Colon resection	L2	12-16

Second-, third-stage labor	L3	10-12

can be administered using patient-controlled (assisted) epidural analgesia (PCEA), which is a hybrid of continuous infusion and patient-assisted boluses to titrate analgesic requirements based on individual patient needs. The goal is to establish a continuous or "basal rate" infusion to optimize the analgesic effect. The PCEA bolus component can then be preset by the anesthesia practitioner to meet individual patient requirements and used in the event of breakthrough pain.[87] Table 44-6 lists the opioids and dosages most commonly used to achieve epidural-based analgesia.

Extended-Release Epidural Morphine (DepoDur). A sustained-release formulation of morphine sulfate (DepoDur; SkyPharma, San Diego, Calif) is newly available for use in the treatment of acute postoperative pain. DepoDur consists of microscopic spherical particles with integral aqueous chambers separated by lipid membranes containing an encapsulated dose of morphine. DepoDur is unique in that it delivers standard morphine sulfate using DepoFoam technology. DepoFoam (also from SkyPharma) is a drug-delivery system composed of multivesicular lipid particles containing nonconcentric aqueous chambers that encapsulate the morphine sulfate, allowing the morphine to be released over an extended period of time (up to 48 hours) without a requirement for subsequent dosing.[87,88] The half-life of DepoDur is dose dependent, but the DepoFoam technology allows for larger doses to be administered than could be given when conventional epidural injection is used. For example, a study done by Carvalho et al.[88] compared analgesia and side effects in groups of cesarean section patients receiving either a single epidural injection of 5 mg of preservative-free morphine or 5, 10, or 15 mg of DepoDur. After cord clamp, the authors noted that patients who received the 10- and 15-mg doses of DepoDur had significantly lower pain scores and analgesic requirements for the first 48 hours after cesarean delivery.

DepoDur is intended to be used as a sole agent and cannot be administered concomitantly with a local anesthetic solution. Because DepoDur is encapsulated by DepoFoam technology, studies have shown that administration of any local anesthetic solution may elicit a physicochemical interaction and cause a reduction in the sustainability of the DepoFoam to release the morphine over an extended period of time. This can result in an increase in the quantity of the encapsulated morphine released to the systemic circulation and place the patient at increased risk for respiratory depression and hypotension. The full extent of this interaction is being investigated by the manufacturer. This recommendation for not mixing with local anesthetics does not preclude the anesthetist from testing the epidural catheter for possible subarachnoid or intravascular migration preceding injection, and it is recommended that a routine test dose be performed prior to injection of the DepoDur, with some added precautions. The manufacturer recommends that the test dose be administered using prescribed techniques, then the catheter should be flushed with at least 1 mL of 0.9% NaCl solution a minimum of 15 minutes prior to injection of the DepoDur. It has also been recognized that sustained levels of analgesia from DepoDur require a minimum dose of 10 mg. Current research shows that when a dose of 5 mg of DepoDur is administered, the terminal half-life of the morphine is comparable to a similar 5-mg dose of standard morphine.[88]

Management of Epidural Anesthesia

After epidural administration of local anesthetic, the spread of the dermatomal block will continue and peak in an amount of time dependent on the factors previously mentioned and the local anesthetic solution used. Typically the time to maximal spread is between 10 and 25 minutes, and the level of the block will regress over time; therefore, consistent monitoring of sensory dermatomal level should be performed. When the sensory level of the block has diminished by one or two dermatomes, as detected by the "scratch" or "ice" test used to denote dermatomal level, then another dose, 30% to 50% of the initial dose, is given to reestablish the initial level of anesthesia. It is important to perform consistent monitoring of the anesthetic level because tachyphylaxis, or the need for an increase in the dosage required to maintain an adequate level of blockade, may occur if the regression is allowed beyond two dermatomal segments. The phenomenon of

TABLE 44-6 Recommended Doses of Epidural Opioids

	ANALGESIA				CONTINUOUS INFUSION RATE			
Agent	**Bolus Dose**	**Onset (min)**	**Peak (min)**	**Duration (hours)**	**Range (mL/hr)**	**Basal Rate (mL/hr)**	**PCEA Bolus (mL)**	**Interval (min)**

Sufentanil 0.0001%					10			

tachyphylaxis is poorly understood but is more likely to occur with short-acting amides such as lidocaine or mepivacaine. It can be avoided by using longer-acting agents (e.g., bupivacaine, ropivacaine, and tetracaine) or using a continuous infusion device.

One of the most frustrating problems that can occur with epidural anesthesia is the phenomenon of an inadequate block, a one-sided block or single-sensory dermatome segment that fails to achieve adequate anesthesia. A variety of techniques are used to deal with this phenomenon. Some anesthetists will attempt to increase the spread of the local anesthetic to the area of missed dermatomes by repositioning the patient with the unblocked side down (dependent) or by administering more local anesthetic solution. An inadequate block could be secondary to coiling of the epidural catheter or an anatomic abnormality. However, inadequate anesthesia during epidural anesthesia placement may be secondary to the technique used during identification of the epidural space. Studies have shown that using air during the loss-of-resistance technique may be a contributing factor in missed dermatomal spread of the local anesthetic. Studies by Beilin et al.,[89] Valentine et al.,[90] and Shenouda and Cunningham[91] report that when air was used during a loss-of-resistance technique, a significant number of patients experienced "missed" dermatomal spread of the local anesthetic solution. They recommend using normal saline during catheter placement to minimize this complication.

Rarely an epidural catheter passes through dura but without penetrating the arachnoid membrane. This is sometimes thought of as intradural placement. Spread of the injected anesthetic in this situation can be very unpredictable. Anesthesia can range from a patchy, inadequate block to a rapid and high level of anesthesia requiring ventilatory support, similar to the total-spinal anesthetic complication. Fortunately, intradural catheter placement is rare, and complications can be avoided by the careful use of test doses, maintained vigilance, and a high index of suspicion. If an intradural catheter placement is suspected, the catheter needs to be removed and replaced after resolution of any side effects (e.g., hypotension, bradycardia). Additionally, it is recommended that the catheter be replaced at a dermatomal level more cephalad to the interspace previously attempted.[5,14]

Complications of Epidural Anesthesia

As with spinal anesthesia, the hemodynamic changes seen with epidural anesthesia are attributed to sympathetic blockade and subsequent arterial and venous dilation. Use of plain local anesthetic solutions in the epidural space to create a high level of blockade will decrease the mean arterial pressure, cardiac output, stroke volume, heart rate, and peripheral vascular resistance. The addition of epinephrine (usually a 1:200,000 to 1:400,000 solution) to the epidural local anesthetic solution diminishes and slows systemic uptake, resulting in lower plasma levels of the local anesthetic and prolongation of its duration of action. However, the epinephrine is thought to be absorbed systemically in low levels, thereby causing β_2-adrenergic vasodilation. The result is lower arterial pressure and peripheral resistance when compared with spinal anesthesia. Treatments of these hemodynamic alterations are very similar to those used for effects of spinal anesthesia. They include ephedrine 5 to 10 mg, phenylephrine 50 to 100 mcg, or a low- to moderate-rate infusion of dopamine, keeping in mind the caveats for use of these potent vasopressors. Atropine or glycopyrrolate is also useful for the treatment of bradycardia.[4,8]

One complication that is more prevalent with epidural anesthesia than spinal anesthesia is backache. The incidence of back pain after epidural anesthesia is between 30% and 45%, especially in the obstetric patient.[15] There have been several studies that have identified various techniques to use to decrease the incidence and severity of back pain after epidural anesthesia. For example, Todd et al.[92] analyzed what effect the addition of ketorolac to the dermal anesthesia solution would have on the overall incidence and severity of back pain after laboring epidural placement and delivery. These authors reported that the addition of 6 mg ketorolac to 3 mL 1% lidocaine dermal anesthetic solution resulted in a decrease in the incidence and severity of back pain in the postpartum period as compared with a similar group receiving 1% lidocaine solution alone for dermal anesthesia prior to entry of the epidural needle through the skin.[92]

Other complications associated with epidural catheters are similar to those associated with spinal anesthesia and have already been discussed. As with spinals, the overall risk of PDPH is low. For placement of epidural catheters, the PDPH rate is 1% to 2%. However, epidural needles are large in diameter compared with spinal needles. Although the goal of an epidural catheter technique is to avoid puncture of the dura, an inadvertent rent created by a 17-gauge Tuohy is a rather large dural perforation and is referred to as a "wet tap" for the quite brisk free flow of CSF that can escape through the needle. With such a rent in the dura, the incidence of PDPH can be as high as 75% in young patients. Epidural catheters are also more likely to place a patient at risk for neuraxial anesthesia complications than the single passage of a smaller-gauge spinal needle because the catheter acts as a foreign body that remains within the patient. The catheter causes mechanical tissue disruption, acts as a physical irritant, may provide a path for infection, and will cause tissue trauma on removal—perhaps as much trauma as that associated with catheter placement. Therefore, although complications are rare overall, patients must be followed closely in the postoperative period for signs and symptoms of neurologic compromise such as spine ache, root pain, weakness, and bowel or bladder dysfunction.

COMBINED SPINAL AND EPIDURAL ANESTHESIA

First described in 1937, the combined spinal epidural (CSE) anesthesia technique has risen in popularity and is used successfully for orthopedic, urologic, and gynecologic surgeries and for providing postoperative pain relief. It also has gained favor in the obstetric suite for providing anesthesia and analgesia for labor and delivery and for cesarean section.[93-97]

CSE anesthesia and analgesia offers the advantages of both spinal and epidural techniques while reducing or eliminating the associated disadvantages.[5,53] The CSE technique is appropriately used in any setting in which the practitioner plans a spinal or epidural anesthetic and desires to exploit the advantages of each technique—usually the quicker onset of the spinal anesthetic combined with the flexibility of an epidural catheter.

History and Development

In 1937, Soresi described the sequential injection of local anesthetic, first into the epidural space, then into the subarachnoid space, using the same small-gauge spinal needle. Soresi described placing an epidural needle (without a stylet) into the epidural space using a hanging-drop technique and injecting 7 to 8 mL of procaine, then advancing the needle into the subarachnoid space, where he injected 2 additional mL of procaine. He reported the anesthesia lasted between 24 to 48 hours. His experience using this technique in more than 200 patients led him to state that "by combining the two methods many of the disadvantages of both methods are eliminated and their advantages are enhanced to an almost incredible degree."[98]

In 1979, Curelaru reported application of the CSE technique in 150 patients. He used a two-puncture technique; he placed an epidural catheter first, using a standardized epidural needle, followed by a subarachnoid puncture, using a spinal needle one or two interspaces below the level of the epidural puncture. Advantages of the technique included "the possibility of obtaining a high quality conduction anesthesia, virtually unlimited in time, the ability to extend over several anatomic regions the surgical field, minimal toxicity, the absence of postoperative pulmonary complications, and the economy." Disadvantages included "the need for two vertebral punctures, the longer induction time of anesthesia, and some difficulty in finding the subarachnoid space after catheterization of the epidural space."[99]

Finally, in 1982 Coates[95] used a single-space technique in which a long spinal needle was inserted through the epidural needle to provide the spinal component of the CSE technique.[94] Coates stated that the technique was "simple, reliable and quick to perform." He was, however, concerned that "the theoretical hazards of this technique include the possible passage of the epidural catheter through the hole in the dura mater and the possibility of subarachnoid effects from epidurally injected drugs by passage through the hole in the dura." Eldor[96] described finding metallic particles while using the needle-through-needle technique, supposedly formed by abrasion of the inner surface of the epidural needle by the passage of the spinal needle. They were concerned that these particles might be introduced into the epidural space. In addition, they were concerned that uneven distribution of the spinal local anesthetic was possible. The delay, they theorized, inherent in introducing the epidural catheter after intrathecal administration of local anesthetic could affect the spread of the anesthetic. These concerns led to the development of a combined spinal-epidural needle with two separate conduits to allow the epidural catheter to be placed first, followed by the spinal puncture. Because the needle had two conduits, it allowed both techniques to be performed with one puncture at one interspace. This innovation led to the development of several needle types, each of which sought to improve on the others.

Equipment and Techniques

Two-Level Technique

The two-level technique is unique in that each component is performed separately at two different interspaces. An epidural catheter is inserted first, followed by a spinal anesthesia needle placed one or two interspaces lower. The primary advantage of this technique is the ability to insert and test the epidural catheter first, then place the spinal anesthetic needle. Once the spinal needle is placed, no delay occurs in positioning the patient, which may be an important factor when using a hyperbaric spinal anesthetic solution. Prior placement of the epidural catheter is not entirely benign. Potential problems include the inability to distinguish the epidural test dose from the spinal block, inability to differentiate the epidural test dose from CSF, epidural catheter laceration by the spinal needle, misdirection of the spinal needle by the catheter, inability to obtain CSF because of compression of the dural sac by the test dose, and an increased risk of dural puncture by the epidural catheter.[91] Other disadvantages include increased discomfort, tissue trauma, and morbidity associated with multilevel interspinous space penetration (e.g., backache, epidural venous laceration, hematoma, infection, and technical difficulties).[97]

Single-Level Technique: Needle Through Needle

First described in 1982, the needle-through-needle technique involves insertion of an epidural needle at the appropriate interspace and then using the epidural needle as a guide for the spinal needle.[92,93] A small (25-, 27-, or 29-gauge) pencil-point spinal needle is inserted through the epidural needle into the subarachnoid space, and local anesthetic is injected. The spinal needle is removed, and an epidural catheter is threaded into the epidural space. The epidural needle is removed, and the catheter is secured. The main advantages are related to performance of a single interspace insertion (e.g., less tissue trauma, backache, and associated morbidity). Disadvantages include the possibility of inadequate spinal block if catheter placement is delayed, potential for increased nerve-root trauma if paresthesias occur during catheter insertion, and the inability to reliably test the catheter with a preexisting spinal block. Inability to obtain CSF because of inadequate spinal needle length is a risk avoided by the use of the appropriate specialized needles.

Specialized Needles

Eldor[96] was the first to develop and patent a combined spinal-epidural needle with two channels—one for the epidural catheter, the other for the spinal needle. The needle is placed at the selected interspace, the epidural catheter is inserted through its designated conduit, and then the spinal needle is placed through its conduit. Once CSF is obtained, the chosen local anesthetic is injected, and the needle is removed. The catheter is taped in place, and the patient is positioned. Purported advantages and disadvantages are similar to those described for the single-level technique. Although the risk of metallic particle formation may be reduced, the risk of trauma to the interspinous ligaments is increased because of a larger needle diameter.

Several other needles have been developed, all seeking to minimize or eliminate potential problems.[96] To reduce external size, decrease needle abrasion, and allow for a direct angle of approach to the dura, a Tuohy needle was modified with a separate back-eye at the bend of the needle, thereby permitting straight passage of the spinal needle. These needles are subject to their own limitations and failure rates as well. The spinal needle can miss the back-eye hole and exit the epidural needle through the main orifice, as occurs in the needle-through-needle technique.

Sequential Technique

Rawal et al.[94] described a single-level "sequential" technique that was developed to minimize the hypotensive effects of the spinal component of CSE anesthesia for cesarean section. An epidural needle is placed at the selected interspace, and a low-dose (7.5 mg of hyperbaric bupivacaine) spinal anesthetic is placed using the needle-through-needle technique. The spinal needle is removed, the catheter is inserted and taped in place, and the patient is placed in the supine position with a left lateral tilt. After 15 minutes, the block is extended by titrating epidural local anesthetic until the desired level is achieved (1.5 to 2 mL for each unblocked segment). Although this technique takes longer to perform, it has been shown to decrease the frequency and severity of the hypotension seen with spinal anesthesia. This technique has also been applied in other types of surgery.

Agents

As discussed previously, local anesthetic agents and their concentration are chosen depending on the effects desired. Appropriate anesthetics for the spinal component include isobaric or hyperbaric 5% lidocaine with or without epinephrine, hyperbaric 0.75% (spinal) bupivacaine, and isobaric or hyperbaric 1% tetracaine. Appropriate anesthetics for the epidural component include 2% lidocaine with or without epinephrine, 0.5% or 0.75%

bupivacaine, 2% or 3% 2-chloroprocaine, and 1% ropivacaine. The concentration of these agents may be adjusted to provide postoperative analgesia in combination with opioids such as morphine and fentanyl. All agents should be preservative free to reduce or eliminate any neurotoxic effects.

Management of CSE Anesthesia

Although the CSE technique may be used in any type of surgical procedure in which a spinal or epidural would be acceptable, this technique may be particularly well suited to providing analgesia and anesthesia in obstetric patients. The CSE technique offers several potential advantages over conventional epidural anesthesia and analgesia.[93]

- Rapid onset of the intrathecal component for women who are in the later stages of labor and in significant pain and distress
- The use of intrathecal opioids (e.g., fentanyl, sufentanil, morphine, and meperidine) in early labor; the minimal-to-absent motor block associated with intrathecal opioids allows the patient to ambulate while in labor

The CSE technique for the laboring patient usually involves the placement of an epidural needle at the selected (usually lumbar) interspace, followed by the placement of the spinal needle using the needle-through-needle technique. Intrathecal opioids (5 to 15 mcg of sufentanil or 25 to 50 mcg of fentanyl) may be given alone or in combination with a small dose (2.5 mg of bupivacaine) of local anesthetic, saline, or both. The spinal needle is withdrawn, and the epidural catheter is inserted. The epidural needle is removed, and the catheter is taped in place. The catheter can be activated at any time if supplemental analgesia or anesthesia is required. Standard testing of the epidural catheter before use is always recommended.

The CSE technique also can be used to provide anesthesia for cesarean section if required. If the patient already has an epidural catheter in place, a test dose (3 mL 1.5% lidocaine with 1:200,000 epinephrine) is given to rule out intrathecal and intravascular placement. After a negative test dose, incremental administration of 2% lidocaine, 0.5% bupivacaine, or 3% 2-chloroprocaine can be used to establish a level of surgical anesthesia.

If a catheter has yet to be placed, and if time allows, the anesthetist can proceed as with any new patient. After the spinal needle is placed, an intrathecal dose of local anesthetic (12 to 15 mg of 0.75% bupivacaine) with or without opioid (10 to 15 mcg of fentanyl, 0.2 to 0.3 mg of preservative-free morphine, or both) is given. The catheter is inserted and taped in place. The spinal anesthetic will set up quickly and allow for urgent (but maybe not emergent) delivery.

Despite the utility and flexibility of the CSE technique, several concerns related to its use exist. The first of these concerns is related to the use of intrathecal sufentanil and its associated hypotension.[100] Controversy exists with regard to whether intrathecal sufentanil causes clinically significant changes in blood pressure and fetal heart rate (fetal bradycardia). Purported mechanisms include pain relief, mild sympatholysis, and uterine hypertonus.[101-103] Studies show no differences in outcome between CSE using intrathecal sufentanil and epidural anesthesia.[104,105]

A second concern with CSE analgesia is the ability to ambulate after receiving intrathecal narcotics. The concern is related to possible motor weakness if low-dose local anesthetic is added and regarding the effects on blood pressure.[106] Hypotension appears within the first 30 minutes after intrathecal fentanyl but remains stable through ambulation and follow-up doses of epidural local anesthetic. Studies demonstrate the safety of allowing ambulation with no apparent deleterious effects.[107]

A third concern with CSE technique in laboring patients is related to complications. Overall, the complications of itching and hypotension, although bothersome, do not appear to significantly affect outcome or patient satisfaction.[89] CSE anesthesia is associated with faster onset, denser motor block, lower anxiety, lower preoperative and intraoperative pain scores, and greater patient satisfaction preoperatively. There were no significant differences in the incidence or severity of hypotension or nausea, the need for supplemental analgesics, or the postoperative assessments of intraoperative pain, anxiety, and satisfaction.[108,109]

Complications of CSE Anesthesia

Spinal and epidural anesthesia both have their own associated complications as discussed. The CSE technique has the same complications and some additional unique complications. Therefore, as always, vigilance is prudent.

Failure to Obtain a Subarachnoid Block

The failure rate for subarachnoid block alone ranges from 3.1% to 17%. With the single-level CSE technique for anesthesia, the range is 0% to 24.5%, and for the two-level technique, the range is 1.6% to 4%.[110-112] Failure with the single-level CSE technique may occur because the epidural needle is not in the epidural space, because the epidural needle is off midline, because the spinal needle is too short (or dull) and does not penetrate the dura, or because the angle of approach of the spinal needle is too oblique to puncture the dura.

One of the most important considerations is the length of the spinal needle—specifically, the length of needle that extends beyond the tip of the epidural needle.[97] Studies have shown an increased success rate when the tip of the spinal needle extends 7 to 15 mm beyond the tip of the epidural needle.[112,113] The angle at which the spinal needle approaches the dura also may be important. As the spinal needle exits a standard epidural needle tip, the angle caused by the epidural needle's curve may be 4 to 5 degrees or more.[114] This factor, combined with inadequate needle length, may result in failure to obtain CSF. This situation has led to the development of a modified Tuohy needle that has a separate backeye at the bend of the needle to allow for a straight-on approach to the dura. Pan[115] determined that the success rate for the needles exiting the correct hole ranged from 50% to 67%. The success rate can be improved to 81% to 94% by bending the spinal needle slightly in the direction of the epidural needle bevel and to 91% to 96% by orientating the epidural needle bevel upward.

Failure rates also may be directly related to level of experience with the technique and are not easily correctable. The problem of spinal needle displacement during connection of the syringe, aspiration, or injection of the local anesthetic has led to the development of "locking" devices that fix the spinal needle in the epidural needle once the dura has been punctured. Their efficacy has not yet been confirmed.

Catheter Migration

Another problem with the needle-through-needle technique is the possibility of catheter migration through the dural puncture caused by the introduction of the spinal needle.[114] Studies that assessed the risk of catheter migration through a dural puncture site demonstrated little to no risk if the dural puncture was made with a 25-gauge or smaller spinal needle, but an increased risk if the dural puncture was made by a larger (18-gauge) Tuohy needle.[116-118] Many factors may result in catheter placement in, or migration into, the subarachnoid space, including patient movement, undetected dural puncture with the epidural needle with

subsequent catheter placement, and (least likely) diffusion of local anesthetic from the epidural space into the subarachnoid space through the dural puncture. The prudent practitioner is advised to adopt a conservative approach that includes a high index of suspicion and frequent aspiration and testing of the catheter.

However, even the question of when to test the epidural catheter can be problematic. The purpose of the epidural catheter test dose is to rule out inadvertent placement or migration of the catheter into the subarachnoid space or into an epidural vein. A preestablished subarachnoid block may preclude the ability to reliably test for subarachnoid catheter placement and mask intravascular placement. To date, no published studies have demonstrated reliable detection of inadvertent subarachnoid catheter placement in someone with a preexisting spinal block.

Increased Spinal Level After Epidural Administration

The CSE technique is known to cause an increased spread of spinal anesthesia after injection of solutions through the epidural catheter. Although controversial, several theories may help explain this phenomenon. The first, the "volume effect" theory, states that the volume of fluid injected into the epidural space compresses the subarachnoid space and the CSF within it, thereby increasing the spread of the intrathecal local anesthetic. This effect has been documented clinically and by the use of contrast media and radiography. The second theory presupposes a "leak" or flow of local anesthetic from the epidural into the subarachnoid space through the dural puncture. This effect also has been demonstrated clinically and by radiography.[119,120] Other radiographic studies have been unable to confirm these results.[118,121]

Metallic Particles

Eldor and Levine[110] noted the production of metallic particles when passing a spinal needle through a Tuohy epidural needle. Subsequently, Eldor[122,123] has implied that scratches in the spinal needle and metallic particles may be associated with an increase in aseptic meningitis and cancer in patients who have received CSE anesthesia via the needle-through-needle technique. No studies have been published to support these assertions, but several studies have examined the issue of metallic particle formation.[124] These studies used electron microscopy, atomic absorption spectrography, photomicrography, and microscopy; none were able to detect metallic particle formation.[118,125]

Postdural Puncture Headache

Conflicting evidence exists regarding whether a greater risk of PDPH is associated with the CSE technique compared with conventional epidural anesthesia and analgesia. Both techniques involve the placement of an epidural needle, with its attendant risk of dural puncture. In addition, the CSE technique involves a dural puncture, usually with a small-gauge, pencil-point spinal needle. Because this type of spinal needle is associated with an extremely low incidence of PDPH, one would expect an equally low incidence with the CSE technique. A review of the literature on the CSE technique shows a PDPH rate between 0% and 2.3% in laboring patients.[126] Theoretic reasons for a low incidence with the CSE technique include the following:

- The epidural needle serves as an introducer for the smaller-gauge spinal needles and allows for a straight approach at the dura.
- CSF leakage through the dural puncture is abated because of the presence of the epidural catheter and fluids, which increases pressure in the epidural space.
- The spinal needle penetrates the dura at a slight angle, which may help dural fibers seal the hole on withdrawal.

Studies suggest that the use of intrathecal opioids as part of the CSE technique may offer a protective effect from PDPH.[127,128] In addition, the success rate in obtaining CSF may be higher when the patient is in the sitting position, rather than the lateral position. The sitting position allows for correct midline placement of the epidural needle and makes it more likely that CSF will be obtained with the spinal needle (higher hydrostatic pressure). Both of these factors contribute to minimization of the number of dural punctures and may decrease the risk of PDPH.

Infection

The incidence of infectious complications associated with epidural and spinal anesthesia has always been considered to be very low—in the range of 0% to 0.04%.[30,129,130] However, perhaps because of close monitoring of this newer technique, an increase has occurred in the number of case reports of patients who have developed complications that may be associated with the use of the CSE technique. Bouhemad et al.[131] cite several cases (three between 1994 and 1998) of bacterial meningitis associated with the use of CSE. The authors believed that potentially infectious skin matter was first introduced into the epidural space during the insertion of the epidural needle and was then introduced into the CSF by the passage of the spinal needle into the subarachnoid space. Because the CSE technique requires invasion of both the epidural and subarachnoid spaces, strict aseptic technique should be practiced. As with other complications associated with the use of CSE, further study of this area is warranted.

Neurologic Injury

Neurologic injury associated with spinal and epidural anesthesia is also very low, ranging from 0.02% to 0.1%, and is usually transient in nature.[5] Although there does not appear to be any increased risk inherent in the CSE technique as compared with either spinal or epidural anesthesia alone, there have been several case reports of cauda equina syndrome in patients who underwent CSE anesthesia.[132,133] In none of these cases was the cause ever identified. Possible causes include preexisting spinal deformity (present in one case), use of lidocaine (present in one case), and an intrathecal catheter (never proved or disproved).

A final concern with the use of the CSE technique is paresthesia on epidural catheter insertion. A preexisting spinal block may mask a significant paresthesia on catheter insertion and result in neurologic injury. Paresthesias during epidural catheter placement range in frequency from 20% to 44%.[134] However, studies show no significant difference in the frequency of paresthesias reported for either technique.[112,134]

CAUDAL ANESTHESIA

Caudal anesthesia can be thought of as a distal approach to the epidural space. Therefore, anesthetics administered or catheters placed via the caudal route will act as epidural administered anesthetics, but first on the sacral dermatomes. A caudal technique is useful for perirectal surgery, urologic surgery, and orthopedic surgery of the lower extremity. Caudal techniques are especially useful in pediatrics but also can be used for labor and delivery and for chronic pain states. With the success of lumbar epidural catheters for labor and delivery, caudal anesthesia is rarely used in this population currently and is less likely to be used in the adult population in general. After the age of 12, sacral anatomy changes and bone growth makes identification of the epidural space by this approach

difficult and the spread of anesthesia less reliable.[8] Therefore, caudal anesthesia is most often used in combination with a light general anesthetic to augment postoperative analgesia in preadolescent pediatric patients.

Equipment and Techniques

The patient can be placed either prone or in a lateral position. The posterior iliac spines and the sacral hiatus are identified. Positioning the patient prone with the legs slightly apart, the heels rotated outward, and a pillow under the buttocks facilitates the palpation of the cornua of the sacral hiatus. In the lateral, Sims, or knee-chest position, identification of the cornua can be enhanced by adjusting the amount of hip flexion. Excess flexion can stretch the skin, making landmark identification difficult. An assistant is often useful when one is positioning patients who are anesthetized.

In pediatric patients, general anesthesia is usually induced, the airway and intravenous access secured, and the patient turned prone or placed in a lateral decubitus position. After aseptic preparation is performed, the index and second fingers of one hand are placed on the cornua of the sacrum, with the hand cephalad and against the patient's back. A 22- to 25-gauge short needle attached to a 10-mL syringe filled with local anesthetic is inserted midline between the cornua at a steep angle to the skin into the sacral hiatus. Alternatively, a 20-gauge over-the-needle intravenous catheter is sufficiently long enough for the block, and the catheter can be passed into the epidural space while the needle is removed. This allows the anesthetist better control when administering the local anesthetic. The needle is inserted, with the bevel of the needle directed toward the sacrum. As the membranes are penetrated and the ventral canal of the sacrum is entered, a popping sensation can be felt. At this point the needle angle is lowered parallel to the sacrum and the spinal canal. The needle is advanced into the epidural space for a distance of 1 to 3 cm but no farther than the second sacral interspace. The second sacral interspace lies 1 to 2 cm below a line drawn between the posterior iliac spines. The needle position is evaluated for entrance into the subarachnoid space or epidural veins via gentle aspiration and examination for CSF or blood return through the needle. Once the appropriate location of the needle is verified, the anesthetic is incrementally injected as with an epidural. During injection the skin area above the end of the needle is palpated. Bulging over the needle tip indicates subcutaneous or superficial injection rather than injection into the epidural space. If the needle is in the subperiosteal area, resistance to injection is felt, and the needle must be repositioned.

Agents

In children, 0.5 to 1 mL of solution per kilogram of body weight is injected to reliably achieve a level of analgesia to the umbilicus. Bupivacaine or ropivacaine, in concentrations of 0.125% to 0.5%, are usually administered with epinephrine 1:200,000, to a maximum dose of 2.5 mg/kg body weight. These dosing regimens have been shown effective for children undergoing subumbilical surgical procedures providing analgesia or anesthesia for the lower extremities and the abdomen, urogenital surgery, inguinal hernia repair, or orthopedic procedures with analgesia that lasts 3 to 5 hours postoperatively.[8,135,136] Clonidine 1 mcg/kg of body weight added to the local anesthetic has been shown to be comparable with opioids that are added to enhance analgesia. Clonidine has fewer side effects than caudal opioids (e.g., delayed recovery, respiratory depression, and nausea).[137] Some patients may be unable to tolerate the loss of lower-extremity motor control. These patients should be identified before the anesthetic is administered and be offered another technique. For example, infants too young to walk greatly benefit from caudal analgesia, but toddlers may be frightened by their inability to move their legs. Ropivacaine may have benefits over bupivacaine, because analgesia in the postoperative period is equivalent, but ropivacaine offers shorter duration of motor blockade and less risk of CNS and cardiotoxicity.[8,135-138]

In adults, the principles of epidural drug administration should be followed, with use of a 3-mL test dose and incremental injections and aspiration. Only 12 to 15 mL is necessary for sacral anesthesia, and up to 20 to 30 mL offers sufficient spread for lower-extremity procedures to approximately the 10th thoracic dermatome. The spread of drug, duration of anesthesia, and desired level of anesthesia are less predictable than with epidural anesthesia because of the variability in the volume, content, and leakage of the caudal canal. The maximum recommended dose of lidocaine or mepivacaine is 10 mg/kg of body weight and 2.5 mg/kg of body weight for bupivacaine.[8] All agents injected into the epidural or subarachnoid spaces should be preservative free.

Management of Caudal Anesthesia

Caudal anesthesia, like epidural anesthesia, is adaptable to a continuous catheter technique. However, if a Tuohy needle is used, the angle of the tip must be kept in mind when one attempts to pass the catheter into the epidural space. Management is similar to that with an epidural catheter.

Complications of Caudal Anesthesia

Caudal anesthesia has complications that are very similar to those of epidural anesthesia. The caudal canal has a sacral epidural venous plexus with vessels that can be unintentional recipients of a needle or catheter tip, with subsequent intravenous injection of local anesthetic. Dural puncture is also possible, although the dural sac usually ends in adults at the lower border of L2, and in infants the sac can extend to S4. High spinal punctures are less likely but have been reported. In addition, the anatomy of caudal anesthesia is variable enough, especially in adults, to cause a high (10% to 15%) failure rate as the needle is unintentionally inserted into false passages. The proximity of the caudal canal to the rectum theoretically makes infection a potential risk, although clinically significant infection is rarely reported.[8,139] The risk of infections, perhaps, will best be shown to be minimized with the use of chlorhexidine solutions instead of povidone-iodine solutions.[140]

In 1899, Alice Magaw described the job of an anesthetist and best summarized the reality of the practice of regional anesthesia. She stated, "While one should be competent in the theoretical part of this important work, there is nothing so helpful to the anesthetist as the hard school of practical experience."[141]

SUMMARY

Regional anesthesia techniques are a vital part of modern anesthesia practice. Our ability to understand and apply neuraxial anesthesia continues to evolve. These techniques are increasingly being used for all types of anesthetics, including many outpatient procedures. Their utility in providing for perioperative pain management has greatly enhanced our ability to provide comfort to our patients.

CHAPTER 45

Regional Anesthesia

Upper and Lower Extremity Blocks

◆ *Charles A. Vacchiano and Andrew Biegner*

The advantages of regional anesthesia techniques as opposed to general anesthesia are numerous and include reduction in nausea and vomiting, decreased urinary retention, reduction in the surgical stress response, fewer recovery room admissions, earlier patient discharge, reduction in blood loss, better communication with and easier positioning of the patient, avoidance of airway compromise and cervical manipulation, reduced environmental exposure to anesthetic gases, and improved postoperative analgesia.[1-4]

The use of long-acting local anesthetics, the introduction of peripheral nerve stimulators, ultrasonography, and the placement of peripheral nerve catheters have significantly altered the landscape with respect to the practice of regional anesthesia and pain management. The best strategy for achieving maximum successful conduction block may be to use a combination of these advances. Although the type of complications associated with peripheral nerve block as compared with general anesthesia are different, the frequency and severity of the complications are likely similar.[2]

SELECTION OF REGIONAL ANESTHESIA TECHNIQUES

When regional anesthesia is chosen for management of pain, the technique should be thoroughly discussed with the patient beforehand. The patient is informed of all optional procedures available, their potential risks, and their potential complications before an anesthesia technique is selected. Once this conversation takes place, the most appropriate anesthesia technique can be selected, and true informed consent can be obtained. Regional anesthesia is used extensively for surgical procedures involving the extremities or the lower abdomen, for the management of labor pain, for the management of obstetric procedures, and for the control of chronic pain syndromes. Frequently, regional anesthesia techniques are used in combination with other techniques to provide analgesia or anesthesia during surgical or obstetric procedures. Regional anesthesia may be the technique of choice when local anesthesia requires supplementation with heavy sedation. These techniques provide the patient with additional anesthesia options when selecting an anesthetic for surgical or obstetric procedures. It is the preferred technique for obstetrics and many other types of procedures.[5-10]

The administration of regional anesthesia to patients with a difficult airway or a full stomach presents both additional benefits and potential risks. The use of regional anesthesia, when appropriate, permits the patient to retain upper airway and pharyngeal reflexes while providing surgical anesthesia. Unless the sedation is reduced to a minimum, the airway may not be protected after the administration of the regional technique. Furthermore, block of the sympathetic nervous system theoretically results in increased gastric and intestinal motility, causing the stomach to empty sooner. However, this benefit may be negated by the perception of pain and anxiety that accompanies injury. If hypotension develops, the patient may have increased nausea and vomiting. When the block is instituted, the patient may lose consciousness as a result of the effects of alcohol if the patient is intoxicated at the time of treatment. At this point, airway support is required, and other problems may arise as well. Regional anesthesia should not be considered an alternative to securing the airway. If the patient's airway cannot be secured in a safe manner in an emergent situation, use of a regional anesthetic should be avoided. The airway concerns must be addressed before the anesthetic technique is initiated so that the patient's safety is maximized.[11]

Absolute Contraindications

Contraindications to the selection of regional anesthesia techniques are few, and some remain controversial. Absolute contraindications include patient refusal, uncorrected coagulation deficiencies, and infection at the site of the block. The most significant absolute contraindication to regional anesthesia is patient refusal. Each patient must be informed of the acceptable techniques that will provide analgesia or anesthesia, as well as significant risks and potential benefits. The discussion must include the advantages and disadvantages of each proposed technique. The patient's questions should be answered completely. This level of communication helps the practitioner uncover misconceptions while educating the patient about regional anesthesia.[12]

Another absolute contraindication is systemic anticoagulation in the patient. Certain drugs and systemic diseases can cause alterations in the coagulation profile. The long-term or extended use of aspirin products or nonsteroidal antiinflammatory drugs (NSAIDs) can prolong bleeding time without significantly altering other laboratory data. The patient's medical and pharmacologic history may provide information about increased bleeding time. Asking the patient about frequent bruising without injury may reveal the first indication of a problem. For instance, physical evaluation of the skin may show evidence of bruising or subcutaneous bleeding of which the patient may not recall the cause. If injury to a large epidural vessel were to occur during the performance of either a spinal or an epidural technique, significant bleeding could develop in the epidural space. A similar injury to the axillary artery in the confined space of the axilla might result in a hematoma that would produce further complications. Injury to a large vessel in the neck during an interscalene technique could result in compromise of the airway. Guidelines for the use of regional techniques in a patient receiving anticoagulation therapy are given in Chapter 44.

Severe bleeding with or without symptomatic hypovolemia or the potential for severe bleeding is a contraindication to the administration of a regional anesthetic. The contraindication can be considered either absolute or relative, depending on the clinical presentation of the patient. Trauma, along with physiologic or pathophysiologic conditions that cause contracted volume states and abruptio placentae, can result in the development

of significant hypotension and tachycardia after the initiation of regional anesthesia, especially spinal or epidural anesthesia. A blockade of the sympathetic nervous system quickly develops, resulting in significant relaxation of the smooth muscles of the vascular bed. When the patient demonstrates symptoms of hypovolemic shock on evaluation, his or her ability to safely tolerate peripheral vasodilation and the subsequent reduction in systemic vascular resistance is reduced. The patient's ability to compensate for falling blood pressure by increasing systemic vascular resistance places the patient at risk for potential hypoperfusion to vital organs and subsequent hypoxic tissue injury.[13]

When an obstetric patient experiences abruptio placentae with or without fetal distress, the anesthesia practitioner must consider other anesthetic procedures. These alternatives should be considered so that hypotension and the compromise to fetal oxygen supply that results from decreased uterine blood flow can be minimized. Regional techniques require time to administer in addition to the reduction in blood pressure that occurs with establishment of the block. Uterine blood flow is dependent on arterial pressure and has few autoregulatory capabilities. However, when an epidural anesthetic has been established for labor, the time required for surgical anesthesia to be instituted may be less with epidural than with general anesthesia. The choice of anesthesia technique must focus on the possible effects of the sympathectomy, even if its development can be slowed or controlled. With the onset of the sympathetic blockade, the fall in blood pressure may be more than the mother and baby can tolerate. The anesthesia practitioner caring for the patient, in consultation with the patient's obstetrician, must decide whether administration of the regional anesthetic should be continued or whether another anesthesia procedure should be selected.[14] Finally, if an active infectious process is present near the location at which regional anesthesia is to be performed, another anesthetic should be chosen.

Relative Contraindications and Precautions

One relative contraindication to regional anesthesia is patient age. In neonates with impairment in ventilatory regulation, regional anesthesia techniques are recommended when either surgery or pain management is required.[15,16] Small children tolerate the administration of a combination anesthetic for many surgical procedures, including hernia procedures, extremity procedures, and circumcision. A general anesthetic can be administered for the surgical procedure, and a regional technique can be used for postoperative pain management. Anatomic landmarks are easily identified in children, which permits implementation without extensive difficulty. Precautions must be taken when the patient is of short stature. This technique should be avoided in children who are unable to tolerate the loss of feeling and strength in the legs. As children begin to acquire independence through increased ambulation, the loss of feeling and movement in the legs may increase their fear. This phenomenon is especially common in children between the ages of 3 and 9 years.[17,18]

Interscalene and axillary blocks have been used to permit immobilization and analgesia of the upper extremity for extended periods of time. Intravenous regional anesthesia (Bier block) has been used in small children aged 8 to 12 years; in these cases a reduced amount of local anesthetic medication is used for the reduction of an arm fracture.[17]

Patients who have difficulty understanding the procedures to be performed or who are unable to cooperate with the practitioner should undergo another type of anesthesia. Such patients may respond negatively to the presence of anyone behind them who may create confusion or cause discomfort; they could perceive this presence as an imminent threat and could respond inappropriately.

Patients with a history of headaches or backaches are at increased risk for experiencing these problems after spinal and epidural analgesia or anesthesia. Such patients should be evaluated and counseled regarding this potential before the administration of subarachnoid or epidural anesthesia. Postanesthesia symptoms of backache or headache become difficult to evaluate without information about the patient's previous pattern of headaches or backaches. Information about the position of the patient during the surgical or obstetric procedure assists in the evaluation of the patient.

Patients with chronic neurologic disorders must be well informed of the potential effects of the regional anesthetic technique. The regional anesthetic may not cause an increase in the patient's symptoms; however, if symptoms of the disorder increase or deterioration results, the regional anesthetic technique may be identified as the cause of the problem.[19,20]

Patients with a history of a documented local anesthetic allergy should undergo further evaluation in a controlled situation by an allergist. A true allergy to local anesthetic agents is rare. The problem may be caused by a preservative in the anesthetic solution or by a metabolic product of local anesthetic hydrolysis (para-aminobenzoic acid [PABA]). Skin testing is helpful but not always practical. Alleged allergic reactions may be related to an intravenous injection of a local anesthetic solution that contains epinephrine. If a regional technique is used in a patient with an allergy, a local anesthetic that is unrelated to the suspected agent should be selected. For example, if the patient is allergic to an ester anesthetic, an amide anesthetic agent should be chosen. Before the anesthetic is administered, the patient should be medicated with histamine-1 and histamine-2 receptor blockers.[21-23]

Patients with fixed-volume cardiac states are at risk for cardiovascular compromise after the initiation of a regional anesthetic. If the patient is unable to respond to changes in systemic vascular resistance by increasing stroke volume as a means of maintaining cardiac output, selected regional anesthesia techniques, including spinal and epidural anesthesia, should be reconsidered. As the heart rate increases to compensate for the falling pressure, the heart may fail, or ischemia may develop. Absolute and relative contraindications to regional block are noted in Box 45-1.

BOX 45-1

Absolute and Relative Contraindications to Regional Block

Absolute Contraindications

- Patient refusal
- Infection at injection site
- Coagulopathy or other bleeding diathesis
- Severe hypovolemia
- Severe aortic or mitral valve stenosis
- Increased intracranial pressure

Relative Contraindications

- Uncooperative patient/psychiatric disease
- Septicemia/bacteremia
- Preexisting neurologic disease
- Chronic headache or backache
- Stenotic valvular disease
- Severe spinal deformity

COMPLICATIONS OF REGIONAL ANESTHESIA

Complications of regional anesthesia can be immediate or delayed. Cardiovascular problems are the most critical immediate complications. However, effects on the respiratory and gastrointestinal (GI) systems can have equally serious consequences. Delayed complications include problems involving the cardiovascular, musculoskeletal, genitourinary, and neurologic systems.

Immediate Complications

The potential of an intravascular injection is increased when local anesthetics are injected into the tissues around nerves and blood vessels. It is especially important to be prepared for a local anesthetic systemic toxicity (LAST) reaction when performing peripheral blocks because high volumes are frequently injected into vascular areas. A complete discussion of the management of LAST is given in Chapter 10. A functional intravenous line and all of the necessary equipment and drugs must be immediately available prior to administration of any regional block.

Delayed Complications

The anesthesia practitioner must be prepared to manage complications that occur after the block has been established or during the postanesthesia recovery period. The choice of needle type may play a role in peripheral nerve injury when the injury is caused by intraneural injection. Nerve fascicles move away from the needle tip, especially when using a short-beveled needle. The use of a long-beveled needle, which tended to impale the nerve, resulted in a greater number of injuries, especially if the needle tip was oriented transversely to the nerve fibers. Patients with preexisting nerve pathology, such as diabetic neuropathy, are at increased risk for prolongation of the block and local anesthetic neurotoxicity. The absence of a motor response to a peripheral nerve stimulator does not exclude the possibility of intraneural needle placement, and seeking nerve stimulator confirmation of apparent intraneural needle position noted on ultrasound can lead to unnecessary trauma to the nerve. Local inflammation is an infrequent occurrence with the use of a peripheral nerve catheter technique; however, bacterial colonization rates of the catheter are high. Even so, the incidence of local infection, abscess formation, and sepsis is rare. The use of aseptic technique and chlorhexidine, which is considered to be the best skin disinfectant currently available, is recommended.[23,24]

Complications Associated with Continuous Peripheral Nerve Blocks

Continuous peripheral nerve blocks (CPNBs) have been shown to improve postoperative pain control and hemodynamic stability, reduce opioid requirements, and decrease nausea and vomiting. There are few studies evaluating the adverse effects and complications of this technique. Permanent neurologic complications are rare after peripheral blocks, but transient neuropathies occur in approximately 3% of patients.[25] Wiegel et al.[26] analyzed 1398 CPNBs performed in 849 orthopedic patients. The CPNBs included interscalene, femoral, sciatic, and a combination of femoral and sciatic blocks performed preoperatively in addition to general or spinal anesthesia. The standard technique included use of a nerve stimulator, injection of a bolus of local anesthetic, placement of the catheter, application of a transparent dressing, a single dose of antibiotic prophylaxis, and infusion of 0.2% ropivacaine at 5 to 8 mL per hour commencing in the postanesthesia care unit for a period of 24 hours. Following this period, bolus doses of 0.2% ropivacaine (10 to 20 mL) were administered every 6 hours on an orthopedic ward.

Patients were questioned about complications during their 3-month postoperative visit. The primary study end-point was the rate of complications, including nerve injury, bleeding requiring surgical intervention, catheter-associated infection, dyspnea, pneumothorax, and local anesthetic toxicity. A unique feature of this study was the extended period of time catheters remained in situ—up to 12 days in some cases. Local inflammation at the catheter insertion site occurred in 9 patients (0.6%), and local infection occurred in 3 patients (0.2%)—all femoral CPNBs. There were 12 patients with transient neurologic deficits (0.9%), and 1 with a permanent neurologic deficit (0.1%). Vascular puncture occurred at a rate of 5.2%, and a catheter was broken in one patient as a result of withdrawing the catheter back into the needle, a practice that should always be avoided. The authors found that while major complications of CPNBs are rare, minor adverse events are not uncommon.[26] A number of potential risks and complications of continuous peripheral nerve block are discussed throughout this chapter, including inaccurate catheter placement, dislodgement or migration, vascular puncture and hematoma, delayed local anesthetic toxicity, nerve injury, infection, pulmonary complications associated with phrenic nerve block, and catheter knotting, retention, or shearing.

Technical Difficulties

Technical problems include difficulties with equipment and supplies. Broken needles, broken catheters, microscopic glass in the epidural and subarachnoid spaces, and injection of the wrong drugs are some of the problems that can be encountered.

Disposable needles are made in two parts: the hub and the barrel. The two parts are joined together and then fused to create a single unit. The weakest point on the needle is at the joint with the hub. Precautions should be taken so that the needle is not inserted so far that the hub abuts the skin surface. In addition, the needle should not be bent. If extreme force is used while the needle is being inserted, the needle is stressed at the hub; this stress could cause the needle to break at the hub. If the needle is not inserted with the hub abutting the skin surface, some portion of the needle can be secured and removed, thus preventing its loss.[10,27,28]

Broken or sheared catheters are a concern in continuous regional anesthesia techniques. A visual inspection of the catheter should occur before it is inserted. The portion of the catheter that is inserted should have a radiopaque marker on the tip. Markings are placed at 1-cm divisions along the catheter, thereby providing an approximate measure for estimations of the length of the catheter that is inserted into the epidural or intrathecal space. When removed, the catheter should be inspected and its intactness verified and recorded on the patient's record. An epidural catheter should not be pulled back through the needle once the tip has passed beyond the bevel opening. The point where the two sides of the bevel join is the sharpest point of the entire needle. As the catheter is pulled back, it is forced against the joint and may be sheared off.

If the catheter is sheared off, radiography can be used to locate the catheter, verify its position, and document the shearing. Catheters in use today have a radiopaque tip and are made of a material of low tissue reactivity. Surgical procedures used in the search for a catheter can delay a patient's recovery. The patient should be told of the problem, where the catheter is located, the composition of the catheter, and any other information that might help reduce concerns about the catheter's location. Most catheters can remain in place without causing problems. However, when the remaining catheter is located in the subarachnoid

space, it must be retrieved. The potential exists for the catheter to migrate cephalad, causing further problems once it reaches the level of the spinal cord or is directed through a foramen into a nerve root.[20]

Glass from broken ampules can be injected into the subarachnoid or epidural space or in the area of the nerve if care is not exercised during preparation of the medication. Ampules should be broken away from the tray and enclosed within a sponge that is then discarded. A filter needle should be used during the withdrawal of all medications from ampules. The filter needle should then be discarded to prevent injection of the particles that have been filtered. The glass particles may act as a foreign body, causing a local reaction and the development of a sterile abscess.

Discharge Information

A useful tool to provide patients who have received a regional anesthetic is a discharge information sheet (Box 45-2). This sheet provides the patient with information about the nature of the anesthetic and what to expect as the block resolves. Most importantly, it should alert the patient to contact the anesthesia provider in the event certain symptoms, which may indicate a potential complication of the regional anesthetic, occur after discharge.

BOX **45-2**

Regional Anesthesia Discharge Information Sheet

What is regional anesthesia?
Regional anesthesia is the injection of a local anesthetic (such as Novocaine) near the nerves that sense pain from the area of your body that had surgery. Regional anesthesia is the same as a dentist injecting local anesthesia into your mouth—it numbs an area of your body so that procedures won't hurt.

What should I expect after regional anesthesia?
After regional anesthesia, the area of your body that had surgery will be numb for several hours. In fact, the area may be numb for up to 24 hours. The block will wear off slowly, and your first sensations will be a tingling feeling in the area that was numb.

What should I do when the block starts to wear off?
As soon as you develop any feeling in the numb area, begin taking the pain medications your surgeon has prescribed. It is much easier to treat pain before it begins than try to catch up later.

What should I be careful about after regional anesthesia?
Because part of your body is numb, you won't know if you injure it. You should take care to protect that part of your body from being bumped, cut, and otherwise harmed, and you should look at it frequently to make sure it isn't injured. You should also avoid lying on the numb area while you sleep.

What complications should I watch for after regional anesthesia?
The site of your body where the injection was made will be sore for a few days. This pain should go away with any over-the-counter pain-relief medicine (e.g., Tylenol, Advil, Motrin). It is not uncommon for the area that was numb to have some strange sensations (e.g., mild numbness, tingling) for a few days after the block.

If you experience any of the following changes, you should immediately phone your health care provider:

- Sensation doesn't begin to return to the numb area after 24 hours.
- The area that was numb regained sensation but is becoming numb again.
- The skin in the numb area turns blue or feels cool.
- There is persistent pain in the area that was numb, even several days after the surgery.

ELECTRICAL STIMULATORS IN REGIONAL ANESTHESIA

Peripheral nerve stimulators are a valuable tool in the practice of regional anesthesia. Although ultrasound-guided blocks are becoming more common, nerve stimulator techniques may be used for select blocks or as an adjunct to an ultrasound technique. Often listed among the benefits of the use of a peripheral nerve stimulator are a reduction in the volume and dose of local anesthetic required to produce a block, increased success rate, and the ability to block nerves that are difficult to locate.

Electrical translocation devices provide a controlled stimulating pulse of variable amplitude that is administered through a conducting device. Location of neural fibers is improved without the need for eliciting repeated paresthesias. Specialized shielded needles have been designed to localize the distribution of the stimulating charge to the tip of the needle. This characteristic reduces confusion from wide-field stimulation of the area around the nerve, thereby enhancing the isolation of the appropriate nerve fibers.

The needle must be advanced slowly, and the amplitude of the unit must be adjusted as the needle approaches the nerve. The negative lead is attached to the skin with an electrocardiogram electrode, and the positive lead is attached to the needle. The electrical device must be equipped with an accurately adjustable amplitude from 0 to 5 mÅ with a digital readout of the amplitude.

When this technique is used, the stimulator should not be turned on until the needle has entered the skin. This measure reduces the discomfort experienced by the patient during the initial advancement of the needle. The patient must be instructed to identify discomfort verbally and to not move during the advancement of the needle.[29] Limiting the sedation helps the patient tolerate the procedure, maintain sufficient alertness to respond to the stimulus, and be cooperative.

Use of an electrotranslocation device can assist the practitioner during the administration of nerve block anesthesia to patients with sensory perception difficulties or neural degeneration, such as that experienced during end-stage renal disease. The use of an electrotranslocation device should not be restricted to brachial plexus techniques. Such a device can be used for enhancing any technique including ultrasound-guided nerve block, in which identification of specific nerve roots improves the success of the block and reduces the amount of medication required for anesthesia of the nerve root.

During a brachial plexus block, the stimulator is adjusted to deliver 2 mÅ after the needle has been introduced into the subcutaneous tissues. As the needle approaches the sheath, the amplitude is continuously reduced so that the muscle response to the stimulus is maintained. When the needle enters the sheath, the amplitude should be reduced to 0.5 mÅ. The muscle response to the stimulus continues to be the same as that obtained when the needle is outside of the sheath. The lower amplitude decreases the discomfort experienced by the patient while enhancing the ability to accurately identify the neurovascular bundle.

Patients may complain of aching or weakness along the path of the stimulated nerve after the regional anesthesia is terminated. This phenomenon is seen after the posterior tibial or the common peroneal nerves are stimulated. Severe or prolonged discomfort occurs when the stimulus is delivered over a long period or at a high current. The response to a stimulus with a lower amplitude is often adequate and results in less discomfort. Placement of the negative electrode has been important in the enhancement of electrotranslocation of the nerve. If the path of the nerve fiber is

BOX **45-3**

Advantages of Using Ultrasound Guidance for Nerve Blocks

- Direct visualization of the nerves and adjacent anatomic structures
- Observing the local anesthetic spread in real time
- Detecting variations in anatomy
- Faster onset times
- Improvement in block quality
- Use of lower, more precise doses of local anesthetics
- Possible increase in safety
- Less painful administration compared with nerve stimulator techniques
- Higher patient satisfaction

located under the negative electrode, a lesser stimulus produces a significant response.

ULTRASOUND-GUIDED REGIONAL ANESTHESIA

The technology and clinical understanding of anatomic sonography has evolved greatly over the past decade. In anesthesia departments throughout the United States, ultrasound-guided regional anesthesia (UGRA) has become a routine technique and may become the "gold" standard for performing regional anesthetic nerve blocks.[30-32] Direct visualization of the distribution of local anesthetics with high-frequency probes can improve the quality and avoid the complications of upper/lower extremity nerve blocks and neuroaxial techniques. Ultrasound guidance enables more accurate needle position and monitoring of the distribution of the local anesthetic in real time. The advantages over conventional guidance techniques, such as nerve stimulation and loss-of-resistance procedures, are significant. The key requirement for successful regional anesthetic block is to ensure optimal distribution of local anesthetic around nerve structures. This goal is most effectively achieved under sonographic visualization. Advantages of using ultrasound-guided techniques are noted in Box 45-3.[33,34] When compared with other forms of nerve localization, UGRA decreases performance time and onset time, and therefore decreases the time for surgical readiness from regional anesthesia. The quality of peripheral nerve block is also improved. To date, there are insufficient data to declare that UGRA improves overall block success. Whether UGRA improves safety has not been proven with large-scale randomized trials. Empirically, by allowing for the use of smaller volumes of local anesthetic as well as visualization of the real-time interaction of the needle, the nerve, and the local anesthetic, it appears the risk of LAST or neuronal toxicity will be reduced.[35,36] An interesting report noted that novice trainees learn the technique at variable rates but generally require 28 supervised trials before competency is achieved.[37]

As noted previously, the key condition for a successful regional anesthetic block is the confirmation of an appropriate volume of local anesthetic around the targeted nerve structures. Proper placement of local anesthetic is most effective under ultrasound visualization. A medical ultrasound machine operates frequencies between 2 and 13 MHz. The average wavelength of an ultrasound beam is less than 1 mm. This limits the use of ultrasound technology to structures that are 1 mm in diameter or larger. In general, higher-frequency ultrasound probes (10-13 MHz) are best suited for visualizing structures less than 4 cm deep from the skin. For deeper structures, lower-frequency ultrasound probes (2-5 MHz) are more clinically useful. Nerve tissue that appears dark or hypoechoic appears dark because it does *not* reflect ultrasound waves. Nerve tissue appears white or hyperechoic because it does reflect ultrasound waves.

The handheld probe emits and collects the ultrasound waves in a fan-shaped beam, which is represented on the display screen in a two-dimensional plane. The on-screen vertical axis represents the distance an anatomic structure or block needle is from the ultrasound probe, whereas the horizontal axis represents the distance to the right or left of the center of the probe. Therefore, the ultrasound waves are used to construct an image of the "slice" of tissue centered on and beneath the ultrasound probe, much like a single image on a computed tomography (CT) scan.

The standard ultrasound image is rendered in shades ranging from white to black depending on the amount of energy that returns to the probe from structures being examined. Hyperechoic tissues reflect a large amount of the ultrasound waves back to the probe and therefore appear white. Hypoechoic tissues reflect fewer ultrasound waves and therefore appear as shades of gray. Anechoic areas do not reflect ultrasound waves and therefore appear black. The amount of reflection of ultrasound waves back to the probe is dependent on the amount of resistance to passage of the waves through a particular tissue. This characteristic is known as *acoustic impedance*. Differences in acoustic impedance at tissue interfaces results in the ability to identify specific anatomic structures. For example, bone has much greater acoustic impedance than soft tissue; therefore the interface between these two tissues will produce a hyperechoic image.[38]

Needles used for regional anesthesia are echogenic but have very small cross-sectional areas. Therefore, the orientation of the needle with respect to the ultrasound beam affects the amount of sound energy reflected and hence the visibility of the needle on the screen. A needle oriented perpendicular to the ultrasound beam (i.e., "side on" to the beam) reflects a large amount of sound energy and is more easily visualized. In contrast, a needle that is parallel to the ultrasound beam (i.e., "end on" to the beam) reflects relatively little sound energy and is more difficult to visualize.

The orientation of the needle to the ultrasound probe during the administration of a regional anesthetic block is typically described in relationship to the image plane. The in-plane or axial/longitudinal approach allows the entire length of the needle (including the tip) to be visualized within the plane of the ultrasound image (Figure 45-1). In contrast, the out-of-plane, or tangential/short axis approach allows only the cross section of the needle to be visualized as a hyperechoic dot where it pierces the plane of the ultrasound image (Figure 45-2). The in-plane approach is favored when possible because it permits visualization of the entire length of the needle at all times; however, the anatomy associated with certain blocks may necessitate the use of the out-of-plane approach.

UPPER-EXTREMITY BLOCK

Frequent injury of the hand, arm, and shoulder, combined with the accessibility of the nerves of the brachial plexus, has encouraged the development of regional anesthesia techniques for surgical procedures of the upper extremity, as well as the diagnosis and control of pain.[39] The widespread use of upper-extremity regional anesthesia is the result of numerous factors, including the availability of equipment to locate and deliver local anesthetics to the nerves of the plexus, the development of local anesthetics that can be applied alone and in combination to produce an appropriate duration of action for the procedure at hand, and the variety of techniques and approaches that can be used.

FIGURE **45-3** Derivation of the brachial plexus from the cervical spine. *n.*, Nerve.

The four primary approaches for blocking the brachial plexus are axillary, interscalene, supraclavicular, and infraclavicular. Because of the ease of performance, the relatively high success rate and low incidence of complications, and the ability to produce anesthesia of the forearm and hand, the most frequently used technique is the axillary approach. The requirement for anesthesia of the upper arm and shoulder is most often met through use of the interscalene approach. This is because of the potential complications associated with needle placement in close proximity to the apex of the lung necessary with supraclavicular and infraclavicular block. The infraclavicular block is a safe and simple technique for providing surgical anesthesia of the lower arm, with an efficacy comparable to other approaches. The disadvantage is a higher risk of pneumothorax. Advantages of the infraclavicular approach include a lower likelihood of tourniquet pain and more reliable blockade of the musculocutaneous and axillary nerves when compared with a single-injection axillary block.[40,41]

The decision to use regional anesthesia rather than general anesthesia (which may be viewed by the surgeon as failure-free and more expedient) for elective and emergency surgical procedures of the upper extremity requires a strong commitment to and expertise in the use of these techniques. Moreover, the astute practitioner with experience and expertise in regional anesthesia does not lose sight of the fact that even in the most skilled hands, upper extremity block is associated with a degree of failure. In this regard, one can never rule out the potential requirement for conversion to general anesthesia and therefore must be cognizant of elements of the patient's history and physical examination that would affect the ability to manage the airway and deliver general anesthesia safely.

Despite the fact that existing patient pathology may suggest a regional anesthetic, it is unwise to base the decision to use an upper extremity block (or any regional technique) solely on the premise that general anesthesia should be avoided, because ultimately, it may be unavoidable. The circumstances should dictate the degree to which "plan B" is considered and executed before administration of the block.

Brachial Plexus Anesthesia

Applied Anatomy of the Brachial Plexus

An understanding of brachial plexus anatomy is mandatory if effective clinical application of regional block techniques of the upper extremity is to be achieved. This includes familiarity with muscle, facial, and vascular anatomy in relation to the origin and distribution of the brachial plexus. However, intimate knowledge of many of the anatomic details with regard to the evolution of nerve roots distributed to the brachial plexus and ultimately to peripheral nerves is not clinically essential for successful blockade. The brachial plexus is a large network of nerves that extend from the neck through the axilla and innervate the upper extremity (Figure 45-3). It is composed of ventral rami, trunks, divisions, cords, and their branches. The supraclavicular portion of the plexus, including the five primary ventral rami and the three nerve trunks and their six divisions, lies in the posterior triangle of the neck. The infraclavicular portion of the plexus, including the three cords and their four terminal branches, lies in the axilla. These nerves combine, divide, recombine, and divide again as they pass between the anterior and middle scalene muscles, through the posterior triangle of the neck, and into the axilla, where they end in the four terminal branches that supply the upper extremity. The resulting nerve pathway, when pictured and contemplated in two dimensions and without the associated bone, muscle, and vascular structures, often leads to difficulty in understanding and applying this textbook anatomy in the clinical setting. When learning brachial

plexus blockade, the value of augmenting written material with an apprenticeship at the hands of a master of the art cannot be overestimated.[42-44]

The archetypal brachial plexus is formed by the rami from the fifth (C5) to the eighth (C8) cervical nerves and the first thoracic (T1) nerve. In a small percentage of individuals, the fourth cervical (C4) or the second thoracic (T2) nerve or a combination of the two contributes to the plexus. After the rami pass the lateral border of the scalene muscles, they reorganize into trunks. The rami from C5 and C6 combine to form the superior or upper trunk, and the ramus from C7 continues alone as the middle trunk. The rami from C8 and T1 combine to form the inferior or lower trunk, which lies on the first rib posterior to the subclavian artery. The nerve trunks are enveloped by a fascial "sheath," the origins of which are from the posterior fascia of the anterior scalene muscle and the anterior fascia of the middle scalene muscle. This forms a closed space at this level known as the *interscalene space*, or more generally as the *sheath of the brachial plexus*.

Cadaver studies have demonstrated the existence of extensive velamentous septa that can form compartments around the contents of this sheath. These septa appear to be incomplete and therefore may not function as mechanical barriers to the spread of local anesthetics. Indeed, a single injection of local anesthesia into this sheath commonly produces complete block of the upper extremity. Nevertheless, anatomic variations do exist, and it is possible that in certain individuals, septa occur that isolate nerves, resulting in so-called "patchy blocks" by preventing exposure to the injected local anesthetic. It has also been shown that injection even outside the sheath can produce neural blockade, albeit with a considerably greater latency period. The lesson to be learned with regard to clinical application of this information is that failure to allot a sufficient amount of time to perform an upper extremity block, and in particular to allow it to "set up," generally produces an unsatisfactory result.[42-44]

At the lateral border of the first rib and posterior to the clavicle, each of the three trunks divides into ventral and dorsal divisions. These divisions are of significant clinical importance to application and evaluation of brachial plexus blockade, because the ventral divisions generally supply the ventral (flexor) portion of the upper extremity, and the dorsal divisions generally supply the dorsal (extensor) portions. As these divisions enter the axilla, the three posterior divisions combine to form the posterior cord, the anterior divisions of the superior and middle trunks combine to form the lateral cord, and the anterior division of the inferior trunk continues to become the medial cord. At that point, the cords are named according to their position in relation to the axillary artery. At the lateral border of the pectoralis minor muscle, each of these cords divides into two branches that reorganize to form the peripheral nerves of the upper extremity. The lateral cord divides and generates the musculocutaneous nerve and the lateral root of the median nerve. The medial cord divides and generates the ulnar nerve and the medial root of the median nerve. The posterior cord divides to generate the axillary and the radial nerves.

Understanding the anatomic relationships that result as the nerve cords give rise to the nerve branches and knowing the areas of the upper extremity these branches innervate are of paramount importance in the clinical application, evaluation, and supplementation of brachial plexus block. The branches of the lateral and medial cords (median, ulnar, and musculocutaneous nerves) predominantly supply the ventral portions of the upper extremity, and the branches of the posterior cord (radial and axillary nerve) predominantly supply the dorsal portions. However, in certain areas of the upper extremity, such as the posterior portion of the fingers and hand, there exists considerable cutaneous representation of the "predominantly ventral" median and ulnar nerves.

The radial nerve (C5 to C8 and T1) is the major nerve supply to the dorsal extensor muscles, such as the triceps, of the upper limb below the shoulder. It supplies sensory innervation to the extensor region of the arm, forearm, and hand. The musculocutaneous nerve (C5 to C7) supplies the flexor muscles, such as the biceps, brachialis, and coracobrachialis, of the ventral portion of the arm. It supplies sensory innervation to the lateral aspect of the forearm between the wrist and elbow as the lateral antebrachial cutaneous nerve. The median and ulnar nerves pass through the arm and provide sensory and motor innervation to the forearm and hand. The median nerve (C6 to T1) is better represented than the ulnar nerve in the forearm, where it supplies most of the flexor and pronator muscles. It also supplies sensory innervation to the ventral portion of the thumb, the first and second fingers, the lateral half of the third finger, and the palm of the hand. The ulnar nerve (C8 and T1) is better represented than the median nerve in the hand, where it supplies motor innervation to most of the small flexor muscles. It has no sensory innervation of the forearm but supplies sensation to the medial part of the third finger, the entire fourth finger, and the remaining portion of the palm of the hand.

Approaches to Brachial Plexus Block

There are multiple approaches to local anesthetic block of the brachial plexus and various techniques applied with each approach. The choice of approach should be based on several factors, including patient considerations, the location of the planned surgical intervention, and especially the skill and experience of the anesthesia practitioner. Although surgical site and practitioner preference often drive the decision regarding which approach and technique are used, the patient's body habitus, comfort, and coexisting disease and the nature and location of the injury are as important, if not more so, than these other concerns. Patient-related considerations should be weighed in the context of the risk of potential complications associated with a given approach, technique, and local anesthetic solution. The following discussion provides a practical approach to anesthesia of the brachial plexus, with a focus on axillary and interscalene approaches.[41]

Interscalene Approach. The interscalene approach to the brachial plexus was first described in 1970 by Dr. Alon Winnie. The interscalene approach is the most proximal brachial plexus block and is typically used to provide anesthesia for surgical procedures involving the shoulder and proximal humerus. It is the only technique that can provide adequate anesthesia and analgesia to the shoulder and the rest of the upper extremity. The catheter is placed at the level of the trunks, where the brachial plexus is relatively compact in size.[45] With the patient in the supine position, the anesthetist asks the patient to lower the shoulder on the side of the proposed anesthetic and surgery site to pull the shoulder away from the brachial plexus, intentionally trying to stretch the neck muscles and improve visualization and access. The patient's head can then either be turned so that the patient looks away from the area of the anesthetic or moved laterally away from the site, maintaining forward vision.

The cricoid cartilage ring is then palpated just below the thyroid cartilage. This anatomic landmark correlates to the vertebral body of C6 and the corresponding area of the transverse process called *Chassaignac's tubercle*. A straight line is drawn posteriorly to cross over the sternocleidomastoid (SCM) muscle, and the lateral border of the SCM is palpated. If this border is difficult to assess, the patient can be asked to raise the head against gentle resistance

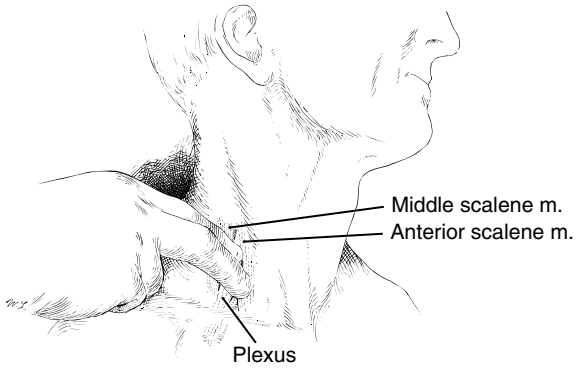

FIGURE **45-4** Technique for identifying the anterior and middle scalene muscles and the major vessels so the interscalene perivascular technique can be accomplished. *m.*, Muscle.

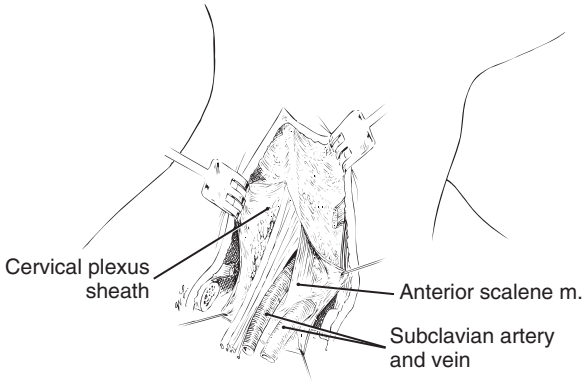

FIGURE **45-5** Three trunks of the cervical plexus are revealed lying alongside the subclavian vessels. *m.*, Muscle.

and then relax. Posterior to this border, the anesthetist palpates for the groove between the anterior and middle scalene muscles with two fingers (Figure 45-4). This is the level of the trunks of the brachial plexus (Figure 45-5).

After cleansing the patient's skin, an intradermal skin wheal of local anesthetic is made at this point on the groove. A 22-gauge, insulated B-bevel needle, usually 1½ inches long, is inserted gently through the skin wheal perpendicularly to the skin and then angled slightly caudad. The needle is attached to an intravenous extension tube with an anesthetic-filled syringe. The patient is told what to expect, and the needle is slowly advanced until a motor twitch response is elicited. The nerve stimulator current is lowered from 1 to 0.5 mÅ to minimize excessive current to the patient and to ensure proper needle position. After gentle aspiration is negative for blood or CSF, a test dose of 1 mL of local anesthetic solution is injected. A fade will be observed in the quality of the motor twitch experienced by the patient. This indicates that the needle is probably within the brachial plexus sheath. If no subjective symptoms of toxicity reaction are present, incremental injections of 3 to 5 mL of local anesthetic, each followed by aspiration to detect blood, are administered until the intended volume is given. In adult patients, the volume is usually 30 to 35 mL.[41,46]

Ultrasound-Guided Interscalene Block. The patient is placed in the supine position with the head rotated toward the nonoperative side and a high-frequency ultrasound probe is placed at the level of the first rib. The anchoring landmarks to be visualized are the subclavian artery and the first rib. The three roots of the brachial plexus are visualized lateral to the

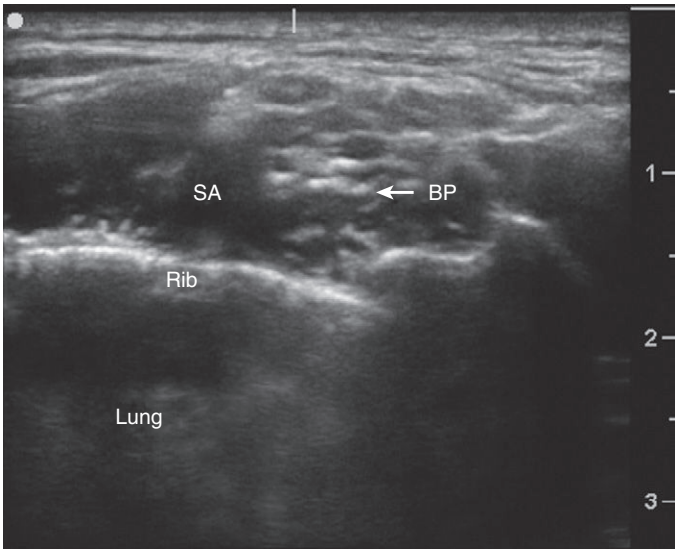

FIGURE **45-6** Transverse view of the brachial plexus lateral to the subclavian artery at the level of the first rib. *SA*, Subclavian artery; *BP*, roots of the brachial plexus, which are reflected as hypoechoic oval structures.

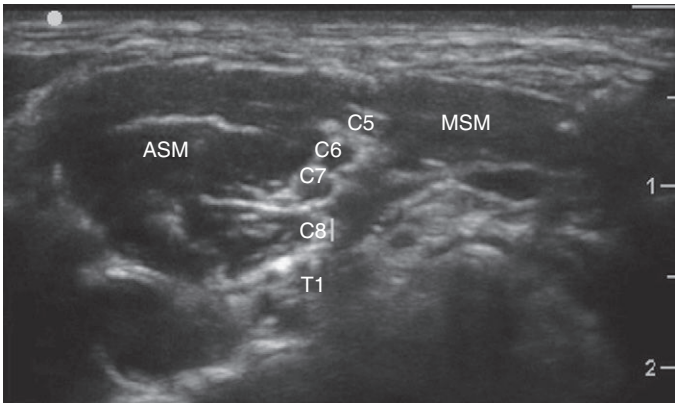

FIGURE **45-7** Transverse view of the brachial plexus at the lateral border of the sternocleidomastoid muscle, at the level of the posterior interscalene space between the anterior and the median scalene muscles. *C5-T-1*, Roots of the brachial plexus, which are reflected as hypoechoic oval structures; *ASM*, anterior scalene muscle; *MSM*, median scalene muscle.

subclavian artery (Figure 45-6). The ultrasound probe is then slid from the first rib up to the level of, or just below, the cricoid cartilage where the brachial plexus is visualized as a group of hypoechoic circular structures lying between the anterior and middle scalenus muscles (Figure 45-7). A 22-gauge, 2-inch needle is inserted posterior to the plexus, in-plane to the ultrasound beam, (Figure 45-8) with the tip of the needle coming to rest in close proximity to the roots of the brachial plexus. Up to 20 mL of local anesthetic solution is injected under direct observation. The local anesthetic solution should create an expanding hyperechoic area that surrounds and engulfs the nerve plexus (Figure 45-9).

Subclavian Approach. The patient is positioned and prepared as for the interscalene approach (Figure 45-10). In addition, some practitioners may place the patient's bed in a 30- to 45-degree head-up position or place a pillow under the patient's shoulder to accentuate the anatomy. The area above and including the clavicle on the surgical side is cleansed and draped.

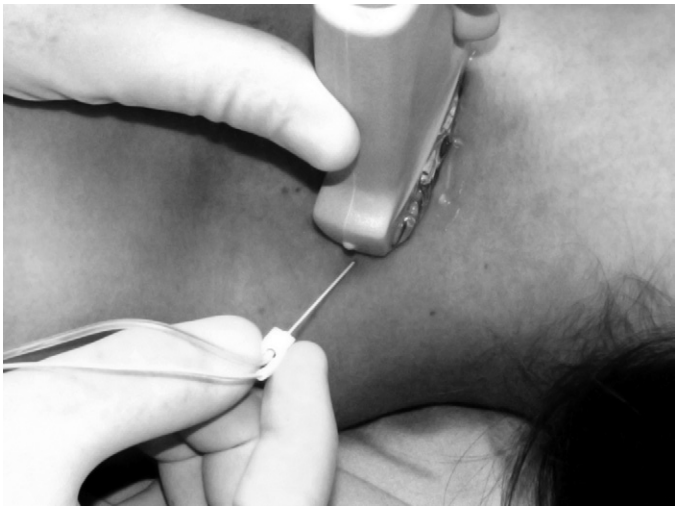

FIGURE **45-8** Needle inserted in-plane at the lateral border of the sternocleidomastoid muscle, at the level of the posterior interscalene space.

FIGURE **45-11** The needle enters the sheath of the brachial plexus at the farthest possible distance from the subclavian artery. *m.*, Muscle.

The pulsations of the subclavian artery in the plexus are behind and below the clavicle, just above the superior surface of the first rib and between the scalene muscles; the artery is palpated behind the midpoint of the clavicle. The anesthetist uses the nondominant hand to palpate for pulsations behind and 1 to 2 cm above the clavicle at this point and uses the dominant hand to place a skin wheal of local anesthetic immediately lateral to this site. Through the skin wheal, the 22-gauge, insulated B-bevel needle, attached to a nerve stimulator, is advanced perpendicularly to the skin, inward, and caudad until a motor twitch is noted in the lower portion of the upper extremity (Figure 45-11). The nerve stimulator current is lowered from 1 to 0.5 mÅ to minimize excessive current to the patient and to ensure proper needle position. After gentle aspiration is negative for blood, a test dose of 1 mL of local anesthetic solution is injected. A fade will be observed in the quality of the motor twitch experienced by the patient. This indicates that the needle is probably within the brachial plexus sheath. If no subjective symptoms suggesting toxicity reactions are present, incremental injections of 3 to 5 mL of local anesthetic followed by aspiration to detect blood are administered until the intended volume is given. In adult patients, the volume is usually 30 to 35 mL.

The anesthetist must watch for the onset of Horner syndrome (i.e., triad of miosis, partial ptosis, and loss of hemifacial sweating) as a positive sign of a successful block. The most important complication of the supraclavicular approach is pneumothorax. The pleura of the lung is immediately inferior to the first rib, and

careful needle placement as described previously is imperative. If landmarks are difficult to define, if the patient is very thin, or if the pleura of the lung is unusually high, the incidence of pneumothorax may increase. The increased incidence of pneumothorax with the supraclavicular approach and the high incidence of Horner syndrome with the interscalene approach led to Charles Pham Dang's development in 1997 of a new approach to the brachial plexus called the *intersternocleidomastoid* (ISCM) *block*.[47]

Intersternocleidomastoid Approach. In the newest supraclavicular approach to the brachial plexus, the ISCM, the puncture site is situated between the heads of the SCM muscle. The novelty of the technique arises from many features, including simple surface landmarks, minimized risk of pleural puncture, and no risk of epidural, subarachnoid, or intravertebral artery injection or catheterization of the perineural space.

Depending on the direction of the needle with the ISCM approach, the brachial plexus can be reached at the level of the trunks (i.e., superior, middle, and inferior). The needle passes successively between the heads of the SCM, behind the clavicular head, through the middle cervical fascia, next to the phrenic nerve, and through the anterior scalene muscle before arriving at the brachial plexus. The following nerves can be reached and stimulated, depending on the direction of the needle, at a depth varying from 3 to 8 cm: suprascapular nerve, superior trunk, middle trunk, and the divisions and cord.[47]

The patient lies supine with the head turned away, arm at the side, and hand positioned on the abdomen. The anesthetist stands next to the patient's head, opposite the side to be blocked. The sternal and clavicular heads of the SCM, as well as the midclavicle, are marked. The puncture site is situated two fingerbreadths above the sternal notch, between the heads of the SCM, medial to the clavicular head. After disinfection and skin-wheal infiltration, the stimulating needle of appropriate length is introduced behind the posterior border of the clavicular head of the SCM. The needle, practically leaning on the sternal head, is advanced laterally, posteriorly, and caudally in the direction indicated by a point situated 1 cm lateral to the midclavicle. The needle makes an angle of 45 degrees to the table and 15 degrees to the clavicle (Figure 45-12). This initial orientation of the needle leads to the suprascapular nerve, the stimulation of which evokes glenohumeral coaptation and contraction of the supraspinatus and infraspinatus muscles. Stimulation of the superior trunk evokes contraction of the biceps brachii and deltoid muscles, elbow flexion, and abduction of the arm. Stimulation of the middle trunk evokes contraction of the triceps brachii muscle and elbow extension. Stimulation of the divisions and cord evokes flexion pronation of the hand and digit flexion in conjunction with pectoral contraction. Movements of the abdomen can be seen from stimulation of the phrenic nerve. They imply withdrawal and redirection of the needle. These motor responses are obtained at a depth of 2 to 8 cm, depending on the collar size. The nerve stimulator current is lowered from 1.0 to 0.5 mÅ to minimize excessive current to the patient and ensure proper needle position. After gentle aspiration is negative for blood, a test dose of 1 mL of local anesthetic solution is injected. A fade will be observed in the quality of the motor twitch experienced by the patient. This indicates that the needle is probably within the brachial plexus sheath. If there are no subjective symptoms suggesting intraneural needle placement, incremental injections of 3 to 5 mL of local anesthetic, followed by aspiration to detect blood, are administered until the intended volume is given. In adult patients, the volume is usually 30 to 35 mL.[47]

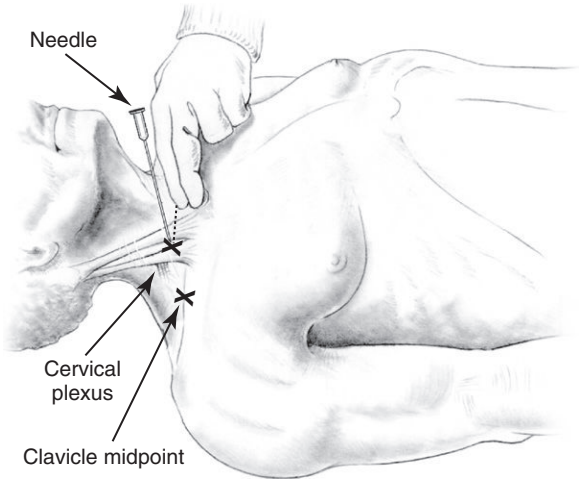

FIGURE **45-12** Technique for intersternocleidomastoid block of the brachial plexus.

Axillary Approach. The axillary approach to anesthesia of the brachial plexus is best suited to surgical procedures at or below the elbow (hand and forearm). However, an injury to the hand or forearm such as a fracture—which also limits the range of motion of the extremity because of patient discomfort—reduces the versatility of this approach. Under these conditions, patient comfort must be weighed against the need for profound anesthesia of the hand or forearm, often in the presence of a full stomach and the desire to avoid general anesthesia. In this instance, access to the axilla can generally be gained by the judicious use of intravenous opioids before slow, careful positioning and support of the extremity in preparation for placement of the block.[48]

The patient is placed in the supine position, with the arm to be blocked abducted 90 degrees from the body. The forearm is flexed to 90 degrees and rested parallel to the long axis of the body. The anesthetist uses the index and third fingers to identify the axillary artery, starting at the lateral margin of the pectoralis major muscle and tracing the artery into the mid- to lower axilla (Figure 45-13). Needle insertion need not occur high in the axilla, as some authors suggest, for successful block. Insertion in the mid- to lower axilla is just as effective; however, it reduces the chances that a local anesthetic will reach the point at which the musculocutaneous nerve leaves the sheath. A well-defined, localized pulsation of the axillary artery is more important to successful blockade than the point at which needle insertion occurs within the axilla. After appropriate preparation of the skin, a local anesthetic intradermal skin wheal is raised just proximal and superior to the palpating index finger. During needle insertion, moderate digital pressure should be applied to the artery to minimize the distance between the skin and subcutaneous tissue and the neurovascular bundle. An appropriate needle connected to a sterile extension tubing and syringe containing 50 mL of local anesthetic is inserted through the skin wheal. At this point the technique diverges, depending on the end-point used to determine when the needle tip lies within the sheath. These end-points include loss of resistance to the advancing needle, penetration of the axillary artery, and elicitation of a paresthesia.[41]

Loss-of-Resistance Technique. The loss-of-resistance technique uses a distinct change in tissue resistance often described as a "pop" as the needle penetrates the fascia and enters the sheath.

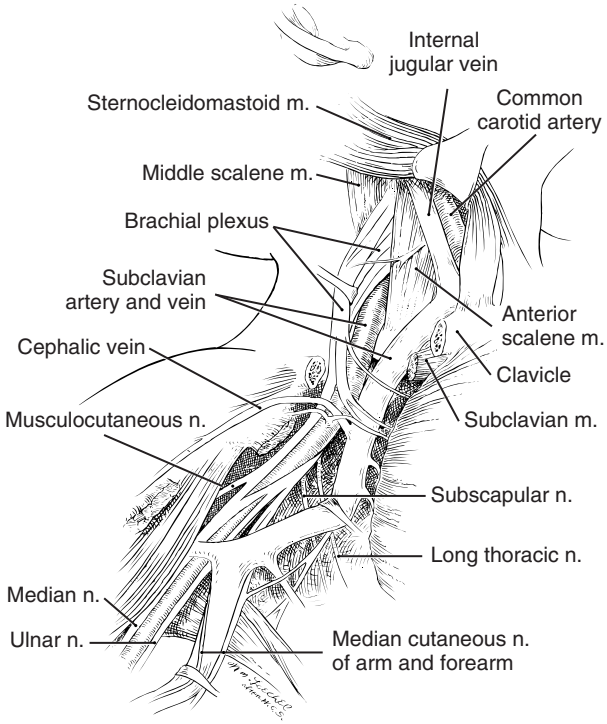

FIGURE **45-13** The brachial plexus at the axilla. *m.*, Muscle; *n.*, nerve.

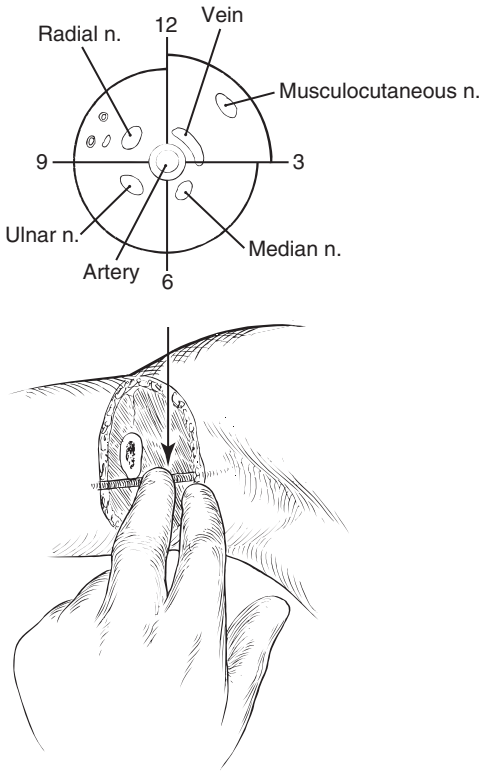

FIGURE **45-14** Identification of the intercostobrachial and brachial cutaneous nerves after completion of the axillary block. *n.*, Nerve.

After the axillary artery is identified, a 22-gauge, 1½-inch, short-bevel ("B-bevel") needle is inserted medially at approximately a 20-degree angle to the skin and parallel to the longitudinal course of the artery (Figure 45-14). Use of a short-bevel needle enhances the loss-of-resistance sensation on penetration of the sheath; however, the drag associated with the attachment of an extension tubing decreases this sensation. Some practitioners disconnect the extension tubing and observe the free needle for a pulsatile movement associated with the needle tip's close proximity to the axillary artery. This is considered a further indication of correct needle placement within the sheath, but it does not guarantee proper placement. The needle is then advanced medially an additional ½ to 1 inch parallel to the axillary artery at an acute angle to the skin.

Before local anesthesia is injected, the patient is instructed to immediately inform the anesthetist if symptoms indicative of rapid intravascular uptake or direct intravascular injection occur. These include dizziness, tinnitus, metallic taste in the mouth ("mouth full of nickels"), circumoral numbness or tingling, visual disturbances, and muscle twitching. If epinephrine has been added to the local anesthetic to reduce vascular absorption of the solution, the patient may also be instructed to report the sensation of having a "rapid" or "hard" heartbeat.

The needle is held fixed in position, and an assistant gently aspirates the syringe while the operator observes for blood in the extension tubing, which would indicate that the needle has entered the axillary artery or vein. In the absence of frank blood in the aspirate, a 3- to 5-mL test dose of the local anesthetic solution is injected and the patient observed and queried for the existence of any of the vascular warning symptoms for a minimum of 1 minute. Barring an untoward event, the remainder of the local anesthetic solution is injected in 5-mL increments, with each injection preceded by gentle aspiration and observation for blood in the extension tubing. During the injection, firm pressure should be applied with several fingers to the area immediately behind the needle insertion site to prevent retrograde flow of the anesthetic solution. Injection of each 5 mL of local anesthetic should be considered a "test dose," because unrecognized penetration of the artery or rapid uptake of the local anesthetic remains a possibility throughout the procedure.

When 40 mL of the local anesthetic solution has been injected, the needle is withdrawn to the level of the skin in preparation for field block, if desired, of the musculocutaneous, medial brachial cutaneous, and intercostobrachial nerves (see Figure 45-14). These nerves may require individual blockade because they exit the sheath high in the axilla (musculocutaneous and medial brachial cutaneous) or lie outside the sheath altogether (intercostobrachial). If care is taken to apply continuous digital pressure immediately below the site of needle insertion during injection of a 40-mL bolus of local anesthetic solution, and the arm is adducted after injection, anesthesia of the musculocutaneous nerve and its terminal distribution, the lateral antebrachial nerve (sensory innervation to the lateral forearm from the elbow to the wrist), can be achieved.

Before the needle is withdrawn from the skin, the musculocutaneous nerve can be independently blocked by injecting 3 to 5 mL of the remaining local anesthetic into the body of the coracobrachialis muscle. The coracobrachialis muscle is located immediately superior to the axillary artery and inferior to the biceps brachialis muscle. After block of the musculocutaneous nerve has been performed, the needle is again withdrawn to the level of the skin and redirected inferior and perpendicular to the artery into the subcutaneous tissue.

The remaining 3 to 5 mL of local anesthetic is injected into the subcutaneous tissue as the needle is advanced to the hub. This subcutaneous "bracelet" of local anesthetic produces conduction block of the medial brachial cutaneous and intercostobrachial nerves necessary to prevent discomfort if a tourniquet is to be used.

After completion of the block, the arm is immediately adducted and held close to the body to promote the cephalad spread of the local anesthetic solution, which can be obstructed by the abducted humeral head.

Transarterial Technique. The transarterial technique uses intentional penetration of the axillary artery and aspiration of blood as the end-point for determining that the needle is within the sheath. After the axillary artery is identified, a local anesthetic skin wheal is raised directly above the artery at the planned point of needle insertion (see Figure 45-14). A 21-gauge, 1½-inch needle is inserted perpendicularly to the skin and advanced slowly until blood is aspirated into the extension tubing by an assistant, who provides gentle aspiration of the syringe. The needle is then advanced along the same plane until blood can no longer be aspirated because the bevel has exited the posterior wall of the artery. Care must be taken to avoid advancing the needle through the posterior wall of the sheath after the artery is exited, which would result in deposition of the local anesthetic outside the sheath.

Failure rate of the transarterial technique has been shown to be significantly reduced when a 26-gauge, ½-inch needle is used as opposed to a 22-gauge, 1½-inch needle.[49] Presumably the shorter needle reduces the chance of exiting the posterior wall of the sheath and deposition of local anesthetic outside the sheath. Before local anesthetic is injected, the patient is instructed to immediately inform the anesthetist if symptoms indicative of rapid intravascular uptake or direct intravascular injection occur. The needle is held fixed in position, and an assistant gently aspirates the syringe while the operator observes for blood in the extension tubing, which would indicate that the needle has entered the axillary artery or vein. In the absence of frank blood in the aspirate, a 3- to-5 mL test dose of the local anesthetic solution is injected, and for a minimum of 1 minute, the patient is observed for and queried regarding the existence of any of the symptoms previously noted.

Barring an untoward event, the remainder of the local anesthetic solution is injected in 5-mL increments, with each injection preceded by gentle aspiration and observation for blood in the extension tubing. Again, to prevent retrograde flow of the anesthetic solution, firm pressure with several fingers should be applied to the area immediately behind the needle insertion site during the injection. Injection of each 5 mL of local anesthetic should be considered a "test dose," because unrecognized penetration of the artery or rapid uptake of the local anesthetic remains a possibility throughout the procedure. When 40 mL of the local anesthetic solution has been injected, the needle is withdrawn to the level of the skin in preparation for field block, if desired, of the musculocutaneous, medial brachial cutaneous, and the intercostobrachial nerves, as noted previously.[38,41]

Ultrasound-Guided Axillary Block. With ultrasound-guided axillary block, the patient is positioned supine and a high-frequency ultrasound probe is placed in the axilla at the crease formed by the pectoralis major and biceps muscles with the ultrasound beam positioned perpendicular to the axillary artery. The anchoring landmarks to be visualized are the axillary artery and the terminal nerve branches of the plexus located in a variable fashion around the axillary artery. The median nerve can be readily visualized, because it is located in close proximity to the axillary artery and tracks down to the cubital area of the elbow. The ulnar nerve is located medial to the artery and remains closer to the skin surface than the median nerve as it tracks down to the proximal forearm. The radial nerve is located just below the artery (Figure 45-15).

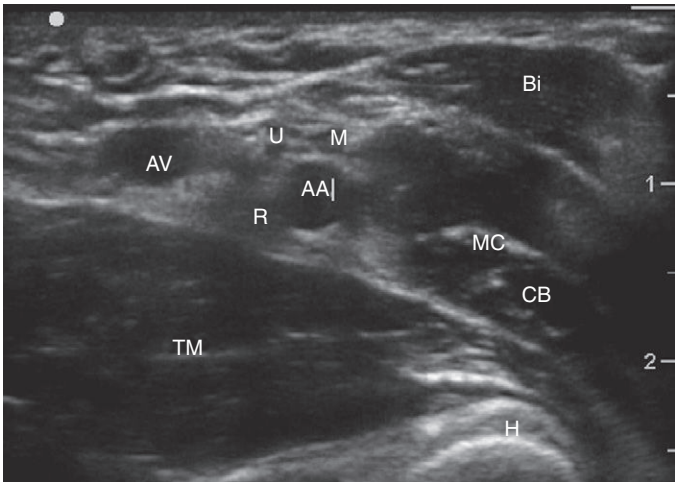

FIGURE **45-15** Transverse view of the axillary segment of the brachial plexus. *AA*, Axillary artery; *AV*, axillary vein; *M*, median nerve; *R*, radial nerve; *U*, ulnar nerve; *MC*, musculocutaneous nerve; *H*, humerus; *CB*, coracobrachials muscle; *Bi*, biceps muscle; *TM*, triceps muscle.

FIGURE **45-16** Needle inserted in-plane in the axilla.

A 22-gauge, 2-inch needle is inserted anterior to the plexus in-plane to the ultrasound beam (Figure 45-16) and advanced until the needle tip comes to rest in close proximity to the terminal branches of the brachial plexus; 20 to 30 mL of local anesthetic is injected under direct observation. The local anesthetic solution should create an expanding hyperechoic area that surrounds and engulfs the nerve plexus (Figure 45-17).

The musculocutaneous nerve is located between the corabrachial and pectoralis major muscles and is usually separated from the radial, median, and ulnar nerves at the level of the axilla (see Figure 45-15). The musculocutaneous nerve generally cannot be blocked by the injection of local anesthetic into the axillary sheath. The musculocutaneous nerve may be blocked independently using a 2-inch, 22-gauge needle in an in-plane or out-of-plane position relative to the ultrasound beam approach. The musculocutaneous nerve will appear as a large, singular hyperechoic structure with small, internal hypoechoic fascicles. A volume of 5 to 10 mL of local anesthetic solution is injected under direct observation.

Continuous Catheter Technique. Postoperative pain control after upper extremity surgery requires adequate analgesia not only

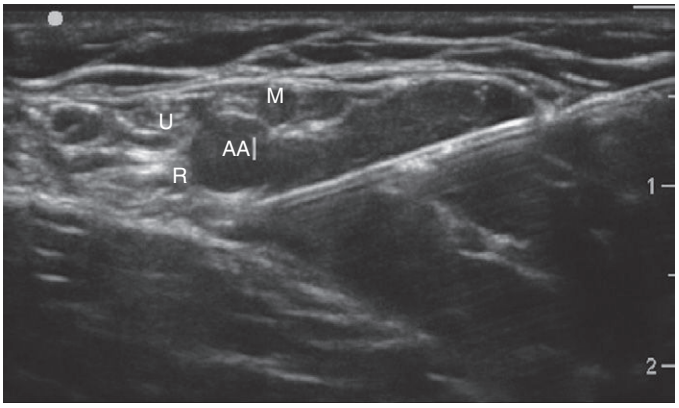

FIGURE **45-17** Transverse view of the axillary portion of the brachial plexus with a needle positioned just below the axillary artery and the formation of a hyperechoic area as a result of local anesthetic injection. *AA*, Axillary artery; *M*, median nerve; *R*, radial nerve; *U*, ulnar nerve.

at rest but also for incident pain. Especially after joint surgery, mobilization is required, as is the need to assess neurologic function. The use of brachial plexus catheters for the surgical anesthetic can have significant benefits by reducing postoperative analgesic requirements, including superior control of incident pain, and can be extended to aid in postoperative rehabilitation of the patient.[49]

Continuous administration of local anesthetics via a brachial plexus catheter inserted at the cervical level can markedly improve analgesia and decrease opioid requirements. The advent of cheaper and reliable pump technology has given rise to a significant growth in the use of continuous peripheral nerve blocks in general, especially continuous brachial plexus blocks.[49]

Under strict sterile technique, a 22-gauge, insulated block needle should be advanced at the level of C6 or the cricoid cartilage into the anterior and middle scalene groove and directed 45 degrees in a caudal, dorsal, and medial angle to reduce the risk of a punctured vertebral artery or inadvertent subarachnoid or epidural placement. The practitioner may feel a slight "pop" as the needle enters the sheath. Before placement of the catheter, the patient should be instructed to report any paresthesia experienced. Use of an insulated needle and a nerve stimulator or ultrasound technology may allow more accurate placement, reduce the risk of intraneuronal injection and trauma, and reduce time for placement of the catheter. When the desired motor stimulation is identified—movement in the upper or lower arm—the current should be gradually reduced to 0.5 mÅ with continued stimulation to ensure close proximity to the neural target. Normal saline, 5 to 10 mL, should then be injected incrementally with intermittent aspiration to guard against accidental intravascular injection. The addition of normal saline will expand the sheet and allow for the passage of the continuous catheter. The catheter should be inserted 3 to 5 cm and secured at the skin. Local anesthetic solution in a volume of 30 to 35 mL should now be injected incrementally, with intermittent aspiration to guard against accidental intravascular injection and to ensure that the continuous catheter works. Continuous infusions of 0.125 to 0.25 mL at a rate of 4 to 6 mL/hr have been shown to be very effective.[49-51]

Selective Blocks at the Elbow

Several other blocks of the upper extremity can be of benefit and may become techniques of choice, especially in outpatients. Selective blocks at the elbow and wrist permit the surgeon to complete the procedure while minimizing the amount of anesthesia

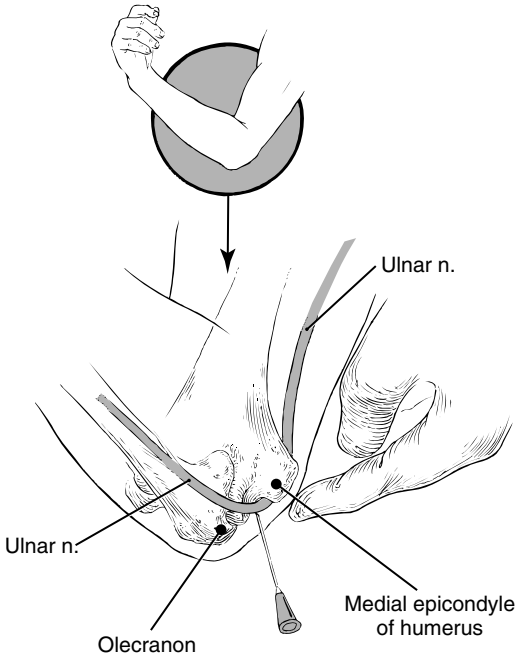

FIGURE **45-18** Technique of ulnar block at the elbow. The patient's elbow is flexed 90 degrees, and the medial condyle of the humerus is identified. *n.*, Nerve.

administered. The blocks at the elbow and wrist are primarily sensory blocks. The patient retains the ability to move the hand during the procedure. Reduction of the area anesthetized, the amount of sedation administered, and the potential for complications minimizes the patient's stay in the outpatient center. The mastery and use of selective nerve blocks of the upper extremity avoids the use of a general anesthetic when the regional anesthetic technique fails to completely block all the nerves that innervate the surgical site.[52-54]

Each nerve that supplies sensory branches to the arm can be blocked at the elbow and the wrist. Use of a nerve locator at the level of the elbow (for the median and radial nerves) and at the level of the wrist (for the ulnar and median nerves) can improve the success rate of the block.

When a tourniquet is used during the surgical procedure, the intercostobrachial nerve and the brachial cutaneous nerve should be blocked in the axilla. These blocks provide sufficient anesthesia to permit the patient to tolerate a tourniquet. The coracobrachial muscle also can be blocked at the level of the shoulder to provide anesthesia so the patient may better tolerate the tourniquet.

Ulnar Nerve Block at the Elbow

As the ulnar nerve traverses the ulnar sulcus of the humerus, it is tightly fixed in the groove. Performing a regional anesthetic technique in this location can increase the risk of nerve entrapment. The volume of the solution should be limited to reduce the amount of pressure exerted on the nerve and the ischemia that could develop from injection of a large volume (greater than 3 mL).[44]

The technique should be performed 1 to 2 cm proximal to the sulcus. The patient's elbow is flexed 90 degrees, and the medial condyle of the humerus is identified. A finger is placed in the ulnar sulcus, extending approximately 1 cm proximal to the condyle (Figure 45-18). The insertion point for the needle is between the medial condyle of the humerus and the olecranon process of the ulna. The needle is inserted at a 45-degree angle to the skin

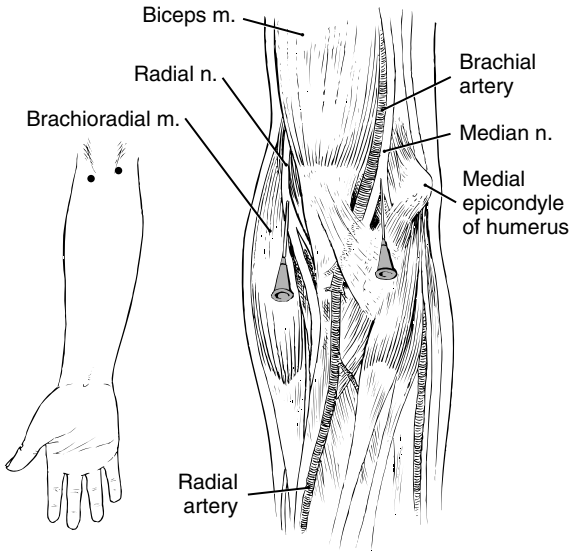

FIGURE **45-19** Performance of median nerve block, positioning the patient's arm on a stable surface with the elbow slightly flexed. After the brachial artery is identified, a short B-bevel needle is inserted slightly medial to the brachial artery. *m.*, Muscle; *n.*, nerve.

and perpendicularly to a line drawn between the medial condyle and the olecranon process. If a paresthesia is elicited on introduction of the needle, the needle is withdrawn approximately 1 mm, and 2 to 3 mL of the solution is injected. If a paresthesia is not elicited, the volume of the solution can be increased. The total volume of the local anesthetic solution is 3 to 5 mL. The onset of action is determined by the local anesthetic used for the procedure. Epinephrine can be used at this level; however, this agent delays the onset.[52-54]

Median Nerve Block at the Elbow

Anesthesia of the forearm and hand can be achieved by a combination of median and ulnar nerve block as either a supplement to another technique or as a primary anesthetic technique. The combination of median and ulnar nerve block provides adequate anesthesia for procedures on the cutaneous portions of the lower forearm, the hand, and the second, third, and fourth fingers. The median nerve block can be used to supplement a partially successful brachial plexus block. The median nerve block should be avoided in patients with carpal tunnel syndrome, if neuritis is present, or if the artery is perforated. If anesthesia is administered to two of the three nerves in the foramen, limited function of the hand remains.

The median nerve block is performed by positioning the patient's arm on a stable surface with the elbow slightly flexed. A line is drawn from the medial to the lateral condyles of the humerus on the anterior surface of the elbow. The brachial artery is then identified as it crosses this line (Figure 45-19). A short B-bevel needle is inserted slightly medial to the brachial artery to a depth of 0.5 to 0.75 cm. Median nerve blocks at the elbow can be facilitated with the use of a nerve locator. When the nerve locator is used, a stimulus of low amplitude elicits a response along the path of the median nerve. If a nerve locator is not used, a paresthesia can be elicited by fan-wise movement of the needle. Identification of the median nerve is necessary for a successful block. Local anesthetic solution (3 to 5 mL) is injected after the nerve is located. As the needle is withdrawn through the fascia, an additional 1 to 2 mL of solution is injected to block cutaneous branches of the nerve.[55,56]

Radial Nerve Block at the Elbow

Block of the radial nerve can be used as an adjunct to axillary perivascular techniques. This block also can be used for surgery of the forearm and hand that is within the distribution of the radial nerve or in conjunction with other nerve blocks.

With the elbow extended and stabilized on a firm surface, the brachioradialis muscle and biceps tendon are identified. The radial nerve is located in the groove formed by the fascial border of the brachioradialis muscle (see Figure 45-19) on the lateral edge and the biceps tendon medially. A line is drawn between the medial and lateral condyles. A short B-bevel needle is inserted along the medial border of the brachioradialis muscle toward the lateral condyle at the point at which the line between the condyles crosses the facial groove. The needle is directed toward the anterior aspect of the lateral condyle so that gentle contact occurs. After contact with the condyle, the needle is withdrawn 2 mm. Local anesthetic solution (3 to 5 mL) is injected. This procedure is repeated two or three times while the needle is moved slightly more proximally for each injection. As the needle is withdrawn into the subcutaneous tissue, 3 to 5 mL of local anesthetic is injected.

An alternate approach to the radial nerve requires identification of the lateral border of the brachioradialis muscle. Measuring 3 to 5 cm proximal from the lateral condyle along the border of the brachioradialis muscle enables palpation of the radial nerve as it parallels the humerus. The nerve is adherent to the bone at this level and can be easily injured during trauma or during the performance of the regional anesthesia. By slight movement of the nerve, a paresthesia can be elicited. A short B-bevel needle is inserted in a plane perpendicular to the humerus and advanced to the proximity of the identified radial nerve. Because of its fixation against the humerus, the needle must be advanced slowly and the position evaluated to avoid injury to the nerve.[55,56]

Selective Blocks at the Wrist

Selective blocks of the ulnar, median, and radial nerves at the wrist can be used for supplying limited anesthesia for the outpatient or as a supplement to brachial plexus anesthesia. Procedures that require a motor block in addition to the sensory blockade should be accomplished by use of another anesthesia technique. Epinephrine is not included in solutions used in nerve blocks below the elbow because of the relatively small blood vessels of the wrist, hand, and fingers and the risk of compromising circulation to these areas.[55,56]

Ulnar Block at the Wrist

With the wrist slightly flexed and stabilized on a firm surface, the ulnar flexor muscle of the wrist is identified (Figure 45-20). A line is then drawn across the forearm at the level of the styloid process of the ulna. A short B-bevel needle is inserted perpendicularly to the skin on the radial side of the ulnar flexor muscle of the wrist, where it is crossed by the line. At this location, the needle is slightly lateral to the ulnar artery, and a small deviation medially can place the needle over the artery. The ulnar artery can be palpated when the wrist is in moderately exaggerated extension. However, severe extension causes the artery to collapse. After the needle is inserted, 2 to 4 mL of local anesthetic solution is injected. An additional 2 mL is injected as the needle is withdrawn from the deep fascia. The dorsal branch of the ulnar nerve is blocked by injection of 3 to 5 mL of local anesthesia in a half-ring around the ulnar aspect of the wrist. The needle is placed subcutaneously at the radial margin of the ulnar flexor muscle of the wrist and advanced to the midportion of the dorsal aspect of the wrist.[55,56]

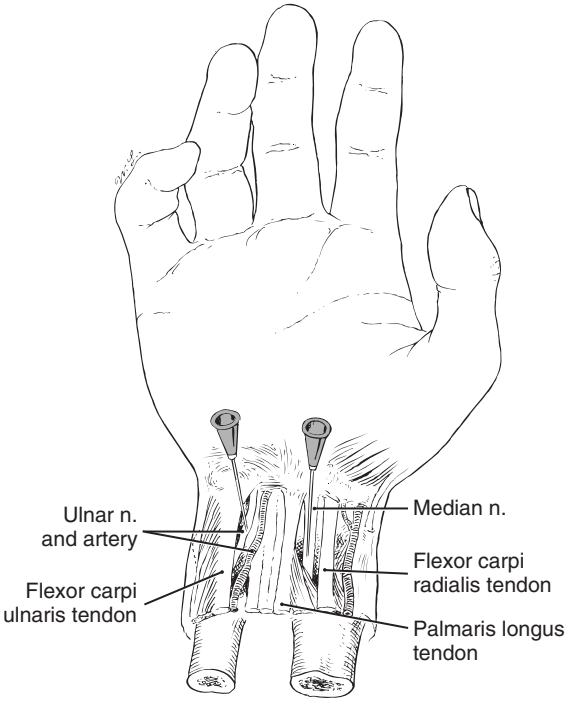

FIGURE **45-20** With the patient's wrist slightly flexed and stabilized on a firm surface, the ulnar flexor muscle of the wrist is identified. A short B-bevel needle is inserted perpendicular to the skin on the radial side of the ulnar flexor muscle of the wrist. *n.*, Nerve.

Median Block at the Wrist

The wrist is stabilized on a firm surface and slightly flexed against resistance. When the wrist is flexed, the long palmar muscle and the radial flexor muscle of the wrist are easily identified (see Figure 45-20). A line is drawn across the wrist that parallels the proximal crease. A short B-bevel needle is inserted perpendicularly to the skin between the two tendons to a distance of 0.5 to 1 cm. The carpal tunnel is a tightly confined space. The nerve is located in the superficial portion of the carpal tunnel. A paresthesia can be elicited during the performance of the procedure. If the sensation persists, the needle must be withdrawn and repositioned. Local anesthetic solution (2 to 5 mL) is injected within the carpal tunnel, and another 2 to 3 mL is injected after the needle is withdrawn from the fascia of the carpal tunnel.[55,56]

Radial Block at the Wrist

The sensory fibers of the radial nerve to the hand are superficial branches at the wrist. Anesthesia of the radial fibers is achieved through the injection of a subcutaneous ring of local anesthetic solution, beginning at the radial flexor muscle of the wrist and extending to the dorsal surface of the ulnar styloid (Figure 45-21). The formation of a continuous ring of local anesthetic around the wrist should be avoided when this procedure is accomplished in conjunction with an ulnar block because circulation to the hand could be compromised.

Another approach to anesthesia of the radial nerve is the identification of the brachioradialis muscle proximal to the wrist. Approximately 6 to 8 cm proximal to the wrist, 5 to 7 mL of local anesthetic solution is injected under the brachioradialis muscle. This technique is the least well tolerated of all of the supplemental blocks and has limited success.[55,56]

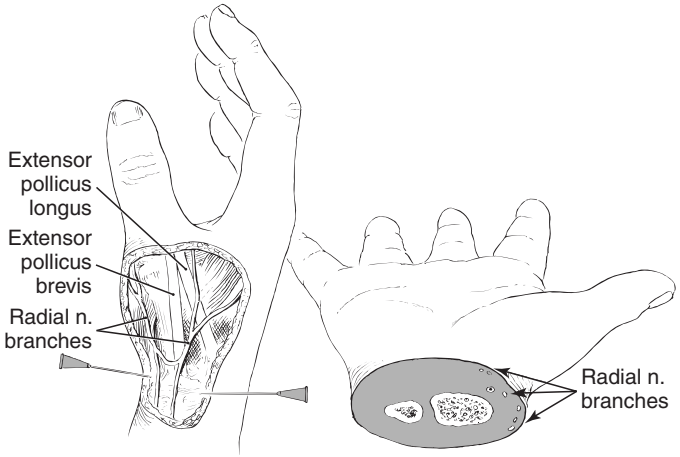

FIGURE **45-21** Anesthesia of the radial fibers is achieved by injecting a subcutaneous ring of local anesthetic solution at the radial flexor muscle of the wrist, extending to the dorsal surface of the ulnar styloid. *n.*, Nerve.

INTRAVENOUS REGIONAL ANESTHESIA (BIER BLOCK)

Intravenous regional block is a technically simple, safe, and rapid means of producing surgical anesthesia of the extremity. The technique is best suited for upper extremity (hand and wrist) soft-tissue surgical procedures of 1 hour or less; however, it has also been used for lower extremity surgical procedures of the foot and ankle. The factor limiting the duration of anesthesia to approximately 1 hour is most commonly discomfort produced by the tourniquet required to initiate and maintain the block. Use of a dual tourniquet system and preoperative and or intraoperative administration of small doses of opioids may extend this time limit to the maximum tourniquet time of 2 hours. The greatest risk associated with intravenous regional anesthesia (IVRA) is the potential for rapid transfer of a large volume of local anesthetic from the extremity to the central circulation in the event of an improperly fitted or inflated tourniquet or tourniquet failure. Therefore, it is important to have emergency equipment, medications, and monitors immediately available when this block is administered. Because of the rapid onset of the block and the limited duration, it is almost always performed in the operating area, where the emergency items needed are readily available. The necessity for intravenous access and manipulation of the affected extremity, the prerequisite for a tourniquet, and the density and duration of the block influence the clinical application of this technique.[55-57]

Intravenous Regional Anesthesia: Upper Extremity Block

A small-bore (23-25 gauge) intravenous catheter is placed in a distal vein of the affected extremity and secured in place, and a heparin lock is attached and flushed with normal saline. The preferred location for access to the venous system of the upper extremity is the dorsum of the hand; however, forearm and antecubital fossa veins have been used. Evidence suggests that use of forearm or antecubital fossa veins increases the possibility of a partial or complete failure of the block when the hand or wrist is the surgical target. It is reasonable to assume that consideration should be given to the area on which surgery is to be performed with regard to access to the venous system because attainment of surgical anesthesia is predicated on the adequate spread of the injected local anesthetic. The patient is placed supine, and several

layers of a suitable padding material are wrapped around the arm in preparation for application of the tourniquet. Although a single tourniquet can be used, a dual tourniquet is recommended because it provides a means to extend the length of the block after the initial onset of tourniquet pain.

After application of the tourniquet, the extremity is elevated and exsanguinated. Exsanguination is accomplished by wrapping an Esmarch bandage at close overlapping intervals tightly around the arm, starting at the fingertips and continuing until the bandage overlies the tourniquet itself. In cases in which application of an Esmarch bandage would cause undue discomfort, exsanguination by simple elevation of the extremity for a minimum of 5 minutes may be attempted. This method may or may not result in adequate block. In addition, an air-inflated splint may be used as an alternative to the Esmarch bandage. After exsanguination, the proximal tourniquet is inflated to 250 mmHg or 100 mmHg above systolic blood pressure, and the Esmarch bandage is removed. A total of 50 mL of 0.5% lidocaine is then injected via the intravenous catheter. The local anesthetic should be free of preservatives (e.g., methylparaben, metabisulfite) and contain no vasoconstrictor. The patient should be carefully monitored during the injection for signs of local anesthetic toxicity. At the conclusion of the procedure the cuff may be deflated for as long as 20 minutes after injection of the local anesthetic. This allows enough time for substantial amounts of the drug to diffuse into the tissues; therefore the drug released systemically will not reach toxic levels.

An alternative block technique uses an additional "tourniquet" (Penrose drain) applied at midforearm in the manner used to start an intravenous line after primary distal tourniquet inflation. Half of the 50-mL volume of local anesthetic is injected with the forearm tourniquet in place; the tourniquet is removed, and the remaining local anesthetic is injected. This technique results in a faster onset and a denser block. Numerous additives to the local anesthetic have been tested, including opiates, clonidine, muscle relaxants, and ketorolac. Ketorolac appears to be the only agent that provides a significant clinical benefit.[58] The addition of 15 to 30 mg of ketorolac to the local anesthetic solution can provide a degree of postoperative analgesia without increasing the risk of postoperative bleeding.[55-57]

Intravenous Regional Anesthesia: Lower Extremity Block

Indications for IVRA of the lower extremity include orthopedic surgery of short duration on the foot, removal of fixation plates and screws from the bones below the knee, and foreign body removal from the foot.

Two significant differences exist between IVRA of the upper and lower extremities. First, the local anesthetic volume (and dose) for IVRA of the lower extremity is approximately double that used for the arm. This obviously increases the risk of local anesthetic intoxication resulting from leakage under the inflated cuff and from release of a large bolus dose of local anesthetic when the cuff is deflated. Second, in order to occlude the arterial inflow at the thigh level (femoral artery), the tourniquet pressure must be higher than in the arm (usually 350 to 400 mmHg), which increases the occurrence and intensity of tourniquet pain.

Two separate 9-cm–wide tourniquet cuffs (adult patient) are applied, and care must be taken that the pneumatic parts of the tourniquets surround the thigh by more than 1.5 turns. Otherwise, the technique is similar to that described for IVRA of the arm.

During brief surgical procedures of the foot or the ankle, the distal tourniquet cuff may be applied on the calf, clearly below the head of the fibula (away from the peroneal nerve), and the proximal cuff left on the thigh. The local anesthetic solution is injected with the distal tourniquet cuff inflated; therefore, the volume and the dose can be the same as for the arm of an adult, that is, 35 to 45 mL of 0.5% lidocaine. The proximal tourniquet is usually not inflated but can be rapidly inflated in the event the distal tourniquet fails.[56,59]

INTERCOSTAL NERVE BLOCKS

The use of the intercostal nerve block has increased in the past several years. The anatomic landmarks are easily identified, thereby facilitating the performance of the block. The procedure is not extremely painful, has a high rate of success, has a low incidence of complications, and provides the patient with significant analgesia. The most common complications are pneumothorax and toxicity from the local anesthetic. The patient who has pain with respiratory effort is able to cough and breathe deeply with reduced discomfort. In the outpatient or ambulatory care setting, surgical procedures can be accomplished with the aid of this regional anesthesia technique.[60]

The use of multiple-level intercostal nerve block can lead to the highest local anesthetic plasma levels of any regional techniques. The high vascularity of the area and large intercostal veins contribute to high plasma levels of local anesthetic. The high plasma concentration can produce toxicity with lower-than-toxic injected doses.

Intercostal nerve block is used for supplementing balanced anesthesia techniques to increase tolerance of the surgical procedure. Sufficient analgesia can be provided to permit the performance of surgical procedures involving the abdominal wall without the need for supplemental blocks. For more involved procedures, additional anesthesia may be required.

Intercostal nerve block can provide analgesia for postoperative pain control when epidural analgesia is not desired or possible. The procedure can provide analgesia during or after chest-tube insertion to limit the patient's discomfort. The landmarks are easily identified in most patients. The procedure can be accomplished with the patient prone, in the lateral position, or sitting comfortably with the upper body supported over a table or a stand. Having obese patients sit up enables easier identification of landmarks. One advantage of using multiple-level intercostal nerve blocks is the reduction in the amount of pain medication required to facilitate normal respiration in the postoperative period. These factors result in a reduction in the potential development of respiratory depression related to the use of intravenous or intramuscular opioids, especially in obese patients.

The intercostal nerve emerges from the intervertebral foramen and follows the rib in the costal groove. This groove is located on the anteroinferior aspect of the rib. The intercostal artery and vein accompany the nerve in the groove. Medial to the posterior angle of the rib, the neurovascular bundle lies between the pleura and the internal intercostal fascia. As the nerve passes the angle of the rib, it begins to run between the two layers of the internal intercostal muscle. At the midaxillary line, the nerve branches send sensory fibers anteriorly and posteriorly to supply skin and subcutaneous tissue. Fibers also provide motor and sensory innervation to the bundles of the superior rectus muscle in the upper abdomen.

Positioning the patient may require modification to facilitate breathing during the procedure. The area of pain may have to be splinted, or other measures may need to be taken to reduce pain-induced movement during the procedure. Ideally the patient should be positioned in the prone position with the arms hanging down. This position pulls both scapulas away from the midline

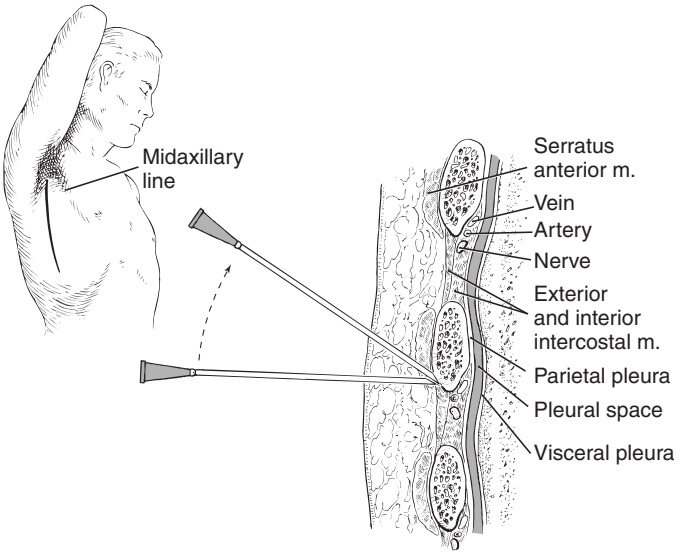

FIGURE **45-22** A 22-gauge, B-bevel needle is inserted perpendicular to the rib and advanced until contact is made with the rib. The needle is slowly walked caudad off the rib. *m.*, Muscle.

and permits the practitioner to perform the block as the nerve root begins to travel in the intercostal groove.

The block can be performed with the patient lying on the unaffected side with the arm extended over the head. This technique is helpful in obese patients and in patients experiencing severe pain, especially when such a patient is prone. When the patient is in the lateral position, preservation of circulation in the downward arm must be preserved.

In postoperative patients, the supine position can be used with the anterior approach to the intercostal nerve. This position is less satisfactory and is associated with a higher incidence of complications.

The rib is palpated posterior to the midaxillary line in the prone patient so that the appropriate landmarks can be identified. In this position, the rib becomes superficial to the muscle bodies. The lateral border of the sacrospinal muscle must be identified before the block is attempted. The sacrospinal muscle lies approximately 7 to 10 cm from the midline.

With a small-gauge (27- to 30-gauge) needle, a skin wheal is raised over the point chosen for the injection. A 22-gauge, B-bevel needle is then inserted perpendicularly to the rib through the skin wheal and advanced until contact with the rib is made. The needle is slowly walked caudad off the rib. As the edge of the rib is cleared, the needle is advanced another 2 to 3 mm (Figure 45-22). The needle should be gently aspirated for verification of needle placement. Use of a "free needle," as described in brachial plexus anesthesia, can facilitate the maneuverability of the needle and increase control.

Once the needle is located in the appropriate location, 3 to 5 mL of the local anesthetic solution is injected. The procedure can be repeated for anesthesia at each dermatome level. If resistance is encountered during the injection, the injection should be terminated and the needle repositioned. If the patient begins to cough or move, the needle position should be reevaluated before injection. Advancing the needle several millimeters can place the needle within the nerve itself, resulting in severe pain or direct injury to the nerve.

Procaine, bupivacaine, tetracaine, and lidocaine have all been used for blocking the intercostal nerves, with varying effects. Because the goal is to provide the patient with extended pain relief, a longer-acting agent is most commonly used. An injection of 3 mL of bupivacaine (0.5%) into the tissues surrounding the intercostal nerve provides the patient with 3 to 9 hours of anesthesia and analgesia. Patient factors such as temperature, presence of infection, and the response to local anesthetics affect the duration of action. The addition of low-molecular-weight dextran to the solution in a ratio of 1 mL of dextran to 3 mL of bupivacaine further extends the duration of action. Dextran slows the absorption of the local anesthetic, thereby reducing the plasma level of the anesthetic and permitting more of the concentrated local anesthetic solution to remain in close proximity to the neural tissue.

Epinephrine 1:200,000 or 1:400,000 should be added to the local anesthetic solution. Bupivacaine's duration of action may be unchanged; however, the rise in the plasma concentration of the local anesthetic is slowed. The addition of epinephrine to tetracaine or lidocaine prevents the rapid absorption of the anesthetic and increases the duration of action. With the use of epinephrine, increased vasoconstriction occurs, an effect that reduces absorption of the local anesthetic. The increased contact time between the neural tissue and the local anesthetic increases the amount of local anesthetic present to be absorbed into the neural fibers.

In addition to the single-shot technique described previously, a continuous intercostal block can be used for providing additional pain relief. The technique was originally described in the mid-1960s. However, it did not gain popularity until 1983, when it was reintroduced as a "new" technique. The continuous technique permits the reinjection of the intercostal fibers without the need for additional invasive procedures. Opioids have been injected in the intercostal nerve sheath with limited enhancement of the analgesia.

The continuous intercostal technique is performed by use of an epidural needle and a catheter in place of a single-shot needle technique. The intercostal groove is located using the technique described for the single-shot technique. When an epidural needle is used for the procedure, resistance is met as the needle passes through the sheath. The nerve can also be identified with a nerve locator or nerve stimulator. After the intercostal neural sheath is identified, the needle is adjusted so that the bevel of the needle directs the catheter toward the midline posteriorly. The epidural catheter is inserted slowly along the intercostal groove 2 to 3 cm. If severe pain or discomfort occurs during advancement of the catheter, the procedure is terminated, and the catheter is removed. Advancement of the catheter may produce electric-like shocks as the catheter brushes the nerve fibers. Severe pain should alert the practitioner of the possibility of an intraneural injection.

As the medication is injected, a band of analgesia develops along the path of the catheter and spreads anteriorly and posteriorly. Other than the direct action of the local anesthetic on the neural fibers, the exact mechanisms of action are unknown. However, paravertebral or epidural distribution of the local anesthetic may facilitate and enhance the block. The medication is injected in 3-mL increments until the desired level and intensity of block are achieved.

Tachyphylaxis develops with repeated injections of local anesthetic. Permitting resolution of the block before reinjection or using another local anesthetic reduces this effect. If an ester is used for the initial blockade, an amide local anesthetic can be used when symptoms of tachyphylaxis develop.

Small doses of fentanyl and morphine have been injected through the catheter. However, the uptake of medication into the vascular compartment is rapid, essentially negating the advantages of this route of administration. The use of opioids in the

intercostal space may increase the incidence of complications, including respiratory embarrassment.

The likelihood of complications, such as pleural injection and pneumothorax, can be reduced by use of a short B-bevel needle. To avoid an intraneural injection, the needle is directed cephalad as it passes over the ridge of the rib. A symptomatic pneumothorax can occur; however, use of a single 22-gauge, short-beveled needle reduces the risk. A leak created by this needle can be minimal. When a larger or A-bevel needle is used, the risk of complications is increased.

In most patients a small leak of air does not cause a symptomatic pneumothorax. Most patients are able to compensate for any reduced ventilatory capacity, and the pneumothorax resolves without intervention. In a small percentage of patients, intervention is needed for relief of the discomfort and dyspnea. Radiologic studies should be performed after completion of the procedures so the status or occurrence of a pneumothorax can be established. The studies can be used during follow-up evaluations and therapy if required.

The use of intercostal nerve block has enhanced the practice of anesthesia and pain control. This technique provides the patient with increased flexibility in the control of pain and reduces the need for opioids. In the ambulatory surgery center, this technique offers increased options to the patient who desires a regional anesthetic technique.[60]

LOWER-EXTREMITY BLOCK

Lower-extremity nerve blocks are well described and can provide high-quality anesthesia and analgesia for lower-extremity surgical procedures. Lower-extremity nerve blocks, although underused, have significant advantages compared with central neuraxial techniques, especially in the ambulatory setting.

Advantages of lower-extremity nerve block include reduced recovery room admissions, decreased nausea and vomiting and urinary retention, and improved postoperative analgesia. These benefits may translate into shortened hospital stays, decreased probability of hospital admission, and an overall reduction in hospital costs and patient charges.

Anatomy of the Lumbar Plexus

The lumbar plexus is formed from the first, second, third, and fourth lumbar nerve roots. Contributions to the plexus originate in the twelfth thoracic nerve. The plexus is formed in front of the quadratus lumborum muscle and behind the psoas major muscle (Figure 45-23). As the major branches from the plexus begin their descent into the leg, the muscle bodies and the connecting fascia tightly bind them. The lateral femoral cutaneous nerve is formed from the second and third lumbar nerves and is the first to leave the compartment. It emerges from the lateral border of the psoas major at its midpoint. The nerve then traverses the iliac muscle obliquely toward the anterior iliac spine. The lateral femoral cutaneous nerve passes under the lateral border of the inguinal ligament and provides the sensory innervation to the lateral aspect of the thigh (Figure 45-24).

The obturator nerve arises from the second, third, and fourth lumbar nerves as an extension of the lumbar plexus. It emerges from the medial border of the psoas major at the level of the sacroiliac joint and is covered by the external iliac artery and vein. The nerve passes into the pelvis minor and runs anteroinferiorly to the obturator canal, which it traverses near the obturator vessels. Because of the proximity of the nerve to the external iliac artery, it can be injured during surgical procedures. This nerve is frequently injured when patients undergo extensive pelvic surgery. The obturator nerve is primarily a motor nerve that has some mixed sensory fibers to the hip, the medial aspect of the femur, and the skin and soft tissue of the lower portion of the thigh.

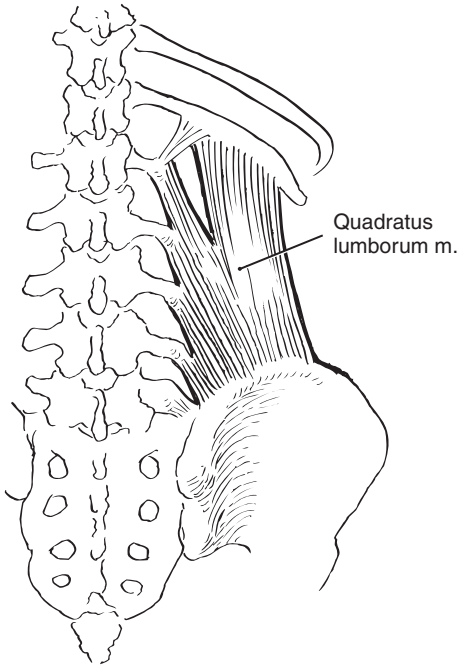

FIGURE **45-23** Location of the lumbar plexus. *m.*, Muscle.

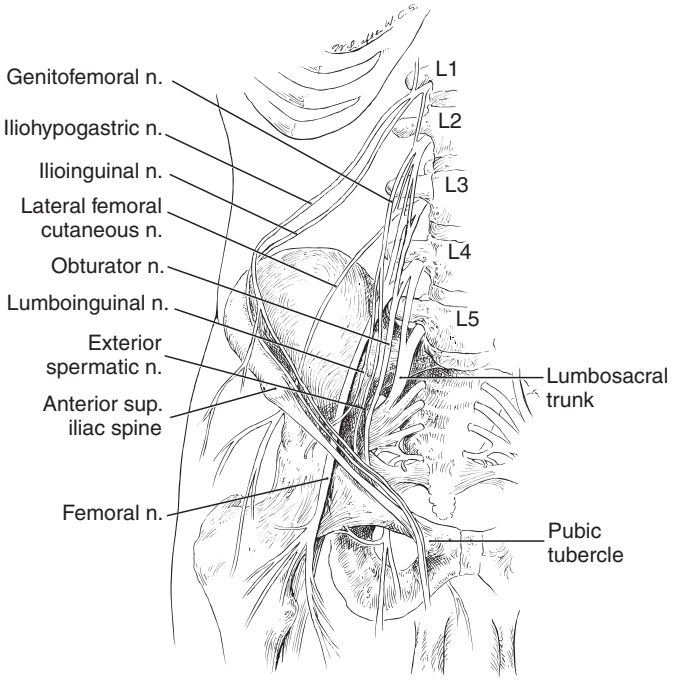

FIGURE **45-24** Origin and position of the nerves of the lower extremity. *n.*, Nerve.

The third nerve in the lumbar plexus is the femoral nerve, which is formed from the contributions of the second, third, and fourth lumbar nerve roots. This nerve forms and appears at the junction of the middle and lower third of the psoas major muscle. It remains within the groove of the psoas major and the iliac muscles and runs deep under the inguinal ligament, where it comes to lie anterior to the iliopsoas muscle and lateral to the femoral artery.

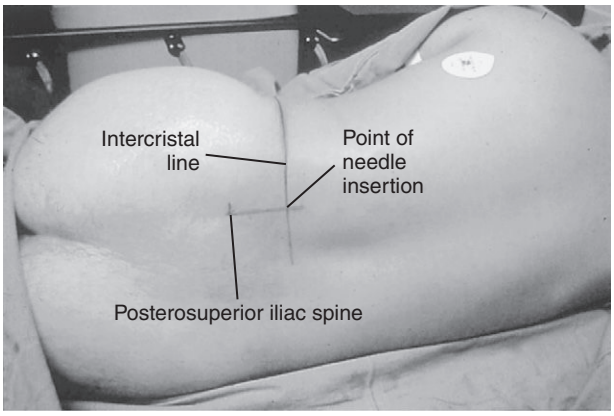

FIGURE **45-25** Lumbar plexus block.

The femoral nerve forms two branches: the anterior and the posterior bundles. This formation usually occurs just after the nerve passes under the inguinal ligament but may occur before it passes under the ligament. The anterior branch provides innervation to the anterior surface of the thigh and the sartorius muscle. The posterior branch provides innervation to the quadriceps muscles, the knee joint, and its medial ligament and is the origin of the saphenous nerve. The femoral nerve is bound by several structures above and below the inguinal ligament. Above the inguinal ligament, the iliaca fascia encapsulates the femoral nerve laterally, the psoas fascia medially, and the transverse fascia anteriorly. The posterior border of this capsule or sheath is made up of the bony structure of the pelvis.

As the femoral nerve joins the femoral artery to enter the leg, the iliopsoas fascia forms the posterolateral wall. The inguinal ligament and the fascia lata form the anterior wall, and the iliopectineal fascia forms the medial wall of the capsule. Winnie et al.[61] suggested that the neural sheath originating with the femoral artery in conjunction with the fascial attachments form a structure similar to the neural sheath in the brachial plexus. With this anatomic design, anesthesia can be provided for the lower extremity through techniques used in upper extremity anesthesia.

Psoas Compartment Block

Immediately after emerging from the intervertebral foramina, the nerve roots form the lumbar plexus. Blockade of the lumbar plexus as a unit can be accomplished by injecting local anesthetic into the fascial sheath surrounding the plexus. This can be done at the level of the psoas compartment.[56,62]

This approach attempts to block the plexus as it lies in the fascial plane bordered medially by the vertebral column, dorsally by the quadratus lumborum muscle, and ventrally by the psoas major muscle.

The patient is placed in either the lateral or sitting position. If placed in the lateral position, the patient should be in a relaxed but curled position similar to that used for spinal or epidural anesthesia, with the operative side uppermost (Figure 45-25).

From the spinous process of L4, a 3-cm line is drawn caudally in the interspinal line. From the end of this line, a 5-cm line is drawn perpendicularly and laterally toward the side to be blocked, usually ending at the medial edge of the iliac crest. This spot identifies the point of needle insertion. A 120-cm insulated block needle is used. A skin wheal is raised, and the needle is inserted perpendicularly to all planes and advanced until contact with bone is made, which identifies the transverse process of L5 and usually occurs at a depth of 5 to 10 cm.

The needle is then withdrawn, redirected slightly cephalad, and advanced until it slides over the transverse process of L5. Using the loss-of-resistance technique, the psoas compartment is usually encountered at the depth of 8 to 12 cm. The tip of the needle now lies in the psoas compartment. Needle placement can be confirmed with the aid of a nerve stimulator, by checking for stimulation of the quadriceps muscles, by eliciting paresthesias into the thigh, or by advancing the needle slightly into the psoas muscle and reconfirming a loss of resistance while withdrawing the needle slightly into the psoas compartment.

After the needle is properly placed, and after careful aspiration, 30 to 40 mL of local anesthetic is injected in 5-mL divided doses. It is often helpful to have the patient remain in the lateral position for a few minutes after injection to limit spread of the drug.

Inguinal Perivascular Technique and Femoral Nerve Block

The inguinal perivascular technique is also known as the *three-in-one block* of the lower extremity. The lumber plexus is "sandwiched" among the psoas major, quadratus lumborum, and iliacus muscles and is enclosed by the fascia of these three muscles.[63-66]

After the patient is positioned supine, the groin is prepared and draped by use of aseptic technique. One possible complication is contamination of the deeper tissues. An immobile needle can be used for improved control of the needle.

The site of injection is 1 cm lateral to the femoral artery and 1 cm inferior to the inguinal ligament. The identified area is prepped with a povidone-iodine (Betadine) solution and then infiltrated with 2 to 3 mL of 1% lidocaine solution subcutaneously. A 22-gauge, 4-cm insulated B-bevel needle is advanced perpendicularly to the skin just lateral to the artery until the femoral nerve is located with the aid of a peripheral nerve stimulator. With a stimulation frequency of 2 Hz, the intensity level is set at 1 mÅ until quadriceps extension is elicited, then decreased to less than 0.5 mÅ. Local anesthetic solution (20 to 30 mL) is injected in 3- to 5-mL increments, with intermittent syringe aspiration. Digital pressure is applied firmly but gently distal to the needle. This action assists in limiting the distal spread of the anesthetic solution by forcing it proximal into the channel formed by the neural sheath and other structures. Digital pressure is continued after the injection for approximately 5 to 10 minutes. Winnie et al.[61] indicated that the total volume of anesthetic solution required to maximize the block must exceed 20 mL. Volumes of less than 20 mL provide a spotty and unpredictable block. Increasing the volume of the solution to 30 mL increases the ability of the solution to contact all three nerves. Bupivacaine (0.5%), ropivacaine (0.5%), and lidocaine (1.5%) are commonly used for this procedure. Anesthesia to the sciatic distribution does not occur with this technique. If the surgical procedure requires anesthesia along the sciatic distribution, a separate procedure must be performed (Figure 45-26).[64-66]

Ultrasound-Guided Femoral Nerve Block

The femoral nerve emerges just below the inguinal ligament, lateral to the femoral artery, and deep to the fascia iliaca. The patient is positioned supine with the groin exposed. The ultrasound probe is placed axially anywhere between the inguinal crease and the inguinal ligament. The anchoring landmarks for visualization are the femoral artery and vein and the femoral nerve (Figure 45-27). The femoral nerve will appear triangular, hyperechoic, and lateral to the femoral artery. A 22-gauge, 2-inch needle is inserted lateral to the femoral nerve, in-plane to the ultrasound beam, and 20 mL of local anesthetic is injected.

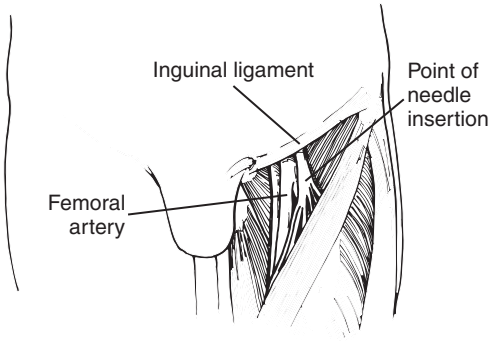

FIGURE **45-26** Femoral nerve block.

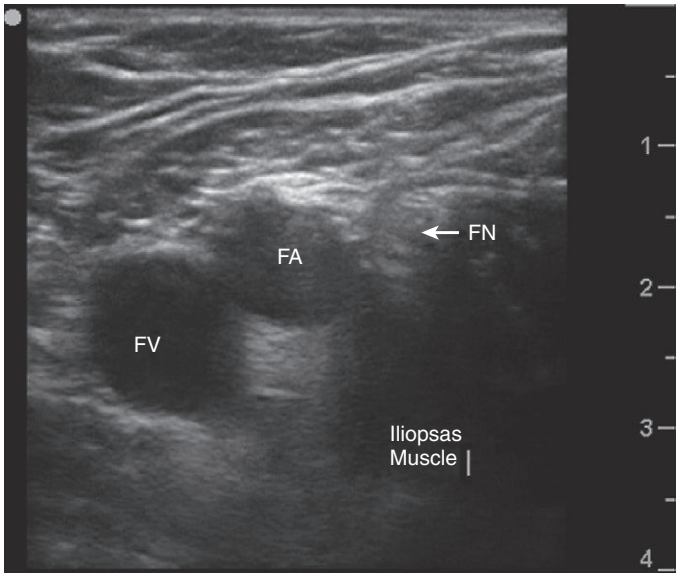

FIGURE **45-27** Transverse view of the femoral nerve lateral to the femoral artery and femoral vein. *FA*, Femoral artery; *FV*, femoral vein, *FN*, femoral nerve.

Continuous Femoral Nerve Block

Extension of the anesthesia and analgesia provided by a femoral nerve block through the use of a continuous catheter technique after surgical procedures of the femur and knee has grown in popularity and application. The success rate is high as long as the surgical procedure does not extend beyond the innervations of the femoral nerve. The landmarks are readily identifiable and include the femoral artery and the femoral crease immediately inferior to the inguinal ligament.

The patient is placed in the supine position and the skin is thoroughly prepped with an antiseptic solution. The practitioner stands on the side to be blocked. Sterile gloves are donned, and the needle insertion site is located at the lateral border of the femoral artery (approximately 1 cm lateral to the arterial pulse) in the femoral crease. A 17-gauge, 3½-inch insulated needle connected to a nerve stimulator set at 1 mÅ, 2 Hz, 100 to 300 μsec is inserted and advanced in the sagittal plane at a 45- to 60-degree cephalad angle. The technique is similar to single-injection femoral nerve block except for the more acute cephalad angle of needle insertion to facilitate threading of the catheter. Following a quadriceps muscle twitch (patellar twitch) at 1 mÅ, the current is reduced to 0.5 mÅ, and the twitch response is reestablished. If a quadriceps twitch is not elicited after initial needle placement, the needle should be withdrawn and redirected slightly more lateral to the femoral artery until the desired twitch response is achieved. An initial bolus of local anesthetic (15 to 20 mL) is injected slowly after negative aspiration for blood, and the catheter is then threaded 5 to 10 cm beyond the tip of the needle. The nerve stimulator can be connected to the catheter to confirm that the tip lies in close proximity to the femoral nerve. The catheter is then secured by one of several mechanisms. Kits available for continuous nerve block often contain a securing device, but the catheter may be secured through use of a suture and/or a clear dressing applied over the catheter. The continuous infusion of local anesthetic is initiated immediately after the bolus injection at a rate of 8 to 10 mL per hour. Typical local anesthetics and concentrations used for this purpose are 0.2% ropivacaine and 0.25% bupivacaine.

Strict aseptic technique should be adhered to during placement and maintenance of the catheter, and it has been recommended that the catheter be removed after 48 hours. In addition, as with all peripheral nerve blocks, complaints of pain during needle insertion or injection suggest intraneural penetration. In this event, the needle should be withdrawn and redirected. Insertion of the needle medially is likely to produce femoral artery and or vein penetration. If this occurs, constant pressure should be applied to the site for a period of not less than 2 to 3 minutes prior to another attempt at locating the nerve. The patient should be counseled with regard to the extended loss of sensation and motor control of the extremity and what action to take in the event of a potential complication upon discharge (see Box 45-2).

Fascia Iliaca Compartment Block

The fascia iliaca compartment block is an anterior lumbar plexus approach with a puncture point distant from the neurovascular sheath. A nerve stimulator is not necessary for this procedure. Described for the first time in children in 1989, fascia iliaca compartment block is widely used for postoperative analgesia after lower limb surgery in children and adults and provides effective postoperative analgesia after hip, femoral shaft, or knee surgery. Compared with three-in-one block, it provides a faster and more consistent simultaneous blockade of the lateral femoral cutaneous and femoral nerves. The fascia iliaca compartment block is performed as described by Dalens et al.[67] and others.[68,69] With the patient in a supine position, a projection of the inguinal ligament is drawn on the skin from the pubic tubercle to the anterior superior iliac spine and trisected. The puncture site is marked 1 cm caudal to the point at which the lateral meets the middle third of the inguinal ligament line. After disinfecting the skin using topical 10% povidone-iodine, a short-bevel needle (24 gauge, 50 mm) is inserted at a 90-degree angle to the skin. An initial loss of resistance is felt as the needle tip crosses the fascia lata. The needle is advanced at the same angle until a second loss of resistance is felt as the fascia iliaca is pierced (a paresthesia is not intentionally elicited), and 30 mL of local anesthetic is injected.

Sciatic Nerve Block

Sciatic nerve blocks, in combination with lumbar plexus, femoral, or saphenous nerve blocks, provide complete anesthesia and postoperative analgesia for lower-extremity surgery. Contrary to common belief, sciatic nerve block is relatively easy to accomplish and master.[70] In a recent review of outpatients undergoing complex knee surgery, it was noted that among the patients who received a combination sciatic nerve block with a femoral nerve block, a lower incidence of nursing interventions for pain occurred in the step-down unit.[63] In addition, patients had fewer hospital admissions and were more satisfied with their surgical procedures.[63,71]

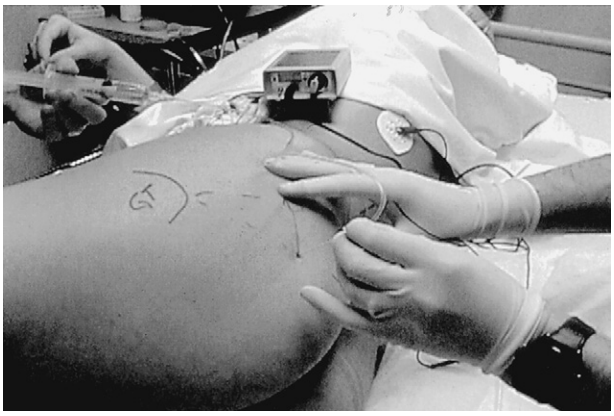

FIGURE **45-28** Sciatic nerve block.

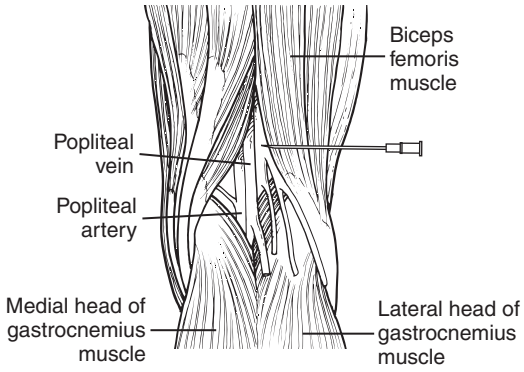

FIGURE **45-29** Popliteal nerve block.

Anatomy of the Sciatic Nerve

The sciatic nerve is the continuation of the upper division of the sacral plexus and is the largest nerve trunk in the body. It supplies the muscles of the back of the thigh, the skin of the leg, and the muscles of the lower leg and foot. It passes out of the pelvis through the great sacrosciatic foramen, below the piriform muscle. It descends between the major trochanter and the tuberosity of the ischium to the lower third of the thigh, where it divides into the internal and external popliteal nerves.[42,43]

Technique of Sciatic Nerve Block

Although posterior and lateral popliteal approaches to the sciatic nerve are performed most commonly for ankle and foot surgery, and higher approaches to the sciatic nerve are performed more commonly for surgery below, above, and at the knee, there is no clinical evidence to support one particular sciatic approach over another. The indications for a given approach are based on the specific surgical requirement (Figure 45-28).[63,71,72]

After standard monitors are placed, the patient is positioned in the Sims position with the operative leg positioned superiorly and flexed at the knee. A line is drawn from the posterior superior iliac spine to the greater trochanter of the femur. A second line is drawn from the sacral hiatus to the greater trochanter, and a third line is drawn perpendicular to and bisecting the first line. The intersection of the second and third lines is the point of needle entry. The identified area is prepared with a Betadine solution and then infiltrated with 2 to 3 mL of 1% lidocaine solution subcutaneously. A 22-gauge, 10-cm insulated B-bevel needle, inserted perpendicularly to the skin, is advanced until the posterior tibial nerve distribution is elicited with the aid of a peripheral nerve stimulator. A stimulation frequency of 2 Hz and an intensity level of 1 mÅ is used until a plantar flexion motor response is elicited. The intensity level is decreased to less than 0.5 mÅ as long as motor response is still present. Local anesthetic solution (10 mL) is injected in 5-mL increments, with intermittent syringe aspiration. The needle is redirected laterally and advanced until peroneal nerve distribution is elicited with the aid of a peripheral nerve stimulator. A stimulation frequency of 2 Hz and an intensity level of 1 mÅ is used until a dorsal flexion motor response is elicited. The intensity level is decreased to less than 0.5 mÅ as long as motor response is still present. Local anesthetic solution (10 mL) is injected in 5-mL increments, with intermittent syringe aspiration. Bupivacaine (0.5%), ropivacaine (0.5%), and lidocaine (1.5%) are commonly used for this procedure.[73,74]

Popliteal Fossa Approach to the Sciatic Nerve Block

The popliteal fossa approach is based on the use of the three anatomic landmarks that define the posterior popliteal fossa: the popliteal crease, the medial border of the femoris biceps muscle laterally, and the tendon of the semitendinous muscle medially.

A line is drawn joining the medial border of the femoris biceps muscle laterally and the lateral border of the semitendinous muscle medially at the level of the popliteal crease. From the middle of this line, a perpendicular line is extended 15 cm cephalad. The site of insertion of the needle is 1 cm laterally. A 10-cm insulated needle connected to a nerve stimulator is introduced through a skin wheal of local anesthesia at a 45- to 60-degree anterosuperior angle. The sciatic nerve usually is located at a depth of 1 to 2 cm in an adult. After careful aspiration, 35 to 40 mL of a local anesthetic is injected (Figure 45-29).

Ultrasound-Guided Popliteal Fossa Approach to Sciatic Nerve Block

The popliteal artery and vein can be located with the ultrasound probe placed in the popliteal region of the knee parallel to the flexor crease. The tibial nerve can usually be visualized at this level, just lateral and/or superficial to the popliteal vessels. Lateral to the nerve lies the biceps femoris muscle. Medial to the nerve lie the *semimembranosus* and *semitendinosus* muscles. Once the tibial nerve is identified at the flexor crease, the ultrasound probe is slid slowly proximal. The tibial nerve is joined by the common peroneal nerve approximately 5 to10 cm above the flexor crease to form the sciatic nerve (Figure 45-30). A 22-gauge, 2-inch needle is inserted lateral to the nerve, in-plane to the ultrasound beam, and advanced until the needle tip is adjacent to the nerve; 20 mL of local anesthetic is then injected under direct observation to envelope the tibial and common peroneal nerves (Figure 45-31).

Ankle Blocks

The ability to administer anesthesia to patients who require surgery of the foot offers valuable additional regional block options. Either a complete or partial block of the foot can provide adequate anesthesia for many of the surgical procedures performed by podiatrists and orthopedic surgeons. The nerves are easy to locate, and the procedures can be rapidly accomplished. This tool can prove invaluable in the care of certain patients, such as those with gangrene of the foot or those with diabetes who have foot ulcers, in whom a local anesthetic procedure would be inadequate.[75]

FIGURE **45-31** Transverse view of the popliteal fossa after injection of local anesthetic. *CP*, Common peroneal nerve; *TN*, tibial nerve; *PA*, popliteal artery; *LA*, local anesthetic.

Anatomy of the Ankle

The ankle block is performed by the blocking of five nerves at the level of the ankle: the tibial nerve, the sural nerve, the superficial peroneal nerve, the deep peroneal nerve, and the saphenous nerve.

Tibial Nerve. The tibial nerve arises from the nerve roots of the fourth and fifth lumbar roots, along with the first, second, and third sacral roots. It is the larger of the two branches of the sciatic nerve. The path of this nerve lies on the medial side of the Achilles tendon. It passes into the ankle with the posterior tibial artery (Figure 45-32). At the level of the ankle this nerve lies behind the posterior tibial artery and between the tendons of the long flexor muscles of the toes and the long flexor muscles of the great toe. The nerve is covered by the flexor retinaculum. Several branches

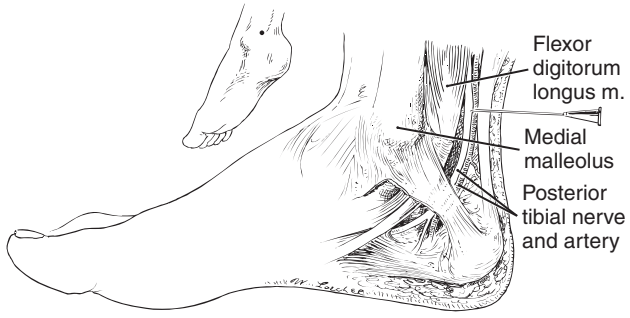

FIGURE **45-32** Path of the posterior tibial nerve, with the posterior tibial artery past the Achilles tendon. *m.*, Muscle.

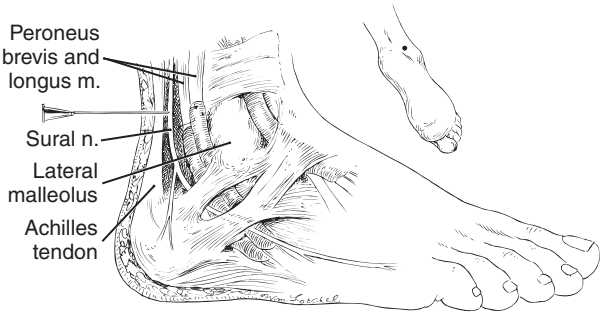

FIGURE **45-33** Path of the sural nerve behind the lateral malleolus into the ankle. *m.*, Muscle; *n.*, Nerve.

leave the neural bundle at the level of the medial malleolus. Two of the branches, the medial and the lateral plantar nerves, traverse the ankle, following under the cover of the abductor hallucis. They provide sensory innervation to the foot.[56,62]

Sural Nerve. The sural nerve is formed from the union of a branch of the tibial nerve and the common peroneal nerve. This nerve travels superficially with the short saphenous nerve behind the lateral malleolus into the ankle, where it provides the sensory innervation to the posterior portion of the sole of the foot, as well as to the posterior portion of the heel and the portion of the Achilles tendon immediately above the ankle (Figure 45-33).[56,62]

Superficial Peroneal Nerve. The superficial peroneal nerve arises from the roots of the fourth and fifth lumbar nerve roots, as well as the first and second sacral nerve roots. The nerve becomes superficial in the middle two thirds of the lower leg and remains subcutaneous as multiple branches proceed into the dorsum of the foot. Just above the ankle (Figure 45-34) the nerve begins to branch; for this reason a single injection site does not provide sufficient anesthesia.[56,62]

Deep Peroneal Nerve. The deep peroneal nerve arises from the same nerve roots as the superficial peroneal nerve. However, it remains within the protection of the anterior tibial muscle and the long extensor muscle of the great toe (see Figure 45-34) as it traverses the leg and into the ankle. As it crosses the ankle, it is covered by the extensor retinaculum. The deep peroneal nerve provides innervation to the short extensors of the toes and provides sensory innervation to the skin on the lateral side of the hallux and on the medial side of the second digit. The nerve and the artery cross each other, so the nerve lies lateral to the anterior tibial artery and medial to the long extensor muscle of the great toe that is in the ankle. This nerve is frequently missed when regional anesthesia is administered to the ankle.[56,62]

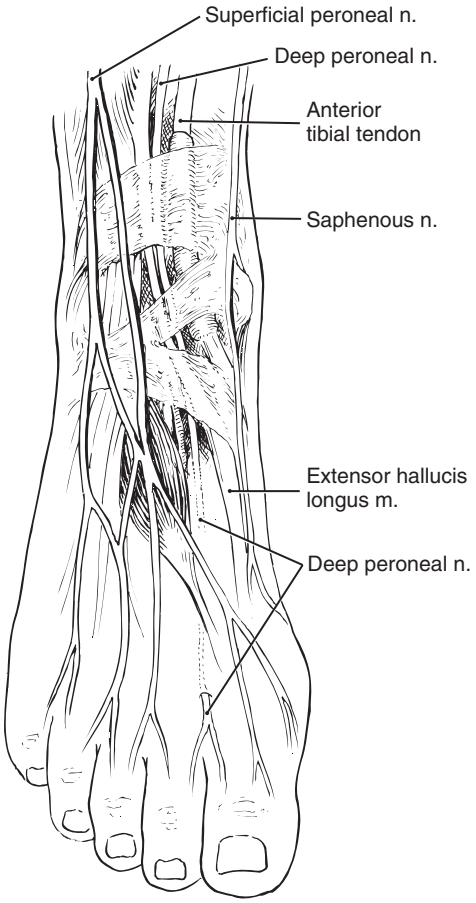

FIGURE **45-34** The superficial peroneal nerve proceeds to the dorsum of the foot subcutaneously through multiple branches. *n.*, Nerve.

Saphenous Nerve. The saphenous nerve is the terminal branch of the femoral nerve and travels subcutaneously from the lateral side of the knee joint. It follows the greater saphenous vein to the medial malleolus and provides sensory innervation to the medial side of the malleolus and the skin of the medial aspect of the lower leg (see Figure 45-34). If the block of this nerve is inadequate, the patient is unable to tolerate a tourniquet above the ankle.[56.62]

Ankle Block Technique

The approach to both the sural and the posterior tibial nerves can be enhanced by placing the patient in the prone position. However, this is not always the most comfortable position. Therefore, the patient should be placed in the most comfortable position that permits sufficient mobility of the foot. Rotation of the foot from side to side can be facilitated by turning the patient onto either side or elevating the foot on towels or pillows. The posterior tibial artery is palpated at the level of the superior portion of the medial malleolus. After the artery is located, the needle is inserted lateral to the artery in a line drawn from the superior portion of the medial malleolus to the lateral malleolus across the Achilles tendon. If the artery is not palpated, the needle is inserted lateral to the Achilles tendon at the level of the superior portion of the medial malleolus. The needle is advanced toward the medial malleolus and lateral to the position of the posterior tibial artery. As the needle is advanced toward the outer aspect of the medial malleolus, a paresthesia may be elicited. If this occurs, 5 mL of the anesthetic solution is injected with the needle held in position, and an additional 3 mL is injected as the needle is withdrawn. If a paresthesia is not elicited, the medial malleolus is gently contacted with the needle tip and withdrawn 2 mm from the bone. The anesthetic solution is slowly injected at this position, and the location is gently massaged after the injection.

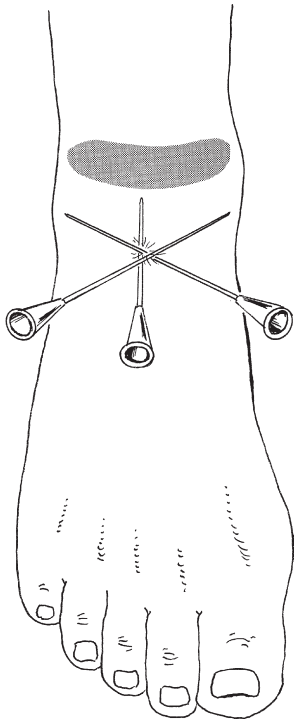

FIGURE **45-35** Direction and redirection of the needle in the ankle block technique.

With the patient in the same position, the line from the medial malleolus across the Achilles tendon is identified on the lateral malleolus. The needle is inserted under the skin along the lateral border of the Achilles tendon in the plane with the line that is between the medial and lateral malleoli. The needle is advanced subcutaneously toward the superior edge of the lateral condyle, and 5 mL of solution is injected in the subcutaneous tissues as the needle is withdrawn. The solution must reach the superior edge of the lateral malleolus to anesthetize all the fibers of the sural nerve.

The patient is then placed in the supine position, and the anterior ankle is prepared for the block. For blocking of the deep peroneal nerve, a line is drawn from the superior edge of the medial malleolus to the superior border of the lateral malleolus across the anterior portion of the ankle. The tendons of the anterior tibial muscle and the long muscles of the great toe are identified by having the patient flex the foot against resistance. Where the line crosses the midpoint between the two tendons, the needle is inserted toward the tibia (Figure 45-35). As the needle advances through the fascia, a paresthesia may be elicited. If the paresthesia is not obtained, the needle is slowly advanced until the needle gently contacts the tibia. As the needle is withdrawn from contact with the tibia, 5 mL of anesthetic solution is injected. The needle is then withdrawn through the fascia, and an additional 3 mL of solution is injected.

With the needle remaining in the subcutaneous tissue, the needle direction is changed. The needle is advanced toward the inferior border of the lateral malleolus. The superficial peroneal nerve is located in subcutaneous tissue at this level. While the needle is

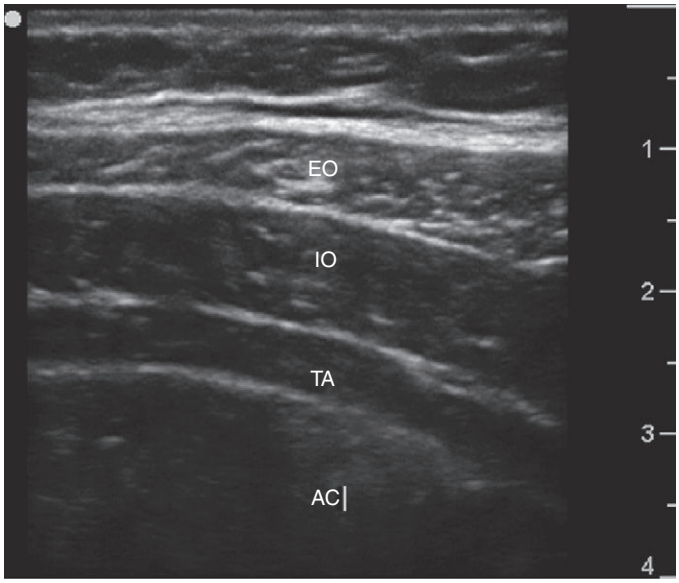

FIGURE **45-36** Anatomy of the transversus abdominis plane block. *EO*, External oblique muscle; *IO*, internal oblique muscle; *TA*, transversus abdominis muscle; *AC*, abdominal contents.

being withdrawn, 5 mL of anesthetic solution is injected. A subcutaneous ring develops that should reach the lateral malleolus.

The needle is withdrawn to the midpoint, and the needle direction is again changed. The needle is redirected to the inferior border of the medial malleolus. The saphenous nerve is in the subcutaneous tissue, superficial to the saphenous vein. If the needle is not superficial, the saphenous vein is entered; 5 mL of solution is injected toward the medial malleolus. As the needle is withdrawn, 3 mL is injected. The deep peroneal and the posterior tibial nerves are the only nerves of the ankle that are not in the subcutaneous tissue.

ULTRASOUND-GUIDED TRANSVERSUS ABDOMINIS PLANE BLOCK

The abdominal wall between the iliac crest and the subcostal margin consists of the external oblique, internal oblique, and transversus abdominis muscles. The transversus abdominis is the deepest muscle layer, and below it lies the peritoneum. The transversus abdominis plane (TAP) block is used to place local anesthetic in the lateral abdominal wall between the internal oblique and the transversus abdominis muscles. The objective is to block the segmental nerves within this plane (T9-12 and L1) with a single injection of local anesthetic. The patient is placed in the supine position with the ultrasound probe positioned transversely between the margin of the twelfth rib and the anterior superior iliac spine. A 21-gauge, 4-inch needle is inserted using an in-plane to the ultrasound beam approach. The needle is inserted through the muscle layers until the tip lies between the internal oblique and transversus abdominis muscles (Figure 45-36). Loss of needle resistance may be appreciated when the needle penetrates the external oblique muscle and again when penetration of the internal oblique occurs; 20 mL of local anesthetic may be injected bilaterally.

SUMMARY

Regional anesthesia techniques for upper- and lower-extremity blocks can be invaluable for specialized surgical procedures and immediate and long-term pain relief. There are a wide variety of techniques to achieve regional anesthesia: subarachnoid, epidural, caudal, brachial plexus, lumbar plexus, selective block of the upper- and lower-extremity nerves, intravenous infusion, intercostal nerve block, and specialized trauma techniques. Placement of these blocks can be facilitated by technology such as the peripheral nerve stimulator and ultrasonographic nerve location. Regional block may be used alone or in combination with general anesthesia and offers patients and surgeons excellent options for safe, effective anesthesia and analgesia.

Obstetric Anesthesia

◆ *Brian J. Kasson*

CHAPTER 46

Parturients who request or require obstetric anesthesia services represent a unique challenge to anesthesia providers. Techniques for providing pain relief during labor and delivery are continuously being refined in an effort to provide the best care possible. A thorough understanding of the anatomic and physiologic changes that occur during pregnancy and the anesthetic considerations associated with such changes are necessary for a safe and effective anesthetic course.

ANATOMIC AND PHYSIOLOGIC CHANGES DURING NORMAL PREGNANCY

The physiologic changes seen in pregnancy result from increased metabolic demands and hormonal and anatomic changes. These changes begin early in pregnancy and continue into the postpartum period. These marked changes have significant implications for the anesthesia provider.

Cardiovascular Changes

Cardiovascular changes begin as early as the fourth week of pregnancy and then continue into the postpartum period.[1] The heart rate is increased by 20% to 30% at term. This increase begins in the first trimester and peaks by 32 weeks of gestation.[2] Normal heart rate (HR) variability does not appear to be changed until late in pregnancy, when tachyarrhythmias are more common.[3] Cardiac output increases by approximately 40% over nonpregnant values.[4] This increase in cardiac output begins in the fifth week of pregnancy and results from an increase in stroke volume (SV) (20%-50%) and, to a lesser extent, heart rate.[5] Cardiac output increases consistently throughout pregnancy.[6] Some studies previously indicated cardiac output decreased in the third trimester, but these results were likely due to aortocaval compression from studying subjects in the supine position.[7] At term, approximately 10% of the cardiac output perfuses the gravid uterus.[8,9] When a woman is in labor, cardiac output increases during uterine contractions as a result of autotransfusion from the contracting uterus to the central circulation.[10]

Immediately after delivery, cardiac output increases as much as 80% above predator values as a result of an increase in central volume from the now contracted uterus and relief of aortocaval compression. As a result, patients with preexisting cardiac anomalies are at an increased risk for decompensation in the immediate postpartum period. Cardiac output gradually returns to baseline within 14 days as HR and SV normalize.[11]

During pregnancy the diaphragm rises, shifting the heart up and to the left, making the cardiac silhouette appear enlarged on x-ray examination. The ventricular walls thicken and end-diastolic volume increases. A physical examination of the pregnant patient may appear to elicit abnormal findings. A benign grade 1 or 2 systolic murmur or a third heart sound may be heard on auscultation.[12] These findings would not be unusual; however, if the systolic murmur is greater than grade 3 or accompanied by chest pain or syncope, further evaluation is necessary. Diastolic murmurs and cardiac enlargement are considered pathologic. Normal pregnancy also may result in signs of cardiac abnormality such as exercise intolerance, shortness of breath, and edema.

Total blood volume increases 25% to 40% throughout pregnancy, in part to prepare for the normal blood loss associated with delivery. Plasma volume increases 40% to 50% whereas red blood cell (RBC) volume increases by only 20%.[13] As a result, a relative or dilutional anemia is commonly seen as the plasma volume increases to a greater extent relative to the actual RBC volume. The increased plasma volume is likely the result of greater circulating levels of progesterone and estrogen resulting in enhanced renin-angiotensin-aldosterone activity.[14] RBC volume increases as a result of elevated erythropoietin levels seen after the eighth week of gestation.[15] The average blood loss for a vaginal delivery is 500 mL, and for an uncomplicated cesarean section, the blood loss is 800 to 1000 mL. Normal blood losses at delivery are generally well tolerated in the healthy parturient as a result of these compensatory mechanisms. In labor each contraction moves 300 to 500 mL of blood from the contracting uterus to the central circulation.[16] Pregnant women have greater baroreflex-mediated changes in HR at term than at 6 to 8 weeks postpartum.[17] In the presence of adequate neuraxial analgesia and little sympathetic stimulation, there is often a corresponding decrease in maternal heart rate during uterine contractions due to the transiently increased preload.

Systemic vascular resistance (SVR) decreases as much as 21% by the end of a term pregnancy, owing in large part to decreased resistance in the uteroplacental, pulmonary, renal, and cutaneous vascular beds.[18,19] At term gestation 10% of the cardiac output perfuses the low resistance intervillous space of the uterus. Baseline central sympathetic outflow is twice as high in normal, term pregnant women as in nonpregnant women.[20] The venous capacitance system loses tone, allowing pooling of the larger blood volume. This decrease in SVR results in little overall systolic blood pressure change during normal pregnancy, despite the increased blood volume.[21] A decrease in diastolic blood pressure of up to 15 mmHg may occur, resulting in a decrease in mean pressure.

Aortocaval Compression

In the early 1950s a syndrome of supine hypotension was identified in term or near-term pregnant women.[22,23] This syndrome is caused by compression of the vena cava by the gravid uterus, which restricts venous return to the heart when the parturient lies in the supine position. Compression can be more severe when the abdomen is tense or when the uterus is larger than normal, as in polyhydramnios or multiple gestation pregnancies. This decreased venous return results in a significant reduction in SV and, ultimately, cardiac output. The resultant hypotension can be severe enough to cause loss of consciousness in some women.

Maximal decreases in blood pressure may require up to 10 minutes to develop; however, some women experience the decrease almost immediately. The normal physiologic responses to aortocaval compression are tachycardia and vasoconstriction of the lower extremities. Despite this attempted compensation, uterine blood flow and therefore fetal oxygenation are reduced.[24] Figure 46-1 depicts changes in aortocaval compression with changes in position.

In addition to compressing the vena cava, the gravid uterus may compress the abdominal aorta. For this reason, supine hypotensive syndrome is more correctly referred to as *aortocaval compression*. When the abdominal aorta is compressed, upper-body blood pressure remains relatively normal, whereas blood pressure distal to the site of aortic compression (uterus and lower extremities) may be significantly reduced.

Compression of the aorta and vena cava can usually be relieved by shifting the uterus to the left (left uterine displacement) or by lying on the side.[25] Left uterine displacement can be accomplished by rotation of the operating room table 15 degrees to the left or by placing a 15-cm-high wedge under the parturient's right hip and back, as shown in Figure 46-1. Most anesthetists have been shown to underestimate the angle of tilt they provide, so care should be taken to ensure adequate left uterine displacement.[26] In women with an exceptionally large uterus, greater displacement may be necessary to be effective. In a small percentage of women, right uterine displacement may be more effective than left displacement, although in the majority of cases, right uterine displacement results in stroke volumes that are no better than those measured with the patient in the supine position.

Neuraxial anesthetics result in an autonomic sympathectomy, thereby reducing compensatory lower-extremity vasoconstriction resulting in a greater potential for hypotension. There has been much debate regarding the optimal position for performing neuraxial anesthesia for labor analgesia and cesarean delivery. Many clinicians feel that the lateral position is optimal to facilitate both maternal and fetal hemodynamics. Researchers compared four positions: supine with a 15-degree left tilt, sitting with neck and hips flexed, and flexed left lateral and flexed right lateral positions. They found that maternal cardiac index (CI) was significantly higher in the right lateral position compared with the sitting and supine positions. It was also higher in the left lateral compared with sitting position. Maternal stroke volume index, heart rate, and systolic blood pressure were higher in the lateral positions compared with the sitting and supine-tilt positions. There were no significant differences in fetal heart rate, pulsatility index, or resistivity index among positions. Although positioning for neuraxial anesthesia may influence maternal hemodynamic variables, there were no difference in healthy fetal blood flow indices among positions, suggesting that these changes are not clinically significant.[27]

Hematologic Changes

In general, the parturient is said to be "hypercoagulable." Levels of factors VII through X and fibrinogen are increased. In the nonpregnant state, fibrinogen levels average from 200 to 400 mg/dL. Late in pregnancy, fibrinogen levels are normally at least 400 mg/dL and may be as high as 650 mg/dL. These increased levels place the parturient at risk for thromboembolic events, which remain one of the leading causes of maternal mortality. The platelet count remains stable or is decreased slightly in the third trimester. The prevalence of maternal thrombocytopenia (platelet count less than 150×10^9/L) in normal pregnancy has been shown to be 11.6% [28] and is not associated with increased morbidity or mortality. The pathogenesis is not well understood but may involve factors such as hemodilution and/or accelerated platelet clearance.[29,30]

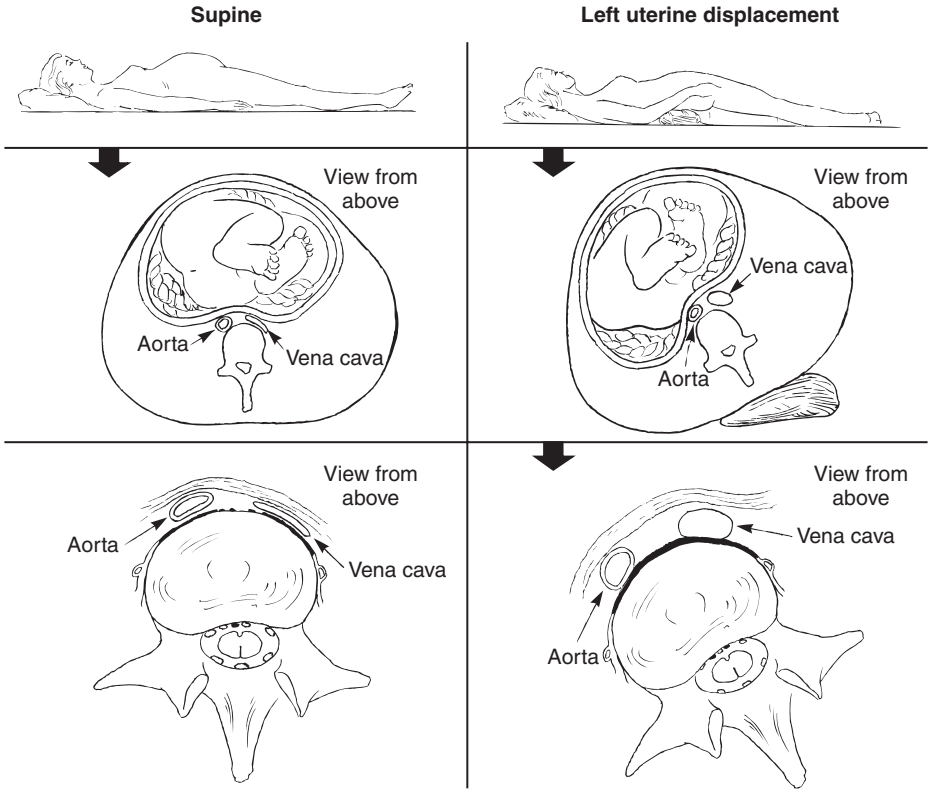

FIGURE **46-1** Effects of left uterine displacement on the diameter of the abdominal aorta and vena cava.

The white blood cell (WBC) count rises in pregnancy. In the third trimester, the mean is 10,500/mm^3, and in labor the count may increase to 20,000 to 30,000/mm^3.[31]

Respiratory Changes

The respiratory changes that accompany normal pregnancy are of particular importance to the anesthesia provider. Capillary engorgement in the upper airway results in a narrowed glottic opening and edema in the nasal and oral pharynx, larynx, and trachea. These changes carry over into labor, as has been shown by the Mallampati score changing as labor progresses.[32] Airway tissues are friable and susceptible to damage and bleeding during placement of airway adjuncts. For this reason, nasal intubation in the parturient should generally be avoided. A 6.5- to 7.0-mm cuffed oral endotracheal tube is recommended when intubation is necessary. Obese patients with enlarged breasts may benefit from the use of a short-handled laryngoscope.

Term pregnancy is accompanied by an increase in oxygen (O_2) consumption of up to 33% at rest and 100% or more during the second stage of labor. Minute ventilation at term is increased by 50%. This is primarily due to a 40% increase in tidal volume, whereas the respiratory rate is stable or increased by only 10%.[33] By 12 weeks' gestation the normal arterial partial pressure of carbon dioxide (CO_2) decreases to approximately 30 to 32 mmHg, and remains in this range throughout pregnancy.[34] Metabolic alkalosis is rarely seen because there is a compensatory decrease in the serum bicarbonate from 26 to 22 mEq/L. The normal arterial partial pressure of O_2 is greater than 100 mmHg.

The functional residual capacity (FRC), expiratory reserve volume, and residual volume are decreased primarily as a result of upward pressure on the diaphragm, with results functionally similar to restrictive lung disease. The FRC plays an important role in preserving O_2 saturation during periods of hypoventilation or apnea. The decrease in FRC (20%) combined with the increase in O_2 consumption in pregnancy commonly results in rapid arterial desaturation in the apneic pregnant patient.[35] Morbid obesity, labor, and sepsis exaggerate this effect.[36] For this reason, pre-oxygenation with 100% O_2 prior to induction of general anesthesia is important. Closing capacity (CC) does not change, which results in a decreased FRC/CC ratio often leading to small-airway closure before the tidal volume has been exhaled. This mechanism may explain the reduction in O_2 saturations seen in parturients during natural sleep. When compared with nonpregnant controls, whose average oxygen saturation during sleep was 98.5%, healthy near-term pregnant women averaged only 95.2%, with temporary desaturations below 90% not being uncommon.[37] The increased cardiac output and a shift to the right in the oxyhemoglobin dissociation curve help to maximize oxygen delivery.

Minute ventilation can increase up to 300% during contractions and cause maternal arterial partial pressure of CO_2 to drop below 15 mmHg. This alkalemia can cause hypoventilation between contractions, resulting in hypoxemia. Some evidence indicates that hyperventilation may cause a decrease in uterine blood flow. However, in animal studies this finding has usually been associated with stressful events such as intubation and invasive procedures. In pregnant, laboring human volunteers, hyperventilation to an arterial partial pressure of CO_2 of 20 mmHg does not appear to harm the fetus. Specifically, the fetus does not develop hypoxia or acidosis as determined by analysis of a scalp blood sample. However, in the presence of a complicated labor with preexisting fetal compromise, the effects could be detrimental.[38]

Nervous System Changes

Beginning in the first trimester pregnant women have an increased sensitivity to local and general anesthetics.[39-42] The exact mechanism remains unclear, but animal studies have demonstrated a variable reduction in the minimum alveolar concentration (MAC) of inhalation agents in rabbits chronically exposed to progesterone.[39] In pregnant rats, the effects of endorphins on pain thresholds are also demonstrated, which may also be an important factor. Additionally, research and clinical experience have demonstrated an increase in the sensitivity of nerves to local anesthetics during pregnancy.[39-43] Mechanical changes within the epidural space also may play a role in the increased block height seen in pregnancy. Epidural veins become engorged as a result of increased intraabdominal pressure and cause a decrease in the volume of both the epidural and subarachnoid spaces.

Gastrointestinal Changes

The parturient is at increased risk for regurgitation and aspiration of gastric contents because of anatomic and physiologic changes associated with pregnancy. A significant number of pregnant women, and women immediately postpartum, have gastric volumes in excess of 25 mL and gastric pH below 2.5.[44] Ultrasound has demonstrated solid food in the stomach of almost two thirds of women in whom neuraxial analgesia had been instituted and in the stomach of more than 40% of laboring women who had not eaten in 12 to 24 hours.[45] Increased levels of gastrin during pregnancy result in greater gastric volume and lower pH. Upward displacement of the stomach by the gravid uterus may result in mechanical obstruction to outflow through the pylorus, delayed gastric emptying, and increased intragastric pressure. Elevated levels of progesterone, a smooth-muscle relaxant, also decrease gastric motility and cause a reduction in lower-esophageal sphincter tone. This explains the heartburn frequently experienced by pregnant women. Gastrointestinal changes do not completely normalize until several weeks postpartum.

The onset of labor is accompanied by a further reduction in the rate of gastric emptying in part due to pain and the use of parenteral opioids. Recently published practice guidelines allow for the modest amounts of clear fluids in uncomplicated laboring patients. Uncomplicated patients undergoing elective cesarean delivery may have modest amounts of clear liquids up to 2 hours prior to induction of anesthesia. The same guidelines state that patients with additional risk factors for aspiration (e.g., morbid obesity, diabetes, difficult airway), or patients at increased risk for operative delivery (e.g., nonreassuring fetal heart rate pattern) may have further restrictions of oral intake.[46] Administration of nonparticulate antacids, H_2 receptor antagonists (to decrease gastric pH), and metoclopramide (to promote gastric emptying, reduce nausea and vomiting, and increase lower esophageal sphincter tone) may be beneficial prior to anesthesia and should be considered. The use of these drugs is advocated when a general anesthetic becomes necessary. When a general anesthetic is used, a rapid sequence induction with cricoid pressure using a cuffed endotracheal tube is necessary from the twelfth week of gestation to the immediate postpartum period.

Hepatic Changes

During pregnancy, levels of aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and alkaline phosphatase increase to the upper limits of nonpregnant normal levels. Serum albumin concentration decreases somewhat, and this decrease may result in increased free fractions of highly protein-bound drugs. Serum cholinesterase activity decreases by 30% or

BOX 46-1

Key Points Regarding Physiologic Changes in Pregnancy

- Cardiac output increases mostly because of an increase in stroke volume and, to a lesser extent, an increase in heart rate.
- Blood volume is markedly increased and prepares the parturient for the blood loss associated with delivery.
- Plasma volume is increased to a greater extent than red blood cell volume, resulting in a dilutional anemia.
- Minute ventilation increases 45%, and this is due mostly to an increase in tidal volume.
- Oxygen consumption is markedly increased; carbon dioxide production is similarly increased.
- Pregnant women have an increased sensitivity to local anesthetics and a decreased minimum alveolar concentration (MAC) for all general anesthetics.
- Platelet count remains stable or decreases slightly; coagulation factors and fibrinogen are increased, resulting in a hypercoagulable state in pregnancy.
- Aortocaval compression results in profound hypotension and can be relieved by left uterine displacement.
- All pregnant women are at increased risk of aspiration because of the anatomic and physiologic changes to the gastrointestinal system and should be considered to have a full stomach after week 12 of gestation.
- Pregnancy and labor are associated with significant airway changes that can result in a difficult intubation. This highlights the importance of careful airway examination prior to general anesthesia.

more during the first or second trimester. Although activity recovers slightly by term, it remains reduced compared with prepregnant values. Despite these decreases in cholinesterase activity, clinically relevant prolongation of the duration of action of drugs that depend on cholinesterase for elimination, such as succinylcholine and remifentanil, is uncommon in women with genotypically normal cholinesterase enzymes.

Renal Changes

During pregnancy, increased cardiac output leads to increased renal plasma flow and increased glomerular filtration rate (GFR). Creatinine clearance rises to 140 to 160 mL/min. As a result, the level of blood urea nitrogen decreases to approximately 8 mg/dL and creatinine decreases to approximately 0.5 mg/dL. Urinary excretion of glucose is common in the absence of disease and is attributable to increased GFR and reduced renal absorption. The urinary excretion of protein in normal pregnancy is slightly elevated toward the upper limits of normal.[47] The gravid uterus may occasionally produce mechanical obstruction of a ureter. Some key points to remember regarding physiologic changes in pregnancy are given in Box 46-1. A summary of the physiologic changes in pregnancy at term appears in Table 46-1.

Uterine Blood Flow

The uterus undergoes tremendous changes during pregnancy. The uterus enlarges, and its blood flow increases to meet both uterine and fetal metabolic demands. Uterine blood flow is supplied by two uterine arteries that are thought to be maximally dilated throughout pregnancy. Placental blood flow on the uterine side is supplied via the maternal arcuate, radial, and spiral arteries. The spiral arteries expel blood into the intervillous space. The maternal venous sinuses receive blood from the intervillous space and return it to the general circulation. Uterine blood flow at term

TABLE 46-1 Summary of the Physiologic Changes in Pregnancy at Term

Parameter	Change	Amount
Heart rate	↑	20%-30%
Stroke volume	↑	20%-50%
Cardiac output	↑	40%
Systemic vascular resistance	↓	20%
Total blood volume	↑	25%-40%
Plasma volume	↑	40%-50%
Red blood cell volume	↑	20%
Coagulation factors	↑↑	
Platelets	No change or ↓	
Minute ventilation	↑	50%
Tidal volume	↑	40%
Respiratory rate	↑	
Functional residual capacity	↓	20%

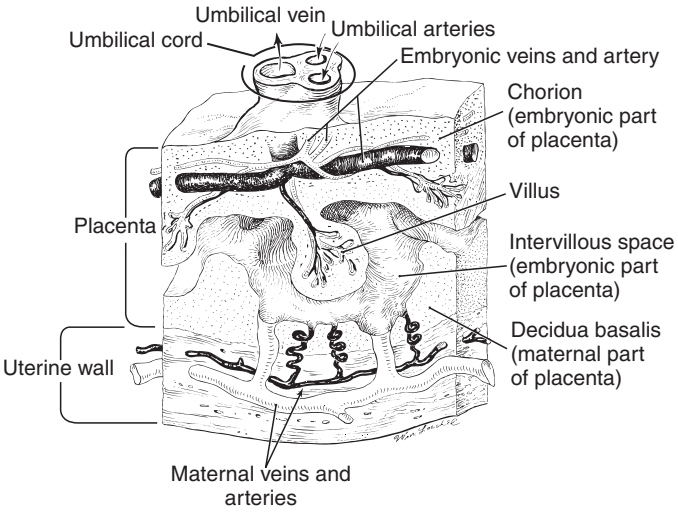

FIGURE 46-2 Cross section of the uteroplacental interface and the maternal and fetal blood supply.

increases to a maximum of 800 mL/min, accounting for approximately 10% of maternal cardiac output. Of this, approximately 150 mL/min supplies nutritive flow to the myometrium, and 100 mL/min flows to the decidua (the lining of the uterus); the remainder flows to the intervillous space.

The fetus sends O_2-poor blood to the placenta via two umbilical arteries. These vessels perfuse capillary networks within placental villi that protrude into the pool of maternal blood. Placental villi are small, fingerlike projections, the purpose of which is to maximize the placental surface area in contact with maternal blood. Each villus contains a capillary network that exchanges respiratory gases, nutrients, and wastes with maternal blood (Figure 46-2). Both O_2 and CO_2 diffuse through placental tissue readily and are considered to be "perfusion limited," meaning their transfer to the fetus is limited only by the perfusion of the placenta, not by the rate of diffusion of the gases. Therefore, decreases in maternal uterine artery blood flow or increases in placental vascular resistance decrease fetal oxygenation.

Autoregulation of intervillous blood flow does not seem to occur. The spiral arteries, however, do constrict in response to α-agonists (e.g., phenylephrine). However, recent human studies indicate phenylephrine does not appear to be harmful to the fetus

when used at clinically relevant doses.[48] Patients with preeclampsia (formerly called *pregnancy-induced hypertension*, or PIH) can develop placental insufficiency at systolic pressures greater than 100 mmHg. Unlike patients who receive neuraxial anesthesia, patients receiving inhalation anesthesia seem to maintain adequate placental blood flow, despite somewhat reduced blood pressure; this may be a function of altered uterine blood flow, altered fetal O_2 requirements, or both.

Placental Transfer and Fetal Effects of Drugs

Placental transfer of free (non–protein-bound) drug is dependent on the magnitude of the concentration gradient, the molecular weight, lipid solubility, and state of ionization. Drugs with molecular weights greater than 1000 daltons (Da) cross the placenta poorly, whereas drugs with weights less than 500 Da cross easily. Most drugs that are administered to the parturient are relatively small compounds and are thus able to cross to the placenta readily. However, size is only one of the determinants of permeability.

Transfer of drugs from the maternal circulation to the fetal unit is determined primarily by diffusion. Factors that favor diffusion include low molecular weight, high lipid solubility, low degree of ionization, and low protein binding. Cell membranes consist primarily of phospholipids such that a drug's degree of lipid solubility favors its passage through a cell membrane. Highly lipid-soluble drugs such as fentanyl cross readily. On the other hand, ionized drugs are polar and water soluble, which inhibits diffusion through lipophilic cell membranes. Local anesthetics are examples of variably ionized basic compounds, whereby the degree of ionization is dependent on the ambient pH; the more alkaline the pH, the greater the degree of nonionization. It is the nonionized portion that crosses phospholipid membranes readily. Nondepolarizing muscle relaxants are an example of large, ionized drugs that are not affected by ambient pH because of the quaternary groups in their structure and are inhibited from crossing the placenta.

When a drug enters the fetal circulation, a variety of factors minimize the effects on the fetus. First among them is dilution. Before reaching the fetus, a drug is diluted in intervillous blood, absorbed by the placenta, further diluted in placental blood, and then circulated to the fetus. Once in the fetus, the drug is distributed within the fetal intravascular volume and redistributed to fetal tissues. Umbilical venous blood from the placenta must first pass through the liver on the way to the fetal heart. The resultant hepatic enzyme activity likely reduces serum drug levels before entering the general fetal circulation. Other factors limit the effects of maternally administered drugs on a fetus. Approximately one fifth of the fetal cardiac output returns directly to the placenta because of shunt flow through the foramen ovale and ductus arteriosus. This shunted blood does not circulate, and any drug it contains does not have a systemic fetal effect.

The acid-base status of the fetus may affect the accumulation of a drug. A fetus who has become acidotic will alter the degree of ionization of a drug, potentially resulting in "ion trapping" leading to accumulation. For a complete discussion of fetal ion trapping see Chapter 10.

LABOR AND DELIVERY

Pain in Labor and Delivery

First-stage labor pain is primarily the result of cervical distension, stretching of the lower uterine segment, and possibly, myometrial ischemia. The resultant nonspecific nociceptor visceral stimulation is carried to the central nervous system by afferent unmyelinated C fibers that enter the cord at the T10, T11, T12, and L1 segments (Table 46-2 and Figure 46-3). Thus the pain of first-stage labor is frequently described as nonlocalized aching or cramping. Second-stage labor begins when cervical dilation is complete and the presenting part descends into the pelvis. At this time, a second pain pathway becomes important. Compression and stretching of the pelvic musculature and perineum produce pain that is mediated by somatic afferent fibers carried via the pudendal nerves that enter the spinal cord at the S2, S3, and S4 levels. A neuraxial anesthetic that extends from T10 to the sacral nerve roots can be effective in relieving the pain of both first- and second-stage labor.

The experience of pain is a highly personal phenomenon, and pain tolerance varies widely from one individual to the next. Many factors outside a parturient's control are also related to the perception of pain; these range from the presence or absence of social support to physical factors such as fetal presentation. Labor and vaginal delivery can be described as a process in which three essential components must work in concert. First, the fetus must be properly positioned and of an appropriate size to ensure passage through the bony pelvis, dilating cervix, and vagina. Second, the uterus must contract regularly and effectively. Third, the pelvic outlet itself must be configured in such a way that the fetus can pass. A flaw in any of these three elements can result in a difficult, painful, and prolonged labor. A few women are able to tolerate labor and delivery without significant discomfort; others experience pain in excess of their ability to cope. When women choose labor analgesia, it can make the birth process more enjoyable and provide the opportunity to better control their bodies and environment, thereby allowing them to maintain personal dignity.

TABLE 46-2 Pain Pathways During Labor

Area	Innervation	Comments
Uterus and cervix	T10 to L1-L2	Pain impulses carried in visceral afferent type C fibers
Perineum	S2, S3, and S4	Pain impulses carried by somatic nerve fibers; pudendal nerves

FIGURE **46-4** Curve representing average dilation for nulliparous patients in labor. (Redrawn with modifications from Miller RD, et al. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010.)

Stages of Labor and Delivery

Labor is defined as progressive dilation of the cervix in response to uterine contractions. Although sporadic and irregular third-trimester contractions are common, labor is not said to begin until those contractions are regular and result in a change to the cervix. Labor is generally divided into three stages. First-stage cervical changes consist of effacement and dilation. The first stage is further divided into at least the latent and active phases. The latent phase is of variable duration and is defined as the period between the onset of labor and the point at which the cervix begins to rapidly change.[49] Active phase usually begins at 2 to 3 cm dilation and is the period during which the cervix undergoes its maximum rate of dilation.

The second stage begins at full cervical dilation (10 cm) and ends with delivery of the fetus. The third stage encompasses the delivery of the placenta. The length of time it takes to progress through these stages is dependent on parity, effective uterine contractions, the size and type of pelvis, and fetal presentation. The Friedman curve is used to track the normal progress of labor (Figure 46-4). Cervical dilation normally progresses 1 to 1.2 cm/hr during the active phase of labor. When labor progress no longer follows the normal pattern, it is considered a "dysfunctional labor," and may require the use of oxytocin to augment contractions.

Intrapartum Fetal Evaluation

Intrapartum fetal heart rate (FHR) monitoring is now used routinely in the United States. Although continuous or intermittent FHR monitoring is not a specific predictor of fetal well-being, it is the most readily available method for the assessment of fetal condition. Intermittent monitoring can be performed using a manual stethoscope known as a fetoscope. Continuous FHR monitoring is accomplished using either external Doppler ultrasonography or an internal fetal electrocardiography electrode. The internal method requires ruptured amniotic membranes and a partially dilated cervix through which the electrode can be inserted. The continuous FHR is recorded in a two-channel format with the FHR displayed directly above a graphic representation of the uterine contractions. In this way it is possible to relate FHR changes to uterine activity. The most commonly used scaling is a paper speed of 3 cm/min on the horizontal axis and 30 beats/min per centimeter of paper for the FHR (vertical axis).[50] In this manner each sequential vertical line is 10 seconds apart and every sixth vertical line (bold) represents a period of 1 minute.

Uterine contractions are monitored either externally via a tocodynamometer or internally with an intrauterine pressure catheter attached to a transducer placed between the fetus and uterine wall. Data obtained from external contraction monitoring is limited to temporal elements such as contraction duration and interval and cannot be used to estimate contraction strength. External monitoring is also subject to a great deal of artifact from maternal movement and errors in transducer placement. Internal contraction monitoring is more reliable and allows for precise determination of intrauterine pressure and, hence, contraction strength. Its use is also predicated on ruptured amniotic membranes and a partially dilated cervix. Internal pressure monitoring is commonly seen with high-risk parturients or those in whom labor augmentation with oxytocin is being used. Most commercially available intrauterine pressure catheter systems also allow for the infusion of fluids into the amniotic space (amnioinfusion), which is thought to reduce the risk of fetal aspiration of meconium-stained amniotic fluid.[51]

Fetal pulse oximetry has been introduced recently but is largely investigational at this time. A wide range in normal values has been reported, and use of oximetry has not been shown to decrease overall cesarean section rates, making its ultimate benefit questionable.[52]

Information about the baseline status of a fetus should be obtained during the preanesthetic assessment. The FHR also can reveal information about the fetal response to anesthetic interventions. This information is useful before neuraxial anesthetic placement, for assisted or operative delivery, and for nonobstetric surgery during pregnancy. Current American Association of Nurse Anesthetists (AANA) practice guidelines state that the Certified Registered Nurse Anesthetist (CRNA) shall be aware of the fetal status prior to each anesthetic intervention and that the fetal status be monitored and documented in the patient's record.[53]

Changes in Fetal Heart Rate

The individual components of the FHR pattern do not occur alone and changes generally evolve over time. Therefore, a full description of a FHR tracing requires a qualitative and quantitative description of baseline rate, variability, presence of accelerations or decelerations, and trends over time.[54] In the presence of a normally functioning uteroplacental unit, fetal oxygenation is limited primarily by uterine blood flow. As stated before, uterine arteries are maximally dilated in pregnancy, which results in the inability of the uterus to autoregulate blood flow. Decreases in maternal blood pressure and uterine artery blood flow ultimately compromise placental blood flow, resulting in fetal hypoxia and acidosis, which can be manifested as fetal heart rate changes. The normal FHR ranges from 110 to 160 beats per minute (bpm). An immature fetus has a higher heart rate. Tachycardia is defined as a HR greater than 160 bpm in a term fetus. It can result from fetal asphyxia, fetal arrhythmias, maternal fever, chorioamnionitis, and maternally administered drugs such as terbutaline and atropine. Ephedrine can increase both FHR and variability if given to the parturient in large enough doses.[55] Fetal bradycardia is present when the FHR is less than 110 bpm. Bradycardia can be caused by maternally administered drugs, hypoxia (fetal or maternal), or fetal head or cord compression.

Variability

FHR variability is thought to be the single best indicator of fetal well-being because it likely indicates adequate fetal oxygen reserve. Variability is the result of interaction between the fetal sympathetic and parasympathetic autonomic nervous systems. Baseline

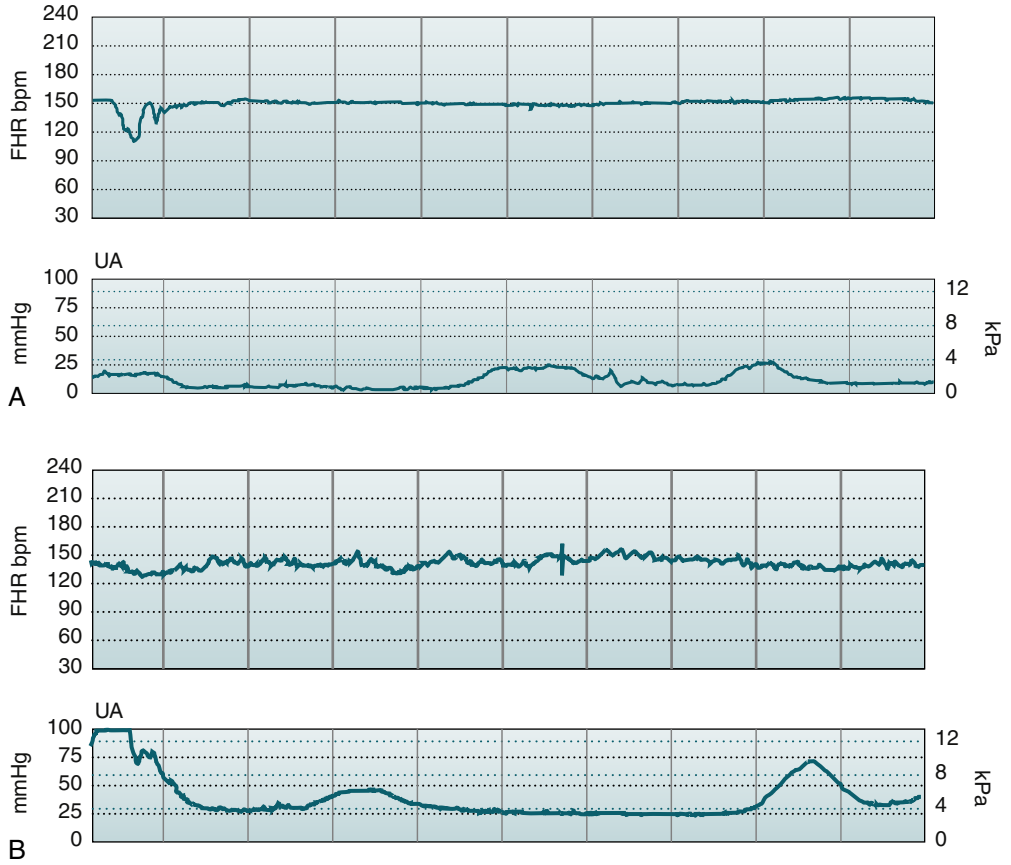

FIGURE **46-5** Examples of fetal heart rate variability. **A,** Absence of variability. **B,** Moderate variability (6 to 25 bpm from peak to nadir). (Redrawn with modifications from Chestnut DH, et al. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. St. Louis: Mosby; 2009:98).

variability is defined as fluctuations in the FHR of two cycles per minute or greater that are irregular in amplitude and frequency.[54] It is quantified by measuring the amplitude from peak to trough in beats per minute. Variability is described as absent, minimal (less than 5 bpm), moderate (6-25 bpm), and marked (greater than 25 bpm). In general, baseline FHR variability increases with advancing gestational age. Variability represents an intact central nervous system (CNS) and normal cardiac function. Hypoxia causes CNS depression, which results in decreased variability. Other causes of decreased variability include fetal sleep, acidosis, anencephaly, drugs (CNS depressants or autonomic agents), and defects of the fetal cardiac conduction system. Administration of opioids to the mother, for example, can decreases FHR variability for up to 30 minutes.[56] Maternal magnesium sulfate administration also may attenuate FHR variability.[57] Variability refers to the baseline FHR and, as such, does not include accelerations or decelerations. Beat-to-beat variability can be accurately assessed only by direct FHR monitoring with a fetal scalp electrode. Examples of absent and moderate FHR variability are shown in Figure 46-5.

Accelerations and Decelerations

An acceleration is an abrupt increase in the FHR above baseline. Accelerations occur in response to fetal movement and indicate adequate oxygenation. A FHR pattern is said to be reactive when there are two or more accelerations in a 20-minute period. Decelerations are not normal and are classified as early, variable, or late.

Early Decelerations. Early decelerations occur in concert with uterine contractions. The deceleration begins when the contraction begins, and it returns to baseline when the contraction ends. An early deceleration occurs with each uterine contraction and has the same appearance from one contraction to the next. Compression of the fetal head resulting in vagal stimulation is thought to be the cause of early decelerations. Early decelerations have the following characteristics:

- Occur with each uterine contraction
- Start and end with the contraction
- Gradually decrease in rate and then end in a return to baseline
- Are uniform in appearance
- Are associated with a mild decrease in FHR (20 bpm or less)
- Are accompanied by a loss in beat-to-beat variability during the deceleration

Variable Decelerations. Variable decelerations are sudden decreases in FHR that occur irrespective of uterine contractions. Variable decelerations are abrupt in both onset and recovery and vary in occurrence, onset, depth, duration, and appearance. Beat-to-beat variability is normally still present during the decelerations. Variable decelerations are thought to be caused by a baroreflex-mediated response to umbilical cord compression. If the fetus is compromised, the recovery phase of the deceleration may be delayed. Variable decelerations have the following characteristics:

- Vary in appearance, duration, depth, and shape
- Demonstrate abrupt onset and recovery
- Maintain beat-to-beat variability with the deceleration

Late Decelerations. Late decelerations begin late in the contraction and represent uteroplacental insufficiency. The lowest point of the deceleration occurs after the peak of the contraction. Like early decelerations, they are smooth in both onset and

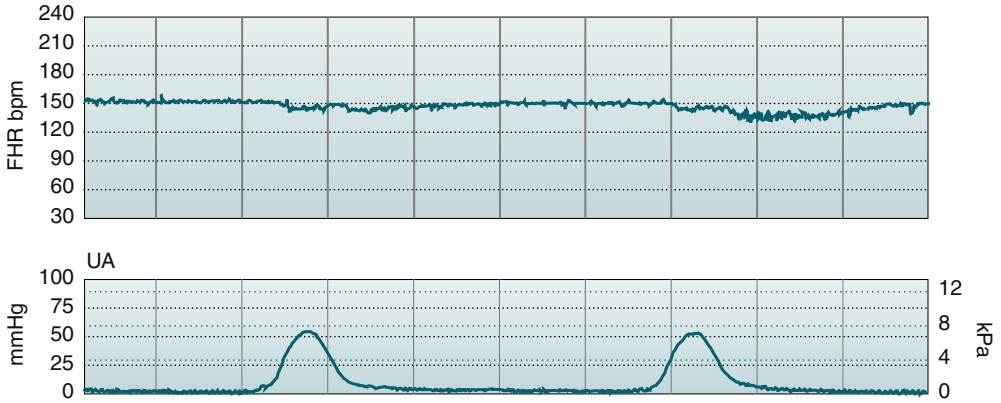

FIGURE **46-6** Fetal heart rate tracing with minimal (0 to 5 bpm peak to trough) variability and repetitive late decelerations. (From Chestnut DH, et al. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. St. Louis: Mosby; 2009:96).

recovery. Late decelerations are normally repetitive. Beat-to-beat variability may or may not be present during the deceleration, depending on the degree of fetal hypoxia and myocardial depression. Late decelerations are nonreassuring and should be investigated for potential causes. Figure 46-6 shows a FHT with late decelerations and minimal variability.

Late decelerations have the following characteristics:

- Occur with each uterine contraction
- Low point of the deceleration after the peak of the contraction
- Gradually decrease in rate and end in a return to baseline
- Are uniform in appearance
- Vary in depth according to the strength of the uterine contraction
- May or may not be accompanied by beat-to-beat variability

Anesthetic Considerations in the Presence of a Nonreassuring FHT

If the FHR tracing recorded during the preanesthesia assessment suggests hypoxia, caution should be used in making the decision to proceed with neuraxial analgesia. Careful consideration must be given to the severity of the fetal hypoxia and to the possibility that it may be worsened by anesthetic intervention. On the other hand, the obstetrician may request a neuraxial anesthetic for a patient with a nonreassuring FHT in anticipation of a possible urgent and unplanned operative vaginal delivery or cesarean section.

Intrauterine resuscitation describes interventions that can be used by the obstetric staff and anesthesia provider to improve the condition of a compromised fetus in utero. These interventions include changing maternal position, rapid infusion of IV fluids, discontinuing oxytocin, maternal oxygen administration, intravenous pressor support in the presence of hypotension, and the use of tocolytic agents.

ANALGESIA FOR LABOR AND VAGINAL DELIVERY

Intravenous Analgesia in the Parturient

Although less effective than neuraxial analgesia, systemic medications can be used for labor pain relief when neuraxial analgesia is unavailable, refused, or contraindicated. From an anesthesia perspective, the use of systemic medications presents several disadvantages. The pain relief they afford is often inadequate, and both fetal and maternal respiratory depression, nausea, vomiting, and decreased lower esophageal sphincter tone may result. Controlled, randomized trials investigating neuraxial versus intravenous analgesia in labor are difficult to design and execute due to high protocol failure rates. Namely, large numbers of parturients cross over from the IV to the neuraxial groups. However, when performed, overall patient satisfaction and pain relief scores are higher in women who receive neuraxial anesthetics compared with those who receive intravenous analgesia.[58,59]

Because opioids are lipid soluble and relatively small (less than 500 Da), they rapidly cross the placenta to gain access to the fetal circulation. Opioids may be administered by IV bolus or patient-controlled analgesia (PCA). The advantage of PCA is it allows the parturient greater control over drug dosing and has resulted in greater patient satisfaction. However, in one study PCA was compared with nurse-administered boluses, and there was no difference in pain scores or maternal and fetal side effects.[60] The use of systemic medications in early labor has declined as the practice of obstetric anesthesia has evolved to include those patients in early labor as candidates for neuraxial analgesia. Current American College of Obstetrics and Gynecology (ACOG) guidelines state that maternal request is a sufficient reason for labor analgesia.[61]

Meperidine

Meperidine crosses the placenta easily and has been recovered from the fetus within 2 minutes of IV administration. Like all opioids, it is capable of causing neonatal respiratory depression, although less so than morphine or methadone. Because of differences in pH and protein binding, the level of meperidine in the fetus is likely to be higher than the maternal blood level. Normeperidine is an active metabolite of meperidine with an elimination half-life of 30 hours. Normeperidine remains in the neonate for several days after delivery and may lead to depression of neonatal behavioral assessment scores.[62]

Historically, larger doses of meperidine were used during labor than are used now, often in combination with other depressant drugs. With contemporary doses (generally less than 100 mg in total), neonatal depression is a less frequent problem. The interval from administration of the drug to delivery of the infant is important. A drug-to-delivery interval of 2 to 3 hours results in the greatest neonatal depression. Both meperidine and normeperidine can be antagonized by naloxone.

Fentanyl

The pharmacologic profile of fentanyl, that is, its high potency and short duration of action, make it a reasonable choice for labor. It is highly lipid soluble and can be detected in fetal circulation after 1 minute of IV administration. Depressant effects, including a reduction in beat-to-beat variability, have been seen.[63] Dosages

for labor range from 25 to 100 mcg IV in hourly increments.[64] or PCA bolus 25-50 mcg with a lockout interval of 3 to 6 minutes and a 4-hour limit of 1-1.5 mg.[63,65]

Morphine

Morphine has been used in early labor to provide analgesia and sedation but is no longer widely accepted due to high rates of maternal sedation, neonatal depression, and an undesirable prolonged duration.[66] Morphine crosses the placenta easily and, in animal studies, crosses the fetal blood-brain barrier more readily than in adults.[67]

Butorphanol and Nalbuphine

Butorphanol and nalbuphine are opioid agonist-antagonists that are associated with a "ceiling effect" whereby incrementally higher doses do not result in increasing respiratory depression. They may also result in less nausea and vomiting than pure opioids. Agonist-antagonists have typically been used in first-stage latent-phase labor to provide sedation and a period of rest. A typical butorphanol dose for labor is 1 to 2 mg IV or IM (intramuscularly). Butorphanol is five times as potent as morphine and has a half-life of 3 hours. Unlike morphine, butorphanol increases pulmonary artery pressure and myocardial work.[64] Butorphanol has no active metabolites. The nalbuphine dose in labor is 5 to 10 mg IV, IM, or SC (subcutaneous) and is equivalent to morphine 10 mg. Nalbuphine results in a greater reduction in FHR variability compared with meperidine.[68] Because these compounds possess significant antagonist properties, their use in opioid-dependent patients should be avoided.

Remifentanil

Remifentanil is an ultra–short-acting opioid receptor agonist. It is rapidly hydrolyzed by plasma esterases to an inactive metabolite. The context-sensitive half-life remains short (3.2 min) regardless of prolonged administration times.[69] This unique pharmacokinetic profile makes it suitable for PCA use in labor. It crosses the placenta readily but is similarly rapidly redistributed and metabolized by the fetus.[70] Douma et al.[71] compared remifentanil, fentanyl, and meperidine PCA in labor and found that remifentanil PCA was associated with the greatest reduction in pain scores; however, the relief was described as mild to moderate. The same group has found that remifentanil PCA is less effective when compared with standard epidural labor analgesia.[72] A PCA bolus of 0.25 mcg/kg with a lockout interval of 2 minutes, a 4-hour limit of 3 mg, and a background infusion of 0.025-0.05 mcg/kg/min is common.[63,73,74] Remifentanil use in labor is a relatively new technique that appears to have an acceptable safety profile. However, its use requires careful monitoring due to the potential for adverse maternal events.[75]

Ketamine

Ketamine is a derivative of phencyclidine that produces a dissociative anesthetic effect. It is an excellent analgesic at subhypnotic doses. Its use as a labor analgesic is limited, however, by its short duration of action and high incidence of amnesia. Low-dose ketamine preserves airway reflexes while causing somatic analgesia, sedation, increased blood pressure, and a dreamlike state. It can be used to supplement a suboptimal neuraxial anesthetic when replacement or adjustment of the neuraxial anesthetic is not possible. Consideration should be given to administering a concomitant dose of a benzodiazepine such as midazolam to reduce the incidence of emergence reactions. Ketamine doses of 01.25 to 0.5 mg/kg produce rapid analgesia with a dose-dependent duration of action of approximately 5 to 15 minutes.

A single induction dose of 1 mg/kg of ketamine increases blood pressure during induction. This may be desirable in an emergent cesarean section where the mother is hypovolemic. The hypertensive effects, however, may be problematic in the parturient with hypertension or preeclampsia. It is the agent of choice for induction in the patient with acute asthma requiring urgent cesarean section. The emergence delirium and hallucinations from ketamine limit the effectiveness of ketamine for routine use in obstetrics. Uterine arterial blood flow does not decrease after ketamine administration. Because it has a high lipid solubility, ketamine crosses the placenta easily. Neonatal depression has not been demonstrated after maternal ketamine doses of up to 1 mg/kg. Doses larger than 1 mg/kg may result in neonatal respiratory depression, muscular hypertonicity, and lower Apgar scores.[76]

Nonpharmacologic Methods

A parturient may very well not choose a neuraxial anesthetic for labor analgesia if that is her informed choice. A multitude of nonpharmacologic techniques are currently in use but, as Wong has stated, the effectiveness of these techniques generally lacks rigorous scientific study and conclusions regarding their efficacy cannot be made.[77] Nonpharmacologic alternatives include hydrotherapy, hypnotherapy, massage, movement, and positioning. Although maternal satisfaction is without a doubt influenced by the degree of pain endured, it is influenced to a greater extent by whether the actual birth event met the mother's personal expectations.[78] The role of an obstetric anesthesia provider is to support laboring women such that they can make informed choices that meet their individual expectations, while at the same time ensuring the safety of both the mother and infant.[79]

Neuraxial Analgesia for Labor and Vaginal Delivery

Neuraxial analgesia is currently the best method of pain relief for labor and delivery. When properly placed and dosed, a neuraxial anesthetic is the only modality available that can provide complete relief from labor pain with minimal depression of the parturient or fetus. Common neuraxial anesthetics include epidural, combined spinal-epidural (CSE), and spinal techniques.

Absolute contraindications to neuraxial anesthesia include patient refusal, uncorrected severe hypovolemia, uncorrected coagulopathy, elevated intracranial pressure, infection at the site of insertion, untreated bacteremia, severe stenotic valvular heart lesions, and a documented allergy to local anesthetics. There are many relative contraindications such as stable preexisting CNS disease, chronic severe headaches and back pain, or poorly controlled chronic hypertension. Patients with these and other preexisting conditions should undergo careful preanesthetic evaluation and consultation that takes into consideration the risks and benefits of the proposed procedure.

Historically, the platelet count at which a neuraxial anesthetic could be safely administered has been considered to be greater than $100{,}000 \times 10^9$/L. However, contemporary practice surveys indicate that most practitioners are comfortable providing a regional anesthetic with the platelet count as low as $80{,}000 \times 10^9$/L.[80] Careful consideration of thrombocytopenic parturients should include a thorough history and physical examination for signs and symptoms of coagulopathy with an emphasis on previously administered medications including herbal supplements. A review of laboratory findings should clearly include all prior platelet counts (to establish any trends) as well as other relevant laboratory findings. The ACOG offers guidelines for assessing the obstetric patient (Box 46-2).

Patients receiving prenatal and/or intrapartum antithrombotic or thrombolytic therapy require special consideration. Normal

American College of Obstetricians and Gynecologists (ACOG) Guidelines for Assessment of the Obstetric Patient

Major Recommendations

The following recommendations are based on good and consistent scientific evidence (Level A):

- Regional anesthesia provides a superior level of pain relief during labor when compared with systemic drugs and therefore should be available to all women.
- Parenteral pain medications for labor pain decrease fetal heart rate variability and may limit the obstetrician-gynecologist's ability to interpret the fetal heart rate tracing. Consideration should be given to other drugs in the setting of diminished short- or long-term heart rate variability.

The following recommendations are based on limited or inconsistent scientific evidence (Level B):

- Patients with platelet counts of 50,000 to 100,000/μL may be considered potential candidates for regional analgesia.
- Regional anesthesia is preferred in women with preeclampsia unless a contraindication to regional analgesia is present.
- Breastfeeding does not appear to be affected by the choice of anesthesia; therefore, the choice should be based on other considerations.

The following recommendations are based primarily on consensus and expert opinion (Level C):

- It is not necessary to routinely obtain a platelet count before administration of regional anesthesia in a pregnant patient without complications.
- Clear liquid intake may be allowed in patients in labor without complications.
- Sodium citrate should be administered promptly to neutralize gastric contents following the decision to perform a cesarean delivery.
- Identifying women with risk factors for failed intubation or other complications of anesthesia and referring them for antepartum anesthesia consultation may reduce this risk.
- To avoid respiratory depression, close monitoring of the cumulative narcotic dosage given to a patient antepartum, intrapartum, and postpartum is essential.
- The decision of when to place epidural analgesia should be made individually with each patient, with other factors, such as parity, taken into consideration. Women in labor should not be required to reach 4 to 5 cm of cervical dilation before receiving analgesia.

pregnancy is associated with a hypercoagulable state that, alone or in combination with certain pathologic conditions, can predispose parturients to thromboembolic events. Conditions that may require anticoagulation therapy in the obstetric population include deep vein thrombosis, antiphospholipid antibody syndrome, factor V Leiden mutations, and protein S and C deficiencies. The concern with neuraxial anesthetics is the potentially catastrophic complication of epidural hematoma. Epidural hematoma results from uncontrolled bleeding in the non-distendable epidural space, which, if untreated, can cause ischemic injury to the cord resulting in persistent neurologic dysfunction. Epidural hematoma is a rare complication that is estimated to occur in less than 1 in 150,000 epidural and 1 in 220,000 spinal anesthetics.[81] The American Society of Regional Anesthesia and Pain Medicine (ASRA) has published consensus statements in an effort to guide practitioners in the management of these often complex patients.[82]

Preprocedure Preparation

History and Physical. It is optimal to complete the history and physical for every patient whose plan includes an epidural anesthetic early in the labor process, often long before the regional anesthetic is indicated. Maternal patience and cooperation is easier to obtain in the absence of significant labor pain. An early history and physical also allows for recognition of potential problems and provides the time for additional work-up when necessary. Valuable time also can be saved with a previously completed history and physical if an anesthetic intervention becomes urgently necessary.

The history should include questions regarding pertinent systemic diseases as well as the obstetric history and course of the current pregnancy. Particular attention should be directed toward problems with previous pregnancies, deliveries, or anesthetics. A review of the patient's medical record to include previous analgesic interventions, such as intravenous narcotics, should be performed. The physical examination should include an inspection of the back, heart, and lungs, as well as an airway examination. It has been recently demonstrated that the airway examination can change during the course of labor.[32] Therefore, a repeat examination is indicated immediately before administering anesthesia in labor regardless of prior examination results.

The maternal vital signs and fetal condition should be documented. This includes dilation, effacement, station, FHR, membrane status, and variability. The obstetric history includes gestational age and the parturient's gravidity (i.e., number of conceptions) and parity (i.e., number of live births). Obtaining a platelet count before the institution of neuraxial anesthesia in healthy patients with uncomplicated pregnancies has not been shown to reduce overall complication rates.[46] However, in the presence of hypertensive disorders or coagulopathies with anesthetic implications, the elective anesthetic should generally be delayed until appropriate laboratory results (e.g., coagulation studies, platelet count) are available. In circumstances of little or no prenatal care, obtaining baseline laboratory values may be indicated due to the possibility of undiagnosed medical conditions.

Informed Consent. Those who provide anesthesia to laboring women have an obligation to obtain informed consent prior to the procedure. The elements of informed consent include a description of the procedure, the risks, benefits, potential complications, and alternatives. However, there are several issues unique to obstetric anesthesia that can complicate informed consent. The first involves capacity and whether a woman in great pain and distress has the ability to understand and reason.[83] Despite the pain of labor, women feel they retain the ability to assimilate information and make good decisions. Jackson et al.[84] found that most women in active labor were able to voluntarily consent and that their ability to understand was not affected by pain, premedication, or duration of labor. Affleck et al.[85] determined that recall of risks by parturients is similar to the recall of risks by other patients and does not appear to be affected by parity or the reported level of pain.

A second confounding issue is caring for the pregnant minor. Competence describes the legal authority to make a decision and is recognized in the United States as occurring at 18 years of age. However, various state laws make exceptions (emancipation) for minors who are free of parental care, control, and custody. This may occur when a minor is married, a member of the military,

or a high school graduate. Becoming pregnant does not necessarily constitute emancipation. With respect to obstetric anesthesia, it is best to include the legal guardian of a minor patient in the informed consent process. Anesthesia providers must have a working knowledge of various local, state, and federal guidelines as well as their institutions' applicable policies and procedures.

Informed consent should include those risks that are reasonably foreseeable, but it does not have to include every possible risk. Material risks are those that a reasonable person would want to be made aware of before deciding on a recommended therapy.[86] They include risks that commonly occur as well as those risks that are rare but may result in severe morbidity and mortality. There exists no distinct and inclusive list of potential risks and complications; however, several recent surveys of practitioners demonstrate some consensus regarding what should be disclosed.[87,88]

Drugs and Equipment. It is the provider's responsibility to ensure that the anesthesia equipment available in the obstetric area is consistent with other anesthetizing locations in the facility.[89]An oxygen source, a positive pressure apparatus capable of delivering 100% oxygen, and an appropriate suction assembly must be present at every location where neuraxial anesthesia is provided. Emergency airway supplies as well as resuscitation drugs need to be immediately available. Emergency drugs include atropine, an induction drug (for terminating a local anesthetic–induced seizure), succinylcholine, ephedrine, epinephrine, calcium chloride (for treating magnesium sulfate overdose), and sodium bicarbonate. Equipment should be checked prior to each anesthetic.

As services are often provided in multiple locations, an "epidural" cart that contains routine supplies as well as emergency equipment is preferred. A standard "crash cart" with defibrillator and a supply of intralipid 20% to treat intravascular injection of local anesthetics should be readily available (see Seizures Related to Local Anesthetics section). Noninvasive automatic blood pressure monitoring and pulse oximetry are required in each labor and delivery room. In addition to proper drugs and equipment, a knowledgeable assistant is essential for the safe insertion of a neuraxial anesthetic. An obstetric nurse who can assist with fetal heart rate monitoring and positioning is desirable. Intravenous (IV) access is required prior to initiating a neuraxial anesthetic and should be maintained throughout its duration. IV insertion sites should take into consideration the vigorous arm movement that can occur during second-stage labor. The dilute concentrations of local anesthetic commonly used in labor analgesia today result in significantly less sympathetic blockade and hypotension compared with traditional high-dose blocks.[90] As a result, the administration of a fixed volume of intravenous fluid is not required before neuraxial analgesia is initiated.[46]

Local Anesthetics

Bupivacaine. Bupivacaine is an amino-amide local anesthetic with a relatively long duration of action and the ability to produce a differential block whereby sensory fibers are blocked more readily than motor fibers. When compared with lidocaine, there is less tachyphylaxis during long-term administration. In lower doses, it has limited placental transfer as well as minimal neonatal effects. These characteristics have made it the most commonly used local anesthetic in obstetric anesthesia. Bupivacaine is marketed as a racemic mixture of the S^- and R^+ isomers. Refractory cardiac arrest has been associated with high concentrations of bupivacaine inadvertently administered intravascularly. It is more difficult to resuscitate patients from bupivacaine-induced cardiac arrest when compared with other local anesthetics. The exact cause remains unclear; however, evidence suggests that toxicity occurs primarily at sodium channels, and there may be qualitative differences in cardiotoxicity caused by low- and high-potency local anesthetics.[91] The epidural administration of 0.75% bupivacaine has been prohibited for use in obstetric anesthesia by the Food and Drug Administration (FDA). Clinical techniques to reduce the incidence of cardiac toxicity include fractional dosing (less than 5 mL), frequent aspiration for blood during injection, and use of a test dose. The use of low concentrations for continuous epidural infusion and low doses (less than 15 mg) for spinal anesthesia are not associated with cardiac toxicity.[92]

Lidocaine. Lidocaine is an amino-amide local anesthetic that has been used extensively in obstetric anesthesia for decades. It has a rapid onset and an intermediate duration of action. When given in the epidural space, it produces a dense motor block when combined with epinephrine, which makes it well suited for epidural anesthesia for cesarean section. This dense motor block, however, makes it less desirable for labor analgesia. Lidocaine administered in the subarachnoid space is potentially neurotoxic.[93] In 1991 four cases of cauda equina syndrome were reported after the use of lidocaine in small-diameter catheters designed for continuous spinal anesthesia. In all four cases, there was initial evidence of a focal sensory block, and to achieve adequate analgesia, a dose of local anesthetic was given that was greater than that usually administered with a single-injection technique. The authors postulated, and subsequent data substantiated, that the combination of maldistribution and a relatively high dose of local anesthetic resulted in neuronal injury.[94] Transient neurologic symptoms consisting primarily of lower extremity pain also have been attributed to 5% hyperbaric lidocaine.[95] (see Chapter 10) For this reason, obstetric anesthesia providers do not use lidocaine in the subarachnoid space.

2-Chloroprocaine. Chloroprocaine is an amino-ester local anesthetic that is rapidly metabolized by ester hydrolysis. As such, its potential to produce cardiac and CNS toxicity after inadvertent intravenous administration is low. It has a rapid onset and brief duration of action. Chloroprocaine is used primarily in obstetric anesthesia to rapidly produce a surgical block in the presence of a preexisting epidural in the case of an emergency cesarean section. The epidural administration of chloroprocaine has been shown to reduce the effectiveness of subsequently administered epidural morphine, possibly by antagonism at the opioid receptors.[96] Neurotoxicity has been reported after inadvertent spinal administration of large doses intended for the epidural space but was likely a result of the low pH and/or the preservatives.[97]

Ropivacaine. Ropivacaine is an amino-amide local anesthetic that is produced as the pure levorotatory enantiomer. It has a propyl group attached to the pipechol ring as opposed to bupivacaine, which has a butyl group attached to the ring. Ropivacaine was developed largely to address the cardiac toxicity associated with bupivacaine. Minimum local anesthetic concentration (MLAC) is defined as the concentration that produces an effective response in 50% of subjects. Studies that address MLAC have found that ropivacaine is approximately 60% to 75% as potent as bupivacaine, which may explain the reduced motor block some studies have found with ropivacaine.[98] At a more clinically relevant dose, to achieve analgesia in 90% of women, bupivacaine and ropivacaine were equipotent.[99] Although equipotent doses of ropivacaine have been shown to produce less motor block when compared with bupivacaine, it has not been shown to influence the mode of delivery, the duration of labor, or neonatal outcome.[100]

Studies to address the potential cardiotoxicity of ropivacaine are obviously limited to animal models and in vitro preparations, and they have found either an advantage for ropivacaine in regard

to toxicity or no difference between ropivacaine and bupivacaine. It is possible that ropivacaine is less cardiotoxic than bupivacaine at high doses, but at the more dilute concentrations clinically relevant to obstetric anesthesia, this difference is less likely important.[101]

Neuraxial Anesthetic Placement

Aseptic technique must always be used during the insertion of neuraxial anesthetics. This includes preprocedure hand hygiene, wearing of sterile gloves, cap and mask (new for each case), removal of rings and watches, and sterile draping of the back.[102] A newly opened single-use container of preparation solution should be used for skin surface disinfection. Chlorhexidine gluconate in an alcohol base should be considered the antiseptic of choice. When compared with other commonly used antiseptic solutions, it is effective against a wider array of pathogens, has a greater degree of potency, shows a more rapid onset of action with an extended duration of effect, and has fewer and less severe localized skin reactions.[103] In addition, the efficacy of chlorhexidine gluconate is maintained in the presence of protein-based organic compounds such as blood and other body fluids. A sterile occlusive dressing should be placed over the catheter insertion site.

Baseline blood pressure and pulse oximetry should be measured and checked at regular intervals once the epidural anesthetic is begun. Typically, blood pressure is monitored every 2 minutes for 15 minutes, then every 5 minutes for another 15 minutes, thereby enabling the early detection and treatment of neuraxial anesthesia–induced hypotension. It is preferable to remain in the anesthetizing location during this time not only to assess the onset and progression of the neuraxial block but also to be in a setting where prompt recognition and treatment of potentially catastrophic complications such as total spinal block can be attended.

The sitting position is often easiest for the patient to maintain and usually offers the anesthetist the maximum interspace width. On the other hand, the use of the lateral position has been found to reduce the incidence of intravascular catheter placement.[104] However, the lateral position can make identification of the midline more difficult due to skin shifting. The lateral position also requires meticulous attention to shoulder position, because the upper shoulder naturally rotates anteriorly, resulting in a concomitant rotation of the vertebral column. The lateral position may help limit movement if the patient is having a difficult time cooperating with positioning. Some obstetric situations that often require rapid neuraxial block placement, such as fetal head entrapment, prolapsed umbilical cord, and footling breech presentation, preclude the use of the sitting position. For this reason, anesthetists must practice and be proficient in both the sitting and lateral positions.

It has long been observed that the failure rate of epidural anesthetics is greater in the obese patient. At the same time, neuraxial anesthetics are particularly desirable in obese parturients because of the increased cesarean section rates and concern surrounding a potentially difficult airway. The distance between the skin and the epidural space increases as the body mass index (BMI) increases, which can make epidural insertion more difficult.[105] However, morbid obesity, when considered alone, is not a predictor of difficult block placement. In a study of 427 morbidly obese patients receiving neuraxial anesthetics, four variables were evaluated to determine whether they could predict difficult insertion. The authors found that only the ability to palpate bony landmarks and the patient's ability to flex her back were significant predictors of difficulty, whereas BMI and the practitioners experience level were not predictive.[106]

The use of ultrasound imaging as an aid in the placement of neuraxial anesthetics is a relatively new and growing technique. The placement of neuraxial anesthetics relies primarily on palpation of underlying anatomy and visualization of surface landmarks and is therefore an essentially blind technique. Preprocedure imaging and, eventually, real-time ultrasound guidance, may ultimately improve clinical practice and the ability to teach these techniques.[107] Ultrasound imaging is particularly useful in determining the skin to epidural space depth, the location of the midline, and the precise interspace. Palpation alone, regardless of BMI, is a relatively ineffective method for determining vertebral interspace, which is of particular importance when performing techniques that involve dural puncture.[108] Morbidly obese patients or those with a history of difficult block placement may benefit from this technique.[109]

The type of epidural catheter used influences the anesthetic. Spiral wire-embedded flexible polyurethane catheters with a soft tip have been shown to result in fewer paresthesias and intravascular placements when compared with nylon catheters.[110] Previous comparisons between multiple- and single-orifice catheters focused on standard nylon (stiff) designs and found an advantage favoring multiple-orifice catheters. Recent work comparing both versions (single orifice and multiple orifice) of soft catheters has found no difference.[111] Multiple-orifice closed-end catheters are less prone to obstruction and likely result in better spread of local anesthetic in the epidural space.[112]

Historically, when larger doses of local anesthetic were used, a bolus of intravenous fluids was given prior to placement of the regional analgesic in an effort to reduce the incidence and magnitude of hypotension. However, when dilute concentrations of local anesthetics combined with lipid-soluble narcotics are used to initiate neuraxial analgesia for labor and are combined with efforts to reduce aortocaval compression, the incidence of hypotension is approximately 5%.[113] Zamora et al.[114] found that a 1-liter preload did not provide any added protection against hypotension but likely resulted in decreasing contraction frequency and was associated with delays in providing pain relief.

Test Doses

It is essential to aspirate for blood or cerebrospinal fluid (CSF) after placement of the epidural catheter and before each subsequent manually administered dose. Negative aspiration does not, however, conclusively indicate that the catheter is not in the subarachnoid or intravascular space. Therefore, the epidural test dose is designed to reveal inadvertent subarachnoid or intravascular injection of local anesthetic without producing systemic toxicity or widespread subarachnoid block. The key is to think of the test dose as the minimum amount of drug required to produce a modestly detectable effect either intrathecally or systemically. As such, the overall volume has little to do with its effectiveness. A commonly administered test dose is 3 mL of lidocaine 1.5% with epinephrine 1:200,000. This 45-mg dose of lidocaine, if unexpectedly administered in the subarachnoid space, will produce a noticeable, but manageable, spinal anesthetic within 3 to 5 minutes while having no appreciable effect when given in the epidural space.

When administered intravascularly, lidocaine 45 mg will often result in early signs and symptoms of modest systemic toxicity such as circumoral numbness, lightheadedness, or auditory changes. The above mentioned test dose also includes 15 mcg of epinephrine that, when given intravascularly into an epidural vein, has been shown to reliably increase HR in nonpregnant patients. The maternal HR should be monitored continuously using either pulse oximetry or electrocardiogram (ECG) during administration of

the test dose to detect these HR changes. In the laboring parturient, increases in HR are a less specific indicator of intravascular injection because of the changes in HR that normally occur during uterine contractions. Even when a test dose is carefully timed to be administered between contractions, it lacks both sensitivity and specificity. As a result, it is not universally accepted for use in obstetric anesthesia. Furthermore, concern exists that epinephrine may cause significant uterine artery constriction in a few patients, resulting in a decrease in fetal O_2 delivery.[115]

Some practitioners believe that by using multiple-orifice catheters in combination with incrementally administered (every 3-5 min) small doses (less than 5 mL) of dilute (less than 0.125%) local anesthetic, an epinephrine test dose is unjustified for labor analgesia. Careful aspiration of the epidural catheter for blood or CSF alone, without the administration of a test dose, may be effective in revealing an intrathecal or intravascular catheter.[116] If a parturient receiving a continuous epidural infusion of dilute local anesthetic remains comfortable, the catheter must, by default, be in the epidural space. On the other hand, if the catheter was intravascular, the parturient would have inadequate analgesia, and if it were intrathecal, a significant motor block would ensue.[117]

Observing for blood or CSF while aspirating the epidural catheter had a 0% false-positive rate and a 0.2% false-negative rate in over 1000 women in whom 60 intravascular or subarachnoid catheter placements were performed.[118] However, a test dose with epinephrine is necessary when administering larger and more concentrated doses such as those given in an epidural for cesarean delivery.[116] Ideally, the administration of every epidural dose should be considered a "test dose" in which the catheter is carefully aspirated and incrementally injected. In summary, every precaution to ensure proper placement of the epidural catheter should be employed including the use of minimum effective doses, careful aspiration, and incremental injection, coupled with the use of intravascular markers when large doses are used. Epinephrine remains the most widely used and studied marker, but its reliability is impaired in the face of beta-blockade, anesthesia, advanced age, and active labor. As an alternative, the use of subtoxic doses of local anesthetics themselves can produce subjective symptoms in unpremedicated patients. Fentanyl has also been confirmed to produce sedation in pregnant women when used as an alternative. The use of ultrasound observation of needle placement and injection may be useful, but has also been reported as not completely reliable. Constant vigilance and suspicion are still needed along with a combination of as many of these safety steps as practical.[119]

Anesthetic Effects on the Progress of Labor

There has been considerable controversy surrounding whether neuraxial analgesics prolong labor or increase the need for assisted or operative delivery. Randomized controlled trials designed to evaluate the effects of neuraxial anesthetics on the outcome of labor are notoriously difficult to design and implement due to ethical considerations and unacceptably high protocol failures. The number of variables involved and the diversity of both patients and study methods make this a difficult topic about which to draw valid conclusions.

It is likely that women who request early labor analgesia have more pain than women who do not, and pain is a marker for risk of cesarean delivery.[120] In a systematic review of 10 trials that enrolled over 2300 patients in which the effects of epidural versus parenteral opioids in labor were examined, Halpern et al.[121] found that epidural labor analgesia was not associated with increased rates of instrumented vaginal delivery or cesarean section. Not surprisingly, patient satisfaction and neonatal outcomes were better after epidural when compared with parenteral opioid analgesia. Another systematic review of seven existing trials found that epidural analgesia using low concentrations of bupivicaine and fentanyl was unlikely to increase the risk of cesarean section but may increase the risk of instrumented vaginal delivery.[122] Although women in those studies had a longer second-stage labor, they had better pain relief. It could be argued that the increased risk of instrumented vaginal delivery was the result of obstetricians choosing this method more frequently because of the presence of a functioning epidural.[123] It has been thought that early initiation of neuraxial analgesia (less than 4 cm) may increase the incidence of labor dystocia and cesarean section. However, a recent large study from China involving almost 13,000 patients found no difference in the duration of labor or cesarean section rate when primiparous women were randomized to receive epidural analgesia at 1 cm dilation versus 4 cm or more dilation.[124] Overall, the use of epidural analgesia does not increase the risk of cesarean section. It may affect the incidence of forceps delivery, but it depends on the medications used. Epidural analgesia does prolong labor, although the clinical significance of this prolongation has not been shown.[125]

Epidural Analgesia for Labor

Epidural analgesia remains a popular, safe, and effective means of providing analgesia for labor. The use of an indwelling epidural catheter gives the anesthetist the ability to produce a segmental block of varying density that can be adapted to the patient's requirements. This is accomplished by changing the volume and concentration of local anesthetic administered. Dosing an epidural with dilute concentrations of local anesthetic often results in satisfactory labor analgesia without producing significant motor block. When necessary, the same labor epidural can be converted to a surgical anesthetic by administering a larger volume of a more concentrated local anesthetic.

Combining a lipid-soluble opioid allows a decrease in concentration of local anesthetic without compromising analgesia while at the same time preserving motor function. Decreasing the dose of both drugs minimizes the potential complications and side effects of each. An epidural for labor analgesia is optimally inserted at the L2 to L3 interspace to allow for effective blockade of the T10 to L1 dermatomes necessary for analgesia in first-stage labor. Analgesia for second-stage labor and subsequent repair, if needed, requires an extension of the block to include the S2 to S4 dermatomes that innervate the perineum and vagina. Adequate analgesia must be balanced against loss of the sensation of labor, which is not desirable during the second stage, and motor block, which is bothersome to the mother during labor and prevents effective pushing during second stage.

Although the small amount of epinephrine present in a test dose should be safe for a healthy fetus, the larger amounts present in the volume of local anesthetic used in epidural infusions carry some risk of umbilical artery constriction in some parturients.[126] Epinephrine-containing local anesthetics also result in significantly enhanced motor block. For these reasons, routine use of epinephrine-containing solutions is not recommended, especially in the preeclamptic patient.

To avoid aortocaval syndrome, after epidural analgesia has been instituted, the patient should be instructed to avoid the supine position. A hip roll, wedge, or pillow should be used to maintain a left or right lateral position. Following the initial and all subsequent doses, the patient should not be left unattended for at least 20 minutes. The anesthetist should remain aware of cervical dilation and the progress of labor after the epidural catheter has been placed. Communication with the obstetric personnel is important

to prevent the use of a drug, dose, or concentration of local anesthetic that is inappropriate for the patient's circumstances.

Maintaining Epidural Analgesia for Labor and Delivery

Although it is possible to maintain epidural analgesia with intermittent bolus administration, this technique is associated with frequent provider interventions as well as periods of analgesia alternating with periods of pain. Hypotension occurs less often when a continuous infusion is used as a result of fewer changes in the level of sympathetic blockade. Continuous infusion results in less total local anesthetic administered (when compared with intermittent boluses), more effective analgesia, and significantly reduced workload. There is also no need for the careful incremental administration of local anesthetic associated with bolus doses.

The parturient's analgesia level and degree of motor block should be frequently assessed and changes in the infusion rate and/or concentration made as needed. An epidural catheter originally sited in the epidural space can potentially migrate into the subarachnoid or intravascular space. If the epidural catheter enters the subarachnoid space some time after placement during a continuous infusion, the resulting gradual increase in motor block can be easily recognized. Alternatively, if the catheter enters the intravascular space, the patient will have a loss of analgesia without overt symptoms of systemic toxicity.

Infusions of bupivacaine (0.0625% to 0.125%) or ropivacaine (0.1% to 0.2%) with fentanyl (1 to 3 mcg/mL) or sufentanil (0.3 to 0.5 mcg/mL) at infusion rates of 8 to 12 mL/hr are commonly used. Lower concentrations may be effective as long as adequate spread is achieved. However, maintaining an adequate sensory level with lower concentrations may necessitate an infusion rate of 10 to 15 mL/hr. In the majority of women, this dilute concentration is associated with minimal motor block, although the block will become denser as the infusion is maintained over time. A higher concentration may be needed as labor intensifies or in women who experience greater pain.

The epidural infusion should be maintained as the parturient transitions to second-stage labor provided the block is stable and effective and adequate motor function has been preserved. The ideal block provides effective analgesia for uterine contractions, dense analgesia of the perineum for delivery, and little motor block. If motor block hinders pushing or if sensory block prevents the parturient from sensing contractions and therefore effectively prevents pushing, the epidural infusion may be decreased or changed to a more dilute solution. On the other hand, the block can be supplemented during second-stage labor if additional perineal analgesia is required. This can be accomplished by injecting a relatively large 6 to 10 mL volume of bupivacaine 0.25%, lidocaine 1% to 2%, or 2-chloroprocaine 2%. Fentanyl 50 to 100 mcg can be added to the aforementioned bolus to further enhance analgesia. Instrumented vaginal delivery generally requires a more dense block, in which case lidocaine 2% with epinephrine 1:200,000 can be used with or without the addition of fentanyl.

Patient-Controlled Epidural Analgesia

Patient-controlled epidural analgesia (PCEA) is an alternate technique that allows the parturient to self-administer bolus doses as needed. It is normally initiated after analgesia has been established with either an epidural of a combined spinal-epidural technique. When compared with continuous epidural infusion, PCEA has several distinct advantages.[127] It reduces the number of unscheduled interventions required by the anesthetist, the total dose of drug used, and lower extremity motor block, all without sacrificing effective analgesia.[128] Maternal satisfaction would be expected to be increased due to enhanced control, but this has not been consistently shown to be the case. The best combination of variables (e.g., background infusion rate, bolus dose, and lockout interval) has yet to be established. The use of a background infusion likely reduces breakthrough pain but has been shown to result in an increase in total local anesthetic used.[129] Background infusion rates of bupivacaine 0.125% or ropivacaine 0.2% between 2 and 10 mL/hr have been used effectively. Bolus doses greater than 5 mL may provide superior analgesia compared with smaller boluses.[130] PCEA also may presumably limit the number of epidural catheter disconnections and reconnections necessary to manually bolus a catheter, hence reducing the potential exposure to pathogens and catheter contamination.

Programmed Intermittent Epidural Boluses

There is evidence to indicate that there may be more widespread distribution of anesthetic solution within the epidural space when large volumes are injected as a bolus compared with a slow infusion.[131] Automated epidural infusion pumps capable of administering programmed intermittent boluses have been recently introduced. With this technique, a bolus dose is automatically administered at regular intervals as opposed to a continuous infusion. Optimal dosing regimens are being studied at this time, but some evidence indicates that larger boluses timed more widely apart appear to increase effectiveness. Wong et al.[132] found that extending the programmed intermittent bolus interval and volume from 15 minutes to 60 minutes, and 2.5 mL to 10 mL, respectively, decreased overall bupivacaine consumption without decreasing patient comfort or satisfaction.

Combined Spinal-Epidural

The combined spinal-epidural (CSE) is a commonly used technique that many practitioners feel provides the best analgesia for labor and vaginal delivery. A CSE combines the best attributes of both techniques while minimizing their respective disadvantages. Analgesia obtained from the spinal component is uniformly effective and has a rapid onset. The epidural catheter allows the analgesia to be prolonged as required and provides the ability to convert the block to a surgical level when operative delivery is indicated.

Several methods have been described for performing the block, including the early technique of spinal needle insertion and removal immediately followed by epidural insertion at the same or different level. Most practitioners now use the "needle through the needle" technique in which the epidural space is identified with an epidural needle followed by placement of a longer small-gauge spinal needle through the existing epidural needle. Care must be taken to avoid displacing the spinal needle during injection. The spinal needle is then withdrawn and an epidural catheter is placed. The "needle through the needle" technique provides the additional benefit of confirming proper epidural needle location. If the epidural needle is not inserted in the midline of the epidural space, the subsequently placed spinal needle will not likely penetrate the dura and CSF flow will not be obtained. Figure 46-7 shows the proper orientation of both the spinal and epidural needles during a CSE technique.

The spinal component of a CSE can be dosed with either a lipid-soluble narcotic alone or in combination with isobaric bupivacaine. Narcotics are commonly used alone in early first-stage labor. For example, fentanyl 15 to 25 mcg or sufentanil 10 mcg in the subarachnoid space can provide analgesia for up to 2 hours with no motor block. Local anesthetic is often combined with the narcotic in late first-stage labor to produce a rapid-onset analgesia

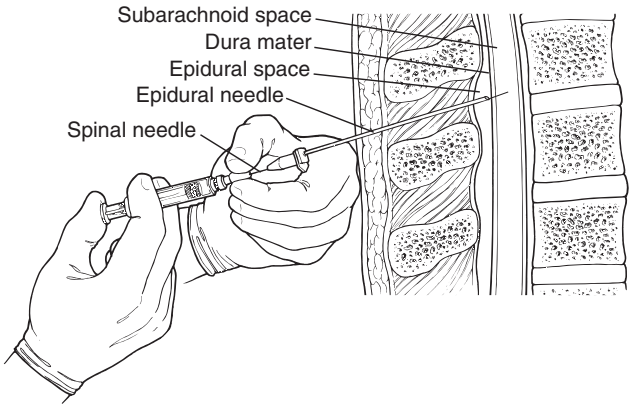

FIGURE **46-7** The proper orientation of both the spinal and epidural needles during the needle-through-needle CSE technique. (From Birnbach DJ, Gatt SP, Datta S. *Textbook of Obstetric Anesthesia*. Philadelphia: Churchill Livingstone; 2000:166.)

with minimal motor block. Isobaric bupivacaine 0.25% 1 mL (2.5 mg) combined with fentanyl or sufentanil provides a more dense analgesia than narcotic alone. Consideration should be given to initiating an epidural infusion before resolution of the spinal component to avoid the need for bolus dosing the epidural catheter.

Spinal Analgesia

In our contemporary practice, a single-shot spinal is rarely an appropriate anesthetic choice for a patient in labor due to its finite duration and lack of flexibility. Because the technique can often be performed quickly, it is generally reserved for multiparous patients in advanced second-stage labor when delivery is clearly imminent or for those exhibiting poor control who can then have an epidural placed with better cooperation. It is also suitable in parturients who have labored without anesthesia and require an instrumented vaginal delivery or those who have delivered without anesthesia and require an extensive repair. In rare cases, multiple single-shot spinal anesthetics, placed every 2 to 3 hours, have been used in parturients with conditions that preclude epidural placement such as a previous history of spinal surgery in which the epidural space has likely been surgically obliterated.

Continuous spinal anesthesia (CSA) using a macro-bore epidural catheter is an option in certain high-risk patients such as the extremely morbidly obese, those with previous spinal surgery or deformity, or those whose dura has been inadvertently punctured with the epidural needle. A CSA may be particularly indicated in a high-risk parturient after failed attempts at a conventional neuraxial anesthetic due to the increased morbidity and mortality associated with general anesthesia. The morbidly obese parturient is at greater risk for cesarean delivery as well as greater risk of failed regional technique.[133] To perform a CSA, an epidural needle is used to identify the subarachnoid space and the epidural catheter is then intentionally threaded into the subarachnoid space. This spinal catheter can then be dosed as a spinal anesthetic using isobaric bupivacaine 0.25% in 0.5-mL to 1-mL increments for labor analgesia. A CSA is not considered a first-line technique because it is clearly associated with an increased risk of postdural puncture headache. There is some evidence to indicate that a catheter left in situ in the subarachnoid space for at least 12 hours results in fewer postdural puncture headaches.[134] It is postulated that the epidural catheter creates a localized inflammatory response where it passes through the dura, which results in decreased CSF leakage when the catheter is ultimately removed. Block level must be carefully monitored when this technique is used. All caregivers in contact with these patients should be notified that the "epidural" catheter is actually subarachnoid to prevent accidental overdose. It is also best to clearly label the catheter as a spinal catheter.

Microcatheters (27-32 gauge) were developed for use in the early 1990s specifically for this purpose but were found to result in an unacceptably high incidence of cauda equina syndrome.[135] The low-flow velocity through the very small-diameter catheter resulted in poor mixing of the lidocaine local anesthetic that was used at the time, creating a pool of concentrated local anesthetic in close proximity to the nerve roots. Microcatheters were subsequently removed from the market by the FDA.[87]

Regional Opioids for Labor Analgesia

The combination of dilute local anesthetics with low-dose opioids allows for the reduced dose of both agents that ultimately results in decreased motor block while preserving acceptable analgesia and minimizing side effects. The agents work by binding to separate and distinct receptors. Local anesthetics work at the nerve axon while neuraxial opioids bind to receptors in the substantia gelatinosa within the dorsal horn of the spinal cord. These receptors are stimulated by the administration of opioids via the subarachnoid or epidural routes. Epidurally administered opioids are believed to be absorbed into the CSF, and ultimately the spinal cord, to exert their action on spinal opioid receptors. Neuraxially administered opioids are known to possess a "ceiling effect" whereby increasing the dose beyond conventional regimens does not result in an increased duration or quality of analgesia. Common side effects are, however, more severe and prolonged at the increased dose levels.

Side effects of epidural and subarachnoid opioid administration include respiratory depression, itching, urinary retention, nausea, and vomiting. IV doses of an opioid antagonist (naloxone) or agonist-antagonist (nalbuphine) are effective at reducing or eliminating the undesirable effects without antagonizing the analgesia and often are more effective against pruritus than an antihistamine.

Fentanyl. When used in combination with local anesthetics, fentanyl in epidural doses of 50 to 100 mcg and subarachnoid doses of 10 to 25 mcg produces good to excellent analgesia in 5 to 10 minutes. Administration of these doses, repeated as often as every 90 minutes in women in labor, has been shown not to affect Apgar scores, umbilical cord blood analysis, or neurobehavioral test results for up to 24 hours after delivery.[136-138] Fentanyl 100 mcg in the epidural space has been shown to be undetectable in breast milk.[139] When opioids are used alone, much higher doses are needed to provide labor analgesia, and even these higher doses are not entirely effective during the second stage of labor. When analgesia from fentanyl administration is at its peak, serum fentanyl levels are lower than those known to produce equivalent analgesia after IV administration. In fact, most women have undetectable plasma fentanyl levels after receiving 100 mcg of epidural fentanyl.[140]

The duration of action of fentanyl in the epidural space is 60 to 140 minutes. Because fentanyl is so much more lipid soluble than morphine, it is absorbed into neural tissue faster; therefore it has a faster onset and shorter duration of action when compared with morphine. As a result, the cephalad migration of fentanyl is much less than that of morphine; therefore fentanyl is associated with a significantly lower incidence of CNS side effects. This is likely why respiratory depression has rarely been reported following subarachnoid or epidural administration of fentanyl in conventional doses.

For continuous epidural infusion, fentanyl concentrations up to 2.5 mcg/mL of local anesthetic can be used without adversely affecting neonatal respiration or neurobehavioral scores.[141]

Bupivacaine (up to 0.125%) or ropivacaine (up to 0.2%) with 1 to 2 mcg/mL of fentanyl is a widely used combination.[142]

Sufentanil. Sufentanil is a highly lipid-soluble drug that enhances receptor affinity, resulting in increased potency. When injected into the epidural space, 98% of the dose is absorbed either by epidural fat or into epidural veins. Little sufentanil reaches the CSF. As a result, relatively higher plasma levels of sufentanil are achieved compared with those of fentanyl after the epidural injection of equipotent doses. When sufentanil is injected directly into the subarachnoid space, plasma levels of the drug are much lower than its CSF levels. One advantage of sufentanil is that it has a shorter plasma half-life than fentanyl; therefore, accumulation should be even less likely to occur when it is used instead of fentanyl.

Morphine. Morphine is relatively lipid insoluble compared with fentanyl or sufentanil. When administered in the epidural or subarachnoid space it has a slow onset of action of 30 to 60 minutes and, when used alone for labor analgesia, is not associated with a high degree of maternal satisfaction. It is this pharmacologic profile that makes it a poor choice for use in labor analgesia. However, morphine is uniquely suited for use as a postoperative analgesic when neuraxial anesthesia is utilized for cesarean section (see next section).

ANESTHESIA FOR CESAREAN SECTION

Birth by cesarean section now accounts for over 30% of all deliveries and is performed over 1.5 million times annually in the United States.[143,144] Common indications include cephalopelvic disproportion, nonreassuring fetal status, arrest of dilation, malpresentation, prematurity, prior cesarean delivery, and prior uterine surgery. The choice of anesthesia depends on maternal status, urgency of the surgery, condition of the fetus, and the patient's desires. This fact highlights the need for strong communication between the obstetrician, nursing staff, and anesthesia provider. The use of neuraxial anesthesia for cesarean section has increased dramatically along with a commensurate decrease in the use of general anesthesia.[145] Neuraxial anesthesia has significant advantages including decreased risk of mortality from failed intubation and aspiration of gastric contents, better neonatal outcomes from the use of less depressant agents, and the ability of the mother to be awake for the delivery. In fact, it has been shown that the risk of maternal death is 16.7 times greater with general anesthesia when compared with regional anesthesia. Recent evidence also suggests that general anesthetic agents are associated with apoptosis of fetal brain neurons in animal models.[146]

Regardless of the anesthetic technique used, left uterine displacement should be provided as soon as possible. The table should be rolled to the left or a wedge placed under the right hip of the patient in order to shift the uterus off the inferior vena cava and abdominal aorta, thereby preserving fetal oxygenation. Fetuses delivered of mothers with left uterine displacement have a lower incidence of CNS depression and acidosis than those delivered of mothers in the supine position.[147] In an awake parturient with a neuraxial anesthetic, it is not a requirement to secure the upper extremities to the armboards. The lower extremities, however, should be secured to prevent movement from the table.

Blood loss during cesarean section is usually between 500 mL and 1000 mL. However, the reported range of blood loss is great—in one study, from 164 to 1438 mL.[148] Many factors affect the volume of blood lost during cesarean section, including surgical time, surgical technique, blood pressure, fetal lie, fetal size, placental implantation, maternal coagulation status, and the ability of the uterus to contract after the placenta has been delivered. Visual estimation of blood loss is inaccurate and often complicated by the presence of large volumes of amniotic fluid and variably saturated sponges. Normal amniotic fluid volume is approximately 700 mL (range 300 mL to 1400 mL) and should be accounted for when estimating blood loss.[149]

Neuraxial Anesthesia for Cesarean Section

A dermatomal level of T4 is required to provide effective anesthesia for cesarean section. This level of block is associated with a rapid and extensive spread of anesthesia that can often result in maternal hypotension and, if untreated, fetal compromise. Common measures to minimize hypotension include left uterine displacement, intravenous fluid administration, and vasopressor use.

A nonparticulate antacid should be administered preoperatively for aspiration prophylaxis. An H_2-receptor antagonist and metoclopramide also can be used preoperatively to increase gastric pH and emptying. Anxiolytics are normally not administered preoperatively in order to minimize fetal depression. Prophylactically administered antibiotics have been traditionally withheld until cord clamping in an effort to prevent fetal transmission and the obscuring of any subsequent neonatal sepsis workup. However, antibiotics administered pre-incision have been shown to decrease the surgical site infection rate from 6.4% to 2.5%, making the practice much more common.[150] Requirements for standard monitoring remain the same as with any anesthetic; however, blood pressure should be assessed at least every 1 minute for the first 20 minutes or until the patient's condition has stabilized. Left uterine displacement is an essential aspect of positioning to preserve maternal cardiac output and, ultimately, utero-placental exchange.

The routine supplemental use of oxygen in the absence of preexisting fetal compromise has not been shown to be of any maternal or neonatal benefit in spite of its common practice.[151] Although supplemental oxygen may reduce postoperative nausea and vomiting after general anesthesia, its administration during cesarean section with neuraxial anesthesia does not decrease the incidence or severity of intraoperative or postoperative nausea or vomiting.[152] Oxygen administration during elective cesarean section appears to increase oxygen free radical activity in both the mother and fetus.[153] Consideration, however, should be given to the use of end-tidal CO_2 monitoring made possible by the use of sampling nasal cannula for those patients susceptible to intraoperative respiratory compromise or in those who have been provided IV sedation.

Spinal Anesthesia for Cesarean Section

Single-shot spinal anesthesia is probably the most commonly used anesthetic technique for cesarean delivery because it offers many distinct advantages. It is relatively simple, has a rapid onset, provides a more reliable block, and uses smaller and therefore less toxic doses of local anesthetic when compared with epidural anesthesia. Its simplicity and rapid onset make it suitable for all but the most emergent cesarean deliveries when compared with general anesthesia. It is considered an economical anesthetic insofar as its rapid onset functions to decrease overall operating room times. Drawbacks include its fixed duration of action and rapid onset of sympathectomy with resultant hypotension. Hyperbaric bupivacaine 0.75% 13 mg is effective in 95% of patients (ED_{95}) and provides 90 to 120 minutes of surgical anesthesia. In practice, neither the patient's height, weight, nor body mass index correlates to the ultimate block level obtained.[154] The compound curvature of the spine in the supine position serves to limit the upward spread of the block when hyperbaric local anesthetics are used. A series

of recent studies has determined that decreasing the bupivacaine dose results in less hypotension but is associated with an increased risk of intraoperative pain, a shorter duration of effective anesthesia, and a slower onset.[155]

When spinal anesthesia is used to produce the T4 block needed for cesarean section, hypotension has been shown to occur in up to 80% of patients despite left uterine displacement.[156] Maternal hypotension results mainly in nausea and vomiting but, if severe and untreated, may lead to cardiovascular collapse, a decreased level of consciousness, and uteroplacental hypoperfusion. The goal should be to prevent, to the greatest extent possible, and effectively treat hypotension before complications arise.

Crystalloid preloading has traditionally been used in an effort to prevent hypotension but has been shown to be minimally effective, possibly due to its rapid redistribution from the intravascular space.[157,158] On the other hand, colloid preloading (hydroxyethylstarch 6%) consistently reduces the incidence and severity of hypotension and may improve maternal cardiac output.[159] Despite these findings, the routine use of hydroxyethylstarch 6% (HES) continues to be debated because of its disadvantages including cost, potential allergic reactions, and pruritus.

The timing of the fluid administration also has been investigated comparing preloading (prior to anesthetic placement) with coloading (given rapidly at the time of intrathecal injection). It appears that crystalloid coloading is somewhat effective compared with crystalloid preloading (not effective), provided the infusion rate and volume are high enough during the first 5 to 7 minutes after spinal injection when the sympathetic block is established.[160] The timing of a colloid administration does not appear to change its degree of effectiveness.[161] Current evidence suggests that combining a prophylactic vasopressor regimen with HES preloading, HES coloading, or crystalloid coloading is the best method of preventing maternal hypotension after the initiation of spinal anesthesia. Crystalloid preloading is clinically ineffective and thus should no longer be used. Routine fluid loading is no longer advocated prior to spinal anesthesia for cesarean delivery in preeclampsia and should be used with caution in women with multiple gestations.[157]

Ephedrine and Neo-Synephrine are vasopressors commonly used to treat maternal hypotension. Ephedrine is a synthetic, nonselective, noncatecholamine sympathomimetic drug. Doses of 5 to 25 mg intravenously are used to treat acute decreases in blood pressure. The duration of ephedrine's cardiovascular effects varies with the dose given. The effect of a 5- or 10-mg IV dose usually persists for 5 minutes. Tachyphylaxis can occur with repeated administration of small doses, resulting in a noticeably reduced clinical effect after subsequent dosing. Ephedrine is metabolized in the liver, and up to 40% is excreted unchanged by the kidneys. It has an elimination half-life of 3 hours.

Ephedrine causes direct β stimulation and indirect α stimulation through the release of endogenous norepinephrine. It has long been used in obstetric anesthesia because it was thought to affect uterine artery blood flow less than other vasoactive drugs in pregnant ewes.[162] However, recent evidence suggests that ephedrine may cross the placenta and stimulate fetal β-adrenergic receptors, resulting in a depression of fetal acid-base status.[163] Although the ultimate clinical relevance of this effect has yet to be defined, many practitioners are now using phenylephrine as a first-line vasopressor to treat maternal hypotension.[48] Hypotension is a primary cause of intraoperative nausea and vomiting in the early period after spinal anesthesia. Hypotension may lead to cerebral hypoperfusion, which is thought to activate the vomiting center. It has also been suggested that hypotension results in gastrointestinal hypoperfusion with the subsequent release of emetogenic substances such as serotonin. Optimum use of vasopressors to prevent hypotension significantly reduces the incidence of intraoperative nausea and vomiting.[48,164]

Phenylephrine is a direct-acting α_1-adrenergic agonist that results in vasoconstriction and an increased peripheral vascular resistance. It can result in a reflex bradycardia with a subsequent decrease in cardiac output. Based on early animal studies, α-agonists were thought to decrease uterine artery blood flow,[162] but phenylephrine has been shown to be safe for the treatment of maternal hypotension during regional anesthesia when given in the conventional dose range.[165] Neonatal blood gas values and Apgar scores remain within normal limits in all healthy subjects after the administration of 80-mcg or 100-mcg bolus doses of phenylephrine.[166] Phenylephrine can be administered by either bolus dosing or continuous infusion; however, the optimal regimen for each has yet to be determined. Many practitioners now feel that the maternal HR should play a role in the selection of a vasopressor. There is evidence to indicate that during phenylephrine infusion there is a dose-dependent decrease in cardiac output that parallels a decrease in heart rate.[167] When the HR is at baseline or above, phenylephrine may be used. When the HR is below baseline, ephedrine will increase the blood pressure and HR without further reductions in CO. Phenylephrine is now established as a first-line vasopressor for maternal hypotension and can be used with ephedrine for heart rate management.

It is common practice to add opioids to hyperbaric bupivacaine for cesarean section spinal anesthesia because they provide additional intraoperative and postoperative analgesia without affecting the block height. Maternal complaints of nausea, vomiting, and visceral pain occur occasionally even in the presence of an adequate T4 block. Intraoperative block quality can be significantly improved with the addition of fentanyl 10 to 20 mcg or sufentanil 2.5 to 5 mcg. The onset of these lipid-soluble opioids is 5 to 10 minutes with an effective duration of 60 to 90 minutes. Morphine can be added in addition to either fentanyl or sufentanil to provide long-acting postoperative analgesia. Morphine has an onset of action (60 to 90 minutes) that coincides with the effective duration of fentanyl or sufentanil so that, when used in combination, the patient has uninterrupted opioid analgesia intraoperatively and for 12 to 18 hours postoperatively.

After the placenta has been delivered, oxytocin should be given at the direction of the obstetrician. Pitocin is the clinically available synthetic equivalent of oxytocin, a naturally occurring hormone synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. In the mature uterus of a pregnant woman, oxytocin causes an increase in the frequency and strength of uterine contractions. Endogenous oxytocin release occurs with stimulation of the cervix, vagina, and breasts.

The half-life of oxytocin varies from 4 to 17 minutes. It is metabolized by liver, kidney, and plasma enzyme pathways in the parturient. Commercially available preparations of oxytocin contain a preservative that may cause systolic and especially diastolic hypotension, flushing, and tachycardia when infused at high doses.[168] The amount of oxytocin added to the IV solution should be tailored to the volume of solution remaining in the bag, the flow rate of the IV, and the patient's condition. If an unusually large blood loss results in hypotension, and fluid resuscitation is required, it may be helpful to infuse the oxytocin at an appropriate rate and to start a second IV line for administering fluid volume at a rapid rate. If the solution with the added oxytocin is infused fast enough to replace volume, it is possible that the high dose of oxytocin may cause further hypotension. In some cases the obstetrician may choose to administer oxytocin directly into the uterine

muscle to maximize its effect. Carbetocin, a long-acting oxytocin agonist, appears to be a promising agent for the prevention of PPH and is currently being widely studied.

If oxytocin does not adequately stimulate uterine contraction, the next drug used is usually an ergot alkaloid (e.g., Methergine, Ergotrate). Because of their potent vascular effects, ergot alkaloids are not administered intravenously. Ergot alkaloids normally cause an increase in blood pressure, central venous pressure, and pulmonary capillary wedge pressure. An intramuscular dose of Methergine 0.2 mg is commonly administered for stimulating uterine contractions. Intravenous administration, which is avoided, may result in arterial and venous constriction, coronary artery constriction, severe hypertension, cerebral bleeding, headache, nausea, and vomiting. Ergot alkaloids are metabolized and eliminated chiefly by the liver. The plasma half-life is approximately 2 hours, but uterine effects last much longer.

When the uterus does not contract well despite the use of oxytocin and ergot alkaloids, prostaglandin F_{2a} (e.g., Carboprost, Hemabate; 250 mcg) can be administered either intramuscularly or directly into the uterine muscle. Prostaglandins are potent stimulators of uterine contractions. The contractions induced by prostaglandins are strong and painful. Nausea, vomiting, and diarrhea are frequent side effects. In addition to causing uterine contractions, prostaglandins may cause hypotension by relaxing vascular smooth muscle; however, cases of severe hypertension after prostaglandin administration also have been reported.[169]

Transversus abdominal plane (TAP) blocks can be used to provide postoperative analgesia in patients who are not candidates for intrathecal morphine, when neuraxial anesthesia is contraindicated, or in those who receive general anesthesia.[170] The sensory nerves that supply the anterior abdominal wall course through the fascial plane between the internal oblique and the transversus abdominis muscles. Local anesthetics injected into this plane block sensory impulses from the anterior abdominal wall and are effective in relieving the pain associated with a Pfannenstiel incision.[171] A suggested technique for spinal anesthesia for cesarean section is outlined in Box 46-3.

BOX 46-3

Spinal Anesthesia Technique for Cesarean Section

- Nonparticulate oral antacid no more than 1 hour prior to surgery
- Administer an IV preload (colloid) or coload (crystalloid or colloid)
- Apply standard monitors and record preprocedure vital signs
- Record preprocedure fetal heart tones
- Consider oxygen administration
- Perform lumbar puncture at L3-L4
  - Sitting or lateral position
  - Small-gauge (24- or 25-gauge) non-cutting needle (e.g., Sprotte, Whitacre, Pencan)
  - Hyperbaric bupivacaine 15 mg in 8.25% dextrose (7.5-15 mg.)
    - Add fentanyl 20 mcg for intraoperative analgesia
    - Add preservative-free morphine 150 mcg for postoperative analgesia
- Supine position with left uterine displacement
- Monitor blood pressure every 1 minute at least until birth
- Confirm block level (T4) prior to surgical start
- Treat hypotension with phenylephrine; if maternal heart rate decreases below baseline or blood pressure is not increased, use ephedrine
- Administer oxytocin as directed at delivery

Epidural Anesthesia for Cesarean Section

An epidural inserted in the operating room for an elective cesarean section is not often the technique of choice because it has a slower onset and requires a much higher dose of local anesthetic to achieve a surgical level of anesthesia when compared with a spinal anesthetic. However, an epidural catheter does provide the flexibility to extend the duration of the block when a long surgical time is anticipated. The slower-onset sympathectomy associated with an epidural may make treating the resultant hypotension easier and can be of value in patients who are particularly susceptible to abrupt changes in blood pressure. Meticulous attention to correct catheter placement and dosing safety is required when this technique is used due to the increased volume and concentration of local anesthetic needed to obtain a surgical block. After a negative test dose and careful aspiration for blood and CSF, lidocaine 2% with epinephrine 1:200,000 can be used when dosed in 3- to 5-mL increments. A total volume of approximately 20 to 25 mL is required to obtain a T4 level. Bupivacaine is generally avoided due to the increased maternal mortality associated with it when toxicity occurs.

When a parturient with an epidural in place for labor analgesia requires a cesarean section, the indwelling epidural catheter should be used to provide surgical anesthesia. Because larger volumes of more concentrated local anesthetic are required to produce surgical anesthesia and unrecognized epidural catheter movement into either the intrathecal or intravascular space is always a possibility, careful aspiration and incremental dosing is again important. After discontinuation of the analgesic infusion, the selection of local anesthetic is largely determined by the urgency required for delivery. The addition of sodium bicarbonate 1 mEq/10 mL to lidocaine 2% with epinephrine 1:200,000 will hasten the onset of anesthesia when a rapid conversion to surgical anesthesia is necessary. Commercially prepared lidocaine containing epinephrine has a low pH in order to preserve the epinephrine. The addition of sodium bicarbonate immediately prior to use increases the biologically active non-ionized fraction of drug.[172] This combination normally results in approximately 90 to 120 minutes of surgical anesthesia. Sodium bicarbonate cannot be added to bupivacaine because it results in precipitation when the pH is raised. 2-Chloroprocaine is rapidly metabolized by ester hydrolysis and, as a result, is associated with a very low incidence of toxicity; it can be used to rapidly convert a labor epidural to a surgical anesthetic with little concern of toxicity but will likely require intraoperative augmentation because it has an effective duration of approximately 45 minutes. The efficacy and duration of epidural morphine analgesia is diminished when administered after 2-chloroprocaine. The precise mechanism of this interaction is unknown but may be the result of opioid receptor antagonism.[96]

In the presence of a well-functioning labor analgesic, the total volume required to raise the block level from the existing T10 to the required T4 is approximately 10 to 15 mL. Although controversial, conversion of a labor epidural to a surgical anesthetic can be initiated in the labor room in an emergency. Careful attention should be directed toward the existing analgesia level, incremental dosing, and maternal vital signs while in the labor room. On arrival to the operating room, the block level can then be assessed and additional doses given as required during the surgical preparation.

Breakthrough pain in labor requiring multiple epidural doses is a significant predictor of subsequent failure of epidural anesthesia and highlights the need to replace inadequate catheters before an unplanned cesarean is required.[173] Efforts should be directed toward avoiding the situation of a failed epidural in the operating room. This includes early recognition and replacement of poorly performing labor epidurals. However, if an inadequate

epidural is identified in the operating room, and the fetal status allows, consideration should be given toward replacing the epidural to a different interspace or the use of a combined spinal-epidural technique in which the spinal is dosed lightly and the epidural is subsequently used to augment the level as needed. In the scenario of a recently dosed inadequate epidural, a superimposed single-shot spinal anesthetic can often produce an unpredictable, and frequently higher than expected, block level. Alternatively, the inadequate epidural can be given time to absorb and resolve before a single-shot spinal. Ultimately, a general anesthetic may be required. A suggested technique for converting an epidural in use for labor analgesia to a cesarean anesthetic is given in Box 46-4.

Combined Spinal-Epidural for Cesarean Section

As with labor analgesia, the combined spinal-epidural (CSE) technique can provide several advantages over either technique when used alone. A lower spinal dose can be used, resulting in decreased hypotension, whereas the block can be augmented to increase the block height or prolong the duration if necessary. The technique, however, is not without its disadvantages. Because the spinal component is injected prior to placement of the epidural catheter, if difficulty is encountered with catheter placement, the patient could remain in the sitting position for a prolonged time, resulting in lower block height. The presence of a dense spinal block makes evaluating subsequent test doses for subarachnoid injection difficult. If a lower spinal dose is used and the block is not adequate for surgery, subsequent epidural dosing will ultimately delay the start of surgery. Some practitioners advocate the CSE technique after attempts with a spinal have been unsuccessful. An epidural needle has a larger diameter and may be less likely to deflect from its intended direction around dense ligaments or bone.

BOX 46-4

Converting an Epidural in Use for Labor Analgesia to a Cesarean Anesthetic

- Administer nonparticulate oral antacid no more than 1 hour prior to surgery.
- Discontinue continuous epidural infusion.
- Administer an IV coload (crystalloid).
- Apply standard monitors and record preprocedure vital signs.
- Record preprocedure fetal heart tones.
- Consider oxygen administration.
- Place in supine position with left uterine displacement.
- Carefully aspirate epidural catheter for blood and cerebrospinal fluid.
- Administer lidocaine 2% with epinephrine 1:200,000 and sodium bicarbonate 1 mEq/10 mL local anesthetic (total dose 10 to 15 mL).
  - Administer 3 mL and observe maternal heart rate (HR) for 60 seconds and level of block for 3 to 5 minutes.
  - If no sign of subarachnoid or intravascular injection, administer 3 to 5 mL and observe for 3 to 5 minutes.
- Treat hypotension with phenylephrine; if maternal HR decreases below baseline or blood pressure is not increased, use ephedrine.
- Confirm block level (T4) prior to surgical start.
- Administer 3 to 4 mg preservative-free morphine (0.5 mg/mL 6 to 8 mL) via the epidural catheter after cord is clamped for postoperative analgesia.
- Administer oxytocin as directed at delivery.

General Anesthesia for Cesarean Section

General anesthesia (GA) may be indicated despite the numerous disadvantages of the technique when compared with regional anesthesia. GA allows for better control of the airway and improved hemodynamic control, making it useful in cases of existing or expected hypovolemic shock. GA is a necessary choice when a neuraxial anesthetic is not in place and a surgical delivery is urgent enough to preclude its placement or when contraindications, such as patient refusal or coagulopathy, are present. It is also an alternative in the presence of a failed neuraxial technique. Neuraxial techniques have progressively eclipsed GA for use in cesarean section primarily in an effort to reduce maternal mortality.[145] Practical steps to decrease the use of GA include referral and evaluation of high-risk parturients early in pregnancy to optimize their medical condition and plan for anesthetic management, considering early neuraxial anesthetic placement to ensure proper functioning, and promptly replacing epidural catheters that are providing suboptimal labor analgesia.[174]

The Difficult Airway. An airway evaluation is an important part of the preparation for anesthesia in any patient and even more so in the parturient. Airway problems tend to occur more frequently in obstetric patients than in other healthy patients; failure to intubate has been reported to occur as frequently as 1 in 250 obstetric patients.[175] This is true at least in part because of the soft-tissue edema often present in the hypopharynx. A patient's airway may significantly change also during the course of her labor and, as such, should be evaluated again prior to an operative delivery. Breast enlargement and cephalad displacement of the thorax can make maneuvering the laryngoscope into the mouth difficult, necessitating the use of a short-handled laryngoscope. Placement of a rolled towel lengthwise along the thoracic spine or widthwise under the shoulders helps to elevate the chest off the operating table. This makes it possible to extend the neck and position the head more optimally, facilitating insertion of the laryngoscope blade and improving visualization of the glottis. Positioning for the obese parturient for laryngoscopy is shown in Figure 46-8.

Airway problems resulting in a failure to oxygenate and ventilate remain the leading cause of anesthesia-related mortality in the obstetric population.[176]Although rapid-sequence induction is the technique most commonly used to minimize the risk of gastric aspiration during induction of general anesthesia, it is *not* indicated if the laryngoscopist has doubts about his or her ability to intubate the patient. In such a case, an alternative method, such as awake intubation, may be necessary. Blind nasal intubation should be performed cautiously, if at all, in the parturient, who commonly has swollen nasal mucosa that are prone to bleeding. The anesthetist should be familiar with and able to perform the steps in an obstetric failed intubation algorithm (Figure 46-9).

Induction. Induction of general anesthesia requires a rapid-sequence technique using cricoid pressure after denitrogenation and preoxygenation for 3 minutes. The standard induction agent in the healthy parturient is propofol (2 to 2.5 mg/kg). As expected, propofol produces neonatal depression but is rapidly redistributed and cleared from the neonate, resulting in a rapid emergence.[177,178] Ketamine (1 mg/kg) or etomidate (0.3 mg/kg) are especially useful in patients who have airway disease or are hemodynamically unstable. Ketamine has been associated with lower analgesic demands during the first 24 hours postoperatively.[179] The indirect sympathomimetic effect of ketamine helps support blood pressure until adequate intravascular volume can be replaced.

The induction of anesthesia should be delayed until all preparation for surgery is complete and the surgical staff indicates they are ready. The operating surgeon should be instructed to delay

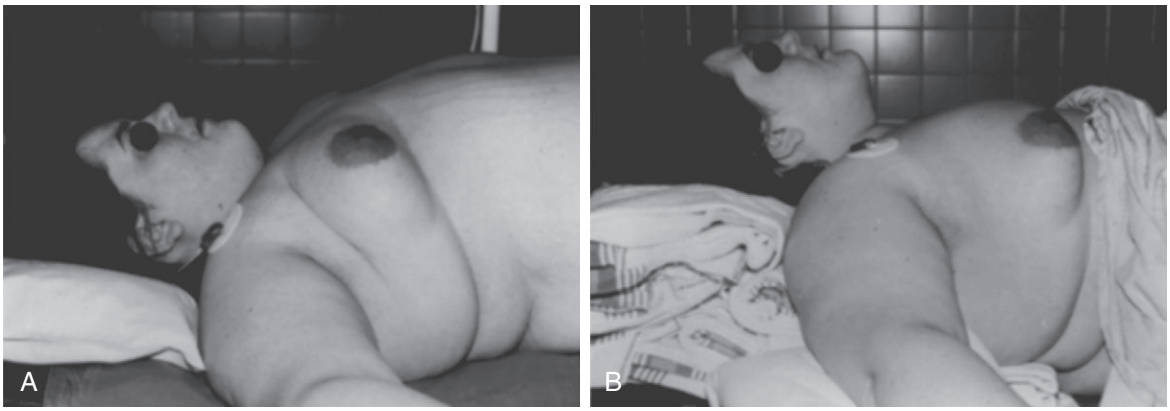

FIGURE **46-8** Positioning for the obese parturient for laryngoscopy. **A,** Standard positioning. **B,** Improved positioning with the elevation of the torso and head. (From Hagberg CA. *Benumof's Airway Management*. 2nd ed. Philadelphia: Mosby; 2007:844.)

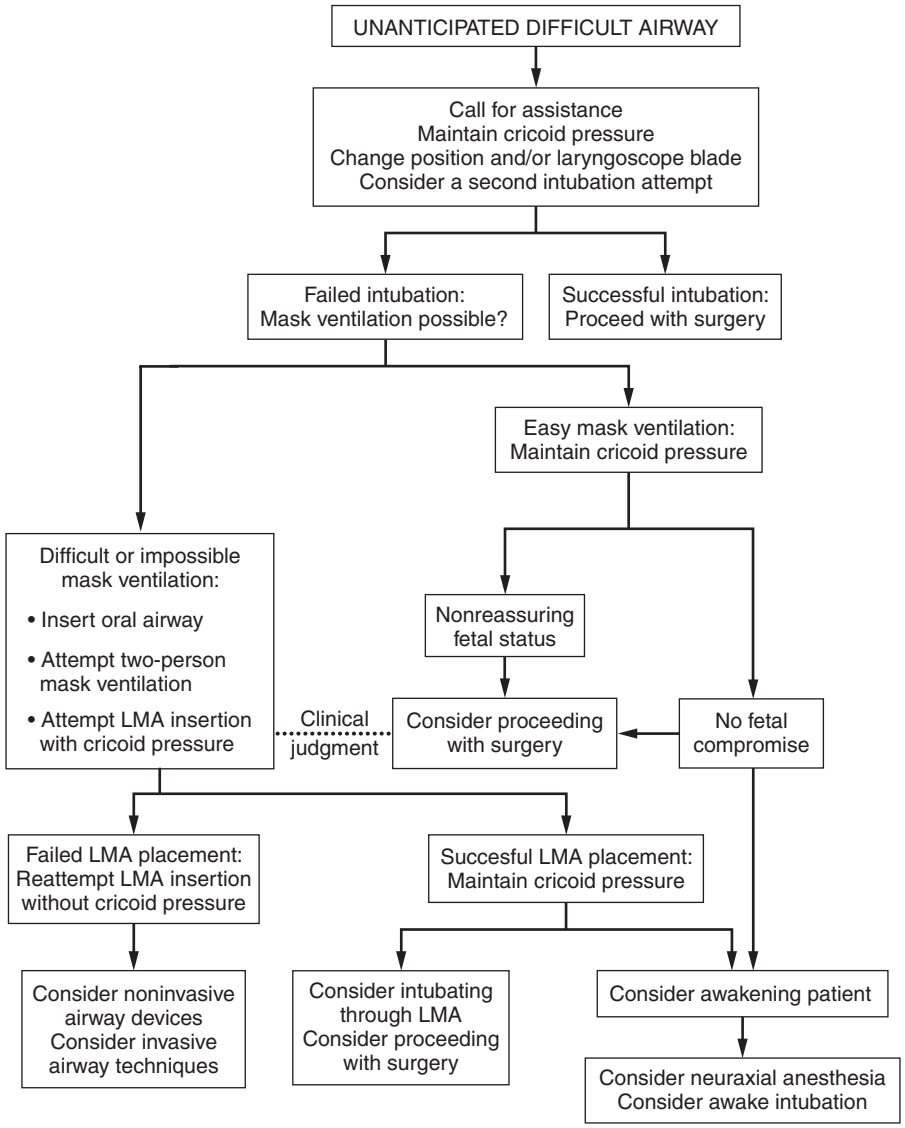

FIGURE **46-9** Unanticipated difficult airway algorithm adapted for use in obstetric anesthesia. It is intended as a guide only. Practitioner's skill set and judgment should guide clinical decisions. (From Chestnut DH, et al. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. St. Louis: Mosby; 2009).

incision until confirmation of endotracheal tube placement is made. The incision is made after verification by capnography, auscultation of breath sounds over the chest and abdomen, and bilateral chest expansion. The reasoning behind this practice is to minimize fetal exposure to depressant drugs.

Succinylcholine (1 to 1.5 mg/kg) remains the muscle relaxant of choice during induction of general anesthesia in the parturient. When succinylcholine is contraindicated, a fast-acting nondepolarizer may be judiciously administered, or an awake intubation may be attempted. Rocuronium 0.5 to 1.0 mg/kg can be used. Although intubation can be accomplished quickly with a fast-onset nondepolarizing muscle relaxant, the duration of action will be longer than with succinylcholine. Pregnancy is associated with fewer fasciculations and less succinylcholine-related muscle pain, therefore, a defasciculating dose of a nondepolarizing muscle relaxant may not be required.

Maintenance of Anesthesia. General anesthesia can be maintained with a volatile inhalational agent and nitrous oxide. The predelivery goal of at least 0.80 MAC should be delivered with a relatively high fresh-gas flow rate consisting of 50% oxygen/50% nitrous oxide to ensure adequate anesthesia and minimize intraoperative awareness. If fetal distress is present or if maternal O_2 saturation is below 97%, high concentrations of O_2 may be used without nitrous oxide. Administering 100% O_2 does result in improved fetal oxygenation compared with 50% O_2, but questions have been raised about the danger of free radical activity in neonates born to women administered greater than 50% O_2.[180] Comparisons of Apgar scores, umbilical venous O_2 tension, time to breathing, and resuscitation efforts in neonates has revealed that infants born to women given 100% O_2 before delivery have slightly better outcomes.[181] Maternal hyperventilation should be avoided during mechanical ventilation because a Pa_{CO_2} less than 20 mmHg can result in decreased uterine blood flow and a shift of the oxyhemoglobin dissociation curve to the left. Maternal Pa_{CO_2} should be maintained at the normal term pregnancy range of 30 to 32 mmHg.

The use of bispectral index (BIS) monitoring remains controversial in that even the most rapid application before an emergency cesarean section takes some time, and its use has not been shown to conclusively prevent recall in all cases.[182] When used, a target BIS score of less than 60 can be obtained at a MAC of approximately 0.8 or above.

Volatile inhalational agents are tocolytic and result in decreased uterine contractility and tone that can result in increased postdelivery blood loss. The uterus continues to contract in response to oxytocin provided the MAC is less than 1.0.[183] In the presence of uterine atony and hemorrhage, their concentration can be decreased at delivery and anesthesia supplemented with narcotics and benzodiazepines as needed. The routine use of intraoperative muscle relaxation is generally not necessary and can be left to the surgeon's preference. Immediately after delivery, the recently distended abdominal musculature is quite flaccid and the surgical team should be accustomed to performing cesarean sections on spontaneously ventilating patients. In the absence of neuromuscular relaxation, the anesthetic depth can be better adjusted to the patient's requirements according to respiratory rate and depth. Intraoperative awareness from inadequate anesthesia may be less likely to occur in a patient who is not surgically relaxed.

Infants delivered by cesarean section under GA are more likely to be depressed and to require active resuscitation compared with those delivered with a neuraxial anesthetic and therefore an individual (other than the anesthesia provider) trained in neonatal resuscitation should be present at delivery.[184] The length of time from uterine incision to delivery has been shown to correlate with the degree of neonatal acidosis.[185] The interval should be recorded. An interval of 3 minutes seems to be the critical value;[186] neonates delivered later than 3 minutes after uterine incision are more likely to be depressed. At the completion of surgery, the patient is extubated awake (i.e., following commands) after full recovery of neuromuscular function has been confirmed and extubation criteria have been met. A suggested method for providing general anesthesia for cesarean section is given in Box 46-5.

BOX 46-5

General Anesthesia for Cesarean Section

- Histamine$_2$-receptor antagonist or proton pump inhibitor and/or metoclopramide intravenously
- Nonparticulate oral antacid no more than 1 hour prior to surgery
- Left uterine displacement
- Apply standard monitors and record preprocedure vital signs
- Record preprocedure fetal heart tones
- Denitrogenation/preoxygenation with 100% oxygen for 3 minutes
- When abdominal preparation is complete and surgical drapes are in place, confirm the surgical team is ready to begin
- Intravenous rapid sequence induction:
  - Cricoid pressure
  - Propofol, ketamine, or etomidate
  - Succinylcholine (rocuronium or vecuronium if succinylcholine is contraindicated)
- Intubation with a 6.0- to 7.0-mm cuffed endotracheal tube
- Pre-delivery maintenance with 50% oxygen/50% nitrous oxide and volatile halogenated agent with a goal of 0.8 minimum alveolar concentration
- After delivery:
  - Increased concentration of nitrous oxide, consider reducing concentration of volatile halogenated agent
  - Opioid titrated as needed
  - Consider a benzodiazepine (midazolam)
  - Muscle relaxant as needed
  - Administer oxytocin as directed
- Extubation awake with intact airway reflexes

Modified from Tsen LC. Anesthesia for cesarean delivery. In: Chestnut DH, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. St. Louis: Mosby; 2009:521.

COMPLICATIONS OF REGIONAL ANESTHESIA

Hypotension

Hypotension is a frequent complication of obstetric neuraxial anesthesia and results from a rapid-onset sympathectomy and subsequent decreased venous return and decreased cardiac output. Hypotension commonly manifests as maternal nausea and vomiting and can impair uterine perfusion. Maternal hypotension of sufficient magnitude and duration results in uteroplacental hypoperfusion and ultimately fetal acidemia. It is defined as a 20% decrease from baseline or a systolic pressure less than 100 mmHg. Efforts to reduce the incidence of hypotension include left uterine displacement, bolus intravenous fluid administration, and the use of vasopressors.

Nausea and Vomiting

Nausea and vomiting is not uncommon during labor and delivery. The causes are often multifactorial and include delayed gastric emptying, administration of opioids, exteriorization of the

uterus, and motion during transport. The aggressive treatment of hypotension can prevent much vomiting. Some clinicians believe that a sympathetic block results in unopposed gastrointestinal vagal stimulation, which predisposes the patient to nausea. The administration of an antimuscarinic agent (glycopyrrolate) before the institution of either an epidural or subarachnoid block may prevent nausea by this mechanism. Opioids administered in either the epidural or subarachnoid space improve block quality and do not increase intraoperative nausea.

Multimodal approaches combining antiemetics with different mechanisms of action may be more effective than single drugs when treating nausea and vomiting.[187] Metoclopramide (10 mg IV) is a frequently given prokinetic that likely reduces the incidence of intraoperative nausea and vomiting. It can be given preoperatively or at cord clamp.[188] The serotonin receptor antagonist ondansetron (4 mg IV) may be somewhat more effective compared with metoclopramide in preventing intraoperative nausea.[189] Scopolamine transdermal patches have been shown to significantly reduce the incidence of post–cesarean section nausea and vomiting resulting from regional anesthesia.[190] Transdermal scopolamine patch begins to be effective in 2 to 4 hours. Although this onset time is long, the duration of action and simplicity of the scopolamine patch (48 hours or longer) make it an attractive choice for parturients with a strong history of PONV. Side effects include dry mouth and dizziness, which, for some patients, will outweigh the benefits of scopolamine.

Postdural Puncture Headache

Postdural puncture headache (PDPH) is a result of a loss of CSF from the subarachnoid space. The total volume of CSF normally present within the subarachnoid space is approximately 150 mL; 75 mL above the foramen magnum, 75 mL caudad to the foramen. Production is approximately 0.35 mL/min or 500 mL/day. PDPH occurs when CSF loss exceeds production. CSF loss occurs through a hole in the dura made during the performance of a subarachnoid block or accidentally during the attempted performance of an epidural block. Because the needle used to place an epidural catheter has a larger diameter (17 to 18 gauge) relative to spinal needles used in contemporary practice, puncture of the dura with an epidural needle can result in the loss of a significant volume of CSF. Loss of CSF is not the only cause of headache after regional anesthesia in the obstetric patient. In a retrospective review of 95 women who had a headache more than 24 hours after delivery, Stella et al.[191] found that tension/migraine and preeclampsia/eclampsia accounted for over 70% of reported headaches whereas a diagnosis of PDPH was made in 16%. More serious causes of postpartum maternal headache include meningitis and intracranial pathology such as cortical vein thrombosis and subarachnoid hemorrhage.

The incidence and severity of PDPH vary with factors thought to be related to the volume and rate of CSF leakage from the subarachnoid space. The incidence of PDPH is inversely related to age and seen infrequently in those older than 70 and younger than 10 years old. Women appear to be slightly more susceptible than men, and pregnancy may increase the incidence. In general, large-diameter needles are more likely to be associated with PDPH when compared with small-diameter needles. A dural puncture with a 17-gauge epidural needle has a 70% PDPH rate compared with less than 1% with a pencil-point spinal needle. With respect to spinal needles, the incidence of PDPH is significantly reduced with the use of pencil-point needles (e.g., Pencan, Sprotte, Whitacre) compared with beveled cutting needles (e.g., Quincke) (Figure 46-10). In a retrospective study of 366 obstetric patients, the incidence of PDPH after the use of a Sprotte needle was 1.5%, compared with 9% after the use of a beveled Quincke needle of similar gauge.[192]

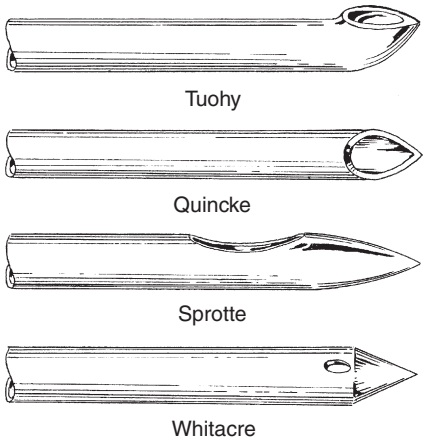

FIGURE **46-10** Physical characteristics of four different types of spinal and epidural needles. Needle diameters are not to scale.

Some evidence indicates that the bevel's orientation as it punctures the dural fibers plays a role. Electron microscopy has confirmed that the collagen fibers composing the dura are oriented primarily longitudinally.[193] Penetrating the dural fibers along their vertical axis may result in less CSF leakage compared with horizontal bevel orientation. The angle at which the needle approaches the dura may also modify the amount of CSF leakage and therefore the incidence of PDPH; however, the angle of approach most often is dictated by anatomy and therefore is difficult for the anesthetist to modify effectively. When inadvertent dural puncture occurs during epidural placement, there is evidence to indicate that placing a subarachnoid catheter reduces the incidence of PDPH.[134] The use of air as opposed to saline in the loss of resistance technique may also be associated with greater PDPH rates. Aida et al.[194] studied 3700 patients who received epidural anesthesia and found that 100 had an inadvertent dural puncture. PDPH occurred in 67% of the patients in the air group as opposed to 10% in the saline group. A head computed tomography (CT) scan was done in all 100 PDPH patients that identified supraspinal intrathecal air bubbles in 78% of those with PDPH.

The hallmark of a PDPH is its postural component. The headache is relieved when supine and returns on sitting or standing. It is commonly fronto-occipital and sometimes is associated with neck and shoulder stiffness. Photophobia may be present in patients with severe headaches, whereas double vision occurs less frequently. Temporary deafness has occurred rarely. The onset of the headache is usually not immediate, but may take 1 to 2 days to become bothersome. It can be mild to severe, and often becomes worse if the patient feels sick and does not consume liquids.

Treatment

Patients should be given a choice of treatments ranging from the most conservative to the most aggressive. PDPH may be a mild irritation for a few days, or it may be debilitating. Conservative treatment is appropriate for mild headaches and includes bed rest, hydration, and oral analgesics. In hospitalized patients who are not taking fluids by mouth, IV hydration is warranted. Liberal hydration does not increase the production of CSF; however, it is important that the patient not be allowed to become dehydrated, because dehydration does decrease CSF production.

Caffeine is a cerebral vasoconstrictor that can be transiently effective in relieving the symptoms of PDPH in some patients.

Serotonin also causes cerebral vasoconstriction. Case reports of serotonin type-1 δ-receptor agonists (sumatriptan) successfully relieving PDPH have also been published.[195]

Severe PDPH that is unresponsive to conservative therapy for 24 hours should be treated with an epidural blood patch. The usual contraindications to an epidural procedure apply as well to this treatment. After resolution of the neural blockade has been confirmed, a blood patch is performed by placing an epidural needle in the epidural space, preferably at the same interspace as the dural puncture or one interspace below. Once the needle is in place, an assistant performs a peripheral venipuncture and draws 20 mL autologous blood using strict aseptic technique. The blood is then slowly injected into the epidural space. The ideal volume for injection appears to be between 15 and 20 mL. If discomfort develops in the back or neck, the injection is temporarily stopped. If the discomfort passes quickly, slow injection of the target volume of 15 to 20 mL may continue (unless discomfort returns). After the desired volume is injected, the Tuohy needle is withdrawn, and the patient should lie quietly for at least 1 hour.[196]

The mechanism of action appears to be two-fold. First, the epidural blood covers the dural defect with a fibrin clot, and second, the injected volume of blood applies pressure to the dura, decreasing the relative total volume of CSF. An epidural blood patch is effective in more than 90% of patients when it is performed 24 hours or more after the dural puncture. A second patch is effective in approximately half of those who do not obtain relief from the first; this brings the total success rate to approximately 95%. Placing further patches does not increase the success rate significantly. A prophylactic blood patch is a technique in which autologous blood is injected through the epidural catheter immediately prior to its removal. However, the patient likely has yet to develop a headache and may then be treated unnecessarily. The absolute sterility and precise location of an indwelling epidural catheter cannot be easily assured. In addition, prophylactic blood patches do not appear to reliably influence the incidence or severity of PDPH.[197]

Seizures Related to Local Anesthetics

Local anesthetic–induced seizures during epidural anesthesia can result from inadvertent direct vascular injection into an epidural vein or accumulation from repeated dosing. The signs and symptoms of local anesthetic toxicity are directly related to their serum concentration and increase in severity as the concentration rises. Early signs of systemic toxicity include circumoral numbness, lightheadedness, and visual and auditory disturbances although both neurologic and cardiovascular signs may occur simultaneously. Unconsciousness, seizures, and cardiovascular depression/collapse follow as plasma concentrations increase further.

Necessary measures to prevent local anesthetic toxicity during epidural anesthesia include aspiration of the catheter for blood prior to injection, use of an appropriate test dose, fractionated dosing, and vigilance for signs of toxicity. The incidence of venous cannulation with an epidural catheter is approximately 6% in the obstetric population. In a recent review of randomized controlled trials, Mhyre et al.[198] identified effective strategies to reduce the incidence of venous cannulation that included insertion in the lateral as opposed to the sitting position, using single-orifice rather than multi-orifice catheters, using wire-embedded polyurethane (soft) rather than nylon (hard) catheters, and limiting the depth of insertion to less than 6 cm.

Clearly, the first step to be taken when any of these signs or symptoms occurs is discontinuation of the injection of local anesthetic. Early recognition of a positive response to a test dose often halts the progression of symptoms. If a seizure occurs, both mother and fetus are at risk of hypoxia. Quick action involves the administration of small doses of a benzodiazepine to end the seizure and support of ventilation and oxygenation. The seizures are not necessarily lethal, but the resultant anoxia and acidosis are. Emergency drugs, a self-inflating breathing bag, masks, laryngoscopes, oral and nasal airways, endotracheal tubes, and stylets should be on all epidural insertion carts. Cardiovascular support is provided symptomatically, when needed. Careful evaluation of the maternal and fetal status should dictate decisions regarding obstetric management. The American Society of Regional Anesthesia and Pain Medicine has recently issued a new practice advisory on local anesthetic systemic toxicity, and it is presented in detail in Chapter 10.[199]

Rescue treatment with 20% lipid emulsion has been shown to be effective in treating local anesthetic–induced cardiotoxicity. The precise mechanism of action remains unknown but may involve the exogenous lipid providing an alternate binding site for the lipid-soluble local anesthetic, often referred to as the lipid sink theory. Although the timing, dose, and duration has yet to be firmly established, its low cost, simplicity of use, and apparent lack of significant side effects leads to the recommendation that 20% lipid emulsion be available wherever regional anesthesia is used. [200]

Total Spinal Block

Total spinal anesthesia is a complication that results from the excessive and unintended cephalic spread of local anesthetic. It can follow the inadvertent injection of a large "epidural" dose of local anesthetic into the subarachnoid space after unrecognized subarachnoid catheter placement or migration of a previously placed epidural catheter into the subarachnoid space. Unintentionally high or total spinal block also can result from a single-shot spinal anesthetic performed after a failed epidural block. It is thought that the large amount of previously placed epidural local anesthetic migrates through the dural hole made by the spinal needle. A total spinal block is normally rapid in onset and preceded by complaints of dyspnea, difficult phonation, and hypotension. In the presence of these symptoms, consideration should be given to alternative diagnoses that include anaphylactic shock, eclampsia, or amniotic fluid embolus.

Accidental Subdural Injection

Occasionally the epidural catheter may be placed inadvertently in the subdural space between the dura and arachnoid membranes. After a negative test dose for intravascular and subarachnoid injection, local anesthetic is administered through the supposed epidural catheter in the normal fashion. After a delay of 10 to 25 minutes, a sudden excessive spread of the block is noted,[187] primarily in the cephalad direction.[201] The magnitude of the spread of the local anesthetic block is significantly greater than would be anticipated if the catheter were in the epidural space and very similar to what would be expected with a subarachnoid injection. Hypotension caused by extensive sympathetic block is usually the primary problem and is treated with ephedrine or other vasopressors as needed. If the block is sufficiently extensive to compromise respiration or airway maintenance, endotracheal intubation is necessary. This complication is uncommon and likely unpreventable. The possibility of respiratory compromise emphasizes the necessity of being prepared to manage such a complication as well as the need for close monitoring after epidural administration.

Cardiopulmonary Resuscitation of the Pregnant Patient

Cardiopulmonary resuscitation (CPR) has been accomplished successfully early in pregnancy, but use of the technique is problematic at best in the near-term parturient. The fetus does not tolerate

decreases in maternal oxygenation and blood pressure well. The mother has a high O_2 demand and a small O_2 reservoir (residual volume). Most importantly, the term or near-term uterus obstructs central venous return in the supine parturient.[202,203] It follows that left uterine displacement is important to the success of CPR in pregnant women. However, lateral tilt has been shown to decrease the force of cardiac compressions and presumably their effectiveness.[204] When the near-term parturient does not respond to resuscitative efforts within 5 minutes, emergent cesarean section is often indicated. This makes possible direct oxygenation of the neonate and has resulted in substantially improved venous return in the mother,[203] ultimately allowing for successful resuscitation.

Neurologic Injuries

Neurologic complications are fortunately rare but may be associated with labor and delivery or neuraxial anesthesia. In a retrospective review of observational studies, Ruppen et al.[204] found the incidence of persistent neurologic injury in obstetric patients who received epidural anesthesia or analgesia to be 1 in 240,000 and the rate of transient (less than 1 year duration) neurologic injury to be 1 in 6700. Obstetric injuries related to childbirth involve pressure and stretching of peripheral nerves by the descending fetus and are identified by the appearance of a single neuropathy. On the other hand, neuraxial anesthesia–related injuries involve a spinal nerve root and, hence, follow a dermatomal distribution. Although neuraxial anesthesia is often cited as the cause of all obstetric nerve injuries, careful identification and evaluation of the defect can indicate otherwise. The American Society of Regional Anesthesia and Pain Medicine has published a practice advisory on neurologic complications that discusses this topic further.[193] Figure 46-11 illustrates the distribution of both peripheral nerve sensory innervation and spinal dermatomes.

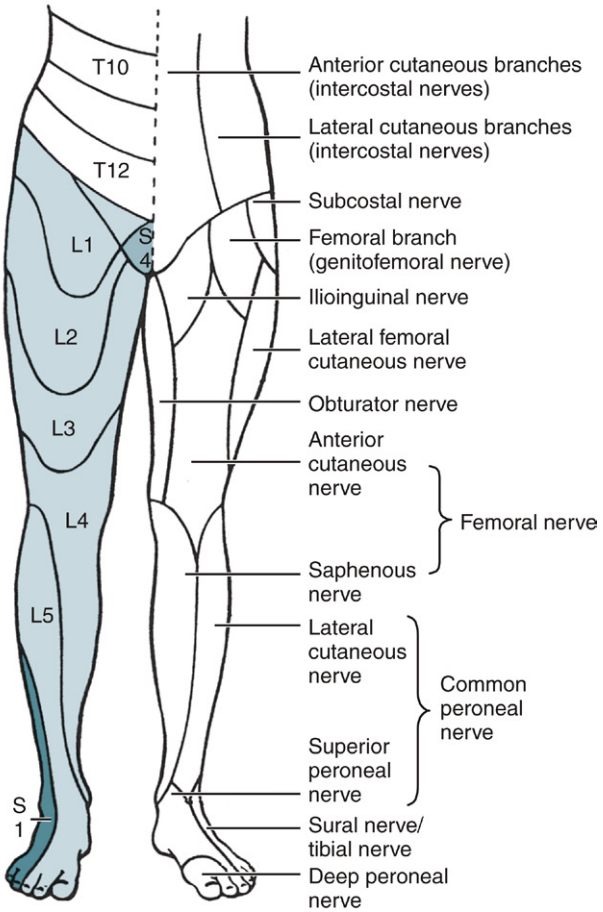

FIGURE **46-11** The dermatomal (right leg) and peripheral (left leg) sensory nerve distributions useful in distinguishing central from peripheral nerve injury. (From Redick LF. Maternal perinatal nerve palsies. *Postgrad Obstet Gynecol.* 1992;12:1-6. In: Chestnut DH, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. St. Louis: Mosby; 2009:705.)

OBSTETRIC COMPLICATIONS

Maternal morbidity and mortality continue to remain a problem in the United States. Using the 2003 to 2006 Nationwide Inpatient Sample, approximately 1.3 per 1000 hospitalizations for delivery was complicated by near-miss morbidity or mortality. The majority of these events (58.3%) occurred in 11.8% of the delivering population. Most of the women have important medical comorbidities or obstetric complications identified prior to admission for delivery. The highest rates were noted among women with pulmonary hypertension (98.0 cases per 1000 deliveries), malignancy (23.4 per 1000), and systemic lupus erythematosus (21.1 per 1000).

Common causes of maternal death include hemorrhage, embolism, preeclampsia, infection, and congestive heart failure.[205]

Prematurity

Premature delivery is a leading cause of perinatal morbidity and mortality. Premature delivery is implicated in more than 50% of all perinatal deaths. Premature labor is defined as regular uterine contractions that occur before 37 weeks of gestation or before 259 days from the last menstrual cycle and that result in dilation or effacement of the cervix. Late preterm births, defined as those of 34 to 36 weeks' gestation, compose approximately 70% of all preterm births.

Fetal size is categorized as: low birth weight, referring to births weighing 500 to 2500 g; very low birth weight, referring to births of 500 to 1500 g; and extremely low birth weight, referring to births of 500 to 1000 g. Preterm labor diagnosis is facilitated by measuring fetal fibronectin and maternal cervical ultrasonography.[206]

The ability to stop premature labor can allow the fetus additional time to mature. It is often given for 48 hours to allow for corticosteroid and latency antibiotic administration, which promote fetal maturation and decrease maternal chorioamnionitis. Stopping labor is termed *tocolysis* (from the Greek *tokos*, meaning "childbirth," and *lysis*, meaning "breaking up"). The cause of preterm labor is not well understood; however, four pathways are supported by a considerable body of clinical and experimental evidence: myometrial and fetal membrane overdistention, decidual hemorrhage, precocious fetal endocrine activation, and intrauterine infection or inflammation. The processes leading to preterm parturition may originate from one or more of these pathways. Common risk factors include multifetal pregnancies and preterm rupture of membranes.[207,208]

Methods of Tocolysis

Although more than 80% of women with preterm labor who are treated with tocolytics have their pregnancies maintained for 24 to 48 hours, few data suggest that tocolysis maintains pregnancy for a longer period. A critical goal of tocolysis is to delay delivery long enough to allow for the administration of corticosteroids, which reduces the risks of the neonatal respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, and overall perinatal death. The initial benefit of corticosteroid therapy occurs approximately 18 hours after administration of the first dose with maximal benefit at about 48 hours. Thus treatment

of acute preterm labor may allow time for the onset of the therapeutic effect of corticosteroids. As a general rule, if tocolytics are given, they should be given concomitantly with corticosteroids. The gestational age range for their use is debatable, but because corticosteroids are not generally used after 33 weeks, most practitioners do not recommend use of tocolytics at or after 33 weeks.[207] Some obstetricians are questioning the use of tocolytics. They cite growing evidence that bacterial colonization of fetal membranes and amniotic fluid triggers an inflammatory response in the mother and fetus and this leads to preterm labor and long-term neurologic and respiratory complications in the neonate. This raises questions about the desirability of prolonging pregnancy in this context. Combined with recent meta-analyses that fail to demonstrate improvements in neonatal outcome with tocolytic use, and a poor maternal/fetal side-effect profile, the case for continued use of these drugs needs to be questioned.[208-210]

A variety of agents are used as tocolytics. These include β-adrenergic receptor agonists, nitric oxide donors, magnesium sulfate, calcium channel blockers, prostaglandin synthesis inhibitors, and oxytocin antagonists. Labor-inhibiting drugs are only marginally effective. Tocolytics act by two primary mechanisms: through generation or alteration of intracellular messengers or by inhibiting the synthesis or blocking the action of a known myometrial stimulant.

Magnesium Sulfate. Magnesium sulfate has been used for decades as a tocolytic, but recent evidence questions its efficacy.[210] Magnesium causes relaxation of vascular, bronchial, and uterine smooth muscle by altering calcium transport and availability. Motor end plate sensitivity and muscle membrane excitability also are depressed. Magnesium hyperpolarizes the plasma membrane and inhibits myosin light-chain kinase activity by competing with intracellular calcium, which in turn reduces myometrial contractility.

The normal serum magnesium level during pregnancy is 1.8 to 3 mg/dL. A serum magnesium level of 4 to 8 mg/dL is therapeutic as a tocolytic, but even toxic levels do not eliminate uterine contractility. At 10 to 12 mg/dL, the patellar reflex is eliminated. Levels above 12 mg/dL cause respiratory depression; at approximately 18 mg/dL, respiratory depression progresses to apnea. The presence of higher levels (25 mg/dL) can cause cardiac arrest. Women given magnesium sulfate must be monitored closely for evidence of hypermagnesemia.

The side effects of magnesium sulfate administration are dose dependent. The most frequent serious side effect is pulmonary edema.[207] As magnesium levels increase, skeletal muscle weakness increases and CNS depression and vascular dilation occur. Magnesium sulfate infusion commonly results in a slight decrease in blood pressure during epidural anesthesia. Magnesium antagonizes the vasoconstrictive effect of α-agonists, so ephedrine and phenylephrine are likely to less effectively increase maternal blood pressure when administered concomitantly with magnesium. Cardiac muscle is not affected to a clinically evident degree when magnesium is administered at therapeutic levels, although magnesium can have profound myocardial effects during a gross overdose. Magnesium is eliminated unchanged by the kidneys.

Patients on magnesium sulfate therapy have partial, if subclinical, neuromuscular blockade. Both depolarizing and nondepolarizing neuromuscular blocking drugs are potentiated by magnesium.[211] Administration of priming or defasciculating doses of neuromuscular blocking drugs may cause significant paralysis when combined with magnesium therapy. The neuromuscular-blocking effects of magnesium can be at least partially antagonized by calcium.

Magnesium sulfate overdose is treatable. In an excellent case report, a 23-year-old gravida received a 20-g bolus of magnesium sulfate superimposed on a therapeutic magnesium (Mg^{2+}) level. She attained a magnesium level of 38.7 mg/dL. She had a respiratory arrest, became hypotensive and bradycardic, and developed a prolonged QRS complex. Resuscitation was successfully accomplished with discontinuation of the magnesium administration, endotracheal intubation and ventilation, IV administration of calcium chloride, and diuresis to facilitate the elimination of magnesium. Vital signs improved dramatically with ventilation and calcium administration, and the woman was extubated 8 hours later after her magnesium level had declined to a therapeutic level.[212]

Neonatal side effects after maternal magnesium administration are rare. A few cases of hypotonia and respiratory depression in neonates after prolonged high-dose maternal magnesium administration have been reported; however, in general, magnesium administration is safe for the neonate. Magnesium is also used in the treatment of preeclampsia, a vasospastic disease of pregnancy that can result in severe hypertension, coagulopathy, and seizure. Magnesium sulfate causes relaxation of vascular smooth muscle, a decrease in SVR, and a decrease in blood pressure. At serum levels of 7 to 9.5 mg/dL, it is an anticonvulsant. It also decreases fibrin deposition, improving circulation to visceral organs that are vulnerable to vasospasm and failure.

β-Agonists. Stimulation of the β_2-receptor system causes smooth muscle relaxation, including relaxation of the uterus. The myometrium has β_2-receptors in cell membranes. Stimulation of these receptors triggers a cascade of biochemical effects, resulting in inhibition of myometrial contractility at the cellular level. β_2 stimulation also causes an increase in progesterone production. Progesterone in turn causes histologic changes in myometrial cells that limit the spread of contractile impulses. The β-adrenergic receptor agonists cause myometrial relaxation by binding to β_2-adrenergic receptors and subsequently increasing the levels of intracellular cyclic adenosine monophosphate (AMP), which activates protein kinase, inactivating myosin light-chain kinase, thus diminishing myometrial contractility.

β_2 stimulation increases blood glucose and insulin levels. When a β-agonist infusion is started, the blood glucose level increases within a few hours and returns to baseline within 72 hours without treatment. Potassium is redistributed from the extracellular to intracellular compartments. This results in a decrease in serum potassium level, sometimes to less than 3 mEq/L. As with glucose levels, serum potassium levels return to normal within 72 hours after initiation of β-agonist therapy.

Clinically used β-agonists cross the placenta and have fetal and neonatal effects. Fetal tachycardia (FHR greater than 160 bpm) is common. Neonatal hypoglycemia may result, especially if maternal serum glucose is elevated at delivery. When maternal and therefore fetal blood glucose levels are elevated, the fetus increases insulin release in response. After delivery the neonate continues to release insulin at an increased rate, even though it is no longer receiving a glucose load from the mother, which can result in a rebound hypoglycemia.

Terbutaline (Brethine, Bricanyl, others) is a synthetic, relatively β_2 receptor–selective, noncatecholamine sympathomimetic amine. Due to the high incidence of tachycardia and other significant side effects and its lack of efficacy, terbutaline use is currently discouraged.[207,209]

Nitric Oxide Donors. Nitric oxide is a vasodilator that is essential for the maintenance of normal smooth-muscle tone and is produced in a variety of cells. Nitric oxide increases cyclic guanosine

monophosphate (cGMP) content in smooth-muscle cells that inactivates myosin light-chain kinases, leading to smooth-muscle relaxation. In a comparison of nitroglycerin (a nitric oxide donor) and magnesium sulfate, the latter was more likely to delay delivery for at least 12 hours. However, transdermal nitroglycerin was superior to placebo in prolonging pregnancy. Maternal hypotension is common, and nitroglycerin is rarely used.[207,209]

Calcium Channel Blockers. Nifedipine is the most commonly used calcium channel blocker agent because it can be administered orally. Calcium channel blockers inhibit the influx of calcium ions through the cell membrane and the release of intracellular calcium from the sarcoplasmic reticulum. This decreases intracellular free calcium, leading to inhibition of calcium-dependent myosin light-chain kinase–mediated phosphorylation, which results in myometrial relaxation. The combination of nifedipine with magnesium for tocolysis is potentially dangerous due to neuromuscular blocking effects that can interfere with pulmonary and cardiac function.[207]

Cyclooxygenase Inhibitors. Cyclooxygenase converts arachidonic acid to prostaglandin H_2. Prostaglandin H_2 serves as a substrate for tissue-specific enzymes, which are critical to parturition. Prostaglandins enhance the formation of myometrial gap junctions and increase available intracellular calcium by raising transmembrane influx and sarcolemmal release of calcium. Indomethacin is the most commonly used tocolytic agent in this class.[207]

Oxytocin Receptor Antagonists. Atosiban is an oxytocin receptor antagonist that blocks the normal effects of oxytocin in the uterus. Normally, oxytocin stimulates contractions by inducing the conversion of phosphatidyl inositol triphosphate to inositol triphosphate, which binds to a protein in the sarcoplasmic reticulum and causes the release of calcium into the cytoplasm. Reports of fetal deaths with the administration of atosiban before 28 weeks of gestation have limited the use of this agent. The FDA has not approved atosiban for use in the United States as a tocolytic.[207]

Anesthetic Considerations

When an anesthetic intervention is planned for a patient who is receiving a tocolytic agent, knowledge of maternal and fetal physiology and of the pharmacology of the tocolytic agent must be integrated.

Regional Anesthesia

When tocolysis fails, preterm deliveries are often accomplished by cesarean section. In this situation, 1- and 5-minute Apgar scores have been shown to be higher in neonates delivered with epidural anesthesia than in those delivered with general anesthesia.[213] Patients on magnesium therapy are often candidates for subarachnoid or epidural blocks as long as careful attention is devoted to volume status. Magnesium causes vasodilation, and maternal hemorrhage is tolerated poorly by parturients on magnesium.[214-215]

General Anesthesia

Succinylcholine is the muscle relaxant of choice during the rapid-sequence induction of an obstetric patient. In patients on magnesium therapy, defasciculation with a small dose of a nondepolarizing neuromuscular blocking agent is not recommended because significant paralysis may result, increasing the risk of aspiration of gastric contents. Magnesium potentiates depolarizing and, especially, nondepolarizing relaxants.[211]

Embolism

Thromboembolism

Thrombotic pulmonary embolism occurs in pregnant individuals five times more often than in nonpregnant individuals and is more likely to occur postpartum than antepartum. It is associated with prolonged inactivity, cesarean delivery, obesity, and increasing age and parity. The patient with pulmonary embolism may have a few minor complaints or a massive cardiovascular collapse. Pleuritic chest pain, dyspnea, hyperventilation, hypocapnia, coughing, hemoptysis, and distention of neck veins are associated with the disorder.

Venous Air Embolism

Venous air embolism can occur during labor, spontaneous vaginal delivery, and operative delivery and is frequently associated with placenta previa. During cesarean section most venous air emboli are detected between the time of delivery and uterine repair.[216,217] Air is entrained into open maternal venous sinuses in the uterine wall when the placenta separates or at the site of a surgical incision. As air accumulates in the pulmonary bed, the resultant increase in pulmonary vascular resistance causes an increase in central venous pressure. A heavy, nonradiating, retrosternal chest pain may persist for 10 minutes after even a small venous air embolism, and dyspnea is common. End-tidal CO_2 drops, because CO_2 cannot return to the lungs. A mill-wheel murmur may be heard over the precordium as a frothy air-blood mixture moves through the heart. This murmur is most pronounced when a large volume of air becomes trapped in the right ventricle. If a sufficient number of pulmonary arteries are affected, cardiovascular collapse can occur.

Amniotic Fluid Embolism

Amniotic fluid embolism is rare and may occur during labor, vaginal, or operative delivery and is occasionally associated with placental abruption. The pathogenesis is almost identical to that of venous air embolism except that patients who develop amniotic fluid embolism are prone to develop disseminated intravascular coagulation (DIC) if they survive the initial insult. Signs and symptoms of amniotic fluid embolism include chills, anxiety, cough, dyspnea, cyanosis, tachypnea, pulmonary edema, and cardiovascular collapse. O_2 saturation has been reported to decrease quickly.[216]

Anesthetic Implications

The incidence of postpartum thromboembolism can be affected by anesthetic interventions. Cesarean sections performed with general anesthesia are associated with accelerated maternal coagulation compared with those performed with regional anesthesia. The anesthetist can help prevent prolonged inactivity in those who have had a cesarean section by providing analgesia sufficient to allow comfortable ambulation. Use of epidural opioid analgesia is often an appropriate solution to this problem.

Because air embolism occurs when open veins are above the level of the heart, raising the head of the bed in order to position the uterus below the heart would seem to be useful for preventing embolization. However, a head-up tilt of between 5 and 10 degrees does not appear to decrease the incidence of venous air embolism during cesarean section and has increased the incidence of hypotension.[218] If embolism is suspected during spontaneous or operative delivery, the obstetrician should be informed immediately. The obstetrician can take steps to stop the entrainment of air or amniotic fluid, which include flooding the surgical field with saline, returning the uterus to within the abdomen, and stimulating uterine contractions.

One hundred percent O_2 should be administered and nitrous oxide, if in use, should be discontinued because it rapidly expands the volume of an air embolus and prevents the delivery of

100% O_2. An arterial line may be needed for monitoring of oxygenation and blood pressure. If the fetus has not been delivered, left uterine displacement improves uterine blood flow and facilitates hemodynamic stability. Pharmacologic support of the cardiovascular system is likely to be needed.

Patient position has been suggested to hinder the movement of the foreign substance into the pulmonary arteries. A slight reverse Trendelenburg (head-up) position with left lateral tilt of at least 15 degrees is designed to trap air in the right atrium, from which it can be aspirated via a central venous catheter.

In the case of amniotic fluid embolism, prompt recognition and action is necessary to prevent maternal mortality. Immediate support of maternal respiration and circulation is required. Treatment for coagulopathy must also begin immediately and ideally with the consultation of a hematologist.

Placenta Previa

Placenta previa is present when the placenta has implanted on the lower uterine segment and either partially or completely covers the opening of the cervix. Placenta previa has an incidence of up to 1%, and the mortality rate for those with it approaches 1%. Placenta previa is more common in women who have had it during a prior pregnancy. It most often results in painless vaginal bleeding before the onset of labor that may stop without intervention or hemodynamically significant blood loss. The potential exists, however, for *sudden* loss of large amounts of blood. The risk of bleeding increases if the placenta is disturbed by manual examination of the cervix. Postpartum bleeding is often increased as well because the lower uterine segment, where the placenta previa was implanted, does not contract as well as the remainder of the uterus. Three variations of placenta previa are shown in Figure 46-12.

Anesthetic Implications

The diagnosis of placenta previa normally indicates an operative delivery. The anesthetist should prepare for increased blood loss and may choose either a general or regional anesthetic technique. Consideration should be given to the parturient's existing volume status and potential for blood loss.

Abnormal Placental Implantation

The placenta normally implants into the endometrium. A placenta implanted on or in the myometrium, the underlying muscular layer of the uterus, is termed *placenta accreta* (on the myometrium), *placenta increta* (into the myometrium), or *placenta percreta* (completely through the myometrium). Abnormal placental implantation likely precludes complete separation of the placenta from the uterine wall resulting in hemorrhage at delivery.

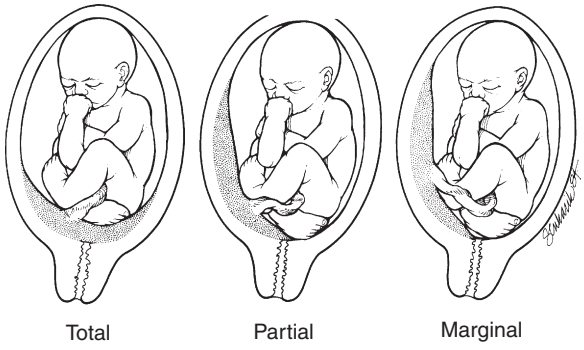

FIGURE **46-12** Three variations of placenta previa. (From Gabbe SG, et al. *Obstetrics: Normal and Problem Pregnancies*. 6th ed. Philadelphia: Saunders; 2012:422.)

Placenta accreta, placenta increta, and placenta percreta (Figure 46-13) are associated with placenta previa and are more common in women who have had a previous cesarean section.

Placental Abruption

Abruption occurs when the placenta begins to separate from the uterus before delivery; this allows bleeding behind the placenta and jeopardizes fetal blood supply. Placental abruption results in hemorrhage, uterine irritability, abdominal pain, and fetal hypoperfusion. Open venous sinuses in the uterine wall may allow amniotic fluid to enter the maternal circulation, resulting in an increased incidence of DIC. The reported incidence of abruption in the general population varies widely but is much higher in women with hypertension (up to 23% among women with preeclampsia).

Anesthetic Implications

In cases of placental abruption without fetal distress, vaginal delivery may still be possible. Because fetal distress can occur without warning, the anesthetist should be prepared to administer anesthesia for an emergency cesarean section. Performing a preanesthetic evaluation as soon as the diagnosis of placental abruption becomes known and confirming adequate IV access is recommended. If the mother is unstable or if fetal distress is present, operative delivery is necessary. Although placental abruption does not usually result in sudden blood loss, a large volume of trapped blood may become apparent at delivery.

Postpartum Hemorrhage

Approximately 4% of all parturients who deliver vaginally experience postpartum hemorrhage (PPH), and the incidence appears to be increasing over time.[218] Often, blood loss is hidden inside the women's body, soaked in laparotomy sponges, absorbed by drapes, or spilled onto the floor. Efforts should be made to objectively quantify blood loss at delivery because clinicians typically underestimate true blood loss.[219] Aggressive treatment has the potential to prevent the development of serious PPH.[220]

PPH may occur because of uterine atony (accounting for 80% of all postpartum bleeding), placental retention, abnormalities of the uterus, lacerations of the cervix or vaginal wall, uterine inversion, and abnormalities of coagulation. Uterine atony is associated with multiparity, prolonged infusions of oxytocin before delivery, polyhydramnios, and multiple gestation. A retained placenta or retained placental fragments must be removed manually. Nitroglycerin, a potent uterine relaxant with a relatively short duration

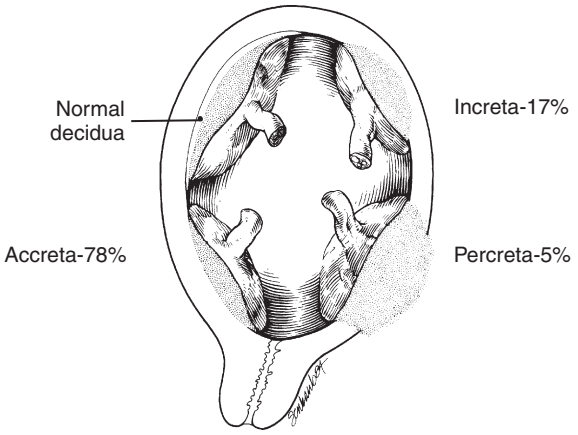

FIGURE **46-13** An example of placenta increta, percreta, and accreta. (From Gabbe SG, et al. *Obstetrics: Normal and Problem Pregnancies*. 6th ed. Philadelphia: Saunders; 2012:424.)

of action, can be used to provide uterine relaxation adequate for placental extraction. Sublingual nitroglycerin spray has been used effectively and offers the added benefits of long shelf life and a ready-to-use preparation.[221] Because nitroglycerin is a potent smooth muscle relaxant and vasodilator, care should be taken to ensure that intravascular volume is adequate before administration.

When hemostasis is not achieved despite the use of vigorous fundal massage and pharmacologic adjuncts such as oxytocin, ergot alkaloids, and prostaglandin, the obstetric staff may elect to attempt the use of an intrauterine balloon. The device is specifically designed for this purpose and is placed in the uterine cavity and normally filled with saline in order to exert a tamponade effect. Balloon tamponade is a minimally invasive and rapidly applied approach that can be used as a temporizing measure while other resources are being mobilized.[222]

Institution-specific massive transfusion protocols and policies can be invaluable in coordinating communication between anesthesia, blood bank, and intensive care staff. Regardless of the approach, planning for the management of PPH is an integral part of an obstetric anesthesia practice.

An atonic uterus, especially an incised uterus, can lose several liters of blood within a few minutes, outpacing the ability of even the most prepared anesthesia providers to replace intravascular volume. Anesthesia at this point becomes trauma anesthesia, the primary purpose of which is the maintenance of vital organ perfusion and oxygenation. Maternal analgesia and amnesia are important but, nonetheless, secondary concerns. Etomidate, ketamine, benzodiazepines, and opioids are useful insofar as they result in minimal hemodynamic depression. If rapid blood loss begins during cesarean section with regional anesthesia, the anesthetist should consider the rapid-sequence induction of general anesthesia. It is difficult to manage volume resuscitation and keep an awake patient both mentally and physically comfortable.

Anesthetic Implications

Anesthesia for uterine exploration can be accomplished with a variety of methods including the use of an already established epidural catheter, a single-shot spinal "saddle block," or a general anesthetic. The choice of technique is ultimately driven by the patient's condition and the urgency of the proposed procedure. The continuous epidural infusion is routinely discontinued at completion of delivery and repair; however, the epidural catheter should always be left in place until the maternal condition has stabilized. In this manner, if a postpartum surgical intervention becomes necessary, reestablishing epidural anesthesia is an option.

Uterine Rupture and Dehiscence

Uterine rupture (complete) is the nonsurgical disruption of all uterine layers. It involves the entire thickness of the uterine wall and the fetal membranes resulting in communication between the uterine and peritoneal cavities. Uterine dehiscence (incomplete) does not include the entire thickness and the maternal peritoneum remains intact. These conditions are most commonly associated with labor in the presence of a previous uterine incision (*t*rial *o*f *l*abor *a*fter *c*esarean or TOLAC) but may occur in an unscarred uterus.[223] The classic description of complete uterine rupture includes sudden, severe, tearing abdominal pain in a multiparous woman in active labor. The pain may suddenly break through a previously adequate labor epidural. Fetal distress often rapidly develops. Unfortunately, uterine rupture does not always present classically. For example, some ruptures occur during periods of mild labor.[224] The clinical finding most commonly associated with uterine rupture is an abnormal FHR tracing.[225] Regardless of presentation, bleeding is often severe. The uterus receives approximately 800 mL of blood per minute (approximately 10% of the cardiac output); therefore, a tear in this organ holds the potential for rapid exsanguination. Mortality from uterine rupture accounts for half of the maternal deaths attributed to blood loss each year. Fetal mortality after uterine rupture is nearly 80%.

Anesthetic Implications

TOLAC is most often successful in those who have had a prior low-transverse uterine incision and in those who have also had a previous vaginal delivery. Labor dystocia, maternal obesity, and the need for induction reduce the likelihood of successful vaginal birth after cesarean section (VBAC). The American College of Obstetricians and Gynecologists has stated that anesthesia providers and physicians must be *immediately available* to provide emergency care during TOLAC.[226] Neuraxial analgesia is not only appropriate during TOLAC but may enhance safety by affording the ability to rapidly provide surgical anesthesia if necessary.

Disseminated Intravascular Coagulation

DIC is a generalized activation of the clotting system. It can occur when a large portion of the vascular system suffers damage or when thromboplastic material enters the general circulation. DIC is frequently associated with three obstetric problems: intrauterine fetal demise, placental abruption, and amniotic fluid embolism. Circulatory shock, which often accompanies DIC, worsens the problem by decreasing peripheral and hepatic blood flow and causing further cell damage. Renal failure may result from the deposit of fibrin and cellular debris in the microvasculature. The consumption of clotting factors results in uncontrolled bleeding. Laboratory studies show decreased levels of fibrinogen and platelets, increased prothrombin and partial thromboplastin times, and excessive amounts of fibrin degradation products.

Anesthetic Implications

Definitive treatment of DIC requires elimination of the cause, which, in the obstetric patient, often requires evacuating the uterus. When a surgical intervention is required, a general anesthetic is often indicated due to the coagulation disorder. Replacing the specifically depleted clotting factors and intensive support of the accompanying multiple organ system involvement is required. There remains no universally accepted treatment for DIC. Platelets, cryoprecipitate, and fresh frozen plasma should be administered to support the platelet count and fibrinogen level. The patient with DIC will require fluid resuscitation as a result of hemorrhage. Increased peripheral and hepatic perfusion limits cellular damage and improves clearance of activated clotting factors.

Breech Presentation

Many obstetricians now choose to deliver breech presentations by cesarean section. In this case, cesarean section usually is elective, and either a regional or a general anesthetic can be used. If the baby is to be delivered vaginally, a neuraxial technique may be requested and, in fact, is strongly indicated at some centers. The pelvic muscle relaxation that is provided may aid in the delivery of the fetal head.

Multiple Gestation

Multiple-gestation pregnancies carry greater risks for both mother and fetuses compared with singleton pregnancies. Many of the risk factors affect anesthetic management. Multiple-gestation pregnancies, especially rare monoamniotic pregnancies, are associated with complications requiring emergent surgical intervention more

often than singleton pregnancies. The multiple fetuses are often small and premature. The large uterus compounds the problems of aortocaval compression; therefore, left uterine displacement should be maintained at all times when the parturient is not lying on her side. If the fetuses are to be delivered vaginally, an epidural is valuable for maternal analgesia and neonatal safety. Because the neonate often is small and premature, a slow, controlled delivery through a well-relaxed birth canal makes birth trauma less likely. The epidural provides pelvic relaxation and reduces maternal discomfort, decreasing the likelihood that pain will induce a forceful reflexive expulsion of the fetus. Either regional or general anesthesia is appropriate for a cesarean section.

Prolapsed Umbilical Cord

A prolapsed cord is present when the cord protrudes through the cervix ahead of the presenting part. The cord may then be compressed against the cervix resulting in impaired flow. Maneuvers to restore blood flow include manual pressure against the presenting part to restore flow. Uterine relaxation or emergency cesarean section may be required. The choice of anesthetic technique is directed by the urgency of the fetal condition.

Preeclampsia

Description

Preeclampsia is a pregnancy-specific multisystem disorder of unknown etiology. The disorder affects approximately 5% to 7% of pregnancies and is a significant cause of maternal and fetal morbidity and mortality. The incidence of preeclampsia is highest in primigravidas younger than 20 years or older than 35 years of age and in women who have had preeclampsia during a previous pregnancy. An imbalance of prostacyclins and thromboxanes, both of which are produced by the placenta, has been demonstrated in preeclampsia.[227]

Preeclampsia is defined as new-onset hypertension and proteinuria after 20 weeks' gestation and is described as mild or severe. Mild preeclampsia exists when the blood pressure (BP) is higher than 140/90 and proteinuria is at least 300 mg/24 hr. Severe preeclampsia is defined as a BP higher than 160/110 and proteinuria is greater than 5 g/24 hr. It is considered severe if blood pressure and proteinuria are increased substantially or symptoms of end-organ damage (including fetal growth restriction) occur. Additional symptoms of severe preeclampsia may include: oliguria (less than 500 mL of urine in 24 hours), cerebral or visual disturbances, pulmonary edema or cyanosis, epigastric or right upper quadrant pain, impaired liver function, thrombocytopenia, and intrauterine growth restriction. Management before the onset of labor includes close monitoring of maternal and fetal status. Management during delivery includes seizure prophylaxis with magnesium sulfate and, if necessary, medical management of hypertension. Delivery remains the ultimate treatment.[228]

Preeclampsia results in increased maternal, fetal, and neonatal morbidity and mortality. The chief cause of maternal mortality is cerebral hemorrhage caused by hypertension. Pulmonary edema, renal failure, hepatic rupture, cerebral edema, and DIC are also associated with preeclampsia. Eclampsia is the onset of seizures in a patient with signs and symptoms of preeclampsia.

Pathophysiology

The precise pathogenesis of preeclampsia is complex and not well understood but likely involves a failure in normal placental angiogenesis resulting in decreased placental perfusion and placental infarcts. Placental ischemia worsens as pregnancy progresses, often causing intrauterine growth restriction. The hypoperfused placenta releases factors into the maternal circulation that damage the maternal endothelium, resulting in system-wide manifestations.

The upper airway edema normally associated with pregnancy can be more pronounced in the preeclamptic patient. The decreased colloid osmotic pressure associated with urinary protein loss combined with increased vascular permeability predisposes the parturient to pulmonary edema and respiratory distress syndrome. Central nervous system effects include headache, hyperexcitability, and hyperreflexia. Thrombocytopenia occurs in up to 20% of women and is related to the severity of the disease process. Increased vascular tone results from hypersensitivity to endogenous catecholamines. Systemic vascular resistance is increased, ultimately resulting in end organ ischemia. Plasma volume is normal in mild disease but may be reduced by up to 40% in severe disease.[229] Hepatocellular necrosis results in hepatic enlargement, which ultimately can lead to hepatic capsule rupture. The hallmark diagnostic sign of proteinuria occurs as a result of glomerular capillary endothelial destruction.

Obstetric Management

Delivery is at present the only definitive way of ending the disease process of preeclampsia. When a fetus is at a gestational age of more than 37 weeks, obstetricians generally proceed with delivery. In the presence of mild preeclampsia prior to 37 weeks' gestation, delivery is delayed while the maternal condition is carefully monitored. If preeclampsia is severe or fetal distress occurs, delivery is usually accomplished expeditiously. Corticosteroids are often administered to enhance fetal lung maturity. In any case, obstetric treatment is aimed at preventing eclampsia (seizures), avoiding decreases in uteroplacental blood flow, and maximizing organ perfusion. Magnesium sulfate is routinely used to prevent seizures in severe preeclampsia both before and after delivery. Magnesium sulfate (which is also used as a tocolytic) causes venodilation, mild CNS depression, a decrease in the rate of hepatic fibrin deposition, and a reduction in uterine activity. Decreasing fibrin deposition prevents further decay in organ perfusion and often greatly decreases liver pain. Hypertension can be treated to prevent maternal complications such as intracranial hemorrhage and hypertensive myocardial ischemia. There is no evidence to indicate that treating the hypertension changes the underlying maternal disease process.

Regional Anesthesia and Preeclampsia

Regional analgesia and anesthesia are generally preferred for both spontaneous vaginal delivery and cesarean section in the preeclampsia patient when they are not contraindicated. A carefully initiated epidural infusion helps control maternal hypertension and may improve organ blood flow. During a cesarean section, regional anesthesia avoids stimulation of the airway, which can aggravate hypertension and possibly cause cerebral bleeding. During a premature vaginal delivery, epidural analgesia allows a slower, more controlled delivery of the infant and decreases the likelihood of trauma to the fetal head.

Because thrombocytopenia and other coagulation problems are associated with severe preeclampsia, careful consideration should be given to the patient's coagulation status before regional anesthesia is initiated. A careful bleeding history should be taken and all prior platelet counts evaluated before insertion of a neuraxial anesthetic in a patient with a diagnosis of preeclampsia. A bleeding time is no longer considered an adequate method of assessing the risk of bleeding.[230] There has, however, been considerable discussion regarding what constitutes an adequate platelet

count. Regional anesthesia is generally not contraindicated in mildly preeclamptic parturients with platelet counts greater than 100,000/mm^3. In parturients with a platelet count between 80,000/mm^3 and 100,000/mm^3, further laboratory studies to include prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen level, and international normalized ratio (INR) are indicated. The provision of a neuraxial anesthetic to a patient with a platelet count below 80,000/mm^3 should take into careful consideration the risks involved.[231]

General Anesthesia and Preeclampsia

Coagulopathy, or a serious deterioration in the maternal or fetal condition, is the most common indication for general anesthesia in the patient with preeclampsia. Laryngoscopy results in an exaggerated hypertensive response, and the concomitant upper airway edema may make intubation more difficult. Difficulty in intubation increases the duration of airway stimulation and potentially worsens hypertension. The challenge during induction of general anesthesia is prevention of a further increase in blood pressure, which may result in intracranial hemorrhage.

Labetalol is generally considered to be the first-line drug in treating the hypertension during anesthesia. Treatment of systolic blood pressures above 160 mmHg should be a guide in order to avoid intracranial bleeding.[232] Esmolol also has been safely used at induction without significant neonatal effects.[233] Opioids administered prior to delivery are normally avoided because they can result in undesirable neonatal and maternal respiratory depression. Maternal respiratory depression can become a significant issue in the event of a failed intubation. Remifentanil has been shown to blunt the hypertensive response to laryngoscopy in healthy pregnant patients but resulted in significant fetal respiratory depression.[234] Control of blood pressure during induction of general anesthesia demands both careful planning and skill.

Nondepolarizing muscle relaxants are markedly potentiated in women with preeclampsia who have therapeutic levels of magnesium. Magnesium sulfate reduces the onset time of rocuronium and prolongs the total recovery time by about 25%.[235] If a nondepolarizing muscle relaxant must be used, small doses should be used and the response should be carefully monitored with a peripheral nerve stimulator.

HELLP *Syndrome*

HELLP syndrome consists of *h*emolysis, *e*levated *l*iver enzymes, and a *l*ow *p*latelet count. From 5% to 10% of women with preeclampsia develop HELLP syndrome. Clinical signs of HELLP syndrome include epigastric pain, upper abdominal tenderness, proteinuria, hypertension, jaundice, nausea, and vomiting. Rarely, HELLP syndrome may result in liver rupture. Some experts believe that a degree of compensated DIC is present in all patients with HELLP syndrome.

ANESTHESIA FOR THE PREGNANT PATIENT UNDERGOING A NONOBSTETRIC PROCEDURE

Occasionally anesthetists must provide anesthesia care for a pregnant woman having nonobstetric emergency procedures. Some key points are noted in Box 46-6.

BOX 46-6

Key Points for the Pregnant Patient Undergoing Nonobstetric Procedure

- A significant number of women undergo anesthesia and surgery during pregnancy for procedures unrelated to delivery.
- Maternal risks are associated with the anatomic and physiologic changes of pregnancy (e.g., difficult intubation, aspiration) and with the underlying maternal disease.
- The diagnosis of abdominal conditions often is delayed during pregnancy, which increases the risk of maternal and fetal morbidity.
- Maternal catastrophes involving severe hypoxia, hypotension, and acidosis pose the greatest acute risk to the fetus.
- Other fetal risks associated with surgery include increased fetal loss, increased incidence of preterm labor, growth restriction, and low birth weight. Clinical studies suggest that anesthesia and surgery during pregnancy do not increase the risk of congenital anomalies.
- It is unclear whether adverse fetal outcomes result from the anesthetic, the operation, or the underlying maternal disease.
- No anesthetic agent is a proven teratogen in humans, although some anesthetic agents, specifically nitrous oxide, are teratogenic in animals under certain conditions.
- Many anesthetic agents have been used for anesthesia during pregnancy, with no demonstrable differences in maternal or fetal outcome.
- The anesthesia management of the pregnant surgical patient should focus on the avoidance of hypoxemia, hypotension, acidosis, and hyperventilation.
- When performing a maternal laparoscopy, use an open technique to enter the abdomen when possible.
- Monitor maternal end-tidal P_{CO_2} with or without arterial blood gas to avoid fetal hypercarbia and acidosis.
- Maintain low pneumoperitoneum pressures or use a gasless technique.
- Limit the extent of Trendelenburg or reverse Trendelenburg positions and initiate any position slowly.
- Monitor fetal heart rate and uterine tone when feasible.

St. Louis: Mosby; 2009:337; Reitman E, Flood P. Anaesthetic considerations for non-obstetric surgery during pregnancy. *Br J Anaesth*. 2011;107(suppl 1):i72- i78.

NEONATAL RESUSCITATION

All labor and delivery personnel should be trained in basic neonatal resuscitation, including anesthetists. The necessary drugs and equipment must be readily available for all deliveries (Box 46-7). The anesthetist in clinical practice may participate in neonatal resuscitation, but a single anesthetist is responsible for attending to the care of the mother.

Approximately 15% of newborns require resuscitation, but this can generally be predicted from the known risk factors (Box 46-8). Tactile stimulation of the newborn will often result in spontaneous respiration. If spontaneous respiration is delayed after stimulation, initiation of assisted ventilation should begin.

The Apgar scoring system is widely used to assess newborns. The score is derived from five parameters including heart rate, respiratory rate, muscle tone, reflex irritability, and color. The assessment is performed at 1 minute and again at 5 minutes. The score is used to guide resuscitation. A score of 8 to 10 is considered normal, 4 to 7 indicates moderate distress or impairment, and 0 to 3 indicates the need for immediate resuscitation.

If the parturient has received prenatal care, there may be previous knowledge or suspicions of a congenital anomaly that may be used to guide resuscitation. In the event of little or no prenatal care, this information may be unavailable.

BOX **46-7**

Equipment and Drugs Needed for Neonatal Resuscitation

Suction Equipment
- Bulb syringe
- Mechanical suction and tubing
- Suction catheters, 5F or 6F, 8F, and 10F or 12F
- 8F feeding tube and 20-mL syringe
- Meconium aspiration device

Bag-and-Mask Equipment
- Neonatal resuscitation bag with a pressure-release valve or pressure manometer (the bag must be capable of delivering 90% to 100% oxygen)
- Facemasks, newborn and preterm sizes (masks with cushioned rim preferred)
- Oxygen with flowmeter (flow rate up to 10 L/min) and tubing (including portable oxygen cylinders)

Intubation Equipment
- Laryngoscope with straight blades, No. 0 (preterm) and No. 1 (term)
- Extra bulbs and batteries for laryngoscope
- Tracheal tubes, 2.5, 3.0, 3.5, and 4.0 mm ID
- Stylet (optional)
- Scissors
- Tape or securing device for tracheal tube
- Alcohol sponges
- CO_2 detector (optional)
- Laryngeal mask airway (optional)

Medications
- Epinephrine 1:10,000 (0.1 mg/mL): 3- or 10-mL ampoules
- Isotonic crystalloid (normal saline or Ringer's lactate) for volume expansion: 100 or 250 mL
- Sodium bicarbonate 4.2% (5 mEq/10 mL): 10-mL ampoules
- Naloxone hydrochloride 0.4 mg/mL: 1-mL ampoules (or 1 mg/mL: 2-mL ampoules)
- Normal saline, 30 mL
- Dextrose 10%, 250 mL
- Normal saline "fish" or "bullet" (optional)
- Feeding tube, 5F (optional)
- Umbilical vessel catheterization supplies
  - Sterile gloves
  - Scalpel or scissors
  - Povidone-iodine solution
  - Umbilical tape
  - Umbilical catheters, 3.5F, 5F
  - Three-way stopcock
- Syringes, 1-, 3-, 5-, 10-, 20-, and 50-mL
- Needles, 25-, 21-, and 18-gauge, or puncture device for needleless system

Miscellaneous
- Gloves and appropriate personal protection
- Radiant warmer or other heat source
- Firm, padded resuscitation surface
- Clock (timer optional)
- Warmed linens
- Stethoscope
- Tape, ½- or ¾-inch
- Cardiac monitor and electrodes and/or pulse oximeter with probe (optional for delivery room)
- Oropharyngeal airways

BOX **46-8**

Risk Factors Suggesting an Increased Need for Neonatal Resuscitation

Antepartum Risk Factors
- Maternal diabetes
- Pregnancy-induced hypertension
- Chronic hypertension
- Chronic maternal illness (e.g., cardiovascular, thyroid, neurologic, pulmonary, renal)
- Anemia or isoimmunization
- Previous fetal or neonatal death
- Bleeding in second or third trimester
- Maternal infection
- Polyhydramnios
- Oligohydramnios
- Premature rupture of membranes
- Post-term gestation
- Multiple gestation
- Fetal size-date discrepancy
- Drug therapy (e.g., lithium carbonate, magnesium, adrenergic-blocking drugs)
- Maternal substance abuse
- Fetal malformation
- Diminished fetal activity
- No prenatal care
- Age younger than 16 or older than 35 years

Intrapartum Risk Factors
- Emergency cesarean section
- Forceps or vacuum-assisted delivery
- Breech or other abnormal presentation
- Premature labor
- Precipitous labor
- Chorioamnionitis
- Prolonged rupture of membranes (more than 18 hours before delivery)
- Prolonged labor (more than 24 hours)
- Prolonged second-stage labor (more than 2 hours)
- Fetal bradycardia
- Nonreassuring fetal heart rate patterns
- Use of general anesthesia
- Uterine tetany
- Narcotics administered to mother within 4 hours of delivery
- Meconium-stained amniotic fluid
- Prolapsed cord
- Abruptio placentae
- Placenta previa

BOX **46-9**

Neonatal Resuscitation Guidelines

- Initial evaluation of the newborn with emphasis on heart rate and respirations. Pulse oximetry should be used for evaluation of oxygenation because assessment of color is often unreliable.
- To avoid hypothermia, preterm babies less than 28 weeks' gestation should be wrapped immediately after birth, up to their neck and without drying, and kept wrapped under radiant heat until their temperature has been verified in the neonatal intensive care unit (NICU). For these infants, delivery room temperature should be maintained at least at 26° C.
- Ventilatory resuscitation should begin with air rather than 100% oxygen in term infants receiving resuscitation at birth with positive pressure ventilation. If despite effective ventilation there is no increase in heart rate or if oxygenation, best guided by pulse oximetry, remains unacceptable, a higher concentration of oxygen should be considered. Oxygen saturation during labor and just after birth is more or less 60% and will increase to ± 90% after 10 min.
- Positive pressure ventilation (PPV) is an extremely important and effective intervention that should be initiated if the infant is apneic or gasping or if the heart rate is less than 100 bpm after 30 seconds of administering the initial steps of resuscitation. Prompt improvement in heart rate is the best indicator of adequate ventilation. The T-piece resuscitator is specifically used for neonatal resuscitation and is the device of choice.
- In births with meconium-stained amniotic fluid, suctioning of the oropharynx and nasopharynx before delivery of the shoulders is no longer recommended. In babies born through meconium-stained fluid, available evidence does not support or refute the routine endotracheal intubation and suctioning, even if they are depressed at birth, and the current practice should not been changed.
- Detection of exhaled carbon dioxide, in association with clinical assessment, for example, increasing heart rate, is the most reliable method for confirming endotracheal tube placement in infants with spontaneous circulation. Colorimetric exhaled CO_2 detectors are useful in identifying airway obstruction during face-mask ventilation in preterm infants.
- Chest compressions are indicated when the heart rate is less than 60 beats per minute despite adequate ventilation for 30 seconds. In the newly born infant, the standard compression: ventilation ratio is 3:1.
- If the arrest is clearly due to a cardiac etiology, a higher compression: ventilation rate (e.g., 15:2) may be considered. Compressions should be delivered on the lower third of the sternum at a depth of one third of the anteroposterior diameter of the chest. The two thumb-circling hands method is recommended because it is less tiring and allows for better depth control.
- The use of drugs is rarely indicated because the most important and effective step is establishing adequate ventilation. If emergency drugs are required, they can be given by three possible routes: venous (e.g., umbilical vein), endotracheal tube, and intraosseous. If the heart rate remains less than 60 beats per minute despite adequate assisted ventilation for 30 seconds and chest compression for an additional 30 seconds, then the administration of epinephrine at the dose of 0.01 to 0.03 mg/kg, intravenously or 0.05 to 0.1 mg/kg via the tracheal route.
- The use of therapeutic hypothermia, both whole-body hypothermia and selective head-cooling, may reduce the risk of death and disability in infants with moderate-to-severe hypoxic-ischemic encephalopathy. Hypothermia is recommended as a treatment for neonates with suspected asphyxia. Hypothermia should be induced, lowering temperature to 33.5° C to 34.5° C within 6 hours of birth, continuing it for 72 hours, and then rewarming over at least 4 hours. Treated infants should be followed up on a long-term basis.
- Healthcare providers may consider not initiating neonatal resuscitation when there are factors associated with almost certain infant death or unacceptable morbidity, or both. The parents must be included in the decision-making process regarding initiating or withholding resuscitation of their infant, particularly in situations when the prognosis is uncertain and morbidity rate is very high. Discontinuing continuous and adequate resuscitation after 10 minutes, if there are no signs of life, is justifiable.

Adapted from Biban P, et al. New cardiopulmonary resuscitation guidelines 2010: managing the newly born in the delivery room. *Early Hum Dev.* 2011;87(suppl 1):S9-S11.

Most newborns do not require neonatal resuscitation. However, about 10% of newborns require some type of resuscitative assistance at birth. The vast majority will require just assisted lung aeration. Approximately 1% require major interventions such as intubation, chest compressions, or medications. The new 2010 guidelines released by the European Resuscitation Council (ERC), the American Heart Association (AHA), and the American Academy of Pediatrics (AAP) are given in Box 46-9.

SUMMARY

Nurse anesthetists play a major role in the provision of obstetric anesthesia care. The practice of obstetric anesthesia has the additional challenge of assuring the safety of the newborn. The satisfaction attained from successful maternal and fetal outcomes is like no other in medicine. Advances in monitoring and prenatal care have allowed for continuous refinements in regional and, when necessary, general anesthesia management of these patients.

Neonatal Anesthesia

◆ *Sass Elisha*

CHAPTER 47

The neonatal period is generally regarded as the first 28 days of extrauterine life. Anesthesia for the neonate is often required as the result of an urgent or life-threatening illness that requires surgical intervention. The normal human neonate is remarkably resilient and well equipped to survive in this hostile environment. The differences between the baby and the adult, however, are clearly greatest in the neonatal period, especially if birth occurs before term. The neonate that is born prematurely and ill is not as resilient as the full-term infant. Therefore, the neonatal anesthetist must have a thorough understanding of normal growth and development, the anatomic and physiologic differences during various stages of maturation, and how immature organ systems affect anesthetic pharmacokinetics and pharmacodynamics. Anesthetic management of the neonate requires integration of this specialized knowledge and refinement of acquired technical skills.

In the past, neonates and in particular preterm, sick neonates were anesthetized with the "Liverpool Technique," which consisted of oxygen, nitrous oxide, and curare. Volatile anesthetics and opioids were not used, and the "stable" state that resulted was due to a sympathetic system in overdrive. However, in the last three decades, our understanding of neonatal physiology, particularly neurobiology, has led to an active program of research in the field of neonatal anesthesia. Neonates, term and preterm, respond to painful stimuli.[1] Signs of distress are clearly evident when neonates are exposed to stimuli that are painful. The behavioral, physiologic, and humoral signs are similar to those seen in older children and adults.[2] Therefore, all neonates require anesthesia for surgery except under extraordinary circumstances. Physiologic development is in a transitional state, and congenital anomalies may be present. Neonates and infants younger than 12 months old exhibit the highest rate of adverse events both intraoperatively and in the postanesthesia recovery room. Preterm infants are more prone to developing respiratory complications.[3]

DEVELOPMENTAL CONSIDERATIONS

Fetal Circulation

The fetal circulatory system relies on the placenta for delivery of oxygen and transport of carbon dioxide (CO_2). The chorionic villus is the functional unit of the placenta. Normally, fetal blood is separated from the maternal blood in the placenta by a thin layer of cells known as *syncytial trophocytes*. Oxygen, CO_2, and small nonionized particles readily pass through this layer, whereas substances with a larger molecular weight are prevented from diffusing across the syncytial trophocytes. Fetal circulation is characterized by high pulmonary vascular resistance (uninflated atelectatic lungs and hypoxic vasoconstriction) and low systemic circulatory resistance (high flow and low impedance of the placental vessels). Fetal deoxygenated blood travels down the aorta and through the internal iliac arteries, arriving in the placenta via paired umbilical arteries. The umbilical arteries divide, forming the arterioles, capillaries, and venules of the intervillous placental space. Oxygenated blood is delivered to the fetus from the placenta via a single umbilical vein. This oxygenated blood bypasses the lungs by flowing through extracardiac (ductus arteriosus, ductus venosus) and intracardiac (foramen ovale) shunts, forming a parallel circulation. The ductus venosus routes oxygenated blood away from the sinusoids of the liver. The oxygenated blood in the inferior vena cava is directed by the eustachian valve toward the atrial septum and passes through the foramen ovale to enter the left side of the circulation. Oxygenated blood passes into the left ventricle and exits the aorta, supplying the coronary arteries. Blood entering the pulmonary artery from the right ventricle flows to the aorta via the ductus arteriosus. Only 5% to 10% of the combined ventricular output flows through the pulmonary circulation.

Transitional Circulation

The transitional circulation is established at the time of birth. With the cessation of placental blood flow, aortic pressure increases. Clamping of the umbilical vein doubles systemic vascular resistance. Pulmonary vascular resistance falls with lung expansion, and increasing partial pressure of arterial oxygen (Pa_{O_2}) produces pulmonary vasodilation, resulting in further decreases in pulmonary resistance. These changes in systemic and pulmonary blood flow produce corresponding changes in intracardiac pressure. Decreases in right atrial pressure with accompanying increases in left atrial pressure change the direction of blood flow through the foramen ovale, resulting in the closure of the foramen ovale as left atrial pressure increases. The foramen ovale may reopen if right atrial pressure is greater than left atrial pressure (e.g., pulmonary hypertension), permitting venous blood to flow from right to left. Within a period of 2 to 3 months, the foramen ovale will be permanently closed. Up to 25% of adult patients may demonstrate a probe patent foramen ovale at autopsy.[4] Closure of the ductus arteriosus is precipitated in part by the increase in systemic vascular resistance and decrease in pulmonary vascular resistance. In utero prostaglandins maintain the patency of the ductus arteriosus. Within a few hours after birth, the muscular wall of the ductus arteriosus constricts, preventing the retrograde flow of blood from the aorta into the pulmonary artery. This functional closure (thrombosis) occurs within 1 to 8 days. Anatomic closure (fibrosis of the ductus arteriosus) requires 1 to 4 months. Ductus closure may be influenced by elevations in the systemic Pa_{O_2} that occur after birth. The majority of portal blood flow continues to enter the ductus venosus after interruption of umbilical vein blood flow. Although the cause of the initiating mechanisms of ductus venosus closure is unknown, the muscular wall of the ductus venosus begins to constrict 1 to 3 hours postnatally. Blood flow is directed into the liver, and portal venous pressure increases.

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn (PPHN) is the result of an abnormal early adaptation to the perinatal circulatory

transition. PPHN is characterized by a sustained elevation of pulmonary vascular resistance (PVR); decreased perfusion of the lungs; and continued right-to-left shunting of blood through the fetal channels (foramen ovale and ductus arteriosus). When PVR remains high after birth, right (and sometimes left) ventricular function and cardiac output are depressed. Moderate or severe PPHN is believed to affect up to 2 to 6 per 1000 live births, and complicates the course of 10% of all infants admitted to neonatal intensive care. These circulatory abnormalities are also responsible for an 8% to 10% risk of death and a 25% risk of long-term neurodevelopmental morbidity. Significant pulmonary hypertension also may develop in neonates and young infants as a result of bronchopulmonary dysplasia (BPD) or cardiac disease. Pulmonary hypertension affects roughly one third of infants with moderate-to-severe BPD.[5-7]

During fetal development, PVR is high but rapidly decreases at birth to near-normal levels, allowing the lungs to become a gas-exchanging organ. Before anatomic closure of the extracardiac and intracardiac shunts, fetal circulation may be reestablished and persist. Persistent PPHN is manifest by increases in PVR and accompanying pulmonary hypertension, which produces a right-to-left shunt across the foramen ovale and the ductus arteriosus, with resultant cyanosis. The presence of congenital cardiovascular or pulmonary disease inhibits functional and anatomic closure of these aforementioned fetal shunts. Persistent fetal circulation is common in preterm infants and infants with metabolic derangements (e.g., asphyxia, sepsis, meconium aspiration, congenital diaphragmatic hernia). Hypoxemia, acidosis, pneumonia, and hypothermia are primary precipitating factors of PPHN. Oxygenation, the avoidance of acidosis, and maintenance of normothermia will attenuate the increase in pulmonary vascular resistance. Continual increases in pulmonary vascular pressure and resistance will precipitate the development of right ventricular hypertrophy (cor pulmonale). Although pulmonary vasodilators may have some utility in decreasing pulmonary vascular resistance, concurrent reductions in systemic vascular resistance can occur and may worsen the shunt.

The primary aim of PPHN therapy is selective pulmonary vasodilation. Treatment of pulmonary hypertension includes optimization of lung function, oxygen delivery, and support of cardiac function. Optimal lung inflation is essential because PVR is increased when the lungs are underexpanded or overexpanded, independent of lung disease. The use of lung recruitment strategies, such as high-frequency ventilation and exogenous surfactant administration, is particularly important in infants with PPHN associated with parenchymal disease, but has limited impact in infants with primary vascular disease. Correction of severe acidosis and avoidance of hypoxemia are important because they both stimulate pulmonary vasoconstriction. Maintaining a normal hematocrit is also important to ensure adequate oxygen-carrying capacity while avoiding polycythemia, because hyperviscosity can increase PVR.

Treatment includes inhaled nitric oxide, sildenafil, milrinone, bosentan, and prostanoids such as prostacyclin, iloprost, or treprostinil.[5]

GROWTH AND DEVELOPMENT

Cardiovascular System

The myocardium of the newborn is immature. The neonatal heart contains the essential structural elements of the adult heart; however, there is cellular disorganization and fewer myofibrils. Although the ventricles are of equal size and shape, the contractile components (sarcoplasmic reticulum and T-tubule system) are immature. Accordingly, the neonatal heart is less capable of generating a response to an increase in resistive load (increase in stroke volume) and is dependent on free ionized calcium for contractility. Despite this immaturity, the neonatal heart is capable of limited increases in stroke volume up to left atrial pressures of 10 to 12 mmHg when afterload remains low. This information suggests that the neonatal heart is operating near the peak of the Frank-Starling curve because there is a limited reserve to increases in both preload and afterload.

During maturation, the left ventricle will hypertrophy through an increase in the number and size of myofibrils. This maturation is a consequence of left ventricular contraction against a higher postnatal systemic pressure. Acute increases in afterload (e.g., acidosis, hypothermia, pain) will produce further reductions in cardiac output. In the immediate postnatal period, left ventricular compliance is low. The neonate may develop congestive heart failure because the stiff left ventricle will not stretch to accommodate large fluid loads. Left ventricular distention from volume overload compresses the adjacent right ventricle, producing additional embarrassment to cardiac output. Likewise, ventilation with high peak pressure will produce left ventricular dysfunction and overload of the right ventricle.

Owing to the immaturity of the contractile elements of the neonatal myocardium, the belief is that pediatric cardiac output is solely dependent on heart rate. Atropine is frequently administered for the treatment of decreased cardiac output. However, marked increases in heart rate fail to a large extent to produce further increases in cardiac output. Although the neonatal myocardium will develop less stretch with volume loading than the older child or adult, volume expansion remains important, albeit to a smaller extent than in the adult, in increasing cardiac output. The combination of hypovolemia and bradycardia produce dramatic decreases in cardiac output that threaten organ perfusion. Epinephrine rather than atropine increases contractility and heart rate and is now advocated for the treatment of bradycardia and decreased cardiac output in pediatric patients. The baroreceptor reflex is not completely developed, limiting the neonate's ability to compensate for hypotension with the reflex tachycardia expected in the older child and adult.

Autonomic innervation of the neonatal heart is predominantly controlled by the parasympathetic nervous system; the sympathetic nervous system is immature at birth. Parasympathetic dominance produces bradycardia with minor clinical interventions such as pharyngeal suctioning and laryngoscopy. Marked variation in the newborn heart rate and rhythm occur secondary to changes in autonomic tone. The electrocardiogram (ECG) recording in the newborn reflects the immaturity of the conduction system. The ECG axis is shifted to the right but shifts to the left with maturation and accompanying hypertrophy of the left ventricle. The P wave is evident; the PR is less than 0.12 second and increases until adolescence. T waves are upright in the recorded chest leads, reflecting right ventricular domination. The newborn heart rate averages 120 beats per minute (bpm) during the first day of life, increasing to 160 bpm at 1 month of age, then steadily decreasing to an average of 75 beats by the adolescent period. Sleep may produce heart rates lower than 100 bpm, whereas pain increases the rate up 200 bpm.

Blood pressure increases immediately after birth, rising to a mean systolic pressure of 70 to 75 mmHg within the first 48 hours. Blood pressure is lower in the preterm infant. As the heart rate decreases with maturation, there is an accompanying increase in blood pressure. Hypotension in an anesthetized newborn is defined as a systolic blood pressure of less than 60 mmHg. In a 1-year-old child, hypotension is defined as systolic pressure less than 70 mmHg. In the older child, hypotension is determined as a systolic pressure of 70 mmHg plus twice the child's age in years. Table 47-1 shows values for heart rate and blood pressure at different ages.

TABLE 47-1 Age-Related Changes in the Cardiovascular System

Age	Heart Rate	Systolic BP	Diastolic BP
Neonate	140	70-75	40
12 mo	120	95	65
3 yr	100	100	70
12 yr	80	110	60

BP, Blood pressure.

Fetal hemoglobin is the predominant hemoglobin species in the newborn, contributing between 70% and 90% of the total. This amounts to a hemoglobin of between 18 and 20 g/dL at birth. Fetal hemoglobin has a higher affinity for oxygen than adult hemoglobin. In utero, this increased oxygen affinity facilitates oxygen uptake as fetal blood circulates through the placenta, increasing the binding of oxygen to fetal hemoglobin and allowing the fetus to exist in a relatively low Pa_{O_2} environment. There is a rapid change in the fetal hematopoietic physiology in the oxygen-rich extrauterine environment. The increased arterial oxygen content after birth results in a decrease in erythroid activity, and hematopoiesis ceases. A decrease in erythropoiesis and decreased life span of the newborn's red blood cells (RBCs) produces a progressive decrease in hemoglobin, reaching a nadir by age 3 months. This "physiologic anemia of infancy" does not compromise the delivery of oxygen, because the oxyhemoglobin dissociation curve shifts to the right and RBC concentrations of 2,3-diphosphoglycerate increase (Figure 47-1). Fetal hemoglobin is replaced by adult hemoglobin during the first 3 to 6 months, producing a rightward shift of the oxyhemoglobin dissociation curve.

It is important to note that the premature infant may experience a dramatic fall in hemoglobin because of insufficient body stores of iron. Newborns should receive vitamin K prophylaxis, because the concentration of vitamin K–dependent clotting factors (II, VII, IX, and X) are 20% to 50% of adult levels. Premature infants generally have lower levels of vitamin K–dependent clotting factors. Maternally ingested drugs such as warfarin and isoniazid may precipitate the development of a coagulopathy.

The newborn's blood volume is dependent on the time of cord clamping (transfusion from the placenta). Blood volume is approximately 80 to 90 mL/kg but may be as high as 100 mL/kg in the premature neonate. The intravascular volume decreases 25% in the immediate postnatal period with the loss of intravascular fluid. Blood volume increases over the next 2 months, peaking at 2 months of age. Table 47-2 provides an estimate of circulating blood volume development.

Respiratory System

In utero, fetal lung development beings with the formation of lung buds, which occurs during the first few weeks after conception. During organogenesis in the second trimester, distinct bronchi and bronchopulmonary segment proliferation that extends downward to the terminal bronchioles is created. There are 10 to 20 million terminal sacs, which, after elongation, begin to develop into alveoli after birth. The process of alveolar formation is accelerated between 12 to 18 months postnatally and increases to 200 to 300 million between 8 to 10 years of age.

Type II pneumocytes are responsible for the production and secretion of surfactant, which begins between 22 and 26 weeks, and concentrations peak between 35 and 36 weeks' gestation. Surfactant decreases surface tension within the alveoli to decrease

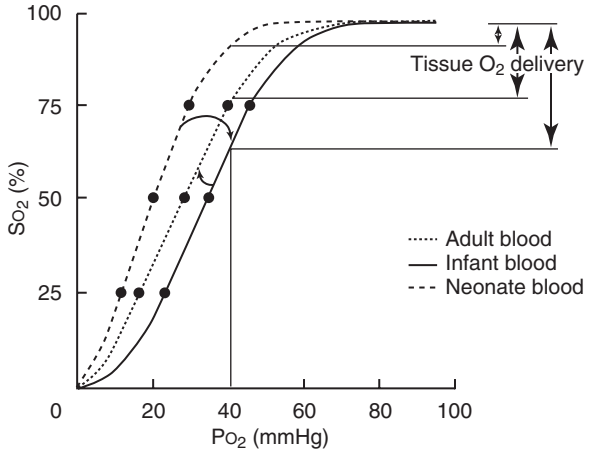

FIGURE 47-1 Schematic representation of oxyhemoglobin dissociation curves with different oxygen affinities. *Top arrows*, Direction of rightward shifting of the oxyhemoglobin dissociation curve (and P50) after birth. By 10 weeks of age, the adult position of the curve is reached. (From Davis PJ, Cladis FP, Motoyama EK. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:62.)

TABLE 47-2 Estimated Blood Volumes by Age

Age Group	Volume (mL/kg)
Premature	90-100
Newborn (less than 1 mo of age)	80-90
Infants 3 mo to 3 yr of age	75-80
Children older than 6 yr of age	65-70
Adults	65-70

alveolar collapse. This relationship can be explained by the Law of Laplace as shown below. In the absence of adequate pulmonary surfactant such as in a premature neonate, alveoli become stiff and noncompliant as depicted in Figure 47-2. Severe atelectasis decreases alveolar surface area available for oxygen and carbon dioxide exchange. Increased physiologic dead space and ventilation perfusion mismatch cause hypoxia and hypercarbia, necessitating mechanical ventilation. The treatment for infantile respiratory distress syndrome includes synthetic surfactant, continuous positive airway pressure, and mechanical ventilation.[8]

$$P = 2T/R$$

P = pressure within a sphere, T = surface tension, R = radius of the sphere

Anatomy

At birth the neonatal larynx is small compared with the mouth and pharynx. The epiglottis is short and small, and the vallecula is shallow so that the tongue approximates the epiglottis. The larynx is pointed toward the nasopharynx, facilitating nasal breathing. The arytenoids are large in proportion to the lumen of the larynx. The subglottic region is smaller than the glottic opening with the cartilages telescoping into one another, forming a conical shape.[9] The cricoid cartilage is the narrowest portion of the airway, and the cricoid lumen is not a round but mostly an ellipsoid structure. It is lined with a pseudostratified epithelium that is easily injured, resulting in significant edema and stridor. A recent study questions this traditional teaching. Video bronchoscopic images and magnetic

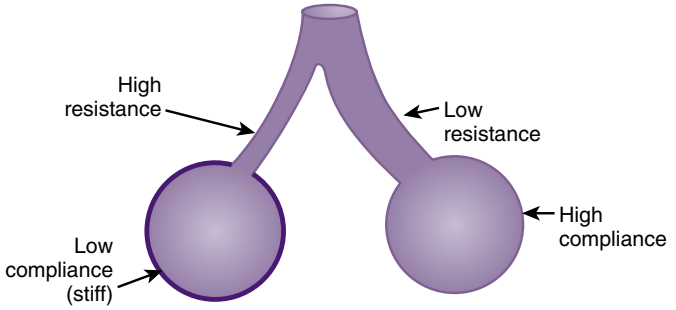

FIGURE **47-2** An idealized state showing the reciprocal relationship between resistance and compliance; gas flow is preferentially delivered to the most compliant regions, regardless of the rate of inflation. Static and dynamic compliance are equal. (From Davis PJ, Cladis FP, Motoyama EK. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:354.)

resonance spectrographs were obtained in 135 children, aged 6 months to 13 years. Measurement of laryngeal dimensions, including cross-sectional area, anteroposterior, and transverse diameters at the level of the glottis and the cricoid were performed. They found that the glottis rather than cricoid was the narrowest portion of the pediatric airway. They also noted that like adults, the pediatric airway is more cylindrical than funnel shaped.[10]

The newborn tongue is large and difficult to manipulate because of the position of the hyoid. In addition, a smaller potential submental space is present, in which it is possible to displace the tongue during laryngoscopy. The anterior position of the larynx and the large tongue increase the potential difficulty of mask ventilation.

The larynx is located more cephalad and anterior, extending from the second to the fourth cervical vertebrae (C2 to C4). The anesthetic implication of the more cephalad location is that placing a neonate in the "sniffing position" for laryngoscopy and intubation will only move the larynx in an anterior direction.

The occiput of the newborn's head is large and prominent. The placement of a rolled towel under the shoulders aids in the visual alignment of the oral, pharyngeal, and laryngeal axes during laryngoscopy (Figure 47-3 and Table 47-3).

Mechanics of Breathing

The neonate's chest wall is pliable for lack of developed musculature and a skeletal structure primarily composed of cartilage. The ribs are horizontal in orientation, providing minimal assistance in the expansion of the chest wall with inspiration. During inspiration the compliant chest wall is noted to collapse inward during respiration (paradoxical breathing). To maintain negative intrathoracic pressure in the face of a compliant chest wall, the neonate and infant actively recruit accessory muscles of respiration (i.e., intercostal muscles). Additionally, exhalation is limited by the adductor muscles of the larynx, which contract and serve as an expiratory valve or brake to maintain end-expiratory pressure. These structural differences are responsible for the decrease in functional residual capacity (FRC) with administration of general anesthesia in the neonate and infant. The previously cited muscular activity responsible for maintaining FRC is lost with the administration of sedatives, inhalation anesthetics, and neuromuscular relaxants. Rapid hypoxemia follows the loss of FRC. FRC may be restored with the application of continuous positive airway pressure or controlled ventilation. The premature infant has an even more pliable chest wall, and paradoxical chest movement may occur with breathing during rest.

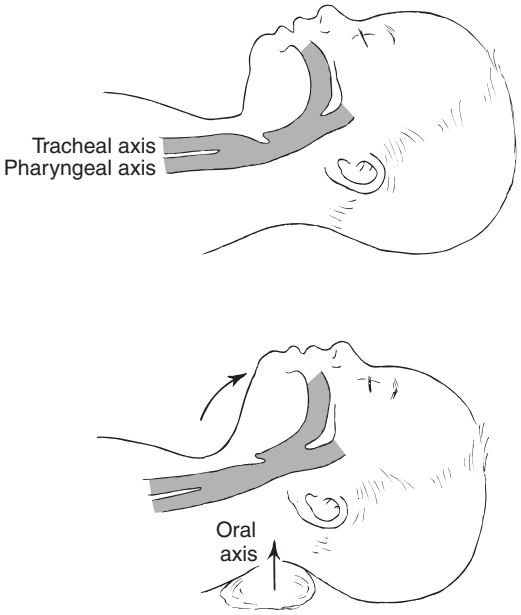

FIGURE **47-3** Alignments of visual, oral, and laryngeal axes during laryngoscopy.

TABLE **47-3** Differences Between the Adult Airway and the Pediatric Airway

	Pediatric	Adult
Laryngeal location	C2-C4	C3-C6
Narrowest location of airway	Cricoid	Glottis
Shape of epiglottis	Longer, more narrow	V-shaped
Right mainstem bronchus	Less vertical	More vertical

The diaphragm contributes to the differences in respiratory function of the neonate and infant. Unlike the adult diaphragm, which is dome shaped, the diaphragm of the neonate and infant is relatively flat. Accordingly, its anterior insertion on the chest wall fails to contribute any mechanical advantage with contraction. Primarily the diaphragm and to a lesser extent the intercostal muscles allow for expansion of the thoracic cavity and the associated increase in negative intrathoracic pressure. As a result, during inspiration, air is drawn into the lungs, and with relaxation of these muscles, air passively exits the lungs due to the elastic recoil. Two types of muscle fibers are present in muscle tissue—specifically, the diaphragm and intercostals. Type 1 muscle fibers are slow twitch muscle fibers and are resistant to fatigue. These fibers are essential for sustained ventilatory activity. Type 2 muscle fibers, also known as fast twitch muscle fibers, are fast twitch but fatigue rapidly. A newborn infant's diaphragm is composed of 25% type 1 muscle fibers as compared to 55% type 1 muscle fibers in the adult diaphragm. Also, type 2 muscle fibers are predominant within the intercostals. Therefore, newborns and young infants are at risk of muscle fatigue, respiratory distress, and respiratory arrest. The anesthetist must assess for respiratory compromise resulting from the depressant effects of residual anesthetic agents, airway obstruction, and postoperative pain. Assisting with respirations and relieving airway obstruction during the perioperative period will promote adequate gas exchange and decrease the degree of atelectasis.

Control of Breathing

The control of breathing is dependent on the Pa_{O_2} sensed via the peripheral chemoreceptors (carotid and aortic bodies), the partial pressure of arterial CO_2 (Pa_{CO_2}), and pH, which influence the central chemoreceptors within the respiratory control center of the medulla. Increases in Pa_{CO_2} produce corresponding increases in tidal volume and respiratory rate, although this response is not as vigorous as in the adult. Increases in Pa_{O_2} will depress the ventilatory response in the newborn, whereas a decreased Pa_{O_2} will increase the ventilatory response. The ventilatory response to hypoxemia produces two distinctly different responses. Initially hypoxemia stimulates an increase in ventilation for the first minute but produces ventilatory depression with a decreasing response for the next 3 to 5 minutes. This response is more robust in the premature infant than in the newborn. Ventilatory depression is more profound in the hypothermic, acidotic, or hypercarbic neonate.

Respiratory depression and/or apnea may develop in the newborn after stimulation of the carina and/or the superior laryngeal nerve, following upper airway obstruction or following lung inflation (Hering-Breuer reflex). The newborn may exhibit periodic breathing with inspiratory pauses lasting 10 seconds, followed by abrupt increases in ventilation. Periodic breathing is more common in the premature infant and occurs more often during rapid eye movement sleep. Apneic episodes are not uncommon in the premature infant; such episodes produce arterial desaturation. Bradycardia and cardiac arrest may follow these apneic episodes. The suspected causes of apnea in premature infants include immature responses of the respiratory control center to hypercarbia or hypoxic stimuli and respiratory fatigue. Infants who have experienced apneic or bradycardic episodes are at risk for these episodes after general anesthesia.

Lung Volumes

The mean values for pulmonary function in the newborn and adult are shown in Table 47-4. The infant's metabolic rate and oxygen consumption are approximately twice those of the adult. The decreased reservoir for oxygen (decreased FRC), coupled with the increased demand for oxygen (increased metabolic rate), results in rapid desaturation when ventilation is interrupted. Airway closure produces a mismatching of ventilation and perfusion. The volume of these poorly ventilated alveoli that contribute to intrapulmonary shunting is greater in neonates than in adults. In addition, increased pulmonary vascular resistance can produce a right-to-left shunt through the foramen ovale or a patent ductus arteriosus, resulting in the rapid development of cyanosis.

Airway Dynamics

Airway resistance is greater in neonates and declines markedly with growth from 19 to 28 cm H_2O/L/sec to less than 2 cm H_2O/L/sec in adults.[11-13] According to Poiseuille's law, airway resistance is inversely proportional to the fourth power of the radius of the airway during laminar flow. A neonate must overcome the resistance to airflow, as well as the elastic recoil of the lungs and chest wall. The rate of ventilation that uses the least amount of muscular energy and generates a satisfactory tidal volume has been found to be 37 breaths per minute in the healthy newborn.

The metabolic cost of breathing in the neonate is similar to an adult, approximately 0.5 mL per 0.5 L of ventilation. This is equivalent to 1% of their metabolic energy. The premature neonate's metabolic cost of breathing is 0.9 mL/0.5 L, almost double the metabolic price. If the neonate has pulmonary problems, the cost could go even higher.[14]

TABLE 47-4 Mean Values for Normal Pulmonary Function in the Newborn and the Adult

	Newborn	Adult
Body weight (kg)	3	70
Tidal volume (mL/kg)	6	6
Respiratory rate (bpm)	35	15
Alveolar ventilation (mL/kg/min)	130	60
Oxygen consumption (mL/kg/min)	6.4	3.5
Total lung capacity (mL/kg)	63	86
Functional residual capacity (mL/kg)	30	34
Vital capacity (mL/kg)	35	70
Residual volume (mL/kg)	23	16
Closing capacity (mL/kg)	35	23
Arterial pH	7.38-7.41	7.35-7.45
Pa_{CO_2}	30-35	35-45
Pa_{O_2}	60-90	90-100
Sa_{O_2} (%)	95-100	95-100

Pa_{CO_2}, Partial pressure of arterial carbon dioxide; *Pa_{O_2}*, partial pressure of arterial oxygen; *Sa_{O_2}*, oxygen saturation.

Airway resistance changes with age. Although the larger airway resistance remains constant, airway resistance in the smaller airways is increased. The increase in airway resistance increases the work of breathing in the neonate. Small airway disease (e.g., pneumonia) produces additional increases in the work of breathing.

Nervous System

The central nervous system in the newborn differs from the older child in the degree of myelination, muscle tone and reflexes, and development of the cerebral cortex. In the peripheral nervous system, myelination begins in the motor roots and progresses to the sensory roots. In contrast, the myelination in the cerebral sensory systems precedes that of the central motor systems. This incomplete myelination is associated with those reflexes that are used to measure neural development, the Moro and grasp reflexes. Myelination of the nervous system is not complete until age 3.

Development of Neuromuscular Junction

The neuromuscular junction (NMJ) undergoes developmental changes during the first 2 months of life. During the maturation process, the NMJ differs in several ways. There is a difference in the maturity, density, sensitivity, and distribution of the postsynaptic acetylcholine receptors; in the rapidity of neuromuscular transmission; and in muscle fiber type.[15] What differentiates the immature receptors from the developed ones is a functional difference that is due to a prolonged opening of the ionic channels. This prolonged channel opening allows the immature muscles to be more easily depolarized. These receptors also have a greater affinity for depolarizing agents and a lower affinity for nondepolarizing muscle relaxants (NDMRs). The clinical implication of these maturational changes is that neonates can have a greater variability in their responses to nondepolarizing muscle relaxants and in the monitoring of the NMJ via a peripheral nerve stimulator. Neuromuscular immaturity may be demonstrated with the appearance of fade after tetanic stimulation in the absence of neuromuscular blocking drugs. It is also worth noting that the type I fibers are more sensitive to NDMRs when compared with type II fibers. The clinical relevance of this difference is that the diaphragm of a neonate has fewer type I fibers as compared to a diaphragm of a

toddler or an adult. This makes the diaphragm of a neonate more responsive to NDMRs than his or her peripheral musculature.[16]

Pain Sensitivity

Pathways required for pain perception can be traced from sensory receptors in the skin to sensory areas in the cerebral cortex of newborn infants. These pain pathways have been demonstrated in the perioral area as early as 7 weeks' gestation. With positron emission tomography scans, neonates demonstrate maximal metabolic activity in the regions associated with sensory perception, such as the cortex, thalamus, and midbrain-brainstem regions. Neonatal anesthesia providers have seen newborns exhibit signs of increased sympathetic activity (e.g., tachycardia and hypertension) in response to surgical stimulation with inadequate anesthesia. The risks associated with inadequate or absent pain control expose the neonate to noxious stimulation that can have significant physiologic consequences. Those consequences in the presence of abnormal cerebral autoregulation could result in intraventricular hemorrhage and pulmonary hypertension.[17]

Lack of development of inhibitory tracts may actually increase the intensity and duration of the painful stimulus. It has been suggested that newborn infants may develop prolonged responses to painful procedures that far outlast the stimuli by hours or days. This is illustrated by several examples. Premature infants mount a metabolic stress response that can be blocked with opioids, increased crying, and interrupted sleep patterns; behavioral changes have been shown to occur for days after circumcision,[18] and with repeated heel lancing, there appeared to be a hyperalgesic response to injury.[19] Other physiologic alterations that have been demonstrated are increased right-to-left shunting, hypoxemia, acidosis, and intraventricular hemorrhage.[17]

Sensory nerve distribution is formed by 20 weeks' gestational age. Pain pathways and receptors are present within the central nervous system at birth. Physiologic stimulation from anesthesia management and surgery dramatically increase circulating catecholamines and other stress hormones. As in adults, during the perioperative experience, pediatric patients exhibit tachycardia and hypertension if light anesthesia is coupled with significant surgical stimulation. Due to the lack of cerebral vascular autoregulation, increased blood pressure can cause intracerebral bleeding, especially in premature neonates. The pain threshold for infants and children may be lower than in older children and adults, possibly because of increased pain sensitivity, behavioral factors, or both. Preoperative and postoperative signs of pain in patients that are preverbal include tachycardia, elevated blood pressure, crying, restlessness, and grimacing.

In recent years, the safety of anesthetic medications and their effect on the developing brain have been questioned. In animal studies, agents that either antagonize N-methyl-D-aspartate (NMDA) receptors or potentiate the neurotransmission of γ-aminobutyric acid (GABA) agents) have been implicated, and no safe doses or durations of exposure of these agents have been defined.[20] One proposed mechanism of action for these effects is by inhibition of brain-derived neurotrophic factor, which stimulates neural development.[21] Neurotoxicity resulting in neuroapoptosis, interference with nerve pathway, and nerve cell development can result in long-term neurocognitive deficits.[20,22-24] The most damage occurs during maturation periods when synaptogenesis rapidly occurs.[25] The Food and Drug Administration (FDA) is addressing this issue by forming a public-private partnership with the International Anesthesia Research Society called SmartTots (Strategies for Mitigating Anesthesia-Related Neuro-Toxicity in Tots). This partnership will seek to mobilize the scientific community, stimulate dialogue among thoughtful leaders in the anesthesia community, and work to raise funding for the necessary research. SmartTots is a multi-year collaborative effort designed to increase the safety of anesthetic drugs for the millions of infants and children who undergo anesthesia each year. Findings from these studies will help establish new practice guidelines. Data, outcomes, and best practices generated by SmartTots will be placed in the public domain.

Several major pediatric centers and subspecialty organizations with specific interest in this matter are part of this research consortium. Some ongoing clinical trials assessing the effects of anesthetics on neurocognitive development are noted in Table 47-5.

TABLE 47-5 Ongoing Clinical Trials Assessing the Effects of Anesthetics on Neurocognitive Development

Ongoing Clinical Trials	Study
Odense University Hospital (Denmark) and the Danish Registry Study Group	A nationwide epidemiologic study comparing the educational achievements of all children who have undergone a surgical procedure before the age of 1 year with that of a general-population control group
Columbia University	A prospective cohort study of children who have exposure to an anesthetic before the age of 3 years and their siblings who were not exposed; the two groups will be followed for neurodevelopmental outcomes
International Collaboration of Institutions from Australia, Canada, Italy, Netherlands, United Kingdom, and United States	Prospective, randomized, investigator-blinded, controlled clinical trial to assess the effects of general anesthesia using sevoflurane versus neuraxial anesthesia using bupivacaine on neurocognitive function in infants over 26 weeks' gestational age; children will be followed with evaluations of neurocognitive development at 2 and 5 years of age

Adapted from Rappaport B, et al. Defining safe use of anesthesia in children. *N Engl J Med.* 2011;364(15):1386-1390.

Cranium and Spinal Column

The most significant neurologic growth and development occurs in utero. The neural tube is nearly completely formed by 3 to 4 weeks' gestational age. It further differentiates over the next 4 to 12 weeks to create other anatomic structures that include the forebrain, facial bones, and spinal cord. Neurogenesis proceeds during weeks 12 to 20, followed by synaptogenesis and increased myelination. Increased density of synaptic connections and glial cells continues to develop until 2 years of age and is estimated to be 50% greater than in the adult brain.[26]

After birth, there is continued rapid functional and structural brain development. The brain doubles in weight within the first 6 months of life and triples in weight within 1 year. At 1 year of age, maturation of the cerebral cortex and brainstem is nearly complete. Myelination of nerve cells continues until 3 years of age. By age 2 years, the child's brain is 80% of the adult weight and 90% by age 5 years. Because of this rapid growth, fontanelles and supple cranial bones allow the skull to accommodate for this increased cerebral volume without increasing intracranial pressure. In 96% of children, the anterior fontanelle closes by 2 years of age. The posterior fontanelle closes at approximately 4 months. The anterior fontanelle can be used to assess increased intracranial pressure (bulging anterior fontanelle) and also

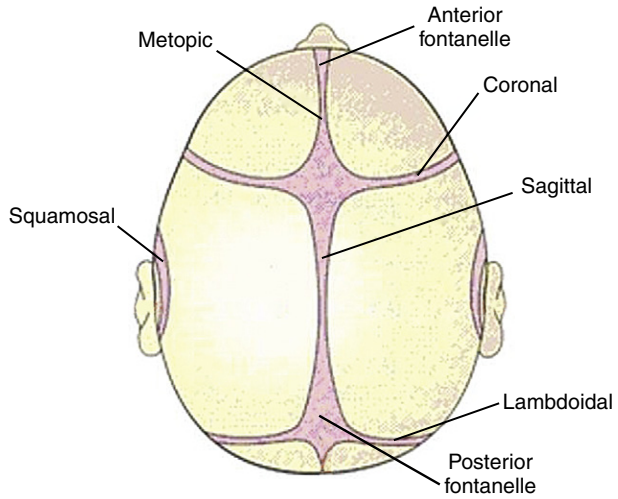

FIGURE **47-4** Cranial sutures and fontanelles in neonates and infants. (Modified from Davis PJ, Cladis FP, Motoyama EK. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:714.)

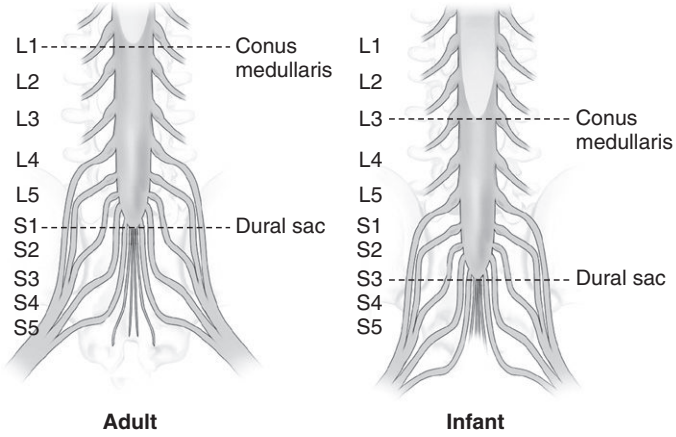

FIGURE **47-5** Comparison of levels of the conus medullaris and the dural sac in the infant and the older child or adult. (From Davis PJ, Cladis FP, Motoyama EK. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:463.)

dehydration (sunken anterior fontanelle). The blood-brain barrier is immature until approximately 1 year of age. Therefore, higher concentrations of medications and toxins that would be impermeable to the adult brain can result in higher cerebral concentrations throughout infancy. There are two major fontanelles, anterior and posterior, as shown in Figure 47-4.[27] Nerve cells within the spinal cord mature until completion at 6 to 7 years of age. As the pediatric patient grows, the conus medullaris and the dural sac migrates cephalad. Although the exact vertebral level of these structures varies slightly, the conus medullaris terminates between L2 and L3 in neonates. The dural sac ends between S2 and S3 until approximately 6 years of age. Being mindful of this information is imperative to providing safe anesthesia during placement of a spinal or caudal anesthetic. By age 8, the spinal cord approximates the adult and ends at L1.[27] Figure 47-5 depicts a comparison between the adult and infant spinal anatomy.

Cerebral Metabolic Requirement

Because of the rapid maturation of the central nervous system (CNS) during infancy and childhood, proper nutrition is essential to ensure normal development. With maturation, there is an increase in the metabolic demands of the CNS. The primary fuel for the brain is glucose, and in the neonate, there are decreased stores of glycogen, making hypoglycemia a major source of morbidity causing apnea, hypotension, bradycardia, convulsions, and brain injury.

Cerebral Blood Flow

Cerebral blood flow (CBF) is closely coupled with cerebral metabolic rate of oxygen consumption ($CMRO_2$). CBF in the premature infant is 40 mL/100 g/minute, and in older children approaches the adult level of 100 mL/100 g/minute. Autoregulation of CBF refers to the ability of the CNS to regulate CBF over a wide range of cerebral perfusion pressures. CBF autoregulation is thought to take place in the neonate, but the specific limits are unknown. Complete loss of cerebral autoregulation may occur with hypoxia, severe hypercapnia (greater than 80 mmHg), blood-brain barrier disruption after head trauma, subarachnoid or intracerebral hemorrhage, or cerebral ischemia, or after the administration of high concentrations of potent inhalation anesthetics and vasodilators (nitroprusside). Changes in CBF will parallel changes in cerebral blood volume, except when cerebral perfusion decreases and autoregulation produces vasodilation to maintain a constant flow. The cerebral vessels are very fragile in preterm and low-birth-weight infants. This fragility predisposes neonates to intracranial hemorrhage. Intracranial hemorrhage may be precipitated by hypoxia, hypercarbia, hyperglycemia, hypoglycemia, hypernatremia, and wide swings in arterial or venous pressure. The intravenous administration of hypertonic solutions may damage these fragile vessels. Therefore, adult-strength sodium bicarbonate should not be administered to neonates.

Autonomic Nervous System Immaturity

At birth, the autonomic nervous system is developed but not mature as in an adult. The sympathetic nervous system innervation to the heart and vasculature is less responsive compared with parasympathetic nervous system innervation. As a result, physiologic stress can cause severe and rapid cardiovascular collapse. As the pediatric patient ages, the child's sympathetic response becomes pronounced, and the child is able to compensate for stress by increasing heart rate and blood pressure. If bradycardia occurs, the anesthetist should focus first on hypoxia as possible cause. Rapid assessment and treatment is essential. Specific causes that could lead to bradycardia and cardiac arrest are included in Box 47-1.

Renal System

Fluid balance is not a concern for the fetus because water and electrolytes equilibrate across the placenta in response to growth and metabolic demands. The fetal kidneys make urine that passes into the amniotic cavity to compose one half of the amniotic fluid, which is then swallowed and absorbed in the gut. Structurally the kidney is different in the neonate. Nephrons are still being formed up to 35 weeks' gestation. The resulting glomerular filtration rate is much lower in a preterm (0.55 mL/min/kg) than a full-term baby (up to 1.6 mL/min/kg) or a 2-year-old child (2 mL/min/kg). Decreased systemic arterial pressure, increased renal vascular resistance, and decreased permeability of the glomerular capillaries contribute to the low glomerular filtration rate (GFR). In addition to the stiff, noncompliant myocardium, the neonate is unable to tolerate fluid overload because of the lower GFR. GFR reaches adult levels by 6 to 12 months of age. The renal medulla is not completely mature, and the potential effect of antidiuretic hormone is diminished. However, all of the hormones that affect the kidney are active even in a very immature infant, albeit with reduced potency. Neonates are *obligate sodium excreters* because of their inability to conserve sodium, even in cases of severe sodium depletion. The renin-angiotensin-aldosterone

BOX 47-1

Causes of Neonatal Bradycardia and Cardiac Arrest

Respiratory (any cause resulting in hypoxia)
- Airway obstruction (laryngospasm, postextubation croup)
  - Bronchospasm
  - Pulmonary aspiration
  - Inadequate oxygen delivery system
  - Pneumothorax

Pharmacologic
- Inhalation anesthetics
- Succinylcholine
- Anticholinesterases

Neurogenic
- Celiac reflex
- Oculocardiac reflex
- Superior/recurrent nerve stimulation (during intubation, airway manipulation)

Metabolic
- Hypoglycemia
- Anemia
- Hypothermia
- Acidosis

system (RAAS) acts to reduce sodium loss from the distal tubule, but the immature renal tubules fail to respond. In addition, the renal tubules have a limited ability to reabsorb glucose. Increasing plasma glucose concentrations may elicit an osmotic diuresis, depleting intravascular volume. Table 47-6 lists the daily electrolyte requirements for the newborn. Renal tubular function is immature until the age of 2 to 3 years. The neonate has a limited ability to concentrate urine compared with an adult (700 vs 1200 mOsm/L). Overall, the neonate has a tendency to accumulate sodium because it is essential for growth. Atrial natriuretic peptide is present, but its effects are blunted. In effect, the neonatal kidney is able to excrete water and sodium but cannot conserve them like the kidney of an older child.[28]

By the end of the first month of life, renal function is approximately 70% of adult levels and by the end of the first year, renal function reaches adult levels.

Fluid Balance

Neonates have a high turnover of fluid. After the first week, a baby needs 150 mL/kg/day of fluid (equivalent to 20 pints a day for an adult). This is because milk has a low concentration of energy compared with solid food, and the neonate cannot physiologically reduce urine output below 1 mL/kg/hr. Neonates also have high insensible losses, particularly from evaporation, as a result of a high surface area/body-weight ratio (four times higher than an adult) and immature skin. These problems are accentuated for the preterm baby. Thirst mechanisms are poorly developed and are affected by sepsis or respiratory distress syndrome. Also, a surge of antidiuretic hormone at birth causes oliguria over the first few days. Table 47-7 summarizes indicators of fluid balance.

Hepatic System

The liver begins to develop at 10 weeks' gestation, and by 12 weeks' gestation, it has already begun to function. Gluconeogenesis and protein synthesis are under way, and by 14 weeks glycogen is found in liver cells. The fetal liver has the ability to synthesize glycogen. Glycogen storage capacity is greatly increased just before birth. Approximately

TABLE 47-6 Daily Electrolyte Requirements of the Newborn

Electrolyte	Daily Requirement
Sodium	2-3 mEq/kg
Potassium	1-2 mEq/kg
Calcium	149-200 mg/kg

TABLE 47-7 Indicators of Fluid Balance

Parameter	Normal Range
Sodium	133-144 mmol/L
Body weight	Should fall by up to 10% below birth, by 1 week, then increase
Hematocrit	Increases (without transfusion) suggest dehydration
Creatinine	Should fall from maternal levels to less than 50 μmol/L after 5 days

98% of this stored glycogen is released from the liver within the first 48 hours of life, and glycogen levels are not restored to adult levels until the third week of life. Glycogen stores are not as large in preterm or small-for-gestational-age (SGA) infants. Therefore preterm and SGA infants should be monitored for the development of hypoglycemia.

The synthetic function of the liver is decreased, and the capability for biotransformation is decreased, with oxidative activities approximately one quarter to one half of adult values.[29] The capacity to enzymatically break down proteins is depressed at birth as a result of a decrement in quantity and quality of hepatic enzymes. Albumin, an essential protein that regulates colloidal osmotic pressure, is produced beginning at 3 to 4 months of gestation, approaching 75% to 80% of adult levels at the time of birth. Plasma levels of albumin and other necessary proteins for binding of drugs are lower in newborns and even lower in premature infants. The lower ability of the newborn to bind drug to plasma proteins results in greater levels of free drug. At approximately 1 year of age, its activity reaches adult levels.

There is little glucuronyl transferase activity in the fetal liver. This enzyme is responsible for the metabolic breakdown of bilirubin. Hyperbilirubinemia may develop in term infants within the first days of life. Bilirubin production as a result of the breakdown of RBCs and enterohepatic circulation is increased because of the aforementioned depressed activity of glucuronyl transferase that is required for hepatic conjugation. Bilirubin levels of 6 to 8 mg/100 mL are not uncommon in term infants. However, premature infants may have levels as high as 10 to 12 mg/mL on the third day of life. Phototherapy and, in rare cases, exchange transfusion are used to avoid the development of encephalopathy (kernicterus). In infants with hyperbilirubinemia, it is imperative that a determination of physiologic versus pathologic jaundice be determined.

Concentrations of clotting factors in the premature infant and the newborn are low; however, hepatic synthesis of essential clotting factors reaches adult levels during the first week after birth. In utero, the liver is the organ responsible for hematopoiesis, but by 4 to 6 weeks after birth, this function is assumed by the bone marrow.

Temperature Regulation

The neonate is decidedly disadvantaged in the ability to regulate body temperature. Large surface area, poor insulation, a small mass

from which heat is generated, and the inability to shiver all contribute to the problem of thermoregulation.

The neonate has a minimal ability to shiver, so sympathetic stimulation of brown fat metabolism (nonshivering thermogenesis [NST]) increases heat production. NST is the neonate's defense against hypothermia. It is metabolically driven heat production that does not involve muscular work. Brown fat stores located in the scapulae, axillae, the mediastinum, and in the retroperitoneal space surrounding the kidneys are metabolically active and contain a high density of mitochondria. Hypothermia stimulates the release of norepinephrine, which acts on brown fat to uncouple oxidative phosphorylation.[30] Heat production follows an increase in the basal metabolic rate stimulated through the release of anterior pituitary hormones.

Perioperative hypothermia has many contributing causes, including a cold operating room environment, anesthetic-induced vasodilation, the infusion of room-temperature intravenous fluids, evaporative heat loss from opened body cavities, use of cool irrigating solutions, and the inspiration of cool/dry anesthetic gases.

It is well recognized that the thermoregulatory response is inhibited by anesthetic agents. Core body temperature may decrease as much as 1° C to 3° C. Heat loss occurs as a result of the internal redistribution of heat, reduced metabolism and heat production, increased heat loss to the environment, and the effects of anesthetic agents on thermoregulatory control. Heat loss occurs more rapidly in neonates because of limited heat production (NST) and the body surface/body weight ratio. The skin (particularly of the premature neonate) is thinner and has less subcutaneous tissue, increasing the rate of evaporative heat loss.[31-34]

Radiant heat loss is responsible for the majority of heat loss.[28] It occurs with the transfer of heat to the environment and is dependent on the temperature differences between the neonate and the environment. Radiant heat loss may be minimized by wrapping the neonate in a warm blanket and isolating the skin from the cold operating table, effectively decreasing the transfer of heat. Radiant heat lamps may be used to maintain temperature during surgical positioning and preparation. Radiant heat lamps increase the temperature of the air between the neonate and the lamps, thereby minimizing radiant heat loss. However, radiant heat lamps are ineffective when operating room personnel or large objects are placed between the lamp and the patient. In addition, the placement of a radiant heat lamp in close proximity to the neonate may produce thermal injury.

An example of conductive heat loss includes placing the neonate on a cold operating table, resulting in heat transfer from the neonate to the table and thereby causing a decrease in core body temperature. Conductive heat loss is minimized with the use of warmed irrigating solutions, the use of warm blankets or heated forced-air blankets to cover the nonoperative areas of the patient, and the prewarming of the operating room. Covering the head with a stockinette or reflective cap dramatically decreases conductive heat loss. The neonate's head may account for up to 60% of the total heat loss during the perioperative period.

Convective heat loss is precipitated by moving air currents. The operating room air circulation is changed 6 to 12 times per hour and, in conjunction with cool ambient temperatures, increases heat loss. The air surrounding the body is warmed and subsequently rises, being replaced by the cooler ambient air. To minimize convective heat loss, the ambient air temperature must be increased. Prudent practice is to preheat the operating room to 26° C for premature and neonatal surgical patients. The premature infant or neonate arrives in the operating room in a heated Isolette and is immediately covered with a warm blanket before being transferred to the operating table. Convective heat loss may be increased when wet cloth is in contact with the infant. Wet diapers and blankets soiled with preparation solutions must be replaced and not allowed to remain in contact with the skin.

Evaporative heat loss occurs through the vaporization of liquid from body cavities and the respiratory tract. Evaporative heat loss is either sensible loss (the evaporation of sweat) or insensible loss (the evaporation of water through the skin). The thin-skinned premature infant is particularly susceptible to insensible evaporative heat loss. Sensible evaporative heat loss may be prevented by removing wet clothing or blankets and thoroughly drying the neonate. Insensible evaporative heat loss may be mitigated by increasing the relative humidity of the operating room, covering the patient with a plastic barrier, and using warmed irrigating solutions. Insensible respiratory tract evaporative heat loss may be prevented with humidification of the inspired gases, which requires attentive temperature monitoring to avoid superheating of airway gases and subsequent airway burns. The addition of in-line humidifiers to the patient breathing circuit adds to the complexity and weight, perhaps increasing the likelihood of unintended tracheal extubation. These humidifiers also may contribute to unintended increases in core body temperature during lengthy surgical procedures. The use of a passive heat and moisture exchanger, added between the patient circuit and endotracheal tube, has been of questionable efficacy.[35,36]

Iatrogenic increases in core body temperature also may occur. Attentiveness in covering the neonate may result in progressive increases in core temperature during prolonged surgical procedures. These steady increases in core temperature may be aggravated by the previous administration of atropine. Surgical procedures also may affect thermoregulation.

ANESTHETIC PHARMACOLOGIC CONSIDERATIONS IN THE NEONATE

Physiologic characteristics that modify the pharmacokinetic (what the body does to the drug) and pharmacodynamic (what the drug does to the body) activity in the neonate include differences in total body water (TBW) composition; immaturity of metabolic degradation pathways; reduced protein binding; immaturity of the blood-brain barrier; greater proportion of blood flow to the brain, heart, liver, and lungs; reduced glomerular filtration; smaller functional residual capacity; and increased minute ventilation.

Pharmacokinetics

Several age-related differences in absorption, distribution, metabolism, and elimination effect pharmacologic responses in the neonate. Absorption and distribution are increased via an increased cardiac output per kilogram of body weight, protein binding limits, body composition, and the immaturity of the blood-brain barrier. Elimination is decreased due to immature metabolic pathways and renal immaturity.

Cardiac Output

Resting cardiac output in the newborn is approximately 200 mL/kg/min. This means faster circulation times that are capable of delivering and removing drugs from their sites of action at a higher rate.

Body Composition

Total body water and extracellular fluid (ECF) are increased in neonates and fall proportionately with postnatal age. The percentage of body weight contributed by fat is 3% in a 1.5-kg premature neonate, 12% in a term neonate. The proportion of fat further doubles by 4 to 5 months of age. These body component changes

TABLE 47-8 Fluid Compartment Volumes

	Premature	Infant	Child	Adult
Total body water (TBW)	80%-90%	75%	65%-70%	55%-60%
Extracellular fluid (ECF)	50%-60%	40%	30%	20%
Intracellular fluid (ICF)	60%	35%	40%	40%

affect volumes of distribution of drugs. Water-soluble drugs such as neuromuscular blocking drugs (NMBDs) distribute rapidly into the ECF, but enter cells more slowly. The initial dose of water-soluble drugs is consequently higher in the neonate than in the child or adult. Delayed awakening occurs because central nervous system (CNS) concentration remains higher than that observed in older children as a consequence of this reduced redistribution.[37] Table 47-8 illustrates the changes in TBW, intracellular fluid (ICF), and extracellular fluid (ECF) during stages of maturation.

Protein Binding

Protein binding of parenterally administered drugs can be diminished in the neonate. Drugs that are normally highly protein bound can have a greater free fraction of the drug and theoretically a greater pharmacologic effect. Albumin and alpha-1 acid glycoprotein (AAG) concentrations are reduced in neonates, but are similar to those in adults by 5 to 6 months. Plasma albumin concentrations approximate adult values by 5 months of age and are lowest in preterm neonates. Binding capacity approaches adult values by 1 year of age.

Blood-Brain Barrier

The blood-brain barrier (BBB) restricts diffusion of compounds between blood and brain. It is immature in neonates, which can have clinical consequences. Small molecules access fetal and neonatal brains more easily than adult brains. BBB function improves gradually, possibly reaching maturity at term. Drugs bound to plasma proteins will not normally cross the BBB. However, the unbound lipophilic drugs passively diffuse across the BBB to achieve equilibrium very quickly. This may contribute to the tendency of drugs like the local anesthetics to produce seizures in neonates. Specific active transport systems across the BBB can be affected by CNS pathology, thereby changing the clinical effects of opioids and other compounds.[37,38]

Metabolism

Generally, due to a large proportion of the cardiac output that traverses the liver in the neonate, there is a more rapid clearance of drugs. However, phase I cytochrome P-450 (CYP) dependent reactions (e.g., oxidation, reduction, hydrolysis) are not fully developed, making some anesthetic-related drugs last longer than anticipated. These processes are fully developed within the first week of life, with remaining cytochrome-dependent metabolic pathways continuing to increase during the first 3 months of life.[39] Phase II reactions (conjugation reactions) increase water solubility to promote renal excretion, and this process is underdeveloped in neonates. Consequently, normal pediatric doses should not be given until the infant has reached the age of 1 month. Some cytochrome-dependent reactions can be induced prior to delivery when the mother is exposed to certain drugs and cigarette smoke.[40,41]

The neonate lacks the capacity to efficiently conjugate bilirubin (decreased glucuronyl transferase activity) and metabolize acetaminophen, chloramphenicol, and sulfonamides. Although the necessary enzyme systems are present at birth, enzyme activity is reduced, increasing drug elimination half-lives.[42-46]

Excretion

Most anesthesia-related drugs are eliminated by the kidney. In the neonate, GFR and tubular function is reduced, particularly in those infants born at less than 34 weeks. However, renal function reaches adult levels by 8 to 12 months of age. Healthy preterm and full-term neonates have relatively normal renal drug clearance by 3 to 4 weeks of age.

Pharmacodynamics

Pharmacodynamics describes the physiologic and pharmacologic mechanisms of drugs. The actions of a drug and its receptor are influenced by the number and type of receptors present and the action of the drug in the receptor population. Neonates can have significant differences in their dynamic response to drugs.

Nicotinic Acetylcholine Receptor

In its fetal form, the nicotinic acetylcholine receptor remains open longer after binding the acetylcholine, protecting or increasing the safety factor of neuromuscular transmission, and this could account for the neonate's resistance to muscle relaxants.[47] As it transitions into its adult form, the receptor open time is decreased after binding, resulting in less propensity for generation of an action potential, manifesting as less resistance to muscle relaxants. There is also a reduction in acetylcholine release in the neuromuscular junction in the neonate, which could account for the increased sensitivity to nondepolarizing muscle relaxants.[48] These opposing factors make a neonate's response to a neuromuscular blocking agent occasionally unpredictable.

Opioid Receptors

The mu (μ) and kappa (κ) receptors are responsible for the respiratory depression associated with opioids. In the neonate, changes in the number and affinity of these receptors may account for the increased respiratory depression that results when opioids are used.

γ-Aminobutyric Acid Receptor

Conventional thought is that the action of general anesthetics may be associated with activation of γ-aminobutyric acid (GABA) receptors.[49,50] The number of $GABA_A$ receptors in the neonate are only one third that of the adult, and half of these receptors have a high affinity for binding with benzodiazepines and other anesthetics.[51] The potency of anesthetics and benzodiazepines in neonates could be explained by the high affinity of these receptors.

DRUGS USED IN NEONATAL ANESTHESIA

Inhalation Agents

Inhaled anesthetic agents equilibrate more rapidly in neonates due to an increased level of ventilation in relation to FRC; increased cardiac output, which is directed mainly to the vessel-rich group of tissues; and reduced solubility of the inhaled anesthetics in blood. In addition, their decreased distribution of adipose tissue and decreased muscle mass affect the rate of equilibration among the alveoli, blood, and brain. The minimum alveolar concentration (MAC) of the inhalation anesthetics is less in neonates than in infants. Neonates have a somewhat lower MAC, which peaks at around 30 days of age and decreases thereafter (Figure 47-6). The anesthetic implication is that induction in this patient population is more rapid and the development of cardiovascular side effects occurs sooner. The margin of safety between adequate anesthesia

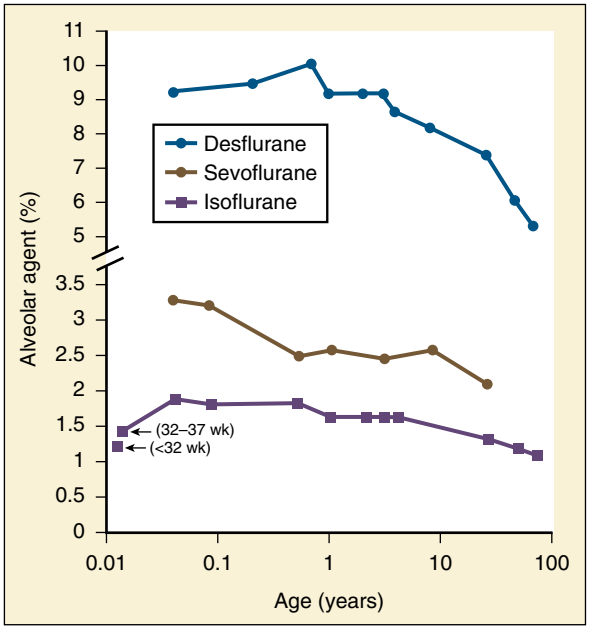

FIGURE **47-6** Effect of age on MAC of anesthetic gases. The MAC of anesthetic gases is dependent on age. MAC is higher at birth than in adults and increases until peaking at 3 to 6 months. The values at 1 year of age are closer to the adult values. (From Greeley WJ. Pediatric anesthesia. In Miller RD, ed. *Atlas of Anesthesia*. Vol 7. Philadelphia: Churchill Livingstone; 1999, 55.)

and significant cardiopulmonary depression is very narrow. Elimination of inhalation agents, and therefore recovery, is also rapid, provided that cardiopulmonary function is not depressed.

In neonates there is both left-to-right and right-to-left intracardiac shunting. In the presence of a left-to-right shunt, there is no increase in anesthetic uptake. However, when there is a right-to-left shunt, there is a slowing of the rate of rise of the alveolar concentration of inhaled agent due to the decrease in the anesthetic concentration in the blood of the arterial system. The clinical implication of a right-to-left intracardiac shunt is that these neonates could have a prolonged induction time.

Potent inhalation agents all depress ventilation in a dose-dependent manner and increase the risk of apnea. Likewise, they readily depress the myocardium and blood pressure because of immature compensatory mechanisms.

Intravenous Agents

Neonates and infants have a higher proportion of cardiac output delivered to vessel-rich tissues (i.e., heart, brain, kidneys, and liver). Intravenously administered drugs are readily taken up by these tissues and are subsequently redistributed to tissues less well perfused (muscle and fat). Intravenously administered drugs may have a prolonged duration of action in neonates and infants because of decreased percentages of muscle and fat. The CNS effects of opioids also may be prolonged because of the immaturity of the blood-brain barrier.[44] Anesthetists have historically been hesitant to use opioids because of their perceived toxicity profile in neonates, particularly morphine. Fentanyl is well tolerated even in the most critical neonates. It is now understood that appropriate anesthetic drugs are necessary for neonatal procedures.[52] Significant amounts of anesthetic drugs may be required for complex neonatal procedures.[53,54] Although some pharmacodynamic evidence suggests that intravenously administered anesthetic doses should be reduced, one must also recall the effect of increased body water. Increased doses of propofol and also ketamine are required, presumably because of a greater volume of distribution.[37,38,55] In most circumstances, when a neonate requires some type of surgical intervention, intravenous access is established prior to arrival in the operating room.

TABLE 47-9 Effective Doses (ED_{95}) of Clinical Neuromuscular Blocking Drugs (mcg/kg)

Neuromuscular Blocking Drugs	Neonate	Infant	Child	Adult
Succinylcholine*	620	729	423	290
Atracurium	120	156-175	170-350	110-280
Cisatracurium	—	43	41	50
Vecuronium	47	42-47	56-80	27-56
Rocuronium	600	600	600	300
Pancuronium	—	55	55-81	49-70

*Should be used for emergency airway stabilization in children younger than 12 years. Not for routine intubation.

Neuromuscular Blocking Drugs

Neonates have an increased sensitivity to the effects of NMBDs. The reason for this is both pharmacokinetic and pharmacodynamic. The increased volume of distribution means that a single NMBD dose for the neonate is the same as for the older child, but reduced clearance and increased sensitivity prolong duration. Neuromuscular blocking drugs are highly ionized and have a low lipophilicity, which limits their ability to cross the blood-brain barrier. These pharmacologic properties restrict the distribution of neuromuscular blockers to the ECF compartment, which is larger in the neonate and infant than in the child and adult (see Table 47-8). Increases in ECF volume and the ongoing maturation of neonatal skeletal muscle and acetylcholine receptors affect the pharmacokinetics and pharmacodynamics of neuromuscular blockers. Table 47-9 references the effective doses of neuromuscular blocking drugs in various age groups.

The neuromuscular junction is incompletely developed at birth. The presynaptic release of acetylcholine is slowed at birth compared with that in the adult, which explains the decreased margin of safety for neuromuscular transmission in the neonate. The acetylcholine receptors of the newborn are anatomically different from the adult receptors, which may explain the sensitivity of the neonate to the nondepolarizing class of neuromuscular blockers.

Neonates are more resistant to the effects of succinylcholine than children and adults. This is illustrated by the intravenous ED_{95} for neonates (620 mcg/kg), infants (729 mcg/kg), children (423 mcg/kg), and adults (290 mcg/kg) (see Table 47-9). The increase in dose requirement is in part a result of the increased volume of distribution within the large extracellular compartment. Plasma cholinesterase activity is reduced in neonates; however, the duration of action after a single dose is of expected duration (6 to 10 minutes). A much prolonged duration of action after a single bolus dose would suggest the presence of an inherited deficiency of plasma cholinesterase activity. Succinylcholine is only used for emergency airway control in children under 12 years of age due to the risk of severe hyperkalemia in patients with undiagnosed myopathies.[56]

The selection of a nondepolarizing neuromuscular blocker should take into consideration the desired degree and duration of skeletal muscle paralysis, the immaturity of organ systems, and the associated side effects of the selected relaxant. Interpatient variability in response to these drugs is greater, particularly

in premature infants and neonates. Monitoring of neuromuscular function must be used to guide repeated administration of these drugs in all neonatal patients, just as it should be used in any patient requiring neuromuscular blockade.

Reversal of Neuromuscular Blockade

The neonate is extremely vulnerable if respiration is impaired due to residual paralysis from a relaxant. Neuromuscular blockade should always be reversed unless mechanical ventilation in the postoperative period is planned. The safest treatment of prolonged apnea is sedation and controlled ventilation until the neuromuscular blocker is eliminated.

It can be difficult to judge adequacy of reversal in neonates. The rule of thumb is to observe flexion of the elbows and hips, knee to chest movements, return of abdominal muscle tone, and presence of facial grimacing. Another measurement is the ability to generate a maximum inspiratory force (MIF) greater than 25 cm of water or a crying capacity of more than 15 mL/kg.[57] Neonates are capable of generating an MIF of −70 cm H_2O with the first few breaths after birth.[58] An MIF of at least −32 cm H_2O has been found to correspond with leg lift, which is indicative of the adequacy of ventilatory reserve required before tracheal extubation.[59] If a peripheral nerve stimulator is used, the train-of-four should demonstrate the standard 90% recovery of the train-of-four.[60]

The two anticholinesterase drugs for reversal of neuromuscular blockade are neostigmine (0.05 to 0.07 mg/kg) and edrophonium (0.5 to 1.0 mg/kg). Neostigmine is routinely used. An anticholinergic agent, atropine (0.02 mg/kg) or glycopyrrolate (0.01 mg/kg), should be given prior to the anticholinesterase to prevent cholinergic side effects. Due to similarities in time to onset and duration of action, glycopyrrolate is usually combined with neostigmine and atropine with edrophonium.

Drug Preservatives

Premature neonates have a reduced ability to metabolize the preservatives benzyl alcohol and sodium benzoate. This accumulation of benzoic acid results in the "benzyl alcohol gasping syndrome," with deterioration of multiple organ systems, severe metabolic acidosis, and gasping respirations. These agents can produce severe CNS toxicity, seizures, and permanent brain damage. Use of preservative-free drugs and solutions is essential.[61]

FLUID MANAGEMENT

Neonatal fluid management varies based on gestational age, birth weight, rate of caloric expenditure and growth, ratio of evaporative surface area to body weight, the degree of renal functional maturation and reserve, and the TBW.[62] Total body water accounts for approximately 75% of body weight in the neonate. This high percentage of TBW results from expansion of the extracellular fluid compartment, which may account for 50% of the TBW. In the first few days of life, a term neonate can lose 5% to 15% of its body weight. Urine output is low, and if the neonate is kept warm and covered, fluid requirements are relatively low, as little as 40 to 60 mL/kg/day.[63,64] Box 47-2 shows the common electrolyte requirements in the newborn.

Assessing Fluid Requirements

In the neonatal period, several physiologic and physical factors can affect fluid requirements. Basically, the smaller the infant, the larger the percentage of body water to total body weight. With the smaller amount of body fat, the major part of body weight is water. The combination of uncontrollable renal loss and a large insensible water loss make the neonate prone to dehydration and hemodynamic instability. There are numerous physical observations that can assist in estimating the fluid status of the patient. Table 47-10 illustrates some of those clinical signs.[65]

Anesthesia and surgery have a significant effect on fluid homeostasis and renal function. The combination of vasodilation, myocardial depression, and blood pressure changes may alter fluid compartment dynamics, vascular capacitance, and/or organ blood flow. The renin-angiotensin system is inhibited as a result of anesthesia.

Water Requirements

Holliday published a seminal work identifying caloric requirements of the "average" hospitalized infant based on body weight. [63] A secondary finding was that the water requirement in milliliters was equivalent to the total energy expended in calories. Table 47-11 gives the water requirements of newborns.

Several things should be considered in planning the fluid management in the neonatal surgical patient:

- Dehydration present before preoperative fasting
- Fluid deficit due to fasting
- Maintenance requirements during anesthesia/surgery
- Estimated third-space loss
- Alterations in body temperature

BOX 47-2

Common Intravenous Fluid and Electrolyte Requirements in the Newborn

Glucose

- Most newborns require 2-4 mg/kg/min.
- SGA/LGA infants may require greater than 15 mg/kg/min on days 1 to 3 of life.
- Glucose tolerance may fluctuate significantly in very low- and extremely low-birth-weight (VLBW and ELBW) infants.

Sodium

- Most neonates require no sodium for the first 24 hours of life.
- On day 2 and beyond, most newborns receive 2 to 4 mEq/kg/day.
- Sodium requirement may change dramatically in response to gastrointestinal, genitourinary, or transcutaneous losses or drug or metabolic effects.
- The ELBW infant may have huge transcutaneous losses, requiring meticulous monitoring and replacement.

Potassium

- Requirements for potassium are minimal for the first 24 to 48 hours of life.
- Subsequently, maintenance delivery is about 1 to 3 mEq/kg/day, always in the presence of a normal urine output.
- Serum levels in the newborn, especially VLBW and ELBW, are higher than in older infants.
- Replace gastrointestinal, genitourinary, or iatrogenic losses cautiously.

Calcium

- Requirements for calcium range between 200 and 400 mg/kg/day (calcium gluconate).
- Requirements for calcium vary with gestational age, history of asphyxia, and growth disturbances (e.g., SGA, LGA).
- Serum levels can be obtained for total Ca^{2+} and/or ionized Ca^{2+}.

From Merves MH. Neonatology. In Tschudy MM, Arcara KM, eds. *The Harriet Lane Handbook*. 19th ed. Philadelphia: Mosby; 2012, 455-475.

Because of the nature of the surgical interventions required by neonates, most will have had their fluid status managed in a neonatal unit. If that is not the case, during the time of preoperative evaluation, deficits should be determined and dehydration or electrolyte imbalance should be reversed. Other issues, such as acidosis, low hemoglobin, poor urine output, and poor perfusion should be resolved.[17]

There is no evidence that children who are denied oral fluids for more than 6 hours preoperatively benefit in terms of intraoperative gastric volume and pH compared with children permitted unlimited fluids up to 2 hours preoperatively. Children permitted fluids have a more comfortable preoperative experience in terms of thirst and hunger.

Current guidelines suggest that for otherwise healthy infants (younger than 2 yr), children (2-16 yr), and adults, fasting from the intake of clear liquids at least 2 hours before elective procedures requiring general anesthesia, regional anesthesia, or sedation/analgesia (i.e., monitored anesthesia care) should be maintained. Examples of clear liquids include, but are not limited to, water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee. The volume of liquid ingested is less important than the type of liquid ingested. It is appropriate to fast from intake of breast milk at least 4 hours and infant formula at least 6 hours before elective procedures. Fast from intake of a light meal or nonhuman milk should be 6 hours or more. Fried or fatty foods or meat may prolong gastric emptying time. Additional fasting time (e.g., 8 hours or more) may be needed in these cases. Both the amount and type of food ingested must be considered when determining an appropriate fasting period[66,67] (see Table 37-2).

Knowledge of the caloric requirements of the neonate can be used to estimate the maintenance fluid requirements. The classic "4-2-1" rule takes the caloric expenditure into consideration because it is calculated by body weight. A neonate weighing less than 10 kg will require 100 mL/kg/day or 4 mL/kg/hr.

Fluid deficits are a result of preoperative fasting or excessive gastrointestinal (GI) losses. Neonates receiving adequate preoperative maintenance will have no deficit and will require no deficit replacement calculated into the fluid management plan. If there has not been adequate maintenance, the fluid deficit can be calculated by multiplying the hourly maintenance rate by the number of hours without feeding. Total deficit restoration may require several hours or even days in the smallest babies. The goal is to restore and preserve the cardiovascular stability and renal perfusion.

In the presence of total parenteral nutrition (TPN), the amount of glucose/kg/min, as well as other components such as sodium, potassium, and calcium currently being administered, should be noted. If at all possible, the TPN should be maintained without interruption. If it must be discontinued, glucose must be monitored vigilantly and dextrose added to the fluid management plan.

Third-space losses need to be replaced with a solution that does not contain glucose (e.g., normal saline, lactated Ringer's, or Plasma-Lyte). In those patients with abdominal lesions such as gastroschisis or necrotizing enterocolitis (NEC), the third-space losses can be very large. These babies may need as much as 25 to 100 mL/kg/hr to replace fluid loss.

Urine osmolality and specific gravity and serum osmolality are important indices in managing intraoperative fluids in neonates. They provide information as to the need for fluid, solute, and electrolyte replacement. Normal urine osmolality in the neonate ranges from 49 to 800 mOsm/L, with an average of 270 mOsm/L. Osmolality should be maintained between 200 and 400 mOsm/L and specific gravity between 1.006 and 1.012. Serum osmolality ranges between 270 and 280 mOsm/kg.[68] Hyperosmolar states can result in intraventricular hemorrhage or kidney damage.

Fluid Management of the Premature Infant

Proper fluid management of the premature infant requires an understanding of several variables: the extensive variability in body fluid composition, renal maturation, neuroendocrine control of intravascular fluid status, and insensible fluid loss with age.[69] Renal tubular function develops after week 24 of gestation, and nephrons mature by week 36.[62] The premature infant has a lower GFR and immature tubular function. The immature kidneys are unable to excrete sodium and excess fluid. The inability to concentrate urine secondary to the inability to reabsorb sodium leads to the excretion of large quantities of dilute urine. Therefore, underestimation of fluid needs leads to more serious consequences than overestimation of fluid needs.[64,70]

Glucose homeostasis is volatile in the premature neonate. Hypoglycemia can be attributed to inadequate glycogen stores and deficient gluconeogenesis. Symptoms of hypoglycemia are jitteriness, cyanosis, apnea, lethargy, hypotonia, and seizures. If not treated rapidly, hypoglycemia in the preterm neonate can lead to neurologic damage. Preterm and SGA neonates can have a glucose requirement of 8 to 10 mg/kg/min to prevent hypoglycemia. Glucose as a D_5 or D_{10} solution followed by a 10% to 15% dextrose solution can be titrated to maintain a serum glucose level greater than 40 mg/dL.[17] It is as important to avoid hyperglycemia, which can result in intraventricular hemorrhage, osmotic diuresis, dehydration, and release of insulin, leading to hypoglycemia.

Electrolyte abnormalities are often seen in preterm neonates. Hypernatremia may result if water loss is greater than sodium

depletion combined with abnormal renal tubular function. Hypokalemia can result from respiratory alkalosis or aggressive diuresis. Hyperkalemia can be caused by infusion of large amounts of potassium-containing fluids.

Blood Replacement

Over the first 6 months of life, many physiologic changes are occurring that can complicate the decision to replace blood in the neonatal surgical patient. Fetal hemoglobin (HgbF), which has a higher affinity for oxygen than adult hemoglobin, can range from 70% to 80% of the neonate's total hemoglobin at birth. It can be as high as 97% in the preterm infant.[71] The clinical implication of this is that the younger the baby, the higher the fraction of HgbF and thus the lower the oxygen-carrying capacity and oxygen delivery to the tissues.

Replacement of blood loss is critical in the surgical neonate, especially the preterm infant. Their blood volume is very small (85 to 100 mL/kg), and a loss of 10 mL could be approximately 10% of total blood volume. The clinical indication for blood administration should not be some predetermined percentage of total blood volume. Maintaining oxygen-carrying capacity and oxygen delivery to peripheral tissues and improving coagulation are the primary concerns. The transfusion trigger in this age group will need to be at higher hemoglobin levels than the older infant or child. Rapid blood loss in neonates can result in cardiovascular complications quicker than in the adult; therefore, transfusion may be required sooner. In the sick neonate scheduled for surgery and particularly in the preterm baby scheduled for surgery, the hematocrit should be approximately 30% to 40%. The decision to transfuse should be based on the underlying and current cardiorespiratory status, ongoing blood loss, anticipated further blood loss, and baseline hemoglobin. Another concern is the presence of congenital heart disease or lung disease, resulting in a decreased ability to oxygenate blood.

The accurate measurement of blood loss in neonates and infants is crucial to any replacement regimen. The margin of safety is reduced in the neonate, and because the oxygen consumption is twice that of the adult, a smaller percentage of blood loss will result in cardiovascular instability. A major cause of cardiac arrest in pediatric surgical patients results from hypovolemia from blood loss and hyperkalemia from transfusion of stored blood.[72] It is mandatory to monitor loss by the weighing of sponges, the use of small calibrated suction containers, and vigilant visual estimation of ongoing blood loss. Every 1 of sponge weight is equal to 1 mL of blood loss.

As noted earlier, volume expansion (VE) in neonates or infants during anesthesia may lead to fluid overload and can be difficult to assess. New techniques to evaluate transfusion effects include the use of transesophageal Doppler (TED), a noninvasive cardiac output monitoring technique, which can provide a comprehensive estimation of the volume status. TED-derived indexed stroke volume measurement is useful to predict and follow VE responsiveness in neonates and infants without myocardial dysfunction.[73]

Estimating Allowable Blood Loss

The estimated blood volume (EBV) and allowable blood loss (ABL) must be calculated prior to induction of anesthesia for any procedure in which blood loss is expected. Estimated blood volume is calculated based on age and body weight (see Table 47-2).

A predetermined acceptable low hematocrit is identified based on the clinical situation and the baby's health. Maximum allowable blood loss (MABL) can be calculated with the formula below in which Hct_0 is the original hematocrit, H_l is the lowest acceptable hematocrit, and H_a is the average hematocrit, $(Hc + {}_0 + Hc_1)/2$.

$$MABL = wt\ (kg) \times EBV \times (Hct_0 - Hct_1)/Hct_a$$

Example: A surgical neonate who weighs 4 kg is going to have an abdominal procedure. Beginning hematocrit is 42%. The lowest acceptable hematocrit is 30%. The MABL for this patient is 106 mL.

$$MABL = 4 \times 320 \times (42 - 30)/(42 + 30)/2 = 106$$

When the blood loss equals or exceeds the calculated allowable loss, transfusion should be considered. The volume of packed red blood cells (RBCs) to be infused may be determined by the following formula:

$$\text{Packed RBCs (mL)} = \frac{(\text{Blood loss} - \text{ABL}) \times \text{Desired hematocrit (30\%)}}{\text{Hematocrit of PRBCs (75\%)}}$$

Using the previous example of a 4-kg infant, with a total blood loss of 100 mL, the volume of packed RBCs (PRBCs) would be 175 − 106 × 30/75 = 27.6 mL.

The administration of PRBCs can lead to a significant increase in the plasma potassium and cardiac arrest. Hyperkalemia associated with massive transfusion has been reported to be the most common cause of arrest in noncardiac procedures.[74] Rapid administration via handheld syringes and small-gauge catheters (23-gauge or smaller) of PRBCs stored less than 2 weeks also have been reported to result in hyperkalemia.[75] Hypocalcemia and cardiovascular instability can result from the rapid administration of blood due to the amount of citrate contained in the stored blood. Whole blood should not be used, and irradiated blood should be given only in immunocompromised patients. Irradiation accelerates the leakage of potassium from red blood cells into serum. To reduce the risk of hyperkalemia, washed or fresh (i.e., less than 7 days old) PRBCs should be used.[71]

ANESTHETIC EQUIPMENT

Anatomic differences in the face and upper airway of neonates affect the design of the masks, laryngoscopes, and tracheal tubes. Physiologically, the need to minimize the resistance and dead space has design implications for breathing systems, connectors, and tubes. Disposable, humidified pediatric circle systems are more commonly used in neonates for some important reasons. These systems have low compliance, they are lightweight, and with the addition of plastic valves have eliminated the high resistance associated with older systems. They also offer a more reliable method of monitoring end-tidal carbon dioxide. Ventilation is usually controlled in these patients, reducing the deleterious effects of the work of breathing in the spontaneously ventilating baby.

The anesthesia machine should be equipped to deliver air when nitrous oxide is not desirable, for example, in the neonate undergoing some type of abdominal procedure or when it is necessary to reduce the inspired oxygen concentration to avoid retinopathy of prematurity (ROP). Most patients are mechanically ventilated. The newest anesthesia machines have ventilators designed to deliver very small tidal volumes at appropriately high rates and pressures. It is also possible to adapt and use the ventilators used in the neonatal intensive care units (NICUs). However, this is not the most desirable method of mechanical ventilation in the operating room. In some pediatric centers, with the most critically ill neonates, certain operative procedures are actually performed in the NICU to avoid disturbing the delicately balanced ventilation patterns and to preserve cardiorespiratory stability.

The anatomy of the upper airway makes a straight blade preferable. The blade is placed along the right side of the mouth,

TABLE 47-12 Recommended Endotracheal Tube Sizes

Neonatal Age	Endotracheal Tube Size
Preterm neonate	2.0-3.0
Full-term neonate	3.0-3.5
3 months to 1 year of age	4.0

sweeping the tongue to the left. The epiglottis is picked up with the tip of the blade and the tracheal inlet exposed. The tube is inserted with the convex side to the left. When the tip approaches the glottic opening, rotate the tube 90 degrees counterclockwise. The advantage of one over another is the characteristic that allows the large tongue of the neonate to be manipulated out of the visual field. There are also modifications of straight blades that allow insufflation of oxygen into the pharynx during intubation.

Oral endotracheal tube (OET) size for neonates cannot be calculated by formula because of the rapid growth during the immediate postnatal period. It can be determined from a table based on kilogram weight (Table 47-12). It is common for the full-term neonate to accommodate a 3.0 mm OET and a premature infant (less than 2 kg) to need a 2.5-mm OET. A clinical shortcut is to look at the size of the tip of the fifth ("pinkie") finger. It is wise to select a tube that will result in an air leak at 20 to 30 cm H_2O pressure to avoid postextubation airway edema.

The length of the trachea (vocal cords to carina) in neonates and infants up to 1 year varies from 5 to 9 cm. Insertion distance of an oral endotracheal tube should be less than 10 cm, falling within the 8 to 10 cm range.

Traditionally, it was taught that in pediatric patients up to 8 years of age, the use of an uncuffed endotracheal tube was the accepted method for endotracheal airway management. The standard of practice in neonatal anesthesia has been the use of uncuffed endotracheal tubes for reasons of airway resistance and tracheal damage from inflated cuffs. The proper use of specially made cuffed endotracheal tubes under certain clinical situations is considered acceptable. Indications include the use of a cuffed OET in certain thoracic or abdominal procedures or when high-pressure or complex ventilatory modes are planned. The advantages include a decrease in air pollution, the use of lower fresh gas flow rates (more economical), the possible avoidance of repeated laryngoscopy and intubation to assess and seal leaks, more accurate capnography readings, and better control of ventilation.[76-78]

Monitoring of the neonate during anesthesia is important in detecting those small changes that can be very significant because of their smaller physiologic margin of safety. The anesthetist should not devalue the use of clinical observation skills—hearing, seeing, touching, and the rest.

The precordial or esophageal stethoscope, as the case allows, is a simple means of assessing heart rate, rhythm, and sound, and secondarily extrapolating vascular volume. Continuous ECG monitoring is used for monitoring of not only heart rate but also for detection of arrhythmias, particularly in the baby that has electrolyte imbalances. Pulse oximetry is the standard of care for all patients in a critical care or surgical environment. The other standard monitoring parameters are blood pressure; inspired oxygen concentration; end-tidal carbon dioxide and inhalation agent concentration; and peak airway and end-expiratory pressure monitoring. Neuromuscular monitoring is technically difficult in the neonate, particularly preterm and very low-birth-weight babies, owing to their small muscle mass. The use of needle electrodes must be justified because of the risk of infection and bleeding.[17] The monitoring of urine output is difficult due to technical problems of size of the catheters and accessibility of the patient.

PREOPERATIVE ASSESSMENT

The perioperative management of any neonate is determined by the nature of the surgical procedure, the gestational age at birth, postgestational age at surgery, and associated medical conditions.

Gestational Age and Postgestational Age at Surgery

The gestational age, postgestational age, and birth weight are critical to the determination of the physiologic development of the neonate. The history of the delivery and the immediate postdelivery course can influence the choice of anesthetic technique and assist in anticipating possible postoperative complications.

One method of classification notes that preterm neonates are classified as *borderline preterm* (36 to 37 weeks' gestation); *moderately preterm* (31 to 36 weeks' gestation); and *severely preterm* (24 to 30 weeks' gestation).[79] Neonates can be classified according to their weight, as well as their gestational age. Full term is considered to be 37 to 42 weeks' gestation. Large for gestational age (LGA) is defined as weight above the 90th percentile at gestational age. Small for gestational age (SGA) refers to weight below the 10th percentile at gestational age. Low birth weight (LBW) is a weight below 2500 g, very low birth weight (VLBW) is a weight below 1500 g, and extremely low birth weight (ELBW) is below 1000 g. Full-term neonates that are SGA often present with conditions requiring surgical intervention. SGA neonates have different pathophysiologic problems from preterm infants (less than 37 weeks' gestation) of the same weight.[80] Gestational age and neonatal problems are closely related. Maternal health problems also can have significant implications for all neonates. Table 47-13 lists several common maternal problems and the possible associated neonatal sequelae.

Prematurity

Because of advances in neonatal medicine, many preterm babies born at exceptionally early gestational age and extremely low birth weights are surviving to be challenged with a plethora of unique diseases and they pose many anesthetic challenges. The premature infant is not an infrequent visitor to the operating room for either elective or emergent surgical intervention. Prematurity presents its own set of complications, which include anemia, intraventricular hemorrhage, periodic apnea accompanied by bradycardia, and chronic respiratory dysfunction. It is beyond the scope of this chapter to address all issues regarding preterm neonates and anesthetic implications.

Premature neonates are challenging to evaluate, and considerable controversy exists regarding the appropriateness of elective surgical intervention and proper postoperative care. Postgestational age (gestational age + postnatal age) should be determined at the time of the anesthetic evaluation. Premature infants of less than 60 weeks' postgestational age have the greatest risk of experiencing postanesthetic complications. The manifestations of prematurity are thought to occur as a result of inadequate development of respiratory drive and immature cardiovascular responses to hypoxia and hypercapnia. Therefore, premature infants have a significant risk of postoperative apnea and bradycardia during the first 24 hours after general anesthesia.[81-83] Box 47-3 lists contributing factors that may influence the occurrence of apnea in premature infants.

Apnea in the Premature Infant

Apnea of prematurity (AOP) is a significant clinical problem manifested by an unstable respiratory rhythm reflecting the immaturity

TABLE 47-13 Maternal History with Commonly Associated Neonatal Problems

Maternal History	Anticipated Neonatal Sequelae
Rh-ABO incompatibility	Hemolytic anemia Hyperbilirubinemia Kernicterus
Toxemia	Small for gestational age and its associated problems Muscle relaxant interaction after magnesium therapy
Hypertension	Small for gestational age and its associated problems
Drug addiction	Withdrawal and small for gestational age
Infection	Sepsis, thrombocytopenia, viral infection
Hemorrhage	Anemia, shock
Diabetes	Hypoglycemia, birth trauma, large or small for gestational age and associated problems
Polyhydramnios	TE fistula, anencephaly, multiple anomalies
Oligohydramnios	Renal hypoplasia, pulmonary hypoplasia
Cephalopelvic disproportion	Birth trauma, hyperbilirubinemia, fractures
Alcoholism	Hypoglycemia, congenital malformation, fetal alcohol syndrome, small for gestational age and associated problems

TE, Transesophageal.

of respiratory control systems. Ventilatory responses to hypoxia and hypercarbia are impaired and inhibitory reflexes are exaggerated in the neonate. Treatment strategies attempt to stabilize the respiratory rhythm. Caffeine and continuous positive airway pressure (CPAP) remain the primary treatment modalities; the methylxanthines such as caffeine are presumed to work through blockade of adenosine receptors. AOP typically resolves with maturation suggesting increased myelination of the brainstem.[84,85]

Apneas occur in 7% of babies born between 34 and 35 weeks, 14% born between 32 and 33 weeks, 54% between 30 and 31 weeks, and in 80% of neonates born earlier than 30 weeks' gestation. Although most apneas resolve by the time the infant reaches 37 weeks' postconceptional age (PCA), 80% of very low-birth-weight infants, in one study, still had significant apneas at 37 weeks. There are a variety of conditions that predispose an infant to apnea, including CNS lesions, infections and sepsis, ambient temperature fluctuations, cardiac abnormalities, metabolic derangements, anemia, upper airway structural abnormalities, necrotizing enterocolitis, drug administration (including opiates and general anesthetics), and possibly gastroesophageal reflux. Various monitoring techniques are used to detect apneic episodes although pulse oximetry and abdominal-pressure transduction are the most common. As noted above, standard therapy is with caffeine 5 to 10 mg/kg.[84-86]

Apnea Prevention and Treatment. Anesthetic techniques with the lowest risk for postoperative apnea appear to be a spinal anesthetic without sedation for lower extremity procedures. Spinals have a high failure rate in neonates (up to 20%). Supplementation with light general anesthesia may be necessary; however, that raises the risk of apnea postoperatively. General anesthesia with desflurane or sevoflurane is preferred due to the rapid emergence. Opiates and intravenous sedatives should be avoided. Caudal anesthesia is also popular. It is performed after instituting a light general anesthetic. Local anesthetic agents are used alone without opiates or other additives.

BOX 47-3

Factors Contributing to the Incidence of Apnea in the Premature Infant

Physiologic Contributors
- Inadequate development of respiratory centers
- Incomplete myelination of central nervous system
- Incomplete cardiovascular development leading to altered responses to stress

Metabolic Contributors
- Hypothermia
- Hypoglycemia
- Hypocalcemia
- Acidosis
- Respiratory instability

Anesthetic Contributors
- Residual anesthetics, opiates, relaxants, sedatives
- Prolonged intubation and ventilation

Intubation provides the safest airway control. Extubation should occur when the infant is wide awake with vigorous purposeful movement. All infants under 62 weeks' postmenstrual age (PMA) should be monitored postoperatively with an oxygen saturation monitor and an abdominal pressure transducer. Infants over 62 weeks' PMA with a significant history of apnea or respiratory disease also should be monitored. Infants over 62 weeks' PMA can be discharged following minor surgery after an appropriate period of recovery (4 hours minimum) if they are stable and otherwise healthy. Higher-risk infants require an overnight stay and monitoring.[84-87]

Preanesthetic Assessment and Neonatal Anesthetic Implications

The anesthesia provider is responsible for coordinating preoperative evaluation and acting as a gatekeeper to ensure that undue risks are minimized. Valuable information is obtained from those caring for the baby in the NICU. It is often best to alter the infant's plan of therapy as little as possible (i.e., management of ventilation, acid base status, glucose, etc). Consultation with the neonatologist is essential.

A birth history is important. A thorough review of the pregnancy course, complications such as gestational hypertension, preeclampsia, gestational diabetes, vaginal bleeding, infections, and any other pertinent information is helpful. Any cigarette, alcohol, or drug (prescription, herbal, illicit) use should be ascertained.

All of the information gathered during the assessment will lead to the anesthetic plan based on the implications of all the transitioning body systems. Table 47-14 gives the characteristics of the body system and the anesthetic implications.

System Review and Examination

The two body systems that are of primary interest in a preanesthetic system review are the respiratory and cardiovascular systems. However, there are other important metabolic and structural problems that can have a significant impact on the anesthesia plan. When performing a physical assessment, one should look carefully for congenital anomalies. A rule of thumb is that if there is one anomaly present, there are probably more because many occur in

TABLE 47-14 Preanesthetic Assessment and Neonatal Anesthetic Implication

System	Characteristics	Anesthetic Implications
Central Nervous System	Incomplete myelination	Judicious use of muscle relaxants
	Lack of cerebral autoregulation	Cerebral perfusion pressure control
	Cortical activity	Pain relief/adequate level of anesthesia
	Retinopathy of prematurity (ROP)	Oxygen saturation (94%-98%)
	Birth history	A review of the pregnancy, including complications such as pregnancy-induced hypertension, preeclampsia, gestational diabetes, vaginal bleeding, infections, and falls; also any cigarette, alcohol, or drug (prescription, herbal, illicit) use
Respiratory		
Birth History		Weeks of gestation, neonatal intensive care unit admission, history of intubation or oxygen requirement, maternal complications including infection with herpes simplex virus (HSV) or HIV, and prenatal smoke exposure
Mechanical	↓ Lung compliance ↓ Elastic recoil ↓ Rigidity of chest wall ↓ $\dot{V}/\dot{Q}$ due to lung fluid ↑ Fatigue of respiratory muscles ↓ Coordination, nose/mouth breathing	Assist or control ventilation during general anesthesia Do not obstruct nasal passages
Anatomic	Large tongue	
	Position of larynx, epiglottis, vocal folds, subglottic region	
Biochemical	Response to hypercapnia not potentiated by hypoxia	Avoid hypoxia Maintain normothermia
Reflex	Hering-Breuer reflex Periodic breathing Apnea	Apnea/no desaturation/stimulation Stimulation/airway support
Cardiovascular	↓ Myocardial contractility/↓ myocardial compliance	Maintain adequate volume Maintain heart rate
	CO rate dependent	Use vagolytic agents
	Vagotonic	
	Limited sympathetic innervation	
	Reactive pulmonary vasculature	Avoid hypoxemia resulting in ↓ PBF and possible shunting
	PDA/FO shunting	
Renal	↓ GFR	Maintain vascular volume/CO
	↓ Tubular function	Avoid overhydration
	Low glucose threshold	Avoid excess glucose (0.5-1.0 g/kg)
Hepatic	Depressed hepatic enzymes	Judicious use of drugs metabolized by liver
	↓ Metabolism and clearance of drugs Altered (decreased) protein binding Hypoglycemia due to ↓ glycogen stores Low prothrombin levels	 Vitamin K (1 mg) before surgery
Hematologic	Fetal hemoglobin (does not readily release O_2 to tissues) Oxyhemoglobin curve shifted left	Avoid hypoxia

CO, Cardiac output; *GFR*, glomerular filtration rate; *PBF*, pulmonary blood flow; *PDA/FO*, patent ductus arteriosus/foramen ovale.

clusters, labeled a syndrome. These problems can occur most often in small- and large-for-gestational-age neonates (Box 47-4).

Head and Neck Abnormalities

Any abnormality of the head and/or neck should raise concerns regarding airway management. The shape and size of the head, with or without the presence of pathology, can make airway management difficult. The small mouth and large tongue can obstruct the airway during mask ventilation. Neonates have very small nares, and when obstructed by an anesthesia facemask, they do not convert to mouth breathing, particularly if the mouth is being held closed. A nasogastric tube can obstruct half of the neonate's airway and should be placed orally. A small and/or receding chin, as seen in Pierre Robin and Treacher Collins syndromes, may make direct laryngoscopy and visualization of the glottis impossible, requiring other types of airway management. Cleft lip, with or without cleft palate, may complicate intubation. Anomalies such as cystic hygroma or hemangioma of the neck can produce upper airway obstruction. In the case of a preterm neonate, it should also be determined whether the patient has retinopathy of prematurity (ROP), cataracts, or glaucoma.

BOX **47-4**

Common Metabolic and Structural Problems in SGA and LGA Infants

Small for Gestational Age (SGA)
- Congenital anomalies
- Chromosomal abnormalities
- Chronic intrauterine infection
- Heat loss
- Asphyxia
- Metabolic abnormalities (hypoglycemia, hypocalcemia)
- Polycythemia/hyperbilirubinemia

Large for Gestational Age (LGA)
- Birth injury (brachial, phrenic nerve, fractured clavicle)
- Asphyxia
- Meconium aspiration
- Metabolic abnormalities (hypoglycemia, hypocalcemia)
- Polycythemia/hyperbilirubinemia

From Gregory GA, Brett C. Neonatology for anesthesiologists. In: Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:515.

Atropine administration could result in significant increases in intraocular pressure and further damage to the eye.

Respiratory System Abnormalities

The incidence of respiratory distress syndrome (RDS) and bronchopulmonary dysplasia (BPD) is inversely related to gestational age at birth. The onset of RDS can be as early as 6 hours after birth. The symptoms include tachypnea, retractions, grunting, and oxygen desaturation. BPD is a disease of the newborn that manifests as a need for supplemental oxygen, lower airway obstruction and air trapping, carbon dioxide retention, atelectasis, bronchiolitis, and bronchopneumonia. Oxygen toxicity, barotrauma of positive-pressure ventilation on immature lungs, and endotracheal intubation have been reported as causative factors. Management of the patient's oxygenation can be challenging. Careful monitoring of the acid-base status, the use of increased peak inspiratory pressure, and positive end-expiratory pressure may be needed to maintain oxygenation during surgery.

Cardiovascular System Abnormalities

In evaluation of the neonate's cardiovascular system, several variables should be examined: heart rate, blood pressure patterns, skin color, intensity of peripheral pulses, and capillary filling time. Presence of a murmur or abnormal heart sound, low urine output, metabolic acidosis, dysrhythmias, or cardiomegaly, alone or in combination, raises the concern of some type of congenital heart lesion, and these patients should be evaluated with a chest x-ray, ECG, echocardiogram, and other indicated cardiac tests. The results of these diagnostic tests will allow for effective planning of the anesthetic, decreasing the possibility of complications (Table 47-15).

It is beyond the scope of this chapter to discuss all anesthetic implications of congenital heart disease in the neonate; however, there are some important assessment points[88]:
- Direction and flow through any shunt
- Baseline oxygenation
- Dependence of the systemic or pulmonary circulation on flow through the ductus arteriosus
- The presence and size of any obstruction to blood flow
- Heart failure (high output, low output, or hypoxic)
- Drug therapy
- Antibiotic prophylaxis against bacterial endocarditis

Central Nervous System Abnormalities

An assessment of the CNS should include the status of the infant's intracranial pressure and intracranial compliance. Intraventricular hemorrhage (IVH) is almost exclusively seen in preterm babies. There is spontaneous bleeding into and around the lateral ventricles of the brain. The more preterm the neonate is and the smaller the weight, the more likely it is that intraventricular hemorrhage will be found. The hemorrhage is usually the result of RDS, hypoxic-ischemic injury, and/or episodes of acute blood pressure fluctuation that rapidly increase or decrease cerebral blood flow. The classic example is laryngoscopy in the presence of inadequate anesthesia.[89] The symptoms of IVH include hypotonia, apnea, seizures, loss of sucking reflex, and a bulging anterior fontanelle. Particular evaluation of the neonate with myelomeningocele (spina bifida) is discussed subsequently.

Preoperative Laboratory Values

Neonates who are premature (younger than 60 weeks' postgestational age), those with concurrent cardiopulmonary disease, and babies in whom major blood loss is anticipated during the surgical procedure should have a complete blood count, electrolytes, blood gases, and serum osmolality measured. The test values will assist in the fluid, electrolyte, and blood replacement during the surgical procedure. Other testing will be dictated by the history and physical.

Preoperative Treatment of Significance for Anesthesia

Many of the preexisting conditions in the neonate will require medical treatment. Table 47-16 illustrates some of the preoperative drugs and their anesthetic implications.

Parental preparation is important. In the case of institutions that do not have a NICU, the patient will have been transferred in from another institution, and the parents may still be in the institution where the baby was delivered. It is imperative that the parents be prepared and the informed consent for anesthesia be obtained. Often this must be done via telephone, or consent is obtained from the father only, who may have accompanied the neonate to the NICU. The anxiety of the parents of a newborn with a serious illness requiring surgical intervention is very high. The anesthetist will foster trust and confidence through a courteous and understandable explanation of the anesthetic experience.

Regional Anesthesia in the Neonate

Regional anesthesia in the neonate can be a useful option when the risks of complications from general anesthesia and endotracheal intubation are very high. These techniques have allowed surgical procedures to be done on critically ill neonates under minimal general anesthesia, with considerable reduction in the need for CNS depressant drugs. The use of regional techniques must be associated with sufficient knowledge about the various techniques, as well as adherence to adequate dosage guidelines and other safety precautions. Regional anesthesia may offer advantages in these patients, although opinions differ on which techniques are appropriate.[90,91] The preterm baby with respiratory distress syndrome and the former preterm baby who is at higher risk for postanesthetic apnea are example candidates for regional anesthesia. An additional benefit to the use of regional anesthesia in this age group is postoperative pain control. The two most common techniques used in the neonate are the spinal and caudal epidural blocks.

TABLE 47-15 Pathophysiology and Clinical Picture of Congenital Heart Defects

Lesion Type	Pathophysiology	Clinical Signs and Symptoms
Shunt Lesion Without Outflow Tract Obstruction		
Atrial septal defects Ventricular septal defects Atrioventricular canal defects Patent ductus arteriosus Aortopulmonary window	Intracardiac L-R shunt Increased pulmonary blood flow	CHF (systemic and pulmonary vascular congestion) No cyanosis (unless high pulmonary blood flow leads to increased left atrial pressure, pulmonary edema, and intrapulmonary $\dot{V}/\dot{Q}$ mismatch and shunt)
Shunt Lesions with Right Ventricular Outflow Tract Obstruction		
Tetralogy of Fallot Ebstein's anomaly Pulmonary stenosis with atrial or ventricular septal defects Eisenmenger's syndrome	Intracardiac R-L shunt Decreased pulmonary blood flow	Cyanosis
Transposition Physiology (Intercirculatory Mixing)		
Dextro-transposition of the great arteries	Intracardiac L-R and R-L shunts are equal	Cyanosis
Single-Ventricle Physiology		
One-Ventricle Lesions		
Hypoplastic left heart syndrome Tricuspid atresia Double-inlet left ventricle	Mixing of systemic and pulmonary venous blood Parallel distribution of pulmonary and systemic blood flow determined by relative circuit resistances	CHF (systemic and pulmonary vascular congestion) Cyanosis
Two-Ventricle Lesions		
Truncus arteriosus Tetralogy of Fallot with pulmonary atresia Severe neonatal aortic stenosis		
Left Ventricular Obstructive Lesions		
Mitral Stenosis		
Valvular Cor triatriatum		
Aortic Stenosis		
Valvular Subvalvular (subaortic membrane) Supravalvular (Williams-Beuren syndrome)	Left ventricular pressure overload from aortic lesions Increased left atrial pressure from left ventricular systolic and diastolic dysfunction; OR obstruction to left atrial emptying	CHF (if high left atrial pressure leads to pulmonary vascular congestion) No cyanosis (unless high left atrial pressure leads to pulmonary edema and intrapulmonary $\dot{V}/\dot{Q}$ mismatch and shunt)
Coarctation		
Shone's syndrome (mitral stenosis, aortic stenosis, coarctation)		
Mixing of Systemic and Pulmonary Venous Blood with Series Circulation		
Partial anomalous pulmonary venous return (PAPVR) Total anomalous pulmonary venous return (TAPVR)	Mixing of systemic and pulmonary venous blood Increased pulmonary blood flow	*CHF* Systemic and pulmonary vascular congestion; pulmonary vascular congestion is severe if pulmonary venous obstruction No cyanosis *PAPVR* Cyanosis *TAPVR* Exacerbated if pulmonary venous obstruction leads to pulmonary edema and intrapulmonary $\dot{V}/\dot{Q}$ mismatch and shunt

TABLE 47-16 Preoperative Treatment of Significance for Anesthesia

Drug	Implication
Diuretics for heart failure bronchopulmonary dysplasia (BPD)	Hypokalemia
Digoxin for heart failure	ECG abnormalities
Steroids for BPD	Hyperglycemia
Immunocompromised	
Anticonvulsants	Cardiac arrhythmia Potent inducer of hepatic enzymes
Indomethacin	Increases risk of bleeding Displaces bilirubin from protein-binding sites Transient hyponatremia
Renal Impairment	
Theophylline or caffeine	Significant toxic side effects; convulsions, tachycardia, tremor
Prostaglandins E_1 or E_2	Ventilatory depression and apnea Hypotension, cerebral irritability, seizures, tachycardia, pyrexia, cardiac irritability, transient oliguria, increased gastric acid
Prostacyclin	Hypotension Inhibition of platelet aggregation Rebound PPHN with withdrawal

PPHN, Persistent pulmonary hypertension of the newborn.

Anatomic differences in the neonate must be considered, particularly the location of the terminal end of the spinal cord, the dural sac, and the volume of cerebrospinal fluid (CSF). The spinal cord extends as far as L3 in the newborn and does not reach the adult position of L1 until 1 year of age. The dural sac extends to S3 to S4 in these babies and does not reach the adult position of S1 until approximately 1 year of age (see Figure 47-5). The volume of CSF is twice that of the adult (4 mL/kg vs 2 mL/kg). This dilutes the local anesthetics injected and could explain the higher dose requirements and shorter duration of analgesia.

Patients in this age group have been reported to have fairly stable cardiovascular responses to regional anesthesia. Bradycardia and hypotension are not often seen. It is thought that this could be due to the immature sympathetic nervous system or the proportionately small blood volume in the lower limbs, decreasing the amount of venous pooling.[92,93] The ventilatory response to the regional anesthetic is related to the level of the block. With a level as high as T2 to T4, there could be intercostal muscle weakness that requires the dependence on diaphragmatic movement for tidal breathing, but tidal volume and respiratory rate are not usually affected.[94]

There are pharmacologic considerations when regional anesthesia is used in neonates. The extracellular space is larger. This means the initial dose of local anesthetic will be diluted into a larger volume of distribution, resulting in a lower initial plasma peak concentration. Local anesthetics, particularly the amides, are broken down more slowly in neonates due to immature hepatic degradation. The major elimination pathway for ester local anesthetics is hydrolysis via plasma cholinesterases, and these levels are lower in the neonate as well. The demonstrations of the previous differences are shorter duration of blocks when compared with adults and larger initial doses of local anesthetic per kilogram to achieve the same extent of blockade.

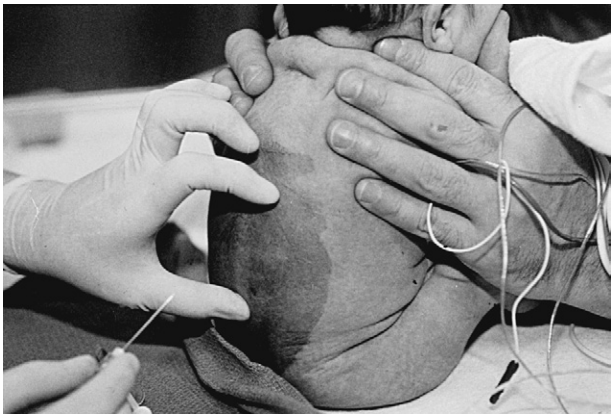

FIGURE 47-7 Spinal block performed in sitting position. Note that the head is in neutral position to prevent airway obstruction. (From Suresh S, et al. Regional anesthesia. In Cote CJ, et al, eds. *A Practice of Anesthesia for Infants and Children*. 5th ed. Philadelphia: Saunders; 2013.)

Most neonates will have a regional technique performed after the induction of general anesthesia because of the age of the patient and the possibility of agitation and continuous movement affecting the placement and success of the block.[95] The use of ultrasound-guided blocks has decreased the risk of complications associated with the placement of spinal and epidural needles and catheters, as well as enabled monitoring the spread of local anesthetics.[96] It is difficult to assess a dermatome level, because these patients are nonverbal.

Spinal Anesthesia

The use of spinal anesthesia in neonates and infants was common in the early part of the twentieth century, but its use declined with the advent of safer general anesthesia in this young age group. There has been a renewed interest in various regional techniques in select patients such as those at risk for apnea of prematurity. It is useful in neonates and infants when presenting for surgical procedures of the lower abdomen. Caudal blocks are common in neonatal anesthesia because of their simplicity and ability to provide excellent analgesia, which helps avoid large amounts of opioid analgesia with potential side effects that can impair recovery. Spinal anesthesia via catheters in the younger infant, neonate, and even preterm neonate remains controversial. The potential for such invasive maneuvers themselves to augment risk can be argued to outweigh the benefits.[97]

Spinal anesthesia can be performed in the sitting or lateral position; however, the neck should be extended to prevent airway obstruction (Figure 47-7). The lumbar puncture is performed at the L3 to L4 or L4 to L5 interspace because the spinal cord ends at L3 in the neonate. A 1½-inch, 22-gauge needle is inserted, and even with this small needle, resistance can be felt when the needle enters the ligamentum flavum, and the characteristic "pop" occurs when the needle enters the subarachnoid space. The distance is approximately 1 cm.[98] Large amounts of local anesthetics are necessary to produce an adequate block (0.14 mL/kg of bupivacaine 0.5%). When the local anesthetic is injected, the neonate should be immediately placed in the supine position, and the legs should be secured with tape to prevent them from being raised for any reason.

Caudal Anesthesia

Caudal anesthesia is the most commonly used regional block in pediatric anesthesia. It can be used for any procedure involving

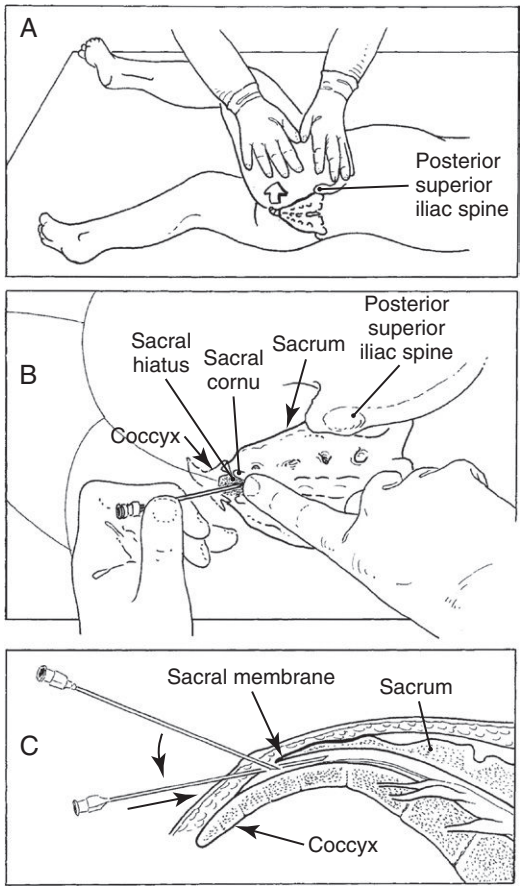

FIGURE **47-8** Performing a caudal block. (From Suresh S, et al. Regional anesthesia. In Cote CJ, et al, eds. *A Practice of Anesthesia for Infants and Children*. 5th ed. Philadelphia: Saunders; 2013.)

innervation from the sacral, lumbar, or lower-thoracic dermatomes.[93] In the youngest patients, the caudal block can be used as an adjunct to general anesthesia or solely for postoperative analgesia. In the neonate, it is most often placed after induction of general anesthesia prior to the beginning of the surgical procedure.

With ultrasound, it is now possible to visualize the injection of local anesthetics in the caudal space as well as monitor the cranial spread. The use of ultrasound is highly recommended in neonates who receive concomitant general anesthesia, but is much more difficult to use in the awake and mobile baby.[91] The patient is placed in the lateral position with the upper knee flexed (Figure 47-8). The landmarks are identified: the tip of the coccyx to fix the midline and the sacral cornua on either side of the sacral hiatus. These landmarks form the points of an equilateral triangle with the tip resting over the sacral hiatus. A 22-gauge needle is placed bevel-up at a 45-degree angle to the skin. When the sacrococcygeal membrane is punctured, a distinctive loss of resistance is felt, and the angle of the needle is reduced and advanced cephalad. Saline should be used with the loss of resistance technique because the use of air has been reported to cause both intravascular air embolism as well as permanent spinal cord injury. With aspiration, if there is not CSF or blood, the local anesthetic can be administered. Any local anesthetic can be used. The volume of the local anesthetic determines the height of the block. Volumes of 1.2 to 1.5 mL/kg provide analgesia and anesthesia to the T-4 to T-6 dermatome. No matter which local anesthetic is used, the concentration is adjusted to deliver no more than 2.5 mg/kg. The addition of epinephrine (1:200,000) or clonidine (1 to 2 mcg/kg) will prolong the block significantly.

ANESTHETIC CONSIDERATIONS FOR SELECTED CASES

Gastrointestinal

Anesthesia and surgery in neonates and infants present unique challenges. The acuity of intraabdominal procedures can range from a simple hernia repair in a healthy neonate to a complex abdominal/thoracic procedure in a critically ill preterm infant.

Pyloric Stenosis

Pyloric stenosis is an obstructive lesion characterized by an "olive-shaped" enlargement of the pylorus muscle. It is a common gastrointestinal anomaly, particularly in males. It is usually diagnosed between 2 and 12 weeks of life, and clinical symptoms include nonbilious postprandial emesis that becomes more projectile with time, a palpable pylorus, and visible peristaltic waves. The procedure to correct the problem is a pyloromyotomy.

Historically, pyloric stenosis was considered an emergency situation. However, as with medical progress on many fronts, the procedure is now considered semi-elective. The use of laparoscopy has become standard and has greatly facilitated the surgical course.[99] It is not wise to anesthetize a neonate emergently for this procedure if the baby is dehydrated or has electrolyte abnormalities. Fluid, electrolyte, and acid-base balance should be corrected prior to anesthesia.

Prior to induction, the neonate's stomach must be emptied via orogastric tube. Some anesthetists will irrigate the stomach via the orogastric tube with warm normal saline until the aspirate is clear and minimal. Others will tilt the baby in various directions to evacuate the remaining contents.

After preoxygenation, the induction should be a modified rapid sequence with properly applied cricoid pressure and gentle positive-pressure ventilation via mask. An awake oral intubation is also common. Oral endotracheal intubation is mandated to protect the airway from any gastric contents that may be residual. Maintenance can be with inhalation anesthetics or in combination with intravenous drugs. These babies should be extubated awake.

Postoperatively, these patients, particularly a preterm or SGA neonate, could exhibit drowsiness, lethargy, or apnea. This could be attributed to electrolyte abnormalities, postgestational age, or residual anesthetics.

Inguinal Hernia

Inguinal hernia is particularly prevalent in the preterm infant. The surgical problem presents the possibility of incarceration of the small bowel in the hernia defect, resulting in ischemia and tissue death. Also of concern is the potential injury to the ipsilateral testicle. These babies routinely have hernia repair prior to discharge from the NICU. The surgical approach can be the standard abdominal incision, or in some centers, laparoscopy is the preferred technology. In most situations, the contralateral side is explored to rule out the presence of another defect because of the high incidence of bilateral involvement. When this procedure is performed by a urologist, the contralateral side is most often not explored.

Because of the many possible patient issues, the anesthetic technique must be tailored for each patient. The most frequent indication for the awake caudal technique in neonates is inguinal hernia repair.[91] Inhalation or intravenous induction is acceptable, as well as airway management with a mask, laryngeal mask airway (LMA), or endotracheal tube. The use of the laparoscopic

approach will necessitate the use of the endotracheal tube. Maintenance can be accomplished with inhalation anesthetics or in combination with intravenous drugs. Small neonates who are at risk for postoperative apnea may benefit from spinal anesthesia.[100]

Congenital Diaphragmatic Hernia

A congenital diaphragmatic hernia (CDH) is a defect of the diaphragm that allows extrusion of the abdominal contents into the thoracic cavity. This disorder has an incidence of 1 in 2500 live births.[101,102] The herniated abdominal contents act as a space-occupying lesion and prevent normal lung growth and development. The diagnosis of congenital diaphragmatic hernia should be made prenatally in virtually all cases where routine maternal ultrasonography is available. The prognosis can be predicted based on whether it is isolated and assessment of lung size and/or the position of the liver. Prenatal intervention may be offered in fetuses that have a predicted poor outcome. The aim of this procedure is to reverse the key determinant of survival—pulmonary hypoplasia. Percutaneous fetal endoscopic tracheal occlusion by a balloon is a minimally invasive procedure that has been shown to be safe and yields a 50% survival rate in severe cases. The outcome can be predicted by the gestational age at birth, the lung size before and after balloon placement, and whether the balloon has been removed prenatally.[103] The lung affected to the greatest extent is on the ipsilateral side, but the other lung can be affected as well. The lungs have reduced-sized bronchi, less bronchial branching, decreased alveolar surface area, and abnormal pulmonary vasculature. There is a thickening of the arteriolar smooth muscle extending to the capillary level of the alveoli. This results in increased pulmonary artery pressure and causes right-to-left shunting.[104]

Neonates with CDH present immediately after birth with dyspnea, tachypnea, cyanosis, absence of breath sounds on the affected side, and severe retractions. Their physical appearance is a scaphoid abdomen and a barrel chest. Between 44% and 66% of neonates with CDH have other anomalies, particularly heart lesions.

The emergent nature of the repair has been reexamined in the past decade, and more emphasis is now placed on stabilizing pulmonary hypertension and other medical issues. A recent review of these cases noted that the median age at operation was 4 days and the median weight was 3800 g. Laparotomy, thoracoscopic repair, and a laparoscopic approach may be used.[105]

Studies published by Azarow et al.[106] and Jona[107] in the late 1990s demonstrated that the ventilation parameters were a major factor in survival of these babies. Permissive hypercarbia with high-frequency, oscillatory ventilation was most successful in improving outcomes. A thorough assessment of the baby, including laboratory values, radiographic findings, and physical symptoms, is mandatory. Listening to breath sounds will assist in evaluating the degree of ventilation on each side of the chest after intubation. Because of the respiratory manifestations of the problem, most of the patients will be already intubated and have intravenous access and arterial lines in place when they arrive in the operating room. If they are not intubated, an endotracheal tube should be placed after a rapid-sequence induction. If a difficult airway is suspected, an awake intubation should be done.

It is important in these patients to administer an anticholinergic (atropine 0.02 mg/kg) intravenously just prior to induction to prevent the bradycardia during induction. If an awake intubation is planned, some type of analgesia should be used to decrease the stress response of airway instrumentation. Ventilation should be delivered gently to avoid inflating the stomach with air, further compromising the pressure in the chest.

The patient's hemodynamic stability should determine the anesthetic drugs used. The use of inhalation agents and narcotics are guided by the cardiovascular stability. Nitrous oxide should be avoided because it will increase the volume of gastrointestinal tissue and further impair ventilation.

Monitoring must include blood pressure, ECG, pulse oximetry, capnography, temperature, and heart rate. To monitor for right-to-left shunting, oximeter probes should be placed preductal (right upper extremity) and postductal (lower extremity). The use of arterial blood pressure monitoring will not only allow beat-to-beat assessment of blood pressure but also provide an outlet for easier blood sampling. All conditions that can increase pulmonary vascular resistance—hypoxia, hypothermia, or acidosis—must be avoided. Carbon dioxide should be kept at normal or slightly elevated levels and oxygen saturation maintained above 80 mmHg. Any derangement of electrolytes must be corrected quickly and any significant blood loss replaced.

In the event that cardiorespiratory instability prevents the neonate from being transported to the operating room, the anesthetist might be required to administer anesthesia in the NICU while the baby is still on extracorporeal membrane oxygenation (ECMO). Under these circumstances, the recommended anesthetic choice is an opioid and nondepolarizing muscle-relaxant technique instead of an inhalation agent. Postoperative ventilation is required, with the goal of keeping the arterial oxygenation greater than 150 mmHg and slowing weaning to lower oxygen concentrations over a 48- to 72-hour period.[104]

Omphalocele and Gastroschisis

Omphalocele and gastroschisis anomalies are both defects in the abdominal wall that occur during gestation when the visceral organs fail to move from the yolk sac back into the abdominal cavity. It is more common to encounter omphalocele in term newborns and gastroschisis in preterm newborns. There are several differences in the two defects that are noted in Table 47-17. The defects occur at the insertion of the umbilicus. They are often associated with other anomalies. Some of those anomalies might be cardiac, genitourinary (bladder exstrophy), metabolic (e.g., Beckwith-Wiedemann syndrome with macroglossia, hypoglycemia, organomegaly, gigantism), malrotation, Meckel's diverticulum, and intestinal atresia. When the omphalocele is in the epigastric region, cardiac and thoracic problems are more prevalent. If the omphalocele is located in the hypogastric area, cloacal anomalies and exstrophy of the bladder are seen more

TABLE 47-17 Differences Between Gastroschisis and Omphalocele

	Gastroschisis	Omphalocele
Covering membrane	No	Yes
Location of defect	Right of umbilicus	Midline including umbilicus
Umbilical cord insertion	Body wall at normal location	Omphalocele membrane
Herniated abdominal organs	Bowel	Bowel and sometimes liver
Associated anomalies	Uncommon	Very common
Prognostic factors	Condition of bowel	Associated anomalies

From Ledbetter DJ. Congenital abdominal wall defects and reconstruction in pediatric surgery: gastroschisis and omphalocele. *Surg Clin North Am.* 2012;92(3):714.

often.[101] These abdominal wall defects have very different surgical management techniques and outcomes. Gastroschisis outcomes have improved dramatically over the past 4 decades but still comprise the largest group of patients needing bowel transplant. Omphalocele outcomes remain poor overall despite many advances in care. Large omphaloceles are one of the most difficult things to manage in pediatric surgery, and there is no standardized closure technique.[108] Both gastrointestinal anomalies, although very different in presentation, are similar as far as the anesthetic management needed.

A newborn with an omphalocele or gastroschisis is usually brought to the operating room very soon after birth to minimize the possibility of infection, the loss of fluid and heat, and the possible death of bowel tissue. A thorough preoperative evaluation must be done to identify the presence of any of the previously mentioned associated anomalies. Historically, the surgical approach was to immediately attempt primary closure of the defect. This entailed placing a large amount of abdominal contents into a cavity that was not usually large enough, and the result was a significant increase in intraabdominal pressure, which impeded ventilation and caused profound hypotension secondary to aortocaval compression. Over the past decade, surgeons have opted for a staged closure, using a Silastic silo as a temporary housing for the bowel. This silo is sutured to the defect, and over the next 3 to 7 days, the silo is reduced to allow for accommodation of the gastric contents and abdominal-wall stretching. The neonate is usually then brought to surgery for complete closure of the defect.[108-110]

The choice of anesthetic agent and technique is determined by several guiding principles: severe dehydration and massive fluid loss from exposed viscera and internal third-spacing of fluid due to bowel obstruction, hypothermia, the potential for sepsis, associated anomalies, and postoperative ventilation requirements. It is not uncommon for the anesthetist's choice to be an opioid and nondepolarizing muscle relaxant technique; however, even with the use of muscle relaxants, the abdominal wall may not allow primary closure. Ventilatory compromise and decreased organ perfusion are major problems as intraabdominal pressure increases. It is imperative to have adequate intravenous access to infuse large amounts of fluid quickly and invasive monitoring to guide the replacement. A pulse oximeter probe on a lower extremity will indicate whether there is compromise in the perfusion to the lower extremities due to obstruction of venous return.

Postoperative ventilation is mandatory on all of these babies, requiring the continued use of paralytics and sedation with an opioid until their clinical status stabilizes.

Tracheoesophageal Fistula and Esophageal Atresia

Esophageal atresia (EA), with or without tracheoesophageal fistula (TEF) can be suspected prenatally by the presence of polyhydramnios and finding an absent stomach bubble on ultrasound. It is normally diagnosed immediately after birth when an orogastric tube cannot pass into the stomach, when there is coughing and choking after the first feeding, or after recurrent pneumonia associated with feedings.[101] In the past this condition was often lethal. Today there is an expectation of almost 100% survival.[111]

There is a significant association of other serious congenital anomalies in these babies. Some sources report as high as 30% to 50% of newborns with AE and TEF have other anomalies, particularly VACTERL (vertebral anomalies, *a*nal atresia, *c*ardiac, *t*racheo*e*sophageal fistula, *r*enal and *l*imb malformations) syndrome. Preoperative echocardiography is mandatory to exclude both associated cardiac defects and a right-sided aortic arch that occurs in 2.5% of cases. An identified congenital heart defect may need to be managed preoperatively after consultation with a pediatric cardiologist, although surgical correction is almost always performed after the TEF/EA surgery. In the case of a right-sided aortic arch, surgical access to the esophagus and the TEF via the typical right thoracotomy is more hazardous, so a left thoracotomy may be performed.[111]

Esophageal atresia with a distal fistula is the most common presentation of TEF in approximately 80% to 90% of patients.[101] The esophagus ends in a blind pouch, and the distal esophagus forms a fistula with the trachea, usually above the carina. There are other configurations of this anomaly, varied by the location of the fistula and the presence or absence of EA (Figure 47-9). The morbidity and mortality of TEF are directly related to the resulting pulmonary complications from aspiration.[112] The focus of the preoperative preparation should be to minimize the pulmonary complications by discontinuing oral feedings, placement of a tube to suction nasopharyngeal secretions that accumulate in the blind esophageal pouch, maintain the infant in a semirecumbent position to minimize aspiration of secretions, and placement of a gastrostomy tube to prevent excess gastric distention from impairing ventilation. The surgical procedure is performed via a thoracotomy incision, usually on the right side. The sequence of the repair is the ligation of the fistula and then anastomosis of the two ends of the esophagus if possible.

Standard monitors should be used. The cardiorespiratory condition of the neonate should dictate the use of more invasive monitoring techniques such as an arterial line, umbilical or radial. Preductal and postductal oximeter probes should be used.[17] In view of the unknown features and potential problems with airway management of patients with these anomalies, some clinicians advocate

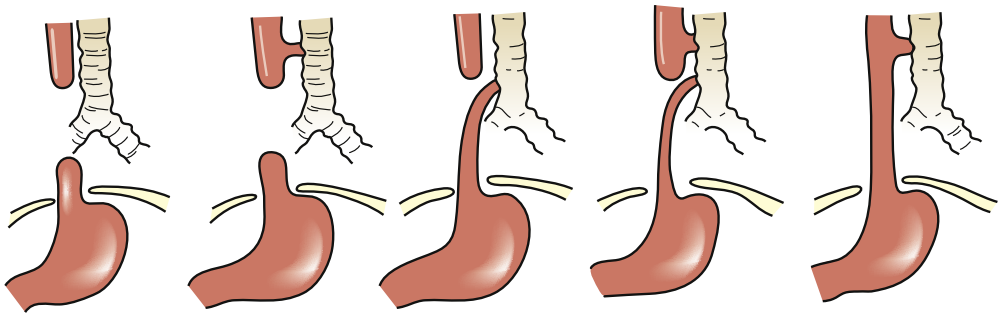

FIGURE **47-9** Anatomic variants and incidence of esophageal atresia with tracheoesophageal fistula. (From Townsend CM, et al. *Sabiston Textbook of Surgery: The Biologic Basis of Modern Surgical Practice*. 19th ed. Philadelphia: Saunders; 2012:1838.)

performing bronchoscopy intraoperatively before intubation and thoracotomy. Bronchoscopy has been used effectively to assess the presence, type, number, size, and location of fistula, as well as to determine or exclude additional fistulas that may otherwise be missed and leave the patient with an ongoing source of aspiration.

The technique of induction should be based on the clinician's evaluation of the airway. Some clinicians feel that an inhalation induction with spontaneous respiration avoids overventilation and reduces the stress of airway manipulation. This technique minimizes the gastric distention from anesthetic gases passing through the fistula and allows proper placement of the endotracheal tube without positive-pressure ventilation. If this technique is used, care must be taken to avoid hypoxemia that will result from the respiratory depression produced by high concentrations of inhalation agents. With any of the described techniques, once the endotracheal tube is placed, proper position must be verified. A common method of verifying the correct position is to actually intubate the right mainstem bronchus and then withdraw the endotracheal tube until breath sounds are heard on the left side of the chest. The tip of the tube is likely between the fistula and the carina (Figure 47-10). Another method, if there is a gastrostomy in place, is to submerge the gastrostomy tube in water and if there are bubbles on ventilation, the fistula is being ventilated and the tube must be repositioned. The bevel of the endotracheal tube should be turned anteriorly to allow the posterior surface of the endotracheal tube to occlude the fistula. In one configuration of TEF, the fistula is located very close to the carina. In this case, the endotracheal tube may need to be placed in the bronchus of the nonoperative lung until the fistula can be ligated. After ligation, the tube can be withdrawn to above the carina.

During the procedure, it is essential to monitor ventilation very carefully. Airway obstruction can occur if the trachea is compressed or if secretions or blood block the openings of the endotracheal tube. This must be corrected immediately.

The neonate without significant pulmonary complications who is awake and moving vigorously is most often extubated in the operating room. Blood and secretions may be present in the endotracheal tube, and it should be suctioned gently prior to removal. If there is any concern about airway obstruction or impaired ventilation, mechanical ventilation should be continued. It is thought that should bag-and-mask ventilation or reintubation be required, undue stress could be placed on the suture lines of the repair with laryngoscopy and neck extension, resulting in damage to the esophagus, necessitating further surgical procedures. Another problem that can occur with early extubation in smaller neonates is an inability to maintain the work of breathing due to preoperative lung disease. If postoperative mechanical ventilation is needed, the endotracheal tube should be positioned 1 cm away from the fistula repair to allow for healing of the suture line. A suction catheter should be clearly marked with a distance for insertion that approximates the distance just above the anastomotic repair.[113] Postoperative pain can be managed with opioids and/or a caudal epidural, placed intraoperatively.

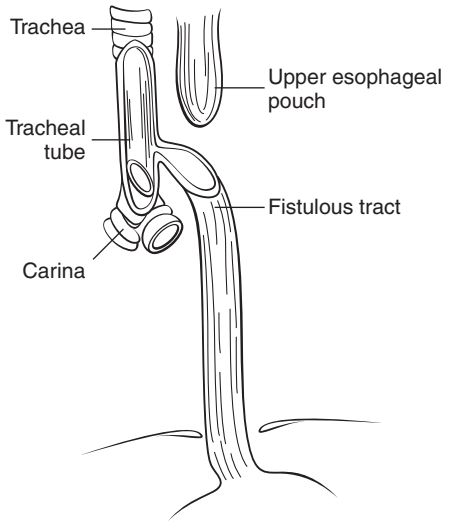

FIGURE **47-10** Correct placement of endotracheal tube—between fistula and carina.

Complications may occur later that could influence anesthetic management. Neonates who have had EA/TEF repair early in life can develop a diverticulum at the site of the old tracheal fistula. This could present problems in the future if inadvertent intubation of the diverticulum occurs. Esophageal stricture could develop at the site of esophageal anastomosis requiring repeated dilation or possible resection.[114]

Malrotation and Midgut Volvulus

Intestinal malrotation in the newborn is usually diagnosed after signs of intestinal obstruction, such as bilious emesis, and corrected with the Ladd procedure.[115] As the intestine is moving from its extraabdominal location during the first trimester of gestation, it can become twisted. The result can be a compromised superior mesenteric artery and intestinal ischemia. This ischemia can cause bowel strangulation, bloody stools, peritonitis, and hypovolemic shock. When this occurs, it is termed *volvulus*.[104]

Many of these neonates are diagnosed in the first week of life when the neonate presents with bilious vomiting, a tender and distended abdomen, and increasing hemodynamic instability. The surgical procedure relieves the obstruction by reducing the volvulus, dividing the fixation bands between the cecum and the duodenum or jejunum, and widening the base of the mesentery.

The major concerns in anesthetic management are airway management, fluid and electrolyte replacement, treatment of sepsis, and postoperative pain management. Any baby with intestinal obstruction will likely have abdominal distention (which could impede diaphragmatic movement) and is at higher risk for aspiration of gastric or intestinal contents. This necessitates the use of a rapid-sequence induction with the proper application of cricoid pressure. If there is concern for difficult airway, awake intubation should be considered. There is likely volume depletion due to peritonitis, ileus, bowel manipulation, and sepsis. It is absolutely necessary to have adequate intravenous access, and it is desirable to have a central line and an arterial line.

The choice of anesthetic agents should be dependent on the neonate's condition. It is not advisable to use nitrous oxide, but other inhalation agents could be acceptable. As with other emergent abdominal procedures, postoperative mechanical ventilation could be required, making the intraoperative choice of an opioid and nondepolarizing muscle relaxant a good choice (Box 47-5).

BOX **47-5**

Advantages of Neuromuscular Blockers in Neonatal Anesthesia

- Controlling efficient ventilation throughout surgery
- Facilitation of surgical procedure
- Reduction of inhalation anesthetic requirements
- Control of the airway via endotracheal tube
- Ability to provide adequate analgesia
- Complete reversibility

Although anesthetic agent choice is not critical, the maintenance of an adequate circulating volume and red blood cells is vital to ensure perfusion of vital organs.

Necrotizing Enterocolitis

NEC is an intestinal inflammation that is a life-threatening emergency situation. It occurs primarily in preterm babies with a gestational age of less than 32 weeks and a weight of less than 1500 g. The etiology of the problem is reported to be secondary to bowel ischemia and immaturity, probable bacterial invasion, and premature oral feeding.[101,104] The origin of infection may be the umbilical cord stump, infection due to circumcision, and similar lesions.[116] Box 47-6 lists the common symptoms of NEC. Diagnosis is confirmed by imaging studies that commonly show fixed dilated intestinal loops, pneumatosis intestinalis, portal vein air, ascites, and pneumoperitoneum. Accompanying laboratory values may show hyperkalemia, hyponatremia, metabolic acidosis, hyperglycemia, or hypoglycemia, and in the most serious cases, signs of disseminated intravascular coagulation.

When an attempt at medical management is unsuccessful, surgical intervention consists of an exploratory laparotomy or laparoscopy with resection of dead bowel, usually a colostomy, and peritoneal lavage.

These neonates are very sick and usually come to the operating room already intubated and on ventilator support. The anesthetic drugs chosen should depend on the patient's condition, but a common choice is a narcotic and relaxant technique. These are thought to be the safest choice in the presence of cardiovascular instability because the inhalation agents may further depress the myocardium and lower the blood pressure to unacceptable levels. Nitrous oxide is avoided, and if there is concern over high oxygen concentrations, saturations can be maintained at a lower level. If cardiac output is low and renal perfusion is below normal, inotropes may be indicated. The amount of third-space loss in these patients is very large and may require multiple blood volumes of crystalloid and colloid combinations to replace intravascular volume. Red blood cells, fresh frozen plasma, and platelets also may be required to increase oxygen-carrying capacity or to treat factor deficiency.[101,104]

The postoperative care should focus on continuation of the fluid resuscitation and cardiorespiratory support and mechanical ventilation until the baby stabilizes.

Imperforate Anus

During the first few days after birth, when there is no passage of meconium, the diagnosis of imperforate anus is considered. The degree of this anomaly can range from a mild stenosis to complete anal atresia that is associated with other anomalies. The VACTERL syndrome contains all the previously mentioned anomalies.[117] In male newborns, the operative procedure may be urgent to allow the passage of meconium via a colostomy. In female newborns, owing to the usual presence of a rectovaginal fistula, the procedure can be delayed for a few weeks. The anesthetic considerations for this neonate are based on the existence of associated anomalies and fluid and electrolyte balance.

BOX 47-6

Common Symptoms of Necrotizing Enterocolitis

- Increased gastric residuals with feeding
- Abdominal distention
- Bilious vomiting
- Lethargy
- Occult or gross rectal bleeding
- Fever
- Hypothermia
- Abdominal mass
- Oliguria
- Jaundice
- Apnea and bradycardia
- Fever

Other Intestinal Obstructive Lesions

Duodenal obstruction, jejunoileal atresia, and meconium ileus can all result in a complete intestinal obstruction. Although each of these pathologies are different in etiology and presentation, the anesthetic management is very much like that for the previously mentioned midgut volvulus.

Neurosurgical

Neonatal Hydrocephalus

Hydrocephalus is usually the result of some existing pathologic process. It is usually due to an obstruction in the CSF or an inability to absorb CSF. The standard treatment is the placement of a shunting catheter from the ventricle of the brain to another location to allow absorption of the fluid. Most often the shunt is placed from the ventricle to the peritoneal cavity. Occasionally the catheter is placed in the right atrium or pleural cavity. In the newborn and neonate, if the hydrocephalus develops slowly, the cranial vault will expand to accommodate the increase in brain bulk. When there is no more ability to expand, intracranial pressure (ICP) begins to increase, and the baby could be in serious trouble. The signs and symptoms of increasing intracranial pressure are a tense anterior fontanelle, irritability, somnolence, and/or vomiting.

Anesthetic management is directed at controlling the ICP and relieving the obstruction. The urgency of the procedure is determined by the preanesthetic assessment of the ICP. The major risk associated with delay is the possible herniation of the brain due to increasing pressure in the cranial vault. Comorbidities such as prematurity and all associated problems must be addressed.

Induction in the presence of increased ICP is usually a rapid-sequence induction and tracheal intubation. A variety of anesthetic agents are acceptable for maintenance, with the goal being to extubate the patient at the end of the procedure. If the neonate is preterm, it is advisable to adjust the oxygen concentration to maintain a lower oxygen saturation. This decreases the risk of ROP. The neurologic status of the neonate could affect the decision to extubate immediately, and mechanical ventilation could be required.

Myelomeningocele

Myelomeningocele is the most common CNS defect that occurs during the first month of gestation. Another common name for this defect is *spina bifida*. It is failure of the neural tube to close, resulting in herniation of the spinal cord and meninges through a defect in the spinal column and back. If the herniation only contains meninges, it is a meningocele. If the herniation contains meninges and neural elements, it is a myelomeningocele. These lesions mostly occur in the lumbosacral region but can occur at any level of the neuroaxis. The repair of the defect is considered urgent and is usually undertaken with the first 24 hours of life to avoid the increasing risk of bacterial contamination of the spinal cord and further deterioration of neural and motor function (Figure 47-11). Most newborns with myelomeningoceles do not have other associated anomalies or congenital heart disease. These neonates, however, often have an Arnold-Chiari malformation.

FIGURE **47-11** A lumbar myelomeningocele is covered by a thin layer of skin. (From Kliegman RM, et al. *Nelson Textbook of Pediatrics*. 19th ed. Philadelphia: Saunders; 2011:2001.)

The Arnold-Chiari malformation is a result of the hindbrain being displaced downward into the foramen magnum, resulting in hydrocephalus. This will necessitate the placement of a ventriculoperitoneal shunt, usually during the myelomeningocele repair. There are usually significant neurologic deficits below the level of the lesion, and evaluation of the degree of deficit is important to anesthetic decision making. Preoperative assessment should include a thorough review of all other organ systems to rule out additional congenital anomalies. Minimal laboratory tests should include a blood count and a type of screen for blood.

Routine neonatal monitoring is necessary, and the use of invasive monitoring techniques should be based on the particular newborns status. Positioning and airway management is one of the biggest challenges for the anesthetist. Most of these babies can be induced and intubated in the supine position with the lumbosacral defect supported in a "donut" ring or with strategically placed towels to avoid direct pressure on the dural sac. If the defect is very large or if there is accompanying severe hydrocephalus, it may be necessary to place the neonate in the lateral position for induction and intubation. If there is a suspicion of a difficult airway, the endotracheal tube may be placed with the patient awake, after administration of atropine and preoxygenation. Adequate intravenous access is essential because of the possibility of significant blood loss during the procedure. If the defect is large, the surgeon may be required to undermine a large amount of tissue for closure, resulting in a large blood loss.

Anesthesia can be induced with an inhalation or intravenous technique. After the endotracheal tube is placed, the procedure is performed in the prone position with appropriate protection of all body parts. In some institutions, the use of muscle relaxants is discouraged to allow for stimulation and identification of neural tissue. Anesthesia can be maintained with a variety of drugs, keeping in mind the goal of extubation at the end of the procedure and the possibility of postoperative apnea.

These patients are prone to hypothermia, and conservation of body heat should include warming the operating room to at least 80° F before the procedure and until the baby is draped. Radiant heat lamps should be used during the preparation and positioning of the patient. A forced-air warmer also should be placed underneath the neonate to maintain body temperature. Anesthetic gases should be humidified to prevent heat loss and minimize pulmonary complications. There has been reported an increased sensitivity to latex in these babies. As a precaution, they should be treated as latex allergic, avoiding all products that contain latex.[118,119]

SUMMARY

Despite the advances in neonatal medicine, surgery, and particularly anesthesia, the anesthetic management of critically ill neonates continues to be a challenge. A thorough knowledge of developmental physiology and knowledge of neonatal disease states and their treatment is imperative to providing safe anesthesia. Many conditions that were once thought to be a death sentence for neonates are now surgically treated with increasingly good outcomes. Neonatal anesthesia requires the anesthetist to have astute clinical observation skills, to be intensely vigilant, and to be capable of sound judgments.

Pediatric Anesthesia

◆ *Sass Elisha and Carla Percy*

CHAPTER 48

Pediatric subspecialty practice requires a mastery of the foundations of pediatric growth and development, the anatomic and physiologic differences during various stages of maturation, and the influence of immature organ systems on anesthetic pharmacokinetics and pharmacodynamics. Anesthetic management for the pediatric patient requires integration and application of this specialized knowledge and refinement of the acquired technical skills of adult anesthetic management.

The content of this chapter provides an extensive discussion of the essentials for pediatric practice. The foundation of anesthetic management is developed through an understanding of pediatric anesthetic morbidity and mortality; the pharmacologic and physiologic differences among adults, infants, and children; and a clinical strategy for anesthetic management.

PEDIATRIC ANATOMY AND PHYSIOLOGY

A thorough understanding of the anatomic and physiologic differences between pediatric and adult patients is of paramount importance in providing safe anesthesia care. Because of the immaturity of children's organ systems—which is most significant until 2 years of age—the psychological and physical stress of surgery, the effects of anesthetic medications, and related pathology all play an integral role in patient outcomes. A thorough discussion of anatomy and physiology for the pediatric patient is presented in Chapter 47.

Pediatric patients are commonly subdivided by age. Categorical groupings include: neonate up to 4 weeks old; infant 4 weeks to 1 year; toddler 1-3 years; preschool 4-6 years; school age 6-13 years; and adolescent 13-18 years.

PEDIATRIC PHARMACOLOGIC CONSIDERATIONS

A complete discussion regarding the recent concern over possible cognitive changes associated with anesthetic drugs in developing children is included in Chapter 47.

Immature organ systems are responsible for the pharmacologic differences that exist between the infant and child. Physiologic characteristics that modify the pharmacokinetic and pharmacodynamic activity include differences in total body water (TBW) composition, immaturity of metabolic degradation pathways, reduced protein binding, immaturity of the blood-brain barrier, greater proportion of blood flow to the vessel-rich organs (i.e., brain, heart, liver, and lungs), reductions in glomerular filtration, a smaller functional residual capacity, increased minute ventilation, and immature receptor responses.

Water freely diffuses across cell membranes and is essential for the transport of cellular nutrients and substrates that support metabolic reactions. Total body water (TBW), expressed in liters, is determined as a percentage of total body weight (1 L of water weighs 1 kg) and steadily decreases with increasing age and varies according to sex and body habitus. Total body water is distributed into the intracellular (ICF) and extracellular (ECF) fluid compartments. With maturation, there is an accompanying decrease in the relative fluid compartment volumes of TBW and ECF during the first year of life, followed by additional decreases in ECF later in childhood. Table 47-8 illustrates the changes in TBW, ICF, and ECF during maturation.

Volume of Distribution

Drug distribution is best described by the volume of distribution, which is determined by dividing the dose of the administered drug by the resulting plasma concentration. Accordingly, body water composition influences the volume of drug distribution. Infants have a larger extracellular fluid compartment and greater TBW content. Due to a dilutional effect, lower plasma drug concentrations occur immediately after administration of water-soluble drugs. Accordingly, a larger drug loading dose is required to achieve the desired plasma concentration. The fat, muscle, and fluid volume compartments are compared in Table 48-1. Higher plasma concentrations occur for lipid-soluble drugs when administered according to weight due to decreased fat and muscle concentrations as compared with an adult.[1]

Protein Binding

Alterations in protein binding theoretically affect the availability of the free-drug fraction of highly protein-bound drugs. Reductions in plasma proteins such as albumin and α-1-acid glycoprotein (AAG) increase the free-drug fraction, which may increase the availability of active drug. Total plasma protein is decreased in the infant, reaching equivalent adult concentrations by 5 to 6 months of age. Albumin, the predominant plasma protein, is responsible for the binding of primarily acidic pharmacologic compounds and AAG, and other proteins are responsible for the binding of basic drugs. Both albumin and AAG concentrations are diminished at birth but reach the adult equivalency by 5 to 6 months, and the fully functional binding capacity of albumin approaches adults at about 1 year old. Albumin concentrations

TABLE 48-1 Body Composition During Growth

	Preterm Newborn (1.5 kg)	Full-Term Newborn (3.5 kg)	Adult (70 kg)
Muscle mass % BW	15	20	50
Fat % BW	3	12	18
Total body water	90%	80%	60%
Extracellular fluid	50%	40%	20%
Intracellular fluid	40%	40%	40%

BW, Body weight.

may fluctuate, decreasing in chronic disease states with parallel increases in inducible AAG concentration. Protein binding of many anesthetic drugs is decreased relative to adults, but there is little clinical consequence. The major factor affecting drug action is the reduced clearance. A highly protein-bound drug with a high extraction ratio and a narrow therapeutic index, such as lidocaine, requires reduced doses.[2] Drug metabolism takes place in the liver, gastrointestinal tract, gastric mucosa, and lungs. In most instances, metabolism reduces drug activity; however, the metabolite may be activated as with a prodrug. The ultimate goal of drug metabolism is the production of a water-soluble compound that can be more easily excreted.

Drug metabolism occurs in two phases. Phase I metabolism consists of three enzymatic reactions (oxidation, reduction, and hydrolysis) catalyzed by the cytochrome P-450 enzyme system. Enzyme systems within the red blood cell, plasma, and other extrahepatic tissues are capable of hydrolyzing a variety of pharmacologic agents, including local anesthetics, the depolarizing relaxant succinylcholine, and the nondepolarizing relaxants atracurium and cisatracurium. Esmolol is hydrolyzed by esterases in red blood cells. Phase I reactions produce a water-soluble metabolic product with the introduction of polar hydroxyl, amino, sulfhydryl, or carboxyl groups for excretion within the bile or urine. Phase II reactions, which are immature at birth, consist of conjugation or synthesis. Conjugation couples the drug with an endogenous substrate (i.e., glucuronidation, methylation, acetylation, and sulfation) to facilitate excretion. The newborn lacks the capacity to efficiently conjugate bilirubin due to decreased glucuronyl transferase activity.

Although the necessary enzyme systems are present at birth, enzyme activity is reduced, thereby increasing drug elimination half-lives. Drugs that produce a prolonged plasma half-life in the pediatric patient include bupivacaine (25 hours),[3] mepivacaine (8.5 hours),[4] diazepam (up to 100 hours),[5] indomethacin (15 to 20 hours),[6] meperidine (22 hours), and phenytoin (21 hours).[7]

Drug Administration

Absorption

The majority of drugs used in anesthesia are given by the inhalation or intravenous routes. Routine medications are also given by oral and rectal drug administration. Drugs are usually formulated as liquids for oral administration in children. Midazolam may be administered orally for premedication, and the rectal route may be selected for the administration of acetaminophen, opioids, and benzodiazepines.[8] Both routes rely on passive diffusion for drug absorption, although the rectal route can be erratic and variable. The resulting plasma drug concentration is dependent on the molecular weight, degree of drug ionization, and lipid solubility.

The degree of ionization of orally administered drugs is dependent on gastric and intestinal pH levels. Acidic drugs are nonionized and are favorably absorbed in an acidic environment such as the stomach. Basic drugs have more favorable absorption in the alkaline medium of the intestine. Most oral medications are absorbed in the intestine. The rate of absorption of most orally administered drugs is slower in neonates and young children because of a delayed gastric emptying time, which prolongs the time to reach the intestines. Gastric emptying time reaches adult values by 6 months of age.[9-11]

Rectal drug absorption is directly affected by drug formulation and rectal blood flow. The superior (upper third of the rectum), middle, and inferior rectal veins carry blood away from the rectal mucosa. The superior rectal vein empties into the portal system, whereas the middle and inferior rectal veins empty into the systemic circulation by way of the inferior vena cava. For example, the administration of acetaminophen into the upper third of the rectum results in a lower plasma concentration because of first-pass metabolism with drug transport to the liver. Opioids and midazolam undergo first-pass metabolism, and their administration into the upper third of the rectum should be avoided.

Acetaminophen is a popular antipyretic commonly administered to children during the perioperative period. Acetaminophen is capable of inducing dose-dependent hepatocyte injury in high doses. Acetaminophen is metabolized by the hepatic microsomal enzyme system, and approximately 80% of the parent drug is conjugated with glucuronic acid and sulfate (phase II metabolism). Animal data suggest that a small amount of the parent drug is metabolized by the cytochrome P-450 enzyme system (phase I metabolism), producing an intermediate metabolite that undergoes conjugation with glutathione and is excreted in the urine. High doses of acetaminophen may deplete glutathione, increasing the accumulation of this intermediate metabolite, which is thought to be responsible for acetaminophen-induced liver necrosis. Glutathione depletion may develop with continued administration of high doses of acetaminophen.[12] Doses used in anesthesia rarely approach toxic levels.

Intravenous acetaminophen (Ofirmev) is marketed for mild to moderate pain and to reduce fever in adults and children. Given in conjunction with an opioid for moderate to severe pain, it has been shown to have an opioid-sparing effect. The recommended dose of Ofirmev for patients 13 years old or older weighing 50 kg or more is 1000 mg every 6 hours or 650 mg every 4 hours IV; the maximum daily dose of acetaminophen by any route is 4000 mg. For patients 2 years old or older weighing less than 50 kg, the recommended dose is 15 mg/kg every 6 hours or 12.5 mg/kg every 4 hours IV.[13]

Types of Agents

Inhalation Agents

The rapid increase in alveolar concentration of inspired anesthetic is quantified by the ratio of the alveolar to inspired concentration (F_A/F_I). Factors that affect the F_A/F_I ratio include the delivered inspired anesthetic concentration, the inhalation agent blood-gas partition coefficient, alveolar ventilation (V_A), cardiac output (Q), and the distribution of Q to the vessel-rich organs (i.e., heart, brain, kidneys, and liver). Although tidal volume is similar between children and adults (5 to 7 mL/kg), children have greater minute ventilation and a higher ratio of tidal volume to functional residual capacity (5:1) compared with the adult (1.5:1). The greater minute ventilation and higher Q in infants and children are responsible for rapid inhalation anesthetic uptake and rapidly increasing alveolar anesthetic concentration. In addition, their decreased distribution of adipose tissue and decreased muscle mass affect the rate of equilibration among the alveoli, blood, and brain. The percentage of blood flow to the vessel-rich organs is greater than in the adult, and the blood-gas partition coefficients are lower in infants and children.[14,15]

The minimum alveolar concentration (MAC) of inhalation anesthetics is an indicator of dose and anesthetic requirements that change with age. Neonates have a somewhat lower MAC, which peaks at around 30 days of age (Figure 48-1). MAC is higher in infants from age 1 to 6 months of age; thereafter, MAC values are known to decrease with increasing age.[16,17] These increased requirements are a reflection of increased basal metabolic rate.

Myocardial depression may be exaggerated when inhalation anesthetics are administered to pediatric patients.[18,19] A more rapid rise in F_A/F_I ratio, the greater percentage of blood flow to the vessel-rich organs, and higher administered anesthetic

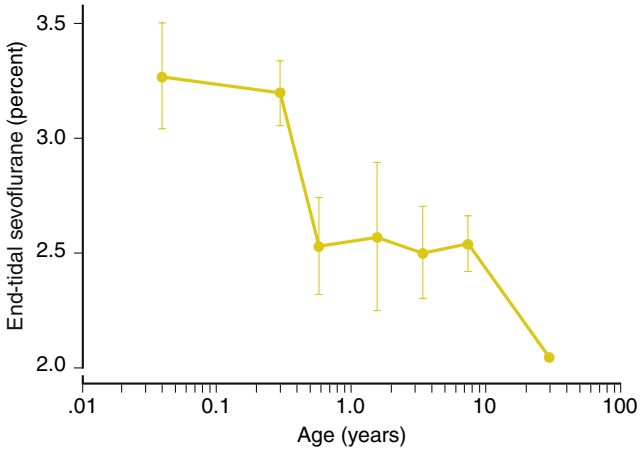

FIGURE **48-1** Effects of age on maximum alveolar concentration. (Data from Lerman J, et al. The pharmacology of sevoflurane in infants and children. *Anesthesiology*. 1994;80:814-824.)

concentrations are central to the cause of myocardial depression. To summarize, inhalation induction is more rapid in pediatric patients and is accompanied by a higher incidence of myocardial depression than in adults.

Sevoflurane. The MAC of sevoflurane in oxygen is 3% for the infant up to 6 months of age, decreasing to 2.5% to 2.8% up to 1 year of age.[20,21] Sevoflurane produces a rapid induction and emergence due to its low blood-gas partition coefficient.[22] Sevoflurane is easily breathed and is readily accepted for mask induction. Sevoflurane is the inhalation agent of choice for pediatric anesthesia. Sevoflurane depresses minute ventilation and, at deeper levels, respiratory rate. At high inspired concentrations, apnea will occur. [23,24]

Sevoflurane metabolism may produce concentration-dependent elevations in serum fluoride levels that decline when sevoflurane is discontinued.[25] Concerns regarding fluoride-induced renal damage have not been a clinical issue. Sevoflurane does not sensitize the myocardium to the effects of endogenous and exogenous catecholamines. As with any inhalation agent, the degree of myocardial depression is dependent on the concentration—higher concentrations cause a greater degree of inhibition of myocardial contractility. The MAC of sevoflurane in oxygen is 2% to 3%.

Isoflurane. The MAC of isoflurane in oxygen is 1.6% in infants and children. Inhalation induction with isoflurane produces more adverse respiratory events (i.e., breath-holding, coughing, and laryngospasm with copious secretions) than sevoflurane. Administration of isoflurane to adults produces dose-dependent decreases in peripheral vascular resistance, whereas increases in heart rate maintain blood pressure. This touted advantage (i.e., increase in heart rate to maintain blood pressure) does not occur in infants. Anesthetic induction in infants with isoflurane produces significant dose-dependent decreases in heart rate, blood pressure, and mean arterial pressure.[26]

Desflurane. The MAC of desflurane in oxygen is 9% for infants and 6% to 10% for children. Desflurane has the lowest blood-gas partition coefficient of all the inhalation anesthetics (0.42), which facilitates a rapid induction, rapid alterations in anesthetic depth, and emergence. Like isoflurane, desflurane is pungent and is associated with more adverse respiratory events during inhalation induction including breath-holding, laryngospasm, coughing, and increased secretions with accompanying hypoxia. After inhalation induction with sevoflurane, desflurane is appropriate for the maintenance of general anesthesia with facemask, endotracheal tube, or laryngeal mask airway. As in the adult population, dramatic increases in desflurane concentrations may induce sympathetic stimulation evidenced by tachycardia and hypertension.[27,28]

Emergence Delirium. A variety of terms are used interchangeably when referring to postoperative agitation. These include *emergence delirium*, *emergence agitation*, and *postanesthetic agitation*. These terms describe altered behavior in the immediate postoperative period manifested as nonpurposeful restlessness, crying, moaning, incoherence, and disorientation.[29,30] These episodes can be very upsetting to the parents and caregivers. Emergence delirium is fortunately self-limiting but may manifest for as long as 45 minutes. The incidence ranges from 10% to 80%. It occurs during the early stage of emergence during initial wakening. No single factor has been identified as the cause of emergence agitation, which is a composite of biologic, pharmacologic, psychological, and social components.[31] Recent hypotheses have implicated the rapid emergence associated with the newer low-solubility anesthetic agents such as sevoflurane and desflurane. This may create a dissociative state in which children awaken with altered cognitive perception, although others dispute the speed of emergence as a factor. There is conflicting research as to the incidence with the slower emergence of isoflurane.[32,33] Proposed causes also include rapid awakening in unfamiliar settings, pain, stress during induction, hypoxia, airway obstruction, noisy environment, anesthesia duration, child's personality, premedication, and type of anesthesia. A recent meta-analysis found that propofol, ketamine, fentanyl, dexmedetomidine, and preoperative analgesia had a prophylactic effect in preventing agitation and treating acute episodes. Midazolam and $5HT_3$ inhibitors do not have a protective effect.[34]

Intravenous Anesthetics

As discussed previously, infants and children have a higher proportion of cardiac output delivered to vascular-rich tissues (i.e., heart, brain, kidneys, and liver). Intravenously administered drugs are readily taken up by these tissues and are subsequently redistributed to muscle and fat, tissues that are less well perfused. Intravenously administered drugs may have a prolonged duration of action in infants and children because of decreased percentages of muscle and fat. The central nervous system (CNS) effects of opioids also may be prolonged because of the immaturity of the blood-brain barrier.[35,36] Although this evidence suggests that intravenously administered anesthetic doses should be reduced, one must also recall the effect of increased body water. Increased doses of propofol and ketamine are required, presumably because of a greater volume of distribution.[37]

Propofol. Propofol has a rapid onset and a short duration of action and is the most popular agent for induction and maintenance of general anesthesia. It also may be combined with an opioid and nitrous oxide to provide total intravenous anesthesia. Propofol may be delivered as a continuous infusion for short diagnostic and radiologic procedures and is used as a primary sedative in chronically ventilated intensive care patients. Its antiemetic properties may reduce the incidence of postoperative nausea and vomiting in children undergoing strabismus correction.[38] Infants require larger induction doses (2.5 to 3 mg/kg) than children (2 to 2.5 mg/kg).[39,40] These induction doses produce decreased systolic blood pressure.[41,42] The pain that accompanies intravenous administration may be reduced with the addition of small amounts of lidocaine. Additional strategies used to decrease the pain during injection include a slower injection of propofol into a rapid-running intravenous line or injection into larger intravenous catheters placed in the antecubital space.[43]

In 1992, Parke et al. reported the deaths of five children who received long-term, high-dose propofol infusions.[44] The large doses were administered by continuous infusion in critical care units with long-term sedation over several days and were not associated with short-term anesthesia use. Additional case reports followed, further characterizing this serious reaction, subsequently referred to as *propofol infusion syndrome*. Propofol infusion syndrome is characterized by severe lactic acidosis, followed by rhabdomyolysis and lipidemia. It frequently results in cardiovascular collapse and death. The likely mechanism involves propofol inhibiting mitochondrial function and uncoupling oxidative phosphorylation (see Chapter 9). Children with mitochondrial defects may have an increased risk with propofol administration.[45,46] Algorithms have been proposed to prevent this adverse drug effect.[47]

Neuromuscular Blocking Agents

Neuromuscular blocking drugs are highly ionized and have a low lipophilicity, restricting their distribution to the ECF compartment. The ECF compartment is larger in the neonate and infant than in the child and adult, causing a dilutional effect and thereby increasing the volume of distribution. Increases in ECF volume and the ongoing maturation of neonatal skeletal muscle and acetylcholine receptors affect the pharmacokinetics and pharmacodynamics of neuromuscular relaxants. Table 47-9 references the effective doses of neuromuscular blocking drugs in various age groups.

The neuromuscular junction is incompletely developed at birth, maturing after 2 months of age.[48] Skeletal muscle, acetylcholine receptors, and the accompanying biochemical processes essential in neuromuscular transmission mature during infancy into childhood.

The presynaptic release of acetylcholine is slowed compared with the adult, which explains the decreased margin of safety for neuromuscular transmission in the neonate. The acetylcholine receptors of the newborn are anatomically different from the adult receptors, which may explain the sensitivity of the neonate to the nondepolarizing class of neuromuscular relaxants.[49] This neuromuscular immaturity may be demonstrated with the appearance of fade after tetanic stimulation in the absence of neuromuscular blocking drugs.[48,50]

Succinylcholine. In the early 1990s a series of unexpected cardiac arrests were reported after the routine administration of succinylcholine in apparently healthy children, with less than 40% of patients successfully resuscitated. After much research it was found that the patients had undiagnosed Duchenne muscular dystrophy. Succinylcholine administration produces massive hyperkalemia and subsequent cardiac arrest in these children.[51] The U.S. Food and Drug Administration (FDA) relabeled succinylcholine, restricting its use to emergency airway management in children.[52,53] It is now used only as a rescue drug in children younger than 8 years old. Most clinicians avoid using it for patients through the early teen years and in patients with muscle disorders. It is contraindicated in patients with malignant hyperthermia.[54,55]

Nondepolarizing Neuromuscular Blocking Agents. Infants and children are more sensitive than adults to the effects of nondepolarizing neuromuscular blocking drugs (see Table 47-9). A lower plasma concentration of the selected neuromuscular relaxant is required to achieve the desired clinical level of neuromuscular blockade. This does not imply that the selected dosage should be decreased because infants have a greater volume of distribution. The larger volume of distribution and slower drug clearance result in longer elimination half-life, decreasing the need for repeated drug dosing (longer dosing intervals). Neuromuscular function monitoring must be used to guide repeated administration of these drugs in all pediatric patients. The degree of neuromuscular blockade should be assessed using physical signs (e.g., strength of movement, spontaneous respirations with adequate tidal volume) and neuromuscular monitoring (i.e., train-of-four and sustained tetanus). Checking neuromuscular function should be accomplished by assessing the adductor pollicis muscle on the forearm because function in this region is more reflective of diaphragmatic activity as compared with the orbicularis oculi (temporal region). The selection of a nondepolarizing neuromuscular relaxant should take into consideration the desired degree and duration of skeletal muscle paralysis, the immaturity of organ systems, and the associated side effects of the selected relaxant.[56,57]

Antagonism of Neuromuscular Blockade. Residual neuromuscular blockade places the infant and child at risk of hypoventilation and the inability to independently and continuously maintain a patent airway. Because of increased basal oxygen consumption, impaired respiratory function will lead to arterial oxygen desaturation and CO_2 retention. The detection of residual neuromuscular blockade requires the integration of clinical criteria and the assessment of neuromuscular blockade via a peripheral nerve stimulator. Conventional doses of the anticholinesterase inhibitors (50 to 60 mcg/kg of neostigmine; 500 to 1000 mcg/kg of edrophonium) combined with appropriate doses of atropine or glycopyrrolate are acceptable for antagonism of nondepolarizing neuromuscular blockade.

Voluntary clinical tests are obviously not applicable to the infant and young child. Useful clinical signs of successful antagonism of neuromuscular blockade include the ability to flex the arms, lift the legs, and flex the thighs upon the abdomen, providing evidence of the return of abdominal muscle tone, in addition to the return of a normal responses to nerve stimulation.[58] Neonates are capable of generating a negative inspiratory force (NIF) of −70 cm H_2O with the first few breaths after birth.[59] A negative inspiratory force of at least −32 cm H_2O has been found to correspond with leg lift, which is indicative of the adequacy of ventilatory reserve required before tracheal extubation.[60,61]

PREOPERATIVE PREPARATION

Preoperative preparation is typically done shortly before scheduled surgery, in the preoperative anesthesia clinic or in the patient's room in the hospital. Patients who are acutely ill or medically unprepared need to be screened appropriately in the preoperative area.

Preoperative Assessment

Parents or caretakers offer invaluable insight into the history of their child. It is important to have good communication and establish the trust of the patient's family member. Parental preparation is important to allay fear and answer questions. A thorough preoperative assessment will foster trust and confidence through a courteous and understandable explanation of the anesthetic experience. Parental anxiety may be driven by personal past anesthetic experiences, such as painful intravenous catheter placement, coerced mask induction, and postoperative pain, nausea, and vomiting. Parents offer invaluable information regarding their child's past anesthetic experiences. When the child appears for a repeat surgical procedure, the parents may have important information relative to what works and may be helpful in detailing a successful approach.

Review of Systems

Reviewing the medical record can answer many questions before approaching the patient/parents for information. Understanding congenital history can help preparation and development of a plan of care. Previous anesthetic records can be useful tools. Table 48-2 lists the anesthetic implications of the review of systems and history.

TABLE 48-2 Medical History and Review of Symptoms: Anesthetic Implications

System	History	Possible Anesthetic Implications
Central nervous and neuromuscular	Seizures	Medications: Drug interactions, possible inadequate serum levels, valproate-induced hepatitis
	Head trauma	Elevated intracranial pressure
	Hydrocephalus	Possible elevated intracranial pressure
	CNS tumor	Possible elevated intracranial pressure, chemotherapeutic drugs and interactions
		Possible risk of malignant hypothermia
Cardiovascular	Heart murmur	Septal defect, avoid air bubbles in IV line
	Cyanosis	Right-to-left cardiac shunt
	History of squatting	Possible tetralogy of Fallot
	Diaphoresis with feedings	Congestive heart failure
	Hypertension	Possible coarctation of the aorta; renal disease; pheochromocytoma
	Transplant recipient	Fixed heart rate; insensitivity to anticholinergic drugs
Respiratory	Prematurity	Increased risk of postoperative apnea; possible lower respiratory tract illness
	Bronchopulmonary dysplasia	Lower airway obstruction; reactive airways; possible subglottic stenosis; possible postoperative hypoxia and apnea; pulmonary hypertension
	Lower respiratory infection, cough	Reactive airways; bronchospasm; medication history; drug interactions
	Croup	Possible subglottic stenosis or anomaly
	Snoring, sleep apnea	Perioperative airway obstruction; hypoxia
	Asthma	β-Agonist or theophylline drugs; pulmonary hypertension or cor pulmonale; steroid use; adrenal insufficiency; postoperative hypoxia
	Cystic fibrosis	Drug interactions; pulmonary toilet; pulmonary dysfunction; reactive airways
	Recent cold	Possible lower respiratory tract infection; reactive airways
Gastrointestinal and hepatic	Vomiting, diarrhea	Electrolyte abnormality; dehydration; full stomach
	Growth failure	Possible anemia
	Gastroesophageal reflux	Risk of aspiration; reactive airways; hypoxia
	Jaundice	Altered drug metabolism; risk of hypoglycemia
	Liver transplant recipient	Altered drug metabolism; immunosuppression
	Frequency, nocturia	Unrecognized diabetes, urinary tract infection
	Renal failure or dialysis	Electrolyte abnormality; hypervolemia or hypovolemia; anemia; medication history
	Renal transplant recipient	Immunosuppression
Endocrine and metabolic	Hypoglycemia	Hypoglycemia
	Diabetes	Insulin requirement; intraoperative hypoglycemia
	Steroid therapy	Adrenal insufficiency
	Pregnancy	Teratogenic effects of N_2O and other drugs; risk of spontaneous abortion
Hematologic	Anemia	Transfusion requirement
	Bruising, excessive bleeding	Coagulopathy
	Sickle cell disease	Anemia; transfusion; hydration; oxygenation; orthopedic tourniquet use
	AIDS	Susceptibility to infection; infectious risk to medical personnel
Allergies	Medication history	Drug reactions; drug interactions
Dental	Loose teeth	Dental trauma; aspiration of tooth

Modified from Coté CJ, et al, eds. *A Practice of Anesthesia for Infants and Children*. 5th ed. Philadelphia: Saunders; 2013.
AIDS, Acquired immunodeficiency syndrome; *CNS*, central nervous system; *IV*, intravenous; N_2O, nitrous oxide.

- *Birth and development*. Was the child born prematurely or term? Did the child experience any neonatal complications or spend any time in the neonatal intensive care unit? Does the child have any history of apnea or bradycardia? Is there any history of sudden infant death syndrome in the child's family? Are there any developmental or learning setbacks?
- *Heart disease*. Does the patient play at school without severe shortness of breath or syncope? Does the child have a heart murmur?
- *Pulmonary problems*. Does the child have asthma, bronchitis, or pneumonia? Does the child currently receive, or has received in the past, supplemental oxygen therapy? Has the child had a recent cold, cough, or respiratory infection? Many times the child will have a persistent runny nose due to an inner ear infection. It is important to ask the parent about the color, consistency, and duration of drainage.
- *Bleeding disorders*. Does the child have sickle cell anemia? Does the child bleed or bruise easily?
- *Liver disease*. Has the child had jaundice or liver problems?
- *Urology problems*. Has the child had problems with the kidneys, ureters, or bladder? Any urinary tract infections?
- *Gastrointestinal problems*. Has the child had gastric acid reflux or a hiatal hernia? Has the child experienced problems with diarrhea or vomiting?
- *Neurologic problems*. Has the child experienced any neurologic symptoms such as seizures?
- *Obstetric history*. Could the patient possibly be pregnant? (controversial topic)
- *Airway*. Does the patient have a history of a difficult intubation? Does the child have trouble opening the mouth? Are there any chipped, missing, or loose teeth?
- *Other concerns*. Does the child have diabetes or hypoglycemia problems? Does the child have any problems with the thyroid or adrenal glands?
- *Medications*. Is the child currently on any medications or has he or she taken any within the last 3 months? Has the child taken steroids within the last year? If so, for what condition?
- *Allergies*. Is the patient allergic to any medication or food? Any problems with latex or other environmental items?

Fasting Status

The risk of pulmonary aspiration in the pediatric patient is extremely low (1 in 10,000).[62] Accordingly, traditional fasting guidelines have become broader. Although the goal of preoperative fasting is to ensure an empty stomach at the time of anesthetic induction, prolonged fasting may produce irritability as a result of thirst and hunger. Prolonged fasting also may alter fluid balance, producing preinduction hypovolemia and hypoglycemia. Hypoglycemia is especially problematic in premature infants. Preoperative access to clear fluids (e.g., apple juice, water) 2 hours before anesthetic induction has been shown to have a minimal impact on gastric volume. Current recommendations by the American Society of Anesthesiologists (ASA) are 2 hours of fasting for clear liquids, 4 hours for breast milk, 6 hours for infant formula and non-human milk and a light meal, and 8 hours for a regular meal including fatty foods (see Table 43-2). The guidelines are commonly referred to as the 2-4-6-8 rule.[63] These parameters are suggested for healthy patients undergoing elective surgery. No gum is to be chewed after midnight; also, prescribed medications can be taken with a sip of water or prescribed liquid mixture. If a patient should present with a history of hiatal hernia while preparing for elective surgery and has not been *nil per os* (NPO; nothing by mouth) for the recommended period of time, providers must collaborate to make the best decision in regard to keeping the patient safe. For a patient such as this, the best decision will likely be to postpone surgery until the proper fasting time has been achieved.

In patients that have not had the proper amount of fasting time or have an injury or anatomic differences that increase their risk for aspiration, it will be important to premedicate with a nonparticulate antacid such as sodium citrate (0.5mL/kg), metoclopramide (0.1mg/kg), and/or an H-2 blocking agent such as ranitidine (2.5 mg/kg).

Upper Respiratory Infection

Upper respiratory infections (URIs) are common in the pediatric age group, are seasonal in occurrence, and may be accompanied by cough, pharyngitis, tonsillitis, and croup. The child with an active or resolving URI has increased airway reactivity, a propensity for the development of atelectasis and mucous plugging of the airways, and the potential to experience postoperative arterial hypoxemia.[64] In addition, bronchial reactivity may persist for 6 to 8 weeks after a viral lower respiratory tract infection. The presence of chronic respiratory disease (asthma or bronchopulmonary dysplasia) requires a thorough assessment and medication review to ensure that the disease is well controlled and the child is not currently experiencing an exacerbation. A history of steroid use necessitates consideration of steroid supplementation throughout the perioperative period.

Healthy children who are scheduled for the placement of tympanostomy tubes frequently have rhinitis. In deciding whether to proceed with anesthesia, additional patient history must be obtained to differentiate between a chronic allergic or an acute infectious presentation and to determine whether there is lower-airway involvement. The assessment of the color and the duration of nasal drainage will assist in deciding whether rhinorrhea is chronic or acute. Purulent nasal discharge associated with pharyngitis, cough, or fever may be indicative of a bacterial or viral URI. Additional information may be obtained by questioning the parents regarding their assessment of the child's current health. Helpful questions include: Does your child appear sick? Is your child eating, sleeping, and playing normally? Is there anyone in the family (including siblings) who is currently ill? Children with chronic allergic rhinorrhea who exhibit a clear nasal drainage without accompanying signs of illness (e.g., no cough, pharyngitis, wheezing, or associated fever) are probably in satisfactory condition for elective general anesthesia with no imposed increased risk.

Lower respiratory tract dysfunction typically accompanies viral or bacterial URI. This combination may be associated with a greater frequency of laryngospasm (fivefold greater incidence) and bronchospasm (tenfold greater incidence) during anesthetic management, particularly when endotracheal intubation is performed.[65] Although mild URI may be inconsequential during the intraoperative period, significant problems may develop in the immediate postoperative period. Studies have noted an increase in the incidence of postintubation croup, hypoxemia, and bronchospasm in patients with URIs compared with asymptomatic children.[65-67]

Multiple factors must be considered when one is deciding whether to cancel an elective procedure. Children with signs and symptoms of acute airway dysfunction should have further medical evaluation by a pediatrician. A white blood cell count of 12,000 to 15,000/mm^3 suggests the presence of infection, and the surgery should be canceled. Clearly, elective surgery should be postponed for children who have a cough and pharyngitis accompanied by

fever and wheezing. Acute verses chronic symptoms need to be deciphered. Children with a fever 38.4° C and higher, malaise, wheezing, dyspnea, rhonchi, nasal congestion, and a productive cough are showing signs of an acute infection necessitating the postponement of surgery.[68,69] Evidence-based recommendations are given in Box 48-1.

Laboratory Testing

Laboratory testing should be ordered preoperatively based upon the patient's medical history and physical examination. Indications for preoperative laboratory testing are listed in Box 48-2. The American Academy of Pediatrics (AAP) states routine laboratory tests do not need to be performed in healthy patients undergoing outpatient surgery.[70] However, in patients presenting with an abnormality, preoperative testing is imperative to guide the surgical and anesthetic plans.

Preoperative laboratory tests should be ordered based on abnormal findings from the medical history and physical examination. Preoperative hemoglobin determination has characteristically been obtained to provide an assessment of anesthetic fitness. An "adequate" hemoglobin concentration is essential for oxygen delivery and has been arbitrarily defined as a hemoglobin of 10 g/dL or a hematocrit of 30%. No scientific studies support or refute this "acceptable" quantity. The determination of an acceptable value requires an understanding of the child's current medical history, the proposed surgical procedure, and an understanding of global oxygen transport and use. The value of a routine hemoglobin determination has been questioned for some time and has been found rarely to affect the anesthetic management of children.[71] The frequency of asymptomatic anemia in a prospective study of 2649 pediatric outpatients was found to be less than 1%, with 7 of 14 anemic patients younger than 1 year of age. However, the frequency of anemia may be as high as 12% in immigrant and indigent children.[72] Children who benefit from preoperative hemoglobin determinations include premature infants less than 60 weeks' postconceptional age, children with concurrent cardiopulmonary disease, children with known hematologic dysfunction (e.g., sickle cell disease), and children in whom major blood loss is anticipated during the surgical procedure.

Premedication

The selection and administration of premedication for the pediatric patient requires an understanding of the desired goals, the planned surgical procedure (inpatient or outpatient procedure), the familiarity and previous experiences with the particular drug, and the availability of nursing staff to monitor the child after the drug's administration (Box 48-3). The ideal premedicant should be dependable, with a rapid and reliable onset and offset, and should be devoid of undesirable effects. The use of "cookbook" doses of premedicants is hazardous and may produce general anesthesia in some children while producing ineffective sedation in others.[73] Table 48-3 lists commonly prescribed pediatric premedicants. Premedication must be individualized to account for differences in maturation and development and the child's previous surgical experiences. The reliance on pharmacologic premedication in preparing the child for the surgical experience should not be routine; rather, it should be reserved for children who are extremely apprehensive. Anxiolytics and sedatives may prolong the time to discharge, thereby increasing patient care costs.[74] Older children may benefit from anxiolytic premedication to decrease preoperative anxiety and modify behavioral changes after discharge. Analgesics are important for children experiencing pain and to provide some postoperative relief.[75] Midazolam is the most common premedicant in the pediatric patient. This short-acting, highly lipophilic benzodiazepine produces amnesia and anxiolysis and in sufficient dosages may also produce sleep (hypnosis). Many pediatric centers develop their own proprietary "cocktail" of a mixture of agents for use in children.

Parental Presence During Anesthetic Induction

Children may have difficulty with parental separation and may require premedication to ease their anxiety. In addition to

BOX 48-1

Recommendations for Patients with Upper Respiratory Tract Infections

When feasible, efforts should be made to make parents aware of the problems with respiratory tract infections and anesthesia, and parents should be encouraged to call before the day of surgery to discuss the symptoms and possible need for delay. There may be a role for pediatricians and other primary care practitioners to play in the process of perioperative evaluation and education.

First, an emergency case mandates judicious airway management and logically must proceed regardless of the presence or absence of respiratory symptoms. In patients undergoing elective nonurgent surgery, initial consideration should be with respect to the severity of respiratory tract symptoms. Often, careful questioning of parents can differentiate acute from chronic symptoms. Patients with severe symptoms such as fever greater than 38.4° C, malaise, productive cough, wheezing, or rhonchi should be considered for delay of elective surgery. A reasonable period of delay would be 4 to 6 weeks.

If mild symptoms are present, such as nonproductive cough, sneezing, or mild nasal congestion, surgery could proceed for those having regional or general anesthesia without endotracheal tube (ETT) placement. The intraoperative plan should include early use pulse oximetry, decision of facemask or laryngeal mask airway use, and careful suctioning of the nasal and oropharynx under deep anesthesia before emergence. Additional management considerations for patients with upper respiratory tract infection (URI) or lower respiratory tract (LRI) undergoing anesthesia include hydration status, use of airway humidification, and the potential benefit of pharmacologic agents such as anticholinergics and beta-agonists to help with airway secretions and airway hyperreactivity.

However, for those patients who require ETT placement for anesthesia, especially children less than 1 year of age, it is important to identify risk factors such as passive smoke exposure and underlying conditions (e.g., asthma, chronic lung disease) because these children may benefit from a slight delay of 2 to 4 weeks. Finally, those patients with resolving respiratory tract infections with severe symptoms or mild symptoms should have the same relative waiting periods fulfilled to minimize risks of proceeding with surgery (i.e., 2 to 4 weeks after resolution of minor URI and 4 to 6 weeks after resolution of severe URI or LRI).

Modified from McKee CT, et al. Should a child with a respiratory tract infection undergo elective surgery? In Fleisher LA, ed. *Evidence-Based Practice of Anesthesiology*. 2nd ed. Philadelphia: Saunders; 2009:475-481.

BOX **48-2**

Indications for Preoperative Laboratory Testing

Complete Blood Count
- Hematologic disorder
- Vascular procedure
- Chemotherapy
- Unknown sickle cell syndrome status

Hemoglobin and Hematocrit
- Less than 6 months of age (less than 1 year of age if born premature)
- Hematologic malignancy
- Recent radiation or chemotherapy
- Renal disease
- Anticoagulant therapy
- Surgical procedures with potential for large blood loss
- Coexisting systemic disorders (e.g., cystic fibrosis, prematurity, severe malnutrition, renal failure, hepatic disease, congenital heart disease)

White Blood Cell Count
- Leukemia or lymphomas
- Recent or concurrent radiation or chemotherapy
- Suspected infectious process
- Aplastic anemia
- Hypersplenism
- Autoimmune collagen vascular disease

Blood Glucose
- Diabetes mellitus
- Current corticosteroid use
- History of hypoglycemia
- Adrenal disease
- Cystic fibrosis

Serum Chemistry
- Renal disease
- Adrenal or thyroid disease
- Previous or concurrent hemotherapy
- Pituitary or hypothalamic dysfunction
- Body fluid loss or shifts (e.g., dehydration, bowel preparation)
- Central nervous system disease

Potassium
- Digoxin or diuretic therapy

Creatinine and Blood Urea Nitrogen
- Hypertensive cardiovascular disease
- Renal disease
- Adrenal disease
- Diabetes mellitus
- Digoxin or diuretic therapy
- Body fluid loss or shifts (e.g., dehydration, bowel preparation)
- Administration of intravenous radiocontrast material

Liver Function Tests
- Hepatic disease
- Exposure to hepatotoxic agents

Coagulation Studies
Prothrombin Time
- Activated partial thromboplastin time (aPTT)
- Leukemia
- Hepatic disease
- Known coagulation disorder (e.g., hemophilia, Christmas disease)
- Concurrent anticoagulant therapy
- Severe malnutrition or malabsorption

Platelet Count or Bleeding Time
- Known coagulation disorder (e.g., hemophilia, Christmas disease)
- Purpura (increase in bruising)

Pregnancy Test
- Serum human chorionic gonadotropin (HCG) in menstruating, sexually active patient

Electrocardiogram
- Family history of prolonged QT interval
- Congenital heart disease
- History of sleep apnea or chronic airway obstruction (adenotonsillar hypertrophy)
- Possible previously undiagnosed heart murmur

Chest Radiograph
- Suspected intrathoracic pathology (e.g., tumors, vascular ring)
- Congenital heart disease
- History of prematurity with residual bronchopulmonary dysplasia
- Obstructive sleep apnea with cardiomegaly

Cervical Spine Radiograph
- Down syndrome (rule out subluxation of atlanto-occipital junction)

BOX **48-3**

Goals for Premedication

- Anxiolysis (especially in children undergoing repeat procedures)
- Amnesia (insertion of intravenous access)
- Analgesia (children in pain)
- Antisialagogue (airway manipulation, but rarely needed)
- Increase gastric pH
- Reduction of gastric volume
- Reduce anesthetic requirements
- Blunting of central nervous system reflex responses
- Subacute bacterial endocarditis
- Allergic reactions (latex)
- Postoperative nausea and vomiting
- Infectious processes

TABLE 48-3 Commonly Prescribed Pediatric Premedicants

Drug Name	Pediatric Dose
Opioids	
Morphine sulfate	0.1-0.3 mg/kg IM 0.05-0.1 mg/kg IV
Fentanyl	0.5-1.0 mcg/kg IV 10 mcg/kg oral transmucosal
Benzodiazepines	
Midazolam	0.07-0.1 mg/kg IM 0.2 mg/kg nasally 0.025-0.05 mg/kg IV 0.25-1.0 mg/kg PO 0.5-1 mg/kg rectally
Ketamine	5-10 mg/kg PO 2-10 mg/kg IM 1-2 mg/kg IV
Clonidine	2.5-5.0 mcg/kg PO 1-2 mcg/kg IV
Dexmedetomidine	0.5-1.0 mcg/kg intranasally 2-5 mcg/kg PO 0.4-0.6 mcg/kg IV infusion in 100 mL saline
Anticholinergics	
Atropine	0.02 mg/kg PO, IV, IM
Glycopyrrolate	0.01 mg IV

IM, Intramuscular; *IV*, intravenous; *PO*, orally.

preoperative medication, many anesthetic departments allow a parent present for anesthetic induction. The frequency of allowing parents to accompany a child during anesthesia induction varies widely among institutions and even individual clinicians. Parents may stay with their children during diagnostic procedures such as bone-marrow biopsy, immunization, dental rehabilitation, and the induction of anesthesia. Anesthesia departments may have age limitations, not allowing parental presence for children less than 12 to 18 months of age. Clearly the parent should not be invited to participate in the induction of a child with a full stomach or perhaps a child with a compromised airway. Studies examining the effectiveness of parental presence are mixed. Parental presence has been demonstrated to reduce the child's anxiety, precluding the need for premedication.[76] However, an evidence-based review noted no advantage, and oral midazolam was found to be more effective for the control of the child's preoperative anxiety than parental presence.[77] Mothers who are motivated to be present in the operating room during the induction of anesthesia may be very anxious, and their children are likely to have high anxiety levels during anesthetic induction. Before entering the operating room with parent and child, a thorough explanation of the expected behavior of the child during anesthetic induction (e.g., excitement, spontaneous involuntary movements, snoring, floppy appearance with unconsciousness) should be provided to the parent or guardian. It is important that there be a clear line of communication between the anesthetist and the parent. In addition, the parent should agree to leave the operating room accompanied by an escort when the child has lost consciousness or when requested to do so. Hospitals and anesthesia departments occasionally request the parent to sign a waiver of liability prior to accompanying the child to the operating room.

BOX 48-4

Manipulation of the T-Piece (Open Circuit)

Manipulation to Increase Pao_2
- Increase inspired oxygen delivery at blender
- Increase fresh gas flow (decreases entrainment of room air from reservoir tubing)
- Increase length of reservoir tubing (increases oxygen storage capacity)

Manipulation to Decrease $Paco_2$
- Increase fresh gas flow (wash out expired air from reservoir tubing)
- Decrease length of reservoir tubing (decreases volume of expired air; also decreases Fio_2)

From Litman RS. *Pediatric Anesthesia: The Requisites*. Philadelphia: Mosby; 2004:102.

ANESTHETIC MANAGEMENT

Airway Management

Pediatric Breathing Circuits

In the United States standard pediatric breathing circuits are generally used in children. Occasionally, an open circuit is used for complex neonatal procedures or during transport. Characteristics of an ideal pediatric breathing circuit include lightweight, minimize dead space, have a low resistance and a low compressible volume, be adaptable for both spontaneous and controlled ventilation, be capable of providing humidification and warming of inspired gases, and permit the collection and scavenging of exhaled anesthetic gases. An easy method to conceptualize pediatric breathing circuits is to characterize the circuit according to the presence of the number of valves within the circuit.[78] A circuit without valves is an open circuit. The Ayre's T-piece is an excellent example of an open circuit (Box 48-4). It is commonly used throughout hospitals to provide supplemental oxygen during patient transport. The T-piece was first used for the delivery of anesthesia to infants undergoing cleft palate and cleft lip repair. The T-piece, which is in a T configuration, is formed by an inspiratory limb for the delivery of oxygen and anesthetic gas, a limb directed to the patient for connection to a facemask or endotracheal tube (ETT), and an opposite expiratory limb that is open to the atmosphere for the removal of exhaled gas. This expiratory limb also may serve as a reservoir for oxygen that may be rebreathed. Because there are no valves, inspired air is drawn from both the inspired limb and expiratory limb. The rebreathing of expired CO_2 can be prevented with the administration of fresh gas flows at least two times the patient minute ventilation. The T-piece can be configured to increase oxygen delivery or decrease $Paco_2$.

The modification of the Ayre's T-piece with the addition of a single valve allows the delivery of positive-pressure ventilation. A variety of modifications of the Ayre's T-piece have been classified by Mapleson. The Mapelson A circuit is best employed for the spontaneously ventilating patient. The Mapleson D system contains an expiratory valve at the distal end of the expiratory limb and is used for controlled ventilation. The Mapleson E system was modified by Jackson-Reese with the addition of a reservoir bag with an adjustable valve at the tail of the bag. Spontaneous ventilation is permitted with the opening of the adjustable valve, whereas closing the valve fills the reservoir bag, and repeated manual compression allows the delivery of continuous positive airway pressure, or positive-pressure ventilation. With an expiratory pause

of sufficient duration and sufficient fresh gas flows, exhaled CO_2 is washed from the reservoir tube, preventing the inhalation of exhaled CO_2 with subsequent inspiration. Fresh gas flows of two to three times the child's minute ventilation are required to prevent rebreathing of exhaled gases. Because of the required high fresh-gas flow rates, this circuit is not economical for children who weigh more than 20 kg.

The circle breathing system has become popular for anesthetic gas delivery in the past decade, because most pediatric centers have abandoned the use of the Bain or Mapleson F circuit for the circle system. Technologic advancements in anesthesia-machine design have decreased the resistance imparted by the absorbent canisters and the one-way inspiratory and expiratory valves. Overall system compliance is greater than that of the open circuits. The breathing tubing for the pediatric circle systems is a smaller diameter than the adult tubing and has a lower compression volume, allowing accurate delivery of desired tidal volumes. The circle breathing system is characterized by the presence of CO_2-absorbent canisters and a total of three valves (a one-way inspiratory valve, a one-way expiratory valve, and a pop off or adjustable pressure-limiting [APL] valve) that directs exhaled gas to the scavenging system. Advantages of the circle system include the conservation of potent inhalation agents, the ability to retain both heat and humidity, and the ease of collecting and scavenging waste gases.

The reservoir bag contains the anesthesia machine–delivered anesthetic mixture inspired by the patient and serves as a visual and tactile monitor of ventilation. Reservoir bags are shaped to allow compression with one hand and are constructed of rubber and latex, although latex-free bags are readily available. Reservoir bags range in size from 0.5 to 6 L. The selected reservoir bag must be appropriate for the patient's size, that is, capable of containing a volume in excess of the child's inspiratory capacity. The use of an inappropriately small reservoir bag may restrict respiratory efforts, and the use of a large reservoir bag inhibits the ability to use the reservoir bag as a monitor of ventilation.[79-81]

Anesthetic Induction

Inhalation (Mask) Induction

Anesthetic induction may be accomplished in a variety of ways and is dependent on the child's current state of health, the age and level of anxiety, the proposed surgical procedure, and the parents' agreement with regard to the proposed anesthetic plan. Inhalation or commonly called *mask induction* is the most popular and is easily accomplished in infants less than 8 months of age, as well as children who do not have initial intravenous access. Mask induction can be offered to children through the age of 16 years who have needle phobia. Standard monitors are applied when appropriate. A pulse oximeter and precordial stethoscope are used initially, and an assistant such as the circulating nurse places the remaining monitors during the induction period, following the loss of consciousness.

Anesthetic induction commonly begins with a 70:30 mixture of nitrous oxide and oxygen via mask or a cupped hand placed on the child's chin, with the anesthetic mixture directed toward the mouth and nose. Some clinicians do not use nitrous oxide and begin with sevoflurane oxygen mixtures instead. A pacifier may quiet the infant during the induction, or the infant may suck on the end of the anesthetist's gloved finger. Sevoflurane is added to the nitrous oxide–oxygen mixture beginning with a 2% concentration, with a rapid increase to 8%. The mask may then be introduced as the inspired concentration is increased. Unconsciousness is produced with inspired sevoflurane concentrations of 6% to 8%. Following the loss of consciousness, nitrous oxide is discontinued, and sevoflurane is administered in 100% oxygen.

At this time the anesthetist should begin to assist respiration and promptly decrease the inspired anesthetic concentration of sevoflurane to 2% to 2.5%. During assisted ventilation, intravenous access should be established. The age of the child, proposed surgical procedure, and ease of airway management during induction are the determining factors for whether to proceed with intravenous access.

Establishing intravenous access in all children before laryngoscopy and endotracheal intubation is advised. For elective surgical procedures, neonates may be managed with a 24-gauge catheter, infants with a 22-gauge catheter, and children with a 20- or 22-gauge catheter. Surgical procedures with expected large third-space fluid loss or blood loss require an additional intravenous catheter. Preferred sites for intravenous access include the nondominant upper extremity (dorsum of the hand, antecubital fossa) and the lower extremity (dorsum of the foot, or the saphenous vein). The deep saphenous vein is most easily accessed with a 20- or 22-gauge catheter. This vein can be identified by placing the thumb over the medial malleolus and moving it toward the anterior portion of the tibia. By extending the foot and piercing the skin parallel to the tibia and passing subcutaneously, the saphenous vein may be entered. To prevent the child from dislodging the catheter, tincture of benzoin is applied to the intravenous site and adjacent skin, and the catheter is secured with a sterile bioclusive dressing. The extremity is secured with a padded board, and the intravenous site is covered with a gauze dressing.

Following the establishment of intravenous access, preparations are made for endotracheal intubation. Intubation may be accomplished using the inhaled anesthetic agent without muscle relaxation or subsequent to the administration of a nondepolarizing neuromuscular relaxant. The administration of a neuromuscular relaxant decreases the potential for the cardiovascular depression that accompanies the administration of high concentrations of inhalation agents that may be required to facilitate laryngoscopy and intubation. The inspired concentration required for acceptable intubating conditions with sevoflurane in children ages 1 to 8 years is 3.54 ± 0.25%. The addition of 66% nitrous oxide decreases the required concentration by 40%.[82] A survey of members of the Society of Pediatric Anesthesia found that inhalation agent administration without neuromuscular blockade was used to facilitate endotracheal intubation 38% of the time in infants (0 to12 months) and 43.6% of the time in children (1 to 7 years old).[83,84] Whichever method is selected, the inhalation agent should be discontinued immediately before laryngoscopy. This practice minimizes the contamination of the operating room with free-flowing inhalation agent from the patient breathing circuit, and the delivery of high inspired anesthetic concentrations is avoided immediately after intubation during the confirmation of ETT placement. Following confirmation that the ETT is secured, the position of the tube at the alveolar ridge or lip is noted on the anesthetic record.

Single Breath Induction

This method can be used for children older than 3 years. The anesthesia circuit is filled with nitrous oxide, oxygen, and sevoflurane. The child is asked to take a deep breath and exhale fully. The mask is then applied to the face, and the child is asked to take in another deep breath. This method is not used to the extent it has been in the past; however, some providers still prefer this method due to the somewhat faster onset of induction.

Intravenous Induction

Intravenous (IV) induction is generally reserved for the child with an existing intravenous line. An IV induction may be clinically indicated when the child has a full stomach or a history of

gastroesophageal reflux. IV induction is quicker and more dependable, facilitating the rapid securing of the airway with endotracheal intubation. Venipuncture can be a frightening experience for the needle-phobic child. Oral premedication with midazolam before the child received the IV in the preoperative area can be given to decrease the child's anxiety and gain cooperation. The eutectic mixture of local anesthetic (EMLA cream) is applied well in advance (30 to 60 minutes) to aid in IV insertion and help decrease anxiety and increase cooperation. IV induction is performed similar to the method used for an adult. Standard monitors are placed after the child is moved to the operating room table, and preoxygenation given, followed by IV induction and securing of airway.

Intramuscular Induction

On rare occasions, an intramuscularly (IM) administered drug may be required in children who are uncooperative, mentally challenged, or who have reduced consciousness or in children who refuse alternative routes (i.e., oral, nasal, or rectal) for premedication. Ketamine is an excellent induction agent in these situations. It can be administered IM, and respirations and protective airway reflexes and vital signs are maintained during loss of consciousness. After intramuscular administration, the child may appear to be in a catatonic state. Parents who witness the administration of ketamine should be warned that their child might exhibit spontaneous involuntary movements and nystagmus. The psychogenic effects may be decreased with the concomitant administration of a benzodiazepine. Intramuscular ketamine in a dose of 4 to 6 mg/kg facilitates inhalation induction in children who are reluctant to be subjected to inhalation induction or venipuncture. Once unconsciousness is accomplished, an IV can be placed and standard anesthetic techniques begun.

Pediatric Airway Equipment

The child's age, weight, and proposed surgical procedure guide the selection of essential pediatric anesthesia equipment. The anesthesia workroom should be appropriately stocked with a variety of sizes of masks, airways, laryngeal mask airways (LMAs), laryngoscope blades, endotracheal tubes, endotracheal tube stylets, blood pressure cuffs, pulse oximeter probes, calibrated pediatric fluid sets, syringe pumps for the delivery of both fluids and drugs, an assortment of intravenous catheters, tape, and armboards.

Airway Equipment

The pediatric facemask is designed to fit the smaller facial features of the child and eliminate mechanical dead space. Contemporary masks are manufactured from transparent plastics and have a soft inflatable cuff that sits on the face. The transparent feature allows continuous observation of skin color and the appearance of gastric contents if vomiting occurs. Appropriately sized oral airways must be readily available. The relatively large infant tongue predisposes to airway obstruction after the induction of general anesthesia. Oral airways that are too large may produce airway obstruction and inhibit venous and lymphatic drainage, producing macroglossia and creating further airway compromise. The oral airway should be inserted with the aid of a tongue blade, displacing the tongue toward the floor of the mouth to allow smooth insertion of the airway. The insertion and rotation of an oral airway should be avoided in children, because the rotation may dislodge loose deciduous teeth. Nasal airways are infrequently used in children less than 1 to 2 years of age. The internal diameter of the nasal airway may unnecessarily increase the work of breathing. Adenoid hypertrophy may make nasal airway placement difficult and produce severe epistaxis.

Endotracheal Tubes. Traditional teaching since the 1960s has been that the use of a cuffed endotracheal tube (ETT) in infants and children less than 8 to 10 years of age should be avoided. Although this adage is widely accepted, recent literature suggests that this belief is not universally applied, is empirical rather than scientifically based, and is a perpetuated "myth" of pediatric anesthesia. The age-old argument against the use of a cuffed ETT in infants and children is quite logical; the narrowest portion of the infant and child airway has traditionally been understood to be at the level of the cricoid cartilage. The lumen of the noncompressible cricoid was thought to be round in shape. Traditional concepts outlining the differences in the adult and pediatric airways are noted in Table 47-3.

Sizing the Endotracheal Tube. Early detailed accounts of the laryngeal framework suggested that the larynx is shaped as a cone, with the apex at the level of the cricoid cartilage.[85,86] The compression of the tracheal mucosa at the level of the cartilaginous cricoid ring by an oversized ETT will produce mucosal edema. This traditional understanding has recently been challenged. Magnetic resonance imaging of sedated children ages newborn to 14 years has demonstrated that the lumen of the cricoid cartilage is not round but elliptical in shape, with the narrowest dimension in the transverse plane at the level of the vocal cords.[87] Another recent study questions this traditional teaching. Video bronchoscopic images and magnetic resonance spectrographs were obtained in 135 children, aged 6 months to 13 years. Measurement of laryngeal dimensions, including cross-sectional area, anteroposterior, and transverse diameters at the level of the glottis and the cricoid were performed. They found that the glottis rather than cricoid was the narrowest portion of the pediatric airway. They also noted that like adults, the pediatric airway is more cylindrical than funnel shaped.[88] Accordingly, the pressure exerted upon the laryngeal and tracheal mucosa with the use of an uncuffed ETT is in the posterior lateral position. This has been verified, as evidenced by the associated pathologic lesions found posteriorly in the subglottis. In addition, trauma that appears within the trachea occurs anteriorly from the impingement of the distal end of the ETT upon the anterior tracheal wall. The goal of ETT selection is the placement of an appropriately sized tube that allows controlled ventilation but minimizes laryngeal or tracheal injury. Because of patient variability, many formulas exist for the determination of the correct ETT size and for the depth of insertion. Despite countless practitioner recommendations, there is no agreed-upon standard formula. In addition, may practitioners fail to appreciate the differences in the internal diameter of small ETTs. Endotracheal tubes for neonates are sized by the internal diameter, yet the external diameters may differ by as much as 0.9 mm among manufacturers in tubes with identical internal diameters.[89]

The approximate size of an ETT for children 2 years of age and older may be determined with the following formula: 16 + age ÷ 4. Another formula used, especially for patients younger than 2 years old, to calculate ETT size is as follows: age ÷ 4 + 4. To accommodate the variability in patient airway size, ETTs a half size larger and a half size smaller should be immediately available.

The depth of ETT insertion from the dental alveoli may be estimated using the "1, 2, 3, 4/7, 8, 9, 10" rule—for example, the ETT is inserted to a depth of 7 cm in a neonate weighing 1 kg and to a depth of 8 cm in a 2-kg neonate. Another approximate method is to insert the ETT to a depth in centimeters three times the internal diameter of the ETT in millimeters. For example, a 3-mm ETT should be inserted to a depth of 9 cm. Uncuffed ETTs are marked distally with a double black line that provides a visual indication of the depth of the ETT. During intubation, the ETT is passed until the double black line has reached the level of the vocal cords. Optimal ETT size is one that easily passes through the glottis and subglottic regions. Clinicians are more inclined to

use a cuffed ETT without inflating the cuff than an uncuffed ETT. One recent study suggests checking cuff pressure for long cases to decrease the incidence of edema and tracheal damage.[90] Confirmation of proper ETT placement is imperative. Positive end-tidal CO_2, chest rise, and bilateral breath sounds are checked. Lung auscultation helps confirm proper ETT position. As the ETT is secured, it is important to not dislodge or pull out the ETT, which would necessitate re-intubation. The provider can place a stethoscope over the patient's mouth to check for leaks for proper cuff pressure. Table 48-4 notes airway device details.[91] Alignment of the head and its effect on the airway are depicted in Figure 47-3.

Laryngeal Mask Airway. The original LMA device was intended as an alternative to the anesthesia facemask rather than endotracheal intubation. The LMA is used for short surgical procedures that do not require endotracheal intubation and resuscitation situations. The LMA is available in sizes specific for the neonate, infant, child, and adolescent (Table 48-5). Many alternative designs for special uses are being introduced. The inflation of the pharyngeal cuff can produce undue pressure on pharyngeal structures. Like the adult ETT cuff, the LMA cuff may be expanded during the course of the anesthetic procedure with the administration of nitrous oxide. The initial volume of air injected into the laryngeal cuff may be regulated by identifying the amount of air and airway pressure that produces an audible leak. This pressure is generally between 15 and 25 cm H_2O. The LMA cuff should be inspected before each use, the volume of air required for cuff inflation should not exceed the manufacturer's recommendation, and the LMA cuff should be periodically checked during the administration of nitrous oxide to prevent overinflation.[92]

TABLE 48-5 Laryngeal Airway Mask Sizes

Laryngeal Airway Mask Size	Suggested Inflation Volume
1	6 mL
1½	10 mL
2	15 mL
2½	21 mL
3	30 mL
4	45 mL
5	60 mL

The LMA has traditionally been removed in the adult when airway reflexes return. Removal of the LMA in the pediatric patient can be associated with biting, pulmonary edema, severe laryngospasm, and separation of the tube from the pharyngeal mask.[93,94] Several studies have examined the appropriate time of LMA removal in children. In one study, oxygen desaturation was more prevalent (31.3%) after awake removal, compared with removal in a deep anesthetic plane (4.5%), whereas airway obstruction occurred more frequently (20%) with deep removal.[95] Researchers have reported a 10% incidence of severe laryngospasm with awake removal, compared with 5% with deep removal.[96]

Special Airway Equipment. Specialized uncuffed and cuffed oral and nasal ETTs may be chosen for otolaryngologic, ophthalmologic, and dental procedures. The RAE (right angle endotracheal; Mallinkrodt; Argyle, New York) tube is premolded, with the acute angle of the tube designed to be positioned over the lower

lip. The nasal RAE tube is premolded with a 180-degree bend that directs the tube toward the top of the head. These tubes facilitate the routing of the breathing circuit away from the surgical field. RAE tubes are longer than straight ETTs and place the distal end of the tube in closer proximity to the carina, thereby minimizing the chance of inadvertent extubation with neck extension. The RAE tube is designed with two Murphy eyes located at the distal end of the tube to facilitate uninterrupted ventilation if the tube migrates in a caudad fashion. However, proper ETT placement must be determined with confirmation of bilateral breath sounds after intubation and repositioning of the head. The use of a precordial stethoscope placed over the left anterior area of the chest will aid the detection of right bronchial migration of the RAE tube.

The clinical application of laser technology for the treatment of airway pathology necessitates the use of a specialized ETT. Endotracheal tube ignition may occur in as many as 1.5% of patients during CO_2 laser laryngeal procedures.[97] Modern polyvinylchloride ETTs absorb infrared light and may be ignited with a direct hit from a CO_2 laser or as a result of burning material in close proximity to the tube. Laser-resistant or "laser-safe" ETTs are available from several manufacturers and are marketed for specific laser applications (e.g., CO_2; neodymium-doped: yttrium-aluminum-garnet [Nd:YAG]; and potassium titanyl phosphate [KTP]). An alternative is wrapping the external surface of a polyvinylchloride ETT with a metallic foil (see Chapter 42).

Maintenance of a Patent Airway

A variety of anatomic and neurologic interactions are essential for the maintenance of a patent pharyngeal airway. It is truly remarkable that airway patency is continuously maintained with changes in posture as well as extremes of head and neck position. The larynx is innervated by a variety of receptors that react to stretch, the flow of inspired and expired gas, and muscle movement. Airway patency is also dependent upon lung stretch reflexes, central and carotid body chemoreceptor reflexes, and CNS arousal mechanisms. Pharyngeal patency is established and maintained through a delicate balance of CNS-derived dilating and collapsing forces upon the pharyngeal airway.[98,99] The pharynx may be conceptualized as a collapsible tube within a box, bordered by the tongue and soft palate, and enveloped by the bony elements of the mandible anteriorly and the cervical vertebra posteriorly. Pharyngeal patency is a function of the overall size of this box, and the amount of soft tissue between the bony elements and the pharynx. An increase in the amount of soft tissue within the box (e.g., obesity, hypertrophy of adenoids and tonsils, large tongue), or a decrease in the size of the bony elements (e.g., small craniofacial structures or craniofacial deformity) will limit the content of the box, resulting in compression of the pharyngeal airway. In effect the pharyngeal airway functions as a Starling resistor.[100]

Airway Management of the Infant and Child

In the awake infant and child, the tongue, the upper airway muscles (i.e., genioglossus, geniohyoid, sternohyoid, and sternothyroid) interact to tent the pharynx, preventing collapse. Anesthetic agents inhibit the neural activity of these airway muscles, resulting in pharyngeal narrowing or collapse.[101,102] The young infant depends upon compensatory mechanisms to maintain pharyngeal patency but is disadvantaged because of an anatomic imbalance (i.e., small maxilla and mandible, large cranium, large tongue).[103] A steadily increasing anesthetic depth during inhalation induction will depress these compensatory mechanisms, leading to pharyngeal narrowing and collapse.

Incomplete airway obstruction may be clinically evident early in the inhalation induction as audible inspiratory or expiratory sounds are evident through the precordial stethoscope. As the obstruction increases, a tracheal tug becomes notable with attempted inspiration. The infant has a compliant chest wall, and because of forceful diaphragmatic contraction, the chest is noted to collapse with inspiratory efforts against partial pharynx collapse. With continued inspiratory attempts, a paradoxical movement of the chest and abdomen (i.e., the contraction of the chest with abdominal expansion) is also appreciated. This thoracoabdominal asynchrony is an important clinical sign of upper airway obstruction. With complete pharyngeal collapse, the audible signs of obstruction are no longer appreciated, and thoracoabdominal asynchrony continues.

Perhaps as a result of immaturity, the CNS regulation of the pharyngeal dilator muscles is ineffective in opening the pharyngeal airway in the infant.[104] The application of continuous positive airway pressure (CPAP) 5 to 10 cm H_2O is essential in the reestablishment of a patent pharyngeal airway until sufficiently anesthetized to allow the placement of an oral airway. The application of CPAP accompanied by airway opening maneuvers (more importantly a chin lift) will reverse the anatomic imbalance, increase tidal volume, and diminish thoracoabdominal asynchrony.[105] The chin lift is an important airway maneuver because it widens the anteroposterior (at the epiglottis) and transverse diameters (at the level of the soft palate) of the pharyngeal airway.[106]

Because of the general anesthetic depression of CNS compensatory mechanisms for the maintenance of a patent pharyngeal airway, tracheal extubation should be undertaken when the young infant is awake and has adequate respirations. Thoracoabdominal asynchrony appearing immediately after extubation is indicative of upper airway obstruction and is not accompanied by traditional sounds of upper airway obstruction (i.e., snoring) as in the adult. Following extubation, the lateral decubitus position may be advantageous in that it has been shown to decrease the compressive effects of soft tissue that surround the pharynx in individuals with obstructive sleep apnea.[107]

Pharyngeal patency improves during the first year of life as the anatomic imbalance is lessened with continued growth of the maxilla and mandible, and CNS regulation matures. This is evidenced by the fact that there is generally less airway obstruction with inhalation induction in older infants and children. However, when airway obstruction develops during inhalation induction, the obstruction is generally easily managed with the previously cited airway opening maneuvers. "Deep" extubation can be safely accomplished in children with the prior insertion of an oral airway, and after extubation, continued maintenance of pharyngeal patency may be facilitated with the application of airway-opening maneuvers previously discussed.

Airway Complications

Two common airway complications with a pediatric patient are laryngospasm and bronchospasm. The larynx is the gatekeeper of the airway, protecting the lungs from the aspiration of foreign material. This function is most evident during swallowing, when the glottic closure reflex is initiated by stimulation of the superior laryngeal nerve facilitating sphincteric closure of the airway. Laryngospasm is a magnified glottic closure reflex in response to noxious stimuli of the superior laryngeal nerve and may persist despite the immediate removal of the stimuli. Laryngospasm precipitates a host of serious complications, including complete airway obstruction, gastric aspiration, postobstruction pulmonary edema, cardiac arrest, and death.[108]

The frequency of laryngospasm is greatest in patients with an upper respiratory infection (95.8/1000).[108] Children exposed to

BOX **48-5**

Risk Factors for Laryngospasm

Preoperative Factors

- Exposure to secondhand tobacco smoke
- Concurrent or recent upper respiratory tract infection
- Gastroesophageal reflux (GERD)
- Mechanical irritants (oropharyngeal secretions)

Intraoperative Factors

- Excitement phase of inhalation induction
- Tracheal intubation/extubation during "light" anesthesia
- Upper airway surgical procedures (e.g., tonsillectomy, adenoidectomy, nasal/sinus procedures, palatal procedures, laryngoscopy/bronchoscopy)

BOX **48-6**

Preventive Measures for Laryngospasm

- Avoid noxious airway/surgical stimulation during "light" anesthesia
- Assure sufficient anesthesia prior to airway instrumentation
- Topical application of lidocaine to suppress laryngeal sensory nerve activity
- Intravenous lidocaine prior to extubation
- Suction oral pharynx prior to extubation
- Tracheal extubation when fully awake
- Administer 100% oxygen for 3 to 5 minutes prior to extubation

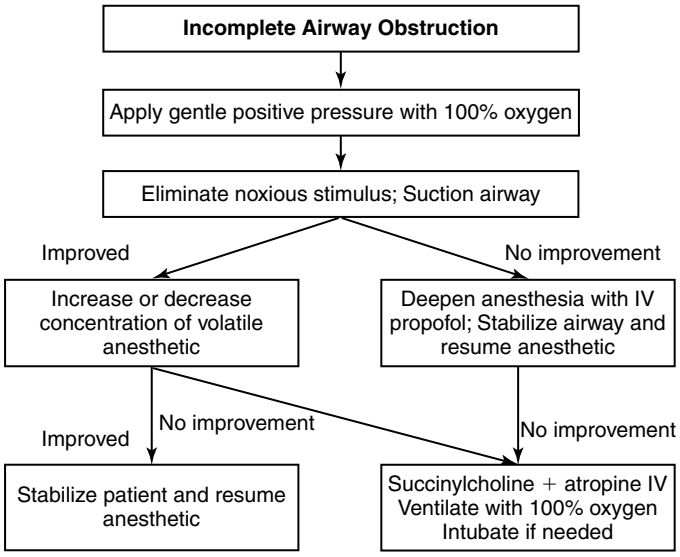

FIGURE **48-2** Incomplete airway obstruction algorithm. (From Wittkugel E. Pediatric laryngospasm. In: Atlee JL, ed. *Complications in Anesthesia*. 2nd ed. Philadelphia: Saunders; 2007:601.)

secondhand tobacco smoke have a 10-fold increase in the relative risk of laryngospasm (0.9% with no exposure, versus 9.4% with exposure).[109] Although laryngospasm may be self-limiting, the clinical importance of proper management is exemplified by the fact that five of every thousand children who experience laryngospasm have a subsequent cardiac arrest.[108]

The incidence of laryngospasm may be greater in the pediatric population because of specific practices in the anesthetic management of infants and children. Several factors are generally associated with the development of laryngospasm (Box 48-5). The risk of laryngospasm is increased when airway instrumentation is attempted before an adequate depth of anesthesia has been achieved, without the benefit of neuromuscular blocking drugs, and in infants and children with residual effects of previous upper respiratory tract infections.

The precise pathophysiologic mechanism responsible for laryngospasm remains elusive. To expand our understanding of laryngospasm and its clinical management, it is best to revisit the original description provided by Fink in 1951.[110] The basic execution of laryngeal closure follows superior laryngeal nerve stimulation. The mechanism resembles a shutter, where the laryngeal inlet is closed by the action of the supraglottic folds, the false vocal cords, and the true vocal cords. Fink has suggested that glottis closure is a dual mechanism. The first response is the closure of the vocal cords (a shutter effect) followed by a ball-valve effect with closure of the false cords and the subsequent rounding of the supraglottic tissue after the shortening of the thyrohyoid muscle. This produces an envelopment of the laryngeal inlet by the supraglottic tissue with continued inspiratory effort, producing complete airway obstruction.

The prevention of laryngospasm requires an understanding of the risk factors. Box 48-6 lists measures that may be undertaken for the prevention of laryngospasm. Prompt recognition and management is imperative to prevent hypoxemia and the subsequent development of bradycardia and cardiac arrest.

Incomplete airway obstruction (Figure 48-2) may be evident as "grunting" or audible inspiratory and expiratory sounds as heard through a precordial stethoscope, accompanied by tracheal tug and thoracoabdominal asynchrony. Management consists of three essential processes. First, the responsible noxious stimuli should be discontinued (e.g., surgical stimulation, attempted airway instrumentation during "light" anesthesia, removal of pharyngeal secretions with gentle suctioning). Next, anesthetic depth should be increased by the delivery of increased concentration of inhalation agent or intravenous administration of a small dose of propofol. Third, gentle positive-pressure ventilation using 100% oxygen should be attempted using a properly applied facemask with concurrent airway opening maneuvers (i.e., slight head extension, chin lift, and jaw thrust). On occasion, this may require two individuals, one to firmly apply the facemask and open the airway, and one individual to attempt positive-pressure ventilation.

The transition to complete airway obstruction (Figure 48-3) becomes evident with the absence of inspiratory and expiratory sounds, as well as the inability to deliver positive-pressure ventilation. The application of positive airway pressure for the treatment of complete airway obstruction may not be successful. Further deterioration of arterial oxygen saturation with accompanying bradycardia may occur despite the continued application of positive-pressure ventilation, and the envelopment of the laryngeal inlet supraglottic tissue may be worsened. The administration of succinylcholine will then be required to break the laryngospasm.

Bilateral firm and direct application of pressure toward the skull base produces an anterior displacement of the mandible. In addition to producing a jaw thrust, the intense stimulation with

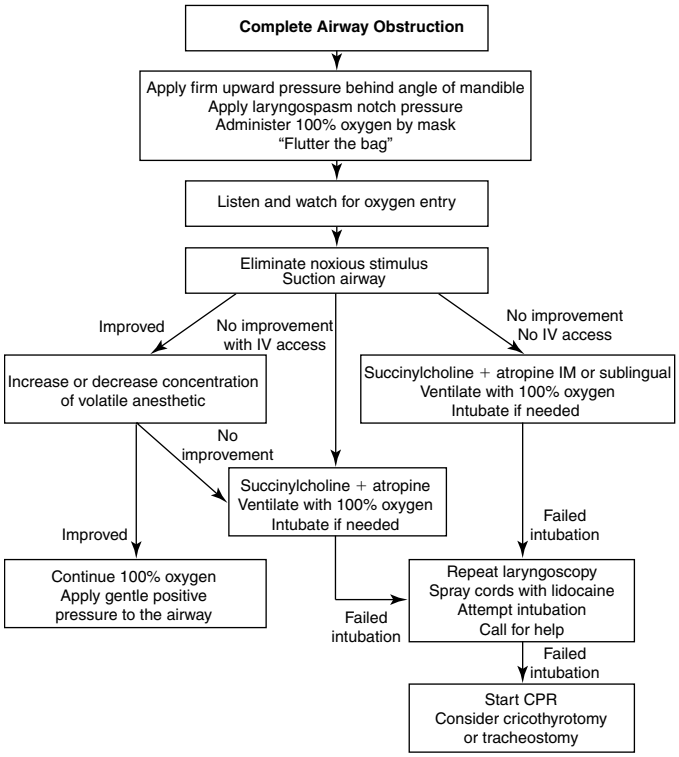

FIGURE **48-3** Complete airway obstruction algorithm. (From Wittkugel E. Pediatric laryngospasm. In: Atlee JL, ed. *Complications in Anesthesia*. 2nd ed. Philadelphia: Saunders; 2007:600.)

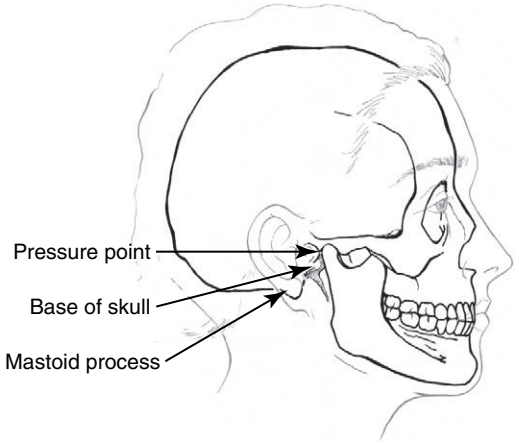

FIGURE **48-4** The laryngospasm notch.

postcondylar pressure in the lightly anesthetized patient often produces a ventilatory sigh.[111] This maneuver may be successful for the treatment of laryngospasm.[112] Figure 48-4 shows the laryngospasm notch.

If complete airway obstruction continues unabated, intravenous administration of atropine and succinylcholine should be administered without delay. In the absence of intravenous access, intramuscular succinylcholine (4 mg/kg) is administered in the deltoid muscle. Following intramuscular administration, the vocal cords will begin to relax within 60 seconds, permitting positive-pressure ventilation and relaxation to facilitate endotracheal intubation. With continued deterioration in arterial oxygen saturation, intubation may be required prior to the onset of skeletal muscle relaxation. In an extreme situation, the application of lidocaine to the vocal cords may produce sufficient relaxation, allowing endotracheal intubation. Severe hypoxia and hypercarbia are known to terminate laryngospasm.[114] Certainly these are not desired treatment options for laryngospasm.

Bronchospasm is increased airway resistance that eventually resolves spontaneously or with pharmacologic intervention. It is the disorder of smooth muscle. It is known that airway resistance increases after instrumentation of the airway. Rarely does this result in the complication of bronchospasm (0.4%); however, in children with known asthma or a current upper respiratory infection, the incidence is increased (4.1%) and can cause the anesthesia provider some concern.[115-117]

Bronchospasm may manifest as an audible wheeze. Under anesthesia, however, the provider may notice an upward slope of the end-tidal carbon dioxide monitoring with a rise in end-tidal carbon dioxide, prolonged expiration, decrease in oxygen saturation, increased peak inspiratory pressures, decrease in tidal volume, and difficulty ventilating. Before the diagnosis of bronchospasm is confirmed, the anesthesia provider must think of possible causes: anaphylaxis to drugs, IV fluids, latex; airway manipulation, irritation, secretions; esophageal intubation; pneumothorax; and inadequate anesthetic depth.[118]

The first intervention when an airway issue is suspected is placing the patient on 100% oxygen. Auscultation of the lungs may reveal wheezing. If the problem is severe, the surgeon should be informed to stop the surgery, and the anesthesia provider should have the operating room staff call for help. Anesthetic depth should be assessed and deepened and the patient should be ventilated by hand. A bronchodilator medication, such as albuterol, should be given via endotracheal tube.

After adequate time has passed, reassess the patient's lungs, oxygenation, color, placement of endotracheal tube, capnography, and overall status.[118] When treating a pediatric patient, their respiratory reserve is minimal. It may be necessary to intervene and treat the bronchospasm with epinephrine sooner than treating an adult for a similar diagnosis. Epinephrine 5 to 10 mcg/kg should be used as the initial subcutaneously injected bronchodilator in children.[119] In life-threatening emergencies, dilute a 1-mg vial of epinephrine in a 10-mL syringe, give 1 to 2 mL (100-200 mcg) IV push, in increments, for a maximum dose of 0.5 mg per dose of a 1:1000 solution and wait for the child's reaction.[120]

Another treatment for bronchospasm is corticosteroids. Intravenous steroids may help long-term treatment but do little in acute emergencies.

Difficult Airway. A difficult airway may be defined as difficulty in accomplishing mask ventilation and/or endotracheal intubation. The identification of the difficult pediatric airway begins with a thorough history followed by physical examination of the mouth, head, and neck. The physical examination should focus upon the assessment of facial skeletal features, specifically the size and shape of mandible and maxilla, size of the tongue in relation to the oral cavity, absence of dentition, presence of loose dentition, and the range of motion of the neck. Box 48-7 lists some features of pediatric airway physical examination. Box 48-8 lists pathologic conditions that impact pediatric airway management.

A history of snoring, difficulty breathing with feeding, current or recent upper respiratory tract infection, and past history of croup should be obtained. Previous anesthetic records are an invaluable resource in determining the history of difficult airway management. However, a prior uneventful anesthetic does not preclude

BOX 48-7

Physical Examination of the Pediatric Airway

- Note the size and shape of the head
- Facial features—size and shape of mandible and maxilla
- Oral examination—size of tongue, loose or missing dentition, prominence of upper incisors
- Range of motion of jaw and cervical spine

BOX 48-8

- Epiglottitis
- Peritonsillar abscess
- Retropharyngeal abscess

the possibility of difficulty of airway management with succeeding anesthetics.

If there is any indication from the history and physical of a potentially difficult airway, these guidelines should be followed:

1. Do not give neuromuscular blocking agents.
2. Prepare a variety of laryngoscope blades, endotracheal tubes, and oropharyngeal airways.
3. Plan for different induction options: awake fiberoptic; sedation, anesthetizing spray, and awake fiberoptic; inhalation induction.
4. After a deep plane of anesthesia is reached, use 100% oxygen.
5. Establish IV access (if not preoperatively), and consider atropine or glycopyrrolate to decrease oral secretions.
6. Always maintain spontaneous respirations.
7. Use external manipulation of the trachea when possible to make visualization of glottis easier.
8. Use and/or availability of adjunct airway equipment: GlideScope, fast-track LMA, blind nasal intubation, light wand, Eschmann stylet, cricothyrotomy.
9. Follow the standardized difficult airway algorithm (see Chapter 22).

Emergence and Extubation

Similar to adults, the end of surgery in the pediatric patient involves return of spontaneous breathing and weaning of anesthetic agents. It is important to have airway equipment readily available in case of the need to quickly reintubate. The child should show signs of alertness such as facial grimacing, spontaneous eye opening, and purposeful movement. It is best to extubate when the child is fully awake. Children are more prone to laryngospasm during extubation, especially when done during stage 2 of anesthesia. Judicious suctioning is also imperative to help prevent adverse airway events.

Deep extubation can be done after prudent suction of oropharynx and stomach in patients with a normal airway and an empty stomach. It should be carefully decided whether the patient is appropriate for a deep extubation. Also, the anesthesia provider must be aware of the level of care in the postoperative care unit where the patient will be recovering. Patients that were difficult to ventilate or intubate, those with a full stomach, and neonates and young infants should be fully awake prior to extubation.

All standard monitors should remain on the patient until extubation. When breathing remains satisfactory, transportation to the postanesthesia care unit (PACU) can ensue. Pediatric patients do well in the lateral position to keep them from obstructing their airway. Also, supplemental oxygen is recommended for all pediatric patients. The anesthesia provider can give a chin lift while feeling for exhalation with the hand and/or observing for condensation in the oxygen mask.

Fluid Management

The maintenance of fluid homeostasis is essential in the comprehensive intraoperative care of the pediatric patient. The restoration and maintenance of pediatric intravascular volume is crucial if cardiac output is to be optimized and tissue oxygen delivery ensured.

Intravascular fluid balance is influenced by a number of preoperative and perioperative circumstances. Preoperative intravenous fluid administration minimizes the degree of dehydration that accompanies the NPO period. Unless there exists a compelling reason to place an intravenous catheter preoperatively, intravenous therapy is generally avoided in the pediatric patient until general anesthesia has been induced via inhalation.

Perioperative fluid homeostasis is altered by a number of factors, including inhalation agent administration, the operating room environmental temperature, iatrogenic hyperventilation, and surgical stress. Potent inhalation agents produce peripheral vasodilation and varying degrees of myocardial depression, decreasing systemic blood pressure and end-organ perfusion. Dehydration after prolonged preoperative oral fluid abstinence aggravates these decreases in systemic blood pressure. The delivery of cold, dry anesthetic gases via an ETT bypasses normal anatomic humidification, increasing the loss of fluid from the respiratory tract. These insensible respiratory fluid losses can be minimized with the use of active or passive humidification systems during the intraoperative period. The operating room temperature also influences fluid balance. Basal caloric and water requirements are increased in a cold environment. Increases in core body temperature of 1° C may increase caloric expenditure by 12% to 14%.

General anesthesia modifies the neuroendocrine control of fluid balance. Surgical stress increases plasma glucose levels. Hyperglycemia results in an osmotic-induced renal loss of free water. Anesthetic agents modify neuroendocrine regulation of fluids and electrolytes. Opioids increase the release of antidiuretic hormone (ADH) from the posterior pituitary.[121] Antidiuretic hormone stimulates the release of aldosterone to conserve water through the renal reabsorption of sodium and water and the excretion of potassium. Decreased glomerular filtration, which parallels the decrease in renal perfusion, alters the kidneys'

TABLE 48-6 Hourly Fluid Requirements: The "4-2-1" Formula

Weight (kg)	Fluid
0-10	4 mL/kg/hr for each kg of body weight
10-20	40 mL + 2 mL/kg/hr for each kg greater than 10 kg
>20	60 mL + 1 mL/kg/hr for each kg greater than 20 kg

Sample Calculated Fluid Requirements	Maintenance Fluid per Hour
4 kg	16 mL
9 kg	36 mL
15 kg	50 mL
30 kg	70 mL

TABLE 48-7 Fluid Replacement for Third-Space Fluid Losses

Expected Surgical Trauma	Administration Rate (mL/kg/hr)	Recommended Intravenous Fluid
Minimal	3-4	Lactated Ringer's
	0.9% NS, Plasma-Lyte	
Moderate	5-6	Lactated Ringer's
	0.9% NS, Plasma-Lyte	
Severe	7-10	Lactated Ringer's
	0.9% NS, Plasma-Lyte	

NS, Normal saline.

ability to handle administered fluid loads. Decreased renal perfusion stimulates the release of renin, which cleaves angiotensin I to form angiotensin II, a powerful vasoconstrictor that acts to increase systemic blood pressure. Renin stimulates the release of aldosterone.

Surgical trauma modifies fluid balance, the degree of which is dependent on the invasiveness of the surgical procedure. Intravenous fluids are used to replace intraoperative blood loss and fluid loss resulting from fluid shifts that develop from evaporative and third-space fluid losses. Physiologic parameters, such as temperature, heart rate, blood pressure, capillary refill time, urine output, and ongoing blood loss, are continually assessed. The rate of intraoperative fluid administration is continuously modified to maintain circulatory homeostasis. Peripheral surgical procedures (extremity procedures) have minimal evaporative or third-space fluid losses. However, intracavitary procedures (intraabdominal or intrathoracic procedures) are associated with greater blood loss, third-space fluid loss, and substantial evaporative fluid losses that approach 10 mL/kg of body weight per hour.

Pediatric Fluid Compartments

The growth of the newborn is accompanied by a decrease in the relative fluid compartment volumes of TBW and ECF volumes during the first year of life, followed by additional decreases in ECF later in childhood. The TBW of the premature infant is as high as 80% of total body weight, whereas the TBW of the term infant is approximately 70% to 75% of total body weight. The adult value of TBW (55% to 60%) is reached between 6 months and 1 year of age. Knowledge of body fluid distribution is important when one is selecting specific fluids and volumes for administration. The differences in TBW, as well as in the ICF and ECF compartments in the premature infant, term infant, child, and adult, can be found in Table 47-8.[122]

Maintenance-Fluid Calculation

The most direct and widely accepted method for determining intravenous fluid requirements is based on body weight. Holliday and Segar proposed a formula for the calculation of hourly maintenance fluids based on caloric expenditure studies in children. The hourly maintenance fluid level is determined by the "4-2-1" formula and is calculated as follows (Table 48-6).[123] For the first 10 kg of body weight, 4 mL of crystalloid intravenous fluid (e.g., lactated Ringer's) is administered for each kilogram of body weight per hour. The hourly maintenance fluid requirement of a child who weighs 10 kg would be calculated as 10 kg × 4 mL/kg/hr = 40 mL/hr. Children weighing in excess of 10 kg but less than 20 kg would receive an additional 2 mL/kg/hr for body weight in excess of 10 kg. The child weighing 14 kg would receive 4 mL/kg/hr for the first 10 kg (40 mL) plus an additional 2 mL/kg/hr, for a total of 48 mL/hr. Children weighing in excess of 20 kg would receive an additional 1 mL/kg/hr in hourly fluid. This hourly maintenance fluid calculation serves as a basic guideline and does not take into account fluid deficits that develop during the NPO period and additional fluid losses (such as blood and third-space losses) that occur during the perioperative period.

Preoperative fluid deficits develop during the period of time in which the child has not received oral or intravenous maintenance fluids. The preoperative fluid deficit is calculated by determining the hourly maintenance fluid rate and multiplying this rate by the number of hours the child has been without intravenous or oral intake. The following calculations are used to determine the preoperative fluid deficit of an 8-kg child who has been NPO for 6 hours:

$$\text{Maintenance fluid} = 8\ \text{kg} \times 4\ \text{mL/kg/hr} = 32\ \text{mL/hr}$$

$$\text{Deficit} = \text{NPO hours} \times \text{maintenance fluid rate}$$
$$= 6\ \text{hr} \times 32\ \text{mL/hr} = 192\ \text{mL}$$

The calculated fluid deficit is replaced following the guidelines of Furman et al.[124]: half of the fluid deficit is replaced during the first hour, with the remainder divided in half and replaced in the subsequent 2 hours. Using the calculations just presented, the following plan for intravenous fluids is developed.

Weight = 8 kg	Hour 1	Hour 2	Hour 3
Maintenance fluid (mL/hr)	32	32	32
Deficit (mL/hr)	96	48	48
Hourly total (mL/hr)	128	80	80

In addition to the calculated maintenance and deficit fluids necessary to replace insensible fluid losses, additional intravenous fluid is required to replace third-space fluid losses that occur with surgical trauma. Lactated Ringer's solution, 0.9% normal saline, and Plasma-Lyte are acceptable for the replacement of insensible and third-space fluid losses at the rate of 1 to 2 mL/kg/hr. Expected third-space fluid losses can be categorized as minimal surgical trauma (an additional 3 to 4 mL/kg/hr), moderate surgical trauma (5 to 6 mL/kg/hr), and major surgical trauma (7 to 10 mL/kg/hr). Table 48-7 lists fluid replacement for third-space losses.

Glucose-Containing Solutions

Historically, glucose was administered during the perioperative period to prevent hypoglycemia, provide free water to replace the

insensible water lost during the NPO period, conserve protein, and avert ketosis by preventing gluconeogenesis.[125] Surgical stress (e.g., surgical incision) elicits a neuroendocrine response, increasing plasma glucose levels. Despite extended periods of fasting, studies have noted that healthy pediatric patients infrequently become hypoglycemic.[126,127] However, very critically ill infants and those weighing less than 10 kg may develop hypoglycemia with prolonged periods of fasting. Routine dextrose administration is no longer advised for otherwise healthy children receiving anesthesia.[128] Most clinicians administer a glucose-free intravenous solution (e.g., lactated Ringer's) for maintenance and replacement of third-space and intraoperative blood loss. If the child has had an extended NPO period, a glucose level may be determined intraoperatively and appropriate adjustments in therapy can be made. Although the CNS is totally dependent on a continuous supply of exogenous glucose for the maintenance of cellular energy requirements, the continuous administration of glucose or elevated plasma glucose levels may worsen neurologic outcome in the event of an ischemic or hypoxic event. This association between hyperglycemia and worsened neurologic outcome has been well established.[129,130]

Hypoglycemia is likely to develop in a variety of clinical circumstances. Examples include infants who are premature, infants of diabetic mothers, children with diabetes who have received a portion of daily insulin preoperatively, and children who receive glucose-based parenteral nutrition. A glucose-containing intravenous solution is administered to these patients as a controlled piggyback infusion, with frequent plasma glucose determinations performed to avoid hyperglycemia. Infants born of mothers with diabetes and infants of mothers who receive glucose-containing solutions during labor may require a continuation of these solutions for the prevention of rebound hypoglycemia. Premature infants who have had less time to store glycogen in the liver than term infants are more susceptible to hypoglycemia. For this reason, premature infants may receive an infusion of 10% dextrose in 0.2% normal saline.

Crystalloid Intravenous Fluids

Crystalloid intravenous fluids contain water, various concentrations of electrolytes, and varying amounts of glucose. These solutions move freely between the intravascular and interstitial fluid compartments. Crystalloid intravenous solutions are advantageous for perioperative administration, because they are the least expensive of the available intravenous solutions and are acceptable for the replacement of preoperative, intraoperative, and postoperative isotonic fluid deficits. Unlike colloid solutions, crystalloid solutions do not produce allergic reactions. Crystalloid intravenous solutions can be further subdivided by their tonicity in relation to plasma (i.e., hypotonic, isotonic, or hypertonic). Tonicity is a measurement of the comparative osmolarity of solutions, which is determined by the sodium chloride content. For example, a hypotonic solution (e.g., 0.45% normal saline) has a lower sodium concentration (less than 130 mEq/L) and an osmolarity less than 280 mOsm/L; an isotonic solution (e.g., lactated Ringer's) has a sodium concentration between 130 and 155 mEq/L and an osmolarity between 280 and 310 mOsm/L; a hypertonic solution (e.g., 3% normal saline) has a sodium concentration greater than 155 mEq/L and an osmolarity in excess of 310 mOsm/L. These sodium-containing solutions move freely about the extracellular space, whereas the sodium-free intravenous solutions such as 5% dextrose in water (D_5W) will be distributed throughout all fluid compartments. Table 48-8 lists the physical constituents and the osmolarities of popular crystalloid solutions. An isotonic solution does not need to be equivalent to plasma in exact physical constituents (e.g., sodium, chloride, potassium) to be considered an isotonic solution, because it is the number of particles dissolved in solution (principally sodium) that determines the osmolarity.

Estimation of Blood Volume

The goal of perioperative blood administration is the maintenance of acceptable oxygen-carrying capacity. Because pediatric patients have a relatively low intravascular volume compared with adults, vigilance and an accurate determination of intraoperative blood loss is fundamental to quality patient care. The intravascular volume may be estimated by multiplying the child's weight by the estimated blood volume. The estimated blood volumes are as follows: premature infant, 90 to 100 mL/kg; full-term newborn, 80 to 90 mL/kg; infants 3 months to 3 years, 75 to 80 mL/kg; and child older than 6 years, 65 to 70 mL/kg (see Table 48-2). For example, the estimated blood volume of a 6-month-old infant who weighs 7 kg is 525 mL (7 kg × 75 mL/kg = 525 mL).

The determination of intraoperative blood loss can be difficult. Subjective estimates of blood loss are grossly inaccurate. Blood

TABLE 48-8 Physical Characteristics of Popular Intravenous Crystalloid Solutions

	Sodium (Na) (mEq/L)	Chloride (Cl) (mEq/L)	Potassium (K) (mEq/L)	Calcium (Ca) (mg/mL)	Lactate (mg/mL)	Glucose (mg/dL)	mOsm/L

collected from the surgical field in suction canisters can be easily measured, but up to one half of blood lost during surgery can be contained in items such as surgical drapes, sponges, and towels and is difficult to measure. Accurate accounting of surgical blood loss related to these items requires weighing them. Every 1 g of weight is equal to 1 mL of blood loss. Ongoing surgical blood loss requires frequent reassessment of the child's blood pressure, heart rate, and urine output. It is best to chart a running total and obtain hemoglobin and hematocrit levels as needed.

Mild dehydration is associated with a less than 5% decrease in body weight. Signs and symptoms are blood pressure, heart rate, and capillary refill within normal limits. Dry mouth and malaise can possibly be seen preoperatively; however, they are not evident if the patient is under general anesthesia. Urinary output of less than 1 mL/kg/hr should be maintained. Moderate dehydration is associated with a 5% to 10% decrease in the patient's body weight. Signs and symptoms include normotension and possible tachycardia with prolonged capillary refill. Patient may exhibit lethargy, thick and/or dry mucous membranes, decreased urine output, and depression of anterior fontanelle. Severe decreases in intravascular volume are associated with a greater than 10% decrease in body weight. Signs and symptoms are tachycardia, hypotension, narrowed pulse pressure, low urine output, decreased central venous pressure, pallor, and slow capillary refill. The patient will have a decreased level of consciousness, mottled and cool skin, and be anuric. A sudden decrease in blood pressure in neonates and infants with rate-dependent cardiac output is indicative of significant intravascular volume depletion.

Fluid management for dehydrated patients includes a 10 to 20 mL/kg fluid bolus over 10 to 30 minutes. After evaluation of fluid bolus, subsequent boluses also may be given. The goal is euvolemia for all surgical procedures.

Permissible Blood Loss

What amount of blood loss may be permitted, while the patient still maintains adequate tissue oxygenation? No published studies are available to guide the anesthetist in determining the optimal and safe lower limits for hemoglobin concentration. Historically a hemoglobin of 10 g/L or a hematocrit of 30% triggered blood transfusion. This "transfusion trigger" has been redefined in light of the risks of blood-borne pathogen transmission. Permissible blood loss must be defined individually for each patient based on current medical condition, surgical procedure, and cardiovascular and respiratory function. Children with normal cardiovascular function may tolerate a lower hematocrit and may compensate with an increased cardiac output if a higher inspired oxygen concentration is provided to improve oxygen delivery. An exception is the premature infant. The incidence of apnea is higher in neonates and the premature infant with hematocrit levels below 30%. The anesthetist, surgeon, and neonatologist should agree upon a target hematocrit level, and this discussion should be documented in the medical record.

Allowable blood loss may be calculated with the following formula:

$$ABL = EBV \times (H_O - H_L) / (H_A)$$

Where ABL is allowable blood loss, EBV is estimated blood volume, H_O is original hematocrit, H_L is the lowest acceptable hematocrit, and H_A is the average hematocrit. In place of H_A, (H_O + H_L) ÷ 2 can be used. For a 6-month-old infant who weighs 7 kg, with a starting hematocrit of 35% and the selection of the lowest acceptable hematocrit of 25%, we calculate the following:

$$ABL = 525 \times (35 - 25) / (25 + 35) / 2 = 174 \text{ mL}$$

Blood loss may be replaced with suitable crystalloid solutions (e.g., 0.9% normal saline, lactated Ringer's) by administering 3 mL for each mL of blood loss. Recall that the intravascular volume is one third of the ECF volume. Accordingly, one must administer 3 mL of an intravenous crystalloid solution to replace each mL of blood loss. A blood loss of 100 mL therefore requires replacement with 300 mL of crystalloid solution. Blood loss that is less than the calculated permissible blood loss may be replaced with colloid (1 mL for every 1 mL of blood loss).

When the blood loss equals or exceeds the calculated allowable loss, transfusion should be considered. Before transfusion is performed, a current hemoglobin and hematocrit should be obtained. The surgeon should be included in the decision process. These discussions and the resultant hemoglobin and hematocrit are recorded in the anesthetic record. The volume of packed RBCs (PRBCs) to be infused may be determined by the following formula:

$$\text{Packed RBCs (mL)} = \frac{(\text{Blood loss} - \text{ABL}) \times \text{desired hematocrit (30\%)}}{\text{Hematocrit of PRBCs (75\%)}}$$

Using the previous example of a 7-kg infant, with a total blood loss of 300 mL, the volume of PRBCs would be 300 − 174 × 30/75 = 50 mL.

Once the blood loss exceeds one blood volume, a coagulopathy can ensue. This occurs because of dilution of platelets and a reduction in circulating clotting factors. Platelets, fresh frozen plasma, and cryoprecipitate transfusions become necessary.

Blood Transfusion

Before blood component therapy is initiated, the proper equipment (e.g., filters, infusion devices, blood warming devices) should be obtained and tested. Blood is usually warmed before infusion. The American Association of Blood Banks has published standards for the use of blood-warming devices. Blood warmers must have a visible thermometer and an audible warning indicating excessive heating (greater than 42° C). Warming devices for adult transfusions (e.g., in-line water baths, countercurrent heating with water through large-bore tubing) are cumbersome to use for the small volumes to be transfused in the pediatric patient. The selected blood component containers may be placed under the forced-air warming blanket, or the measured aliquot of blood drawn into a syringe may be warmed with the hand. Syringes should not be placed into water baths, because bacterial contamination may occur.

Blood administration need not be complicated. It is difficult to accurately determine the amount of blood administered when it is infused via adult-intended warming devices. Accurate accounting of transfused blood products is facilitated by drawing the measured quantity by syringe with subsequent delivery of the measured quantity. A suitable device is an infusion set with an 80-mm blood component filter. This three-way infusion set is spiked into the blood component container, and the second limb of the set is placed into a stopcock, preferably located at the intravenous site. A syringe is attached to the remaining limb of the infusion set, allowing measured aliquots of blood to be drawn from the blood component container and then injected into the intravenous site.

The use of adult blood units is wasteful when the small infant requires transfusion. The blood bank can dispense small aliquots of blood into a calibrated syringe or provide 50- to 100-mL bags of the selected blood product transferred from an assigned donor unit. Blood used for neonatal transfusion is preferably less than 1 week old, to preserve 2,3 diphosphoglycerate levels, and

irradiated to prevent graft-versus-host disease. When packed RBCs are transfused, the blood should not be diluted prior to transfusion; this may contribute to hypervolemia. One rule of thumb states that in the absence of ongoing blood loss, 4 mL/kg of packed red cells will be required to raise the hemoglobin level by 1 g/dL.[131]

POSTOPERATIVE CARE

Similar to an adult patient, standard monitoring is continued when the pediatric patient arrives in the PACU. Although all the parameters are important, special attention to oxygenation is crucial. Postoperative hypoxia may be the result of several factors, but postextubation croup and laryngospasm are more likely in children than adults.[132]

After the "hand off" to the PACU nurse, the awakening patient begins the final phase of the perioperative process. All children wake up differently from anesthesia, it is not easy to predict. Some children awaken with emergence delirium (see previous discussion). This dissociative state of consciousness may leave the child restless and inconsolable. In most young children, it is important to let the parents help attend to the child's cries. Having a family member try to calm the patient may help the situation.

As mentioned earlier, oxygenation is an important area of concern in the PACU. Airway obstruction, obstructive sleep apnea, postextubation croup, and apnea of prematurity can all occur and need to be recognized with prompt intervention. Airway obstruction can be due to the positioning of the patient's head or oropharyngeal structures. Simply repositioning the head can sometimes relieve this problem. It would seem removal of the hypertrophic tonsil and adenoids would alleviate obstructive sleep apnea immediately postoperatively; however, surgical edema may cause these patients to continue to obstruct in the immediate postoperative period. Positioning and adequate oral suctioning can help prevent obstruction and possible laryngospasm.

The incidence of postextubation croup has been reported to be 1.6% to 6%. Prevention of tracheal irritation is the best way to prevent this problem. Using the right ETT size with pressures near 20 cm H_2O, prevention of friction of the tube in the trachea by securing properly, and prevention of unplanned extubation are ways to help decrease the risk of developing postextubation croup.[133]

Patients who were born before 36 weeks' gestation and whose postconceptual age is less than 60 weeks have a greater risk of central apnea. For this reason, these patients should be kept overnight for observation after any surgical procedures. The risk of apnea if the patient has received regional anesthesia versus receiving general anesthesia is less; however, these patients should be admitted and monitored postoperatively as well.[134]

Discharge from the PACU is typically done by a scoring system that includes blood pressure, heart rate, respirations, temperature, pain, nausea/vomiting, physical activity, and level of consciousness. The goal is for the patient to return to preprocedure parameters before discharge. One common method that is used is the modified-Aldrete scoring (see Chapter 51). When evaluating a patient in the ambulatory surgery center to be "fast tracked" a score of 12 or higher is needed.[135] When fast tracking is anticipated, the anesthetic can be planned to allow for short PACU times and quick discharge to home.

REGIONAL ANESTHESIA

During the past 10 years, the use of pediatric regional anesthesia has become established. Regional anesthesia provides perioperative analgesia minimizing the risk of respiratory depression, modifies the metabolic responses to anesthesia and surgery, and may improve patient outcomes.[136-138] Although the popularity of combined regional anesthetic techniques for adults has increased, the use of pediatric regional anesthesia has been more limited. Regional anesthesia is generally performed during general anesthesia, and the detection of intravascular injection and the signs of local anesthetic toxicity are masked during general anesthesia. Also, there is a limited ability to properly assess the sensory level of block in the sedated preverbal child and the consequences of accidental dural puncture are more difficult to assess and treat.

Unlike the adult patient, the pediatric patient will generally receive a peripheral or centrally administered regional anesthetic after the induction of general anesthesia. The inherent fear of needles and pain, the fear of neurologic injury in a combative child, and the difficulty in providing adequate sedation to ensure patient mobility during the introduction of the block often necessitates the safe execution of the regional anesthetic during general anesthesia. Perhaps the risk of neurologic injury is lower in the anesthetized child who is not resistant and combative during attempted epidural or caudal anesthesia now that the use of ultrasound-guided blocks are routine.[139] See Chapter 47 for a complete description of caudal anesthesia in children.

OUTPATIENT ANESTHESIA

Outpatient surgery is now the mainstay of modern surgical and anesthesia practice.[140] Many specialties are performing procedures in the ambulatory surgery center including otolaryngology, ophthalmology, general surgery, urology, plastic surgery, orthopedics, radiology, dentistry, and others. The postoperative goals are the same for all surgeries: normal vital signs, minimal pain and nausea, and return of preoperative level of consciousness. However, with ambulatory surgery, the discharge criteria are more rigid due to the fast-paced nature of the perioperative process. It is of the utmost importance that the patient be able to take oral medications without nausea when he or she leaves the surgery center. The typical surgery does not have a large amount of planned blood loss or large fluid shifts.

There are few absolute contraindications to ambulatory surgery for the pediatric patient. Children who were previously premature, either less than 35 weeks' gestation, or those less than 60 weeks' postconceptual age, are at risk for postoperative apnea.[141,142] These children require an overnight stay in the hospital for observation. Those children with obstructive sleep apnea (OSA) are also not candidates for a surgery center. However, this topic is controversial. Tonsils and adenoids are frequently removed for obstructive sleep apnea in the pediatric patient. After removal, the anatomy returns to its normal state after a couple of weeks; therefore, obstruction is a risk in the immediate postoperative period. Patients need to be carefully screened in the preoperative period by the surgeon and anesthesia provider to determine whether they are at high risk for hypoxia and hypercarbia postoperatively. Careful questioning of the patient and parents can help determine whether the patient is suitable for same-day surgery.

Patients that are not candidates for an outpatient surgery are those with a personal or familial history of malignant hyperthermia (MH). These patients need careful attention to avoid the triggers of MH. Although administering anesthesia can be routine, these patients need to be observed closely for increases in temperature postoperatively. If the patient develops MH in the surgery center, transfer to a higher level of care becomes an urgent issue.

Induction, airway management, and maintenance of anesthesia are similar when giving anesthesia in the hospital and surgery

center. Laryngeal mask airways may be used more often in surgery centers due to the generally short, simple procedures and healthier patients. When the patient is spontaneously breathing, the anesthesia provider can decide to extubate the patient deep or awake. Other factors that influence procedures and patient selection for a surgery center are the need for postoperative analgesia and minimizing postoperative nausea and vomiting (PONV). Local anesthesia injection by the surgeon or regional anesthesia is imperative, if applicable, for multimodal pain management. Patients also may be given acetaminophen before or during surgery. Nausea can be managed by using multimodal techniques and indentifying high-risk patients.[143,144]

PEDIATRIC ANESTHETIC MORBIDITY AND MORTALITY

Anesthetic morbidity and mortality differ between the pediatric patient and the adult patient. Accordingly, children require individualized and specialized anesthetic care. When compared with adults, children often present for surgery with unique symptoms. Their lack of ability to communicate effectively further complicates proper diagnosis and interventions. Fortunately, with a well-conducted history and physical and effective caregiver communication, a safe anesthetic may be planned and executed.

The Pediatric Perioperative Cardiac Arrest Registry (POCA), an ongoing database of pediatric cardiac arrest established in 1994, is a self-reporting, voluntary registry recording institutional cardiac arrests in children up to 18 years of age from as many as 80 participating institutions in Canada and the United States. The POCA data provides a retrospective assessment of contributing factors rather than determining causation of cardiac arrest. The initial registry results for the years 1994 to 2005 found 373 cardiac arrests in more than 1 million pediatric anesthetic experiences. One hundred and ninety three arrests (49%) were judged to be anesthesia related.[145] When cardiac arrest occurred, children with congenital or acquired heart disease (HD) were more likely to progress to cardiac arrest as compared with those without HD (50% vs 38%).[146] The patients with HD had higher ASA classifications (ASA III or above) and were more difficult to successfully resuscitate. Hyperkalemia from blood transfusions and hypovolemia were additional cardiovascular-related causes for cardiac arrest. Other reasons for cardiac arrest included respiratory-related causes (most often laryngospasm) and vascular injuries from central line placement. Medication-induced cardiac arrest has decreased since sevoflurane has replaced halothane as the inhalation agent of choice during perioperative management. Figure 48-5 shows the causes of anesthesia-related cardiac arrest associated with heart disease versus non–heart disease.

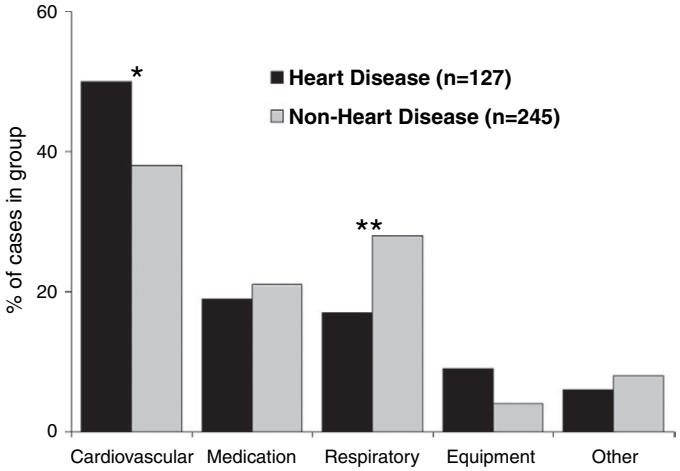

FIGURE **48-5** Causes of anesthesia-related cardiac arrest associated with heart disease (n = 127) versus non–heart disease (n=245). *P=0.03, **P=0.01. (From Ramamoorthy C, et al. Anesthesia-related cardiac arrest in children with heart disease: data from the Pediatric Perioperative Cardiac Arrest (POCA) registry. *Anesth Analg*. 2010;110[5]:1376-1382.)

SUMMARY

Anesthetic morbidity and mortality is greater in the pediatric patient and is multifactorial in origin. Pediatric subspecialty practice requires the anesthetist to master the foundations of pediatric growth and development, the anatomic and physiologic changes with maturation, and the influence of anesthetic agents upon immature organ systems. Anesthetic management of the pediatric patient requires integration of this specialized knowledge, refinement of the acquired technical skills of adult anesthetic management, and the ability to apply this knowledge when caring for pediatric patients. This chapter has reviewed pediatric pharmacology, airway management, and fluid and blood product management for the pediatric patient.

49 CHAPTER Geriatrics and Anesthesia Practice

◆ *Henry C. Talley and Costellia H. Talley*

As a result of health care improvements and progress in overall living conditions, the number of people in the world that are 65 years and older has increased by 300% over the last 50 years. During the next decade, it is estimated that there will be a 39% increase in persons 65 years and older, bringing the number of potential patients within this age group to 55 million. For the first time in history, by the year 2050, the number of individuals 60 years of age and older will exceed the number of younger adults. In the United States (U.S.), it is projected that between 2004 and 2050 the number of older adults 65 years of age or older that are minorities will double. During this time, the population of older adults will become more racially and ethnically diverse with the number of African Americans over the age 65 years doubling, while the number of Asian American and Hispanic American will triple. Furthermore, the composition and characteristics of this population will change. The aging baby boomers (the generation born between 1946 and 1964) will have an influence on the healthcare system, because this generation will have higher levels of education, be more financially stable, be less functionally impaired, more likely to live alone, and will take more time to research anesthesia practices; therefore, anesthesia providers must continue to stay abreast of changing demographics to meet the needs of this population. This demographic shift will have significant implications for anesthesia practitioners and how they approach the surgical and anesthetic management of the geriatric patient. The purpose of this chapter is to provide a resource that reviews normal physiologic changes of the older adult and the perioperative considerations related to managing the older adult.

Definitions of aging are often subjective and place an arbitrary marker on chronologic age; however, this section will operationally define "older adults" as persons 65 years or older. Although aging is not routinely associated with surgical risk, the challenges related to anatomic and physiologic changes that occur with aging impact every aspect of the perioperative course. First, whether or not an anesthesia practitioner is willing to accept an older person as a candidate for anesthesia is one of the most important decisions providers must make. Beginning with the preoperative evaluation of the older patient, providers must understand the heterogeneity of this group, the increased variability of anesthetic response, and the diverse conditions that often occur during the aging process.[1-3] However, the risk of adverse events (i.e., cognitive and functional disorders and cardiac complications) must remain key issues in the decision to proceed.

Perioperative response is difficult to foresee because of progressive decline in baseline physiologic functions, changes in American Society of Anesthesiologists (ASA) physical status classification, and age-related comorbid conditions; all of which also can impact the chance for perioperative complications. Fortunately, most anesthetics can be managed without difficulty given that the provider delivers high-quality care with constant vigilance. Perioperative complications in the older adult are directly related to negative outcomes, including morbidity and mortality in the postoperative period. Cardiac, pulmonary, and neurologic complications are the most commonly occurring postoperative complications in the elderly. Likewise, methods for studying outcome in this diverse population depend, in large part, on what is known about the underlying cause of the presenting problem. Although it is not the intent of this chapter to dictate how the practitioner should practice, every effort has been made to provide a targeted review of the changes that occur with aging and show how these changes might offer the practitioner additional evidence to be considered in their current practice, thus providing a foundation for modifying the current options to improve perioperative outcomes if required.

THE PREANESTHETIC EVALUATION

One of the basic elements of the care of surgical patients requiring anesthesia is the preanesthetic evaluation. Preanesthetic evaluation is thoroughly discussed in Chapter 19; however, the preoperative evaluation of the older adult warrants some special considerations. The preoperative evaluation in the older adult helps reduce the cost of the perioperative course and increases the quality and care in this group. The time spent conducting the preoperative evaluation is usually the anesthesia practitioner's first introduction to the patient.

Although aging is not synonymous with increased surgical risk, progressive decline of baseline functions, age-related comorbid disease, and ASA physical status classification place older adults at greater risk for perioperative complications and death. A speedy recovery, avoidance of functional decline, and maintenance of independence postoperatively are the most important goals in the perioperative care of older adults. The greatest challenge when providing care for older high-risk surgical patients is preventing, detecting, and managing complications. Managing older high-risk patients requires vigilance and rapid and appropriate response to potential problems. Therefore, the significance of a thorough preanesthetic evaluation takes into account the body system changes; likewise, it cannot be overemphasized that pharmacokinetic and pharmacodynamic alterations that accompany aging should be taken into consideration to optimize outcomes.

Three primary factors are associated with perioperative risks in older adults: (1) reduced reserve capacity and functional decline; (2) comorbidities (atypical disease presentations); and (3) untoward reactions to medications, anesthesia, and surgery (outcomes that are difficult to predict).[4,5] These risks are most often associated with age-related physiologic changes. The process of aging is responsible for both the normally accepted chronologic alterations of life and the associated increases in the chance of disease and death.

AGE-RELATED PHYSIOLOGIC CHANGES IN THE OLDER ADULT

Aging is a time-related occurrence during the life cycle of an organism and can be defined as a time-dependent biologic continuum that begins with birth and persists with gradual impairments of organ subsystems, ultimately causing any organism to become more susceptible to illness and death. By the age of 30 years, most age-related physiologic functions in humans have peaked and gradually decline thereafter. Aging is not synonymous with poor physiologic function. Because chronologic age (age in years since birth), which is often used in clinical practice, and biologic age (functional status) differ, chronologic age alone is no longer a reliable indicator of morbidity or of mortality. The degree of functional status that remains with increasing age varies. For example, a 75-year-old patient who bicycles 3 miles every day, has no evidence of coexisting diseases, and lives a healthy lifestyle is considered "physiologically young." Whereas a 75-year-old patient who is sedentary, has a history of hypertension and diabetes mellitus, and is a chronic smoker may be deemed as "physiologically old." In addition, changes in organ function manifest as decreased margins of reserve. Aging patients may be able to maintain homeostasis but become increasingly less able to tolerate changes, or restore homeostasis, when exposed to surgical stress, trauma, or diseases.

In the adult surgical population, it is generally accepted that the older patient has the highest risk of postoperative adverse outcomes. Postoperative adverse outcomes are primarily cardiovascular, neurologic, and pulmonary in origin.[4,6,7] However, 21% of noncardiac surgical patients, age 70 years and older, will have one or more adverse postoperative events;[4,8] of those older patients who experience postoperative adverse outcomes, there is a twofold risk of death within 3 months when compared with older patients who do not have adverse outcomes.[8,9] Likewise, postoperative adverse outcomes dramatically increase in-hospital stay and healthcare costs.

Body Composition and Thermoregulation

Age-related changes to the body composition and its ability to thermoregulate are characterized by loss of lean body mass, increased total body fat, decreased metabolic rate, decreased total body water, and a reduction in blood volume of 20% to 30%.[10] Numerous factors may contribute to the decrease in lean body mass and increased total body fat in the older person. Aging is associated with decreases in all the senses; thus, it is speculated that the decrease in smell and taste may cause foods to be less appetizing. Practitioners must be vigilant because disease and aging cause decreased lean body mass that may mimic or be confused with malnutrition. Even so, malnutrition should not be discounted in the aging patient because it may contribute to decreased albumin levels that can affect protein binding of medications. For the older adult surgical patient, decreases in caloric intake combined with illness depletes body caloric reserves necessary to withstand the stress of anesthesia and surgery. Regrettably, no clearly beneficial preoperative medication has been identified that stimulates the appetite in older adults. As a result of decrease in total body water, older adults are more vulnerable to hypotension and have difficulty compensating for positional changes.

Thermoregulation in the elderly patient is impaired. In the older adult, there is a decrease in the function of the hypothalamus. Hypothermia is more pronounced and lasts longer because of a lower basal metabolic rate, a high ratio of surface to body area mass, and less effective peripheral vasoconstriction in response to cold. It is particularly detrimental in the elderly patient because it also slows anesthetic elimination, prolongs recovery from anesthesia, impairs coagulation, and increases the chance that the patient will shiver.[11] Shivering increases oxygen consumption by up to 400%, which leads to hypoxia, acidosis, and cardiac compromise. It is known that inhaled anesthetics inhibit the temperature regulating centers in the hypothalamus; thus, the aging adult has this added insult to an already inhibited hypothalamus. Thermoregulatory vasoconstriction can cause significant peripheral vasoconstriction, predisposing older adults to produce less heat per kilogram of body weight; therefore, older adults may be unable to maintain their heat in the cooler environment of the operating room. Likewise, once temperature decreases in the elderly patient, it is difficult to restore normal body temperature. Methods to maintain normothermia in the older adult patient should involve prevention of heat loss and active warming initiated in the preoperative area and continued perioperatively. Methods include the administration of all fluids and blood transfusions through a warming device, a thermal mattress or forced air warmer, and an environmental humidity higher than 50%. Age-related changes in the kinetics of medications also occur. The decrease in blood volume will produce a higher-than-anticipated initial plasma concentration when intravenous anesthetic agents are administered. This may be evident upon induction because moderate-to-severe hypotension may result. There is also a decreased volume of distribution with water-soluble medications, leading to plasma concentrations that are higher than normal. Likewise, with the increase in total body fat in older adults, fat-soluble medications have a longer half-life, possibly causing an extension of the pharmacologic properties and a slower excretion from the body.

Cardiovascular System

Age-related changes in the cardiovascular system involve structural and functional changes in the heart, vessels, and autonomic nervous system. In the older adult, the heart and vascular system is less compliant, leading to a faster propagation of the pulse pressure waveform, increase in afterload, and an increase in systolic blood pressure, leading to ventricular thickening (hypertrophy) and prolonged ejection times. The combination of ventricular hypertrophy and slower myocardial relaxation often results in late diastolic filling and diastolic dysfunction. When these changes occur, atrial contraction becomes important in the maintenance of adequate ventricular filling. Even though the elderly have higher amounts of circulating catecholamines, they exhibit decreased end-organ adrenergic responsiveness. Therefore, the older adult has a reduced capacity to increase heart rate in response to hypotension, hypovolemia, and hypoxia. Prolonged circulation time causes a faster induction time with inhalation agents but delays the onset of intravenous drugs. There is calcification of the conducting system with loss of sinoatrial node cells, which predisposes the elderly to atrial fibrillation, sick sinus syndrome, first- and second-degree heart blocks, and arrhythmias. Hence a higher proportion of this population may present with, or require, permanent pacemakers and/or automatic internal defibrillators. Calcification is not limited to the conducting system, but may be present in the valves (primarily aortic and mitral), predisposing elderly patients to valvular stenosis or regurgitation.

Hypertension is a risk factor for perioperative complications, with the risk doubling for every 20-mmHg systolic/10-mmHg diastolic increase in blood pressure. With aging, pulse pressure widens due to a greater proportionate increase in systolic blood pressure compared with diastolic blood pressure. Decreased vein compliance can lead to decreased venous return and reduced atrial filling. Likewise, there is decreased sensitivity of baroreceptors in

TABLE 49-1 Age-Related Cardiovascular Changes and Anesthetic Implications

Age-Related Change	Mechanism	Consequences	Anesthetic Implications
Myocardial hypertrophy	Apoptotic cells are not replaced and there is compensatory hypertrophy of existing cells; reflected waves during late systole create strain on myocardium leading to hypertrophy	Increased ventricular stiffness, prolonged contraction, and delayed relaxation	Failure to maintain preload leads to an exaggerated decrease in CO; excessive volume more easily increases filling pressures to congestive failure levels; dependence on sinus rhythm and low-normal HR
Myocardial stiffening	Increased interstitial fibrosis, amyloid deposition	Ventricular filling dependent on atrial pressure	—
Reduced LV relaxation	Impaired calcium homeostasis; reduced β-receptor responsiveness, early reflected wave	Diastolic dysfunction	—
Reduced β-receptor responsiveness	Diminished coupling of β-receptor to intracellular adenylate cyclase activity, decreased density of β-receptors	Increased circulating catecholamines; limited increase in HR and contractility in response to endogenous and exogenous catecholamines; impaired baroreflex control of BP	Hypotension from anesthetic blunting of sympathetic tone, altered reactivity to vasoactive drugs; increased dependence on Frank-Starling mechanism to maintain CO; labile BP, more hypotension
Conduction system abnormalities	Apoptosis, fibrosis, fatty infiltration, and calcification of pacemaker and His-bundle cells	Conduction block, sick sinus syndrome, AF, decreased contribution of atrial contraction to diastolic volume	Severe bradycardia with potent opioids, decreased CO from decrease in end-diastolic volume
Stiff arteries	Loss of elastin, increased collagen, glycosylation cross-linking of collagen	Systolic hypertension Arrival of reflected pressure wave during end-ejection leads to myocardial hypertrophy and impaired diastolic relaxation	Labile BP; diastolic dysfunction, sensitive to volume status
Stiff veins	Loss of elastin, increased collagen, glycosylation cross-linking of collagen	Decreased buffering of changes in blood volume impairs ability to maintain atrial pressure	Changes in blood volume cause exaggerated changes in cardiac filling

BP, Blood pressure; *CO*, cardiac output; *HR*, heart rate; *LV*, left ventricular.

the aortic arch and carotid sinuses in response to blood pressure changes, which results in increased episodes of hypotension. Age-related changes in the cardiovascular system of the older adult also include changes in the heart's regulation of calcium causing the myocardium to generate force over a longer period after excitation, thereby prolonging the systolic phase of the cardiac cycle.[12]

The myocardium in the older adult has decreased sensitivity to beta adrenergic modulation, physiologically evident as decreased heart rate and lower cardiac dilation at the end of diastole and systole. The combined effect of decreased cardiac reserve and decreased maximum heart rate adversely affects the compensatory mechanisms of the older adult under the stress of anesthesia and surgery. Older adults undergoing noncardiac surgery are at risk of cardiovascular complication as a result of anesthesia and surgery. Although there is evidence supporting the use of beta-blockers as an effective method of reducing adverse perioperative cardiovascular events after noncardiac surgery in select high-risk surgical patient populations, this approach is currently under considerable scrutiny and debate. No matter what approach is taken, complete assessment of the cardiovascular system in the older adult undergoing noncardiac surgery is essential according to the American College of Cardiology/American Heart Association (ACC/AHA) Guidelines for Perioperative Cardiovascular Evaluation for Noncardiac Surgery. According to the ACC/AHA, functional capacity is an objective quantification of the patient's exercise tolerance and can be measured in metabolic equivalents (METs).[13] Research suggests that for every 1 MET that a patient attained, there is a corresponding reduction in annual mortality of 11%.[14] The MET corresponds to the amount of oxygen consumed by a 70-kg male at rest (≈ 3 mL oxygen per kg body weight per minute). Those patients able to perform greater than 4 METs are at decreased risk for perioperative cardiac complications.

In general, older adults may have higher blood pressures caused by increased peripheral vascular resistance, decreased arterial elasticity, and cardiac workload; likewise, older adults may have decreased cardiac output and stroke volume due to decreased conduction velocity and reduction in venous blood flow. Age-related cardiovascular changes and their anesthetic implications are noted in Table 49-1. The preoperative assessment should include the identification of major risk factors for preoperative cardiovascular complications, which include significant exercise intolerance, angina, history of myocardial infarction within the past 6 months, ventricular arrhythmias, acute coronary syndrome, decompensated congestive heart failure, and valvular disease. To assist in the prediction of postoperative cardiac outcome in patients undergoing noncardiac surgery, classic preoperative cardiac risk assessment and guidelines such as the Goldman Cardiac Risk Index (GCI) may be used. The GCI applies nine independent factors to assess the level of hemodynamic stress inflicted upon the vital organs and the risk of adverse cardiac factors are assigned points accordingly (Table 49-2).

The use of beta-blockers is common in older adults with chronic heart failure, hypertension, and ischemic heart disease. However,

TABLE 49-2 Goldman Cardiac Risk Index

History	
Age older than 70 years	5 points
Myocardial infarction within 6 months	10 points
Cardiac	
Signs of CHF: ventricular gallop or JVD	11 points
Significant aortic stenosis	3 points
Arrhythmia other than sinus or premature atrial contractions	7 points
5 or more PVCs per minute	7 points
Medical Conditions	
P_{O_2} < 60; P_{CO_2} > 50; HCO_3 < 20; K < 3; BUN > 50; Creatinine > 3; elevated SGOT; chronic liver disease; bedridden	3 points
Surgery	
Emergency	4 points
Intraperitoneal, intrathoracic or aortic	3 points
Add total points above to find risk index for cardiac complications in table below:	

Points	Class	Range
0-5	I	1%-7%
6-12	II	3%-11%
13-25	III	14%-38%
25-53	IV	30%-100%

Adapted from Fleischer LA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. *J Am Coll Cardiol.* 2007;50(17):1707-1732.
BUN, Blood urea nitrogen; *CHF,* congestive heart failure; *JVD,* jugular venous distension; HCO_3, bicarbonate; P_{CO_2}, partial pressure of carbon dioxide; P_{O_2}, partial pressure of oxygen; *PVC,* premature ventricular contractions; *SGOT,* serum glutamic oxaloacetate transaminase.

for patients that present to the operating room who may not have had the benefit of chronic titration of this class of medication, a practical approach for the anesthesia provider might include the administration of oral medication prior to induction and intraoperative intravenous administration to control heart rate.

Cardiovascular disease is the most common concomitant illness in the older adult and the primary cause for perioperative and postoperative risk in the older adult. The most frequently associated cardiovascular coexisting diseases are hypertension, coronary artery disease, congestive heart disease (CHF), and myocardial ischemia. Myocardial infarction is the most common cardiac complication and the leading cause of death in the postoperative period. Likewise, a patient with preexisting congestive heart failure has a greater than twofold risk of developing postoperative complications.[15]

Respiratory System

There are various age-related alterations of the respiratory system that have an impact on oxygenation in the elderly patient. Older patients develop calcifications of the chest wall, intervertebral joints, and intercostal joints. This, along with decreased intercostal muscle mass, contributes to a decrease in chest wall compliance. In addition, there is a flattening of the diaphragm, a loss of intervertebral disc height, and changes in spinal lordosis, which may further diminish chest wall compliance. Changes also occur with the lung parenchyma. There is a generalized loss of elastic tissue

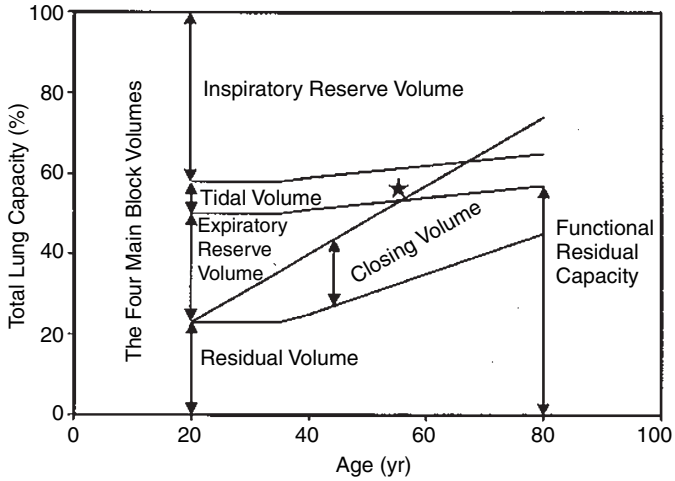

FIGURE 49-1 Changes in lung volumes with aging (erect position). Residual volume (RV) and functional residual capacity (FRC = ERV + RV) gradually increase by aging, whereas expiratory and inspiratory reserve volumes (ERV, IRV) and thus vital capacity (VC = ERV + IRV) decrease. Specific (height-adapted) total lung capacity (TLC) does not change with aging. Forced expiratory volume in 1 second (FEV_1) can be significantly reduced in older people and FEV_1/FVC may be as low as 65% to 55%. Closing volume (CV) is increased and the closing capacity (RV + CV) may even be larger than FRC, thus closing the small airways during normal tidal breathing *(star)*. This may significantly impair pulmonary gas exchange. (From Zaugg M, Lucchinetti E. Respiratory function in the elderly. *Anesthesiol Clin North America.* 2000;18[1]:47-58.)

recoil of the lung. Consequently, there is reduced functional alveolar surface area available for gas exchange. In elderly patients, even in the absence of disease, an increase in lung compliance impairs the matching of ventilation and perfusion, increases physiologic shunt, and results in the reduction of oxygen exchange at the alveolar level. Since lung elastic recoil is necessary for maintaining small airway caliber, an increased lung compliance causes small airway diameter to narrow, and eventually increases the closing volume (i.e., lung volume at which small airways in the dependent parts of the lung begin to close). The closing volume exceeds functional residual capacity (FRC) at approximately 65 years of age in the erect position and at age 45 years in the supine position. Other dynamic and static lung volume changes include a decrease in vital capacity (VC), an increase in residual volume (RV), and an increase in FRC with decreases in inspiratory reserve volume (IRV) and expiratory reserve volume (ERV). Total lung capacity remains unchanged or may slightly decrease due to its correlation with height. There is also a decrease in forced expiratory maneuvers. The forced vital capacity (FVC) and the forced expiratory volume in 1 second (FEV_1) are both decreased due to the loss of lung elastic recoil, decrease in small airway diameter, and subsequent airway collapse with forced expiration (Figure 49-1). Overall, the elderly have impaired efficiency of gas exchange. Impaired oxygenation is reflected by a decline in resting arterial oxygen tension (Pa_{O_2}), which remains somewhat stable, at approximately 83 mmHg, after 75 years of age. This decline in Pa_{O_2} is attributed to the premature closing of small airways and the reduction in the alveolar surface area.[16]

The regulation of breathing is also affected with aging. The central (medulla) and peripheral (carotid and aortic bodies) chemoreceptors affect ventilation with changes in pH, Pa_{O_2}, and Pa_{CO_2}. In the elderly the ventilatory response to hypoxemia and hypercarbia is decreased, predisposing them to increased episodes

TABLE 49-3 Age-Related Pulmonary Changes and Anesthetic Considerations

Structural Changes	Consequences	Anesthetic Considerations
Chest wall	Impaired gas exchange	Risk for respiratory failure
Stiff/decreased compliance	Increased WOB	Careful use of NDMRs, opioids, and benzodiazepines
Flattened diaphragm		
Lung parenchyma	Impaired gas exchange	Risk for respiratory failure
Increased lung compliance	Increased $\dot{V}/\dot{Q}$ mismatch	Avoid high pressure/large TV
Increased small airway closure	Increased anatomic dead space	Consider alveolar recruitment maneuvers (PEEP)
	Decreased alveolar surface area	Limit high inspired O_2
	Decreased PCBF	Maintain $Paco_2$ near normal preoperative value
	Decreased Pao_2	Consider regional/local with sedation
Muscle strength		Risk for respiratory failure
		Risk for aspiration
Decreased	Increased WOB	Adequate hydration
	Decreased protective airway reflexes	Consider RSI with GA
		Ensure fully reversed prior to extubation
		Consider postoperative CPAP or BiPAP
		Vigilant monitoring
		Encourage cough/deep breathing postoperatively
Control of breathing		Risk for respiratory failure
Decreased central/peripheral chemoreceptor sensitivity	Increased hypoventilation	Consider postoperative CPAP or BiPAP
	Increased apnea	Vigilant monitoring
	Decreased ventilator responses	Encourage cough/deep breathing postoperatively
		Supplemental oxygen postoperatively

WOB, Work of breathing; *NDMRs*, nondepolarizing muscle relaxants; $\dot{V}/\dot{Q}$; ventilation-perfusion; *PEEP*, positive end-expiratory pressure; *TV*, tidal volume; *PCBP*, pulmonary capillary blood flow; *GA*, general anesthesia; *RSI*, rapid sequence induction; *CPAP*, continuous positive airway pressure; *BiPAP*, bilevel positive airway pressure.

of apnea. Another challenge associated with oxygenation is the progressive decrease in laryngeal and pharyngeal support that accompanies aging, which can result in airway obstruction. In addition, protective airway reflexes (i.e., coughing and swallowing) are decreased, which increases the risk for pulmonary aspiration. Age-related pulmonary changes and their anesthetic implications are noted in Table 49-3.

Similar to other organ systems, pulmonary changes in the elderly are extremely variable among individuals. Regardless of these variations, an in-depth assessment of the respiratory system and identification of coexisting diseases that affect the pulmonary system is important in order to optimize preoperative respiratory function.

Older patients are at an increased risk for pulmonary-related coexisting diseases (e.g., chronic obstructive pulmonary disease [COPD], pneumonia, sleep apnea), which are associated with increased morbidity and mortality.[17,18] The presence of pulmonary disease increases the risk of hypoxia, pneumonia, and atelectasis. COPD is a significant risk factor for the development of postoperative pulmonary complications.[19] The incidence of postoperative respiratory complications is three- to sixfold in persons who smoke.[17,20] Although smokers have a higher incidence of postoperative pulmonary complications, pulmonary complications may paradoxically increase in patients that quit smoking 2 months or less prior to surgery.[20-23] Despite this, short-term smoking cessation is still advised.

Postanesthesia respiratory complications are common in the older adult, often requiring upper-airway support during the immediate postoperative period. Pulmonary complications account for nearly 40% of perioperative deaths in persons over the age of 65 years. ASA classes of greater than II predict a twofold risk of respiratory complications.[20] Moreover, older patients are more prone to develop atelectasis and pulmonary infection. Therefore, preoperative pulmonary evaluation of the older patient should focus on identifying those persons presenting with limited pulmonary reserve and recognizing factors that aid in maximizing performance status. In patients over 70 years of age, the number of stairs a patient can climb before the surgery is inversely proportional to cardiopulmonary complication rates after the operation.[24] In addition to age, pulmonary complications are increased based on length of surgery, obesity, and sex (females slightly higher).

Renal Function

Age-related changes in renal function are particularly significant because of the many roles of the kidneys. Older adults have a significant baseline decrement in renal function relative to their younger counterparts. Changes in renal function in the older patient are characterized by a progressive atrophy of kidney parenchymal tissues, deterioration of renal vascular structures, decreased renal blood flow, and an overall decrease in renal mass. The cumulative effect is a decrease in the glomerular filtration rate resulting in decreased renal drug clearance and decreased renal blood flow from age 20 years to age 90 years (approximately a 25%-50% decline). The combined effect is particularly apparent with diminished renal clearance of hydrophilic agents and hydrophilic metabolites of lipophilic agents.

Because of the vital role that the kidneys play in the maintenance of fluid and electrolyte balance, their contribution to acid-base balance, and to the excretion of drugs and their metabolites, it is essential that great consideration is given to the renal function of the aged patient. The decrease in glomerular filtration rate and impairment of the diluting segment of the nephron can easily predispose the patient to fluid overload if overzealous intravenous fluid is administered.[11] The production of renin and aldosterone is decreased with age, causing impairment of sodium conservation. Sodium conservation and hydrogen ion excretion are decreased, resulting in an impaired ability of the kidneys to respond to changes in electrolyte concentrations, intravascular volume, and free water.[11,25] The kidneys do not respond to nonrenal loss of water and sodium and as a result, dehydration can commonly occur. The serum creatinine is often unchanged if there is no renal failure because of decreased creatinine production from the overall declining skeletal muscle mass associated with aging. Creatinine clearance is the best indicator of drug clearance. Estimation of serum creatinine using the Cockroft and Gault creatinine clearance formula is a common method for estimating creatinine clearance in the healthy older adult.[11,26]

$$\frac{(140 - \text{age in yrs}) \times (\text{weight in kg})}{72 \times (\text{serum creatinine in mg/dL})}$$

The factor 0.85 should also be included in the numerator when this formula is applied to females; however, when this formula is applied to the critically ill or those patients on medications that directly affect renal function, caution must be employed. This formula often overestimates creatinine clearance. Therefore, older patients with renal impairment may be at increased risk for (1) fluid overload; (2) accumulation of metabolites and drugs that are excreted by the kidneys; (3) decreased drug elimination, which can prolong the effects of a wide range of anesthetic drug and adjuncts; and (4) electrolyte imbalances, which can lead to arrhythmias by affecting cardiac conduction.[11,27] Furthermore, overhydration in a compromised heart with marginal reserves must be cautiously avoided because the physiologic changes in the kidneys of older adults decrease the ability to excrete a large-volume load.[11] Perioperative management of renal function should be geared toward preventing acute renal failure during the preoperative planning phase.

Hepatic Function

The age-related physiologic changes in hepatic function may cause decreased clearance, prolonged half-life, and either increased or decreased volume of distribution of the drugs. After the age of 50 years, there is a steady decline in the weight of the liver, which is about 2.5% of the total body weight throughout adulthood until age 50. By the age of 90 years, the liver is approximately only 1.6% of the total body weight.[28,29] The changes in hepatic function may affect hepatic drug clearance, particularly if the patient has a concomitant disease, smokes, or is consuming multiple medications that alter blood flow or up- or down-regulate hepatic functional biochemistry. Furthermore, increased body fat and decreased water content in the older patient has considerable impact on the volume distribution (Vd) of many drugs. The Vd of hydrophilic drugs in the older patient may be decreased, causing an increase in plasma concentration. The Vd of lipophilic drugs in the older adult may be increased, causing a decrease in their plasma concentration.

Age-related physiologic changes in hepatic function and disease processes can produce kinetic changes to anesthetic agents in older adults. The effect of age on phase I drug metabolism is somewhat variable. Phase I drug metabolism involves oxidation, reduction, and hydrolysis and is primarily mediated by the cytochrome P450 system. Phase II drug metabolism involves conjugation reactions, sulfonic acid, or acetylation. Age has been identified as an insignificant factor during phase II drug metabolism. Changes in pharmacologic responses are discussed later.

Because of the high prevalence of concomitant illnesses, the older adult is more likely to take multiple prescriptions, over-the-counter medications, and herbal remedies, which also increases the risk of adverse reactions. Therefore, the potential for drug interactions is increased as a result of age-related changes in hepatic function.

As previously stated, age-related changes in hepatic function are characterized by a decrease in liver mass, a decrease in portal and liver blood flow, decreased serum albumin, and decreased enzyme activity; therefore, the dosing of drugs dependent on hepatic metabolism must be carefully considered. The decrease in overall liver mass results in a reduction in the rate of plasma clearance and a prolongation of the effects of opiates. Furthermore, the delivery of drugs to the liver is highly influenced by hepatic blood flow. Age-related changes in hepatic function should be presumed to modify the metabolism of most of the anesthetic agents as well as the nondepolarizing neuromuscular blocking agents.[10] In general, we can anticipate an increase in duration of activity of the drugs that are most commonly used in anesthesia care.

Endocrine System

Age-related changes of the endocrine system have widespread effects on other body systems and processes. The endocrine system has multiple feedback loops and is strongly influenced by anesthesia and surgical stress. Anesthesia and surgery cause a neuroendocrine stress response that is reflected by increased secretion of many hormones including epinephrine, norepinephrine, adrenocorticoids, and growth hormone (insulin antagonist), which causes insulin resistance at the tissue level. [30] Furthermore, increased hepatic production of glucose, impaired insulin secretion, and impaired breakdown of fats and proteins have widespread consequences.[31]

Although risk stratification of patients exists (e.g., ASA Physical Status, Goldman's cardiac risk index, and Lee's revised Cardiac Risk Index), defective glucose/insulin control further increases the risk for adverse reactions in patients with cardiovascular disease and increases the risk of perioperative complications. Older adults are more susceptible to the effects of increased glucose due to hyperglycemia-induced immune defects and age-related immune senescence.[32] Diabetes affects perioperative cardiovascular risk and autonomic dysfunction and is associated with an increased risk for stroke, myocardial infarction, ketoacidosis, and deterioration in renal function. Patients with long-term diabetes often have compromise in one or more organ systems.[33] These factors place patients with diabetes at increased risk for developing complications during the perioperative and postoperative period. The extent of endocrine and metabolic changes experienced is influenced by preoperative diabetes control, type of diabetes, magnitude of surgery, and perioperative complications.

Assessment of the older patient with diabetes includes identification of the type of diabetes, diabetes control (hemoglobin A1c), length of disease, and complications from diabetes. Patients with a history of diabetes for greater than 10 years are particularly at increased risk for complications.[30] Perioperative assessment of the degree of endocrine dysfunction is essential, along with ongoing monitoring and timely intervention when appropriate.

Central Nervous System

Age-related physiologic changes of the central nervous system (CNS) are characterized by a progressive loss of neurons and neuronal substance, decrease in neurotransmitter activity, and decreased brain mass. These losses are most prominent in the cerebral cortex, particularly the frontal lobes. The associated physiologic changes cause a decrease in cerebrospinal fluid, a decrease in nerve conduction velocity, and degeneration of peripheral nerve cells. In addition, there is a decreased number of myelinated nerve fibers. The regulation of brain function, including neuronal membranes, receptors, ion channels, neurotransmitters, cerebral blood flow, and metabolism, is affected by general anesthetics at all levels. Consequently, there are changes in mood, memory, and motor function. In addition, cellular processes that participate in neurotransmitter synthesis and release, such as intraneuronal signal transduction and the second messenger system, may be altered.[34] The CNS changes experienced by the older patient results in an increased sensitivity to anesthetic agents; as a result, there may be an increased risk for postoperative delirium or cognitive dysfunction.

The older patient may experience increased sensitivity to drugs because the number of receptors available are decreased.[35] As a rule, older patients frequently experience an exaggerated response to CNS-depressant drugs with particular sensitivity to general anesthetics, hypnotics, opioids, and benzodiazepines.[29] The dose of induction agents should be decreased by as much as 30% to 40% in older patients, arguing for very meticulous titration.

CNS changes in the elderly also affect neuraxial anesthesia. Because the number of myelinated nerve fibers are decreased, this poses a risk for neural damage with regional anesthetics. Likewise, anatomic changes in the aging patient, such as decreased intervertebral disc height, narrowing of the intervertebral foramina, decreased space between the posterior spinous processes, presence of calcifications, and changes in normal lordosis, contribute to difficulties associated with patient positioning and spinal or epidural needle placement. It is also postulated that the dura is more permeable to local anesthetics and that the CSF specific gravity increases whereas its volume decreases. All of these alterations in the nervous system may produce a more enhanced spread of local anesthetics for subarachnoid blocks.[36] Because elderly patients have an impaired baroreceptor response, severe hypotension refractory to adrenergic stimulation may result from postsubarachnoid sympathectomy. This could potentially be detrimental in the presence of impaired cardiac function. There is also an enhanced spread of local anesthetics with epidural blockade. In addition, the use of an epinephrine "test dose" for identification of intrathecal injection is less reliable in the elderly because of the decreased end-organ adrenergic responsiveness.[37] Therefore, a decreased dose of local anesthetic is recommended for subarachnoid and epidural blockade. Overall, subarachnoid and epidural blockade are generally not contraindicated in the elderly patient. A plan of anesthesia should be developed based on patient history and surgical procedure while considering the risks and benefits in an effort to decrease postoperative morbidity and mortality.

POSTOPERATIVE DELIRIUM

The most common type of complication in older adults is neurologic.[38] The most frequently occurring neurologic complication in older adults is postoperative delirium. Depending on the type of procedure, the rate of postoperative delirium ranges from 15% to 53%.[39] In older adults, other common neurologic postoperative complications are stroke and peripheral nerve damage.

Although normal intellectual function peaks between the ages of 20 and 30 years, it reaches a relative level of stability and remains so until 83 to 87 years, and then begins to decline. General anesthesia may deteriorate the mental capacity in those with preexisting problems and may have a strong association with postoperative cognitive dysfunction.[27] Although often used interchangeably, delirium and cognitive dysfunction are distinct conditions that occur in the older adult. Cognitive dysfunction is often subtle and comprised of an extensive range of psychoneurologic changes that occur in several functional domains. However, some older adults experience a transient reversible state of cognitive alteration after surgery: postoperative delirium, a common postoperative complication associated with the older adult. Delirium is associated with several adverse events that include depression, function decline, prolonged hospitalization, increased healthcare costs, and death.

Postoperative delirium is characterized by disruption of perception, thinking, memory, psychomotor behavior, sleep-wake cycle, consciousness, and attention.[40,41] Delirium occurs in 10% to 26% of patients over the age of 65.[42,43] The exact cause of delirium is not known but is likely multifactorial. Risk factors that have been associated with the development of delirium are older age, male gender, dementia, history of alcohol abuse, depression, duration of anesthesia, poor functional status, abnormal electrolytes and glucose, Parkinson's disease, cardiovascular disease, dehydration, metabolic diseases (e.g., diabetes, hyperthyroidism), anticholinergic drugs used intraoperatively, patients requiring admission to the intensive care unit, inadequate pain control, and type of surgery.[44-50] Postoperative delirium is believed to be related to anesthesia-stimulated vasodilation with a resultant hypermetabolic state in the brain. This hyperbolic state leads to oxidative stress and irregularities in the cholinergic, dopaminergic, histaminergic, and noradrenergic neuronal systems. Hence, synthesis and release of acetylcholine from cholinergic cells may be reduced, causing disorientation and memory impairment or agitation and hallucinations.

Symptoms associated with delirium typically begin early during the postoperative period and can last for several days or weeks. Delirium is associated with increased risk of postoperative adverse reactions (i.e., pulmonary edema, myocardial infarction, respiratory failure, pneumonia, and death), increased length of hospital stay, increased healthcare cost, and poor functional and cognitive recovery.[27,47,51-53] Delirium is more common in patients having orthopedic procedures (i.e., femoral fractures) and patients undergoing cardiac surgery, with incidence rates of 28% to 60% and 32% to 47% in these surgical populations, respectively.[47,54-56] In cardiac surgery patients, the presence of four preoperative factors (depressive symptoms, impaired cognitive function, prior stroke or transient ischemic attacks [TIA], and abnormal albumin) has been independently associated with postoperative delirium.[56-59]

For practical clinical purposes, the most common CNS disorder in the older patient is delirium. A history of neurologic deficits and neurologic diseases are most often associated with risk of delirium; therefore, symptomatology related to these disorders should be included in the preoperative evaluation and consultation requested when needed.[60]

POSTOPERATIVE COGNITIVE DYSFUNCTION

Postoperative cognitive dysfunction (POCD) is often reported as being part of the same continuum as postoperative delirium. Even though they are both neurocognitive disorders that contribute to increased hospital costs, morbidity, and mortality, there are differences. POCD is characterized by an array of cognitive impairments such as memory deficits, difficulty with concentration, impaired comprehension, and delayed psychomotor speed.

BOX 49-1

Risk Factors for Postoperative Cognitive Dysfunction

- Genetic disposition
- Lower educational level
- High alcohol intake or alcohol abuse
- Increasing age
- High ASA status
- Preexisting mild cognitive impairment
- History of cerebrovascular accident
- Major operations, redo operations
- Cardiac surgery
- Longer duration of surgery and anesthesia
- Intraoperative cerebral desaturation
- Postoperative delirium
- Postoperative infection

From Grape S, et al. Postoperative cognitive dysfunction. *Trends Anaesth Crit Care*. 2012;2(3):98-103.
ASA, American Society of Anesthesiologists.

Unlike postoperative delirium, the onset of POCD is subtle and neurocognitive deficits may not present themselves until weeks to months after surgery. This ultimately results in the inability to work, a decline in activities of daily living, and perhaps a need for assisted care.

Currently, there are no universally accepted diagnostic criteria for POCD, nor is there a standard definition. In order to diagnose POCD, a battery of time-consuming and sophisticated neurocognitive tests must be done preoperatively as well as postoperatively in identifying cognitive decline after surgery and anesthesia. Establishing baseline cognitive function is critical because preoperative cognitive impairment may be present prior to surgery. However, preoperative test timing, specific test(s), and test interpretations remain inconsistent and debatable. Risk factors for POCD are also controversial, with advanced age being the most agreed upon. Other risks may include lower educational level, longer duration of anesthesia, preoperative depression, preoperative cognitive decline, postoperative infection, and second operation[61] (Box 49-1). The cause of this neurocognitive postoperative complication is still unknown and appears to be multifactorial. However, several theories have been postulated. Common theories include cerebral hypoperfusion (severe hypotension and embolic events), the inflammatory process associated with surgery, and general anesthetics.[62] In a recent study on mice, Freche et al.[63] purported that repeated exposure to sevoflurane resulted in an increase in the hippocampal phosphorylation of the protein tau and memory impairment. However, with human studies, a link between the tau phosphorylation and memory impairment is yet to be reported.

Presently, there is no cure for POCD. Patients who suffer from POCD may or may not recover to their preoperative cognitive state. Because POCD pathogenesis is multifactorial and unclear, strategies should be aimed at prevention. Unfortunately, there are no proven effective strategies. However, based on the knowledge that the elderly have decreased nervous system function and decreased cognitive reserve, efforts should consist of identifying risk factors and tailoring anesthetic management to minimize them. Recommendations are aimed at maintaining oxygenation and cerebral perfusion. Because it is speculated that POCD may be caused by general anesthesia and/or surgery, it is only prudent that surgeries should be as short or as minimally invasive as possible. Other recommendations for the prevention of POCD are listed in Box 49-2.

BOX 49-2

Recommendations for the Prevention of Postoperative Cognitive Dysfunction

- Keep anesthesia and surgery as short and as minimally invasive as possible
- Use short-acting and rapidly metabolized drugs
- In patients at risk, prefer inhaled over intravenous anesthetics
- Neuroprotective drugs currently under investigation:
  - Piracetam
  - Ketamine
  - Pexelizumab
  - Remacemide

It is apparent that further research is needed regarding the pathophysiology, prevention, and treatment of POCD. Furthermore, standardized preoperative neurocognitive assessment, especially in the elderly population, needs to be initiated to help identify patients with cognitive impairment. The elderly surgical population is increasing, and there must be an increased focus on the risk for postoperative neurologic events, specifically, postoperative delirium and POCD.

AGE-RELATED PHARMACOLOGIC IMPLICATIONS IN THE OLDER ADULT

Exaggerated responses to anesthetic drugs and a prolonged duration of action are often seen in the elderly. These differences in drug response are due to both pharmacokinetic and pharmacodynamic changes associated with aging. Pharmacokinetic alterations occur in the volume of distribution, renal and hepatic clearance rates, compartmental redistribution, and elimination half-lives. A decreased blood volume results in a decrease in initial volume of distribution, which produces a higher-than-expected initial concentration of drug with an intravenous bolus injection. Changes in steady-state volumes of distribution (Vd_{ss}) vary. In aging patients who have an increase in body fat, decrease in lean body mass, and a decreased total body water, there is an increased Vd_{ss} for lipophilic drugs and a decrease for hydrophilic drugs.[64] Decreased plasma protein binding in the elderly theoretically results in an increase in the free plasma concentration for drugs that are highly protein bound. A decrease in renal function resulting from lower renal blood flow, glomerular filtration, and tubular secretion leads to increased serum concentration and prolonged effects of drugs dependent on renal elimination. The elimination of hepatic-dependent drugs varies. Phase I metabolism may be reduced, but phase II metabolic pathways are not affected by age.[65]

Pharmacodynamics changes in the elderly include altered receptor density and binding, changes in signal transduction, and impaired cellular responses. Drug-induced changes tend to be longer lasting and require a greater length of time for recovery to preanesthetic steady state. The minimal alveolar concentration (MAC) of inhalational agents decreases roughly 6.7% per decade from the MAC value of 40-year-old adults.[66-68]

COMORBIDITY

Comorbidity, the co-occurrence of more than one disease, is higher in older adults.[69,70] Over 50% of individuals over the age of 70 years will have at least one chronic illness, and 30% will have two or more.[4] Hypertension is the most common comorbidity in the elderly, followed by coronary artery disease. Other common conditions are diabetes, arthritis, and chronic obstructive pulmonary disease (COPD).

Congestive heart disease, COPD, and/or malignancy are the strongest predictors of mortality in older adults with hip fracture repair at 1 month and at 1 year postoperative.[71,72] In a sample of patients undergoing noncardiac surgery, congestive heart failure and decreased functional status were the greatest predictors of postoperative neurologic and cardiac adverse outcomes.[15]

FRAILTY

Frailty is an emerging concept in terms of a perioperative risk factor for complications and mortality. Frailty rates of 4.1% to 50.3% have been reported in surgical patients.[73-76] Frail older adults are more likely to have complications postoperatively.[8,76] In addition, frail older adults are also at increased risk for longer length of hospital stay and discharge to a skilled or assisted living facility.

There is no agreed upon definition of frailty. This may be related to the complexity of the syndrome and the fact that frailty often overlaps with other syndromes. However, most agree that frailty is a biologic state associated with increased vulnerability to adverse outcomes that result from decreased resistance to stressors as a result of deterioration in multiple physiologic systems. Frailty is classified as primary or secondary. Primary frailty occurs as part of the intrinsic process of aging. Secondary frailty is related to the end stage of chronic illnesses and is caused by inflammation and wasting, for example, heart failure, COPD, inflammation, and wasting associated with cancer. Frailty markers include older age, age-associated declines in lean body mass, endurance, strength, balance, walking performance, and reduced activity.[77] Fried et al.[77] defined frailty as meeting three of five phenotypic criteria: low energy, slowed waking speed, low grip strength, low physical activity, and/or unintentional weight loss. Frailty also has been operationalized as a frailty index.[78] The frailty index defines frailty as the proportion of accumulated deficits over time, including diseases, disability, geriatric syndromes, psychosocial risk factors, and physiologic and cognitive impairment. It is suggested that the frailty index may be more sensitive to the identification of adverse outcomes than Fried's frailty phenotype.

ETHICAL ISSUES IN THE TREATMENT OF THE OLDER ADULT

Changes in the healthcare system and advances in medical treatment have resulted in a number of ethical dilemmas for healthcare providers. Research on health services delivery has found confounding variations in the quality and quantity of care provided to patients with severe chronic illness across the United States as they age and approach the end of life; more care does not necessarily lead to better quality of care, patient satisfaction, or outcomes.[79] Discrepancies between withholding versus withdrawing care or ordinary versus extraordinary treatments can complicate clinical decision making by healthcare providers. These findings raise three very important ethical issues for the healthcare provider: (1) impartiality in the delivery of limited resources across health service areas; (2) the promise to "do no harm" in providing of appropriate amounts of care to patients; and (3) transparency regarding local healthcare practice to facilitate informed decisions about healthcare choices. In this era of healthcare accountability, educators, clinicians, and employers must remain steadfast when addressing those ethical principles that drive change while simultaneously providing more efficient, more effective, and more patient-centered care to our older patients.[79,80] It is widely accepted that chronologic age is possibly an independent risk factor for anesthesia and surgery; its specific role as a risk factor is difficult, at best, to ascertain. Therefore, age, as an independent factor, should not be regarded as a reason to exclude an older adult for any procedure.

SUMMARY

Integrating care across the lifespan continuum can improve the anesthetic outcome of the geriatric patient and may minimize the physical structure and functional complications encountered in this population. Emphasis on biologic age as it relates to chronologic age requires the anesthetic practitioner to sometimes make alterations in the perioperative course. The goal of anesthesia for the older adult patient is the same as any other patient; however, strategies to ensure success in this immensely heterogeneous group are often more complex than with younger patients. Anesthesia for the elderly patient is no longer an empiric specialty; the practice of anesthesia for elderly patients is built on evidence-based concepts.

Physiologic, psychological, and functional status changes such as normal and anesthesia-related thermoregulation can be impaired in the older adult and are major contributors to perioperative outcome.

CHAPTER 50

Postanesthesia Recovery

◆ *Jan Odom-Forren*

The term *perianesthesia patient care* reflects a continuum of care, because the patient is moved from the preanesthesia holding or admitting area to the operating room (OR) and then to the postanesthesia care unit (PACU). *Postanesthesia recovery* refers to those activities undertaken to manage the patient after completion of a surgical or nonsurgical procedure in which anesthesia, analgesia, or sedation was administered. The primary purpose of postanesthesia recovery is critical assessment and stabilization of patients after these procedures, with an emphasis on prevention and detection of complications.[1] Care in the postanesthesia Phase I unit centers on providing postanesthesia nursing care and transitioning the patient to the intensive care setting, the surgical floor setting, or Phase II outpatient care.[2] The focus of this chapter is on the postanesthesia care of patients with the goals of improving postanesthetic safety and quality of life, reducing postoperative adverse events, providing a uniform assessment of recovery, and streamlining postoperative care and discharge criteria.

POSTANESTHESIA CARE UNIT ADMISSION

Before the patient is transferred, PACU personnel should be notified not only to expect the transfer but also to have any necessary equipment (e.g., ventilator, nebulizer, invasive monitoring equipment, pharmacologic infusions, capnograph) ready and waiting. Knowledge of the patient's acuity enables the PACU staff to best plan the patient's care and assign that care to an appropriately experienced practitioner.

Both the anesthesia provider and the PACU nurse should collaborate in the patient's admission to the PACU. The immediate priority is evaluation of respiratory and circulatory adequacy. During this initial assessment, any signs of inadequate oxygenation or ventilation are identified, as well as the cause (Boxes 50-1 and 50-2). Although many of the signs of respiratory compromise could have multifactorial explanations, assessment of the adequacy of oxygenation and ventilation ensures that respiratory inadequacy is not contributory. Any evidence of respiratory compromise requires immediate correction.

Electrocardiographic (ECG) monitoring is initiated for determination of cardiac rate and rhythm. Any deviation from preoperative or intraoperative findings is noted and evaluated. Also, blood pressure is measured, and adequacy of organ perfusion is determined. Any necessary invasive monitoring, such as an arterial line, is initiated. Any evidence of cardiocirculatory compromise requires immediate correction.

The anesthesia provider should be active during the patient's transfer and stabilization in the PACU. Assistance in the initiation of oxygen therapy, maintenance or verification of airway adequacy, and assessment of circulatory status familiarizes PACU personnel with the patient and fosters a smooth transfer of care. After initially stabilizing the patient, the anesthesia provider can communicate relevant preoperative and intraoperative data to the PACU nurse.

ANESTHESIA REPORT

To ensure patient safety and continuity of care, the anesthesia provider must give a verbal handoff report to the PACU nurse that specifies the details of the surgical and anesthetic course, the preoperative conditions that warrant or influence the surgical and anesthetic outcome, and the PACU treatment plan, including suggested interventions and end-points. Transfer of the patient from the OR to the PACU is a critical patient handoff and should include an opportunity for the PACU nurse to ask questions and the anesthesia provider to respond. Communication errors can occur during the process of a handoff. To decrease these communication errors, handoff information needs to be standardized and communicated in a logical and meaningful manner.[3] A coherent order for the presentation of this information is presented in Box 50-3.

The importance of the anesthesia report is reflected in the American Association of Nurse Anesthetists (AANA) guideline from the *AANA Scope and Standards for Nurse Anesthesia Practice*: "Standard VII: Transfer the responsibility for care of the patient to other qualified providers in a manner which assures continuity of care and patient safety."[4] The American Society of Anesthesiologists (ASA) points to the importance of a verbal report to the responsible PACU nurse but also goes on to state, "The member of the Anesthesia Care Team shall remain in the PACU until the PACU nurse accepts responsibility for the nursing care of the patient."[5]

INITIAL POSTANESTHESIA CARE UNIT ASSESSMENT

Many postanesthesia assessment approaches (e.g., head-to-toe, major body systems assessments, and scoring systems) are currently used in PACUs, and each approach has its benefits and limitations. The assessment approach should accomplish the following:

- Determine the patient's physiologic status at the time of admission to the PACU
- Allow the periodic reexamination of the patient so that physiologic trends become obvious
- Establish the patient's baseline level so that the effect of previous medical conditions can be assessed and predicted as they affect current physiology
- Assess the ongoing status of the surgical site and its effect on any preexisting conditions and recovery
- Assess the patient's recovery from anesthesia and note residual effects
- Prevent or immediately treat complications that occur
- Provide a safe environment for the patient who is impaired either physically, mentally, or emotionally
- Allow the compilation and trend analysis of patient-specific characteristics that relate to discharge or transfer criteria[1,6]
- Anesthesia personnel must assist in management of the patient until PACU providers secure admission vital signs and attach

BOX 50-1

Signs and Symptoms of Inadequate Oxygenation

Respiratory
- Shallow, rapid respirations or normal, infrequent respirations
- Tachypnea
- Dyspnea
- Oxyhemoglobin saturation less than 90%

Neurologic
- Anxiety, restlessness, inattentiveness
- Altered mental status, confusion
- Dimmed peripheral vision
- Seizures
- Unresponsiveness

Skin
- Diaphoresis
- Cyanosis

Cardiac
- *Early:* Tachycardia
  - Increased cardiac output
  - Increased stroke volume
  - Increased blood pressure
- *Late:* Bradycardia, hypotension
- Dysrhythmias

Modified from Marley RA, Hoyle BL. Respiratory care. In Schick L, Windle PE. *PeriAnesthesia Nursing Core Curriculum*. 2nd ed. St. Louis: Saunders; 2010:625-693.

BOX 50-2

Causes of Hypoxemia

- *Hypoventilation*—Alveolar ventilation is abnormally low in relation to oxygen uptake or carbon dioxide output
- *Diffusion limitation*—Oxygen, carbon dioxide are affected as they cross the blood-gas barrier by simple passive diffusion
- *Shunt*—The entry of blood into the systemic arterial system without going through ventilated areas of lung
- *Ventilation-perfusion relationships*—A mismatch of ventilation and blood flow

Modified from Mason RJ, et al. *Murray and Nadel's Textbook of Respiratory Medicine*. 5th ed. Philadelphia: Saunders; 2010.

appropriate monitors. To optimize safety, the anesthesia provider cannot shift responsibility to PACU personnel until the patient's airway status, ventilation, and hemodynamics are appropriate.

Aldrete Scoring System

The most commonly used assessment approach is a combination of the Aldrete scoring system[7] and the major body systems assessment. The Aldrete scoring system evaluates the patient's activity, respiration, circulation, consciousness, and oxygen saturation level (Box 50-4). Patients receive a numeric score of 0, 1, or 2 in each area, with 2 representing the highest level of function.[8] The Aldrete postanesthetic scoring system is the most widely used scoring system in PACUs, although its predictive value in determining recovery from anesthesia has not been studied prospectively.

Major Body Systems

The major body systems assessment systematically evaluates the body systems that are most affected by anesthesia and the surgical procedure. After the patient is admitted to the PACU, an assessment of cardiorespiratory stability and a more in-depth cardiac assessment are performed. Respiratory assessment comprises rate, depth of ventilation, auscultation of breath sounds, and oxygen saturation level. Type of oxygen delivery system and presence of any artificial airway should be noted.[9] The heart is auscultated,

BOX 50-3

Anesthesia Admission Report

General Information
- Patient name
- Patient age
- Surgical procedure
- Name of surgeon and anesthesia provider(s)
- Type of procedure

Patient History
- Acute (indication for surgery)
- Chronic (medical history, medication use, allergies)

Intraoperative Management
- Anesthetic agents, including dose and technique
- Time of last opioid administration
- Use of reversal agents
- Intraoperative medications (antibiotics, antiemetics, vasopressors)
- Estimated blood loss
- Fluid and blood administration
- Urine output

Intraoperative Course
- Unexpected response to anesthetic administration
- Unexpected surgical course
- Laboratory results (arterial blood gas, glucose, hemoglobin)

Postanesthesia Care Unit Plan
- Potential and expected problems
- Suggested interventions
- Limits of acceptability of laboratory tests
- Discharge criteria
- Responsible contact person

and the quality of heart sounds, the presence of any adventitious sounds, and any irregularities in rate or rhythm are noted. Unexpected findings are compared with preoperative data. Arterial pulses are evaluated for strength and equality. An ECG strip is obtained on admission to the PACU and compared with the preoperative ECG. In addition, body temperature and skin color and condition are assessed and the findings documented.

After respiratory and cardiac assessments are completed, the neurologic system is evaluated, with a focus on the level of consciousness, orientation, sensory and motor function, and pupil size, equality, and reactivity. The patient is assessed on ability to follow commands and move extremities purposefully and equally.[6]

The renal system assessment focuses on fluid intake and output (e.g., blood, crystalloids, and colloids), as well as on volume and electrolyte status. The anesthesia provider relates intraoperative fluid totals in the verbal report, and the PACU nurse notes and documents all intravenous (IV) lines, irrigation solutions, and infusions that enter the patient. All output devices, including drains, catheters, and tubes, are inspected, and the color and consistency of any drainage are noted.

The surgical site is examined. The amount and color of any drainage on the bandage are noted. The patient is also assessed for pain or discomfort, such as nausea, with appropriate interventions administered.

All data obtained in the admission assessment should be documented in a manner that facilitates data collection, trend analysis, and retrieval. Recommended criteria for the initial assessment of a patient in the PACU are included in Box 50-5.

ONGOING ASSESSMENT

Perioperative and postanesthetic management of the patient includes ongoing assessment and monitoring of the following[5]:
- Respiratory function (e.g., obstruction, hypoxemia, hypercarbia)
- Cardiovascular function (e.g., hypotension, hypertension, dysrhythmias)

BOX **50-4**

Postanesthesia Recovery Score

Activity
0 = Unable to lift head or move extremities voluntarily or on command.
1 = Moves two extremities voluntarily or on command and can lift head.
2 = Able to move four extremities voluntarily or on command. Can lift head and has controlled movement. *Exceptions:* Patients with a prolonged block such as with bupivacaine (Marcaine), who may not move an affected extremity for as long as 18 hours; patients who were immobile preoperatively.

Respiration
0 = Apneic; condition necessitates ventilator or assisted respiration.
1 = Labored or limited respirations. Breathes by self but has shallow, slow respirations. May have an oral airway.
2 = Can take a deep breath and cough well; has normal respiratory rate and depth.

Circulation
0 = Has abnormally high or low blood pressure; blood pressure within 50 mmHg of preanesthetic level
1 = Blood pressure within 20-50 mmHg of preanesthetic level
2 = Stable blood pressure and pulse. Blood pressure 20 mmHg of preanesthetic level (minimum 90 mmHg systolic). *Exception:* Patient may be released by anesthesia provider after drug therapy.

Neurologic Status
0 = Not responding or responding only to painful stimuli.
1 = Responds to verbal stimuli but drifts to sleep easily.
2 = Awake and alert; oriented to time, place, and person.

O_2 Saturation
0 = O_2 saturation less than 90%, even with O_2 supplement.
1 = Needs O_2 inhalation to maintain O_2 saturation greater than 90%.
2 = Able to maintain O_2 saturation greater than 92% on room air.

Modified from Ead H. From Aldrete to PADSS: reviewing discharge criteria after ambulatory surgery. *J Perianesth Nurs*. 2006;21:259-267.

BOX **50-5**

Criteria for Initial Assessment: Phase I Postanesthesia Care Unit

Initial assessment and documentation include:
1. Integration of data received at transfer of care
   a. Relevant preoperative status
   b. Anesthesia/sedation technique and agents
   c. Length of time anesthesia administered
   d. Pain and comfort interventions and plan
   e. Medications administered
   f. Type of procedure
   g. Estimated blood loss and replacement
   h. Complications during course of anesthesia and response to treatment
2. Vital signs
   a. Respiratory status—airway patent, breath sounds, type of artificial airway, mechanical ventilatory settings, oxygen saturation, end-tidal CO_2 (if ordered)
   b. Blood pressure—cuff or arterial line
   c. Pulse—apical, peripheral
   d. Cardiac monitor, rhythm documented
   e. Temperature/route
   f. Hemodynamic pressure readings: central venous, pulmonary artery, and wedge; intracranial pressure as indicated
3. Pain level, level of emotional comfort
4. Neurologic function to include level of consciousness; pupillary response as indicated
5. Sensory and motor function as appropriate
6. Position of patient
7. Condition and color of skin
8. Patient safety needs
9. Neurovascular: Peripheral pulses and sensation of extremity(ies) as applicable
10. Condition of dressings and visible incisions
11. Type and patency of drainage tubes, catheters, and receptacles; effectively secured
12. Amount and type of drainage
13. Hydration status/fluid therapy: Location of lines, condition of IV site, and amount of solution infusing
14. Procedure-specific assessment (i.e., firmness of abdomen)
15. Postanesthesia scoring system if used

Modified from American Society of Perianesthesia Nurses (ASPAN). *Perianesthesia Nursing Standards and Practice Recommendations 2010-2012*. Cherry Hill, NJ. ASPAN; 2010.

- Neuromuscular function (e.g., inadequate reversal of neuromuscular blockade)
- Mental status (e.g., delayed awakening, emergence delirium)
- Pain
- Temperature (e.g., hypothermia)
- Nausea and vomiting
- Fluids
- Urine output and voiding

Respiratory Function

In postoperative patients, airway problems that interfere with oxygenation and ventilation are always related to an increase in the resistance to gas flow in the airway.[10] However, the most common cause of airway obstruction in the immediate postoperative phase is the loss of pharyngeal muscle tone in a sedated or obtunded patient.[11]

Obstruction

In postanesthesia patients, the tongue causes most upper airway obstructions. Obstruction occurs when the tongue falls back into a position that occludes the pharynx and blocks the flow of air into and out of the lungs. Signs and symptoms of an upper airway obstruction include snoring and activation of accessory muscles of ventilation. Intercostal and suprasternal retractions may be noted. However, patients are usually somnolent and may be difficult to arouse. Risk factors for an upper airway obstruction include anatomy (e.g., obesity, large neck, or short neck), poor muscle tone (secondary to opioids, sedation, residual neuromuscular blockade, or neuromuscular disease), or swelling (secondary to surgical manipulation, edema, or anaphylaxis).

The goal for the relief of a tongue obstruction is a patent airway. Treatment consists of a series of interventions. The initial intervention may be as simple as stimulating the patient to take deep breaths, or it may require repositioning of the airway via a jaw thrust or a chin lift. Placement of an oral or a nasal airway may be required. The nasal airway is tolerated much better by patients emerging from general anesthesia, and unlike the oral airway, it is unlikely to cause gagging or vomiting. If the obstruction remains unrelieved, reintubation may be required, with or without adjunctive mechanical ventilation.

Laryngeal obstruction may occlude the airway as a result of partial or complete spasm of the intrinsic or extrinsic muscles of the larynx. Laryngospasm may be the result of a reflex closure of the glottis (intrinsic muscles) or the larynx (extrinsic muscles).[10] Glottic closure usually manifests as intermittent obstruction; laryngeal closure manifests as complete obstruction. Airway irritation that predisposes a patient to laryngospasm may be the result of laryngoscopy, secretions, vomitus, blood, artificial airway placement, coughing, bronchospasm, or frequent suctioning. Symptoms that suggest laryngospasm include agitation, decreased oxygen saturation, absent breath sounds, and acute respiratory distress. Incomplete obstruction may manifest as a crowing sound or stridor.

Treatment of laryngospasm must be immediate. Positive-pressure ventilation with 100% oxygen is the initial intervention. If this intervention is ineffective, a subparalytic dose of IV succinylcholine (0.1 mg/kg) may be given by the anesthesia provider. If succinylcholine is administered, assisted ventilation for 5 to 10 minutes is required, even if the obstruction has been relieved. Reintubation should be performed if severe airway edema is present or if the obstruction persists despite treatment interventions. During the crisis, the anesthesia provider should consider medication for sedation, such as midazolam, to alleviate the possibility of an awake or partially awake patient.

Steroids and topical or IV lidocaine have been included in the prevention and management of airway irritability. Other preventive strategies include obtaining meticulous hemostasis during surgery, suctioning the oropharynx before extubation to clear any retained blood or secretions, and extubating the patient when he or she is in either a very deep plane of anesthesia or the awake state.[10] When obstruction occurs, rapid intervention is imperative because the arterial carbon dioxide pressure ($PaCO_2$) increases 6 mmHg in the first minute of total obstruction and an additional 3 to 4 mmHg each minute thereafter.[11]

Hypoxemia

Hypoxemia, defined as low arterial oxygen pressure (PaO_2) (usually less than 60 mmHg), is characterized by nonspecific signs and symptoms ranging from agitation to somnolence, hypertension to hypotension, and tachycardia to bradycardia. Pulse oximetry may confirm low oxygen saturation (less than 90%); arterial blood gas analysis may confirm a PaO_2 of less than 60 mmHg. Hypoxemia, if untreated, can result in organ ischemia.

Hypoxemia can be the result of a delivered airway obstruction, low concentration of oxygen, hypoventilation, impaired alveolar-capillary diffusion, ventilation-perfusion mismatches, or increased intrapulmonary shunting.[11,12] The most common causes of hypoxemia in the PACU include atelectasis, pulmonary edema, pulmonary embolism, aspiration, bronchospasm, and hypoventilation. A brief explanation of these pathologic states follows.

Clinical issues with pulse oximetry have to be considered when used to determine oxygen saturation levels. The relationship between percent of hemoglobin saturated with oxygen (SaO_2) and the partial pressure of oxygen in the blood (PaO_2) is symbolized by the oxyhemoglobin dissociation curve (see Figure 26-8). Shifts in the curve are caused by abnormal values of pH, temperature, partial pressure of carbon dioxide, and 2,3-diphosphoglycerate. The patient's level of hemoglobin must also be considered, because if too low, even fully saturated hemoglobin is not adequate to meet tissue needs.[1]

Atelectasis

Atelectasis is the most common cause of postoperative arterial hypoxemia and can lead to an increase in right-to-left shunt. Atelectasis may be the result of bronchial obstruction caused by secretions or decreased lung volumes. Hypotension and low cardiac output conditions can also contribute to the development of decreased perfusion and atelectasis. Treatment includes the use of humidified oxygen, coughing, deep breathing, postural drainage, and increased mobility. Incentive spirometry and intermittent positive-pressure ventilation also may be used.[13]

Pulmonary Edema

Pulmonary edema, which is caused by fluid accumulation within the alveoli, may be the result of an increase in hydrostatic pressure, a decrease in interstitial pressure, or an increase in capillary permeability.

An increase in hydrostatic pressure is usually the result of fluid overload, left ventricular failure (especially in the presence of systolic hypertension), mitral valve dysfunction, or ischemic heart disease. Increased capillary permeability may be the result of sepsis, aspiration, transfusion reaction, trauma, anaphylaxis, shock, or disseminated intravascular coagulation and is frequently referred to as *adult respiratory distress syndrome*.[10]

A decrease in interstitial pressure is often seen after prolonged airway obstruction, such as laryngospasm. Acute pulmonary edema that occurs shortly after relief of severe upper airway obstruction is called *postobstruction* or *negative-pressure pulmonary edema* or *noncardiogenic pulmonary edema*. The airway obstruction causes extreme negative intrapleural pressure that increases the pulmonary transvascular hydrostatic pressure gradient. The rapid movement of fluid from pulmonary vasculature to interstitium exceeds the clearing capacity of the pulmonary lymphatic system, and the alveoli become flooded.[14] Other causes of noncardiogenic pulmonary edema are bolus dosing with naloxone, incomplete reversal of neuromuscular blockade, or a significant period of hypoxia.[15]

Pulmonary edema is characterized by hypoxemia, cough, frothy sputum, rales on auscultation, decreased lung compliance, and pulmonary infiltrates seen on chest radiography. Treatment of pulmonary edema is directed toward identification of the cause and reduction of hydrostatic pressure within the lungs. Oxygenation must be maintained (particularly in the presence of profound hypoxemia) via oxygen mask or continuous positive airway pressure (CPAP) with mask, or if necessary, intubation, mechanical ventilation, and the addition of positive end-expiratory pressure (PEEP) ventilation. Diuretics (most commonly furosemide) and fluid restriction are a part of treatment. Dialysis may be used if the fluid retention results from renal failure. Afterload reduction, which is achieved through the use of nitroglycerin or sodium nitroprusside, may be used to decrease myocardial work.[10] Patients with noncardiogenic pulmonary edema usually recover quickly after the acute phase and have no permanent sequelae.[15]

Pulmonary Embolism

Pulmonary embolism is a leading cause of morbidity and mortality, accounting for 50,000 to 90,000 deaths annually in the United States. Most cases of pulmonary embolism are not fatal; however, two thirds of all deaths caused by a pulmonary embolism occur within 30 minutes of an acute event.[16]

Patients can be considered to be at risk for pulmonary embolism if three conditions, known as *Virchow's triad*, exist: venous stasis, hypercoagulability, and abnormalities of the blood vessel wall. These conditions are accentuated in the presence of obesity, varicose veins, immobility, malignancy, congestive heart failure, and increased age and after pelvic or long-bone surgery or injury. However, 90% of all pulmonary emboli arise from deep veins in the legs.[16,17] Thrombosis in postoperative patients seems to be related

to surgical tissue trauma and liberation of tissue factor that leads to thrombin formation. Leukocyte reactivity and surgery-induced hemostatic changes also may contribute[18] (Box 50-6).

A pulmonary embolism should be suspected in a patient who complains of or whose presenting signs include acute-onset tachypnea, dyspnea, and tachycardia, particularly when the patient is already receiving oxygen therapy. Signs and symptoms also may include chest pain, hypotension, hemoptysis, dysrhythmias, and congestive heart failure. Although the clinical symptomatology may be suggestive of a pulmonary embolism, confirmation requires pulmonary angiography. Pulmonary angiography is infrequently performed because of its high risk and associated mortality. A ventilation-perfusion scan may also prove useful.

Treatment of a pulmonary embolism is directed toward the correction of hypoxemia and support of hemodynamic stability. Preventive measures may include the use of antiembolic stockings or sequential compression devices. Subcutaneous heparin therapy also may be initiated. Once the occurrence of a pulmonary embolism has been confirmed, IV heparin therapy is started for the prevention of further clot formation. The goal of heparin therapy is an activated partial thromboplastin time that is 1.5 to 2 times the control value. Several new drugs are under development that will have fixed doses and not require laboratory monitoring.[19]

Aspiration

Aspiration is a potentially serious airway emergency that can compromise patient safety and stability on the induction of, or the emergence from, anesthesia. Aspiration may occur in the OR, in the PACU, or at any time during transfer. Patients may aspirate foreign matter (e.g., a tooth, food), blood, or gastric contents. Each type of material is associated with a characteristic clinical presentation.

Foreign matter aspiration may result in cough, airway obstruction, atelectasis, bronchospasm, and pneumonia. A profound reflex sympathetic nervous system (SNS) response might also cause hypertension, tachycardia, and dysrhythmias. In the absence of complete upper airway obstruction, complications are often localized and treated with supportive care once the foreign matter has been expelled or removed by bronchoscopy.[16]

Aspiration of blood may result from trauma or surgical manipulation and also may cause minor airway obstruction that is rapidly cleared by cough, resorption, and phagocytosis. Massive blood aspiration interferes with gas exchange through mechanical blockage of airways and leads to chronic fibrinous changes in air spaces or pulmonary hemochromatosis from iron accumulation in phagocytic cells. Aspiration of blood may result in infection, particularly if particles of soft tissue are aspirated along with the blood. Treatment involves correction of hypoxemia, maintenance of airway patency, and initiation of antibiotic therapy, if indicated.[15]

Aspiration of gastric contents is the most severe form of aspiration and may result in a chemical pneumonitis. Patients have diffuse bronchospasm (secondary to reflex airway closure), hypoxemia (compromised alveolar-capillary membrane), atelectasis (loss of surfactant), interstitial edema (loss of capillary integrity), hemorrhage, and adult respiratory distress syndrome. Gastric aspiration also may cause laryngospasm, infection, and pulmonary edema.

For this reason, the prevention of gastric aspiration, rather than its treatment, is the goal. Patients who are at risk for gastric aspiration (e.g., obese or pregnant patients or those with a history of hiatal hernia, peptic ulcer, or trauma) may be given histamine-2 (H_2) blockers, gastrokinetic agents, nonparticulate antacids, or anticholinergics before anesthesia induction. Prophylactic medications are not recommended for those patients who are not at risk.[20] Rapid-sequence induction is likely used. Intraoperatively a nasogastric tube may be inserted and is usually then removed to decrease gastric volume and decompress the stomach. Postoperatively the patient should be left intubated until airway reflexes return.

Treatment of gastric aspiration is directed toward correction of hypoxemia and maintenance of hemodynamic stability. Antibiotics are indicated only if signs of infection (e.g., fever, leukocytosis, positive culture results) are present. No beneficial effect of corticosteroids has been determined. Administration of corticosteroids may be indicated with the presence of inflammatory pneumonitis, but the immunosuppressant effect may exacerbate any secondary bacterial pneumonia.[21]

If aspiration causes hypoxemia, increased airway resistance, atelectasis, or pulmonary edema, institution of support with supplemental oxygen, PEEP, or CPAP and mechanical ventilation is often necessary. Pulmonary edema is usually secondary to increased capillary permeability, so diuretics should not be used to decrease intravascular volume. Bacterial infection does not always occur, so prophylactic antibiotics might merely promote colonization by resistant organisms. If evidence of secondary bacterial infections appears, specific antibiotic therapy is instituted, based on sputum samples obtained for Gram stain and culture or on prevailing colonization experience within the institution.[15]

Bronchospasm

Bronchospasm results from an increase in bronchial smooth muscle tone, with resultant closure of small airways. As a result of the strong increase in inspiratory force against these closed airways, airway edema develops, causing secretions to build up in the airway. Clinically, the patient demonstrates wheezing, dyspnea, use of accessory muscles, and tachypnea. Airway resistance is increased, and increased peak inspiratory pressures are noted if the patient is receiving mechanical ventilation.[10,22]

Bronchospasm may result from aspiration, pharyngeal or tracheal suctioning, endotracheal intubation, histamine release secondary to medications, or an allergic response, and it may be seen in greater frequency in patients with a history of asthma or chronic obstructive pulmonary disease.

Treatment of bronchospasm requires confirmation and removal of the precipitating cause. Pharmacotherapy is instituted, with the goals of decreasing airway irritability and promoting

bronchodilation. Medications used in the management of bronchospasm include salmeterol (Serevent) and β_2-agonists such as albuterol (Proventil, Ventolin), salbutamol, and terbutaline and, if the condition is life threatening, IV epinephrine. Anticholinergics such as atropine sulfate and glycopyrrolate have been given via nebulization to decrease secretions. Both IV and inhaled lidocaine attenuate histamine-induced bronchospasm; however, inhaled lidocaine works at a lower serum level than IV lidocaine.[22] Steroids have been used if the underlying cause is an inflammatory disease such as asthma.[15]

Hypoventilation

Hypoventilation is a common, easily recognizable complication in the PACU. It is manifested clinically by a decrease in respiratory rate that results in an increase in $Paco_2$ secondary to a decrease in alveolar ventilation. This may occur because of a decrease in central respiratory drive, poor respiratory muscle function, or a combination of both.[11]

Depression of central respiratory drive can occur with both IV and inhalation anesthetics. Central respiratory depression is most profound on admission to the PACU, although the time and route of anesthetic administration may suggest otherwise. For example, an IV dose of fentanyl given just before the patient emerges from anesthesia may not peak until later in the PACU. An intramuscular dose of an opioid takes substantially longer to peak than does an IV dose.[16]

Patients also may demonstrate a secondary stage of respiratory depression once certain stimuli are removed. For example, a patient may be admitted awake and breathing to the PACU with an endotracheal tube in place. After extubation, because of the loss of stimulation from the endotracheal tube, the patient may become hypercarbic secondary to residual opioid effects and hypoventilation.[10] Verbal and tactile stimulation, deep breaths, and repositioning the patient may increase ventilatory function and decrease carbon dioxide. Capnography may be of use in patients at risk.[15]

Poor respiratory muscle function can result from many conditions. Some of the most common situations are inadequate reversal of neuromuscular blocking agents, surgery involving the upper abdomen, positioning, obesity, and diseases involving the neuromuscular system.

Inadequate reversal of neuromuscular blocking agents can result in hypoventilation secondary to respiratory muscle weakness. Factors that can adversely affect neuromuscular blockade and reversal include certain medications, hypokalemia, hypermagnesemia, hypothermia, and acidosis.[23]

Medications that have been associated with prolongation of blockade include the aminoglycoside antibiotics (e.g., gentamicin, clindamycin, and neomycin), as well as magnesium and lithium. Hypermagnesemia and hypothermia may potentiate neuromuscular blockade. Hypokalemia and respiratory acidosis inhibit reversal.[23]

Upper abdominal surgery also can affect respiratory muscle function. Hypoventilation occurs because of a reduced vital capacity secondary to poor diaphragmatic function. A reduction in vital capacity of up to 60% has been noted on the first postoperative day.[11] Obesity, especially when combined with upper abdominal surgery, further contributes to hypoventilation because of the increased intraabdominal pressure in obese patients.

Diseases of the neuromuscular system also can affect ventilation. Patients with muscular dystrophy, myasthenia gravis, Eaton-Lambert syndrome, Guillain-Barré syndrome, or other muscle diseases can exhibit postoperative muscle weakness. Patients with severe scoliosis also exhibit poor respiratory muscle function. It is often in the best interests of patients with these disorders that they remain intubated in the PACU until complete return of function occurs, and any residual anesthetic effects are absent.

Cardiovascular Function

Hypotension

Classically, *hypotension* has been defined as a blood pressure of less than 20% of the baseline or preoperative blood pressure. However, the clinical signs of hypoperfusion, rather than numeric values, should be the indicators of compromise. Because the autonomic nervous system preferentially maintains blood flow to the brain, heart, and kidneys, signs of hypoperfusion to these organs (including disorientation, nausea, loss of consciousness, chest pain, oliguria, and anuria) reflect the failure of physiologic compensation. Hypoxia, which results from hypoperfusion, may cause lactic acidosis. Intervention must be implemented in a timely fashion so that cerebral ischemia, cerebrovascular accident (CVA), myocardial infarction or ischemia, renal ischemia, bowel infarction, and spinal cord damage do not develop.[24]

Hypotension in the PACU is most commonly caused by hypovolemia secondary to inadequate replacement of intraoperative fluid and blood loss. As a result, initial treatment should focus on restoring circulating volume. The patient should be assessed for active bleeding and a 300- to 500-mL fluid bolus of physiologic saline or lactated Ringer's solution should be given. If no response is noted, myocardial dysfunction should be considered the cause of hypotension.

Primary cardiac dysfunction, as is the case with myocardial infarction, tamponade, or embolism, results in an acute fall in ventricular emptying and cardiac output. Secondary cardiac dysfunction occurs as a result of the negative chronotropic and negative inotropic effects of medications.

Low systemic vascular resistance (SVR) also can contribute to hypotension. Numerous anesthetic agents cause histamine release with subsequent vasodilation (e.g., morphine, atracurium), whereas others cause vasodilation by directly relaxing arterial smooth muscle (e.g., volatile inhalation anesthetics, local anesthetics used for producing spinal anesthesia). Sensitivity to vasodilators such as hydralazine, sodium nitroprusside, and nitroglycerin also can produce profound hypotension. Sepsis may be another cause of low SVR.

Dysrhythmias that interfere with cardiac conduction and subsequently compromise cardiac output also can produce hypotension. Tachydysrhythmias prevent optimal ventricular filling and emptying. Conduction blocks compromise myocardial effectiveness, resulting in a lowered cardiac output and hypotension. See Box 50-7 for a differential diagnosis of hypotension in the postoperative patient.

Intervention should always include supplemental oxygen therapy while the cause of the hypotension is being investigated. Volume status should be evaluated, and preoperative and intraoperative fluid administration should be considered. Hypotension caused by artifact of the measurement system also should be considered—for example, a blood pressure cuff that is too large or too small or an inappropriate transducer height. The presence of hypotension secondary to myocardial dysfunction suggests the need for coronary vasodilators, inotropic therapy, and afterload reduction (e.g., through nitroglycerin therapy, dobutamine therapy, or both). Secondary myocardial dysfunction may require that administration of the causative medications be discontinued. Vasodilation resulting in lower SVR and symptomatic hypoperfusion can be treated with vasoconstrictive agents, either by IV bolus (ephedrine) or by infusion (dopamine or epinephrine).

BOX **50-7**

Differential Diagnosis of Hypotension in the Postanesthesia Care Unit

Intravascular Volume Depletion
- Persistent fluid losses
- Ongoing third spacing of fluid
- Bowel preparation
- Gastrointestinal losses
- Surgical bleeding

Increased Capillary Permeability
- Sepsis
- Burns
- Transfusion-related acute lung injury

Decreased Cardiac Output
- Myocardial ischemia/infarction
- Cardiomyopathy
- Valvular disease
- Pericardial disease
- Cardiac tamponade
- Cardiac dysrhythmias
- Pulmonary embolus
- Tension pneumothorax
- Drug induced (β-blockers, calcium channel blockers)

Decreased Vascular Tone
- Sepsis
- Allergic reactions (anaphylactic, anaphylactoid)
- Spinal shock (cord injury, iatrogenic high spinal)
- Adrenal insufficiency

Hypertension

Hypertension, defined as a 20% to 30% increase relative to the baseline blood pressure, is a common finding in the PACU and can be caused by stimulation of the SNS and pain, respiratory compromise, visceral distention, and significant increases in plasma catecholamine levels that produce vasoconstriction (Box 50-8).

Pain remains the leading cause of hypertension and tachycardia in the PACU and results in stimulation of the somatic afferent nerves, producing a pressor response known as the *somatosympathetic reflex*.[24] The use of analgesics attenuates the sympathetic response, thereby normalizing blood pressure.

Hypoxemia and hypercarbia cause direct stimulation of the vasomotor area of the medulla, resulting in increased vasomotor tone, increased arteriolar constriction, and increased blood pressure.[24] Correction of the respiratory compromise should result in normalization of blood pressure.

Distention of the bladder, bowel, or stomach causes stimulation of afferent fibers of the SNS, producing an increase in plasma catecholamine levels. Catheterization of the bladder and decompression of the bowel or stomach remove the offending stimulus.

Hypertension also may develop as a sequela of hypothermia. Increased catecholamine secretion is an important endocrine response to cold.[24] As cooling occurs, blood vessels become more sensitive to catecholamines, resulting in arteriolar and venous constriction. Rewarming reverses the process. As vasodilation occurs, reperfusion of the extremities and skin decreases systemic elevations in pressure.

Preexisting hypertension exists in many of the patients who develop hypertension in the PACU. The degree of elevation in pressure is greater if preoperative antihypertensive medications are withdrawn suddenly. Ideally, patients receive their antihypertensive medications on the day of surgery.

Hypertension also may be seen secondary to revascularization and baroreceptor stimulation after vascular or cardiac surgery, including carotid endarterectomy. Pharmacologic intervention is required for the protection of graft sites and the prevention of hemorrhage. Sodium nitroprusside and nitroglycerin are agents of choice for vasodilation.

A significant number of patients, especially those with a history of essential hypertension, will require pharmacologic blood pressure control in the PACU.[11] Agents that may be used for the reduction of blood pressure include hydralazine and labetalol hydrochloride. Hydralazine relaxes vascular smooth muscle, preferentially favoring the arteriolar circulation. Labetalol is both an α- and a β-blocking agent, causing peripheral vasodilation and slowing of the heart rate. Other beta blockers used postoperatively include metoprolol and esmolol. Beta-blockers assist in controlling the sympathetic responses of patients during recovery. α-2-agonists also can be used postoperatively to assist when needed. Many other agents are available and may include the patient's usual prescription antihypertensive for mild increases. Patients who were on β-blockers prior to surgery should be given a β-blocker the day of surgery. One of the surgical care improvement measures (SCIP) that is evaluated during the perioperative period is SCIP-cardiovascular-2. SCIP cardiovascular-2 measures the number of "surgery patients on a beta blocker prior to arrival who received a beta blocker during the peri-operative period."[25]

Dysrhythmias

Dysrhythmias seen in the PACU most commonly have an identifiable cause that is not an actual myocardial injury. The major postanesthetic and surgical factors that lead to a relatively high incidence of perioperative dysrhythmias include hypokalemia, hypoxia, hypercarbia, altered acid-base status, circulatory instability, and preexisting heart disease.

Arterial desaturation is a common postoperative complication that may result from obstruction or hypoventilation or less commonly from pulmonary embolism, pulmonary edema, or aspiration. A direct consequence of hypoxia is myocardial ischemia and depression of cardiac contractility. Signs of cardiac irritability may be manifested by atrial and ventricular dysrhythmias, conduction delays, and heart block.

Hypercarbia caused by reduced alveolar ventilation results in elevation of the arterial carbon dioxide tension, which in turn stimulates the SNS and sensitizes the myocardium to the arrhythmic effects of endogenous catecholamines. Among the earliest signs of hypercarbia are tachycardia and hypertension, which may progress to ventricular dysrhythmias.

Hypokalemia may occur secondary to hyperventilation, respiratory alkalosis, gastric suctioning, insulin administration, and

diuretic use. The ECG may demonstrate widening of the QRS complex, U waves, and ST-segment abnormalities that may progress into premature ventricular complexes, ventricular tachycardia, and ventricular fibrillation.

Acid-base disturbances may occur as a result of alterations in ventilation, gastrointestinal losses, and lactic acid production during hypotension or shock. The cardiovascular effects include increased cardiac excitability and irritability.

Hypotension may result in impaired oxygen transport and compromised coronary circulation, leading to myocardial ischemia with associated conduction deficits. The use of vasoconstrictive medications designed to treat the hypotension also may contribute to the development of dysrhythmias. Patients with preexisting heart disease, particularly those who have a history of myocardial infarction, are at continued risk for myocardial ischemia throughout the perioperative period.

Hypothermia prolongs the refractory period, contributing to the development of sinus bradycardia and atrial fibrillation. Conduction deficits may progress to atrioventricular block and eventually to ventricular fibrillation.[26]

Vagal reflexes are usually transient and are produced by the Valsalva maneuver or direct eye, vagal nerve, or carotid sinus pressure. Severe sinus bradycardia with possible ventricular escape beats may occur. Vagotonic medications such as neostigmine also can produce these dysrhythmias.

The presence of residual anesthetics in both blood and tissue in patients admitted to the PACU may contribute to dysrhythmias. Ketamine may contribute to sympathetic stimulation, resulting in tachyarrhythmias and hypertension, as can vagolytic drugs such as atropine and glycopyrrolate. Opioids such as morphine, fentanyl, and sufentanil may result in the indirect development of dysrhythmias. Respiratory depression, a potential side effect of opioids, may result in hypoxemia and hypercarbia, both of which are known to be dysrhythmogenic. Anticholinesterase agents may produce severe bradyarrhythmias or heart block.[27]

Surgical stress and pain can significantly increase plasma catecholamine levels. Although this sympathetic response may be mitigated by anesthetic administration, norepinephrine and epinephrine concentrations are consistently elevated in PACU patients who are in pain. Administration of analgesic medications may blunt this sympathetic response; however, cardiac irritability, tachycardia, and conduction dysrhythmias may occur.

Neuromuscular Function

Reversal of Neuromuscular Blockade

Incomplete reversal of neuromuscular relaxation can lead to postoperative airway obstruction and hypoventilation. Residual paralysis compromises cough, airway patency, ability to overcome airway resistance, and airway protection. Intraoperative use of shorter-acting relaxants might decrease the incidence of residual paralysis but does not eliminate the problem. Reversal agents such as neostigmine and edrophonium chloride will be given in conjunction with either atropine or glycopyrrolate.[23] A new reversal agent, sugammadex, is designed specifically to reverse rocuronium. The main advantage of sugammadex is reversal of neuromuscular blockade without relying on inhibition of acetylcholinesterase.[28] Marginal reversal can be more dangerous than near-total paralysis, because an agitated patient exhibiting uncoordinated movements and airway obstruction is more easily identified. A somnolent patient exhibiting mild stridor and shallow ventilation from marginal neuromuscular function might be overlooked. Insidious hypoventilation leading to respiratory acidemia or regurgitation with aspiration can occur later into recovery. Patients with coexisting neuromuscular abnormalities such as myasthenia gravis, Eaton-Lambert syndrome, or muscular dystrophies exhibit exaggerated or prolonged responses to muscle relaxants. Even without muscle relaxant administration, such patients can exhibit postoperative respiratory insufficiency from inadequate neuromuscular reserves.

Simple bedside tests help assess mechanical ability to ventilate. Forced vital capacity of 10 to 12 mL/kg and inspiratory pressure more negative than −25 cm H_2O imply that strength of ventilatory muscles is adequate to sustain ventilation. Sustained head elevation in a supine position, hand grip, and ability to bite down, swallow, and stick out the tongue are easily assessed parameters. These measures, along with tactile train-of-four and double-burst stimulation assessment, more accurately predict a patient's ability to maintain sustained ventilation.

Mental Status

Emergence Delirium

Postoperatively, emergence delirium is the alteration in neurologic functioning that causes the most concern to the practitioner. *Delirium* is defined as a condition that is characterized by extreme disturbances of arousal, attention, orientation, perception, intellectual function, and affect and is most commonly accompanied by fear and agitation.[29] There have been recent attempts to differentiate emergence delirium from agitation,[30,31] with *agitation* defined as mild restlessness and mental distress. Agitation can be due to pain, physiologic compromise, or anxiety. Delirium can be confused with agitation or be the source of agitation, and the two conditions can be very difficult to differentiate.[31] The incidence of postoperative delirium has been described to be 3% to 20%; with some procedures, the incidence may be as high as 75%. A recent study found an incidence of 4.7% in adult PACU patients.[32] Emergence delirium also appears to occur with greater incidence among combat veterans compared with the general military population of the same age.[33] The causes of postoperative delirium have been classified into four categories: withdrawal psychosis, toxic psychosis, circulatory and respiratory origin, and functional psychosis.[29]

Withdrawal psychosis is caused by withdrawal of various substances such as alcohol and illicit drugs. Alcohol withdrawal can be dangerous because it can cause delirium tremens. Clinical symptoms of delirium tremens may include hallucinations, extreme combativeness, and confusion.[29]

Amphetamine-induced delirium usually appears 1 hour after amphetamine use and disappears within 6 hours of use. Cocaine-induced delirium results from alteration of neurotransmitters. Management of withdrawal psychosis may include protection of patient safety and use of benzodiazepines or other sedatives.[29]

Toxic psychosis is caused by exposure to toxins, including toxic fumes that may occur in the OR, as from a malfunctioning laser. Adherence to the Occupational Safety and Health Administration's regulations and its mandates on monitoring help to limit the occurrence of these events.[34]

Circulatory and respiratory causes of emergence delirium most commonly include hypoxemia and hypercarbia, which may be the result of central respiratory depression, airway obstruction, or perfusion deficits. The primary cause of postoperative emergence delirium is always considered to be hypoxemia until proved otherwise. As a result, sedation of the agitated patient should never be considered until hypoxemia has been ruled out as the cause of agitation.

Functional psychosis is defined as a brief reaction of paranoia and other changes not caused by an organic abnormality. This diagnosis is made by exclusion after known organic causes have been ruled out.[34]

Although this classification is useful, other more frequently occurring causes of emergence delirium may be seen in the PACU. Confusion and agitation are common during recovery from inhalation anesthetics. Sevoflurane in particular has been associated with emergence delirium in children.[30] Many drugs used during the perioperative period have been reported to contribute to postoperative delirium. Ketamine, a phencyclidine derivative, is associated with hallucinations, delirium, and unpleasant dreams, particularly in patients between 16 and 65 years of age. Local anesthetics can cross the blood-brain barrier and may cause postoperative delirium. Nitrous oxide may cause acute mental status changes with prolonged exposure. Other anesthetic adjuncts associated with delirium include butyrophenones (e.g., droperidol), naloxone, and muscle relaxants, which can cause dissociative reactions, heightened pain perception, and hypoxemia, respectively. Delirium also has been reported as a side effect of antibiotic therapy (e.g., cefazoline, penicillin, streptomycin, chloramphenicol), antituberculosis drugs (e.g., isoniazid, cycloserine), antiviral agents (e.g., acyclovir), anticonvulsant medications (e.g., carbamazepine, phenytoin), and antiparkinsonian agents (e.g., levodopa, bromocriptine). Adverse reactions to medications that result in delirium have been reported with digitalis, antidysrhythmics (e.g., amiodarone, flecainide, lidocaine, mexiletine), β-blockers, calcium channel blockers, contrast dye, corticosteroids, chemotherapeutic agents, immunosuppressants, H_1 and H_2 blockers, antipsychotic medications, and clonidine.[33]

Premedicants, including anticholinergics, benzodiazepines, and opioids, may induce untoward reactions. Anticholinergics, specifically atropine and scopolamine, have been noted to cause central anticholinergic syndrome. These drugs cross the blood-brain barrier, altering the neurotransmitter balance and causing agitation, combativeness, and lack of cooperation. Benzodiazepines may contribute to postoperative delirium, especially in the elderly.[35] Flumazenil (Romazicon) remains the only benzodiazepine antagonist available to reverse the effects of benzodiazepine-induced delirium. Flumazenil 0.2 mg should be given over a 15-second interval with a redose after 1-2 minutes if the desired level of consciousness is not achieved. The doses may be repeated up to 1 mg with a 3 mg total to be administered within an hour. Seizures have been known to occur rarely, so the patient should continue to be observed. Opioids, particularly morphine, have been cited as a contributing factor to postoperative delirium secondary to respiratory depression and hypoxemia. In patients with renal failure, meperidine may cause excitation because of accumulation of normeperidine, a neuroexcitatory metabolic by-product. If naloxone is given to reverse the opioid, the dose should be in very small increments until the desired effect.

Metabolic disturbances associated with postoperative delirium include acidosis and alkalosis, electrolyte imbalance (e.g., magnesium, calcium, sodium), and porphyria. Treatment is directed at correction of the cause.

Other causes of postoperative delirium include pain, visceral distention (bowel and bladder), anxiety (including separation anxiety in children), hyperthermia, and hypothermia. Again, treatment is directed at correction of the cause. In a study of adult postanesthesia patients, the most common causes of emergence delirium were presence of an endotracheal tube, pain, and anxiety.[32] In children, determination of cause and treatment of delirium is complex, with pain and anxiety more easily recognized and treated than other anesthetic-related causes. Voepel-Lewis et al.[36] developed an algorithm for assessment, reassessment, and treatment decisions in children with emergence delirium.

Once hypoxemia has been eliminated as a cause of postoperative delirium, and all known causes have been evaluated, sedation may prove useful in controlling the agitation and providing for patient safety. Most events are time limited to the PACU and are resolved before discharge. Figure 50-1 summarizes the factors that contribute to postoperative delirium and treatment options.

Delayed Awakening

Delayed awakening is a common, often easily explained postoperative finding and can be defined as a clinician's expectation in a specific circumstance that the patient "should be awake by now" but is not. Although delayed awakening may slow turnover of PACU beds and delay patient discharge from the PACU, the causes and consequences of delayed awakening are rarely serious. The most common causes of delayed awakening are as follows:

- Prolonged action of anesthetic drugs
- Metabolic causes
- Neurologic injury

Prolonged action of anesthetic drugs is the most common cause of delayed awakening.[11] This may occur secondary to alterations in drug pharmacokinetics and pharmacodynamics. Pharmacokinetic alterations include changes in drug distribution secondary to mobilization of drugs from body tissue stores, redistribution, or decreased protein binding; changes in metabolism; and excretion secondary to renal or hepatic dysfunction. Pharmacodynamic alterations include increased patient sensitivity to drug effects because of extremes of age, hypothermia, or concomitant alcohol and drug use. Other patients at risk for delayed awakening are those with preexisting cognitive or psychiatric disorders, patients who chronically take sedative medications, patients who were intoxicated with alcohol or illicit drugs at the time of anesthesia, and those who were physically exhausted prior to surgery.[37]

Prolonged effects of inhalation anesthetics may be seen secondary to alterations in ventilation. Hypoventilation limits exhalation and prolongs elimination of inhalation agents.[38] Retention of

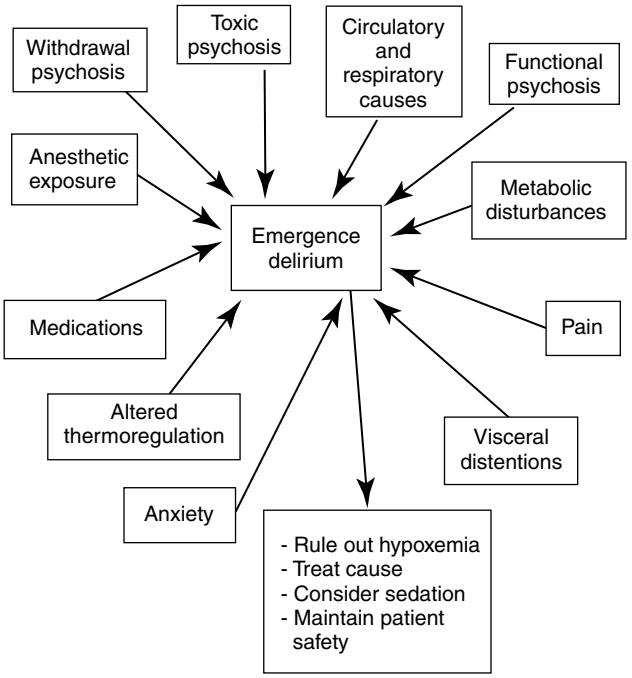

FIGURE **50-1** Emergence delirium in the postanesthesia care unit: contributing factors and treatment.

carbon dioxide contributes to narcosis, particularly in the presence of inhalation agents, and compounds the problem.

The potentiating effects of combining inhalation agents with IV anesthetics and opioids can also contribute to delayed awakening. Premedications, particularly the long-acting benzodiazepines diazepam and lorazepam, may contribute to delayed awakening, especially in the elderly.[39] Prolonged effects of inhalation and IV agents also may occur secondary to multiple drug interactions. Prolonged neuromuscular blockade may mean the patient is awake but unable to move. Some herbal supplements have the potential to cause delayed awakening, especially kava kava, St. John's wort, and valerian.[37]

Metabolic causes of delayed awakening include hypoglycemia, hyperglycemia, and electrolyte disturbances. Diabetic patients have an increased risk of postoperative hypoglycemia. Taking the usual insulin dose (or half the dose) on the morning of surgery, the patient's nothing-by-mouth (NPO) status, and the stress of surgery all contribute to the development of hypoglycemia.[39] It is important to monitor serum glucose levels intraoperatively and postoperatively. The current SCIP measure evaluates the postoperative serum glucose of cardiac surgery patients.[25] Central nervous system changes may occur as blood glucose levels fall below 50 mg/dL.[38] It is good practice to obtain a baseline blood glucose level of all diabetic patients before they are admitted to surgery. Procedures requiring general anesthesia that are longer than 2 hours will have greater glucose variations and require more frequent monitoring and treatment. Blood glucose levels of greater than 600 mg/dL can produce hyperosmolar, nonketotic, hyperglycemic coma. Approximately half of these patients have type 2 diabetes, but the syndrome can occur with severe dehydration (especially in the elderly), uremia, pancreatitis, sepsis, pneumonia, CVA, and large surface burns. Minimizing blood glucose variability during the perianesthesia period should be part of any glycemic control strategy.[39]

Electrolyte disturbances, specifically alterations in sodium, calcium, and magnesium, can prolong awakening. Dilutional hyponatremia, occurring secondary to water intoxication, may develop after transurethral prostate resection surgery, producing sedation, coma, or even hemiparesis. Hypocalcemia, seen after parathyroidectomy and occasionally thyroidectomy, may delay awakening. Hypermagnesemia, which may occur after prolonged administration of magnesium sulfate to women with eclampsia or preeclampsia, may result in sedation and muscle weakness after general or regional anesthesia for cesarean section.[39]

Neurologic injury is a rare cause of delayed awakening of the non-neurosurgical patient. Potential causes of neurologic injury include CVA, intracranial hemorrhage, increased intracranial pressure, uncontrolled extreme hypertension (especially in the anticoagulated patient), air or fat emboli, and uncontrolled hypotension (especially in patients with hypertension or occlusive carotid disease).[38]

Evaluation of the patient who fails to awaken begins with an assessment of the patient's preoperative status and a review of intraoperative events. Oxygenation and gas exchange must be assessed and verified with pulse oximetry, physical assessment, and arterial blood gas analysis. When prolonged drug effects are suspected as the cause of delayed awakening, care must be taken to ensure the adequacy of ventilation and oxygenation through appropriate patient monitoring.

Residual drug effects should be considered. If possible and not contraindicated, reversal of medications should be attempted. Flumazenil reverses benzodiazepines, and naloxone reverses the opioids.[37]

If other contributing factors are found, intervention should be initiated. Hypothermia necessitates rewarming, and electrolyte disturbances require correction. Hypoglycemia and hypocalcemia are treated with the IV administration of glucose and calcium, respectively. Hyperglycemia is treated with IV insulin to lower blood glucose levels and 0.5% normal saline to correct dehydration.

A neurologic cause of delayed awakening is usually either a diagnosis that is initially expected because of patient status or known because of intraoperative events or a diagnosis of exclusion (i.e., suspected after all other causes have been ruled out). At this point, a computed tomography (CT) scan and neurologic consultation are warranted for a more in-depth evaluation.[11,37]

Pain

Relief of surgical pain with minimal side effects is a primary goal of PACU care and a very high priority for both anesthesia provider and patient. Patients should be assessed on admission to PACU and at frequent intervals using a verbal rating scale or visual analog scale to assess for severity of pain (Figure 50-2).[9,40-42] When prioritizing pain assessment, the patient's self-report of pain is the most important measure of pain. Other measures to assess pain intensity include the patient's exposure to painful procedures; behavioral signs, such as crying or agitation; a proxy pain rating by someone who knows the patient well; and physiologic indicators, such as elevated vital signs.[42] Inadequate postoperative analgesia is a major source of preoperative fear and postoperative dissatisfaction in surgical patients. Apfelbaum et al.[41] found that approximately 80% of postoperative patients experienced acute pain, with most of the patients experiencing pain they described as moderate,

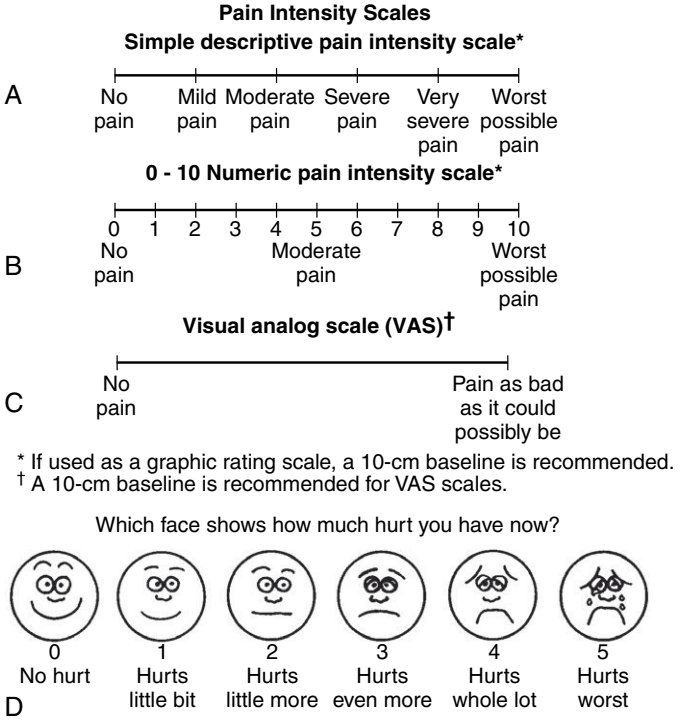

FIGURE **50-2** Pain intensity scales. (**A-C** from Acute Pain Management Guideline Panel. *Acute Pain Management in Adults: Operative Procedures: Quick Reference Guide for Clinicians* [AHCPR Publication No. 92-0019]. severe, or extreme. In addition to improving patient comfort, relief of pain reduces SNS response and helps avoid hypertension, tachycardia, and dysrhythmias (Table 50-1).

New research is underway to determine other predictors of severe postoperative pain. Yang et al.[42] looked for predictors of acute postoperative pain in 236 female patients. A multiple logistic regression determined that severe postoperative pain occurred significantly more often in patients with the CYP2D6 poor metabolizer (PM) genotype and smokers.

Incisional pain may be effectively treated with careful titration of IV opioids with frequent cardiorespiratory assessments. Short-acting IV opioids are useful to expedite discharge and minimize nausea in ambulatory settings. Ketorolac or IV acetaminophen are effective analgesics with antiinflammatory characteristics that lower opioid requirements.[40]

Other analgesic modalities provide effective pain relief beyond the PACU. IV opioid loading in the PACU is important for smooth transition to patient-controlled analgesia. Injection of opioids into the epidural or subarachnoid space during anesthesia or in the PACU often yields prolonged postoperative analgesia.[40] Epidural opioid analgesia is effective after thoracic and upper abdominal procedures and helps wean patients with obesity or chronic obstructive pulmonary disease from mechanical ventilation. Epidural analgesia also may improve surgical outcomes after orthopedic and urologic procedures. With epidural or intrathecal opioid administration, immediate and delayed ventilatory depression can occur, along with other side effects such as nausea and pruritus.

Patient-controlled analgesia (PCA) allows patients to administer their own pain medication. The most commonly used methods of PCA are intravenous or epidural. Patient therapy should be initiated in the PACU after the patient's initial pain level is under control. Oral opioids are used often with outpatients and have been studied in appropriate orthopedic patients with success. One device called the MOD (Medication on Demand) allows patients to access oral analgesics at the bedside. Medications already in use, such as fentanyl and sufentanil, are currently undergoing development for new drug delivery systems that include intranasal, dry powder inhalation, nebulization, transmucosal, sublingual, and buccal sprays.[43] The newest nonopioid available in intravenous format is acetaminophen (Ofirmev). The onset of analgesia occurs within 5 to 10 minutes of IV administration, with the peak analgesic effect occurring within 1 hour and duration of 4 to 6 hours.[44] Availability of acetaminophen in the postoperative patient adds an effective nonopioid as an option when developing a multimodal plan of pain management.

Placement of long-acting regional analgesic blocks reduces pain, controls SNS activity, and often improves ventilation. For example, interscalene block yields almost complete pain relief from shoulder or upper extremity procedures, with only moderate inconvenience from motor impairment. Paralysis of the ipsilateral diaphragm can impair postoperative ventilation in patients with marginal respiratory reserve. Caudal analgesia is effective in children after inguinal or genital procedures, whereas infiltration of local anesthetic into joints, soft tissues, or incisions decreases the intensity of pain. Other uses of local anesthesia include continuous wound infusion, in which the catheter is inserted at the end of the case by the surgeon, and perineural infusions, in which the anesthesia provider inserts the catheter near the affected peripheral nerves or a nerve plexus.[45] Deposition of long-acting liposomal formulations of bupivicaine (Exparel) to the surgical site can provide pain relief post discharge.

Opioid treatment for postoperative or chronic pain is frequently associated with adverse effects, the most common being dose-limiting and debilitating bowel dysfunction. Postoperative ileus, although attributable to surgical procedures, is often exacerbated by opioid use during and after surgery. Postoperative ileus is marked by increased inhibitory neural input, heightened inflammatory responses, decreased propulsive movements, and increased fluid absorption in the gastrointestinal tract. The current management of opioid-induced bowel dysfunction among patients receiving opioid analgesics consists primarily of nonspecific ameliorative measures. Clinical studies with the agent alvimopan suggest that it may normalize bowel function without blocking systemic opioid analgesia in abdominal laparotomy patients with opioid-related postoperative ileus.[46]

Nonpharmacologic interventions may include positioning for comfort, verbal reassurance, touch, applications of heat or cold, massage, transcutaneous electrical nerve stimulation, relaxation techniques, imagery, biofeedback-controlled breathing, and use of the patient's support system (e.g., parent or significant other),

TABLE 50-1 Harmful Effects of Unrelieved Pain

Domains Affected	Specific Responses to Pain
Endocrine	↑ ACTH, ↑ cortisol, ↑ ADH, ↑ epinephrine, ↑ norepinephrine, ↑ GH, ↑ catecholamines, ↑ renin, ↑ angiotensin II, ↑ aldosterone, ↑ glucagon, ↑ interleukin-1, ↓ insulin, ↓ testosterone
Metabolic	Gluconeogenesis, hepatic glycogenolysis, hyperglycemia, glucose intolerance, insulin resistance, muscle protein catabolism, ↑ lipolysis
Cardiovascular	↑ Heart rate, ↑ cardiac workload, ↑ peripheral vascular resistance, ↑ systemic vascular resistance, hypertension, ↑ coronary vascular resistance, ↑ myocardial oxygen consumption, hypercoagulation, deep vein thrombosis
Respiratory	↓ Flows and volumes, atelectasis, shunting, hypoxemia, ↓ cough, sputum retention, infection
Genitourinary	↓ Urinary output, urinary retention, fluid overload, hypokalemia
Gastrointestinal	↓ Gastric and bowel motility
Musculoskeletal	Muscle spasm, impaired muscle function, fatigue, immobility
Cognitive	Reduction in cognitive function, mental confusion
Immune	Depression of immune response
Developmental	↑ Behavioral and physiologic responses to pain, altered temperaments, higher somatization, infant distress behavior, possible altered development of the pain system, ↑ vulnerability to stress disorders, addictive behavior, and anxiety states
Future pain	Debilitating chronic pain syndromes: postmastectomy pain, postthoracotomy pain, phantom pain, postherpetic neuralgia
Quality of life	Sleeplessness, anxiety, fear, hopelessness, ↑ thoughts of suicide

particularly in children. Nonpharmacologic interventions should supplement and not replace pharmacologic therapy.[9]

Most of the current guidelines for pain management are very general and do not offer specific guidelines associated with different types of surgery.[47] The newest outlook for evidence-based guidelines in the field of pain management are procedure-specific guidelines offered via a web-based program called "PROSPECT" (Procedure-Specific Postoperative Pain Management).[48,49] An international panel of surgeons and anesthesiologists reviews procedure-specific pain research and grades the evidence.[48] Then clinical practice guidelines and recommendations are developed after consensus by the working group (Figure 50-3). The PROSPECT website offers procedure-specific guidelines for managing pain associated with abdominal hysterectomy, herniorrhaphy, open colon resection, laparoscopic cholecystectomy, thoracotomy, total hip arthroplasty, and total knee arthroplasty.[49]

Hypothermia

Hypothermia is a condition marked by an abnormally low internal body temperature (below 36° C), that occurs when systemic heat loss exceeds heat production.[50] Many patients are admitted into the PACU with hypothermia, which can prolong recovery, compromise physiologic stability, and contribute to postoperative morbidity. The patient's interaction with the environment determines the degree of heat loss. Heat loss may occur via radiation, convection, conduction, or evaporation.

Radiant heat loss involves the loss of heat from a warm or hot surface (the body) to a cooler one (the environment). It does not require that the two surfaces be in direct contact with each other. Radiant heat loss accounts for 40% to 60% of heat loss to the environment. It is especially profound in the elderly, debilitated, and neonatal populations.[51,52]

Convective heat loss depends on the existence of a temperature gradient between the body and the ambient air. This type of heat loss may occur in the OR, particularly in laminar flow rooms, and accounts for 25% to 50% of heat loss.[31,52]

Conductive heat loss involves loss of heat from a warm surface that comes into contact with a cooler one; it accounts for as much as 10% of heat loss in the OR, where patients lose heat to cooler OR tables, sheets, drapes, skin preparation fluids, and IV fluids or irrigants.[51,52]

Evaporative heat loss involves transfer of heat during the change from a liquid to a gas. Evaporative heat loss occurs via perspiration, respiration, or exposed viscera during surgery. Evaporation accounts for as much as 25% of heat loss in the OR.[51,52]

Patients at high risk for the development of hypothermia can be identified. Elderly patients are at risk because of their decreased subcutaneous fat and alterations in their hypothalamic function. Neonates are at risk because of their immature thermoregulatory center and their high surface-to-volume ratio. Intoxicated individuals are at risk because of vasodilation and depression of their heat regulatory center. Patients taking vasodilators, nonsteroidal antiinflammatory agents, and phenothiazines have alterations in thermoregulation that are caused by either vasodilation or suppression of the thermoregulatory center.[53] Other risk factors are female gender, decreased ambient room temperature, length and type of surgery, preexisting conditions such as peripheral vascular disease or burns, use of cold irrigants, and use of general or regional anesthesia.[50,51,53,54]

General anesthetics depress the thermoregulatory center, with a usual temperature drop of 1° to 3° C. General anesthesia reduces the vasoconstriction threshold; general anesthesia and regional anesthesia both cause peripheral vasodilation, which results in a core-to-peripheral redistribution of heat.[55] Opioids and muscle relaxants depress voluntary shivering as a mechanism for the generation of heat. Any patient in whom a body cavity is entered may lose heat via convection and evaporation. Irrigation solutions used in genitourinary procedures or with cardioplegia in cardiac surgery cause internal cooling.[56]

Physiologically, hypothermia results in decreased oxygen availability by shifting of the oxyhemoglobin dissociation curve to the left. Shivering may increase oxygen demand by 400% to 500%. Metabolically dependent processes slow, thereby decreasing drug biotransformation. Renal transport processes are slowed, thereby decreasing glomerular filtration. Cardiac rate and rhythm disturbances, including bradydysrhythmias and premature ventricular contractions, may occur. Central nervous system depression may

be profound.[57] Other adverse effects of perioperative hypothermia include patient discomfort, increased adrenergic stimulation, coagulopathy, impaired wound healing, surgical site infection, and increased hospital costs.[50,51,54,58,59]

Treatment of hypothermia should ideally be focused on prevention. Assessment of the patient's need for prewarming begins preoperatively, and active warming measures can be instituted for hypothermic patients.[9,50,60] As a result of positioning, operating time, and anesthetic exposure, therapeutic intervention most often begins in the PACU. Every patient in the PACU should be assessed for hypothermia and care provided as suggested in the multidisciplinary American Society of PeriAnesthesia Nurses (ASPAN) evidence-based clinical practice guideline for the promotion of perioperative normothermia (Figure 50-4).[50] Passive rewarming is designed to maximize basal heat production. Active rewarming consists of the use of external rewarming techniques and may include the use of heated blankets, heated water blankets, and radiant warmers. In a systematic review, Moola and Lockwood[60] determined that single strategies such as forced-air warming were more effective than passive warming; however, combined strategies, including using prewarming preoperatively, use of warmed fluids plus forced-air warming as other active

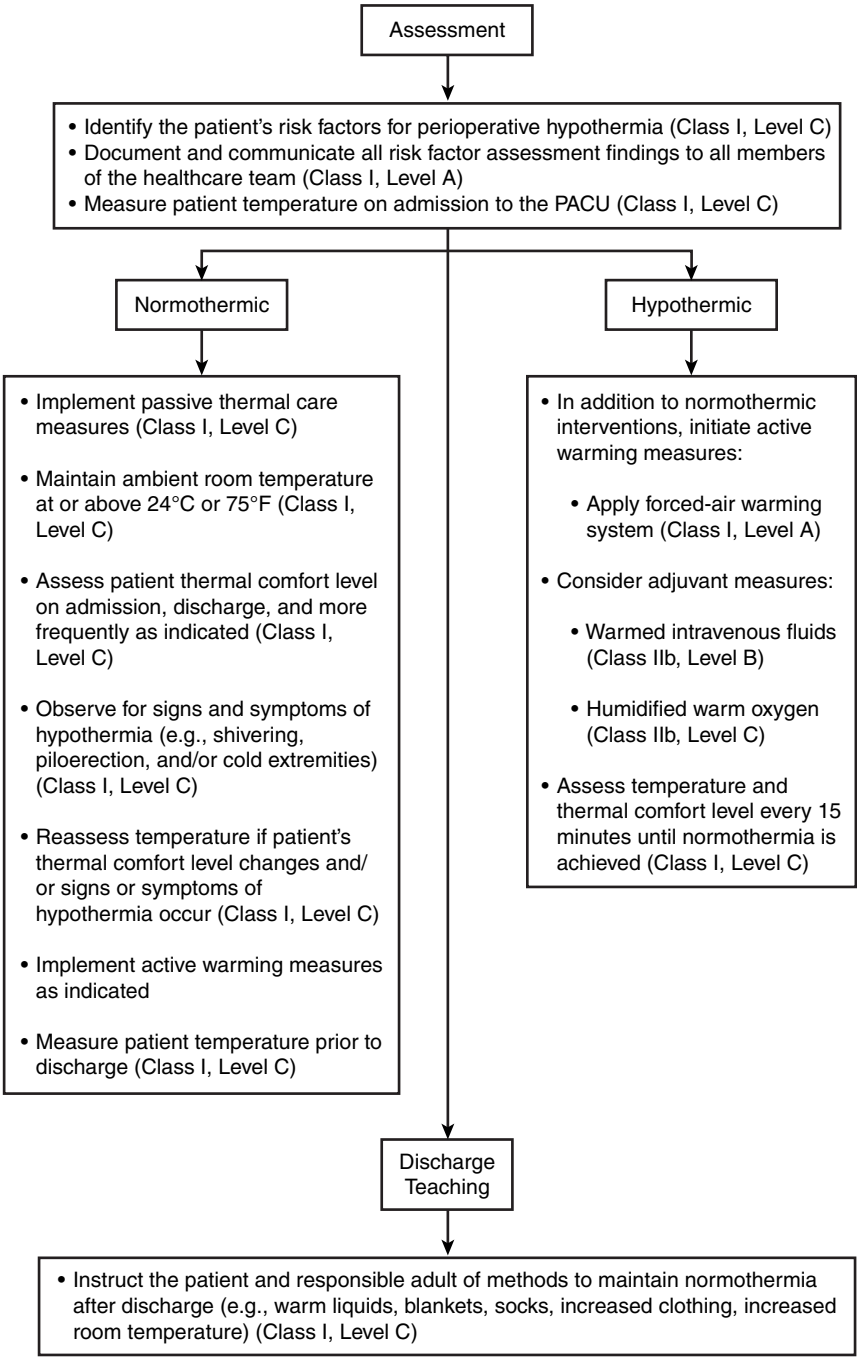

FIGURE **50-4** Preoperative, intraoperative, and postoperative patient management recommendations for promotion of normothermia. *PACU,* Postanesthesia care unit. (From Hooper et al. ASPAN's evidence-based clinical practice guideline for the promotion of perioperative normothermia. 2nd ed. *J Perianesth Nurs*. 2010;25:346-365.)

strategies were more effective in vulnerable groups. Forced-air rewarming systems are the most effective method for treating hypothermia.[5]

Postoperative shivering consists of muscular tremor and rigidity. It is often associated with body heat loss, although hypothermia alone does not fully explain the occurrence of shivering. Shivering is self-limiting, never becomes chronic, and is rarely associated with major morbidity. However, it affects the comfort of patients and may sometimes lead to more serious complications.[61] Treatment is rewarming. However, when clinically indicated, small doses of meperidine, ketamine, dexmedetomidine, hydrocortisone, granisetron, and ondansetron can be effective in the treatment of shivering during emergence and recovery.[62]

Nausea and Vomiting

In 1914 the first journal devoted solely to the topic of anesthesia featured an original article titled "Prophylaxis of Postanesthetic Vomiting."[63] More than 90 years later, postanesthetic vomiting is still one of the major problems faced in the PACU. Postoperative nausea and vomiting (PONV) affects 20% to 30% of all surgical patients, and the chance for PONV can be as high as 70% to 80% for high-risk patients.[64] Post-discharge nausea and vomiting (PDNV) is now being considered as an equally troublesome and all-too-frequent patient complication. The incidence of vomiting is lower than nausea.[65-67] Risk factors can be divided into three categories: patient specific, anesthetic related, and surgery related. Risk factors for PONV are listed in Box 50-9.[68]

The patient-specific risk factors listed in Box 50-9 are independent predictors for PONV. Females experience PONV two to three times more often than males, although these differences do not show up until after puberty. Being a nonsmoker and having a history of motion sickness or PONV are also independent predictors of PONV. Other associated factors are migraines, better health status as defined by the ASA risk classification, and anxiety. Children ages 11 to 14 experience an increased incidence of PONV. The highest rate occurs in young adults but decreases in older adults.[64,68-70]

BOX 50-9

Primary Risk Factors Associated with Postoperative Nausea and Vomiting

Patient Specific
- Female gender
- Age less than 50 years old
- Nonsmoker
- History of PONV
- History of motion sickness

Anesthetic Related
- Use of volatile anesthetics
- Use of nitrous oxide
- Intraoperative and postoperative use of higher doses of opioids

Surgery Related
- Duration of surgery more than 1 hour
- Type of surgery, especially laparoscopy

Data from Murphy MJ, et al. Identification of risk factors for postoperative nausea and vomiting in the perianesthesia patient. *J Perianesth Nurs*. 2006;21:377-384; Gan TJ, et al. Society for Ambulatory Anesthesia guidelines for the management of postoperative nausea and vomiting. *Anesth Analg*. 2007;105:1615-1628; Apfel CC, et al. Who is at risk for postdischarge nausea and vomiting after ambulatory surgery? *Anesthesiology*. 2012;117(3):475-486.
PONV, Postoperative nausea and vomiting.

The choice of anesthetic agent may influence the incidence of PONV. Early vomiting in the PACU is commonly the result of anesthetic agents.[71] PONV occurs more often with inhalation anesthetics than with total intravenous anesthesia (TIVA) techniques, and the risk of PONV decreases significantly after regional anesthesia. The use of nitrous oxide has been associated with PONV, but its relationship may not be as important as originally thought.[68] Desflurane, isoflurane, and sevoflurane have not shown significant differences in the incidence of nausea and vomiting after their use. Propofol, used as an induction agent and IV anesthetic, is associated with a lower incidence of postoperative nausea and vomiting, whereas etomidate and ketamine may increase this adverse effect.[72] Propofol does not appear to reduce the incidence of PDNV possibly due to the short half-life.[67] Postoperative use of opioids is strongly correlated with PONV, although the effect of low doses of intraoperative opioids is less well defined.[68]

The duration of surgery contributes to the incidence of PONV. Longer procedures are associated with a longer exposure to inhalation agents and possibly a larger dose of opioids during the surgery. The type of surgical procedure also has been cited as a contributing factor in PONV, although the evidence is conflicting about site and types of surgeries.[68,70] In children, strabismus and orchiopexy surgery are associated with a higher incidence of PONV. Patients undergoing tonsillectomy and adenoidectomy have a high incidence of nausea and vomiting as a result of swallowed blood.[73] In adults, an increased incidence of nausea and vomiting has been noted in patients undergoing laparoscopy procedures, especially cholecystectomy, breast surgery, gynecologic surgery, intracranial/neurosurgery, and otologic and ophthalmic procedures.[15,68,70]

Simplified risk-assessment instruments are available that identify patients' risk for PONV. One tool in widespread use is Apfel's risk assessment tool.[64] The patient is scored based on four risk factors: gender, smoking status, history of PONV or motion sickness, and postoperative use of opioids. A patient's risk increases with the number of risk factors present. An assessment of risk factors should be done preoperatively and the management of patients at risk guided by the number of risk factors and chance of PONV. The expected incidence of PONV and PDNV based on the number of risk factors is noted in Table 50-2.

The Society for Ambulatory Anesthesia and ASPAN offer clinical practice guidelines and recommendations for antiemetic prophylaxis and treatment of PONV and PDNV.[69,70]

Management of nausea and vomiting should originate from a prophylactic rather than a therapeutic approach, particularly in patients identified as at risk. The patient who experiences PONV may begin with nausea, a subjective feeling of discomfort or need to vomit.[68] Nausea can be rated on a verbal descriptor scale or numeric rating scale to determine its severity. Every individual clinician and anesthesia department has developed techniques to address these issues. Commonly, antiemetic prophylaxis will be given to patients at risk. The number and variety of agents administered will be increased according to the number of risk factors present. This is referred to as a multimodal approach. Smaller doses of drugs with differing mechanisms are chosen to allow for a broader array of potential coverage.[74] If a patient experiences PONV and has already received an antiemetic, a rescue drug or drugs with a different mechanism are chosen.[69,70,75,76] Other rescue interventions should be implemented, including verification of adequate hydration, since supplemental IV crystalloids are

associated with a lower incidence of several PONV outcomes.[77] Appropriate nonpharmacologic therapy, such as aromatherapy, may be instituted.[69]

Drugs that block the serotonin receptors (5-HT_3) are ondansetron, dolasetron, granisetron, and palonosetron. Droperidol blocks the dopamine (D_2) receptor sites (although the Food and Drug Administration [FDA] black box warning about QT prolongation and required ECG monitoring must be kept in mind). Other D_2-blocking agents are prochlorperazine or metoclopramide. For histamine receptors, promethazine or diphenhydramine can be used. Glycopyrrolate or scopolamine patches may be used for the muscarinic receptors. Dexamethasone is often given in conjunction with a 5-HT_3 blocking agent or droperidol. Substance P is another neurotransmitter that belongs to the neurokinin family of neurotransmitters. Substance P has affinity for neurokinin 1 (NK-1) receptors. The only neurokinin antagonist at the present time is aprepitant, which can be given orally as a prophylactic agent.[15,76]

Side effects (e.g., agitation, restlessness, drowsiness) may be associated with the use of some antiemetics. Prophylaxis using a combination of antiemetic drugs has been suggested as an effective strategy for minimizing postoperative nausea and vomiting.[70,76,78] Ephedrine also has been used for maintaining systemic blood pressure, thereby minimizing cerebral ischemia and preventing postoperative nausea and vomiting.[70] The FDA warning for droperidol is intended to increase awareness of the potential for cardiac dysrhythmias during drug administration and to encourage consideration of alternative medications for patients at high risk for cardiac dysrhythmias.[79] Droperidol currently carries a warning about cases of sudden death at high doses (greater than 25 mg) in patients at risk for cardiac dysrhythmias. Recent research has shown QT prolongation (i.e., delayed recharging of the heart between beats) within minutes after injection of a dose of droperidol at the upper end of the labeled dose range. Prolonged QT is dangerous as it may result in a fatal heart arrhythmia known as *torsades de pointes*. Historically the typical dose of droperidol given to adults with symptoms of postoperative nausea and vomiting is in the range of 0.625 to 2.5 mg IV.[80]

Nonpharmacologic interventions also may be appropriate for the patient with PONV in addition to pharmacologic interventions.[15,69,70,81] Acupuncture, transcutaneous electrical nerve stimulation, acupoint stimulation, and acupressure have been shown to be effective in reducing the incidence of PONV and need for rescue medication. P6 stimulation has been shown to be effective, as well as Korean hand acupoints.[69,70,82] Aromatherapy (e.g., isopropyl alcohol or peppermint oil) has been used to treat PONV.[15,81,82] There are limited studies to date, but some show improvement in PONV. Aromatherapy was identified by the ASPAN guideline as an option with limited evidence but little risk to the patient.[69] Some commonly used antiemetics for PONV and PDNV are listed in Table 50-3. The physiologic and pharmacologic effects of drugs, and the brain and peripheral sites that influence vomiting are shown in Figure 12-3.

TABLE 50-2 Incidence of PONV and PDNV Based on the Number of Risk Factors

Number of PONV Risk Factors	Incidence %
1	10-20
2	40
3	60
4 or more	80

PONV risk factors include: female gender, age younger than 50 years, history of motion sickness and/or PONV, nonsmoking, and the use of postoperative opioids.

Number of PDNV Risk Factors	Incidence %
0	10
1	20
2	30
3	50
4	60
5	80

PDNV risk factors include: female gender, history of motion sickness and/or PONV, age less than 50 years, the use of postoperative opioids, and PONV in the PACU.

Fluids

The goal of fluid management during the perioperative period is to maintain adequate intravascular fluid volume, left ventricular filling pressure, cardiac output, systemic blood pressure, and oxygen delivery to tissues. Appropriate concentrations of body fluid and electrolytes in the perioperative patient is essential to normal physiologic function of all body systems.[83] According to the ASA practice guidelines,[5] routine perioperative assessment of patients' hydration status and fluid management reduces adverse outcomes and improves patient comfort and satisfaction. On the patient's admission to the PACU, intravascular volume is estimated, with consideration given to preoperative status, type and duration of surgery, estimated blood loss, fluid replacement, and hemostasis. Monitoring urine output as an index of intravascular volume can be misleading. Surgery and anesthesia impair renal tubular concentrating ability, and glycosuria causes osmotic diuresis, each falsely indicating that intravascular volume is adequate. Central venous pressure, pulmonary arterial pressure, or transesophageal ultrasound monitoring can help clarify volume status. Symptoms such as poor skin perfusion, for example, cool, pale, and clammy skin, particularly in the feet; oliguria; hypotension; tachycardia; and tachypnea can indicate hypovolemia.[83]

A reduction in circulating intravascular volume decreases ventricular filling and cardiac output. SNS-mediated tachycardia, increased SVR, and venoconstriction might compensate for a 15% to 20% loss of intravascular volume. Greater deficits can cause hypotension. Failure to replace preoperative fluid deficit and fluid or blood lost during surgery frequently causes hypovolemia. In the PACU, ongoing hemorrhage, sweating, and exudation of fluid into tissues (i.e., third-space losses) exacerbate hypovolemia. Blood loss is often occult, as with retroperitoneal bleeding, diffuse oozing related to coagulopathy, or hemorrhage into muscle after trauma or orthopedic procedures. Third-space losses can continue for up to 48 hours after surgery and can be massive during high-permeability pulmonary edema or accumulation of ascites. In a hypothermic, venoconstricted patient, a low intravascular volume might maintain cardiac output on PACU admission but cause hypotension when venous capacity increases during rewarming.[50]

Urinary Output and Voiding

Monitoring kidney function during recovery reduces morbidity in patients with marginal cardiovascular or renal status. The ability to void after spinal or epidural anesthesia should be assessed, because autonomic effects of regional anesthetics or opioids interfere with sphincter relaxation and promote urine retention.[84-86] Urinary retention is common after urologic, inguinal, and genital surgery and frequently delays discharge. It is reasonable to discharge inpatients to a surgical floor and selected ambulatory surgical patients from the facility before they void.[5] However, it is important to ensure that urine output is monitored after discharge from the PACU to avoid urinary retention. A predictor of postoperative urinary retention (POUR) was the presence of greater than 500 mL of urine in the bladder immediately after spinal anesthesia.[84] The amount of urine retained in the bladder can be assessed with use of a bladder scanner.[85] A decision can be made at that time if it is appropriate to do an in-and-out catheterization to drain the urine. The incidence of POUR can contribute to an extra 26 minutes in the length of stay in the PACU. This longer length of stay was not statistically significant, but the authors deemed it clinically significant.[84] It is prudent to give ambulatory patients who are discharged without voiding a specific time interval in which to void (e.g., 6 to 8 hours after discharge). If retention persists, the patient should be instructed to contact a healthcare facility. Patients with indwelling catheters should have urinary output recorded hourly. The Joint Commission added SCIP-9 measure as a required indicator in 2011. That measure requires that the urinary catheter is removed on postoperative day 1 (POD 1) or postoperative day 2 (POD 2) with day of surgery being day zero.[86]

Urine color is not useful for assessment of renal tubular function such as concentrating ability, but color can signal hematuria, hemoglobinuria, or pyuria. Urine osmolarity is a more reliable index of tubular function than specific gravity, which is affected by molecular weight.

Oliguria (less than 0.5 mL/kg/hr) occurs frequently during recovery and usually reflects an appropriate renal response to hypovolemia or systemic hypotension. However, a decreased urine output might indicate abnormal renal function. The acceptable degree and duration of oliguria vary with underlying renal status, the surgical procedure, and the anticipated postoperative course. If events related to the surgical procedure could jeopardize renal function (e.g., aortic cross-clamping, severe hypotension, massive transfusion), oliguria must be aggressively evaluated. In patients without catheters, bladder volume and interval since last voiding should be checked to help differentiate between oliguria and inability to void. Urinary catheters should be checked for kinking and obstruction by blood clots or debris. Patient position might also place the catheter tip above the urinary level in the bladder.[85]

Polyuria, a state of profuse urine output, usually reflects generous intraoperative fluid administration. Osmotic diuresis caused by hyperglycemia and glycosuria is another cause, particularly if glucose-containing crystalloid solutions have been infused. Polyuria might also reflect intraoperative diuretic administration. Sustained polyuria (4 to 5 mL/kg/hr) can indicate abnormal regulation of water clearance, especially if urinary losses compromise intravascular volume and systemic blood pressure. Polyuria related to diabetes insipidus occurs secondarily to intracranial surgery, pituitary ablation, head trauma, increased intracranial pressure, and inadvertent omission of preoperative vasopressin. The diagnosis is made by comparing urine and serum electrolytes and osmolarity. High-output renal failure also should be considered as a cause.[16]

TABLE 50-3 Antiemetic Drugs for Postoperative and Postdischarge Nausea and Vomiting

Drug	Usual Adult Dose	Comment
5-HT$_3$ Antagonists		
Ondansetron (Zofran)	4-8 mg IV	Effective for prevention of both nausea and vomiting; more effective for PONV than PDNV
Granisetron (Kytril)	1 mg IV or transdermal patch	Patch may be effective for PDNV
Dolasetron (Anzemet)	12.5 mg IV	Used for PONV
Palonosetron (Aloxi)	0.075 mg IV	Long duration may make it effective for PDNV
Dopamine Antagonists		
Droperidol (Inapsine)	0.625-1.25 mg IV	See text for discussion of black box warning
Metoclopramide (Reglan)	10-20 mg IV	Contraindicated in patients with gastric obstruction due to prokinetic effects
Prochloperazine (Compazine)	10 mg IV	Sedation prominent
Antihistamines		
Hydroxazine (Atarax)	12.5-25 mg IV	Sedation prominent
Promethazine (Phenergan)	12.5-25 mg IV	Sedation prominent
Diphenhydramine (Benadryl)	25 mg IV or IM	Sedation prominent
Glucocorticoid		
Dexamethasone (Decadron)	4-8 mg IV	More effective for PDNV than PONV
Anticholinergic		
Scopolamine Transdermal (Transderm-Scop)	2.5 cm^2 patch contains 1.5 mg scopolamine	Long duration may make it effective for PDNV
Neurokinin Antagonist		
Aprepitent (Emend)	40 mg PO	Long duration may make it effective for PDNV

IV, Intravenous; *IM*, intramuscular; *PO*, oral; *PONV*, postoperative nausea and vomiting; *PDNV*, postdischarge nausea and vomiting; *5-HT$_3$*, serotonin.

DISCHARGE FROM THE POSTANESTHESIA CARE UNIT

The patient leaving the PACU may be discharged to home, an ambulatory surgical unit, a surgical inpatient unit, or an intensive care unit. The choice of a discharge facility should depend on the patient's need and physical status and the availability of appropriate resources.

When possible, before discharge, each patient should be sufficiently oriented to assess his or her physical condition and be able to summon assistance. Airway reflexes and motor function must be adequate to prevent aspiration. Ventilation and oxygenation should be acceptable and demonstrate sufficient reserve to safely cover minor deterioration in unmonitored settings. To detect hypoxemia, oxygen saturation should be monitored for an appropriate period of time after discontinuation of supplemental oxygen. Before discharge, patients should be observed for a period of time after the last IV opioid or sedative is administered to assess peak effects, as well as side effects. Hemodynamic measurement and indexes of peripheral perfusion should be relatively constant. Achievement of normal body temperature (greater than 96.8° F) should occur before discharge home or to a medical floor; the intensive care unit (ICU) staff can continue an active warming process. Resolution of shivering is important. Acceptable analgesia must be achieved and vomiting appropriately controlled. Likely surgical complications must be determined (e.g., bleeding, vascular compromise, pneumothorax, complications of coexisting diseases such as coronary artery disease, diabetes, hypertension, or asthma). The results of postoperative diagnostic tests should be reviewed. The routine requirement for urination before discharge should not be part of a discharge protocol and may be necessary only for selected day-surgery patients. Likewise, the requirement of drinking clear fluids should not be a part of a discharge protocol and may be necessary only for selected patients (e.g., diabetic patients) and determined on a case-by-case basis.[5]

Outcome indicators applied to discharge criteria should be written with a patient focus—for example—"Before discharge, the patient will maintain vital signs within the preoperative range." Examples of discharge criteria are found in Box 50-10. The patient's ability to meet these criteria constitutes clearance for discharge from the PACU but does not imply readiness for discharge to home. Two clinicians, Aldrete[87] and Chung et al.,[88] have piloted scoring systems designed to evaluate the patients for outpatient discharge.

The Aldrete modified postanesthesia recovery (PAR) score is a modification of the original Aldrete score for PAR (Table 50-4). This modification of the scoring system changed assessment of "color" to assessment of "oxygen saturation." This scoring system is for use when patients are discharged from PACU phase I. A further modification of the Aldrete scoring system for outpatients' street fitness is given in Table 50-5.

BOX 50-10

Postanesthesia Care Unit Discharge Criteria

- Regular respiratory pattern
- Respiratory rate appropriate for age
- Absence of restlessness and confusion
- Vital signs within preoperative range
- Pulse oximetry indicates 95% saturation* or value equal to preoperative saturation
- Arterial blood gas values within normal limits†
- Ability to maintain patent airway
- Surgical stability of operative site or system

*Unit policies may dictate another number needed for oxygen saturation on discharge. There is no known accepted saturation level for discharge; most units require at least 92%.
†Not routinely obtained before discharge.

TABLE 50-4 Aldrete Postanesthesia Scoring System

			Admit	15 min	30 min	45 min	60 min
Activity	Able to move voluntarily on command	Four extremities	2	2	2	2	2
		Two extremities	1	1	1	1	1
		No extremities	0	0	0	0	0
Respiration	Able to breathe deeply, cough freely		2	2	2	2	2
	Dyspnea or limited breathing		1	1	1	1	1
	Apnea		0	0	0	0	0
Circulation	BP ± 20 mmHg of preanesthesia level		2	2	2	2	2
	BP ± 20-50 mmHg of preanesthesia level		1	1	1	1	1
	BP ± 50 mmHg of preanesthesia level		0	0	0	0	0
Consciousness	Fully awake		2	2	2	2	2
	Arousable on calling		1	1	1	1	1
	Not responding		0	0	0	0	0
O_2 Saturation	Able to maintain O_2 saturation greater than 90% on room air		2	2	2	2	2
	Needs O_2 inhalation to maintain O_2 saturation greater than 90%		1	1	1	1	1
	O_2 saturation less than 90% even with O_2 supplementation		0	0	0	0	0

From Marshall S, Chung F. Assessment of 'home readiness' discharge criteria and post-discharge complications. *Curr Opin Anesthesiol.* 1997; 10:445-480.
BP, Blood pressure; O_2, oxygen.

Chung et al.[88] developed the Postanesthesia Discharge Scoring system as a simple, objective tool to assess the readiness of patients to be discharged to home (Box 50-11). A score of 9 is needed for the patient to be discharged. Although studied retrospectively, the scoring system has yet to be tried as a predictive index in a widespread clinical trial. Regardless of the method used to assess readiness for discharge, the assessment should be documented in an objective manner using criteria agreed upon by the departments of anesthesia, nursing, and surgery.

Fixed PACU discharge criteria must be used with caution, because variability among patients is tremendous. Scoring systems that quantify physical status or establish thresholds for vital signs are useful for assessment but cannot replace individual evaluation.

Fast-tracking outpatients after general anesthesia has assumed increased importance in ambulatory anesthesia because of the cost-savings potential when patients are transferred directly from the OR to the less labor-intensive phase II recovery area. Given the inherent risks of complications associated with bypassing the PACU, effective and reliable fast-track criteria that allow anesthesia providers to rapidly assess a patient's postoperative alertness, physiologic stability, and comfort level immediately before transferring the patient from the OR are clearly needed.[89] An outpatient should be discharged to a responsible adult, who will accompany the patient home and able to report any postprocedure complications. In addition, outpatients should be provided with written instructions regarding postprocedure diet, medications, activities, and a phone number to call in case of emergency.[1]

Ideally, each patient should be evaluated for discharge by a qualified anesthesia provider using a consistent set of criteria that take into consideration the severity of the underlying disease, the anesthetic and recovery course, and the level of care at the destination, especially for ambulatory patients.

TABLE 50-5 Modified Postanesthesia Recovery Score for Outpatients' Street Fitness

Parameter	Description	Score
Activity	Able to move four extremities voluntarily on command	2
	Able to move two extremities voluntarily on command	1
	Able to move no extremities voluntarily on command	0
Respiration	Able to breathe deeply and cough freely	2
	Dyspnea or limited breathing	1
	Apneic	0
Circulation	BP ± 20 mmHg of preanesthetic level	2
	BP ± 21-49 mmHg of preanesthetic level	1
	BP + 50 mmHg of preanesthetic level	0
Consciousness	Fully awake	2
	Arousable on calling	1
	Not responding	0
O_2 Saturation	Able to maintain O_2 saturation greater than 92% on room air	2
	Needs O_2 inhalation to maintain O_2 saturation greater than 90%	1
	O_2 saturation less than 90% even with O_2 supplement	0
Dressing	Dry	2
	Wet but stationary	1
	Wet but growing	0
Pain	Pain free	2
	Mild pain handled by oral medications	1
	Pain requiring parenteral medications	0
Ambulation	Able to stand up and walk straight*	2
	Vertigo when erect	1
	Dizziness when supine	0
Fasting and feeding	Able to drink fluids	2
	Nauseated	1
	Nausea and vomiting	0
Urine output	Has voided	2
	Unable to void but comfortable*	1
	Unable to void and uncomfortable	0

*May be replaced by Romberg's test or picking up 12 clips in one hand.

SUMMARY

Postanesthesia care units are vital to the safe recovery of patients from surgery and anesthesia. Nurses provide the skillful bridge to ensuring a successful perioperative experience. They assess and monitor patients for residual anesthetic effects and surgical complications and reinstitute care for preexisting medical problems. Integrating care provided by the nurse with that of the anesthesia and surgical teams is essential in the modern surgical center.

BOX 50-11

Postanesthesia Discharge Scoring System

Vital Signs
2 = Within 20% of preoperative value
1 = 20%-40% of preoperative value
0 = Greater than 40% of preoperative value

Activity and Mental Status
2 = Oriented 3 separate times and a steady gait
1 = Oriented 3 separate times or a steady gait
0 = Neither

Pain, Nausea, Vomiting
2 = Minimal
1 = Moderate, requiring treatment
0 = Severe, requiring treatment

Surgical Bleeding
2 = Minimal
1 = Moderate
0 = Severe

Intake and Output
2 = Postoperative fluids and void
1 = Postoperative fluids or void
0 = Neither

CHAPTER 51

Pain Management

◆ *Sandra K. Bordi*

In the United States it is estimated that approximately 76 million people suffer from some type of pain, including acute, chronic, and/or postsurgical.[1] Even though advances have been instituted to help practitioners recognize and treat pain, the incidence of unrelieved pain continues to be a major concern. In 1992 the Agency for Healthcare Research and Quality (AHRQ) devised the first clinical practice guidelines (CPGs) for pain management. Subsequently, other groups including the American Pain Society (APS), American Society of Anesthesiologists (ASA), and the American Academy of Pain Management (APM) have instituted CPGs for management of acute and chronic pain. In addition to these associations, others have developed CPGs specific to patient populations (e.g., elderly and pediatrics) and to types of pain (e.g., cancer pain, postoperative pain, and chronic noncancer pain) in an effort to improve pain management. Even though there are CPGs, pain management remains inadequate. Several professional and regulatory groups have proposed standards, responsibilities, and outcome measures to improve pain management. The Joint Commission (TJC) developed pain management standards that were implemented in 2001. TJC clearly outlined the responsibilities of hospitals, home-care agencies, nursing homes, behavioral facilities, and out-patient clinics seeking accreditation (Box 51-1). The implementation of these standards is a momentous step in the improvement of pain management.

As providers of anesthesia care in the United States, certified registered nurse anesthetists (CRNAs) are integral to the research and management of acute and chronic pain. It is their professional and ethical responsibility to participate in the assessment, management, and treatment of pain based on each patient's unique needs in a holistic and multidisciplinary manner.[2] Only recently have CRNAs been recognized as experts in the area of pain management, and their knowledge and skills are essential in pursuing effective pain management modalities.

PAIN

Definition

Pain remains a very complex and multidimensional experience. It was defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[3] The inherent context of this definition is that pain is a physiologic, emotional, and a behavioral experience.[4] Commonly used pain terminology is listed in Box 51-2.

Classification of pain is primarily based on longevity (acute versus chronic) and/or the underlying pathophysiology (nociceptive or non-nociceptive).[5] Nociceptive pain is associated with the stimulation of specific nociceptors and can be either somatic or visceral. *Somatic pain* refers to pain that has an identifiable locus as a result of tissue damage causing the release of chemicals from injured cells that mediate pain. Somatic pain is well localized, sharp in nature, and generally hurts at the point or area of stimulus. Conversely, *visceral pain* is diffuse, can be referred to another area, and is often described as "dull," "cramping," "squeezing," or vague in nature. Visceral pain is often associated with the distention of an organ capsule or the obstruction of a hollow viscus. It is also often accompanied with autonomic reflexes such as nausea, vomiting, and diarrhea.[6] In contrast, non-nociceptive pain can be categorized as being *neuropathic* or *idiopathic*. *Neuropathic pain* is caused by damage to peripheral or central neural structures resulting in abnormal processing of painful stimuli. It is a dysfunction of the central nervous system (CNS) that allows for spontaneous excitation in chronic pain states. Neuropathic pain is often described as "burning," "tingling," or "shocklike."[7] *Idiopathic pain* or *psychogenic pain* is also associated with chronic pain states and is used to describe pain that has no apparent cause. Neither nociceptive nor neuropathic mechanisms can be identified as a cause for pain, and psychological symptoms are commonly present. Patients in chronic pain states often exhibit more than one type of pain along with a psychological component. Therefore, psychological, cultural, and environmental factors should be addressed when assessing patients with chronic pain.[6]

Anatomy and Physiology

Somatic nociceptive pain is most commonly defined in terms of four processes: transduction, transmission, perception, and modulation. *Transduction* is the transformation of a noxious stimulus (chemical, mechanical, or thermal) into an action potential.

BOX 51-1

The Joint Commission Pain Management Standards

The Joint Commission pain management standards require organizations to:

- Recognize the right of patients to appropriate assessment and management of pain
- Screen patients for pain in their initial assessment, including the nature and intensity of the pain
- Record the results of the assessment in a way that facilitates regular reassessments and follow-up
- Establish policies and procedures that support the appropriate prescription or ordering of effective pain medications
- Educate patients and their families about effective pain management
- Address patient needs for symptom management in the discharge planning process
- Ensure staff education regarding pain assessment and management

From Berry PH, Dahl JL. The new JCAHO standards: implications for pain management nurses. *Pain Manag Nurs*. 2000;1(1):3-12.

A noxious stimulus is detected by pain receptors, or nociceptors, which are free nerve endings. These peripheral nociceptors that conduct noxious stimuli to the dorsal horn of the spinal cord are categorized according to morphology (diameter, myelination, and conduction velocity). The myelinated A-delta (Aδ) primary afferent neurons conduct action potentials at velocities between 6 and 30 m/sec and elicit fast-sharp pain. They are responsible for the initial mechanical or thermal pain that is felt and alert an individual of tissue damage, thereby resulting in the reflex withdraw mechanism. The smaller nonmyelinated C fibers conduct at velocities significantly slower, between 0.5 and 2 m/sec. Because C fibers respond to mechanical, thermal, and chemical injuries, they are also known as polymodal fibers. Due to their slow conducting velocity, a delayed, slow, second pain is elicited by C fibers.[8] Slow pain is commonly described as "dull," "burning," "throbbing," and "aching."

Consequently, when peripheral tissues (skin, bone, and viscera) receive chemical, thermal, or mechanical stimuli or are traumatized by either surgery or injury, a series of biochemical events take place in peripheral pain transduction. These events include the release of chemical mediators from the inflammatory response and the release of neurotransmitters from nociceptive nerve endings (Figure 51-1). The chemical mediators and neurotransmitters released are extensive, with the more prominent substances listed below:

- *Substance P* is a peptide found and released from the peripheral afferent nociceptor C fibers and is involved with slow, chronic

BOX 51-2

Pain Terminology

Algesia: Increased sensitivity to pain.
Algogenic: Pain producing.
Allodynia: A normally nonharmful stimulus is perceived as painful.
Analgesia: The absence of pain in the presence of a normally painful stimulus.
Dysesthesia: An unpleasant painful abnormal sensation, whether evoked or spontaneous.
Hyperalgesia: A heightened response to a normally painful stimulus.
Neuralgia: Pain in the distribution of a peripheral nerve(s).
Neuropathy: An abnormal disturbance in the function of a nerve(s).
Paresthesia: An abnormal sensation, whether spontaneous or evoked.

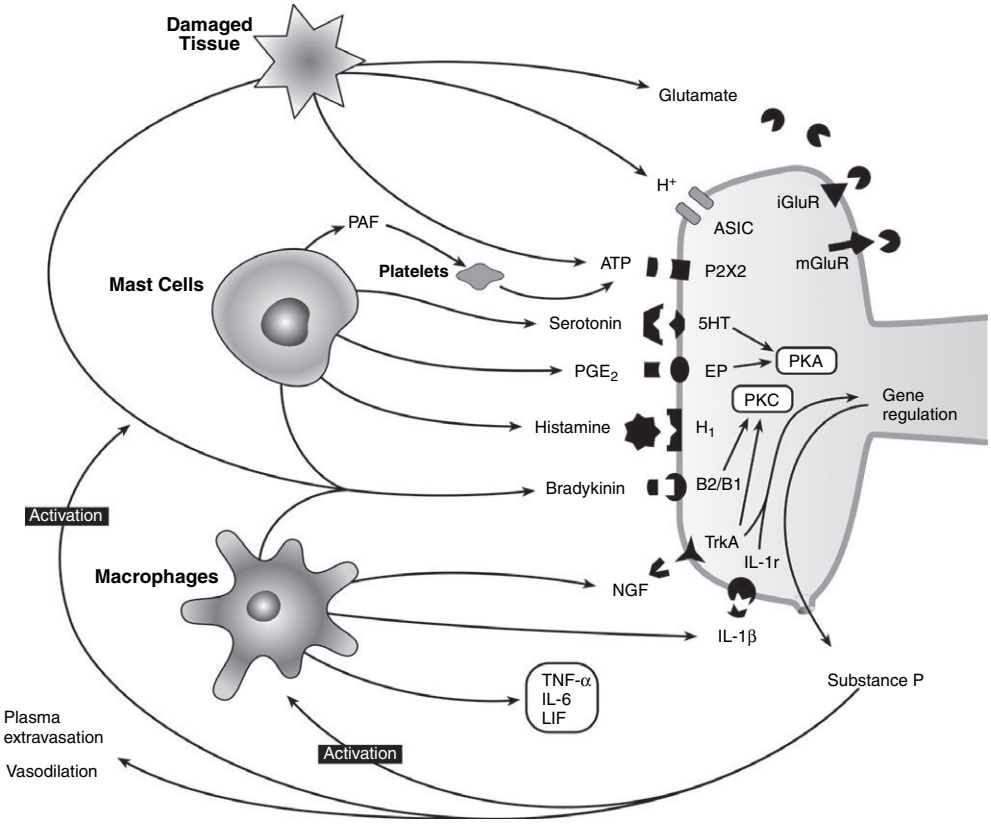

FIGURE **51-1** Inflammation and peripheral nociception. After tissue injury, mast cells, macrophages, and neutrophils are activated and/or are recruited to the area. In addition, small nociceptor nerve endings are also triggered. A variety of algogenic substances are released as a result of the inflammatory response and from the nociceptor nerve endings. These algogenic substances contribute to the pain process either directly (i.e., increasing excitability of nerves) or indirectly via second messenger (i.e., PKA, PKC) responses. *PAF*, Platelet-activating factor; *ATP*, adenosine triphosphate; *P2X2*, primary receptor family for ATP; H^+, excess free hydrogen ion; *5HT*, 5-hyroxytryptamin receptor; PGE_2, prostaglandin E_2; *EP*, prostaglandin E receptor; H_1, histamine-1 receptor; *B2/B1*, bradykinin 1 and bradykinin 2 receptor; *NGF*, nerve growth factor; *TrkA*, tyrosine kinase receptor A; *Il-1β*, interleukin-1β; *Il-1r*, interleukin 1 receptor; *PKC*, protein kinase; *PKA*, protein kinase A; *iGluR*, ionotropic glutamate receptor; *mGluR*, G protein–coupled metabotropic glutamate receptor; *TNF-α*, tumor necrosis factor-α; *IL-6*, interleukin-6; *LIF*, leukemia-inhibiting factor. (Modified from Dougherty P, et al. Neurochemistry of somatosensory and pain processing. In: Benzon HT, et al, eds. *Essentials of Pain Medicine*. 3rd ed. Philadelphia: Saunders; 2011:8-15.)

pain. It acts via the G-protein–linked neurokinin-1 receptor, resulting in vasodilation, extravasation of plasma proteins, degranulation of mast cells, and sensitization of the stimulated sensory nerve.[9]

- *Glutamate* is a major excitatory neurotransmitter released in the CNS and from the Aδ and C primary afferent nerve fibers. Its effects are instantaneous, producing initial, fast-sharp pain.[8]
- Bradykinin is a peptide released during the inflammation process and is notably algesic. It has a direct stimulating effect on peripheral nociceptors via specific bradykinin receptors (B1/B2).
- *Histamine* is an amine released from mast cell granules, basophils, and platelets via substance P. It reacts with various histamine receptors to produce edema and vasodilation.
- *Serotonin (5-hydroxytryptamine [5-HT])* is an amine stored and released from platelets after tissue injury. It reacts with multiple receptor subtypes and exhibits algesic effects on peripheral nociceptors. Like histamine, serotonin can potentiate bradykinin-induced pain.
- *Prostaglandins (PGs)*, along with *thromboxanes* and *leukotrienes*, are a metabolite of arachidonic acid. PGs, specifically, are synthesized from cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). They are associated with chronic pain; PGs sensitize peripheral nociceptors, causing hyperalgesia.
- *Cytokines* are released in response to tissue injury by a variety of immune and nonimmune cells via the inflammatory response. Cytokines including interleukin-1β (IL-1β), interleukin-6 (IL-6), and tumor necrosis factor-α (TNF-α) can lead to the increased production of PGs, thereby exciting and sensitizing nociceptive fibers.[10]

These chemical mediators and neurotransmitters stimulate the peripheral nociceptors, causing an influx of sodium ions to enter the nerve fiber membranes (depolarization) and a subsequent efflux of potassium ions (repolarization). An action potential results, and a pain impulse is generated.

Transmission is the process by which an action potential is conducted from the periphery to the CNS. There are multiple pathways that carry noxious stimuli to the brain. The spinothalamic (anterolateral) system, which carries pain signals from the trunk and lower extremities, will be discussed here. The primary afferent neurons (Aδ and C fibers) have cell bodies located in the dorsal root ganglia of the spinal cord. Upon entering the dorsal cord, these fibers segregate and ascend or descend several spinal segments in the tract of Lissauer. After leaving the tract of Lissauer, the axons of the primary afferents enter the gray matter of the dorsal horn where they synapse with second-order neurons and terminate primarily in Rexed's laminae I, II, and V (Figure 51-2). Two types of second-order neurons exist: (1) nociceptive neurons, which receive input solely from primary afferent Aδ and C fibers and (2) wide-dynamic-range (WDR) neurons that receive input from both nociceptive (Aδ and C fibers) and non-nociceptive (A-β) primary afferents. Wide-dynamic-range neurons are therefore activated by a variety of stimulants (innocuous and noxious) (Figure 51-3).

Second-order neurons then cross the midline of the spinal cord through the anterior commissure and ascend in the anterolateral pathway of the spinothalamic tract to the thalamus. In the lateral thalamus and the intralaminar nuclei, second-order neurons synapse with third-order neurons, which then send projections to the cerebral cortex. *Perception* of pain occurs once the signal is recognized by various areas of the brain, including the amygdala, somatosensory areas of the cortex, the hypothalamus, and the anterior cingulate cortex.

Modulation of pain transmission involves altering neural afferent activity along the pain pathway; it can suppress or enhance pain signals. Suppression of pain impulses occur through local inhibitory interneurons and descending efferent pathways. The descending efferent modulatory pathways from the brain are considered the body's "analgesia system" or pain control system.[8]

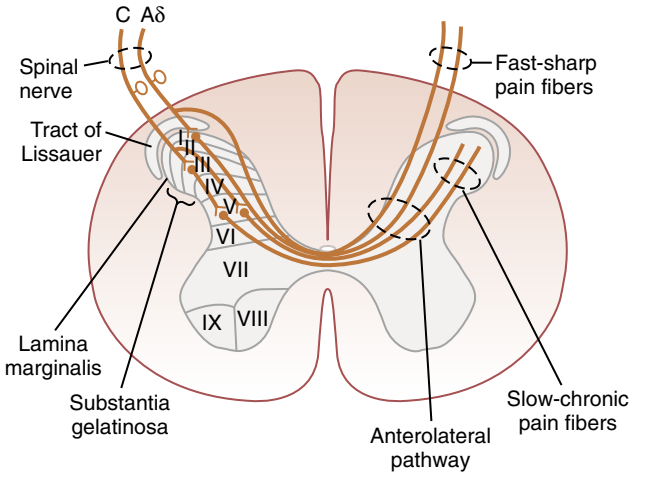

FIGURE 51-2 Transmission of primary afferents in the dorsal horn and tract of Lissauer. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology.* 12th ed. Philadelphia: Saunders; 2011:585.)

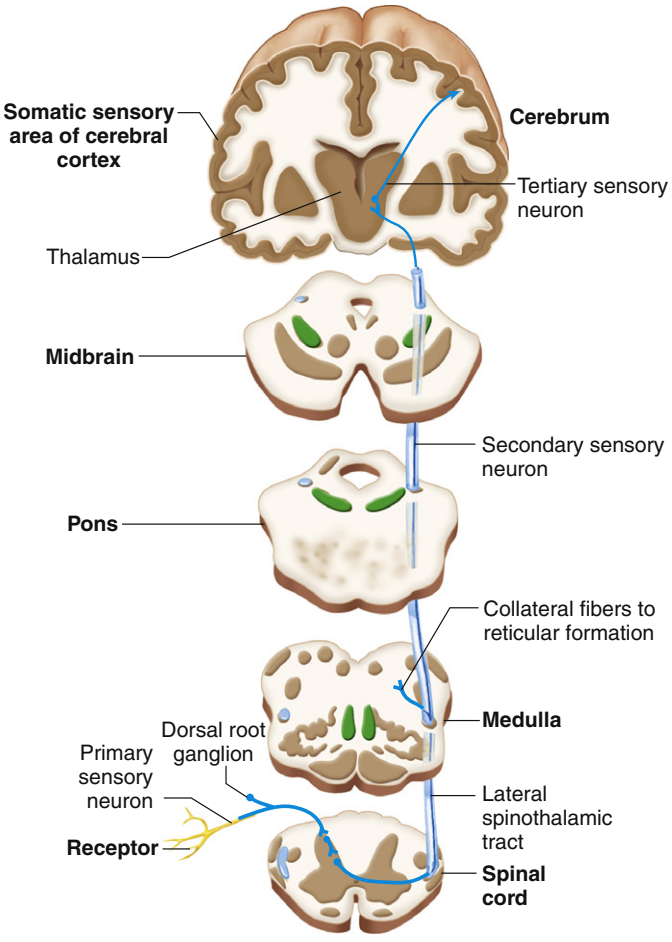

FIGURE 51-3 Ascending lateral spinothalamic tract. (From Patton KT, Thibodeau GA. *Anatomy and Physiology.* 8th ed. St. Louis: Mosby; 2013:448.)

It is proposed that the descending dorsolateral efferent pathway is activated via a noxious stimulus. Descending axons from the cerebral cortex, hypothalamus, thalamus, periaqueductal gray area (PAG), nucleus raphe magnus (NRM), and locus coeruleus (LC) via the dorsolateral funiculus (DLF) synapse with and suppress pain transmission to the brainstem and the spinal cord dorsal horn. Several neurotransmitters and their receptors play critical roles in the inhibitory modulation of pain, including the inhibitory endogenous opioids (enkephalin/dynorphin). Action potentials arrive at the substantia gelatinosa via the DLF and activate enkephalin-releasing neurons. Enkephalin then binds to the opiate receptors on presynaptic first-order or postsynaptic second-order afferent fibers, which decrease substance P release, thereby suppressing ascending pain transmission. Other inhibitory neurotransmitters released via the descending pathway include glycine, norepinephrine, serotonin, and gamma-aminobutyric acid (GABA) (Table 51-1). Pharmacotherapies for pain control are aimed at many of these neurotransmitters and their receptors.

Pain modulation is enhanced in the presence of "central sensitization." Central sensitization refers to the neural plasticity that occurs in the CNS. When tissue or neural injury exists, repetitive stimulation and activation of nerves results in changes in neurotransmitter levels and signaling in the CNS. For example, the repetitive firing of dorsal horn nociceptors causes activation of lower non-nociceptive threshold mechanoreceptors (A-β afferents) to trigger a pain response. There are also other factors involved in central sensitization, including the inflammatory response and an increase in receptive field size.[11] Central sensitization is associated with chronic pain states and is addressed in more detail later in this chapter.

Acute Pain

Acute pain is caused by noxious stimulation due to traumatic injury (chemical, thermal, or mechanical), surgery, or acute illness. Generally, the intensity of acute pain diminishes over the course of healing; however, social, cultural, and personality factors may affect this. Its duration is usually self-limited and resolves within 1 to 14 days. Acute pain is responsive to pharmacotherapy and treatment of the precipitating cause. Unfortunately, poorly controlled acute pain may lead to chronic pain states. Therefore, optimal pain management is crucial in expediting the healing process and for the prevention of chronic pain.

TABLE 51-1 Pain-Modulating Neurotransmitters

Neurotransmitters	Receptor
Excitatory Neurotransmitter	
Substance P	Neurokinin-1 (NK1), Neurokinin-2 (NK2)
Glutamate	NMDA, AMPA, kainate
Inhibitory Neurotransmitter	
Glycine	Chloride linked (GlyR)
GABA	$GABA_A$, $GABA_B$, $GABA_C$
Enkephalin	Mu, delta, kappa
Serotonin	5-HT (5-HT1-3)
Norepinephrine	$Alpha_2$ adrenergic

NMDA, N-methyl-D-aspartate; *AMPA*, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; *GlyR*, glycine receptor; *GABA*, gamma-aminobutyric acid; *5HT*, 5-hydroxytryptamine.

It is well documented that acute pain causes adverse physiologic consequences involving multiple organ systems, which can contribute to morbidity and mortality in surgical patients. Neuroendocrine responses that are triggered primarily by the sympathetic nervous system (SNS) in response to surgical stress and pain initiate these effects. Factors such as the extent of the surgical field, the number of pain receptors involved in the area, bleeding, infection, anxiety, and presence of coexisting diseases may accelerate the endocrine stress response.

The activation of the sympathetic nervous system in response to the stress of pain from surgery or trauma results in many cardiovascular responses. The increased release of catecholamines from the SNS and adrenal glands, along with cortisol, produces an increased heart rate, increased vascular resistance (peripheral, systemic, and coronary), increased myocardial contractility, and increased arterial blood pressure. These ultimately increase the myocardial demand and myocardial oxygen consumption. Additionally, in the presence of coexisting cardiovascular disease, atherosclerotic plaque from vascular walls may rupture, thereby decreasing oxygen supply further. This may lead to dysrhythmias, angina, myocardial ischemia, and myocardial infarction. Overall, the incidence of increased myocardial oxygen demand and decreased myocardial oxygen supply can have deleterious effects in those patients with coexisting cardiovascular disease. Therefore, aggressive pain management is essential in reducing the incidence of postoperative cardiac complications.[12]

The presence of pain can have significant effects on the respiratory system. These effects are most pronounced in those patients having surgery or trauma in the upper abdominal area and thorax. Inadequate pain management causes a measurable decrease in tidal volume because of limited thoracic and abdominal movement. Specifically, there are decreases in vital capacity, inspiratory capacity, and functional residual capacity (FRC), as well as a decreased physical ability to clear the airway, due to unrelieved pain. Additionally, muscle spasm below and above the site of injury caused by the noxious stimuli promotes limited movement of the respiratory muscles. Patients often voluntarily decrease the movement of the thorax and abdomen (splinting) and are reluctant to breathe deeply or cough in an attempt to limit pain, which can lead to atelectasis and pneumonia.[13,14] These pulmonary alterations may be aggravated in those patients with preexisting pulmonary dysfunction (e.g., asthma, chronic obstructive pulmonary disease) or in those with decreased FRC (e.g., morbidly obese, elderly). Consequently, those affected by postoperative respiratory compromise due to inadequate pain management also may be at risk for deep venous thrombosis and subsequent pulmonary embolism due to a decrease or delay in mobilization. See Table 51-2 for physiologic consequences of acute pain.

The physiologic effects and the consequences of inadequate pain management have been reported to have an impact in delaying postoperative stay, patient recovery, and an overall increase in healthcare costs.[15] It also negatively impacts the patient's surgical/hospitalization experience, resulting in reduced patient satisfaction.

Acute Pain Assessment

To devise a plan for intraoperative and postoperative surgical pain management, a preoperative pain assessment and discussion with the patient should be conducted. A thorough preoperative assessment should involve a physical and medical history assessment, including laboratory and diagnostic tests that are patient and surgery specific. Inquiries specific to preoperative pain also should be addressed; these are found in Box 51-3. Part of the preoperative

TABLE 51-2 Physiologic Effects of Acute Pain

Organ System	Physiologic Effect	Adverse Outcome
Cardiovascular	Increased heart rate	Dysrhythmias
	Increased PVR	Angina
	Increased ABP	Myocardial ischemia
	Increased myocardial contraction	Myocardial infarction
	Increased myocardial work	
Pulmonary	Decreased VC	Ventilation/perfusion mismatch
	Decreased TV	Atelectasis
	Decreased TLC	Pneumonia
	Muscle spasms (respiratory/abdominal)	Hypoventilation
	Decreased ability to cough/deep breathe	Hypoxia
		Hypercarbia
Gastrointestinal	Decreased gastric emptying	Nausea/vomiting
	Decreased intestinal motility	Paralytic ileus
	Increased smooth muscle sphincter tone	
Coagulation	Increased platelet aggregation	Thrombosis
	Venostasis	DVT/PE
Immunologic	Decreased immune function	Increased risk of infection
Genitourinary	Increased urinary sphincter tone	Oliguria
		Urinary retention
Psychological		Fear
		Anxiety
		Depression
		Feelings of helplessness
		Anger

pain assessment process also should consist of identifying those at high risk for increased postoperative acute pain. A recent study identified that the most important predictors of acute postoperative pain after elective surgery include: (1) the presence of preoperative pain, (2) patient fear regarding the outcome of his/her surgery, (3) patients who catastrophize pain, and (4) expected pain postoperatively.[16] Overall, goals for pain management should be based on patient physical/medical assessment, history, invasiveness of the surgical procedure, an individual's pain response, and prediction of identifying those who are at high risk for developing increases in acute pain postoperatively. The patient should be informed of the varying modalities for postoperative pain control, and a unique pain management plan should be implemented by both the patient and care providers. Furthermore, realistic expectations for postoperative pain control should be discussed.

BOX 51-3

Preoperative Pain Assessment

- Determine the existence of chronic pain
- Current medications (prescription and OTC)—continuous or prn for pain
- Inquiry regarding previous injuries
- Location of pain
- Quality of pain
- Intensity of pain
- Adjunctive therapies (e.g., acupuncture, TENS, injection therapy, SCS)
- Exacerbating factors
- Alleviating factors
- Limitations in movement
- Coexisting psychological diseases

OTC, Over-the-counter; *TENS*, transcutaneous electric nerve stimulation; *SCS*, spinal cord stimulator; *prn*, as needed.

As discussed earlier, adequate postoperative pain control is essential in the recovery process. Assessing the adequacy of postoperative pain control through vigilance and by using simple assessment tools is vital. Because pain is subjective, the most reliable pain assessment tool is primarily via self-report. Pain assessment scales, which are both clinically valid and used in research, are available and are based on measuring pain intensity. The common pain intensity scales include the visual analog scale (VAS), the numerical rating scale (NRS), and the Wong-Baker FACES scale. Even though these scales are available and are used in the clinical setting, they are not all-inclusive. The NRS, VAS, and Wong-Baker FACES scales assign a numerical value to an individual's pain, which is subjective and multidimensional. In addition, they do not take into consideration the patient's age or variations in cognitive level. The NRS is most often used by practitioners in assessing pain by asking the patient "What is your pain level on a scale of 1 to 10, with 10 being the worst pain you have ever experienced and 0 being pain-free?" Although this is a quick tool used to assess pain, it lacks the depth of determining the quality of pain or exacerbating factors that affect pain. Inevitably it is the provider's responsibility to investigate the patient's pain, be it surgical or nonsurgical, and intervene with a treatment modality. Key to successful acute pain control is vigilant reassessment and evaluation of the patient's response to a given treatment and changing treatment modalities, if necessary, in an effort to alleviate pain.

Preemptive Analgesia

Preemptive analgesia is a concept first postulated approximately 100 years ago. It was asserted that by administering analgesics prior to noxious stimulation, a decreased pain response would result. The premise is that peripheral and central sensitization results from noxious stimulation, thereby causing an increase in postoperative pain. Preemptive analgesia in preventing central sensitization remains controversial. For example, in an animal study by Chang et al.,[17] preincisional treatment with an *N*-methyl-D-aspartate (NMDA) antagonist was not found to be more beneficial than postincisional treatment. Likewise, Hariharan et al.[18] found in a human study that local anesthesia administered prior to incision with abdominal hysterectomy did not reduce the intensity of postoperative pain. However, in contrast, Arici et al.[19] concluded that preemptive intravenous (IV)

paracetamol provided "good quality" postoperative analgesia and a reduction in morphine administration postoperatively. Similarly, Persec et al.[20] reported that the administration of intrathecal clonidine reduced postoperative pain significantly more than did administration of intrathecal levobupivicaine.

Regardless of the controversies surrounding preemptive analgesia, a multimodal approach to acute and chronic pain management is common practice. Multimodal pain management consists of using a combination of analgesics that work on a variety of receptors with different mechanisms of action, both peripherally and centrally, resulting in additive or synergistic effects in an effort to improve pain control.

Acute Pain Analgesics

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are best known for their use in the management of mild to moderate postoperative pain and pain related to inflammatory conditions. They are the most common analgesic adjuvants used in multimodal analgesia remedies. When using NSAIDSs and opioids together, a synergistic effect results in analgesia along with an overall decreased dose of opioids and decreased opioid side effects. NSAIDs vary in chemical structure but all possess antiinflammatory, antipyretic, and analgesic properties. They produce their therapeutic effects by inhibiting cyclooxygenase (COX) and thereby preventing conversion of arachidonic acid to prostaglandins. Prostaglandins (primarily PGE_1 and PGE_2) are responsible for sensitizing and amplifying peripheral nociceptors to the inflammatory mediators (substance P, bradykinin, and serotonin), which are released when tissue is traumatized. Therefore, prostaglandins do not directly produce pain but instead contribute to hyperalgesia. Centrally, prostaglandins mediate pain by enhancing the release of substance P and glutamate in first-order neurons, increasing nociceptive transmission at second-order neurons, as well as inhibiting the release of descending inhibitory neurotransmitters (Figure 51-4).

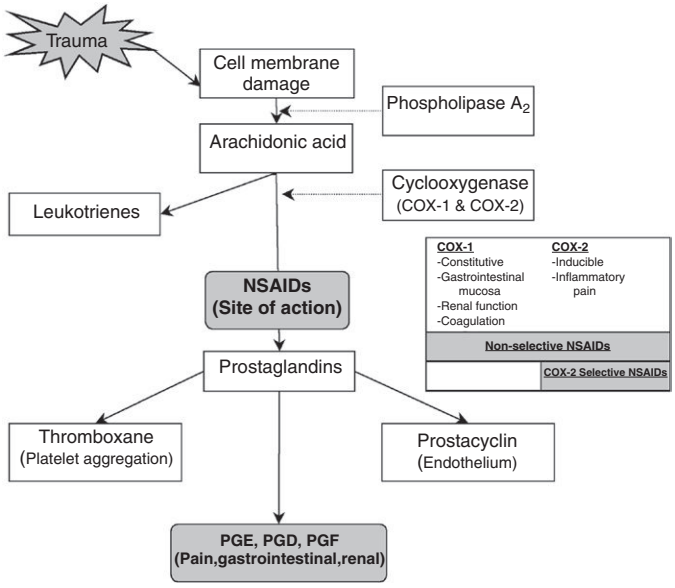

FIGURE **51-4** Nonsteroidal antiinflammatory drugs (NSAIDs) site of action and influence of prostaglandins. (From Benzon HT, et al, eds. *Essentials of Pain Medicine*. 3rd ed. Philadelphia: Saunders; 2011:131.)

COX exists in two isoforms: COX-1 and COX-2. COX-1 is constitutive, widespread throughout the body, and necessary for homeostasis. It is responsible for platelet aggregation, gastric mucosal integrity, and renal function. Conversely, COX-2 is an inducible enzyme that in the presence of inflammation releases prostaglandins, thereby mediating pain, fever, and carcinogenesis.[21] Until recently, all of the NSAIDs were nonselective in their COX inhibition. As a result, in addition to the analgesia effects from the inhibition of the COX-2 isoform, inhibition of COX-1 was responsible for the detrimental side effects of gastric irritation, renal microvasculature constriction, and platelet inhibition. Presently in the United States, celecoxib is the only COX-2–selective NSAID available. Others have been withdrawn from the market because of cardiovascular side effects. Celecoxib is available orally and is used for treating acute surgical pain, chronic pain syndromes, and cancer pain in conjunction with other analgesic approaches. It is metabolized by the liver extensively via cytochrome P450 (CYP450). A contraindication for celecoxib administration includes known hypersensitivity to sulfonamides because it contains sulfa. In addition, celecoxib should also be avoided in patients with a history of asthma or allergic reaction to aspirin or other NSAIDs, because COX-2 inhibitors can convert arachidonic acid to the precursor of leukotrienes, potentially causing bronchoconstriction and/or anaphylaxis.

Ketorolac. Ketorolac, a nonselective COX inhibiter, is also available for short-term acute postoperative pain, administered either alone or in combination with other analgesic modalities. Ketorolac can be administered orally, intravascularly, intramuscularly, and intranasally. Comparatively, the analgesic potency of ketorolac 30 mg intramuscular (IM) is equivalent to approximately 12 mg of morphine IM.[22] Because of the potential adverse effects caused by the inhibition of COX-1, ketorolac should not be administered beyond 5 days.[23] Contraindications for administering ketorolac include coagulopathies, renal failure, active peptic ulcer disease, gastrointestinal bleeding, history of asthma, hypersensitivity to NSAIDs, and surgery that involves a high risk for postoperative bleeding. In addition, controversy exists regarding bone healing and ketorolac administration. Ketorolac's inhibition of COX-1, COX-2, and prostaglandin synthesis interrupts normal prostaglandin effects on osteoblast and osteoclast functioning that promotes bone healing.[24,25] However, currently there are no recommendations regarding ketorolac administration and orthopedic procedures.

Acetaminophen. Acetaminophen reduces prostaglandin synthesis by an uncertain mechanism. It has minimal antiinflammatory effects with mainly analgesic and antipyretic properties. It is suitable for acute mild to moderate postoperative pain and fever. Oral acetaminophen is frequently combined with weak opioids (e.g., oxycodone, hydrocodone, codeine) for the treatment of moderate postoperative pain and chronic pain syndromes. Because it lacks the negative effects of typical NSAIDs (e.g., platelet inhibition, gastrointestinal irritation, renal toxicity), acetaminophen is an ideal drug for multimodal analgesia for surgical pain. Acetaminophen is metabolized primarily by the liver and is therefore contraindicated in patients with liver failure. Parenteral acetaminophen (Ofirmev) is also available for the treatment of acute mild to moderate pain and is effective in treating moderate to severe pain with adjunctive opioid analgesics.[26] Dosing for adults weighing over 50 kg is 1000 mg every 6 hours or 650 mg every 4 hours infused over 15 minutes to a maximum of 4000 mg/day. Dosing in children over 2 years of age and under 50 kg is 15 mg/kg every 6 hours or 12.5 mg/kg every 4 hours to a maximum of 75 mg/kg/day. Onset of action is approximately 10 minutes with a duration of action of 4 to 6 hours. Adverse effects of IV acetaminophen are rare when dosed accordingly, with more common side effects being nausea, vomiting, headache, and insomnia.[27]

Opioids

Opioid analgesics remain the drugs of choice for treatment of moderate to severe pain in the early postoperative period. Opioids produce analgesia by binding to and activating G-protein coupled opioid receptors (GPCRs) peripherally and in the CNS. Centrally, opioid receptors are predominantly found in the dorsal horn of the spinal cord, specifically Rexed's lamina II of the substantia gelatinosa, and supraspinally in the periaquadectal grey (PAG) area, medial thalamus, amygdala, and limbic cortex. Peripherally, they are found on afferent sensory nerve fibers as well as in the gastrointestinal tract, lungs, and joints.[28] There are several subtypes of opioid receptors, with the principal ones being mu (μ), delta (δ), and kappa (κ). When bound by opioids presynaptically, these GPCRs cause a biochemical change that decreases adenylate cyclase activity, thereby inhibiting calcium channels resulting in a decreased release of excitatory neurotransmitters such as substance P. Postsynaptically, there is an increase in outward potassium conductance with a subsequent hyperpolarization and an inhibition of excitatory neurotransmission.[29]

A thorough understanding regarding opioid pharmacodynamics and pharmacokinetics is essential when choosing a specific opioid. This is discussed in Chapter 11. Perioperatively, the more common opioids used for acute pain are fentanyl, morphine, and hydromorphone. These are predominantly administered parenterally but can be administered in a variety of routes depending upon the opioid (e.g., orally, epidurally, intrathecally, via intraarticular, and transdermally). Common side effects found with most opioids are dose dependent and include respiratory depression, pruritus, urinary retention, constipation, and nausea and vomiting.

Fentanyl. Intravenously, fentanyl's analgesic potency is approximately 80 to 100 times more than morphine. Its short onset of action (2-5 minutes) makes it an ideal opioid for treating acute pain. The duration of action of fentanyl is approximately 30 minutes to 1 hour because it is metabolized by the liver via the *N*-dealkylation into inactive metabolites and excreted by the kidneys. Fentanyl can be administered intrathecally, epidurally, and intravenously via postoperative patient-controlled analgesia (PCA). It is also available transdermally for the treatment of chronic pain. Because fentanyl is highly lipophilic, its administration intrathecally is limited due to its short duration of action, with a single dose lasting 2 to 4 hours.[30] Likewise, the duration of action for a single dose of epidural fentanyl (50-200 mcg) will be approximately 2 to 3 hours.[30,31] Intrathecal and epidural fentanyl can be given as a single dose or a continuous infusion and is discussed in Chapter 44.

Morphine. Morphine is the prototypical opioid by which all others are compared and is the most widely used for acute and chronic pain management. Metabolism of morphine is via hepatic glucuronidation, resulting in the metabolites morphine-3-glucuronide and morphine-6-glucuronide (M6G) with the latter being the active metabolite. Both metabolites are excreted via the kidneys; however, in patients with renal failure M6G may result in prolonged effects.

Morphine is commonly used to treat moderate to severe perioperative and postoperative pain. Morphine can be administered intravenously, intrathecally, epidurally, or orally. When administered IV, the onset of analgesia is approximately 20 minutes with duration of action being approximately 4 to 5 hours, depending on the dose administered. Unlike fentanyl, morphine is hydrophilic, making penetration of the blood-brain barrier and spinal cord more difficult. This results in a delayed onset of action (20-30 minutes) and a prolonged duration of action (8-24 hours) for single-dose intrathecal or epidural morphine. However, intrathecal morphine does result in a more profound analgesic effect as compared with IV or epidural administration.[32] Similar to fentanyl, morphine can be given in a single dose or continuous intrathecal or epidural infusion. Likewise, patient-controlled analgesia intravenously is also an option for morphine administration.

Hydromorphone. Hydromorphone is a derivative of morphine and is approximately 7 to 8 times more potent. Metabolism of hydromorphone is via hepatic conjugation; however, unlike morphine, it lacks the active metabolite M6G. Therefore administration in renal patients is considered safe. IV administration results in analgesia in approximately 15 minutes with a duration of action equivalent to morphine, approximately 4 to 5 hours. Hydromorphone is an ideal opioid for moderate or severe acute perioperative pain and is used for chronic pain management. Modes of administration include oral, intrathecal, epidural, intraarticulate, and intravenous PCA. When administered via single dose intrathecally or epidurally, onset of action is more rapid than morphine (approximately 15 minutes), with a duration of action of approximately 10 to 16 hours.[30] The common side effects associated with morphine administration remain similar to hydromorphone when equivalent doses are administered.[33] Hong et al.[34] reported that there were no differences between morphine and hydromorphone in efficacy of pain control or in opioid-related side effects with patients receiving intravenous PCA.

Acute Pain Analgesic Adjuncts

N-Methyl-D-Aspartate (NMDA) Antagonists

Ketamine, a noncompetitive NMDA antagonist and a phencyclidine derivative, is primarily used as an anesthesia induction agent. It is also used as part of a multimodal approach for perioperative pain control in conjunction with other medications. Ketamine prevents the activation of the NMDA receptor, which, along with the AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptor, has been associated with the development of "wind-up" or central sensitization and chronic pain states. The NMDA receptor, at rest, remains closed due to a magnesium plug. Activation of the receptor involves the simultaneous binding of the excitatory neurotransmitter glutamate, which causes an influx of calcium, resulting in an increase in second messengers. The upregulation of second messengers produces a hyperexcitability of the NMDA receptors, which causes neuronal plasticity, excitability, and wind-up. In chronic neuropathic pain states such as complex regional pain syndrome type I and phantom limb pain, it is well established that ketamine is beneficial in reducing hyperalgesia and allodynia.[35] Likewise, ketamine may be helpful in reducing acute perioperative pain, and research suggests that it also exhibits antiinflammatory effects.[36]

Ketamine is rapidly acting in that an anesthetic IV dose response is seen in 30 to 40 seconds with a duration of 80 to 180 minutes. In addition to IV administration, it can be administered intramuscularly, nasally, rectally, via epidural, and intrathecally. Metabolism of ketamine is predominantly by the liver and produces norketamine.

Because ketamine exhibits both anesthetic and analgesic effects, its use has drawn more interest in the perioperative setting. Its administration at higher doses and as the sole anesthetic is less desirable because of psychomimetic adverse effects. Recently, ketamine has been used in "low doses" either as a single dose administered on induction of anesthesia and/or as a continuous infusion. There is no conclusive, consistent consensus in regard to what is considered "low-dose" ketamine. Studies report minimal adverse effects with subanesthetic doses of ketamine, as well as decreased perioperative opiate consumption. However, randomized control

trials and reviews have noted mixed results regarding efficacy of low-dose ketamine and postoperative analgesia.[37,38] Himmelseher et al.[39] suggest that dosing be made according to surgical procedure invasiveness and that dosing continue throughout the surgical procedure after the initial noxious stimulus and continue postoperatively.

Alpha$_2$ Adrenergic Agonists

Clonidine and dexmedetomidine are α_2 adrenergic agonists that are used as analgesic adjuncts for multimodal anesthesia. They exhibit their analgesic effect by interacting with the G-coupled α_2 receptors, both centrally (dorsal horn of the spinal cord) and peripherally. Activation of the α_2 receptor results in inhibition of adenyl cyclase and decreased cyclic adenosine monophosphate (cAMP) levels. It also activates postsynaptic potassium channels while inhibiting presynaptic voltage-gated calcium channels, thereby reducing neurotransmitter release. In addition, it is suspected that activation of central α_2 adrenoreceptors in the locus coeruleus are responsible for supraspinal analgesia.[40]

Clonidine, a centrally acting selective partial α_2 adrenergic receptor agonist can be administered orally, intravenously, rectally, transdermally, intrathecally, epidurally, and via an intraarticulate route. Its half-life is approximately 5 to 13 hours. Metabolism of clonidine is via the liver with the remainder of the drug being excreted unchanged in the urine. Because clonidine exerts its effects on both α_2 and α_1 receptors (220:1 α_2 to α_1), side effects such as sedation, hypotension, and bradycardia can occur. Clonidine has been reported to decrease postoperative morphine requirements when used with maintenance infusions intraoperatively. When combined with local anesthetics in peripheral nerve blocks and/or intrathecal administration, postoperative analgesia has been effective with decreased time to first supplemental analgesic request.[40]

Dexmedetomidine is a highly selective α_2 adrenergic agonist. It is approximately 7 to 10 times more selective for the α_2 receptors (1,620:1 α_2 to α_1) as compared with clonidine.[40] Like clonidine, it exhibits sedative, anxiolytic, analgesic, sympatholytic, and vagomimetic effects with little or no respiratory depression. Dexmedetomidine is most commonly administered intravenously; however, it can be administered intramuscularly, transdermally, or intranasally. It has a rapid onset of action, approximately 5 minutes, with a short duration of action, and an elimination half-life of approximately 3 hours. Metabolism of dexmedetomidine is via extensive hepatic glucuronide conjugation with the absence of active metabolites. Hepatic clearance may be decreased in the presence of liver disease. Dexmedetomidine is often used for procedural sedation in nonintubated patients, sedation for intubated and mechanically ventilated patients, as well as a general anesthesia adjunct. Similar to clonidine, dexmedetomidine decreases postoperative analgesic requirements and decreases postoperative morphine consumption.[41]

Local Anesthetics

Unlike the previous analgesics whose actions are targeted at specific receptors on primary nociceptors and in the CNS, resulting in reduced presynaptic transmitter release and decreased postsynaptic excitability, local anesthetics inhibit conduction of action potentials along a nerve fiber. Local anesthetics block sodium channels in both afferent and efferent neuronal membranes, thereby inhibiting pain transmission. They are often given as the sole anesthetic; however, for optimal postoperative analgesia, local anesthetics should be administered with adjuvant medications.

TABLE 51-3 Methods of Administering Local Anesthetics

Route	Technique	Mode of Delivery
Topical		SS
Local infiltration	Subcut, subdermal	SS
	Intraarticular	SS, C
Neuraxial	Subarachnoid	SS, C, PC
	Epidural	
	Caudal	
Peripheral nerve blocks	*Lower extremity*	SS, C, PC

	Ankle	
	Upper extremity	
	Brachial plexus	SS, C, PC
	Cervical plexus	SS, C
	Intercostal	SS, C, PC
	IV regional (Bier block)	SS
	Digit	SS
Systemic	IV	SS
Diagnostic/ interventional	Trigger point injection	SS
	Somatic nerve blockade	SS
	Sacroiliac injection	SS
	Facet injection	SS
	Epidural steroid injection	SS
	Selective sympathetic blockade	SS
	Intervertebral disc injection	SS
	Differential nerve blockade	SS

IV, Intravenous; *SS*, single shot; *C*, continuous; *PC*, patient-controlled.

Nerve morphology (diameter and myelination) affects the sensitivity of nerve blockade achieved. An understanding of local anesthetic properties such as potency, onset of action, and duration of action is crucial in choosing a specific local anesthetic. These are addressed in Chapter 10. Metabolism of local anesthetics is determined by the chemical class. Amide local anesthetics are metabolized primarily by the liver, whereas ester local anesthetics are metabolized via plasma cholinesterase. Conditions that alter liver function (hepatic disease) and/or decrease plasma cholinesterase levels will inevitably reduce the rate of metabolism.

Methods for administering local anesthetics are listed in Table 51-3. The most common techniques for acute pain management are local infiltration of the operative area, peripheral nerve blocks, as well as epidural and subarachnoid blocks with adjuvant medications (primarily opioids). Prior to surgical incision, local anesthetic can be injected intradermally or subcutaneously near the incisional area to decrease the inflammatory response; local anesthetic infiltration reduces up-regulation of peripheral nociceptors. Common local anesthetics used for operative area infiltration include bupivicaine or ropivacaine due to their longer duration of action.

Peripheral nerve blocks can be administered as a single injection or via a continuous catheter technique. Chapters 44 and 45

provide a thorough description of regional techniques and peripheral nerve blocks. Most peripheral nerve blocks consist of a bolus dose of local anesthetic injected to infiltrate an area, or a peripheral nerve site. These techniques are primarily used for minor surgical procedures that provide analgesia in the immediate postoperative period. Likewise, the use of continuous catheters or continuous peripheral nerve blocks (CPNBs) involves an initial bolus dose of local anesthetic followed by a continuous infusion near the surgical site and adjacent to a nerve. CPNBs are increasing in popularity; they provide prolonged analgesia in those patients who are expected to have moderate-to-severe postoperative pain lasting more than 24 hours. CPNBs are commonly used for the brachial plexus, intercostal, femoral, and sciatic nerves.

Both subarachnoid and epidural blockade (primarily epidural) have been found to be useful in the management of postoperative pain. The primary site of action of local anesthetics when injected in the subarachnoid or epidural space is the nerve roots of the spinal cord. Because neuraxial anesthesia (local anesthetic with or without opioids) provides profound analgesia, some clinicians use the epidural technique with light general anesthesia during the surgical procedure; at the end of the procedure, the epidural catheter is left in place for postoperative pain management. Medications (e.g., local anesthetics, opioids, and adjuvant medications) can then be administered as bolus injections, continuous infusion, or via a patient-controlled device. The continuous epidural technique can be used for thoracic, abdominal, and lower-extremity surgery.

Local anesthetics are used not only for acute postoperative pain management but also commonly used in the diagnosis and treatment of several chronic pain states. Examples of diagnostic and interventional uses include facet joint injection, sacroiliac injection, selective sympathetic blockade, and trigger point injection.

Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) was developed in the early 1970s with the advent of microprocessor technology. This administration technique has changed the face of acute pain management and has become a standard technique for postoperative pain control. Intravenous PCA involves self-administration of predetermined doses of analgesics. This ideally results in the patient's ability to self-medicate to his/her pain needs and allows for more effective pain control while avoiding peaks (opioid side effects) and troughs (pain) in plasma concentrations that are commonly present with "as needed" IV administration. Current PCA models have different variables for administration allowing for selective dosing. These variables include: (1) an initial loading dose, (2) a demand dose or bolus dose, (3) a lockout interval, (4) a basal continuous infusion rate, and (5) 1-hour and 4-hour maximal dose limits.[42-44] The initial loading dose is administered by the programmer or postanesthesia care nurse for initial set-up in titrating the analgesic and/or for "breakthrough pain." The demand or bolus dose is the quantity of analgesia administered to the patient on activation of the PCA demand button. The length of time after a demand dose is given by the patient, during which another demand dose will not be delivered, is the lockout interval. The lockout interval prevents overdosage with continual demand, with lockout intervals between 5 and 10 minutes being optimal.[43,44] A basal or continuous infusion is the administration of analgesics at a constant given rate regardless of the patient using the demand button. Continuous infusion rates are predominantly only administered in chronic opioid-dependent patients because continuous infusion in opioid-naïve patients may result in overdose and increased risk for respiratory depression/arrest. Likewise, in chronic opioid-dependent patients, a continuous infusion may suffice their daily equivalent dose of opioid with demand doses assisting with their postoperative analgesia. However, extreme caution and vigilance should be used in monitoring these patients. A maximal dose limit of 1-hour or 4-hour intervals is proposed to be another safety mechanism against overdose. Nevertheless, this remains controversial because opponents argue that if a patient reaches his or her 1-hour or 4-hour demand dose limit, then he or she probably requires more analgesia.

TABLE 51-4 Intravenous Patient-Controlled Analgesia Regimens

Drug Concentration	Size of Bolus	Lockout Interval (min)	Continuous Infusion
Agonists			
Morphine (1 mg/mL)			
Adult	0.5-2.5 mg	5-10	—
Fentanyl (0.01 mg/mL)			
Adult	10-20 mcg	4-10	—
Hydromorphone (0.2 mg/mL)			
Adult	0.05-0.25 mg	5-10	—
Methadone (1 mg/mL)	0.5-2.5 mg	8-20	—

From Miller RD, et al. *Miller's Anesthesia*, 7th ed. Philadelphia: Churchill Livingstone; 2010.

Because PCA requires the patient to control the delivery system, candidates for PCA must be cooperative, able to understand the concept, follow the directions of use, and be able to push the demand button. In addition, education should be provided to the patient and family members regarding the PCA delivery system.

The medications most often used for PCA are morphine, hydromorphone, and fentanyl. Meperidine is not recommended because of its neurotoxic metabolite, normeperidine. The neurotoxic side effects that are not reversible with naloxone include shakiness, tremor, twitches, multifocal myoclonus, and grand mal seizures.[45,46] Other medications that can be used via IV PCA include local anesthetics, ketamine, and clonidine. Dosing guidelines for specific medications are institution specific. A sample IV PCA dosing guideline for opioid-naïve patients is found in Table 51-4.

CHRONIC PAIN

The IASP defines chronic pain as pain that has no apparent biologic value and lasts longer than 3 months in duration or beyond the normal course of healing. It is often associated with insomnia, lost work days, impaired mobility, and emotional distress (i.e., anxiety, depression, anger, and fear). Chronic pain can be classified as being malignant (related to cancer and its treatment) or nonmalignant. Nonmalignant chronic pain is the focus of this discussion, with its categorization ranging from neuropathic, inflammatory, musculoskeletal, and idiopathic or a combination thereof. Management of the chronic pain patient is complex with cultural, emotional, biologic, and social influences all needing to be addressed. Treatment is aimed at reducing pain, improving activities of daily living, and enhancing functioning. In accomplishing this, an interdisciplinary approach to chronic pain management is essential. A team consisting of a pain management specialist, a psychologist, a physical therapist, an occupational therapist, and the patient is critical for the development of a comprehensive, specialized treatment plan.

Physiology

The transition from acute to chronic pain can be initiated or maintained by peripheral and/or central mechanisms. Physiologic mechanisms of acute pain, as previously described, include changing the chemical environment within the area of the nerve fibers that results from the inflammatory process. These changes consist of the release and accumulation of algogenic substances (e.g., bradykinin, serotonin, Il-6, IL-1β, prostaglandins) along with the release of neurotransmitters (e.g., substance P, glutamate). Exposure to these substances in the periphery induces enhanced excitability of the nerves, reduces nociceptive thresholds, and renders high-threshold nerve endings responsive to normally non-noxious stimuli.[8-10] This process is termed *peripheral sensitization* and may contribute to chronic pain states. It is clinically manifested as hyperalgesia.[47]

Despite the sequelae regarding chronic inflammation and its effects on nerve excitability and alteration in stimulus threshold, changes also can occur directly to nerve endings when nerve injury is present. Nerve injury may result in the sprouting of new hyperexcitable nerve endings, which fire ectopically. If nerve sprouting is unsuccessful, a neuroma may form, causing abnormal mechanosensitivity. Regenerated and/or damaged nerves also have reduced thresholds, which render them responsive to non-noxious stimuli. Pain that is initiated or caused by changes in the peripheral or central nervous system is defined as neuropathic pain. Clinical manifestations of neuropathic pain may include "shooting," "burning," or "stinging" sensations that are accompanied by hyperalgesia and allodynia.[48]

Central mechanisms involved with chronic pain include the continuous effects of chronic inflammation with hyperexcitability and sensitization of second-order neurons in the dorsal horn. Sensitization of the WDR neurons as well as an increase in the release of excitatory neurotransmitters, specifically glutamate, results in a phenomenon termed *wind up*. Repetitive stimulation of afferent C fibers causes a longer sustained depolarization of the cell with subsequent susceptibility to afferent input and sensitizes low-threshold afferents, leading to an increased neuronal receptive field size.[9,11]

Glutamate, the primary excitatory neurotransmitter released by primary afferents in the dorsal horn, is believed to play a role in the development of wind up. It acts at several receptors sites in the dorsal horn including the metabotropic, kainite, AMPA, and the NMDA receptors, with the latter being most recognized for its role in wind up and central sensitization. The NMDA receptor is an ionotropic receptor and, at rest, remains closed because of a magnesium plug. Activation of the receptor involves simultaneous binding of glutamate, which causes an influx of calcium inside the cell and results in an increase in second messengers such as protein kinases and phospholipases.[47,48] Other excitatory neurotransmitters, such as substance P and calcitonin-gene–related peptide, bind to and activate their receptors, also triggering up-regulation of these second messengers. The up-regulation of second messengers produces hyperexcitability of the NMDA receptors, resulting in long-term neuronal plasticity, excitability, and eventually gene transcription changes, which all contribute to central sensitization and chronic pain states.[47]

Acute and Chronic Pain

Overall, many peripheral and central physiologic factors are involved in pain processing and with peripheral and central sensitization (Figure 51-5). However, there are still many deficiencies in our knowledge regarding neurotransmitters, receptors, and the pathophysiology of pain and chronic pain states. Specific chronic pain states and syndromes are extensive and beyond the scope of this chapter.

In the presence of a chronic pain state, interdisciplinary treatment includes medicinal therapy in an attempt to improve analgesia and to enhance functional ability. Because the nature of nonmalignant chronic pain syndromes may be inflammatory, neuropathic, musculoskeletal, or idiopathic, or a combination thereof, a multimodal approach to medications may be needed as part of the treatment regimen. In addition to the acute pain analgesics previously presented, other common analgesics used for the treatment of chronic pain syndromes are discussed here.

Chronic Pain Analgesics and Adjuncts

Anticonvulsants

Anticonvulsants or antiepileptics are commonly used in certain neuropathic pain syndromes when treatment is refractory to traditional analgesics. First-generation anticonvulsants, such as carbamazepine and phenytoin, have been used for many years for neuropathic pain; however, more recently the second-generation anticonvulsants gabapentin (Neurontin) and pregabalin (Lyrica) are the most widely used. Anticonvulsants inhibit neuronal excitation and stabilize nerve membranes in an effort to decrease repetitive neural ectopic firing, which is common in neuropathic pain.

Gabapentin and pregabalin are used for the management of postherpetic neuralgia, diabetic neuropathy, trigeminal neuralgia, and other neuropathic pain and chronic pain syndromes. Their mechanism of action is similar, because it is believed that both block the alpha 2 delta (α2δ) subunit of the presynaptic voltage-gated calcium channels in the CNS, thereby preventing excitatory neurotransmitter release.[49] Pregabalin and gabapentin are structural analogs of GABA, which lack affinity to the GABA receptors. Both exhibit anticonvulsant, anxiolytic, and antihyperalgesic effects.[50] When compared with gabapentin, pregabalin displays a pharmacokinetic profile that requires less dosing with fewer side effects.[49-51]

Common side effects are dose dependent and include dizziness, somnolence, peripheral edema, and weight gain.[49] Currently, pregabalin and gabapentin are available in the oral form only. Because neither drug undergoes hepatic metabolism, drug-to-drug interactions are minimal. The unchanged form of the drug is excreted by the kidneys; therefore, patients with compromised renal function may require dose modifications.[51] Pregabalin and gabapentin use is not limited to chronic pain syndromes. They are also being effectively used in multimodal techniques for acute postoperative pain management, which resulted in lower reported pain scores and lower opioid consumption.[50,52,53] Lastly, patients presenting for surgery who are routinely taking anticonvulsants as part of a chronic pain syndrome treatment regimen should continue taking their medication throughout the perioperative period because this will optimize their pain management.

Antidepressants

Several antidepressants are being used for chronic pain syndromes. Similar to anticonvulsants, they are effective in the treatment of neuropathic pain syndromes. Common antidepressants include the tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and selective norepinephrine and serotonin reuptake inhibitors (SNRIs) (Table 51-5). In the presence of central sensitization, the descending inhibitory pathway, which uses inhibitory neurotransmitters (i.e., serotonin and norepinephrine), is altered. It is believed that antidepressants may exert their analgesic effects by blocking the reuptake of serotonin and norepinephrine in the CNS, thereby increasing their availability. They may also act at other sites via (1) blocking of sodium and calcium channels, (2) decreasing PGE_2 and TNF-α, (3) blocking NMDA receptors, and (4) enhancing opioid

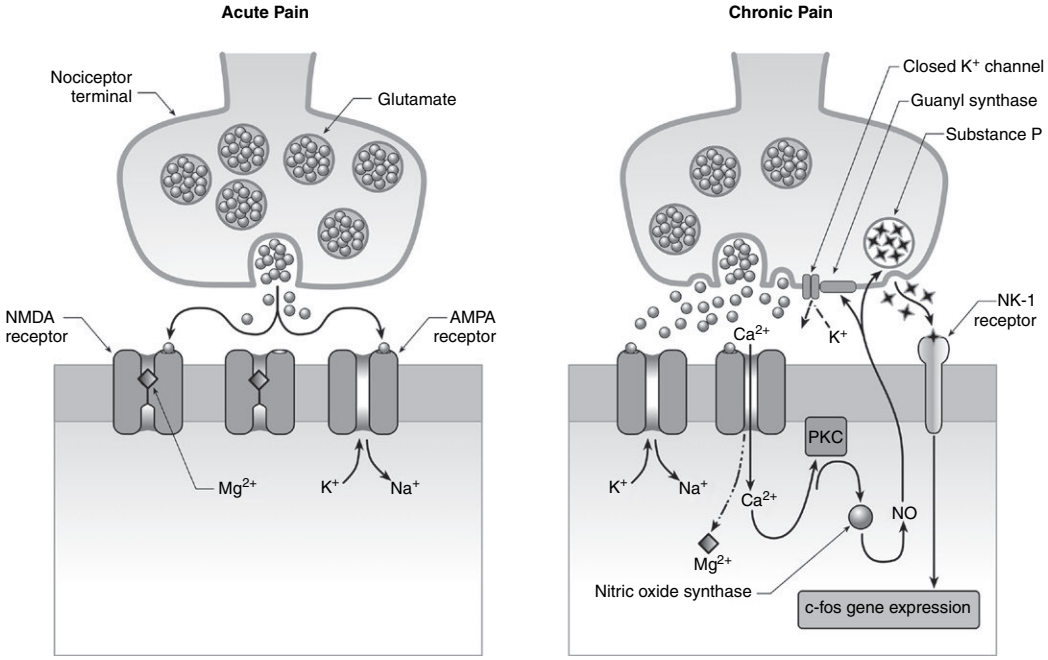

FIGURE **51-5** Comparison of acute and chronic pain. Acute pain signals trigger glutamate release, thereby activating AMP receptors and fluxing Na^+ and K^+. Typically in acute pain, the NMDA receptors remain blocked by the Mg^{2+} ion "plug." Hence, weak stimulation normally activates the AMPA receptors and not the NMDA receptors. With chronic pain, there is continuous stimulation that forces the Mg^{2+} plug out of the NMDA receptor. This allows a large amount of Ca^{2+} to flux into the cell where it reacts with second messengers (i.e., PKC and NO synthase) to produce NO. NO leaves the cell and reacts with guanyl synthase. Guanyl synthase closes the K^+ channel, which may contribute to opioid resistance. NO also stimulates the release of SP, which leads to gene expression changes, increased sensitization, and neural remodeling. *NMDA*, *N*-methyl-D-aspartate; *AMPA*, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; *PKC*, protein kinase; *NO*, nitric oxide; *NK-1*, neurokinin-1; *c-fos*, protein oncogene encoded by the FOS gene in humans.

TABLE 51-5 Common Antidepressants Used for Chronic Neuropathic Pain

Drug Class	Generic Name	Trade Name
TCAs	Amitriptyline	Elavil
	Nortriptyline	Pamelor
	Imipramine	Tofranil
SNRIs	Venlafaxine	Effexor
	Duloxetine	Cymbalta
	Milnacipran	Savella
SSRIs	Fluoxetine	Prozac
	Citalopram	Celexa

TCA, Tricyclic antidepressant; *SNRI*, selective serotonin-norepinephrine reuptake inhibitors; *SSRI*, selective serotonin reuptake inhibitors.

receptors, which may account for additional analgesic effects.[54] Analgesic dosage is much lower than the recommended antidepressive dose, and their analgesic effects may not occur until 4 to 10 days after initiating treatment.

TCAs (amitriptyline and nortriptyline) tend to have more side effects than the selective serotonin reuptake inhibitors (SSRIs) and selective serotonin-norepinephrine reuptake inhibitors (SNRIs) because they antagonize other receptors including muscarinic (e.g., dry mouth, blurred vision, and urinary retention), histaminergic (e.g., sedation, appetite stimulation with subsequent weight gain), and adrenergic (e.g., orthostatic hypotension, prolonged QT interval). They are contraindicated in patients with a history of a recent myocardial infarction, prolonged QT interval, cardiac dysrhythmias, or unstable congestive heart failure. Drug levels can be monitored to ensure unintentional overdose. The metabolism of all antidepressants is primarily hepatic. TCAs are commonly used for the treatment of postherpetic neuralgia, headaches, and fibromyalgia.

SNRIs (duloxetine, venlafaxine) are generally better tolerated than the TCAs because of the lack of affinity for the adrenergic, histaminergic, and cholinergic receptors. Therefore, they are preferred for those patients with cardiac disease. Both drugs (duloxetine and venlafaxine) have similar side effects: nausea, dry mouth, somnolence, headaches, and sexual dysfunction.[55] Likewise, the concomitant use of SNRIs with SSRIs or triptans is not recommended because this may precipitate a *serotonin syndrome*. Serotonin syndrome is an acute toxicity of serotonin manifesting as anxiety, agitation, delirium, seizures, hyperthermia, diaphoresis, tachycardia, hypertension or hypotension, hyperreflexia, myoclonus, and muscle rigidity. Symptoms vary from mild to life threatening, and diagnosis is based on patient medication history, physical examination, and exclusion of other neurologic disorders.[56,57]

SSRIs for the treatment of chronic pain are still under investigation because very few clinical trials have been done. They are primarily used for the treatment of depression, and their analgesic effects, thus far, are relatively weak.[58] Regardless of the type of antidepressant being taken for chronic pain, they should be continued throughout the perioperative period.

BOX 51-4

Systemic Effects of Steroids

Endocrine
- Adrenal-pituitary insufficiency
- Hypercortisolism
- Hyperglycemia
- Cushing's syndrome

Cardiovascular
- Hypertension
- CHF
- DVT
- Cardiomyopathy

Musculoskeletal
- Muscle weakness
- Osteopenia/osteoporosis
- Avascular necrosis of bone
- Pathologic fractures
- Truncal obesity

Dermatologic
- Skin thinning
- Alopecia
- Petechiae
- Facial flushing
- Striae
- Hirsutism

Renal
- Sodium and water retention

Gastrointestinal
- Peptic ulceration
- Gastritis
- Hyperacidity

Neurologic/Psychological
- Headache
- Vertigo
- Euphoria
- Restlessness
- Insomnia
- Mood swings
- Depression

CHF, Congestive heart failure; *DVT*, deep vein thrombosis.

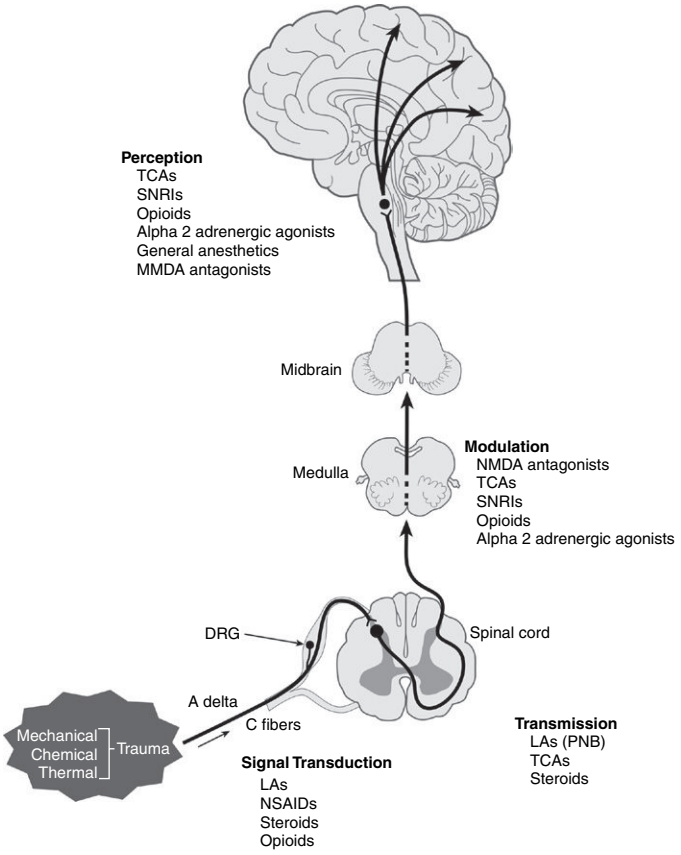

FIGURE **51-6** Pharmacotherapy and pain processing targets. The four processes of somatic nociceptive pain are signal transduction, transmission, modulation, and perception. Pharmacotherapy has an overall inhibitory effect on these processes. Modulation occurs primarily in the dorsal horn of the spinal cord, but also takes place in supraspinal structures. The endogenous descending inhibitory modulating pathway is also involved in pain inhibition, and it is not present in this illustration. *TCA*, Tricyclic antidepressant; *SNRI*, selective serotonin-norepinephrine reuptake inhibitor; *NMDA*, *N*-methyl-D-aspartate antagonist; *NSAIDs*, nonsteroidal antiinflammatory drugs; *LA*, local anesthetic; *PNB*, peripheral nerve block.

Corticosteroids

Exogenous corticosteroids (glucocorticoids) are administered in a variety of routes (e.g., orally, intravenously, epidurally, caudally, and via intraarticular) as adjunct analgesics for multiple types of acute onset and chronic pain syndromes. They exert multiple effects on the body including autoimmune, antiinflammatory, antiedema, and antiallergic. Typical disease processes and pain syndromes that are treated with corticosteroids include rheumatoid arthritis, osteoarthritis, herpetic neuralgia, chronic low back pain, and chronic neck pain. In the treatment of acute and chronic pain syndromes, corticosteroids exert their effects in several ways. They are primarily known for their antiinflammatory effect because they prevent the release of arachidonic acid by inhibiting phospholipase A2 on cell membranes. Through this mechanism, they decrease inflammatory cytokines (Il-6, IL-1, TNF-α) and prostaglandins. When corticosteroids are injected epidurally, it is also purported that corticosteroids exhibit nociceptive properties by blocking C fiber transmission. In addition, they suppress ectopic firing of nociceptors in the presence of nerve injury, which produces a direct membrane-stabilizing effect.[59]

Side effects of corticosteroids are reflective of supraphysiologic doses that usually exceed the rate of endogenous steroid production, which is approximately 20 mg per day of hydrocortisone or its equivalent.[59] Many organ systems can be affected with long-term steroid use (Box 51-4). These effects are variable among patients and are dependent upon the degree of hypothalamic-pituitary-adrenal axis (HPA) suppression, which is attributed to the type of steroid, duration of use, frequency of ingestion, route of administration, and dosage. However, when corticosteroids are administered as an intermittent injection (e.g., epidural, intraarticular, caudal) versus chronic daily use, side effects are usually mild and transient. It has been purported by Kay et al.[60] that weekly epidural steroid injections given over 3 weeks caused dramatic HPA suppression with normal cortisol levels returning within 1 month. Similarly, it has been found that a single epidural steroid injection can cause HPA suppression from 4 to 5 days of injection and lasting up to 5 weeks.[61] Currently, there is no consensus among pain management specialists on the dosing, frequency, or total number of repeated steroid injections. Regardless, in the event of a major surgical procedure after the recent administration of an epidural steroid, it may be prudent to administer a dose of exogenous steroid (Figure 51-6).

Methadone

Methadone is a synthetic opioid historically used for the treatment of opioid addiction in detoxification or treatment programs. Recently its use is increasing for the treatment of severe acute pain as well as for chronic cancer and noncancer pain management. Structurally, methadone is a racemic mixture of two enantiomers, d-isomer (S-methadone) and l-isomer (R-methadone). The d-isomer (S-methadone) is responsible for antagonizing the NMDA receptor and inhibiting serotonin and norepinephrine uptake, which possibly contributes to its benefits in the

treatment of neuropathic pain, along with the prevention of opioid tolerance and hyperalgesia.[62] The l-isomer (R-methadone) is responsible for binding to opioid receptors, thereby owing to its analgesic effects.

Methadone is a viable option for chronic pain patients who have tolerance (intolerable side effects or inadequate analgesia) to current opioids. It can be administered orally, intravenously, rectally, and subcutaneously. Due to its high degree of lipid solubility, it is well absorbed via the gastric mucosa with peak analgesic effects in 30 to 60 minutes. When given intravenously, the drug has peak effects that are seen in 15 to 20 minutes. Unlike other opioids, methadone has a long half-life of approximately 15 to 60 hours. This long half-life is ideal for maintenance programs, thereby preventing withdrawal symptoms. However, when methadone is administered for chronic pain states, it is difficult to initiate, to titrate, and to convert from another opioid, which makes dosing a challenge.[63]

Metabolism of methadone is primarily via the CYP450 enzyme, specifically CYP3A4 and CYP2B6, into inactive metabolites that are excreted in the urine.[64] Therefore, any medications that inhibit (e.g., phenytoin, carbamazepine) or induce CYP450 may dramatically alter methadone metabolism.[65]

Side effects of methadone are similar to other opioids including respiratory depression and excessive sedation; respiratory depression peak effects occur later than the analgesic peak effects. A unique side effect of methadone includes QT interval prolongation, which could lead to potentially lethal ventricular tachyarrhythmias and torsades des pointes. Patients taking methadone on a continuous basis should be carefully monitored with a cardiac evaluation. An electrocardiogram should be obtained pretreatment, after 30 days of initiating methadone, and annually thereafter. An additional electrocardiogram is recommended when methadone dosage exceeds 100 mg per day. A QT interval that exceeds 500 ms is deemed a risk factor for lethal arrhythmias, and discontinuation of methadone or a dose reduction is advisable.[66]

Due to methadone's long half-life, its use in acute pain management is limited but effective. Gottschalk et al.[67] reported improved postoperative pain control for patients undergoing complex spine surgery after a single dose of methadone injected prior to surgical incision as compared with a continuous sufentanil infusion. Those who received the preincisional methadone injection had a significant reduction in opioid requirements 48 to 72 hours after surgery.[67] In the event that methadone is chosen as an analgesic for perioperative pain management, an electrocardiogram is warranted preoperatively with identification of those at risk for prolonged QT interval. These risk factors include the concomitant use of antiarrhythmic agents, some TCAs and calcium channel blockers, the presence of hypokalemia, and a history of prolonged QT interval. Furthermore, chronic pain patients are often taking a combination of medications such as benzodiazepines and other CNS depressants, which poses an added risk for respiratory depression and sedation.[65]

Methadone's lack of active metabolites, long half-life, and low cost make it desirable for chronic nonmalignant pain management. Nonetheless, prolonged use of methadone and other opioids for the treatment of chronic pain are associated with the risks of dependence, tolerance, addiction, and in rare instances, misuse.

Dependence can be either physiologic or psychological in nature. Physiologic dependence is a pharmacologic property of opioid drugs defined by the manifestation of a "withdrawal syndrome" after abrupt discontinuation of the opioid, or after the administration of an opioid antagonist (naloxone) or a mixed agonist-antagonist. Because opioids inhibit cAMP, any abrupt discontinuation of the opioid can cause a rebound disinhibition of cAMP and subsequent withdrawal symptoms. Withdrawal symptoms include autonomic nervous system responses such as increased irritability, restlessness, tremors, chills, muscle cramps, sweating, mydriasis, abdominal pain, diarrhea, and tachycardia.[68] Physiologic dependence should always be assumed to exist after repeated administration of an opioid for more than a few days.[69,70] To prevent opioid withdrawal syndrome, opioids should always be tapered before being discontinued, and daily scheduled opioids should be continued perioperatively.

Psychological dependence is characterized by the craving for an opioid drug to achieve a psychological effect, resulting in the continual use of the drug despite harm to self or others. Psychological dependence is inappropriately referred to as "addiction." Psychological dependence is more accurately described as a component of addiction and is defined by the American Academy of Pain Medicine, the American Pain Society, and the American Society of Addiction Medicine as a "primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving."[71] Iatrogenically induced psychological dependence or addiction of opioids is rare when they are taken for medicinal reasons.[72]

Pseudoaddiction is often confused with psychological dependence because the behavior of the patients can be the same. That is, patients with both of these conditions exhibit what appears to be drug-seeking behavior. However, in the patient who is pseudoaddicted, the origin of the behavior is inadequate analgesia. When these patients receive adequate analgesia, they no longer demonstrate drug-seeking behavior.

Tolerance refers to a change in the dose-response relationship induced by repeated exposure to the drug and manifested as a need for a higher dose to maintain an analgesic effect. Tolerance may be the result of several mechanisms, such as enzyme induction due to continued opioid administration or down-regulation of opioid receptors.[73] Other mechanisms involved with tolerance continue to be debatable and include changes in drug-receptor interactions, cellular alterations, as well as long-term adaptations in gene expression.[74,75] The development of tolerance to an opioid is a normal physiologic response. When tolerance to an opioid occurs, opioid rotation is suggested. Opioid rotation involves switching from one opioid to another in an effort to improve analgesia and decrease side effects.

Opioid-induced hyperalgesia (OIH) is a phenomenon that occurs with chronic opioid therapy, which attributes worsening pain to high, escalating doses of opioids. Complaints of pain in locations different from the original pain area, whole-body hyperesthesia, allodynia, agitation, multifocal myoclonus jerks, and seizures are manifestations of OIH.[76] OIH is often improved with reducing or discontinuing the opioid. The exact mechanism of action of OIH is not fully understood. However, there are many proposed theories. For instance, central activation of NMDA receptors via glutamate may play a role in OIH, as well as a shifting of the pain modulation system from a descending inhibitory pathway to a facilitating pronociceptive pathway.[77,78] It also has been suggested that prostaglandins stimulate glutamate release, which may contribute to the development of OIH.[79] Diagnosing OIH is difficult because it resembles opioid tolerance. Once diagnosed, treatment strategies consist of weaning the patient from high-dose opioids and starting non-opioid analgesics (e.g., NMDA receptor antagonists, NSAIDs, COX-2 inhibitors).[76,78]

Chronic Opioid Therapy and Perioperative Pain Management

Chronic opioid therapy (COT) for the treatment of chronic nonmalignant pain is escalating in the United States. It is inevitable that COT patients, along with patients who are on drug maintenance programs for opioid addiction, will require elective or emergent surgery. This patient population presents many challenges for the anesthesia provider in regard to perioperative analgesia. A recent observational study found that patients using COT are at risk for higher than normal levels of postoperative pain and slower pain resolution than those not on COT for chronic pain or without preexisting chronic pain.[80] Thus it is imperative to collaborate with the patient and the surgical team to develop a unique and realistic perioperative pain management plan. As with treating patients in acute pain, a multimodal approach to pain management should be implemented.

Preoperative

Preoperatively, preferably prior to the day of the surgical procedure, an investigation regarding the types of medications, dosages, and duration of therapy is helpful in determining the extent and severity of the chronic pain syndrome. Inquiries specific to preoperative pain and the patient's chronic pain state should be addressed; these are shown in Box 51-3. If the patient is on an opioid maintenance program for addiction, methadone dosage should be verified by the prescribing physician/clinic. Chronic opiate therapy, including methadone, should be continued throughout the perioperative period because this will provide uninterrupted dosing for the patient's baseline opioid requirement and avoid withdrawal. If the patient has not taken his/her daily scheduled opioid, an equivalent dose of opioid should be administered preoperatively. In the event the patient has a transdermal fentanyl patch, it should remain on throughout the perioperative period unless a collaborative decision has been made based on the invasiveness of the surgical procedure to remove it. If the patch is removed, a continuous IV infusion of fentanyl should be initiated and maintained perioperatively. Alternatively, equipotent morphine also can be administered. Likewise, if a patient has an implanted intrathecal or epidural opioid infusion system, it should continue perioperatively.[81] Other medications taken for chronic pain (e.g., antidepressants, anticonvulsants, α_2 agonists) should be continued on the day of surgery.

The preoperative assessment is the ideal setting in which to establish a positive rapport with the patient, especially in the presence of a chronic pain state or a maintenance program. Chronic opiate therapy patients can be highly anxious, fearful, or depressed, and reassurance that their pain will be aggressively treated is paramount. Furthermore, realistic expectations regarding pain control should be discussed. Administering a benzodiazepine, along with initiating multimodal analgesia with adjuvant analgesics, is optimal and should be started within 1 to 2 hours prior to surgery.[82] This is also the time to discuss options for regional anesthesia/analgesia techniques. These techniques would be of great benefit for intraoperative and postoperative analgesia in the COT patient.

Intraoperative

There are no data supporting a specific opioid for pain control intraoperatively for COT patients, nor have any specific dosing guidelines been established. The specific opioid selected is an anesthesia provider preference with patient coexisting diseases and surgical procedure dictating one versus another. The intraoperative opioid selected should provide adequate baseline opioid requirements as well as render intraoperative and postoperative analgesia. Intraoperative opioids may need to be increased 30% to 100% as compared with the opioid-naïve patient because of receptor down-regulation and/or tolerance. Titration of opioids to heart rate and blood pressure response, in addition to pupil size, may be useful for estimating adequate analgesia with general anesthesia. Respiratory rate and depth also may be monitored in the spontaneously breathing awake or anesthetized patient to estimate adequate analgesia. In the event that a specific opioid is not efficacious, opioid rotation is recommended.[83] Cross tolerance among opioids may be incomplete. Hence, a specific opioid will not produce a similar degree of tolerance as a different opioid within the same class. Opioid antagonists and agonist-antagonists should be avoided because these will precipitate an acute withdrawal syndrome.

Nonopioid analgesic adjuncts (ketamine, clonidine, and dexmedetomidine) also should be a part of the multimodal approach to perioperative pain management. These will aid with analgesia and produce opioid-sparing effects. In a recent randomized control study, COT patients with chronic back pain undergoing back surgery were administered ketamine 0.5 mg/kg IV on induction. A continuous ketamine infusion of 10 mcg/kg/min was initiated after induction and discontinued upon wound closure. Unlike the placebo group who received saline, the COT group required less morphine 48 hours postoperatively.[84]

Lastly, it is recommended that regional anesthesia with local anesthetics and opioids be a part of the anesthetic plan whenever possible in COT patients; this will reduce opioid requirements and provide analgesia. If regional anesthesia is used, intrathecal, and/or epidural opioid administration is not adequate for baseline opioid therapy. Equipotent IV opioids should be given as the baseline therapy for the prevention of withdrawal.[85] Another option for perioperative analgesia includes peripheral nerve blocks with a continuous catheter infusion of local anesthetic.

Postoperative

If the patient is not a candidate for regional anesthesia/CPNB or did not benefit from it, then intravenous PCA should be considered. Setting appropriate parameters for the PCA in the COT patient can be very challenging. A basal continuous infusion is suggested to replace the daily dose of opioid with demand doses varying among individuals.[56,86] When COT patients are able to resume oral intake, dosing is variable among individuals with gradual weaning to their presurgical therapy regimen. Consultation with a pain specialist regarding PCA dosing and opioid conversion for various routes of administration for COT patients is highly recommended. Other recommendations for perioperative pain management for the patient on COT are found in Table 51-6.

SUMMARY

Pain physiology and treatment are continuously being researched. It is essential that nurse anesthetists are knowledgeable and current with the advances in pain assessment, management, and treatment modalities. CRNAs are in a unique position to initiate and participate in the treatment of pain across the life span and for a variety of disease states in a holistic manner. Including patients in their pain treatment plan empowers them to adhere to treatment modalities and to manage their own pain. As educators, CRNAs have the opportunity to share their knowledge regarding effective pain management in an effort to improve the health and well-being of patients.

TABLE 51-6 Recommendations for Perioperative Management of the Chronic Opioid Therapy Patient

Preoperative	Intraoperative	Postoperative
Pain assessment	Continue baseline opioid (oral, transdermal, IV, intrathecal pump)	Multimodal analgesic techniques
Precise opioid use (dose/type)—continue DOS	Increases in intraoperative opioids due to tolerance—titrate or continuous infusion	Maintain baseline opioid
Adjuvant medications for CP—continue DOS	Consider opioid rotation	Titrate opioids aggressively to achieve adequate pain control
Reassurance and address fears/anxiety	Multimodal approach	PCA—primary or supplementary for epidural/regional
Multi-modal pain plan—consider NSAIDs, acetaminophen, 1-2 hrs prior to surgery, anxiolytics	Consider regional, LA wound infiltration, PNB, CPNB, epidural/SAB	Continue applicable regional techniques
Consult with addiction specialist/clinic if indicated—continue methadone maintenance	Consider adjuvants—ketorolac, ketamine, clonidine, dexmedetomidine	Continue ketamine or low-dose ketamine infusion, if started in the OR
Plan for postoperative analgesia	Anticipate increases in inhalation agent	Monitor for respiratory depression
	Avoid opioid antagonists and mixed agonists	Continued assessment of analgesia
		Implement nontraditional comfort measures

CP, Chronic pain; *DOS*, day of surgery; *PCA*, patient-controlled analgesia; *LA*, local anesthetic; *PNB*, peripheral nerve block; *CPNB*, continuous peripheral nerve block; *SAB*, subarachnoid blockade; *IV*, intravenous; *NSAIDs*, nonsteroidal antiinflammatory drugs.

52 CHAPTER Anesthesia for Therapeutic and Diagnostic Procedures

◆ *Adree N. Williams*

Considering the evolving patient population and dynamic needs of a healthcare system under redesign, it should come as no surprise that the world of anesthesia, including the setting, is also under reconstruction. Although most anesthetics were traditionally administered in the operating room, it is no longer unusual for services to be provided outside the operating suite in a variety of locations that are far from the traditional setting. Estimates today indicate that up to 55% of the procedures that require anesthesia services are taking place outside the conventional operating room.[1] These include diagnostic, interventional, and traditional surgery involving cardiology, vascular, emergency department, gastroenterology, gynecology, hematology, oncology, thoracic, neurologic and neurosurgical, plastic, ophthalmology, orthopedic, psychiatric, radiologic, and other diagnostic and dental procedures.[2] Patients treated in these new settings deserve the same safe, vigilant attention, anesthetic administration, and recovery care as those patients treated in the operating suite. The key for the anesthesia provider is to make sure the therapeutic and diagnostic environment where anesthesia is to be performed is as familiar, as well equipped, and as safe as it is in the operating room.

Although certain therapeutic and diagnostic procedures are sometimes performed without anesthesia, the patient's condition or the requirements of the test or procedure may necessitate administration of an anesthetic. Anesthesia could range from local anesthetic infiltration and regional anesthesia techniques to monitored anesthesia care involving enteral minimal sedation, parenteral moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia. Patients can range in age from pediatric to geriatric. In remote locations, patients who require anesthesia could be confused or disoriented, uncooperative, unwilling or unable to understand the requirements of the procedure, claustrophobic, anxious, or mentally disabled. As medical technology rapidly progresses, more patients will be seen outside the operating room for therapeutic and diagnostic procedures. Older and medically higher-risk patients are being treated more often in this environment.[1,3-5] Of the patients treated in these settings, 20% are over the age of 70 and 69% have ASA classifications of 3 to 5.[1,3,4] The therapeutic or diagnostic procedure might require the patient to lie still for an extended length of time or cause moments of painful, visual, and audio stimulation alternating with long periods of no stimulation, which makes anesthesia delivery challenging for the anesthetist. Some reasons why these procedures present a special challenge to the anesthesia team are noted in Box 52-1.

Given the rapid advances in medical knowledge and technology, coupled with a strong societal impetus to reduce healthcare costs, more therapeutic and diagnostic procedures will be performed in remote locations.[1,3]

ADMINISTRATION OF ANESTHESIA IN REMOTE LOCATIONS

Special Considerations

The operating room provides an ideal environment for the administration of anesthesia and the performance of surgical procedures because of its familiarity for medical staff and the rapid availability of needed anesthesia equipment, medications, supplies, and well-trained adjunct personnel. The anesthesia setting in a remote location must possess the same level of safety and high standards. Many considerations and plans must be made before a patient can safely receive anesthesia for a therapeutic or diagnostic procedure in a remote location. Box 52-2 provides a comprehensive checklist of the requisites that will facilitate planning and gathering needed equipment, supplies, and medications.

A policy must be developed that outlines the organization of emergency services for either in-hospital or office-based facilities. Office-based facilities should have a plan for regular emergency training of personnel, interoffice communication during an emergency, communication with emergency medical personnel, and transportation to the nearest hospital emergency department.

An anesthesia machine and portable anesthesia cart with the listed equipment, supplies, and medications should be dedicated strictly for use in remote locations. This can save preparation time whenever a procedure is required in a remote location. It also increases patient safety and decreases the risk of a mishap resulting from lack of necessary equipment and materials.

As part of the planning process before patient treatment, it is important to familiarize oneself with the personnel and the work area in the remote environment. The workplace allotted for anesthesia care may be small, crowded, and different from the usual operating room setting. Pre-planning is important to make this *different* location *familiar* to the anesthetist and safe for the patient to receive the anesthetic and therapeutic or diagnostic procedure. No remote location should ever limit the ability to manage these anesthetic procedures or prevent equipment, medications, supplies, positive-pressure ventilation, resuscitation, and suction from being readily available.

The Anesthesia Patient Safety Foundation is a good resource for seeking information regarding new anesthesia-related developments, new anesthesia products, and discussion of safety issues.

The American Association of Nurse Anesthetists (AANA),[6] the American Society of Anesthesiologists (ASA),[7,8] and The Joint Commission[9-13] have established written standards and professional commentary to provide for the basic rights and safety of patients, along with the safety of anesthesia providers and ancillary personnel. As technology advances, these standards are adapted and new recommendations are made.

Licensed registered nurses who are not qualified anesthesia providers have become involved in the monitoring of patients and the administration of medications for procedural sedations involving therapeutic and diagnostic procedures, as well as for certain surgical procedures.

The AANA and the ASA separately and together have issued statements in regard to criteria (Box 52-3) that must be met by non-anesthesia providers to protect the safety and well-being of the patient.[14,15]

BOX **52-1**

Unique Challenges of Anesthesia Administration Outside Operating Rooms

- Working with individuals who do not understand the nuances of anesthetic management and may not appreciate the fine line between a stable and uneventful case and a potentially dangerous or lethal one
- Less efficient or effective scheduling, resulting in inefficient or hurried patient preparation
- Equipment that is less well maintained than in the operating room
- Greater variation in physical set-ups and anesthesia and monitoring equipment, resulting in the clinician's decreased familiarity with the environment and the equipment
- Greater variability in the time needed to obtain patient records, which can cause delays in collecting adequate information about patient history and the procedures to be performed
- Inadequate monitoring of stock items, which therefore may be missing or in short supply
- Nursing and support personnel who do not follow rigorous preprocedure check-in processes
- Working with individuals whom the anesthesia provider has not met before or does not know well
- Being positioned away from the patient or in a different room for long periods during the procedure
- Being at a distance from the core areas where anesthesia personnel congregate, so less local support is available when problems arise, there are fewer opportunities to discuss questions or concerns, and there are fewer opportunities to collaborate if problems appear

Modified from Frankel A. Patient safety: anesthesia in remote locations. *Anesthesiol Clin*. 2009;27(1):127-139.

Standards for the Delivery of Anesthesia in a Remote Location

A. Perform a complete preanesthesia assessment.

The patient, parent(s), or legal guardian(s) must be thoroughly and unhurriedly interviewed before the performance of an anesthetic procedure. The preanesthesia assessment should be performed in consideration of the patient's right to privacy and confidentiality and which safeguards their dignity and respects aspects of their psychological, cultural, and spiritual values. During this assessment, information is obtained regarding the patient's medical history (prior allergy must be assessed), anesthesia history (noting any prior complications and responses to prior anesthetic experiences), surgical history, and medication history (including tobacco, alcohol, and any substance abuse). A complete physical assessment of the patient is made, along with inspection of the head, neck, mouth, and airway. The anesthetist's head and neck assessment can be especially beneficial to the patient's well-being, because common oral conditions and suspicious head/neck, skin, and oral pathologic lesions can be detected and referred for further evaluation by a dentist or a physician. Early referral for diagnosis and treatment of any disease contributes to patient cure and recovery to wellness, as well as reduced morbidity and mortality.[16] Lung and heart sounds are auscultated. Review is made of objective diagnostic data such as patient laboratory values, radiographs, and electrocardiogram (ECG). Important findings are noted in the patient's anesthesia record. A physical status classification is then assigned the patient.

Box 52-4 outlines specific patient conditions that alert the anesthetist to a need for special attention and care for anesthetics provided for therapeutic and diagnostic procedures.

B. Obtain informed consent for the planned anesthetic intervention from the patient or legal guardian.

The anesthesia provider should discuss the course of the anesthetic care and enumerate the following in understandable terms appropriate for the patient or guardian:

- How the anesthetic procedure will be performed
- Possible risks of the anesthetic procedure
- Pertinent possible reactions or complications the patient might expect while receiving a typical anesthetic, along with informing the patient or guardian that the anesthetist has permission to make changes or adjustments as deemed necessary in his or her professional judgment
- Possible options to the type of anesthetic to be received by the patient
- The ability for the patient/parent(s)/guardian(s) to have any concerns addressed and questions answered

At times, anesthesia for therapeutic and diagnostic procedures will require only minimal, moderate, or deep sedation, which by definition may not include patient amnesia. Only general anesthesia ensures amnesia as a standard of care. Therefore, discussion of what the patient can reasonably expect should take place at this time.[17,18] It is far easier to discuss these points with the patient before the anesthetic procedure than to explain these points after the fact.

C. Formulate a patient-specific plan for anesthesia care.

The art and science of anesthesia mandate that the safest and least invasive anesthetic technique be administered to the patient to simplify delivery of the anesthetic and to avoid complications for the patient while in the remote location.

D. Implement and adjust the anesthesia care plan based on the patient's physiologic response.

Immediately before implementation of anesthesia, reassess the patient (e.g., vital signs, airway status, and response to preprocedure medications given), and document a reassessment note in the anesthesia record. The Joint Commission defines "immediately" as the moments just before the sedation is administered. Also, make sure all anesthesia equipment, supplies, and medications are checked and immediately available in case the patient needs a change in the anesthetic plan.

E. Properly prepare, dispense, and label all medications to be used for the patient.

All medications drawn up prior to the case must be labeled with the drug name, strength (concentration), amount (if not apparent from the container), and expiration date (if not used within 24 hours). Medications drawn up and used immediately for the procedure do not require labeling.

F. Adhere to appropriate safety precautions, as established with the institution, to minimize the risks of fire, explosion, electrical shock, and equipment malfunction.

This standard is important for the patient, the anesthesia provider, and ancillary personnel for the prevention of accidents and injury. It is also important from a medicolegal standpoint. The anesthesia provider should also be an integral part of the team involved with protocols for preventing wrong site, wrong procedure, and wrong person surgery, also known as the *Universal Protocol* established by The Joint Commission.[19-23] Safety must be a consideration for scheduling obligations of anesthesia personnel because anesthesia for therapeutic and diagnostic procedures is often more involved and complex when compared with anesthesia delivered in the operating room.

G. Monitor and document the patient's physiologic condition as appropriate for the type of anesthesia and specific patient needs.[6,7]

BOX **52-2**

Requisites for Administration of Anesthesia in Remote Locations

Utilities

- Adequate workspace
- Adequate overhead lighting
- Adequate number of and current-carrying capacity of electrical outlets
- Electrical service with either isolated electric power or ground fault circuit interrupters
- Uncluttered floor space
- Two-way communication devices—telephone, intercom, Internet availability (instant messaging), personal digital assistant (PDA) device, two-way radios. Consider devices with power independent of the electrical service.
- Backup power
- Suitable area for postprocedure recovery (All building codes, fire codes, safety codes, and facility standards must be met.)

Equipment

- Local infiltration, intravenous sedation, regional and general anesthesia
- Patient chair, cart, or operating surface that can be quickly placed into Trendelenburg position
- Regularly serviced and functioning equipment
- Patient monitors
- Pulse oximeter
- Electrocardiograph
- Blood pressure monitor with a selection of adequate-sized cuffs
- Capnograph
- Anesthesia awareness/level of consciousness/anesthesia-depth monitor
- Body temperature monitor
- Oxygen supplies
- Minimum of two oxygen sources must be available with regulators attached (compressed oxygen should be the equivalent of an E cylinder)
- Positive-pressure ventilation sources, including a self-inflating resuscitator bag capable of delivering at least 90% oxygen and a mouth-to-mask unit
- Defibrillator—manual biphasic or automatic external defibrillator (AED) (charged, ready, and easily accessible)
- Suction source or a suction machine (electric-powered suction, battery-powered suction, or foot pump suction devices are available), tubing, suction catheters, and Yankauer suctions
- Lockable anesthesia cart to permit organization of supplies, including endotracheal equipment, laryngeal mask airways, dental laryngeal mask airways, tube of water-soluble lubricating jelly, Combitubes, an assortment of various-sized disposable facemasks, nasal cannulas, Connell airways, disposable facemasks with oxygen tubing, oral and nasal airways, syringes (1-mL tuberculin syringe, 3 mL, 5 mL, 10 mL, 20 mL, 60 mL), needles, intravenous catheters, tourniquet, intravenous fluids and tubing, alcohol pads, adhesive tape, sterile intravenous site covers, disposable gloves, stethoscopes, precordial stethoscope with monaural earpiece and extension tubing, precordial stethoscope adhesive disks, and appropriate anesthetic medications
- Battery-powered flashlight for the illumination of the patient, the anesthesia machines, and the monitors along with spare batteries
- Syringe pump, wall plug/transformer, and spare batteries
- Warm blankets, electric blanket (check with hospital policy before using an electric blanket), or forced-air warming devices with the appropriate blanket; towels, or hat to cover the patient's head to preserve body warmth
- Blankets, towels, or foam for padding for protection of skin integrity, bony prominences, and body extremities
- Emergency medications to include, at a minimum: adenosine, aminophylline, amiodarone, atropine, dextrose 50%, diphenhydramine, ephedrine, epinephrine, flumazenil, hydrocortisone, lidocaine, naloxone, nitroglycerin, phenylephrine, succinylcholine, verapamil, and a bronchial dilator inhaler such as albuterol or nebulized epinephrine (such as Primatene mist)
- Preoperative anesthesia evaluation forms
- Anesthesia consent form
- Anesthesia charts, clipboard, black ink pens, indelible ink pens

Additional Requirements for General Anesthesia

- Oxygen fail-safe system
- Oxygen analyzer
- Waste gas exhaust scavenging system
- End-tidal carbon dioxide ($ETCO_2$) analyzer, extra $ETCO_2$ filter, and extension sample tubing
- Vaporizers—calibration and exclusion system
- Respiratory monitoring apparatus (for the anesthesia circuit reservoir bag)
- Alarm system
- Anesthetic medications (Note that some anesthetic medications must be kept refrigerated until ready for use. To have fresh and active medications, check with the drug manufacturer's package insert or the bottle label.)
- In addition to the emergency medications listed above, consider the following:
  - Premedication drugs—midazolam, pentobarbital, ketamine, nitrous oxide, diazepam, chloral hydrate
  - Induction drugs—propofol, etomidate, ketamine
  - Maintenance drugs—bottles of sevoflurane, isoflurane, desflurane, propofol, ketamine, dexmedetomidine
  - Narcotics—midazolam, diazepam, fentanyl, alfentanil, sufentanil, remifentanil
  - Muscle relaxants—succinylcholine, rocuronium, cisatracurium, atracurium, vecuronium
  - Muscle relaxant reversal agents—edrophonium, neostigmine, atropine, glycopyrrolate
  - Cardiovascular drugs—labetalol, esmolol, verapamil, hydralazine
  - Narcotic reversal drugs—naloxone
  - Antiemetic drugs—ondansetron, dolasetron, granisetron, metoclopramide, droperidol*
- Emergency cart and equipment
- Basic airway equipment (adult and pediatric)
- Nasal and oral airways
  - Facemask (appropriate for patient)
  - Laryngoscope handle assortment with spare batteries
  - Assortment of laryngoscope blades and spare light bulbs, endotracheal tubes (adult and pediatric), laryngeal mask airways (LMAs), and dental LMAs
- Combitube
- Self-inflating resuscitator bag (Ambu bag)
- Difficult airway equipment
- Laryngeal mask airway
- Light wand
- Emergency cricothyrotomy kit
- Defibrillator—manual biphasic defibrillator or automatic external defibrillator (AED)
- Supplemental oxygen and nitrous oxide tanks with attached and functional regulators; allow for safe transportation and storage of tanks

BOX 52-2–cont'd

Requisites for Administration of Anesthesia in Remote Locations

- Emergency medications
- Cardiopulmonary resuscitation (CPR) compression board
- Suction equipment (suction catheter, Yankauer type)
- Malignant hyperthermia emergency drugs, equipment, and the phone number for the Malignant Hyperthermia Association of the United States (MHAUS) for live help during the treatment of malignant hyperthermia on-site (United States and Canada: 1-800-MH HYPER or 1-800-644-9737. Outside the United States and Canada: 001-1-315-464-7079). More information is available at the Malignant Hyperthermia Association of the United States website at: http://www.mhaus.org.

*Be aware of droperidol use in patients with prolonged QT syndrome.

BOX 52-3

Criteria for the Management and Monitoring of Patients Undergoing Sedation Delivered for Therapeutic or Diagnostic Procedures by Non-Anesthesia Providers

- Guidelines for patient monitoring, drug administration, and protocols are available for dealing with potential complications or emergency situations, developed in accordance with accepted standards of anesthesia practice.
- A qualified anesthesia provider or attending physician selects and orders the agents to achieve sedation and analgesia.
- Registered nurses who are not qualified anesthesia providers should not administer agents classified as anesthetics, including but not limited to ketamine, propofol, etomidate, nitrous oxide, and muscle relaxants. (A computer-assisted personalized sedation device [CAPS] is being developed to enable a non-qualified anesthesia provider [physician-nurse team] to safely and effectively administer propofol for colonoscopy or esophagogastroduodenoscopy [EGD] procedures.)
- The registered nurse managing and monitoring the patient receiving an analgesia sedation shall have no other responsibilities during the procedure.
- Venous access shall be maintained for all patients having sedation and analgesia.
- Supplemental oxygen shall be available for any patient receiving sedation and analgesia and, when appropriate, in the postprocedure period.
- Documentation and monitoring of physiologic measurements including but not limited to blood pressure, respiratory rate, oxygen saturation, cardiac rate and rhythm, and level of consciousness should be recorded at least every 5 minutes.
- An emergency cart must be immediately accessible to every location where analgesia sedation is administered. This cart must include emergency resuscitative drugs, airway and ventilatory adjunct equipment, defibrillator, and a source for administration of 100% oxygen. A positive-pressure breathing device, oxygen, suction, and appropriate airways must be placed in each room where analgesia sedation is administered.
- Back-up personnel who are experts in airway management, emergency intubations, and advanced cardiopulmonary resuscitation must be available.
- A qualified professional capable of managing complications is present in the facility and remains in the facility until the patient is stable.
- A qualified professional authorized under institutional guidelines to discharge the patient remains in the facility to discharge the patient in accordance with established criteria of the facility.

- *Monitor ventilation continuously*. Ventilation may be monitored in the patient undergoing mild, moderate, or deep sedation with a precordial stethoscope or by direct auscultation of the patient's ventilatory effort. Verify intubation of the trachea by auscultation, chest excursion, and confirmation of carbon dioxide in the expired gas. In cases of moderate or deep sedation, the ASA has set forth new guidelines mandating the measurement of end-tidal carbon dioxide unless the patient, procedure, or equipment interfere or preclude monitoring. Continuously monitor end-tidal carbon dioxide ($ETCO_2$) during controlled, assisted, or spontaneous ventilation, including any anesthesia or sedation technique requiring artificial airway support. Use spirometry and ventilatory pressure monitors as indicated.[13]
- *Monitor oxygenation continuously* by clinical observation, pulse oximetry, cerebral oximetry, and, if indicated, arterial blood gas analysis.
- *Monitor cardiovascular status continuously* via electrocardiography and heart sounds. Record blood pressure and heart rate at least every 5 minutes.
- *Consider the use of a monitor of anesthesia awareness/level of consciousness/depth of sedation* via electroencephalographic processing for procedures intended to produce loss of consciousness.[24] It is recommended that consciousness monitoring be used when available; however, the research remains inconclusive regarding the effectiveness of this evolving technology.[25,26]
- *Monitor body temperature continuously* in all patients when clinically significant changes in body temperature are intended, anticipated, or suspected. Maintenance of normothermia must be an integral part of the anesthetic plan to preserve essential body functions (Box 52-5) and to prevent complications leading to patient morbidity and mortality.[27,28] Temperature monitoring is a standard of care when delivering general anesthesia to the patient and optional while performing mild, moderate, or deep sedation.
- *Monitor neuromuscular function and status* prior to the procedure and recovery when neuromuscular blocking agents are administered.
- *Monitor and assess patient positioning and protective measures* at frequent intervals. Periodic assessment of eye protection, skin, bony prominences, and extremities is necessary.
- *Perform a complete anesthesia equipment safety check daily and document in the patient's medical record*. An abbreviated check of all equipment is acceptable before each subsequent anesthetic is administered.

Patient indications for the necessity of anesthesia in remote locations are listed in Box 52-6.

BOX **52-4**

Specific Patient Conditions That Warrant Anesthesia-Care Vigilance

- Mental impairment with no possibility of cooperation
- Severe gastroesophageal reflux; delayed gastric emptying; aspiration risk
- Gastroparesis secondary to diabetes mellitus
- Orthopnea; obstructive sleep apnea
- Decreased level of consciousness; depression of airway protection reflexes
- Increased intracranial pressure
- Known difficult intubation; assessed oral, dental, craniofacial, cervical, or thoracic abnormalities that could preclude airway access and maintenance
- Respiratory tract infection; unexplained fever
- Morbid obesity
- Therapeutic or diagnostic procedures that impede access to the airway
- Therapeutic or diagnostic procedures that are complex, lengthy, painful, or invasive
- Positioning that is complex, atypical, painful; prone position
- Patient suffering acute trauma
- Patients at extremes of age
- Prematurity
- Physical status 3 or 4

BOX **52-5**

Reasons for Maintaining Normothermia for Therapeutic and Diagnostic Procedures

- To decrease sympathetic activity related to vasoconstriction while hypothermic
- To decrease cardiac morbidity and cardiac demand during recovery from hypothermia
- To minimize patient morbidity and discomfort related to being cold and shivering
- To maintain the normal pharmacokinetics of administered medications (Hypothermia decreases the normal metabolism of medications.)
- To decrease anesthesia recovery time (Hypothermia impairs the rapid recovery from anesthesia.)
- To maintain bodily metabolic functions (The enzymes involved in body metabolic chemical reactions function ideally at normothermia.)
- To maintain normal blood coagulation and to decrease blood loss. (The coagulation cascade is impaired or delayed during hypothermia.)
- To decrease the incidence of wound infection
- To decrease the incidence of complications that may require hospitalization

H. Precautions shall be taken to minimize the risk of infection to the patient, the operator, and ancillary personnel.

Clean equipment and fresh medications and supplies (to include personal protective equipment and supplies) should be used to ensure safety.

I. There shall be complete, accurate, and time-oriented documentation of pertinent information on the patient's anesthesia record.

Document baseline patient vital signs before the anesthetic procedure and the therapeutic or diagnostic procedure has begun.

BOX **52-6**

Patient Indications for the Necessity of Anesthesia in Remote Locations

Central Nervous System

- Presenile dementia
- Drug-induced mental disorders
- Major depressive disorders or schizophrenia
- Hysteria, unspecified (includes fear of pain)
- Phobic disorders, unspecified (claustrophobia)
- Transient cerebral ischemia
- Cerebrovascular disease, other and ill-defined

Cardiovascular

- Hypertensive heart disease, malignant, benign, unspecified
- Ischemic heart disease, acute or subacute forms
- Old myocardial infarction
- Coronary atherosclerosis, bundle branch block, other and unspecified cardiac dysrhythmias
- History of atrial or ventricular fibrillation or flutter

Pulmonary

- Bronchitis, acute, chronic, or unspecified
- Chronic airway obstruction
- Radiation-induced pulmonary disease, acute or chronic

Other

- Acquired hypothyroidism
- Electrolyte imbalance
- Morbid obesity
- Adverse effects not classified elsewhere
- Opioid, barbiturate, cocaine, cannabis, amphetamine, or unspecified drug dependence
- Combative patient
- Patient with low pain thresholds or experiencing severe pain
- Chronic liver disease or cirrhosis
- Gastrointestinal (GI) tract hemorrhage, unspecified

Pediatric

- Procedure is lengthy or painful
- The child is uncooperative or seems uncomfortable
- The operative or diagnostic area of interest lies close to critical anatomic structures
- The child is completely covered, which impedes quick access to the airway
- If an air embolus may be avoided by using an endotracheal tube or laryngeal mask airway

Modified from Bader AM, Pothier MM. Out-of-operating room procedures: preprocedure assessment. *Anesthesiol Clin*. 2009;27(1): 121-126; Cutter TW. Radiologists and anesthesiologists. *Anesthesiol Clin*. 2009;27(1):95-106.

Documentation must be made of all vital signs: heart rate, blood pressure, pulse oximeter readings, patient temperature, and the presence of $ETCO_2$. Also, documentation that includes names and quantities must be made of all fluids and drugs administered. A narrative must be written concerning the technique(s) of anesthesia used and any unusual events that occurred during the anesthetic period. An anesthesia form approved by the AANA is available on their website.

J. After the anesthetic treatment for therapeutic or diagnostic procedures, transfer the responsibility for care of the patient to other qualified personnel in a manner that ensures continuity of care and patient safety.

Anesthesia care does not end with the completion of the therapeutic or diagnostic procedure. The patient may receive postanesthesia

care at the site of the therapeutic or diagnostic procedure. Those sites that preclude postanesthesia recovery at that particular location must be safely transported to a separate area for postanesthesia care. From there patient care can be transferred to another qualified healthcare provider along with a full verbal report. To whom the report was given must be documented as well. The transported patient must be accompanied by a person capable of initiating basic life support (CPR), and that person must have immediate access to portable anesthesia monitors, equipment, and supplies, especially if transport will require some time and/or distance. Recovery from anesthesia can be divided into three phases. Phase I recovery encompasses the recovery from sedation, during which assessment is made of adequate patient oxygenation and respirations, cardiovascular function, neuromuscular function, mental status, body temperature, pain, postoperative nausea and vomiting (PONV), fluid status, urine output, the ability to void, and any bleeding or drainage, which must be noted and continually assessed. Treatments may be administered as necessary for any adverse signs or symptoms elicited by the patient. Phase II recovery encompasses the adequate resumption of psychomotor functions, such as the ability to communicate, ambulate, and consume fluids. Finally, before discharge from this area, a responsible individual must be present to escort the patient home and be available to observe and assist the patient for the next 24 hours. In phase III recovery, the patient regains full preanesthetic psychological and physical recovery.[29] It is important to remember that phase III may occur several hours or days later, depending on the anesthetic technique and patient variables, but with newer anesthetics, recovery time has dramatically decreased. Postanesthesia recovery and discharge guidelines are discussed in Chapter 50.

K. Reimbursement.

Third-party payers of anesthesia services may require documentation of the necessity for anesthetic services for therapeutic and diagnostic procedures. Box 52-6 lists some patient indications that can require the need for anesthesia in remote locations.

L. Conclusion.

The standards listed in this section describe the minimum requirements for treatment and monitoring of any patient who requires anesthesia care. The standards must be followed wherever and whenever anesthesia is given. Adherence to standards is considered essential in a malpractice case, and an anesthetic incident will be judged according to those standards.[30] The omission of any monitoring standard should be documented and the reason for such omission stated on the patient's anesthesia record. Any anesthetic procedure, including those performed in a remote location, should not begin until the anesthetist feels sufficiently comfortable, safe, and well prepared to deliver the anesthetic treatment required for the patient.

Guidelines for Sedation

Therapeutic and diagnostic procedures can be performed with various types of sedation. Sedation is possible with enteral, parenteral (intravenous), and inhaled medications. It is important to remember that the depth of sedation in a patient is a continuum of progressive changes in cognition, respirations, and protective reflexes.[31] Sedation does not have strict boundaries. The patient may quickly progress from one level of sedation/anesthesia to another; therefore, it is essential that the competent anesthesia provider is able to rescue patients in each level, as well as have quick access to vital equipment, supplies, and trained and qualified ancillary personnel who are familiar with anesthesia delivery, emergencies, and monitoring.[3,31-33]

Box 52-7 lists ancillary personnel requirements the anesthetist should consider during the planning stages of anesthesia for therapeutic and diagnostic procedures.

BOX 52-7

Considerations and Requirements of Ancillary Personnel for Areas of Anesthesia Delivery for Therapeutic or Diagnostic Procedures in Remote Locations

- Training in basic life support
- Awareness of and training in emergency protocols
- Familiarity with anesthesia responsibilities; to serve as an assistant
- Assist with patient positioning and comfort
- Training in postprocedure observation and recovery

Modified from Robbertze R, et al. Closed claims review of anesthesia for procedures outside the operating room. *Curr Opin Anaesthesiol.* 2006;19:436-442; Metzner J, et al. The risk and safety of anesthesia at remote locations: the US closed claims analysis. *Curr Opin Anaesthesiol.* 2009;22(4):502-508; Frankel A. Patient safety: anesthesia in remote locations. *Anesthesiol Clin.* 2009;27(1):127-139.

The Joint Commission and the ASA publish definitions for the four levels of sedation and anesthesia in their *Comprehensive Accreditation Manual for Hospitals: The Official Handbook (CAMH)*.[31] Box 52-8 lists definitions of the four levels of sedation and anesthesia as described by The Joint Commission and the ASA. Figure 52-1 illustrates the continuum of sedation described by the two aforementioned groups. From these definitions, standards are provided to practitioners for the administration of safe and high-quality care to patients.[32]

Accepted standards for moderate sedation/analgesia and deep sedation/analgesia state the following[11,31,32,34]:

1. The process from minimal sedation (anxiolysis) to general anesthesia is a continuum, and individuals vary in their responses to medications.
2. Qualified individuals with appropriate credentials (e.g., nurses, certified registered nurse anesthetists [CRNAs], anesthesiologists, dentists) who are trained in professional standards and techniques do the following:
   a. May administer pharmacologic agents to achieve a desired level of sedation.
   b. Must monitor patients carefully to maintain the patient's vital functions at the desired level of sedation. Appropriate equipment must be available for monitoring heart rate via ECG, respiratory rate and adequacy of pulmonary ventilation, oxygenation via pulse oximetry, and blood pressure measurement at regular intervals (at least every 5 minutes).
   c. Must be competent to evaluate the patient before performing the moderate sedation/analgesia and deep sedation/analgesia.
   d. Must be competent to support the patient's psychological functions and physical comfort.
   e. Must be competent in the administration of sedatives, analgesics, hypnotics, and other medications to produce and maintain moderate sedation/analgesia and deep sedation/analgesia.
   f. Must be competent to rescue the patient who unavoidably or unintentionally moves into a deeper than desired level of sedation and analgesia. In the case of the CRNA, competency is mandatory for all levels of the sedation continuum. This includes competency in management of a compromised airway, the provision of oxygen, and the initiation of emergency rescue procedures such as basic life support (BLS), advanced cardiac life support (ACLS), or pediatric

BOX **52-8**

The Continuum of Depth of Sedation: The Four Levels of Sedation and Anesthesia

Minimal Sedation (Formerly Known as Anxiolysis)
A drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

Moderate Sedation/Analgesia (Formerly Known as Conscious Sedation)
A drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained. (NOTE: Reflexive withdrawal from a painful stimulus is not considered a purposeful response.)

Deep Sedation/Analgesia
A drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

Anesthesia (General Anesthesia)
Consists of general anesthesia and spinal or major regional anesthesia. It does not include local anesthesia. General anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

Modified from The Joint Commission. *Comprehensive Accreditation Manual for Hospitals: The Official Handbook (CAMH)* (refreshed core). Chicago: The Joint Commission; 2009; American Society of Anesthesiologists: *Continuum of Depth of Sedation: Definition of General Anesthesia, and Levels of Sedation/Analgesia*. Accessed September 19, 2012, at the ASA website http://www.asahq.org/for-members/standards-guidelines-and-statements.aspx.

advanced life support (PALS). In addition, for patients undergoing deep sedation/analgesia, one must also have competency to manage an unstable cardiovascular system.

g. Must be competent to assess and treat problems the patient may attain related to the therapeutic or diagnostic procedure he or she is having performed.
h. Must properly document the patient's response to care.
i. Must supervise recovery of the patient after the sedation in a postsedation area or a postanesthesia recovery area.
j. Must discharge the patient. This may be done in consultation with qualified personnel and/or the physician, surgeon, or dentist.

3. Adequate numbers of qualified and competent personnel must be present during the performance of moderate sedation/analgesia, deep sedation/analgesia, and general anesthesia to serve as a skilled second pair of hands if necessary. This should include not only qualified anesthesia providers as described earlier but also nurses, assistants, technicians, and other office staff to meet the needs of the patient.[31]

The Pediatric Patient

The pediatric population can pose complex challenges for the delivery of anesthesia (Box 52-9). Pediatric patient behavior and degree of cooperation can range from very helpful to extremely anxious. Fortunately, several common anesthetic medications can help patients with slight to high levels of anxiety. Pediatric sedation and anesthesia increases the quality of care the patient receives by greatly reducing anxiety and by eliminating movement when necessary for therapeutic or diagnostic procedures.

First and foremost in the practice of nurse anesthesia are patient safety and guardianship of patient welfare. Important lessons can be learned from the literature regarding anesthesia in pediatric patients. Children under the age of 5 years seem to be at the greatest risk for adverse events, even with no underlying disease. Adverse events have occurred more commonly with the use of multiple drugs, especially sedative medications.[35-39] The problems encountered most often are respiratory events: respiratory depression, respiratory obstruction, and apnea.[36-38]

Adverse events can be reduced by proper adherence to patient selection and a comprehensive preoperative assessment, proper dosage of medications to minimize unexpected responses, proper monitoring, skilled administration of anesthesia, and proper recovery time. The anesthesia provider must plan to minimize the possibility of adverse reactions.[36-39] General patient selection criteria to help minimize the possibility of adverse events are seen with patients 6 months of age and older and applied during the preoperative assessment. It is during this time that the temperament of the child can be assessed.[40] Consideration must be made for the type of procedure to be performed, past medical history, past sedation/anesthesia history, current medication therapy, allergies, and respiratory or airway difficulties.[35,37,40] Questions regarding the degree of patient stimulation expected throughout the procedure, amount of anticipated blood loss, ability to maintain normothermia, and ability to have close proximity in which to monitor the patient, are all questions the anesthesia provider is responsible for addressing. It is found that adverse reactions are reduced with procedures that last less than 1 hour.[39] Clear communication with the technician and the medical practitioner is essential to clarify the requirements for the patient to be safe and properly anesthetized for the procedure.

The pediatric patient and the parent or legal guardian must be properly prepared for the planned therapeutic or diagnostic procedure. Clear explanation of the entire anesthetic process to the parent or guardian is based on the developed treatment plan and is offered in age-appropriate terms for the pediatric patient.[35,40] "Inform before you perform."

Fasting times are constantly being reevaluated in clinical anesthesia and must be stringently adhered to. Fasting guidelines are discussed in Chapters 19 and 48. Premedication with oral, intranasal, intramuscular, or rectal sedatives may be necessary. Common pediatric premedications and doses are chosen as appropriate.[40-44]

It is essential to have qualified personnel to assist in the safe care of pediatric patients receiving anesthesia in remote locations for therapeutic or diagnostic procedures. An extra pair of trained hands enhances the ability for the patient to receive safer care throughout the entire procedure.

Knowledge of the most common causes of adverse pediatric anesthesia events can help the anesthetist plan for and avoid these events (Box 52-10).[36,37,39] Most anesthesia adverse events are caused when multiple anesthetic agents are used. Adverse

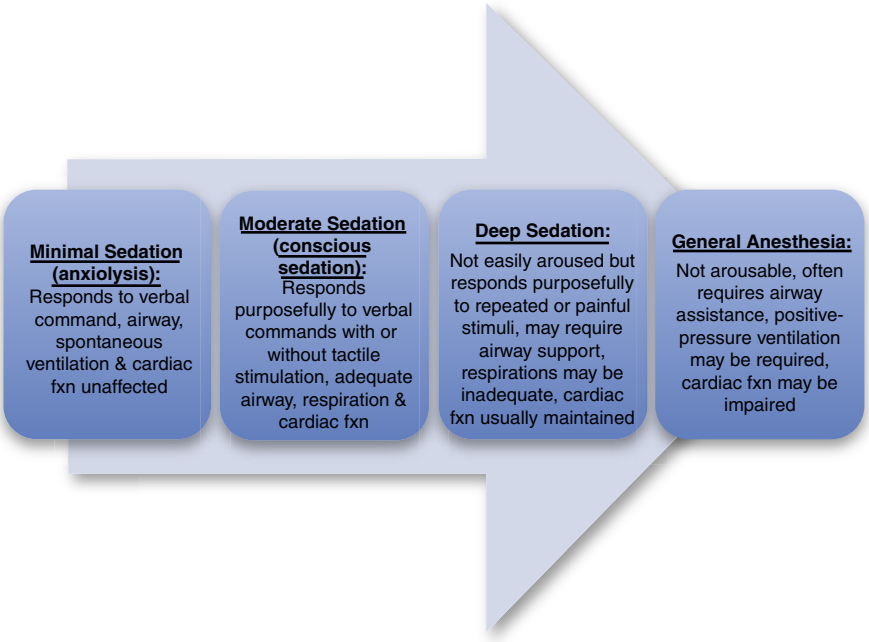

FIGURE **52-1** Depth of sedation continuum.

BOX 52-9

Goals of Pediatric Anesthesia

- Foremost, to provide safety and welfare to the patient
- To minimize physical discomfort/pain or to provide more profound analgesia when necessary to the patient
- To minimize negative psychological consequences of the therapeutic or diagnostic procedure for both the pediatric patient and the parent(s)/guardian(s). This can be accomplished by the provision of proper preprocedure discussions along with sedative medications, analgesics, and amnestic agents for the patient
- To ideally obtain patient cooperation and safely control uncooperative or endangering behavior
- To obtain immobility of the patient to achieve therapeutic or diagnostic procedure goals
- To provide the patient a safe discharge to the guardian and to home
- To minimize or eliminate patient complications from applied therapeutic or diagnostic procedures and administered anesthetic medications

Modified from Cravero JP, et al. The incidence and nature of adverse events during pediatric sedation/anesthesia with propofol for procedures outside the operating room: a report from the Pediatric Sedation Research Consortium. *Anesth Analg*. 2009;108:795-804.

BOX 52-10

Most Common Causes of Pediatric Anesthesia Adverse Events for Therapeutic or Diagnostic Procedures

- Drug errors
- Nitrous oxide in combination with any other sedative medication
- Inability to rescue the patient from an adverse anesthetic event
- Unmet monitoring standards—especially respiration, oxygenation
- Respiratory depression/hypoventilation/apnea
- Airway obstruction
- Bradycardia secondary to hypoxia
- Laryngospasm/stridor
- Vomiting, aspiration, diarrhea
- Hypotension
- Inadequate sedation/paradoxical excitation (sustained irritability or combativeness)
- Prolonged sedation after the procedure

events are not dependent on the class of the drug (e.g., opioids, benzodiazepines, barbiturates, antihistamines, local anesthesia, intravenous anesthesia, inhaled anesthesia) or the route of administration (e.g., oral, rectal, nasal, intramuscular, intravenous, local infiltration, inhalation).[37,38,45,46]

The Geriatric Patient

As a result of a number of factors, including better nutrition, more physical activity, less tobacco and alcohol use, and improved medical care and medical technologies, more Americans are living longer. In 2008 the U.S. Census Bureau released population projections stating that the population of people within the United States currently over the age of 65 is 14.8% and will reach 20% by 2025 and 24.6% by 2050, with continued increased life expectancy.[47] The increasing elderly population is placing, and will continue to place, many demands on the public healthcare system. Medical technology is advancing, and therefore more procedures requiring anesthesia will be performed in elderly patients. It is estimated that 20% to 40% of anesthesia cases may be performed outside of the traditional operating room and that the elderly prefer ambulatory settings, with trends pointing toward more invasive therapeutic or diagnostic procedures.[48] Perioperative complications can increase with age. Special considerations related to the physiology of aging are necessary if anesthetic treatment is to be performed safely.[48,49]

The elderly have a greater prevalence of comorbidities such as atherosclerosis, infections, autoimmune diseases, chronic disorders, and cancer. The immune system gradually and slowly diminishes in function with age. Therefore, the ability to heal and fight foreign bacteria, viruses, and malignant cells diminishes. There are no fewer T cells in a person at an older age than at a younger age, but T-cell function is decreased in the elderly. Many of the body's cells begin to diminish in function or to function abnormally. Cells also may have increasing difficulty in membrane transfer of nutrients and waste.[49]

The normal aging process results in an increase in the ratio of adipose tissue to aqueous body tissues.[49-50] This means more lipid-soluble anesthetic drug is stored. Basal metabolic rate and liver and kidney function all decrease with age. This results in a decrease in the rate of metabolism and excretion of anesthetic drugs. Nervous system function generally produces decreases in the perception of sight, hearing, touch, smell, taste, pain, and temperature sensations. Cerebral atrophy occurs with aging, resulting in an overall loss of neurons in the neocortex.[50] This suggests increased sensitivity to anesthetic medications. The elderly are at an increased risk for perioperative delirium and postoperative cognitive dysfunction.[48] Therefore, the dosage requirements for anesthetic drugs usually are decreased. The geriatric patient's level of activity is one indicator of cardiovascular function and this generally decreases with age; this decrease in activity usually correlates with limited physiologic reserves. Patients may be restricted in their activity because of arthritis or other debilitation. Circulation time is decreased. Skeletal muscle size is decreased with decreases in physical activity, which decreases total oxygen consumption and blood-flow needs to the muscles, resulting in decreased cardiac output.[50] The ability of the cardiovascular system to respond to the effects of anesthetic drugs, fluid administration, and the stresses of therapeutic and diagnostic procedures can cause decreased cardiac function, resulting in hemodynamic instability and reduced circulation to vital organs.[48-50] Tissue oxygenation can decrease because of changes in ventilation ability and lung tissue. Lung compliance is decreased, resulting in ventilation-perfusion mismatch. Aging itself brings on the increasing inability to respond to hypoxia and hypercapnia, especially while experiencing the effects of anesthesia. Therefore, the anesthetist must always ensure and constantly monitor the supply of adequate amounts of oxygen to the elderly patient and be ready to offer needed respiratory support. The ability to thermoregulate is also decreased with age.[48] Body metabolism, enzyme function, and the coagulation cascade best function at 37° C. Changes in mental status or even delirium can occur more frequently in geriatric patients. All of these factors must be taken into consideration when one provides anesthesia to all patients, but especially to geriatric patients.

Significant variability exists in each of these vital functions among patients. Geriatric patients who are more physically fit have a decreased mortality, reduced incidence of cardiovascular disease, lower blood pressure, reduced blood cholesterol, and most important, better bodily reserves when they become surgically challenged or sick.[49] A thorough and comprehensive preanesthetic assessment is necessary, from which a plan of treatment can be deduced.[48]

To prevent confusion, delirium, or cognitive impairment in the elderly, agents with short half-lives and durations are ideal.[51,52] Carefully consider the use of drugs that are synergistic or antagonistic in their effects. Such drugs as propofol, midazolam, fentanyl, alfentanil, remifentanil, and local anesthetics are ideal because doses are calculated and titrated according to the patient's responses. Most literature reports no difference of outcome in the elderly as a result of anesthetic choice when either a regional anesthetic or general anesthesia is used.[48]

Several electroencephalographic (EEG) processing monitors are available that help in assessment of patient responses to anesthetic medications. These devices monitor anesthesia awareness/level of consciousness/depth of sedation, and response to anesthetic medications, which allows for more precise titration of anesthetic medications according to the patient's needs. Care must be taken to preserve body warmth and ensure the continual delivery of adequate warmth when necessary. Ensure the protection of the eyes, skin, and the extremities while moving the patient and during the procedure by skin padding of bony prominences.[40] Consideration must also be given to the preprocedure, and postoperative care of the elderly patient in regard to possible malnutrition, depression, immobility, cognitive dysfunction, pulmonary difficulty, dehydration, acute pain, and chronic pain.[48] Finally, consider verbal and written postoperative instructions to both the elderly patient and caregivers/significant others who will accompany the patient and be present to both monitor and care for the elderly patient after a therapeutic or diagnostic procedure.[51]

A new formulations of propofol is available for use in anesthesia for therapeutic and diagnostic procedures (see Chapter 9 for a complete discussion). Fospropofol (Lusedra) is a water-soluble prodrug that is enzymatically converted to propofol. The formulation contains no lipids, egg, or preservative products and therefore has a decreased likelihood of allergic reactions or bacterial growth. Pain on injection is also decreased since it is not a lipid formulation. Because of its need to be converted to propofol, Fospropofol has a delayed onset and slightly prolonged duration when compared with propofol.[52] Some studies suggest that it is an ideal sedative choice for the geriatric patient with multiple comorbidities due partly to its lower rate of apnea and respiratory depression.[52-54]

ANESTHESIA FOR SPECIFIC PROCEDURES IN REMOTE LOCATIONS

Cardiology Procedures

Automatic Implantable Cardiac Defibrillator and Cardiac Pacemaker

Procedure Overviews. It is estimated that between 170,000 and 462,000 people within the United States experience sudden cardiac death each year, and of those, 50% to 70% do not survive the event.[55] Patients who experience sudden cardiac death are usually around 60 years of age, and their most common underlying rhythm is pulseless ventricular tachycardia (VT) or ventricular fibrillation (VF).[55,56]

Defibrillation is the application of a flow of electric current through the appropriate chambers of the heart to completely depolarize the entire myocardium to restore a suitable heart rhythm to sustain life.[57-59] If enough stores of high-energy adenosine triphosphate molecules remain and are available within the myocardium, automaticity can resume. Fibrillating myocardium rapidly consumes high-energy phosphate molecules.[50,59] It has been proven that early defibrillation, along with cardiopulmonary resuscitation, can result in high long-term survival rates. The automatic implantable cardiac defibrillator (AICD) is designed to bypass the delay patients experienced before receiving defibrillation. The AICD is composed of two basic parts: a pulse generator and a lead electrode for detection of dysrhythmias, delivery of a defibrillating shock, cardiac pacing, telemetry, and provision of diagnostic data. The pulse generator is a hermetically sealed titanium can that contains a computer microprocessor, resistors, transformers, capacitors, and a battery. The battery is designed to deliver 120 shocks and usually lasts for 3 to 6 years. The computer

is programmed with algorithms to detect VT and VF. If VF occurs, an electric shock is administered within 10 to 15 seconds of detection (much of the time delay results from the charging of the capacitor). VT is treated with overdrive pacing called *antitachycardia pacing* (ATP). ATP is an extremely successful procedure. AICD implantation has been a crucial technique for prevention of sudden cardiac death.[60]

A cardiac pacemaker is used to treat bradycardia, atrioventricular block, sinus nodal dysfunction, and other dysrhythmias. The pacemaker is used concurrently with other therapies for management of dysrhythmia and hemodynamics. The pacemaker consists of a pulse generator containing a computer and a battery that is designed to last 6 to 10 years. Attached to the pulse generator is a lead, which delivers the current used to depolarize the myocardium, and an anode, which completes the electrical circuit. Two different types of pacemaker leads are available. A unipolar pacemaker lead uses one lead as the cathode and the pulse generator as the anode. Unipolar leads are less likely to fail. A bipolar pacemaker uses two separate leads that are close together, the advantage of which is a sharper signal with less noise. The leads are inserted under fluoroscopic guidance via the cephalic vein or the subclavian vein into the cardiac chamber, usually the right ventricle in the case of an AICD and the right atrium and right ventricle for a cardiac pacemaker. The leads are then tunneled and connected to the pulse generator, which is then inserted into a subcutaneous pocket in the patient's pectoral region or into a subpectoral muscle pocket.[60] Figure 52-2 shows a postoperative radiograph of a pacemaker pulse generator, computer, and battery inserted into a patient. Figure 52-3 shows a postoperative radiograph of a unipolar pacemaker lead inserted into the right ventricle of a patient. Research and continual improvements allow more people to receive better and more reliable AICD and cardiac pacemaker therapy.

Anesthetic Considerations. The AICD or cardiac pacemaker procedure may be performed in the operating room, in a special cardiac procedure room, or in the cardiac catheterization suite by a cardiologist or other physician.[61] Routine monitors are attached to the patient, with special attention paid to a properly functioning five-lead ECG. The ECG monitor screen must be available to the anesthesia team, the operating physician, and the AICD or pacemaker manufacturer's technical service representative, who is always present during insertion. The procedures are usually adequately performed with local anesthetic and moderate sedation/analgesia or deep sedation/analgesia, although some clinicians prefer a general anesthetic.

AICD insertion requires purposeful triggering of VF in an attempt to test thresholds and functioning of the AICD.[62] A range of anesthesia techniques from mild sedation with local anesthesia infiltrate to general anesthesia may be required depending upon factors such as surgeon preference, procedural length, number of thresholds tests, and patient physical and mental status. As in all anesthetic procedures, endotracheal intubation may be required to secure the airway in case a cardiac emergency arises.

After insertion of the cardiac pacemaker and before wound closure, the device is threshold tested by the pacemaker manufacturer's technical service representative to ensure adequate contact between the leads and the myocardium.[60,61] After wound closure and dressing application, all computer-function programming of either the AICD or the cardiac pacemaker can then be performed with a pacemaker programmer that connects to a portable wand. The wand is placed within close proximity to the implanted pulse generator by the manufacturer's technical service representative, which allows a telemetric connection to properly program or interrogate the AICD or cardiac pacemaker.

Postanesthesia Care. When the procedure is completed, the patient is transported to the recovery room with oxygen and observed for any hemodynamic or cardiovascular ECG changes.

AICDs are generally well tolerated by patients. Some patients display anxiety or depression because of the possibility of sudden cardiac death, device failure, inappropriate shocks, and recalls of certain devices.[61] Shocks from the AICD are described as a sudden, heavy blow to the chest. Medical technology is ever improving, and the demand for AICDs and cardiac pacemakers increases annually.

Cardioversion

Procedure Overview. Cardioversion is the discharge of electrical energy, synchronized to the R wave of the QRS complex of the electrocardiogram, to convert hemodynamically unstable supraventricular rhythms such as atrial flutter or atrial fibrillation

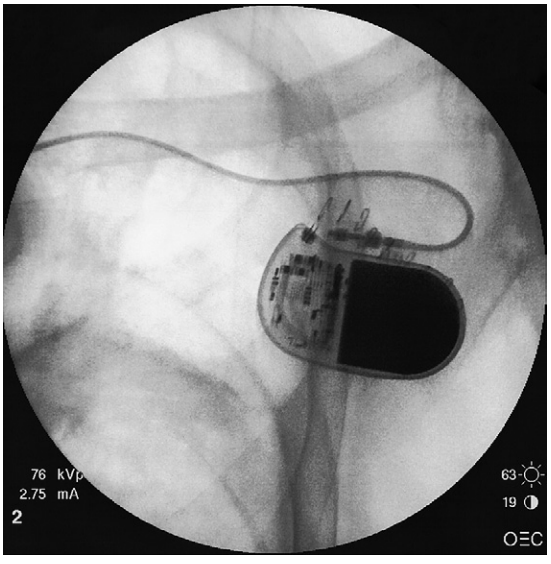

FIGURE **52-2** Radiograph of a pacemaker pulse generator, computer, and battery inserted into a patient.

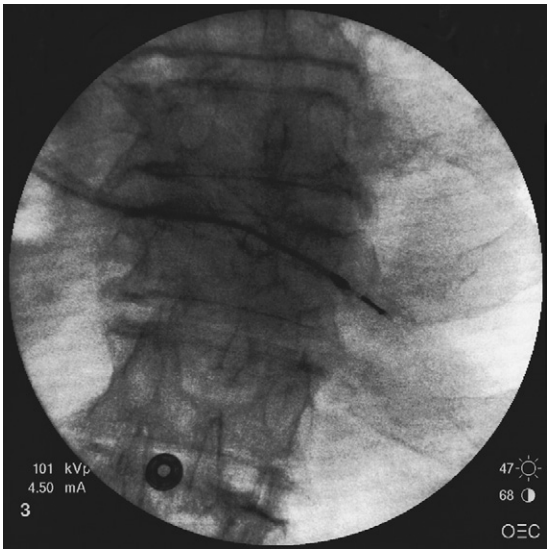

FIGURE **52-3** Radiograph of a unipolar pacemaker lead inserted into the right ventricle of a patient.

or hemodynamically stable VT. These rhythms can be life threatening if left untreated. Atrial flutter and atrial fibrillation are associated with the development of congestive heart failure and with the formation of thromboemboli, which can lead to stroke. Cardioversion is usually a scheduled and planned procedure unless the patient's condition warrants otherwise. Patient optimization may not be possible if there is urgency for cardioversion as a result of hemodynamic instability. Much less electrical energy is required to synchronously cardiovert a patient when compared with asynchronous defibrillation.[58] Defibrillation is an unplanned and usually emergent application of unsynchronized electrical energy. Cardioversion is believed to be therapeutic because it closes an excitable gap in the myocardium, which causes currents to reenter and excite the electrical system of the heart.[61]

Anesthetic Considerations. Because cardioversion is usually a nonemergent and planned procedure, patient conditions usually can be optimized. Proper nothing-by-mouth (*nil per os* [NPO]) status must be observed unless the cardioversion is deemed urgent or emergent. Standard monitors are applied, with special attention paid to the ECG. A monitor of anesthesia awareness/level of consciousness/depth of sedation via electroencephalographic processing can be used to assess consciousness during cardioversion.[63-64] Intravenous access is necessary. The energy required for cardioversion is measured in joules (watt-seconds). The cardiologist or physician uses a cardioverter-manual monophasic or biphasic defibrillator for the procedure. The optimal shock dose for cardioversion of atrial flutter and other supraventricular tachycardias is 50 to 100 J.[57-59,65] The operator applies cardioversion-defibrillator paddles with conduction gel or defibrillator pads to the patient's skin. One paddle or pad is placed parasternally over the second and third intercostal space. The other paddle or patch is placed over the area of the apex of the heart.[56-59] The cardioverter-defibrillator is set to the synchronized (sync) mode. Visible synchronization marks are placed by the cardioverter atop the tallest R waves of the ECG. Energy shocks are delivered initially at 50 to 100 J and are titrated progressively, up to 360 J as necessary, after observation of the effectiveness of the synchronized shock.[58-59,65]

Midazolam may be administered as both a sedative and amnestic agent before cardioversion. The patient is then assisted in breathing oxygen via facemask and Ambu bag with high-flow oxygen. Because of the intense and brief pain of cardioversion, an ultra–short-acting general anesthetic such as propofol or etomidate is administered.[63-64] After the loss of eyelash reflex occurs, an "all-clear" signal is given by the operator. Positive-pressure respirations are temporarily suspended, with care taken not to touch any part of the patient or the patient's bed. Then the synchronized shock or shocks are administered.[64,65] Muscle relaxation is not necessary. As always, an assortment of oral airways, nasal airways, laryngeal mask airways (LMAs), endotracheal tubes, and laryngoscopes with blades and suction should be readily available in case complications occur. If cardioversion is required in a patient who has not fasted, general anesthesia with tracheal intubation is necessary to prevent aspiration of gastric contents.[64]

Postanesthesia Care. It is hoped that the patient's heart is now beating in a desirable cardiac rhythm and that the patient's blood pressure is stable. Spontaneous respirations return, along with swallowing and coughing reflexes. The patient is observed for any reactions to the anesthetic, and care is turned over to the nurse accompanying the patient.

Radiofrequency Catheter Ablation

Procedure Overview. Radiofrequency catheter ablation (RFCA) uses a catheter with an electrode at its tip, which is guided under fluoroscopy to an area of heart muscle that has demonstrated accessory electrical conductive pathways.[66-68] RFCA has all but replaced arrhythmia surgery and is now considered the foremost therapy for the treatment of many arrhythmias in pediatric and adult patients.[66-67] Supraventricular tachycardia is the most common tachyarrhythmia in children, and symptomatic supraventricular tachydysrhythmias are most often treated by RFCA.[66] Accessory electrical conductive pathways are distributed unevenly along the right and left atrioventricular valve annuli.[66] Left-sided accessory pathways are most common, but both right- and left-sided accessory electrical pathways can be accessed and ablated.[66-67] Other treatments possible with RFCA are modification of the sinus node or AV node, ablation of atrial flutter and atrial tachycardia, and ablation of focal atrial fibrillation and VT foci.[66-68] Patients must undergo electrophysiologic studies to determine the origin and pathway of the arrhythmia, as well as the mechanism of action, before RFCA can be chosen as a therapy.

Cryoablation is now being used prior to RFCA, or in place of RFCA. Liquid nitrous oxide is circulated through the catheter tip to cause temperatures at the tip of −22° C to −75° C. At a higher temperature (−22° C or lower), tissue can be temporarily "ice mapped," which is a trial to see whether this nonpermanent freezing of the tissue will successfully eliminate the dysrhythmia. If the ice mapping is successful, then the probe is further cooled, causing permanent destruction of the arrhythmogenic tissue. Cryoablation causes less discomfort and has been found to be safer to use in cases of dysrhythmias in the area of the atrioventricular (AV) node, where iatrogenic complete AV heart block can be caused. Iatrogenic AV block is relatively common and may require placement of a transvenous pacemaker.[69-70]

RFCA is an extremely safe and successful procedure, with success rates of 95% overall. Many patients no longer need their antiarrhythmic medications soon after therapy.[65-66]

RFCA is now being used as treatment for liver metastases from colorectal cancer. RFCA is providing a new treatment option for those patients with high risks for surgery but who would be at a lesser risk for the less-invasive RFCA.

Anesthetic Considerations. Electrophysiologic studies conducted before RFCA are time-consuming procedures that may require moderate sedation in adults or general anesthesia in children. RFCA can be performed in the operating room, in a special cardiac procedure room, or in the cardiac catheterization suite by a cardiologist. The electrode catheter is guided via the femoral artery and vein to the area of the accessory electrical pathway or an area of arrhythmogenic focus.[66,69] The internal jugular vein also may be used. The electrode is then energized with radiofrequency energy, and cells within the path of the electrode are obliterated. The procedure can produce brief periods (less than 1 to 2 minutes) of mild to moderate retrosternal, angina-like pain.[69]

RFCA is a short procedure. Patients must remain perfectly still, except for respiratory movement, during the procedure.[68-69,71] Many adults can be anesthetized with moderate sedation/analgesia along with local anesthetic applied by the operator.[71] Children may be best treated with general endotracheal anesthesia using either an LMA or an endotracheal tube to secure the airway. If general endotracheal anesthesia is used, the patient may be held apneic for a short period of time while the catheter is accurately directed and the ablation procedure performed.[69] Full monitors and an intravenous catheter are necessary. Total intravenous anesthesia (TIVA) using propofol as the key medication has been used. TIVA with propofol and ondansetron has a much lower rate of nausea (postoperative nausea and vomiting [PONV]) than does use of an inhaled anesthetic and an antiemetic. Careful attention must be paid to the ECG, because

the patient must stop taking any antiarrhythmic drugs before the electrophysiologic study and RFCA are performed.[66-69,71]

Possible thermal injury to the esophagus is a concern during RFCA of the left atrium resulting in esophageal ulcerations or an atrioesophageal fistula, which is an extremely rare but often fatal complication of RFCA. Insertion and use of an esophageal temperature probe during general anesthesia is essential, as is the position of the probe. The probe should be inserted so that it is alongside the esophageal tissues with no space in between. Constant monitoring and communication with the procedural team is a necessity for prevention, identification, and treatment of complication.[72-74]

Postanesthesia Care. Patients must be monitored during recovery from administered anesthetics after RFCA. Patients also must be observed for possible RFCA procedural complications such as bleeding, ECG changes, cerebrovascular accidents, cardiac tamponade, or damage to the aortic valve.[66-69]

Percutaneous Coronary Intervention

Procedure Overview. Percutaneous coronary intervention (PCI) encompasses a wide variety of procedures performed in the cardiac catheter laboratory (CCL). PCI is being performed on adults and is now more commonplace on younger and sicker patients. The CCL is generally located remotely from the operating rooms and the blood bank. It consists of a large procedural area with a small control room. PCI procedures use x-radiation/fluoroscopy doses "as low as reasonably achievable" (the ALARA principle), as well as the use of intravenous radiocontrast media. The heart is commonly accessed via the femoral artery (although the brachial or radial artery can be used). The right heart and pulmonary circulation are commonly accessed via the femoral vein.[75-76]

Anesthetic Considerations. PCI necessitates access to major blood vessels and the heart itself. Box 52-11 lists possible PCI complications that affect the safety of the anesthetic and may require interventions from the anesthetist. Consideration for rapid access to competent anesthesia help has to be prepared well in advance of PCI anesthesia. Anesthesia techniques can range from intravenous moderate sedation/analgesia or deep sedation/analgesia to general anesthesia, aided with local anesthetic infiltration at the insertion site and alongside the major vein (usually the femoral vein) used for insertion of the PCI armamentaria.[75-76]

Postanesthesia Care. Care of the patient undergoing PCI usually does not end with completion of the PCI procedure. Arrangements can be made for observation and ongoing care of the patient in a telemetry environment or in the intensive care unit, depending on the criticality of the patient. Immediate postanesthesia concerns are continuing dysrhythmias, hypothermia, current fluid status, changes in fluid status, PONV, hemodynamic status related to hemorrhage, and analgesia.[76]

BOX 52-11

PCI Complications That May Affect the Delivered Anesthetic and Require Anesthetist Intervention

- Supraventricular dysrhythmias
- Ventricular dysrhythmias
- Severe and rapid hemorrhage
- Pain
- Anaphylaxis related to administration of intravenous contrast media
- Vasovagal response
- Cardiac arrest
- Thromboembolic events
- Hypotension/hypertension
- Respiratory instability

Gastroenterology Procedures

Colonoscopy, EGD, and ERCP

Procedure Overview. Endoscopy came into popular use in the early 1960s with the invention of a snare for collecting intestinal polyps for biopsy. Endoscopy for gastrointestinal procedures is the use of a flexible fiberoptic endoscope that transmits brilliant, coherent, high-resolution, magnified, direct visual images to the operator. The operator can then examine, biopsy, dilate, or cauterize portions of the gastrointestinal tract. The endoscopist may pass accessory devices down the endoscope such as biopsy forceps, dilation devices, cytology brushes, measuring devices, needles for injection, Doppler probes, ultrasound probes, and probes to measure electrical activity and pH. Even foreign bodies may be removed with the aid of a snare passed through an endoscope. Endoscopes are available in different diameters for use in pediatric to adult patients.[77]

An upper endoscopy, such as an esophagogastroduodenoscopy (EGD), is an accurate way for the operator to evaluate the mucosa of the esophagus, stomach, and duodenum. A colonoscopy allows total diagnostic visualization of the mucosa of the tortuous colon from the anus to the cecum. Endoscopic retrograde cholangiopancreatography (ERCP) is used for the diagnosis of obstructive, neoplastic, or inflammatory pancreatobiliary structures. The use of ERCP is decreasing because of the availability of less-invasive and noninvasive techniques. Box 52-12 provides a brief list of indications for colonoscopy, EGD, and ERCP.[77] Use of endoscopic ultrasound (EUS) has been growing since its inception in the 1980s and continues to broaden possibilities for the patient and practitioner. Once used solely for diagnostic and cancer staging purposes of the pancreas, periluminal structures, and biliary tract, it is now being used for therapeutic modalities such as cyst drainage and celiac plexus neurolysis for pain, and for fine-needle injection of therapeutic medication.[78-79]

Endoscopy for gastrointestinal procedures may be performed by a gastroenterologist, general surgeon, family practitioner, or proctologist. The endoscope is passed into the gastrointestinal tract with the aid of lubricant. The endoscope has controls to change the direction of the flexible tip, allow flushing with water, application of suction, or insufflation of air or carbon dioxide within the portion of the gastrointestinal tract being observed.[77]

Anesthetic Considerations. Because of the expectations of patients, endoscopically caused discomfort, and the desirability for no patient movement, some degree of sedation and, in some cases, general anesthesia is used. A proper preanesthetic assessment of the patient must be performed, focusing on the areas of age, ability to cooperate, level of anxiety, mental disability, allergies, fluid status, laboratory electrolyte values, cardiac history, hypertension, bleeding history, clotting status, respiratory status, obesity, drug and alcohol abuse, gastroesophageal reflux, and pregnancy.[13,32]

Endoscopy has been safely performed in pregnant patients.[77] Consideration should be given to any anesthetic drugs administered to the parturient, because transfer can occur through the placenta to the fetus. Rarely, elective procedures should be reconsidered and performed only after consultation with the patient's physician or obstetrician. Urgent endoscopic procedures must be performed. None of the common sedative drugs such as propofol or

the opioid fentanyl have been demonstrated to cause teratogenic changes in the fetus. Benzodiazepines are typically avoided in the parturient, especially in the first trimester, due to reported teratogenic effects on the fetus. Midazolam also has been shown to cross the placenta and cause neonatal central nervous system (CNS) depression.[80] Studies of the obstetric effect of anesthetic drugs are limited because of the infrequent requirements for surgery during pregnancy and the ethical difficulties associated with performing controlled trials.

Patients must adhere to proper NPO guidelines. Bacteremia is possible as a result of endoscopic procedures. Necessary medications may be given, such as cardiac medications, antihypertensives, and antibiotics.[77] Preemptive analgesia with gargled flavored viscous lidocaine may help reduce the patient's gag reflux, making an endoscopy of the upper gastrointestinal tract more feasible.[81] Moderate sedation/analgesia is usually accomplished with the short-acting sedatives midazolam or propofol and analgesics such as remifentanil, alfentanil, or fentanyl. Deep sedation can be achieved with titration of propofol until effective along with an analgesic medication.[81-84] Upper endoscopy may necessitate the use of any antisialagogue such as glycopyrrolate.[82-83]

Colonoscopy requires thorough cleansing of the lumen of the colon of fecal material. The colon may be partly prepared with a cleansing enema. Full preparation of the colon is accomplished commonly with orally administered balanced electrolyte solutions in a volume of up to 4 L. Other types of solutions are also available.[77] Patients often find this preparation the most distressing portion of the procedure. The bowel preparation can lead to abdominal cramping, diarrhea, weakness, and nausea. Patients who arrive for the procedure require reassessment and the insertion of an intravenous catheter with intravenous fluid, usually lactated Ringer's solution or normal saline. Conventional monitors, including pulse oximeter, noninvasive blood pressure monitor, and ECG, are attached. The patient is supplied with oxygen through a disposable nasal cannula or disposable facemask, ideally with end-tidal carbon dioxide monitoring as discussed previously. Patients are usually asked to assume a left lateral decubitus position and are able to remain on the transport stretcher for the procedure duration. It is optimal for the body to be flexed, the head and back bent downward toward the knees and for the patient's legs to be bent toward the abdomen to optimize visualization of the gastrointestinal tract. Patient anxiety, distention because of insufflation, and acute discomfort during the maneuvering of the endoscope usually necessitates the administration of deep sedation or a general anesthetic in some cases. The depth of sedation required may be titrated with the use of an available monitor of anesthesia awareness/level of consciousness/depth of sedation via electroencephalographic processing.[85-86] Strong vagal nerve stimulation can occur as a result of distention of the colon. This may cause hypotension, bradydysrhythmias, and ECG changes.[77,85-86]

EGD and EUS requires a patient assessment with special emphasis on any cardiac history, hypertension, bleeding disorders, nausea (PONV), dysphagia, and gastroesophageal reflux. The patient must be NPO according to guidelines. Occasionally, patients require moderate sedation or deep sedation because topical anesthesia and even hypnosis have been found less effective.[81-84] An intravenous catheter is inserted, with fluids such as lactated Ringer's or normal saline attached. The patient is connected to standard monitors. Oxygen can be supplied through a disposable nasal cannula or a disposable facemask preferably with end-tidal carbon dioxide monitoring. EGD is generally performed with the patient positioned supine or in a left lateral decubitus position. After the patient is adequately sedated, the operator inserts a hollow oral airway gently into the patient's mouth, and the endoscope is advanced through this airway, allowing direct visualization of the larynx, hypopharynx, esophagus, and stomach, and through the pylorus into the duodenal bulb.[77,84]

ERCP requires thorough assessment of the patient, including a review of laboratory values of a complete blood count, serum liver chemistries, and amylase or lipase levels to evaluate liver function, and clotting studies. Patients also must be evaluated for anticoagulant medications, bleeding history, and prosthetic heart valves.[77,87] Allergies must be evaluated, especially those to iodinated contrast media.[88] Patients who require ERCP are usually more ill than patients seen routinely for colonoscopy or EGD.

BOX 52-12

Indications for Colonoscopy, Esophagogastroduodenoscopy, and Endoscopic Retrograde Cholangiopancreatography, with Anesthetic Implications

Colonoscopy
- Gastrointestinal bleeding and occult bleeding
- Evaluation of an abnormality on barium enema
- Polypectomy
- Unexplained iron deficiency anemia
- Significant diarrhea
- Chronic inflammatory bowel disease
- Malignancy
- Dilation of stenotic lesions
- Foreign body removal

Esophagogastroduodenoscopy
- Persistent and recurrent dyspepsia (heartburn)
- Persistent nausea or vomiting (PONV)
- Dysphagia (difficulty swallowing)
- Chest pain with a negative cardiac evaluation
- Iron deficiency anemia
- Suspected small bowel malabsorption
- Malignancy
- Stomach or esophageal ulcer
- Control of bleeding
- Ligation or sclerosis of varices
- Dilation of strictures
- Percutaneous gastrostomy
- Polypectomy
- Removal of foreign body

Endoscopic Retrograde Cholangiopancreatography (ERCP)
- Suspected biliary ductal disorder
- Suspected pancreatic ductal disorder
- Biliary drainage
- Pancreatic drainage
- Biopsy
- Bile or pancreatic juice collection
- Mapping of the pancreatic duct before intended surgery
- Manometry of the sphincter of Oddi or other ductal mapping

Data from Waye JD, et al. Colonoscopy and flexible sigmoidoscopy. In: Yamada T, ed. *Textbook of Gastroenterology*. 5th ed. Oxford: Wiley Blackwell; 2009:2917-2932; Yusuf TE. Endoscopic retrograde cholangiopancreatography, endoscopic sphincterotomy and stone removal, and endoscopic biliary and pancreatic drainage. In Yamada T, ed. *Textbook of Gastroenterology*. 5th ed. Oxford: Wiley Blackwell; 2009:2933-2957; Stockland AH, Baron TH. Endoscopic and radiologic treatment of biliary disease. In: Feldman M, et al, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 9th ed. vol. 1. Philadelphia: Saunders; 2010:1185-1200.

The patient must be NPO according to guidelines. Intravenous access is obtained and fluid is administered. Standard monitors are applied, and oxygen is supplied to the patient via a disposable facemask or nasal cannula, or as appropriate for anesthesia plan. The procedure requires that the patient be in a prone, semi-prone, or slightly left lateral decubitus position. Deep sedation or general anesthesia are usually required.[87-90]

Pediatric endoscopy has been performed with patients under deep intravenous sedation with agents such as propofol, midazolam, and alfentanil (when the patient will allow placement of the intravenous catheter) and under general endotracheal anesthesia.[83] Propofol has been found to provide anterograde amnesia during the procedure with no provided retrograde amnesia.[82-83] The use of a eutectic mixture of local anesthetics lidocaine and prilocaine (EMLA cream) facilitates the placement of the IV catheter. EMLA must be applied to undamaged skin, under an occlusive dressing for a period of 45 to 60 minutes, before the IV catheter is inserted.[83] When general anesthesia is administered, a sturdily secured endotracheal tube should be considered because of relative inaccessibility to the airway, as in the patient position required for pediatric colonoscopy or for EGD in which the oral cavity will be shared with the operator.[83]

These procedures can cause bowel rupture or duct rupture. One must be ready with immediate airway and hemodynamic support as necessary, along with monitored emergency transport to the operating room for surgical intervention.[77]

Postanesthesia Care. Postprocedure morbidity differs with each of the described procedures. All patients must be monitored in a postanesthesia care area until they have recovered from the sedation or general anesthetic.

Colonoscopy patients have intestinal distention, which is relieved with encouragement to pass flatus. Rectal bleeding, nausea, hypotension, and vomiting also may be seen. Administration of a bolus of intravenous fluids along with an intravenous antiemetic agent.[91-92]

EGD morbidity relates to bleeding, nausea, vomiting, aspiration, dysphagia, and hypotension. Treatments such as those used for colonoscopy may be indicated.[91-92]

ERCP morbidity relates to possible reactions to iodinated contrast media. Patient reactions can be mild (such as nausea, vomiting, pruritus, diaphoresis, flushing, or mild urticaria), moderate (such as faintness, severe vomiting, profound urticaria, mild bronchospasm, mild hypotension, mild tachycardia, or bradycardia), or severe (hypotensive shock, angioedema, respiratory arrest, cardiac arrest, convulsions, or death).[91] Postprocedure bleeding, nausea, and vomiting (PONV) are possible and can be treated as described previously.

Gynecology Procedures

Assisted Reproductive Technologies

Procedure Overview. *Assisted reproductive technologies* (ARTs) refers to all techniques used to retrieve and fertilize the human oocyte. In vitro fertilization (IVF) is the most common technique used to artificially fertilize the human oocyte. Research by reproductive endocrinologists has advanced technology since the first "test-tube baby" was born in 1978 and continues to result in new and more effective techniques. The Centers for Disease Control and Prevention (CDC) reports that approximately 12% of women over childbearing age within the United States have used some form of fertility aid in an attempt to become pregnant. In 2009, 146,244 cycles of ART resulted in 45,870 live births and 60,190 infants, and the numbers of ART procedures continues to grow.[94] The procedure, which takes approximately 20 to 30 minutes to complete, is generally performed by a gynecologist who has had an advanced training fellowship in reproductive endocrinology and infertility.

The procedure is performed by initially stimulating maturation of the follicle with a gonadotropin-releasing hormone agonist, which induces pituitary-gland suppression and creates quiescent ovaries to prevent the production of a single dominant follicle. Follicle-stimulating hormone (FSH) and human menopausal gonadotropin are then administered, which induces 10 to 15 ovarian follicles. The patient is then given human chorionic gonadotropin (hCG), which induces the follicle to mature and move into the follicular fluid. The oocyte is retrieved transvaginally, transabdominally, or via laparoscopy with an ultrasonically guided probe 34 to 36 hours after hCG administration. All visible follicles are collected, washed, incubated for 4 to 6 hours in a culture medium, and examined microscopically. Most follicles contain only one oocyte.[93-94] Fertilization occurs in the IVF laboratory. The oocyte is identified and has minimal exposure to ambient room temperature, room air, and especially any chemical odors. Sperm are washed and centrifuged. Fresh media is added next to the centrifuged sperm, and those sperm that swim to the media, which can number 50,000, are placed with the oocyte. Male factor infertility, which affects 37% of couples seeking ART procedures, requires direct intracytoplasmic injection of sperm; 16 to 20 hours later, the fertilized oocytes are examined for evidence of fertilization. Within 3 to 5 days after fertilization is verified, the embryo (which has developed into 8 to 10 cells) is transferred into either the fallopian tube or (more commonly) the uterus. Timing must be coordinated with proper maturation of the uterine endometrium.[93-95] ART is found to increase the risk of multiple gestations. Also, it has been reported that atypical implantations of the fertilized ovum or zygote, such as abdominal, cervical, ovarian, or tubal pregnancy, occur more frequently with ART.[95] Common ART techniques are listed in Table 52-1. IVF was first performed over 30 years ago and is accepted now because of increased success rates, 31.4% in 2009. The CDC estimates that according to their research, over 1% of all live births within the Unites States today occur as a result of ART.[94]

Patients are assessed for antibodies to human immunodeficiency virus types 1 and 2 (HIV-1, HIV-2) and human T-cell lymphotropic virus type 1 (HTLV-1), hepatitis B antigen, and antibodies to hepatitis B and C. Patients are also tested for chlamydia, syphilis, gonorrhea, and cytomegalovirus. Smokers require twice as many attempts at successful IVF than nonsmokers, so smoking is actively discouraged.[93-95]

Anesthetic Considerations. IVF is generally performed on patients who are ASA class 1 or 2 in their third or fourth decade of life. Although IVF is a relatively simple procedure for the reproductive endocrinologist to perform, especially outside the operating room, IVF is an uncomfortable procedure and requires that patients do not move while the probe is guided for retrieval and later reimplantation. The vaginal wall must be pierced for the desired ovary to be accessed. Also, major blood vessels are present in the proximity of the ovaries, and their injury could lead to complications.[96]

Anesthesia requirements vary with the individual needs of the patient and the reproductive endocrinologist.[93,96] Multiple ART procedures may need to be performed until one of them is successful, so safe yet inexpensive anesthetic techniques are desirable.[94-95] Minimal sedation, moderate sedation/analgesia, regional intrathecal anesthesia, paracervical block, or general anesthesia can be administered to assist in making the procedure as comfortable and successful as possible.[93,95-96] Moderate sedation with analgesia is usually sufficient for most patients. None of the anesthetic techniques cause differences in reproductive outcome.[93,95-96]

TABLE 52-1 Common Assisted Reproductive Technology Techniques

Procedure	Description
In vitro fertilization (IVF)	Oocytes are removed, fertilization occurs in the laboratory, and the embryo is placed transcervically into the uterus or into the distal portion of the fallopian tube(s).
Gamete intrafallopian transfer (GIFT)	Oocytes and sperm are transferred into one or both fallopian tubes for fertilization. *Advantage:* Oocyte retrieval and gamete transfer occur with a single procedure. *Disadvantages:* Requires at least one patent fallopian tube and laparoscopic surgery. Fertilization cannot be confirmed.
Zygote intrafallopian transfer (ZIFT)	Fertilized embryos are placed into the fallopian tube. *Advantages:* Fertilization is confirmed. Laparoscopic surgery can be avoided if fertilization has not occurred. The embryos can be transferred at an appropriate developmental stage. *Disadvantage:* Requires a two-stage procedure, with added risks and costs. Requires at least one patent fallopian tube.
Tubal embryo transfer (TET)	Cleaving embryos are placed into the fallopian tube.
Peritoneal oocyte and sperm transfer (POST)	Oocytes and sperm are placed into the pelvic cavity.

Modified from Speroff L, et al. *Clinical Gynecologic Endocrinology and Infertility*. 6th ed. Baltimore: Lippincott Williams & Wilkins; 1999:1133-1148; Tsen LC. Anesthesia for assisted reproductive technologies. *Int Anesthesiol Clin*. 2007;45:99-113.

Anesthetic medications generally considered safe for use in anesthesia for ART are listed in Box 52-13. Anesthetists should consider using safe anesthetic techniques with quick onset and a short duration. It should be noted that propofol, lidocaine, and alfentanil have been shown to accumulate in the follicular fluid. Although no deleterious effects of any anesthetics have been identified, this area continues to be studied.[96-97] No data from human trials have ever condemned the use of local anesthetic agents for oocyte retrieval. Morphine has been shown to adversely affect fertilization of sea urchin eggs in vitro by allowing more than one sperm to enter the oocyte in 30% of cases, so it is not used because of the existence of safe alternatives such as fentanyl, alfentanil, remifentanil, and meperidine. Midazolam, when titrated in small doses to provide mild to moderate sedation and anxiolysis, has been shown to be safe, with no accumulation in follicular fluid or being a teratogen. Ketamine (0.75 mg/kg) with midazolam (0.06 mg/kg) used as moderate sedation/analgesia is safe as an alternative to general anesthesia with isoflurane. The literature has suggested the use of caution if the anesthetist desires to select a potent inhaled agent (especially sevoflurane and desflurane) because of possible negative effects to ART outcomes.[97] Nonsteroidal antiinflammatory agents such as ibuprofen, indomethacin, ketoprofen, ketorolac, meloxicam, naproxen, or oxaprozin are avoided owing to inhibition of prostaglandin synthesis and possible effects on embryo implantation.[96-97] Droperidol and metoclopramide have been shown to induce rapid hyperprolactinemia and should be avoided. Low plasma prolactin levels are associated with higher incidences of pregnancy.[97] Box 52-14 lists common anesthetic agents that could cause problems with ART.[96-97] The necessity for any medication given to the patient should be carefully considered, and the anesthetic technique should be kept simple and basic.

BOX 52-13 Anesthetic Medications Used for Assisted Reproductive Technologies

Intrathecal
- Bupivacaine
- Lidocaine
- Fentanyl
- Morphine

Paracervical Block
- Bupivacaine
- Lidocaine
- Mepivacaine

Intravenous Sedation or Total Intravenous Anesthesia
- Fentanyl
- Alfentanil
- Remifentanil
- Meperidine
- Ketamine
- Midazolam
- Propofol

Inhalation Agents
- Nitrous oxide

BOX 52-14 Common Anesthetic Agents That Could Cause Problems with Assisted Reproductive Technologies

- Morphine
- Sevoflurane
- Desflurane
- NSAIDs—ibuprofen, indomethacin, ketoprofen, ketorolac, meloxicam, naproxen, oxaprozin
- Droperidol
- Metoclopramide
- Postanesthesia care: As in all cases of anesthetic administration, the patient is assessed in a postanesthetic recovery area. Vital signs and pulse oximetry are assessed and must be stable. If intrathecal anesthesia was used, the patient must have a recovery of sensorium, be able to ambulate, and be able to void. All patients must be free of nausea.

NSAIDs, Nonsteroidal antiinflammatory drugs.

Office-Based Surgery

General Dental Procedures

Procedure Overview. Anesthesia for dental procedures and dental surgery can present many challenges. The demand for dental care and visits from patients are increasing. Dentistry has changed from a role of therapeutic treatment of dental disease to a role of prevention. The old mainstay was that 50% of the population never visited a dentist. This group used dentistry only for treatment of extreme pain or in an emergency. Latest demographic statistics show that this has changed for the better. Overall, rates vary drastically across the U.S. population, with approximately 44.5% of the population visiting a dentist at least once annually. More women see dentists annually than men, and as employment status, income, and educational levels increase, so do the number of annual visits to the dentist. Also, children ages 6 or younger and adults ages 65 or older are seeing dentists more frequently than in the past.[98] These numbers are expected to increase drastically

as with the United States government Healthy People Initiative adding oral health to the objectives for the current and coming years.[99]

Dental procedures may be performed in an operating room, a specially equipped hospital suite, an ambulatory surgical center, or a dental office operatory (dental surgical area).[100] Anesthesia may be required for dental procedures in the following areas of dentistry[101]:

- *Pediatric dentistry*—an age-defined specialty that provides primary and comprehensive preventive and therapeutic oral health care for infants and children through adolescence, including those with special healthcare needs.
- *Oral and maxillofacial surgery*—the specialty that includes the diagnosis, surgical, and adjunctive treatment of diseases, injuries, and defects involving both the functional and esthetic aspects of the hard and soft tissues of the oral and maxillofacial region.
- *Periodontics*—the specialty that encompasses the prevention, diagnosis, and treatment of diseases of the supporting and surrounding tissues of the teeth, or their substitutes, and the maintenance of the health, function, and esthetics of these structures and tissues.
- *Endodontics*—the specialty that is concerned with the etiology, diagnosis, prevention, and treatment of diseases and injuries of the pulp and associated periradicular (concerning the root of the tooth) conditions.
- *Prosthodontics*—the dental specialty involved with the diagnosis, treatment planning, rehabilitation, and maintenance of oral functions, comfort, appearance, and patient health associated with clinical conditions of missing or deficient teeth and/or oral and maxillofacial tissues along with biocompatible substitutes.
- *General dentistry*—encompasses the etiology, diagnosis, and treatment of conditions of oral, head, and neck tissues; the general dentist may perform procedures that encompass any or all of the dental specialty areas, depending on the training, abilities, and experiences of the general dentist.
- *Dental hygienist*—a licensed oral health professional trained to treat patients by the removal of dental plaque and calculus (tartar) above or below the gingiva.[100-101]

Anesthetic Considerations. Important considerations that must be part of the anesthesia treatment plan for the dental setting are outlined in Box 52-15. The patient may require minimal sedation, moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia for dental surgery. The anesthesia required depends on the patient-related factors of fear, anxiety, age, medical condition, level of cooperation and behavior, gagging, ineffective local anesthesia in the past, mental impairment, and physical disability. A thorough, documented patient assessment along with appropriate laboratory studies and possible physician consultation regarding patient clearance for physically and/or psychologically stressful dental surgery are necessary.[102-104] In pediatric dentistry, a comprehensive and personalized discussion with the parent or guardian (with or without the patient present) of what the anesthetic procedure will entail, coupled with an opportunity for the parent or patient to engage in dialogue and ask questions, can alleviate the stress of the upcoming procedures for all parties.[102]

The dental operatory must be of adequate size for both access and egress of both the patient and personnel. Proper considerations and advanced planning must be made to accommodate patients according to the Americans with Disabilities Act.[105-106] Also, the anesthetist must have full and rapid access to both the patient and all required equipment and supplies. Full monitors are necessary.

BOX 52-15

Considerations Related to Anesthesia in the Dental Setting

- Anesthesia may be administered in an unfamiliar area. Carefully plan, equip, and set up the operatory so that it is as familiar and comfortable as in an operating room.
- The established airway will be shared with the dental surgeon.
- The potential exists for heavy bleeding because of the vast blood supply to the head and neck region.
- There could be the use of small instruments, burs (dental drill bits), files, implants, and filling materials in the mouth, with the potential of falling into the oropharynx or being aspirated.
- Patients may be receiving dental prosthetic devices such as crowns, bridges, or full or partial dentures, which can also affect the airway.
- There exists the possibility of intense pain, transmitted primarily by the maxillary and mandibular divisions of the trigeminal nerve.
- Patients usually display a high level of anxiety, and adequate time must be incorporated into the schedule to allow for safe anesthetic treatment.

Consider the use of the antisialagogue glycopyrrolate, because dental surgery can stimulate the flow of saliva. Excess salivation can lead to coughing, choking, laryngospasm, or aspiration in the sedated patient. Delivery of anesthesia in the dental operatory should be as familiar as if it were in an operating room. Postoperative problems in dentistry generally are minimal but can involve pain, swelling, bleeding, PONV, the vasovagal response, airway problems, hypoxemia, or hypothermia, as a result of anesthetic procedures other than local anesthesia administered. Hypothermia can be addressed by the use of an electric blanket; forced-air warming may or may not be feasible for the dental operatory.

General dentists and board-certified dental specialists are also trained to administer intraoral local anesthesia, which is a cardiac depressant and may cause either CNS depression or excitation. Local anesthesia for dentistry is commonly administered with an aspirating syringe/needle system. Local anesthetic is available in 1.8-mL glass capsules, both with and without epinephrine, or levonordefrin (Neo-Cobefrin) as a vasoconstrictor.

Dental specialists and specially trained general dentists can be licensed by state dental boards to administer the continuum of anesthesia, from minimal sedation to general anesthesia while performing the dental surgery. The dental literature reports good long-standing success rates and safety, but caution is necessary.[107-109]

Each dental specialty has particular anesthetic considerations, which are discussed in the following sections.

Pediatric Dentistry. Pediatric dental patients can require the continuum of anesthesia from enteral minimal sedation to parenteral moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia if the patient is behaviorally uncooperative, immature, frightened, or mentally disabled or because of the necessity to perform all necessary dental surgery in one session. Pediatric dentists may have a patient immobilization device available, commonly called a *papoose board*, to safely restrain the patient until anxiolytic anesthesia can be administered. Anesthetic choices such as oral or intravenous ketamine; a mixture of oral chloral hydrate, meperidine, and hydroxyzine; intravenous diazepam; midazolam; and propofol have been used with success.[107,109-110] Premedication with orally administered midazolam

dissolved in a small amount of the liquid forms of acetaminophen, ibuprofen, aspirin, or low-sugar clear juice is commonly used. For the liquid forms of acetaminophen, ibuprofen, or aspirin, the anesthesia provider should refer to the package insert for the proper dosing based on the patient's weight. Intranasal or rectal midazolam can be used alone or given before general endotracheal anesthesia and has proved as effective as nitrous oxide for sedation.[107,109-110] After an inhaled mask or intravenous induction, endotracheal intubation via either the oral or nasal route can be performed to allow the pediatric dentist full access to the mouth. Pediatric dentists typically are and should be very cognizant of the importance of sharing the airway during surgery. Typical pediatric dental procedures include restorative dentistry, such as fillings of amalgam or composite, and placement of stainless steel crowns for posterior teeth, polycarbonate crowns, composite crowns, or stainless steel crowns with porcelain for anterior teeth, pulpotomies, tooth extractions, and space maintainers. Successful treatments can be provided along with stress reduction for the patient, parents or guardians, and for the healthcare providers with appropriate airway maintenance under deep sedation or general anesthesia.[107-110]

Oral and Maxillofacial Surgery. Procedures performed within the specialty of oral and maxillofacial surgery (OMS) are among the most invasive in dentistry. Oral surgeons perform uncovering of teeth for orthodontic treatment; extraction of impacted, severely carious, and multiple teeth; insertion of dental implants, treatment of infections of the head and neck; surgical remodeling of maxillary and mandibular alveolar bone; facial cosmetics; and removal of soft-tissue or bony tumors, as well as many other procedures. These procedures can produce both severe pain and heavy bleeding. Many OMS procedures are performed within the office setting. Oral and maxillofacial surgeons receive 6 years of postdoctoral training and become licensed by the state dental board to perform the continuum from minimal sedation to anesthesia (general anesthesia) care. Patients can have challenging physical and mental conditions; therefore, a thorough preanesthetic assessment is necessary.[111] The patient's airway is shared with the oral surgeon; therefore, nasal intubation may be necessary. It may be possible to perform some oral surgical procedures while carefully working around an unsecured tube or with a standard or reinforced LMA. Local anesthesia in combination with intravenous sedation (propofol, midazolam), inhalation sedation (nitrous oxide), inhaled potent endotracheal anesthetics, and total intravenous general anesthesia are techniques available for office-based OMS.[103,111] Remifentanil has become a useful adjunct with the techniques listed to counteract the intense stimulation of OMS.[112] An anesthesia awareness/level of consciousness/depth of sedation monitor is also useful for careful anesthetic titration.[110]

Periodontics. Periodontal procedures can involve painful stimulation. Periodontists generally work in a particular quadrant of the patient's mouth and administer local anesthetic for the particular area of surgery. Periodontal treatment involves surgery of the teeth, gingiva, connective tissue, periodontal ligament, and alveolar bone, as well as insertion and maintenance of dental implants. Local anesthetics are administered with a normal epinephrine 1:100,000 concentration, unless contraindicated, along with greater than normal epinephrine concentrations (1:50,000) injected directly into the gingiva because of its local anesthetic ability and for hemostasis. Periodontal surgery can involve lengthy procedures with moderate amounts of hemorrhage, and can be well managed with minimal sedation (both enteral or with inhalation sedation) or moderate sedation/analgesia.[103,111] Use of standard monitoring is necessary. Midazolam with a propofol infusion helps achieve the goals of safety and comfort for periodontal surgical patients.[103]

Endodontics. Anesthesia for endodontic procedures is similar to that described for periodontal surgery. Local anesthesia provides adequate comfort, but in the presence of patient anxiety related to the length of endodontic procedures, minimal sedation (both enteral or with inhalation sedation) or moderate sedation/analgesia can make the procedure tolerable and less anxiety producing for the patient. A dental dam is usually applied around the tooth and held in place with a special clamp to prevent aspiration of dental burs and endodontic files.

General Dentistry and Prosthodontics. General dentistry can encompass all procedures from all of the dental specialties, depending on the interest and training of the general dentist. Anesthesia can be delivered along the continuum of care to ensure safety for the patient and to fill the requirements of the particular dental procedure.[100,103-104]

Dental Hygiene. Dental hygienists are also involved with providing dental care to patients who may require anesthesia along the continuum from minimal sedation/analgesia to deep sedation/analgesia with combinations of inhalation nitrous oxide/oxygen, local anesthesia, and intravenous medications. Thorough treatment can generate tooth or gingival sensitivity and pain. Even in the absence of pain, special populations such as pediatrics, the mentally handicapped, and those with severe anxiety disorders may require some degree of anesthesia for even routine dental care. Procedures range from routine hygiene to deep scaling and root planing of teeth with heavy dental accretions.

Postanesthesia Care. Patients should be allowed to recover in a quiet, monitored environment. Intravenous access allows the titration of additional analgesia or antiemetics as necessary. Fortunately, patient morbidity from general anesthesia for dental procedures is low.[113] Patients who receive inhaled sedation are less stressed postoperatively than those who receive general anesthesia, but TIVA procedures with proper airway maintenance and supplemental oxygen also prove to be a great success.[102,104,113]

Invasive dental procedures can be another source of distress in children, which can lead to crying, nausea, vomiting (PONV), and bleeding postoperatively. The addition of the potent opioid morphine, ketorolac, or both greatly aids patient comfort in the postsurgical anesthesia recovery area. The use of oral minimal to moderate sedation in pediatric patients ages 2 to 34 months has been found to have no effect on behavior when the individual requires treatment later.[102,109] Adolescents who have undergone sedation for childhood dental therapy are found to possess a high level of anxiety regarding dentistry, when compared with adolescents without that history.[109-110]

Psychiatric Procedures

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is the intentional inducement of a generalized seizure of the CNS for an adequate duration of time to treat patients with certain severe neuropsychiatric disorders.[114] The American Psychiatric Association continues to support ECT as a safe and evidence-based medical treatment when administered by trained, qualified personnel.[115] ECT in general, however, continues to be a topic of controversy. Research studies differ in the effectiveness of ECT. Most studies agree that the short-term effects of ECT are substantial; however, they argue the long-term benefits.[116-119]Antidepressant medication administration, along with ECT, is well tolerated by patients, and both therapies can be beneficial. Most patients receive three treatments per week and can undergo a total of 6 to 12 treatments overall.[114,118] When

clinical improvement is seen, it typically occurs within the first three to five treatments, and positive response to treatment is seen in 50% to 90% of patients, even those who had been treatment resistant.[116,119] Death from ECT itself is possible but is rare. ECT is also used in certain patients who experience mania, catatonia, vegetative dysregulation, inanition, suicidal drive, and schizophrenia with affective disorders, and has begun to be used for patients with Parkinson's disease.[114,116-119]

ECT is one of the most controversial and invasive treatments in medicine. The first documented use of ECT was in 1938. Early ECT was performed without anesthesia, with the occurrence of many adverse effects such as bitten tongues, broken bones, and broken teeth. Treatment involves placement of electrodes with a conducting gel, either right-sided unilaterally or bitemporally bilaterally. An alternating current of electricity is passed through the electrodes.[114] Theories for the mechanism of ECT are related to profound changes in brain chemistry, such as enhancement of dopaminergic, serotonergic, and adrenergic neurotransmission. Another theory postulates the release of hypothalamic or pituitary hormones, which have antidepressant effects. Finally, ECT produces anticonvulsant effects that raise the seizure threshold and decrease seizure duration, exerting a positive effect on the brain.[114]

Anesthetic Considerations. Anesthesia for ECT involves the administration of an ultra-brief general anesthetic to provide lack of consciousness to the patient for the procedure (Table 52-2).

A thorough preanesthetic assessment must be performed, with consideration given to the possible critical physiologic hemodynamic responses generated by the induced seizure activity. Box 52-16 lists possible physiologic effects as a result of ECT.

Few absolute and relative contraindications to ECT exist (Box 52-17).[114,120,121]

Patients may have results of laboratory studies, a pharmacologic regimen, and ECG readily available because of their psychiatric hospitalization. Informed consent is obtained whenever possible from the patient or legal guardian. An intravenous catheter is inserted in a peripheral vein. The patient is monitored with a pulse oximeter, ECG, noninvasive blood pressure monitor, temperature-monitoring device, and peripheral nerve stimulator. Use of $ETCO_2$ monitoring has been suggested because hypercarbia and hypoxia shorten seizure duration. Suction, oxygen, a positive-pressure Ambu bag and facemask, and rubber bite protectors must be present, as well as necessary airway and cardiovascular resuscitation equipment, medications, and supplies. ECT is usually performed in a dedicated psychiatric suite or special treatment room.[121-122]

The patient is preoxygenated before induction. Anticholinergics may be administered as an antisialagogue or to prevent asystole.[122-124] The induction agent is administered intravenously. Either propofol or etomidate may be used without compromise of the therapy.[125-128] Ketamine also has been used, although an enhanced hemodynamic response and increased intracranial pressure are possible after using ketamine.[121,123] After loss of consciousness, positive-pressure ventilation is applied to the patient via the breathing bag and a facemask and is continued until after treatment is completed and spontaneous respirations resume. To assess the duration of the induced convulsion, the psychiatrist usually applies a tourniquet (or manual blood pressure cuff inflated to slightly greater than the systolic blood pressure) above a lower extremity so that the muscle relaxant cannot reach the skeletal muscle in the extremity. A rubber bite block is gently placed in the patient's mouth to prevent biting of the teeth, lips, and tongue, and an ultra–short-acting muscle relaxant is administered. Succinylcholine is typically the muscle relaxant of choice for electroconvulsive therapy because of its rapid onset, short duration, and independent reversibility.[121-123] Nondepolarizing agents can be used; however, induction dosage is typically adjusted to create a shorter duration of neuromuscular blockade.[123,129] A nerve stimulator must be used,

TABLE 52-2 Anesthetic Medications Used for Electroconvulsive Therapy

Drug	Dose
Anticholinergics	
Atropine	0.4-1 mg IV or IM
Glycopyrrolate	0.005 mg/kg IV or IM
Anesthetics	
Alfentanil	0.2-0.3 mcg/kg IV
Etomidate	0.1-0.3 mg/kg IV
Ketamine	0.5-1 mg/kg IV
Propofol	0.75-1.5 mg/kg IV
Muscle Relaxants ***Depolarizing***	
Succinylcholine	0.5-1 mg/kg IV (onset 30-60 seconds)
Nondepolarizing	
Cisatracurium	0.15-0.25 mg/kg IV (onset 1-2 min)
Atracurium	0.3-0.4 mg/kg IV (onset 6 min)
Rocuronium	0.3-0.9 mg/kg IV (onset 1-2 min)

BOX 52-16

Possible Physiologic Effects of Electroconvulsive Therapy

Cardiovascular

Parasympathetic Response During Tonic Phase of Seizure

- Decreased heart rate
- Hypotension
- Bradydysrhythmias

Sympathetic Response During Clonic Phase of Seizure

- Tachycardia
- Hypertension
- Tachydysrhythmias

Cerebral

- Increased cerebral blood flow (increases of 100% to 400% above baseline are possible)
- Increased intracranial pressure

Other

- Increased intraocular pressure
- Increased intragastric pressure

Adapted from Lee M. Anesthesia for electroconvulsive therapy. In: Atlee JL, ed. *Complications in Anesthesia*. 2nd ed. Philadelphia: Saunders; 2007:903-905; Reti IM, et al. Safety considerations for outpatient electroconvulsive therapy. *J Psychiatr Pract*. 2012;18(2):130-136.

and appropriate neuromuscular blockade reversal agents should be administered if necessary. The electrodes are applied, the proper waveform and current level are selected, and the electroconvulsive seizure is induced. The seizure lasts from 30 to 90 seconds; the motor seizure is shorter than the seizure duration as seen on an electroencephalogram (EEG). Use of an anesthesia awareness/level of consciousness/depth of sedation monitor correlates with the EEG, and it can be a useful tool for the anesthetist and the psychiatrist.[122] The level of sedation displayed by this monitor correlates with the proper point to induce seizure, the duration of seizure, and the potential for awareness during the ECT procedure.[121-122] At the end of the seizure, spontaneous respirations resume, the patient is transferred to a recovery area, and vital signs are continually monitored until the patient is determined to be stable and able to be safely discharged.[114,120-122] Certain anesthetic medications and techniques such as hyperventilation can affect seizure duration (Box 52-18).

Adult patients about to undergo ECT should follow fasting guidelines of at least 6 hours for solids and 2 hours for liquids. Necessary bronchodilators may be taken. Oral medications, such as antihypertensives, cardiac medications, anticoagulants, and thyroid medications, may be taken with a sip of water up to 1 hour before the procedure.[120-122] Rapid-sequence induction of general anesthesia with applied cricoid pressure and endotracheal intubation can be performed. One must take into consideration the total number of ECT treatments to be received, weighed against the necessity for repeated intubations and the fact that most patients, even obese patients, have rarely been found to aspirate as a result of ECT.[120] The CRNA may perform a rapid-sequence induction and apply cricoid pressure until the protective reflexes return and the danger of aspiration is eliminated, rather than intubating the patient.

Postanesthesia Care. The intentional creation of CNS convulsions has profound effects on the patient's physiology. Patients usually experience temporary cognitive and memory impairment after ECT.

BOX **52-17**

Absolute and Relative Contraindications to Electroconvulsive Therapy

Absolute Contraindications to ECT

- Pheochromocytoma
- Recent myocardial infarction (less than 4-6 weeks ago)
- Recent cerebrovascular accident (3 months ago or less)
- Recent intracranial surgery (3 months ago or less)
- Intracranial mass lesion
- Unstable cervical spine

Relative Contraindications to ECT

- Angina
- Congestive heart failure
- Cardiac rhythm management device (pacemaker, automatic internal cardiac defibrillator [AICD])
- Severe pulmonary disease
- Major bone fracture
- Glaucoma
- Retinal detachment
- Thrombophlebitis
- Pregnancy

Modified from Lee M. Anesthesia for electroconvulsive therapy. In: Atlee JL. *Complications in Anesthesia*. 2nd ed. Philadelphia: Saunders; 2007:903-905; Reti IM, et al. Safety considerations for outpatient electroconvulsive therapy. *J Psychiatr Pract*. 2012;18(2):130-136.
ECT, Electroconvulsive therapy.

The first type of impairment that may be seen is postictal confusion, in which the patient is transiently restless, confused, and agitated immediately after the convulsive episode and for approximately 30 minutes. The agitation can be difficult to manage for the recovery nurse. Some patients require physical restraint or sedation with a benzodiazepine or an antipsychotic medication such as haloperidol. One theory postulates that the anxiety is a result of increased plasma lactate levels possibly caused by inadequate neuromuscular blockade and that increasing the dose of muscle relaxant is necessary with next treatment.[122,129]

A second type of cognitive impairment that may be seen later is anterograde memory dysfunction, in which the patient may rapidly forget new information. The patient may not remember things that he or she does or is told in the days after ECT. Anterograde amnesia usually subsides within days or a few weeks. However, it can be frightening to the patient. A third cognitive dysfunction is retrograde memory dysfunction, which is the forgetting of memories from several weeks to several months before the ECT treatment. No evidence suggests that ECT causes any brain damage, nor does it impair the long-term ability for the patient to learn and retain new information. The cognitive effects described vary depending on the frequency and the number of ECT treatments the patient has received. The quantities of energy used to elicit the convulsions and the placement of the electrodes are also

BOX **52-18**

Effects of Common Medications and Conditions on Seizure Duration

Medications That Can Prolong Seizure Duration

- Alfentanil with propofol
- Aminophylline
- Caffeine
- Clozapine
- Etomidate
- Ketamine (a proconvulsant)

Conditions That Can Prolong Seizure Duration

- Hyperventilation/hypocapnia

Medications That Can Shorten Seizure Duration

- Diltiazem
- Diazepam
- Fentanyl
- Lidocaine
- Lorazepam
- Midazolam
- Propofol
- Sevoflurane

Medications with No Apparent Effect on Seizure Duration

- Clonidine
- Dexmedetomidine
- Esmolol (may possibly shorten seizure duration)
- Labetalol (may possibly shorten seizure duration)
- Nicardipine
- Nifedipine
- Nitroglycerin
- Nitroprusside

Modified from Stensrud PE. Anesthesia at remote locations. In: Miller RD, et al. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2477-2479; Wagner KJ, et al. Guide to anaesthetic selection for electroconvulsive therapy. *CNS Drugs*. 2005;19:745-758.

factors. Even the type of anesthetic drugs used is believed to be involved.[114]

Cardiovascular stimulation also occurs with ECT. The sympathetic and parasympathetic nervous systems are stimulated sequentially. Therefore, the patient may experience an increase in heart rate and blood pressure, followed by a period of bradycardia or even asystole. This can lead to increases in myocardial oxygen demand, arrhythmias, and transient ischemic changes in susceptible individuals. Transient cardiac changes can be managed before ECT with anticholinergics, intravenous local anesthetics such as lidocaine, or intravenous narcotics such as remifentanil.[114,121-122,130,131] Changes after ECT can be managed with β-blockers such as esmolol or labetalol, calcium channel blockers, or other antihypertensives.[131]

Finally, patients also may experience headache, muscle aches, or nausea. Symptoms of headache or muscle ache respond well to acetaminophen, aspirin, or nonsteroidal antiinflammatory agents such as intravenous or intramuscular ketorolac or oral ibuprofen.[120-122] Nausea can be caused by the stress and anxiety before the ECT treatment, the anesthetic agents used, the seizure itself, or air in the stomach from assisted ventilation. Nausea can be treated with agents such as ondansetron, dolasetron, granisetron, or metoclopramide.[120-122]

New Therapies for Major Depressive Disorders

Two new therapies for severe major depressive disorders are now available, which often require anesthetic treatment: repetitive transcranial magnetic stimulation (rTMS) and vagus nerve stimulation (VNS).[132,133] Neuroanatomic studies have suggested that patients with major depressive disorder (MDD) have dysfunction within the frontal cortical-subcortical-brainstem neural network, specifically the dorsolateral prefrontal cortices (DLPFC). ECT and antidepressant medications do not act in these discrete areas of the brain, but new therapies stimulating these focal areas of the brain are now approved and in use in the United States.

Repetitive Transcranial Magnetic Stimulation and Magnetic Seizure Therapy. Repetitive transcranial magnetic stimulation (rTMS) uses electric current passing through an electromagnetic coil that has been placed on the scalp. The coil delivers brief, rapidly changing magnetic field pulses to specific areas of the brain. These bursts of pulses are called a "train" of stimuli. Multiple trains of rTMS may be delivered in one session. The scalp and skull are transparent to magnetic fields, an advantage over ECT, in which the scalp and skull are resistors to the electrical stimulation. To produce antidepressant effects, a convulsion must be initiated by trains of rTMS, because subconvulsive trains of rTMS are ineffective.[132,134-136]

Convulsive magnetic energy levels are determined by the use of motor threshold (MT). MT is the point at which a single pulse of magnetic energy begins to elicit an electromyographic response, that is, a twitch, usually of the abductor pollicis brevis muscle of the thumb or first dorsal interosseous muscle of the index finger.[132,134] Treatment with rTMS is safe and well tolerated, with reduced cognitive side effects when compared with ECT. Patients are found to recover much more rapidly from rTMS or MST therapy as compared with ECT.[136,137]

Magnetic seizure therapy (MST) uses a higher-intensity, more frequent, and longer-duration magnetic seizure-inducing dose when compared with the magnetic dose required for rTMS. MST can stimulate tonic-clonic seizures in more localized and focal regions of the prefrontal cerebral cortex when compared with ECT, as well as generalized tonic-clonic seizures that resemble ECT.[135-137] MST does not produce the rigid bilateral masseter muscle contractions noted during ECT but can produce elevations in blood pressure and heart rate similar to ECT.[137]

After rTMS some patients experience mild headache, disorientation and inattention (although patients become reoriented much more quickly than with ECT), retrograde amnesia, some anterograde amnesia, transient auditory threshold increases due to the high-frequency clicking sound heard during coil discharge (which can be alleviated with the use of foam earplugs), and (rarely) generalized seizure.[134,135] A single TMS treatment may be all that is necessary for treating certain severe MDD nonpsychotic patients along with their medications, although rTMS may be necessary.[132]

The literature describes anesthesia requirements for rTMS or MST from none needed to ultra-brief general anesthesia as for ECT.[132,134-137] A patent and secure intravenous catheter is established, and full monitors are applied. Glycopyrrolate 0.004 mcg/kg is administered as an antisialagogue along with ketorolac, 0.4 mg/kg, 2 to 3 minutes prior to induction of ultra-brief general anesthesia. Etomidate 0.15 to 0.2 mg/kg can be used for induction, as well as propofol, 1 to 2.5 mg/kg. Succinylcholine, 0.5 to 1 mg/kg, can be used as the muscle relaxant after isolation of a lower extremity for observation of seizure duration. Use the smallest amount of muscle relaxant necessary to enable recovery from paralysis prior to the return of consciousness. The anesthetist can then manually hyperventilate the patient's lungs with a facemask to an ET_{CO_2} value of 30 to 34 torr. At this point, the magnetic stimulus may be applied.[135,137]

Vagus Nerve Stimulation. VNS requires surgical implantation of a programmable battery-powered electrical stimulator that connects with the patient's left vagus nerve (cranial nerve X). The stimulator is usually implanted in the patient's chest with minimal sedation, moderate sedation/analgesia, deep sedation/analgesia, or under general anesthesia. Because of the delicacy of the surgery and its proximity to vital structures, no extraneous patient movement is permitted. Although originally approved for treatment-resistant epilepsy, the VNS is now approved for major depressive episodes that have not responded to four antidepressant medication trials.[133,138,139]

Radiologic and Diagnostic Procedures

Medical science has been able to use the sciences of physics, chemistry, and computers to produce remarkably accurate images of the internal structure and function of the body to aid medical diagnosis. Energy is transmitted to the patient and interacts with patient tissues. This energy is then detected, processed, and displayed on a computer console, which allows images to be selected for further investigation and diagnosis. Some medical images are created in real time and allow observation of flow or changes in tissue resulting from treatment.

Procedure Overviews

Computed Tomography. Computed tomography (CT) uses x-rays generated from a rotating anode x-ray generator. The patient is placed supine on a flat, wooden, wheeled platform and moved inside the scanning gantry. X-rays are then projected through the patient at different angles, penetrating tissues differently according to the atomic numbers of the atoms within the tissue. Dense tissue such as bone attenuates (reduces the energy of) the x-ray beam more than less dense tissue such as muscle, yielding high-resolution images of the scanned tissue. The patient images are then detected, and the computer acquires the image data. Finally, an image analyzer projects the analyzed data in the form of a tomogram or body section slice onto an operator console and a

physician-viewing console. CT is excellent for imaging bone. The diagnostic quality of a CT scan is enhanced with the injection of intravenous contrast media (ICM). Contrast media containing iodine may be administered to the patient enterally or parenterally to further attenuate the x-ray beam to enhance the images for CT vascular or gastrointestinal studies.[140,141]

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) uses the dipole moment (i.e., the ability of the atomic nucleus to behave as a magnet) of the hydrogen atom. The patient is placed supine within the scanning gantry or bore of the magnet. The magnet used for MRI can be a permanent magnet or a powerful superconducting electromagnet cooled with liquid helium to 4° Kelvin. Magnetic strength is measured in teslas (T); 1 T is equivalent to 10,000 gauss or oersted. MRI magnets can generate field strengths of 0.15 to 4 T, although MRI magnetic field strength generally ranges from 0.15 to 2 T. The quality of the MRI image is directly related to the strength of the magnetic field.[140,142] The spin of the electron in hydrogen will align the hydrogen atoms parallel to this powerful magnetic field. The patient's water-containing tissues are then excited with variable radiofrequency pulses. After the proton in hydrogen receives this radiofrequency energy, it emits radiofrequency energy with three-dimensional–appearing spatial information. MRI technology now allows its use within the operating room with an open-bore, portable, 0.12-T, low-intensity magnet to assist the neurosurgeon with diagnostic decisions.[140,143] Contrast media are also used in MRI studies to enhance the patient's tissues and allow the scan to provide further diagnostic information. MRI contrast is most commonly gadopentetate dimeglumine, which contains the element gadolinium bound as a chelated structure and administered primarily parenterally but rarely enterally.[140,143,144]

The FDA classifies the MRI as a class II device. Class II devices require special labeling, mandatory performance standards, and post-market surveillance by the FDA. The electromagnetic energy greatly drops off just outside the margins of the bore of the electromagnet. This is called the *fringe field*. There are no known reports of harmful physiologic effects from magnetic fields.[140,141]

Because of the potential of danger of the powerful electromagnetic attraction of ferromagnetic objects to both the patient and healthcare personnel, the American College of Radiology divides the MRI suite into four zones:

- Zone 1 has public access and no supervision, such as the hallway outside the MRI suite.
- Zone 2 has public access and limited supervision, such as the entrance into the MRI suite.
- Zone 3 has limited access and explicit supervision, such as immediately outside the MRI scanner room where MRI controls may be located.
- Zone 4 is the MRI scanner room itself and has strict and controlled access that is under constant supervision.[145]

Interventional Radiology (Vascular and Nonvascular) and Radiotherapy or Radiosurgery. Interventional radiology (IR) involves minimally invasive procedures and therapies performed by radiologists, especially in patients at high medical risk.[121,146-147] Major IR therapies include angiography, the embolization of blood vessels such as arteriovenous malformations or for epistaxis, the delivery of chemical or physical vascular occlusive devices, the removal of thrombi, ablation of aneurysms, and angioplasty of blood vessels with stent placement.[121,146-148] Box 52-19 lists indications for endovascular embolization procedures. See Chapter 25 for a discussion of interventional vascular surgery and Chapter 28 for interventional neuroradiology procedures.

BOX 52-19

Indications for Endovascular Embolization

- Arteriovenous malformation
- Arteriovenous fistula
- Intracranial aneurysm
- Recurrent epistaxis
- Hemoptysis
- Traumatic solid organ hemorrhage
- Preoperative major organ tumor embolization for blood loss reduction
- Gastrointestinal hemorrhage
- Uterine leiomyoma (fibroid)
- Uterine hemorrhage
- Pelvic fracture hemorrhage
- Postoperative hemorrhage after prosthetic hip or knee replacement
- Varicocele

From Higgins GA. Embolization procedures. In Atlee JL. *Complications in Anesthesia*. 2nd ed. Philadelphia: Saunders; 2007:912-914.

Radiation is a treatment itself for both benign tumors (e.g., low-grade astrocytoma, meningioma, pituitary adenoma, craniopharyngioma, schwannoma, pineocytoma, chemodectoma, low-grade papillary neoplasms) and aggressive tumors (e.g., germinoma, primitive neuroectodermal tumor, chordoma, intermediate-grade pineal tumor, immature teratoma, undifferentiated sarcoma, anaplastic oligoastrocytoma, and metastatic tumors). Radiation surgery is the delivery of a single massive dose of radiation to the target tissue. Radiation therapy is the delivery of smaller doses of radiation over several sessions.[149]

Gamma radiation is used for radiotherapy and radiosurgery. The gamma radiation is introduced to the patient by the use of either a GammaKnife or a CyberKnife. Each uses beams of gamma rays obtained from the radioactive decay of cobalt 60 or from a linear accelerator. The CyberKnife is used by first obtaining stereotactic three-dimensional images, which then allow computer-controlled robot arm guidance of the CyberKnife. The CyberKnife therapy delivers a sequence of many hundreds of gamma beams to the cancerous tumor from many different directions. GammaKnife therapy delivers gamma radiation to the cancerous tumor simultaneously in a single dose.[148,149]

Interventional Neuroradiology. Interventional neuroradiology (INR) is the diagnosis and treatment of CNS diseases endovascularly to deliver therapeutic medications or devices. INR was first used in the early 1980s, when digital subtraction angiography was developed. Digital subtraction angiography first uses an original angiograph of the blood vessels to be studied. Then a contrast medium is injected into the same blood vessels, and opaque structures such as bone and tissues can be digitally subtracted or removed from the angiographic image, leaving a clear picture of the blood vessels.[150]

Improvements in vascular access techniques, new thin and flexible catheters and guidewires, and the development of innovative coils and therapeutic medications have made new treatments possible. Conditions that once required extensive surgery, with accompanying patient morbidity and mortality, can now be performed less invasively.[146,150] Some major procedures performed with INR are mechanical or chemical removal of emboli or thrombi that cause stroke, the physical occlusion of malformed vascular structures such as arteriovenous malformations with chemicals or flow-directed balloons, dilation of stenotic blood

BOX **52-20**

Some Indications for Radiologic and Diagnostic Procedures

Computed Tomography
- Assessment of the airway with neck or thoracic tumors
- Assessment of bony trauma, especially the spine
- Assessment of head trauma
- Assessment of increased intracranial pressure
- Assessment of neoplasms
- Imaging of brain tumors
- Imaging of intracerebral hemorrhage

Magnetic Resonance Imaging
- Central nervous system imaging
- Imaging of the blood-brain barrier
- Kidney imaging
- Liver imaging
- Urinary bladder imaging

Interventional Radiology (Vascular and Nonvascular), Radiotherapy, and Radiosurgery
- Angiography
- Catheterization of ducts, and vascular lesions for drainage of cysts or hemangiomas (e.g., liver hydatid cyst, renal cyst, soft-tissue hemangiomas)
- Catheterization of tumors for delivery of chemotherapy directly to tumors (e.g., liver tumors)
- Embolization or embolectomy or thrombofragmentation of vascular lesions and tumors (pulmonary thrombi or emboli)
- Radiosurgery
- Stereotactic radiosurgery
- Radiotherapy
- Transluminal dilation, angioplasty, and stent insertion for vascular stenosis, biliary stenosis, or tracheal malacia

Interventional Neuroradiology
- Angioplasty and stent placement for an atherosclerotic lesion
- Angioplasty or endovascular ablation of cerebral vasospasm from aneurysmal subarachnoid hematoma
- Balloon angioplasty of cerebral vasospasm
- Brain arteriovenous malformation embolization
- Carotid artery stenting
- Carotid cavernous fistula and vertebral fistula treatment
- Carotid test occlusion
- Dural arteriovenous malformation embolization
- Embolization of highly vascularized intracranial tumors
- Glomus tumor treatment
- Intracranial aneurysm ablation
- Juvenile nasopharyngeal angiofibroma treatment
- Meningioma treatment
- Sclerotherapy of venous angiomas
- Spinal cord lesion embolization
- Therapeutic carotid occlusion
- Thrombolysis of acute thromboembolic stroke
- Trigeminal nerve rhizotomy or glycerol injection
- Vein of Galen malformation treatment
- Vertebroplasty for back pain/vertebral body fractures

vessels, and embolization (blocking blood flow) of cerebral vascular aneurysms using catheter-deployed coils.[146,150,151]

Box 52-20 lists some current uses for each of the previously mentioned radiologic and diagnostic procedures. As technology advances, more uses will be seen.

Anesthetic Considerations

Computed Tomography. CT scans require that the patient remain as motionless as possible for several minutes to an hour. Patient motion can produce artifacts in the diagnostic images to be read by the radiologist. Patients must lie on a flat, lightly padded wheeled platform, which is rolled into the short-bore scanning gantry of the CT scanner. Although the majority of patients are able to cooperate and tolerate CT, others may not be able because of extremes in age, concurrent medical conditions, or mental disability. The CT scan is neither physically invasive nor painful. Patients enter the CT scanner without precautions for ferromagnetic objects as for an MRI scan. CT is more rapidly performed than an MRI scan, especially if a spiral CT scanner is used.

The patient may require anesthesia anywhere along the continuum from minimal sedation to general anesthesia. Use of ferromagnetic anesthesia equipment and supplies around the CT scanner is not a concern. A standard anesthesia machine, laryngoscope and blades, and intravenous infusion pumps can be used as if in the operating room. An LMA is an appropriate alternative choice as a minimally invasive and secure airway in the patient without contraindications to its use. An LMA is contraindicated in patients with gastroesophageal reflux disease or a full stomach. Attention must be paid to securing the airway, and the anesthesia breathing circuit, the leads for the ECG, the noninvasive blood pressure cuff, the intravenous line, and the pulse oximeter must extend into the scanning gantry. The anesthetist must allow for extra lengths of anesthesia circuitry and electrical monitoring leads because of patient movement that will occur during intermittent repositioning of the mechanized table that positions the patient within the scanning gantry.[121,141]

Sedation can be performed with a variety of agents, including midazolam, pentobarbital, diazepam, or propofol. General anesthesia can be performed with TIVA, such as with intravenous propofol, or with potent inhaled agents.

All personnel must be aware of the use of ionizing radiation during the CT scan and should take precautions to be shielded from any exposure to the radiation. Radiation exposure is cumulative over a lifetime, and every precaution must be made to protect oneself from any unnecessary doses of radiation, which can cause genetic mutation and may lead to cancer. Protection can be accomplished with the use of a lead-glass barrier, a lead apron, a lead thyroid collar, and lead-glass safety glasses. Radiation dose badges are available that attach to clothing. The badge monitors the dose of radiation received and is evaluated monthly.[141] Federal technical information and guidelines for working in conjunction with radiation is available from the U.S. Environmental Protection Agency.[152]

ICM can cause an unexpected allergic reaction in some patients, varying from itching with hives to severe, life-threatening anaphylactoid and anaphylactic reactions.[144,153] Adverse reactions to ICM are more likely to develop in patients with asthma, a history of allergy or in patients with multiple morbidities. These reactions can be divided into renal or general, and subdivided into acute and delayed. Fatal reactions are rare. Contrast-media–induced renal impairment can be reduced with the use of low-osmolality contrast media and extracellular volume expansion.[154] ICM also can cause local tissue sloughing and necrosis if the ICM extravasates from the vein into the surrounding tissue.[153,154] Clinicians should be familiar with treatment protocols to minimize patient morbidity (Box 52-21).

ICM is typically a water-soluble, iodine-containing solution of two available types: media that can dissociate into ions in solution and media that will remain in a neutral state in solution. ICM is also formulated as high-osmolar contrast media (HOCM), which

BOX **52-21**

Considerations and Treatment Protocols for Preventing Intravenous Contrast Medium Extravasation

Considerations

- Use intravenous catheters (as opposed to metal needles or butterfly needles).
- Avoid use of the same vein if the first attempt at intravenous catheterization was missed.
- Ensure the intravenous catheter is patent and is free flowing.

Treatments

- Attempt to aspirate as much ICM as possible.
- Elevate the affected limb.
- Apply ice packs for 20 to 60 minutes until swelling resolves.
- A heating pad may be necessary in place of ice for swelling.
- Observe the patient for possible tissue damage related to continual contact with ice or heat.
- Observe the patient for 2 to 4 hours before discharge; consider medical/surgical consultation if necessary.
- Follow up with patient assessing for residual pain, increased or decreased temperature, hardness, change in sensation, redness, or blistering.

Modified from American College of Radiology. Extravasation of contrast media. In: *Manual on Contrast Media*. vol. 7. 2010. Accessed December 1, 2011, at American College of Radiology website http://www.acr.org/SecondaryMainMenuCategories/quality_Safety/contrast_manual/Extravasation.aspx.; Doughtery L. Extravasation: prevention, recognition and management. *Nursing Standard*. 2010;24:48-55.
ICM, Intravenous contrast medium.

contain few dissolved particles and iodine atoms, and low-osmolar contrast media (LOCM), which contain greater numbers of dissolved particles with iodine. An HOCM solution causes fluid shift from the cell to the vein with the ICM, whereas an LOCM solution is closely iso-osmolar, inducing less fluid shift from the cell. Nonionized LOCM is a more costly contrast medium for the patient. Some advocate that it should be the only contrast medium used for CT with dye studies.[144,153,154]

Reactions are possible with either type of ICM solution, although fewer reactions occur with LOCM.[153-154] Some reactions may present anywhere from a half hour to a week after the administration of the ICM. Reactions to ICM are theorized to be caused by the ICM molecule's serving as an antigen and affixing itself to either mast cells or basophils. This causes release of mediators such as histamine and tryptase, which can inhibit coagulation, dilate blood vessels, release complement, or even stimulate an IgE-modulated immune reaction.[144,153,154]

A new ICM using gold nanoparticles is available and undergoing tests prior to use in humans. It has many advantages over iodinated ICM, such as higher radiation absorption, yielding better images with lower x-ray dose, low allergenic response, and longer imaging times due to its nanoparticle size.[155,156]

A thorough preanesthetic assessment for a patient about to undergo CT should include questions pertaining to asthma, allergies, and any previous reactions to any contrast media. Diabetic patients taking metformin must withhold the medication due to the risk of lactic acidosis. This problem is mainly observed in patients with diabetic nephropathy. Other patients at risk for reactions to ICM are patients with multiple medical problems, especially those with cardiac disease or with preexisting azotemia, patients of advanced age, and patients being treated with nephrotoxic agents such as the aminoglycoside antimicrobials gentamicin, tobramycin, streptomycin, amikacin, kanamycin, and neomycin or nonsteroidal antiinflammatory agents. ICM is contraindicated in pregnant patients.[144,153]

Clinicians may use preventive measures in patients who may be at risk for a reaction to ICM. The radiologist should use the smallest amount of contrast agent necessary. To safeguard against the possibility of renal failure, the patient should be adequately hydrated beginning 1 hour before the procedure and continuing for another 24 hours. Patients who are at risk for possible anaphylactoid reactions should be pretreated with corticosteroids such as methylprednisolone or prednisone administered by mouth or intravenously. In cases of moderate or severe previous ICM reactions, a histamine-1 (H_1) blocker such as diphenhydramine and an H_2-blocker such as cimetidine or ranitidine should be given together either intravenously or by mouth.[144,153,154]

ICM is probably the most frequently used agent that causes anaphylactoid reactions. Anaphylaxis recognition and treatment are outlined in Chapter 41 As little as 1 mL of ICM can initiate these reactions.[144,153,154]

Magnetic Resonance Imaging. MRI can take up to an hour or longer. During this time, the patient must remain extremely still to reduce motion artifacts. These artifacts can cause unfaithful representations of the tissues being studied. The motions of breathing, the heart, blood flow, swallowing, and even cerebral spinal fluid flow produce artifacts in a highly sensitive MRI scan.

Patients must remain within the bore of the magnet for an MRI scan for longer periods of time than for a CT scan. During this time, the MRI suite's ambient temperature is cold.

The patient is exposed to varying magnetic fields of up to 4 T, along with additional exposure to variable radiofrequency radiation. Blood flow is decreased by strong magnetic fields, and blood pressure compensates by rising. Patients also have reported symptoms of vertigo, nausea, headache, and visual sensations.[140,143]

The MRI machine produces loud vibratory and knocking noises as coils are switched on and off during the course of the study. The size of the MRI magnet bore may preclude the morbidly obese or claustrophobic patient from MRI scanning, although a more open-bore MRI is available. Most patients are content with an explanation of what to expect during the procedure and with reassurance. Some patients need minimal or moderate sedation. Patients with claustrophobia or those who cannot or will not remain motionless during the study, as well as critically ill patients, may require deep sedation or general endotracheal anesthesia.[140,142,143,145] MRI is not painful, so opioids are not usually required. Sedation has been performed with oral and intravenous midazolam, ketamine, pentobarbital, or propofol.[140-143,145] Minimal sedation requires full monitoring. Deep sedation or general anesthesia requires intravenous access and full monitoring. The LMA has served as an excellent, relatively noninvasive airway for MRI. Some anesthesia providers prefer general endotracheal intubation. Children who cannot or will not cooperate experience better MRI scans with general endotracheal anesthesia in shorter periods of time, despite longer recovery times, when compared with sedation.[35,45]

Because of the intense magnetic field always present in the MRI suite, anesthesia providers must be aware of every item on their persons and every item that is to be used in conjunction with anesthesia administered to the patient. Ferromagnetic (iron-containing) substances are attracted at astonishing rates of speed into the bore of the magnet. Personal items such as pens, certain types of eyeglasses, jewelry, watches, pagers, personal computers, calculators, name badges, coins, audiotapes, videotapes, and credit cards are some of the items that should never enter the MRI suite, as well as any ferromagnetic anesthesia equipment, medication

BOX 52-22

Potentially Harmful Items When in Proximity to MRI

- Automatic implantable cardiac defibrillators (AICD)
- Cardiac pacemakers
- Certain mechanical heart valves
- Cochlear implants
- Deep brain neurostimulators
- Dorsal column stimulators
- Pacing wires
- Penile implants
- Permanent eyeliner or tattoos
- Prostheses (including dental prostheses)
- Implanted pumps (such as baclofen, narcotic, or insulin pumps)
- Internal plates, wires, or screws
- Metallic aneurysm clips (clips manufactured after 1995 and certified MRI compatible can be scanned)
- Certain metallic implants (history of recent orthopedic implants inserted within 3 months, dental implants)
- Metallic sutures
- Shrapnel and metal fragments (especially intraocular metal shrapnel)
- Tissue expanders with metallic ports

MRI, Magnetic resonance imaging.

BOX 52-23

List of Available MRI-Compatible Equipment and Supplies

- MRI-compatible anesthesia machine
- Pulse oximeter
- Intravenous bag pole
- Liquid crystal temperature monitoring strip
- Thermocouple temperature probe with radiofrequency (RF) filter
- Respiratory rate monitor
- Noninvasive blood pressure monitor
- Pulse oximeter
- Electrocardiograph
- Electrocardiograph patches
- Electrocardiograph cable
- Capnograph
- Laryngoscope with lithium batteries and aluminum spacers
- Laryngoscope blades
- Nerve stimulator
- Intravenous infusion pump
- Oxygen tanks
- Precordial stethoscope
- Esophageal stethoscope
- Patient carts
- Tables and trays

MRI, Magnetic resonance imaging.

vials, and supplies. If a patient were present within the bore of the MRI, injury or death could be possible from the missile created. As newer and more powerful 3-T MRI scanners become more prevalent, previously "safe" items could cause injury. Metals known to be safe within the proximity of the MRI bore are stainless steel, nonferrous alloys, nickel, and titanium. Materials and equipment constructed of plastic are safe.[121,141,143]

Patients possessing certain medical therapeutic devices may be prohibited from an MRI scan. MRI lists devices or metal that patients may possess that could be affected by the MRI and cause patient morbidity or mortality (Box 52-22).[141,142-145] Further investigation by the anesthetist in concert with the radiologist or MRI technician regarding the metal content and MRI compatibility of these metal items is necessary.

Cardiac pacemakers may be effected several ways by the electromagnetic field: reprogramming may occur, the pacemaker may be inhibited, it may revert to an asynchronous mode, the reed switch may close, the pacemaker may become dislodged, or it may become heated by the magnetic field.[140,142-143,145]

Manufacturers have developed a host of MRI-compatible anesthesia equipment and supplies (Box 52-23). This host of equipment and supplies allows performance of the anesthetic procedure directly within the MRI suite. Be aware that some equipment designated by the manufacturer as MRI compatible may not be compatible as magnet strengths increase.[145]

Facilities that cannot afford MRI-compatible equipment and supplies can provide anesthetic services to their patients by inducing anesthesia outside the MRI suite. The patient is placed on an MRI-compatible cart or a detachable MRI scanning table that fits within the bore of the electromagnet, where anesthesia may be then induced. With the aid of extra-long circuits, extension intravenous tubing, and properly insulated monitor cables, the anesthesia can be maintained with full monitors and a standard anesthetic machine outside the MRI suite. The patient is then carefully moved on a flat, relatively hard, wheeled platform into the bore of the electromagnet. Attention should be paid to isolate any monitor leads or intravenous tubing from touching the skin of the patient. Any monitor leads and intravenous tubing should be kept in straight alignment, because the intense magnetic fields in the MRI suite can induce current flow in coiled leads or tubing, and severely burn the patient.[145] Flexible LMAs and endotracheal tubes that contain wire windings also can be sources of burns. The American College of Radiology recommends strong attention to and the elimination of induced current, which can be large tissue loops, such as the loop created by the hand touching the hip or thigh, or the loop created when the feet or calves of the legs touch.[145]

Consideration must be given to the MRI contrast media administered to patients. Fortunately, the dyes used for MRI contrast are nonionic gadolinium chelates and have extremely low allergy rates.[144,153-154] Nausea is a common side effect. Urticaria (hives) and anaphylactoid reactions occur in less than 1% of patients.[154] The risk of a reaction to MRI dye is increased in patients with a history of asthma or other allergies or drug sensitivities, especially to iodinated contrast dyes.[153,154] Proper equipment, medications, and supplies must be immediately available for management of a reaction if one occurs. Treatments for anaphylactoid and anaphylactic reactions are discussed in Chapter 41.

Although MRI does not use ionizing radiation, patients and personnel are exposed to constant levels of magnetic force while in the MRI suite. Acute exposure to magnetic fields under 2.5 T have not been shown to have adverse effects in humans. All care providers must make their own determinations regarding how much magnetic exposure they will accept during a patient's MRI scan. Doses both to the patient and to all personnel should be minimized.[141,145] Pregnant anesthesia personnel have no restrictions on presence in the MRI scanner room during all of the required anesthesia preparations necessary to treat the patient, but the American College of Radiology recommends that personnel not be present in the MRI scanner room during the scan. Pregnant patients should discuss risks and benefits with their physician.[145]

If the anesthesia provider is away from the patient during the procedure, it should be ensured that all airway circuitry, monitoring leads, and intravenous connections are secure and tight. A respiratory monitoring apparatus (RMA) built into the anesthesia circuit reservoir bag will soon be available to monitor respiration with both visual and audible signals pertaining to movement of the RMA relative to the patient's respiratory rate and tidal volume.

When the environment could pose physical danger, anesthetists must be cognizant of their own safety and physical well-being while administering anesthesia for patients, especially during repeated exposures of radiation and/or chemicals. Therefore, a means for remote observation and monitoring either via a clear window, a camera, or telemetry must be available, although controversies regarding the traditional standards of physical presence during the conduct of anesthesia exist.[141,145] In conjunction with recognized standards of safety, the anesthetist must use monitors with both audible and visual alarms and have clear and continual view of the patient and the anesthesia monitors. Consideration must be made for safe and rapid access to the patient should the need exist.[141,143,145]

The functional MRI (fMRI) is a tool used to better differentiate residual pathologic tissue from normal healthy tissue to perform higher-quality tumor resection. An fMRI scan requires the patient to remain motionless and cooperative to avoid artifact. It is known that anesthetic agents can alter cerebral blood flow and cerebral oxygen metabolism, which can affect the interpretation of the fMRI scan. Therefore fMRI use for uncooperative or pediatric patients may preclude its use in this cohort of patients. Anesthesia research will provide the anesthetist tools to enable this population to receive both an anesthetic and needed fMRI.[143,145]

Positron Emission Tomography (PET) Scan. Positron emission tomography (PET) scan is used for the imaging and detection of malignant disease, neurologic function, and cardiovascular disease. The isotope fluorodeoxyglucose (FDG) is injected and is then absorbed into metabolically active cells. The absorbed isotope emits minute amounts of positron antimatter, which are detected and produce high-resolution images of diseased tissue. The patient must remain still for about an hour after the injection of FDG to minimize the amount of the muscle uptake of this glucose-like molecule. The patient must have fasted to minimize blood glucose levels. Any sedation medications containing sugar should also be avoided.[157-159]

Interventional Radiology (Vascular and Nonvascular), Radiotherapy, Stereotactic Radiosurgery, Interventional Neuroradiology. As skills, techniques, and technology progress, more procedures will be performed with radiation or under radiologic guidance.[146] These procedures all require the absolute immobility of the patient, with periods of controlled apnea, which assist in the viewing or treatment of the targeted area of the patient, especially during whole-body therapeutic radiation treatment.[146,148-150] These procedures are also time consuming, taking up to several hours to complete. Procedures may be necessary in patients of various age groups from infants to geriatrics and in all states of health.[150,151] A thorough preanesthetic assessment is imperative.

With the exceptions of angiography or radiotherapy, procedures for IR are painful, are physically invasive to the patient, and may need to be accomplished over several treatment sessions. Treatment may be required electively or urgently.[146] Patients may require anesthesia along the continuum from minimal or moderate sedation/analgesia, local or regional anesthesia, with the trend moving toward general anesthesia because of the superior image quality obtained in a motionless patient, especially if the patient is held apneic for a brief period of time by the anesthestist.[146,147,151] Full monitors and intravenous access are required. Additional catheterization and monitoring of arterial pressure and central venous pressure may be necessary.[150,151] Certain procedures require monitoring of the patient's neurophysiologic status for changes. The patient also may need to be assessed awake and then resedated at times during the procedure.[150] Anesthetics that can be used are midazolam, propofol, ketamine, isoflurane, and the other potent inhaled general anesthetics.[146,149,151] Dexmedetomidine, a selective α_2-adrenoreceptor agonist is also being explored for its reduction of intraprocedure and postprocedure anesthetic requirments.[150] To assess and monitor the patient's neurologic functioning, rapid recovery from anesthesia at the end of the case is ideal.[150]

It may be necessary to manipulate or manage normal systemic blood flow, normal cerebral blood flow, or other regional blood flow. The anesthetist may be called on to control deliberate hypertension or deliberate hypotension, manage anticoagulation, and manage unexpected procedural complications.[148-150]

Intraoperative radiation therapy (IORT) is the delivery of radiation to the patient via a linear accelerator, at times in conjunction with tumor surgery. If surgery is performed coincidental to the dose of radiation, normal tissues may be able to be moved away from the ionizing radiation beam. Normal tissues and organs can be shielded with lead beforehand. Some facilities use a dedicated IORT suite, whereas others use an operating room with transport of the patient to the radiation oncology suite. General anesthesia is performed if the surgical and radiation procedures are concurrent. All personnel must leave the room during IORT and stereotactically guided GammaKnife or CyberKnife surgery so that high-dose radiation can be delivered to the patient while personnel are protected from the scattered radiation. The radiation oncology suite is heavily shielded and has a lead or iron door that can take from 30 to 60 seconds to open. The patient is monitored via closed-circuit video and hands-off anesthesia delivery during treatment.[149]

Complications can occur rapidly and be life threatening. Foremost is the possible complication of hemorrhage. A sedated patient experiencing hemorrhage may show sudden signs of headache, nausea and vomiting, and vascular pain. A patient under general anesthesia may experience sudden bradycardia. The airway must be secured first if necessary, followed by support of the cardiovascular system, discontinuation of heparin, and administration of protamine (1 mg/100 units of total heparin dose administered). Other possible complications are radiocontrast reactions, embolization of particles or tissue, perforation of an aneurysm, and obliteration of unintended physiologically necessary arteries. Patient safety necessitates skilled and competent staff assistance in treatment of complications. Complications may necessitate the safe transfer of the patient to the operating room.[148-150]

Postanesthesia Care

Physiologic stability is the goal in any patient undergoing a radiologic or diagnostic procedure. The patient must be observed for possible reactions to dyes administered by the radiologist. The patient must be relieved of pain. Cardiovascular status must be stable. Hospital admission may be necessary for observation after any complication experienced by the patient or suspected to have occurred. One should always err on the side of patient safety and patient welfare.

REMOTE ANESTHETIC MONITORING USING TELECOMMUNICATIONS TECHNOLOGY

Communications technology in conjunction with reliable and accurate electronic monitoring (telemonitoring) have made it possible to perform anesthetic monitoring with the anesthetist

in one location and the therapeutic or diagnostic procedure in another physically remote, geographically isolated, or environmentally extreme environment.

The anesthetist may be involved with communication and monitoring involving land-line telephone, cellular telephone, wireless walkie-talkies, amateur (ham) radio communications, satellite communications, real-time audio and video, computer/monitor interlinks, the internet, and videoconferencing software.

The purposes of telemonitoring are the benefits to patients requiring therapeutic or diagnostic procedures with the added safety of available expert care to assist the anesthetist in performing anesthesia in a challenging environment. Anesthetists can collaborate and use their combined skills during the entire anesthetic procedure—from preoperative planning to postprocedure care and eventual discharge. Telemonitoring also provides a tool for mentoring and teaching.

SUMMARY

New procedures and patient treatments are evolving and moving out of the traditional operating room. This demands evolution of anesthesia providers, equipment, and techniques for the provision of anesthesia services to patients in need of such service. Although anesthesia providers are required to be flexible in order to adapt to these dynamic changes in the healthcare world, this should never be at the cost of patient safety. The same standards that apply in the operating room setting should always be adhered to outside of the operating suite. Clinicians must be absolutely comfortable that all required equipment, medications, and supplies are available, as would be true in a typical, fully equipped operating room. It is easier and safer to prepare beforehand than to gather the items needed for safe anesthesia delivery later or go without them. Where cases of "minor" surgery or patient intervention may exist, cases of "minor" anesthesia do not.

Anesthesia Complications

M. Roseann Diehl and Kay K. Sanders

CHAPTER 53

Every day healthcare professionals practice within enormously complex environments; unexpected patient outcomes or complications can occur at any time. Public interest regarding patient safety has increased significantly over the past decade, largely as a result of the staggering number of preventable deaths cited in the Institute of Medicine's (IOM) 1999 landmark report.[1] The results of this report led to implementation of a broad range of improvement efforts concentrating on the prevention and detection of errors in health care. Complications can arise as consequences of another concurrent disease or of mishap. Often these complications appear unexpectedly, and they have been experienced by well-intentioned healthcare professionals who are surrounded by complex clinical conditions, poorly designed processes, and suboptimal communication patterns.[2,3]

This chapter is more than a simple compilation and review of various types of anesthetic complications. Our goal is to provide more insight into common and emerging types of anesthetic complications and to introduce organizational concepts that often surround complications in anesthesia. We discuss how to deal with complications systematically and examine the underlying human factors and lapses in communication involved in the development of critical incidents.

MORTALITY IN ANESTHESIA

Risks related to anesthesia have declined over the past several decades; however, the exact cause of this decline is unclear.[4] Anesthesia has had a 10-fold decrease in mortality since the 1980s and is often cited as reaching a six-sigma defect rate (99.99966% of end-products are statistically free of defects or 3.4 defects per million).[4,5] Outcome measures studied related to the risk of anesthesia include mortality, morbidity, patient satisfaction, and quality of life.[6] Perioperative risk related to anesthesia is multifactorial and depends on several interactions between the anesthesia, surgical procedure, and patient health. Increased safety measures (e.g., use of pulse oximetry) would be expected to improve outcomes, but no randomized controlled trials have been able to document such a conclusion.[7]

It is difficult to use mortality data to extrapolate conclusions about the safety of anesthesia, because no standard definition of what anesthesia mortality really is has been established. In addition, significant morbidity involving patients who do not die has not been considered in regard to safety. Some perioperative mortality data mainly include perioperative death to which human error has contributed versus all causes of death during or after anesthesia.[4,8] Secondly, there is a lack of consensus related to the period of time after anesthesia that should define anesthesia-related mortality. Depending on which studies are referenced, this time frame can vary from 24 hours to 30 days after anesthesia.

Another issue that clouds outcome data related to morbidity and mortality is that older patients with multi-morbidities are now considered operable as a result of improved technology (e.g., less invasive procedures) resulting in higher perioperative surgical and anesthetic risk.[7] Actual data are difficult to analyze because most studies use coroner's registries, voluntary reports, surveys, and malpractice claims as primary data sources for perioperative death. As a result, prevalence data available for anesthesia-related mortality are approximate estimates as documented in Table 53-1.

Death attributable to anesthesia is rare.[9] Anesthesia has evolved significantly regarding drug efficacy, equipment safety, and operative/procedural setting. Over 60% of surgical procedures are now performed in an ambulatory setting. Procedures associated with greater perioperative risk are increasingly being performed on an outpatient basis, and the use of regional techniques has increased.[10] Emerging claim areas in which an increase has occurred over the years include regional anesthesia (16% of all claims), chronic pain management (18% of all claims), and acute pain (9% of all claims).[6] By contrast, claims related specifically to surgical anesthesia have declined from 80% during the 1980s to 65% as compared with all anesthesia malpractice claims since 2000.[6]

The American Society of Anesthesiologists (ASA) classifies the patient's physical status related to incidence of mortality on a scale of 1 to 5 based on comorbid conditions, 1 being the healthiest individual with no comorbidities and 5 being the individual that will likely die if surgery is not performed within 24 hours. The most current incidence of anesthesia mortality in a patient with an ASA physical status of 1 is 0.04 per 10,000 (0.0004%) anesthetics. Patients with comorbid conditions have higher risk. For example, an ASA physical status 2 risk is 0.5 per 10,000 (0.005%) anesthetics, an ASA physical status 3 risk is 2.7 per 10,000 (0.027%) anesthetics, and an ASA physical status 4 risk is 5.5 per 10,000 (0.055%) anesthetics.[9] Death still remains the leading outcome in the ASA Closed Claims Project Database representing 26% of the most common complications from 1990 to 2007. The most common events leading to injury in anesthesia claims included regional blocks (20% of claims), respiratory (17% of claims), cardiovascular events (13% of claims), and equipment problems (10% of claims)[6,8] (Box 53-1).

MORBIDITY IN ANESTHESIA

The term *morbidity* is indicative of disease, incorporating any complication, excluding death occurring during the perioperative period (Box 53-2). The incidence of adverse outcomes with minor morbidity is quite high (18%-22%). For example, hoarseness has been cited to occur in 14% to 50% of patients and may accompany a traumatic lesion in the larynx or hypopharyx in 6.3% of patients. Drug errors (0.1%), equipment malfunction (0.23%), postoperative nausea and vomiting (PONV) (10%-79%), accidental dural perforation (0.5-0.6%) are all fairly common anesthesia-related morbidities. Therefore, if morbidity is included in the definition of harm caused by anesthesia and linked to anesthesia safety within the framework of six sigma, then anesthesia remains far from being 99.99966% free of defects (Figure 53-1).[4]

Anesthesia risk remains even today in several areas including perioperative airway control during general anesthesia, perioperative management of hemorrhage, and circulatory perturbations associated with regional anesthesia. Human error contribution to morbidity is a significant concern identified in 51% to 77% of anesthesia-related deaths.[4,9] It is difficult to quantify human error related to morbidity, and more research should be conducted in this area.

TABLE 53-1 Anesthesia-Related Deaths by Type of Complication (United States 1999-2005)

Type of Complication	Number of Deaths	%
Complications of anesthesia during pregnancy, labor, and puerperium	79	3.6
Cardiac complications	60	2.7
Overdose of anesthetics	1,030	46.6
Inhaled anesthetics	233	10.5
IV anesthetics	419	19.0
Other and unspecified general anesthetics	254	11.5
Local anesthetics	86	3.9
Unspecified anesthetics	38	1.7
Adverse effects of anesthetics in therapeutic use	940	42.5
Opioids and related analgesics	439	19.9
Benzodiazepines	42	1.9
Opioids and related analgesics	40	1.8
Local anesthetics	137	6.2
Unspecified anesthetic	257	11.6
Other complications of anesthesia	162	7.3
Malignant hyperthermia	22	1.0
Failed/difficult intubation	50	2.3
TOTAL	2,211	100.0

BOX 53-1

Complications of Anesthesia Identified by ASA Closed Claims Database

- Aspiration of gastric contents
- Failed intubation
- Esophageal intubation
- Other problems with the induction of general anesthesia
- Inadequate ventilation
- Airway obstruction
- Respiratory failure
- High spinal or massive epidural
- Neuraxial cardiac arrest
- Local anesthetic toxicity
- Drug reaction
- Anaphylaxis
- Overdose of sedatives
- Prolonged hypotension or hypertension
- Intraoperative cardiac arrest during anesthesia of undetermined etiology

From Metzner J, et al. Closed claims' analysis. *Best Pract Res Clin Anaesthesiol.* 2011;25:263-276.
ASA, American Society of Anesthetists.

Teamwork and communication represent another cause of adverse outcomes contributing to 43% to 65% of sentinel events occurring in the operating room (e.g., wrong side/site, transfusion error). Communication breakdown (oral 36%, written 20%) and absence of help (44% of failures) when needed also contribute to morbidity.[4]

Anesthetic complications are the seventh leading cause of pregnancy-related mortality in the United States, accounting for 1.6% of all pregnancy-related deaths. An 18-year retrospective study of maternal mortality was conducted in the state of Michigan, where all pregnancy-associated deaths within 1 year of the termination of pregnancy for any cause were reviewed. Eight anesthesia-related and seven anesthesia-contributing maternal deaths were cited, and the pattern of deaths illustrates three key points. First, all anesthesia-related deaths from airway obstruction or hypoventilation took place during emergence and recovery, not during induction of general anesthesia. Second, system errors contributed to the majority of deaths, for example, lapses in standard postoperative monitoring, missed diagnoses (e.g., cardiomyopathy, ischemic heart disease, sleep apnea). Third, obesity and African-American race are important risk factors for anesthesia-related maternal mortality.[11]

Future morbidity/mortality issues will likely include more acute and chronic pain issues, regional anesthesia, issues related to oversedation, and management of the difficult airway. Analysis of these rare events is imperative, and can improve practice and ultimately patient safety. According to the Anesthesia Patient Safety Foundation (APSF), anesthesia-related mortality does not directly reflect patient safety during anesthesia. No patient should be harmed during anesthesia, but when a critical event does occur resulting in morbidity, the incident should be explored together with anesthesia-related mortality in order to assess the true level of patient safety during anesthesia.[12]

PATIENT FACTORS AND POSTOPERATIVE MORTALITY IN PATIENTS OVER 70 YEARS

The population of older patients is growing in number, and increasingly these patients require surgery and anesthesia. Preventing, detecting, and managing morbidity and mortality is the greatest challenge facing anesthesia providers. Several large studies using worldwide databases have recently been published with an attempt to identify patient risk factors that could predict postoperative mortality. The most important resource available to date related to exploring complications and mortality after surgery is the National Surgical Quality Improvement Program (NSQIP) database in the United States. The NSQIP was established in the

BOX 53-2

Morbidity Classification

Minor morbidity: Moderate distress without prolonging hospital stay. No permanent complications (e.g., postoperative nausea and vomiting).
Intermediate morbidity: Serious distress prolonging hospital stay vor both. No permanent complications (e.g., dental injury).
Major morbidity: Permanent disability or complication (e.g., spinal cord injury; anoxic brain injury).

From Haller G, Laroche T, Clergue F. Morbidity in anaesthesia: today and tomorrow. *Best Pract Res Clin Anaesthesiol.* 2011;25(2):123-132.

early 1990s as part of the U.S. Veterans' Administration Health System and is now run by the American College of Surgeons, containing data on millions of surgical patients. The database has been associated with hundreds of publications centered on perioperative risk.[13]

One such study from the NSQIP database extracted data on 25,000 patients aged 80 years or more and 550,000 patients aged less than 80 years who had noncardiac surgery under general, spinal, or epidural anesthesia. In the cohort over 80 years of age, the top five variables associated with 30-day mortality were (1) ASA physical status, (2) preoperative plasma albumin concentration, (3) emergency surgery, (4) preoperative functional status, and (5) preoperative renal impairment.[13,14]

The Australian and New Zealand College of Anaesthetists (ANZCA) Trials Group recently published the REASON study (Research into Elderly patient Anaesthesia and Surgery Outcome Numbers), which was a prospective observational study of 4100 patients in 23 hospitals.[14,15] Patients 70 years and older undergoing noncardiac surgery and expected to stay at least one night in the hospital were included. The major findings of this study were that 1 in 20 patients (5%) died within 30 days of surgery, and one in 5 (20%) had at least one major complication within 5 days of surgery. Four preoperative factors emerged predicting postoperative mortality similar to the results of the NSQIP database study: age, ASA physical status, albumin, and those patients who had an accident and needed emergency surgery were at increased risk. A useful statistic from the REASON study is that patients aged 70 years who are an ASA physical status 1 or 2 have a 30-day mortality of 1% for inpatient surgery. Patients 80 to 89 years had an odds ratio for 30-day mortality of 2.1, meaning this age group was twice as likely to die as compared with healthy patients 10 years younger. Additionally, those patients who were 90 years of age had an odds ratio for 30-day mortality of 4.0 or were 4 times as likely to have postoperative mortality as compared with healthy patients in their 70s (Table 53-2). The most important postoperative complications were systemic inflammation, acute renal impairment, and unplanned critical care admission.[14,15]

The National Confidential Enquiry into Patient Outcome and Death database in the United Kingdom provides reports on aspects of patient care and safety. A 2010 report explored remedial factors in the processes of care of patients aged 80 years and older who died within 30 days of a surgical procedure. Out of 1120 patients, 85% had an ASA physical classification of 3 or 4, most having nonelective surgery. Only one third of these patients who died had acceptable perioperative care.[15] The authors concluded that the impact of comorbid conditions upon the frailty of a patient is underappreciated, and that increased vigilance in this patient population is warranted.

TABLE 53-2 Factors Associated with Increased 30-Day Mortality

Factors	Odds Ratio Compared with Healthy 70-Year-Old Patients
Age 80-89	2.1
Age 90	4.0
ASA 3	3.1
ASA 4	12.4
Plasma albumin <30 g/L	2.8
Emergent surgery	1.8
Thoracic surgery	2.6
Systemic inflammation	2.5
Acute renal impairment	3.3
Unplanned ICU admission	3.1

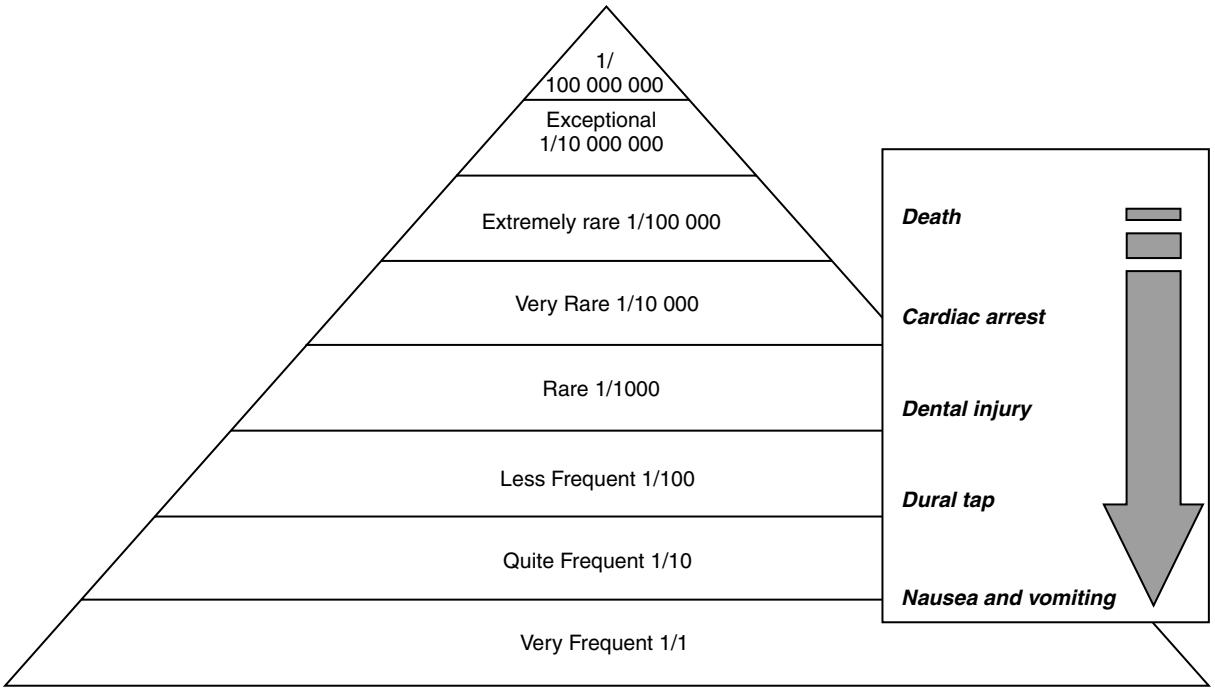

FIGURE 53-1 Anesthesia morbidity. (From Haller G, Laroche T, Clergue F. Morbidity in anaesthesia: today and tomorrow. *Best Pract Res Clin Anaesthesiol*. 2011;25[2]:123-132.)

Until recently the risk of surgery, with accompanying anesthesia, was viewed as the prime determinant of mortality. However, NSQIP data extracted from 8500 patients concluded that after accounting for age, ASA status, albumin, and emergency surgery complexity are important in about 5% of cases.[15] This reinforces the fact that surgery itself is safe, and patient factors are more important than operative procedure factors.

One emerging area in the care of older patients is the attempt to define and quantify frailty and risk of postoperative complications. Five domains of frailty have been described as depicted in Box 53-3. They include age, sex, comorbidities, physical status, and type of surgeries. Patients with 2 or 3 domains were considered to have intermediate frailty, and those having 4 to 5 domains were classified as frail. The odds ratio was 2.0 for postoperative complications in those who were considered to have intermediate frailty and 2.5 for frail patients.[16]

While age has often been the focus of perioperative concern, comorbidity, quantified with ASA physical status, is probably more important. Frailty is the new addition to this paradigm. Risk assessment should begin with patient factors that are more strongly associated with outcome than type of operation. Preoperative albumin should be measured regularly in patients over 70 years of age.

BOX 53-3

Domains of Frailty Measurements

1. Unintentional weight loss greater than 4 kg in the past year
2. Exhaustion measured by assessing effort and motivation
3. Decreased grip strength
4. Slowed walking speed
5. Low physical activity

From Makary MA, et al. Frailty as a predictor of surgical outcomes in older patients. *J American Coll Surg.* 2010;210(6):901-908.

POSTOPERATIVE COGNITIVE DYSFUNCTION

Postoperative cognitive changes after anesthesia have been reported in both the elderly for over a century and more recently in children displaying behavioral and developmental disorders after anesthesia.[17] It has been postulated that anesthetic agents can produce neurotoxic effects leading to postoperative neurologic, developmental, and behavioral complications. Postoperative cognitive problems can be categorized as postoperative cognitive dysfunction (POCD), delirium, dementia, confusion, learning, and memory problems.

Elderly Undergoing Noncardiac Surgery

The two most common postoperative cognitive disorders in the elderly are delirium and POCD and can be difficult to diagnose. A comparison of these two disorders can be found in Table 53-3. Delirium is defined as a disturbance of consciousness that is accompanied by a change in cognition that cannot be attributed to a preexisting psychological state. Presentation of postoperative delirium is variable, and patients may exhibit hyper or hypoactive cognitive or motor states. Postoperative delirium usually occurs during the first postoperative days as an acute, fluctuating loss of orientation and impairment of attention and memory. The incidence of delirium is approximately 20% in hospitalized elderly patients, and 80% in sedated intensive care unit (ICU) patients. Delirium is independently associated with increased hospital stay and mortality. Age and preexisting disease are important risk factors, in addition to medication side effects, electrolyte or fluid defects, and withdrawal symptoms.[17] Delirium research has focused on identification and treatment of risk factors prior to surgery. Factors associated with an increased postoperative delirium include advancing age, sensory deprivation (visual or hearing impairment), sleep deprivation, social isolation, physical restraint, use of bladder catheter, polypharmacy, psychoactive drugs, comorbidities, severe illness, cognitive impairment, hyper-/hypothermia, dehydration, malnutrition, and low serum albumin.[18]

TABLE 53-3 Characteristics of Postoperative Cognitive Problems in the Elderly

Postoperative Cognitive Problem	Onset	Symptoms	Anesthetic Issues
Delirium	Acute Hours/days	Decreased awareness of environment Fluctuating course Hyperactive state • Increased psychomotor activity • Rapid speech • Irritability • Restlessness • Disruptive to others Hypoactive state • Calm appearance • Inattention • Decreased mobility • Difficulty answering simple orientation questions • May be confused with depression/fatigue	Avoid polypharmacy and long-acting sedatives (e.g., benzodiazepines) Use propofol, paracetamol, opioids as needed Regional techniques better Schedule surgery early after injury or illness Early geriatric consultation Effective pain management
POCD	Weeks/months (usually not detectable during first days after surgery)	Affects wide variety of cognitive domains • Memory • Information processing • Executive function Difficult to manage job Impaired attention Normal consciousness	Recognize risk factors Anesthetic issues undefined

Adapted from Monk TG, Price CC. Postoperative cognitive disorders. *Curr Opin Crit Care.* 2011;17(4): 376-381; Björkelund KB, et al. Reducing delirium in elderly patients with hip fracture: a multifactorial intervention study. *Acta Anaesthesiol Scand.* 2010;54(6): 678-688.

Recent randomized controlled trials suggest that pain management and depth of general anesthesia are important modifiable factors for postoperative delirium after hip fracture surgery. Regional anesthesia with light propofol sedation compared with deep sedation was associated with a 50% decrease in postoperative delirium.[19] Another recent study reported a 35% reduction in postoperative delirium after hip arthroplasty using a multifactorial approach. Perioperative interventions consisted of supplemental oxygen, systolic blood pressure greater than 90 mmHg, transfusion for hemoglobin less than 10 g/dL, adequate pain relief, intravenous fluid supplementation, normothermia, avoidance of polypharmacy, spinal anesthesia, propofol sedation, and use of paracetamol as well as opioid as needed.[20] A Cochrane review concluded that regional anesthesia has a slight benefit over general anesthesia in reducing acute postoperative confusion after hip arthroplasty, but could not find a difference regarding mortality or other outcomes.[21]

POCD presents as a subtle deterioration of memory, concentration, and information processing distinct from delirium and dementia and is not a formal psychiatric diagnosis. Neuropsychologic testing is necessary for detection and must show that an individual has new onset of deficits in at least 2 areas of cognitive function lasting for a period of at least 2 weeks, and diagnosis is made when all other neurocognitive disorders can be ruled out. These diagnostic criteria make it impossible to accurately identify POCD during hospital stay, and symptoms can persist for weeks or months postoperatively.

One of the first large prospective studies describing postoperative cognitive decline after noncardiac surgery described an incidence of 25% at 1 week and 10% at 3 months after surgery. Advancing age was the only significant predictor for POCD at 3 months after surgery. Other similarly designed studies report POCD in up to 30% to 40% of adult patients of all ages at hospital discharge.[17]

General anesthesia has been implicated as the cause of postoperative cognitive problems. However, two large recent prospective studies demonstrated that type of anesthesia did not impact long-term cognitive outcome. A study comparing coronary angiography with light sedation, total hip arthroplasty with general anesthesia, and coronary artery bypass graft surgery under general anesthesia found a 16% to 17% incidence of POCD at 3 months in all three groups. Therefore, POCD may be independent of the type of anesthesia and surgical procedure.[22]

The concept of cerebral oxygen reserve offers one hypothesis regarding the significant differences in the degree of cognitive symptoms. Patients with preoperative vascular risk factors may be at greater risk for POCD. Several other etiologies have been proposed, including brain hypoxia caused by arterial hypoxemia or low flow, residual concentrations of general anesthetics such as benzodiazepines, or long-lasting effects of general anesthetics on cholinergic or glutaminergic neurotransmission, as well as psychological factors related to illness and environment during hospitalization.[17]

Elderly Undergoing Cardiac Surgery

The incidence of overall mortality after coronary artery bypass grafting has continued to decline; however, delirium and POCD remain a major concern in patients undergoing cardiac procedures, with an incidence ranging from 30% to 80%.[23] It has been assumed that the use of extracorporeal cardiopulmonary bypass was the primary culprit; however, large prospective randomized studies comparing on-pump versus off-pump bypass techniques have not shown any significant reduction in the incidence of postoperative neurologic injury.[24-26] The etiologic explanation could still involve the increased amount of atheromatous plaques and vascular disease in these patients, but this has yet to be clarified. Therefore, efforts to reduce incidence of postoperative neurologic injury have shifted focus towards patient risk factors (e.g., degree of aortic atherosclerosis, carotid arteries, and brain involvement).[23]

Pediatric Postoperative Cognitive Development Dysfunction

A great deal of concern has recently arisen regarding the safety of anesthesia in the pediatric population. Anesthetic agents have been implicated in pediatric developmental delays that have undergone prolonged procedures and/or multiple procedures (Figure 53-2).[27] A growing body of evidence in animals suggests that under certain circumstances, anesthetic drugs could adversely affect neurologic, cognitive, and social development of neonates and young children.[27,28]

Exposure to certain anesthetic agents during sensitive periods of brain development in animal studies has been postulated to result in widespread neuronal apoptosis and functional deficits later in development. So far *N*-methyl-D-aspartate (NMDA)

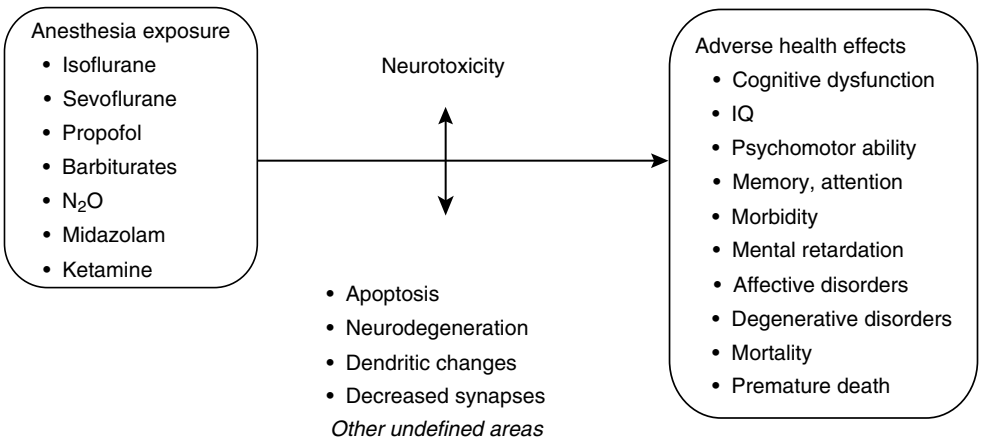

FIGURE **53-2** Conceptual framework for pediatric anesthetic neurotoxicity. (Adapted from Sun L, et al. Early childhood general anaesthesia exposure and neurocognitive development. *Br J Anaesth*. 2010; 105[suppl 1]:i61-i68.)

receptor antagonists and γ-aminobutyric acid (GABA) agonists have been implicated. However, no safe doses of these agents or safe duration of administration of these agents have been defined.[28,29] For example, 5-day-old non-human primates exposed to ketamine for either 9 or 24 hours experienced neuroapoptosis. A similar neurologic damaging effect was observed in the fetuses of pregnant rhesus monkeys (third trimester) exposed to ketamine for 24 hours. No effect was seen when ketamine exposure duration was 3 hours. Neuroapoptosis also has been demonstrated in primates given isoflurane on postnatal day 6.[28] The Food and Drug Administration (FDA) and others are currently conducting more studies to address the neurocognitive and neurobehavioral aspects of anesthetic-induced apoptosis.

Studies in children have attempted to assess effects of anesthetics on the developing human brain. A retrospective cohort analysis followed a birth cohort of 383 children who underwent inguinal hernia repair during the first 3 years of life and compared them with 5050 children in a control sample who had undergone no hernia repair before the age of 3 years. The children who underwent hernia repair were twice as likely as those who did not to have a developmental delay or behavioral disorder.[28] Another recent study retrospectively examined children (younger than 4 years) who were exposed to a single anesthetic (n = 449), two anesthetics (n = 100), or more (n = 44) related to the development of learning disabilities. No increased risk of learning disabilities was found with a single anesthetic. However, significant increased risk of learning disabilities was associated with two or more anesthetics and also increased with greater cumulative exposure to anesthesia.[29] It appears that windows of anesthetic vulnerability exist that are dependent on the exposure time, amount, and type of anesthesia. However, no definitive conclusions can be drawn on the basis of these nonrandomized studies in humans because of the substantial potential for confounding and bias. Interpretation is difficult due to the retrospective nature of the studies, lack of precise information in terms of age, agent, duration, and dose of anesthetics, specific agents used, variable outcome end-points used, and the method outcomes that were assessed.[27] Although withholding anesthesia in children who need surgery is unreasonable, obtaining more information about safe use is imperative. If anesthetic agents are found to affect the developing brain, strategies for mitigating and managing such risks can be implemented.[27-29]

CARDIOPULMONARY COMPLICATIONS

Intraoperative Cardiac Arrest

Currently, cardiac arrest during anesthesia is usually a concomitant and not a causative factor. Incidence of intraoperative cardiac arrest has been cited as 0.2 to 1.1 per 10,000 adults and 1.4 to 2.9 per 10,000 children.[30,31] Cardiac arrest during neuraxial anesthesia is less frequent compared with general anesthesia, with an incidence of 0.04 to 1.8 per 10,000 anesthetics. Etiologic factors can be grouped into categories: preoperative complications (65%), surgical procedures (24%), intraoperative pathologic events (9%), and those attributable to anesthetic management (2%).[31] Excessive surgical bleeding has been identified in 70% of surgical procedure-related deaths, and major causes of intraoperative pathologic events (e.g., myocardial ischemia, pulmonary embolism, and severe dysrhythmias). Fifty-percent of anesthetic management–related events were caused by airway or ventilatory problems, followed by medication errors and infusion/transfusion mishaps. Perioperative cardiac arrest is multifactorial in origin including factors such as patient comorbidities, inadequate risk estimation, inappropriate anesthetic management, and human error or misjudgment.[30,31]

Sudden Cardiac Arrest

Sudden cardiac arrest (SCA) is a leading cause of death in the United States, accounting for an estimated 325,000 deaths each year. Approximately 6 cases per 100,000 individuals have been reported.[32] Ninety-five percent of victims die before ever reaching emergency assistance. The most common underlying substrate of sudden cardiac arrest is ischemia and/or left ventricular dysfunction (Table 53-4).[33] Hypertrophic cardiomyopathy is the most common underlying cause of sudden cardiac death in young athletes.[32] However, there are also patients with preserved left ventricular function who are at risk for sudden cardiac arrest. Many of these individuals are walking around with long QT syndrome (LQTS).[34] Long QT syndrome has gained increased attention because of young athletes collapsing unexpectedly in sudden cardiac arrest. Long QT syndrome is an arrhythmogenic inherited or acquired cardiovascular disorder, with a prevalence of approximately 1 per 2500 to 10,000, causing sudden death as a result of episodes of syncope, seizures, and ventricular tachycardia. Only about 60% of patients are symptomatic at the time of diagnosis. Induction of general anesthesia has provoked LQTS without any prior clinical diagnosis or preoperative abnormal clinical findings.[35] Sudden sympathetic stimulation during intubation may be a cause or it could be QTc (interval corrected for heart rate) prolongation, as well as drugs that have positive adrenergic properties (e.g., ketamine, pancuronium). Careful anesthetic management should include treatment with beta-blockers preoperatively. Heart rate should be maintained below 130 beats/minute. It is recommended to avoid any pharmacologic agents that have the potential to further prolong the QT interval (Table 53-5).[36] Episodes of torsades de pointes may be short lived and self-terminating, but treatment with magnesium sulfate is considered the treatment of choice. Temporary pacing is also an effective method for controlling torsades de pointes (Figure 53-3).[35,37]

Perioperative episodes of sudden cardiac arrest in the pediatric population sparked the formation of the Pediatric Perioperative Cardiac Arrest Registry in 1994 to study the causes and outcomes from perioperative cardiac arrests in anesthetized children. Results from a recent examination of arrests from 1998 to 2004 indicate that cardiovascular causes of arrest accounted for the highest proportion of arrests (41%); among these the most common identifiable single cause was hypovolemia related to underestimation of blood loss and inadequate peripheral IV access (Figure 53-4).[38] Cardiac arrests due to medication errors were most common during the mid-1990s; this statistic has dropped significantly during more recent years. One explanation for this is a decline in the incidence of cardiac depression from decreased use of halothane.[38]

Myocardial Infarction

The Perioperative Ischemic Evaluation (POISE) trial data using surgical data from 56 countries suggests that perioperative myocardial infarction (MI) is the most common cardiovascular complication after noncardiac surgery, with an incidence of 5% in patients 45 years or older with cardiovascular risk factors.[39] Patients who suffer a perioperative MI have a 30-day mortality of between 11.6% and 21.6%.[40] Over 200 million noncardiac surgical procedures are performed annually worldwide, which equates to 10 million perioperative myocardial infarctions and more than 1.1 million deaths. This is a significant public burden considering that perioperative MIs are commonly undiagnosed and undertreated.[39]

TABLE 53-4 Causes of Sudden Cardiac Death

Underlying Heart Disease	Incidence	Description
Ischemic heart disease	Greater than 50% luminal narrowing Less than 20 yr, 0% 20-29 yr, 24% 30-40 yr, 58%	Atherosclerotic coronary artery disease, generally with normal cardiac function
Sudden arrhythmic death syndrome	Brugada syndrome 5:10,000 (0.05%) Long QT syndrome 1:2500 (0.04%) Short QT syndrome Catecholaminergic polymorphic VT 1: 10,000 (0.01%) Wolff-Parkinson-White syndrome 0.9%-3%	Brugada syndrome—hereditary channelopathy with right ventricular conduction delay and ST elevation in right precordial leads (dome or cove-like) associated with incomplete or complete right bundle-branch block and ultimately VF Long QT syndrome—channelopathy with QT interval (greater than 480 ms) Short QT syndrome—channelopathy with QT interval (less than 340 ms) Catecholaminergic polymorphic VT—genetically mediated, cardiac channelopathy induced by exercise or emotional stress with structurally normal hearts Wolff-Parkinson-White syndrome—preexcitation syndrome with an accessory pathway (Bundle of Kent) causing atrioventricular reentrant tachycardia and/or VF with structurally normal hearts; shortened PR, delta waves, and widened QRS may be present
Hypertrophic cardiomyopathy (HCM)	1:500 (0.2%) of general population 36% of all sudden cardiac deaths (additional 10% of cases have unexplained increase in cardiac mass not meeting full criteria for HCM	Inherited disease characterized by myocyte disarray, asymmetric hypertrophy of left ventricle (typically at the septum), occasional LV outflow tract obstruction, and predisposition for unstable ventricular arrhythmias
Arrhythmogenic right ventricular cardiomyopathy	1:5000 (0.02%) general population	Right ventricular wall-thinning and fibrofatty tissue infiltration
Congenital right ventricular cardiomyopathy	18% congenitally abnormal coronary arteries 12% anomalous coronary artery origins and hypoplastic anatomy	Also called *arrhythmogenic right ventricular dysplasia* (ARVD); rare form of cardiomyopathy in which the heart muscle of the right ventricle is replaced by fat and/or fibrous tissue
Commotio cordis	5% (nonspecific causes) 19.9% (athletic injury)	Blunt chest wall impact
Myocarditis	Less than 5%	Myocardial inflammation
Aortic disorder	3%-8%	Thoracic dissection/rupture

VT, Ventricular tachycardia; *VF*, ventricular fibrillation; *LV*, left ventricle.

Characteristics and short-term prognosis of perioperative MI have evolved over the past two decades. Fewer patients with nonoperative MI have ST-segment elevation, and more patients have non–ST segment elevation. Short-term mortality is decreasing. A large cohort study using POISE data extracted from over 8000 patients reported that most MIs occur within 48 hours of surgery (74.1%); 65.5% were asymptomatic.[40] Independent predictors of perioperative MI from this cohort are depicted in Table 53-6.

PULMONARY COMPLICATIONS

Perioperative pulmonary complications are common, often equal to or outnumbering cardiac events. There is no unifying definition of what constitutes a postoperative pulmonary complication (POPC). Commonly cited POPCs are listed in Box 53-4.[41] This discussion highlights the complications associated with manipulation and management of the airway.

Complications Associated with Supraglottic Devices

Airway mortality does not happen because of failure to intubate. Airway mortality occurs due to failure to ventilate. A major challenge for any evidence-based evaluation of airway management techniques is the extremely low incidence of severe adverse events directly attributed to inadequate ventilation.

Incidence of difficult mask ventilation has been cited to be 1.4% to 5%.[42-44] A recent study of 94,630 anesthetics reported impossible mask ventilation in 0.2% of patients, and within this group, 25% were also difficult to intubate.[44] Combined difficult mask ventilation and difficult intubation has been encountered 0.4% of the time. Finally, the incidence of cannot ventilate–cannot intubate is a very small, but devastating 0.008%.[42] Complications related to mask ventilation are underappreciated and underestimated and listed in Box 53-5.

Many airway devices exist today to assist with difficult or cannot ventilate and/or difficult to intubate situations. A considerable body of evidence (level 3b and 4) (Table 53-7),[46] over 300 publications (no greater than 3000), exists regarding successful use of the classic laryngeal mask airway (cLMA) in patients with difficult-to-manage airways. The intubating LMA also has been used successfully 97% to 100% of the time for ventilation in both the anticipated and unanticipated difficult airway.[47,48] Level 4 evidence of successful ventilation in patients with difficult airways has been described for many other supraglottic devices in a recent

TABLE 53-5 Pharmacologic Agents Known to Prolong the QT Interval

Type of Drug	Examples
Class 1a antidysrhythmic agents	quinidine disopyramide procainamide
Class 1c antidysrhythmic agents	flecainide
Class III antidysrhythmic agents	sotalol amiodarone
Butyrophenone antipsychotics	droperidol haloperidol
Phenothiazine antipsychotics	thioridazine
Atypical antipsychotics	pimozide quetiapine risperidone zotepine
Selective serotonin reuptake inhibitors	fluoxetine paroxetine sertraline
Macrolide antibiotics	erythromycin clarithromycin azithromycin
5-HT-1 agonists	zolmitriptan naratriptan
Antimalarial agents	halofantrine
Antihistamines	terfenadine
Prokinetic agents	cisapride
Anesthetic drugs	halothane isoflurane sevoflurane succinylcholine atropine glycopyrrolate

From Roden DM. Clinical practice: long QT syndrome. *N Engl J Med*. 2008;358(2):169-176.

review: LMA ProSeal, Supreme LMA, i-gel, Ambu Aura-i and Air-Q intubating laryngeal airways, Cobra perilaryngeal airway, CobraPLUS, and Laryngeal Tube.[47,48] However, even with current evidence of successful use of various supraglottic devices in difficult airways, there is still not enough evidence to judge one individual device superior.

As useful as these devices are, they are not without complications. The LMA has been associated with inadequate seal,

BOX 53-4

Commonly Cited Postoperative Pulmonary Complications

- Laryngospasm
- Bronchospasm
- Airway obstruction
- Desaturation
- Pneumonia
- Pulmonary embolism
- Aspiration pneumonia
- Reintubation/mechanical ventilation without identifiable cause
- Severe coughing
- Stridor
- Pleural effusion
- Pneumothorax
- Respiratory infection not otherwise specified
- Aspiration pneumonitis

From Johnson DC, Kaplan LJ. Perioperative pulmonary complications. *Curr Opin Crit Care*. 2011;17(4):362-369.

induced laryngospasm, and aspiration of gastric contents, to name a few. Failed placement has been documented to occur in 1% to 5%, although this decreases with operator experience.[45] Other supraglottic device complications tend to be similar to those found with the LMA and result from cuff overfilling, dislodgment, trauma during insertion, and insufficient anesthesia depth during insertion.[45]

Complications of Endotracheal Intubation

The phrase "cannot intubate" represents an infrequent, but serious challenge for the provider, but also represents an increased anesthetic risk to the patient. There is a close relationship between difficult intubation and traumatic intubation. Difficult intubation has been documented as a significant factor in 39% of all airway injury claims. Eight-seven percent of these were temporary, and 8% resulted in death. In 21% of claims, the standard of care was not performed.[45]Airway management plans when dealing with difficult airways must have backup plans that require the same level of thought as the primary airway plan. All airway plans can fail. Early recognition by the anesthesia provider that the current plan is not working and good communication throughout the procedure are both crucial. This may seem obvious, but unless all plans have been thought out, the clinical situation can quickly deteriorate. To date, fiberoptic intubation of the spontaneously breathing patient is the gold standard for elective intubation in the anticipated difficult airway.[49]

Video laryngoscopy has recently emerged as an alternative for anticipated difficult airway cases and has become widely available.[50] These devices may seem like a panacea for difficult airway management, but they have several limitations. Most devices are primarily designed for orotracheal intubation and require some mouth opening to allow the device to pass. Several case reports citing pharyngeal mucosal perforation and trauma while using the GlideScope have been published.[51-53] This complication could be minimized by increased vigilance and visual observation when passing the rigid stylet because there is a potential blind spot in the oropharynx when attention is focused on the GlideScope monitor. Care should be taken to cautiously pass the endotracheal tube and not use unnecessary force during insertion or a too-large laryngoscope blade.

Complications of endotracheal intubation encompass both hemodynamic pathophysiologic effects as well as associated anatomic injuries as depicted in Box 53-5. Fifty percent of dental trauma occurs during laryngoscopy; sore throat occurs as often as 40%, and occurs greater than 65% when blood is noted on airway instruments. Trauma to the larynx, although not as common, has been documented in 6.2% of cases; 4.5% of these developed hematomas of the vocal cords. Granulations of the laryngeal area can occur as a result of long-term intubation, and vocal cord paralysis can cause long-term hoarseness. Supraglottic complications induced by long-term intubation may be prevented by early tracheostomy.[45] For a more comprehensive list see Box 53-5.

INTRAOPERATIVE AWARENESS

Unintended awareness during the administration of anesthesia is a dreaded complication for the anesthesia provider and a significant source of fear for many patients. Awareness can occur during general anesthesia or monitored anesthesia care primarily as a result of underdosing of anesthesia relative to specific patient circumstances. An estimated 20,000 to 40,000 patients experience awareness during anesthesia annually in the United States alone, an incidence of approximately 0.1% to 0.4%.[54] The actual incidence of intraoperative awareness remains uncertain and likely is underestimated because of the limited nature of most postoperative interviews, which include the following: (1) no standardized or structured approach, and (2) single postoperative visitation by anesthesia personnel. As a result, many cases of awareness may not be elicited. The Brice Questionnaire developed in 1970 has been traditionally acknowledged as an accepted tool for detecting awareness postoperative and has been modified over the years in recent studies (Box 53-6). A multicenter study in the United States estimated an incidence of awareness under general anesthesia with explicit recall (specific recollection of events) of approximately 0.023%, slightly lower than other large studies (0.13%).[55,56] High-risk cases (e.g., trauma, obstetric, cardiovascular) possess 10 times the risk for awareness with an incidence of 1 case in 100.[57] See Table 53-8 for a list of risk factors for awareness.

Episodes of awareness occur most often during maintenance of anesthesia, less during induction, and least during emergence. Patient movement has been cited in about 1 out of every 7 awareness case reports, and development of tachycardia and hypertension occurs in about 1 out of every 5 episodes of awareness.[58]

BOX 53-5

Airway Management Complications

Mask Ventilation

- Mucosal, skin irritation, conjunctivitis due to cleansing agents
- Soft-tissue damage from excessive pressure
  - Corneal abrasion, retinal artery occlusion, blindness
  - Damage to mandibular branch of facial nerve causing transient facial nerve paralysis
  - Damage to mental nerves causing lower lip numbness
- Broken teeth, mucosal tears
- Worsening obstruction from malposition of tongue
- Subluxation of the temporomandibular joint
- Gastric distention increasing risk for aspiration
- Gastric rupture
- Subcutaneous emphysema

Laryngeal Mask Airway

- Folding of epiglottis tip causing labored breathing, coughing, laryngospasm, and obstruction
- Excess lubricant that causes coughing or laryngospasm
- Lack of protection from aspiration of gastric contents
- Laryngospasm, coughing
- Sore throat
- Increased intracuff pressures with prolonged procedures using nitrous oxide and carbon dioxide
- Dysarthria
- Edema of epiglottis, uvula, posterior pharyngeal wall
- Hypoglossal nerve paralysis
- Postobstruction pulmonary edema
- Tongue cyanosis

Endotracheal Intubation

- Damage to teeth
- Mucosal injuries
- Lip injuries
- Swelling tongue
- Sore throat
- Trauma to larynx/vocal cords
- Arytenoid dislocation/subluxation
- Tracheobronchial trauma
- Barotrauma
- Nerve injury
- Cervical spine injury
- Vocal cord paralysis
- Temporomandibular joint injury
- Laryngospasm
- Bronchospasm
- Hemodynamic perturbations

Extubation

- Hemodynamic perturbations
- Laryngospasm
- Laryngeal edema
- Bronchospasm
- Negative-pressure pulmonary edema
- Aspiration
- Airway compromise
- Difficult/accidental extubation

From Hagberg C, Georgi R, Krier C. Complications of managing the airway. *Best Pract Res Clin Anesthesiol.* 2005;19(4):641-659.

TABLE 53-7 Levels of Evidence

Level of Evidence	Descriptor
1a	Systematic review of RCTs
1b	Single RCT
1c	All or none study (e.g., all individuals died before therapy was available, but some now survive on the therapy, or when some individuals die before the therapy became available, but now none die on the therapy)
2a	Systematic review of cohort studies
2b	Single cohort study or low-quality RCT
2c	Outcome studies investigating outcomes of healthcare practices using epidemiology to link outcomes (e.g., quality of care, quality of life)
3a	Systematic review of case-control or historical-control study
3b	Single case-control or historical-control study
4	Case report or case series
5	Expert opinion or ideas based on theory

BOX 53-6

Assessing Incidence of Awareness

Modified Brice Interview

- What was the last thing you remember before going to sleep?
- What is the first thing you remember after waking up?
- Do you remember anything between going to sleep and waking up?
- Did you dream during your procedure?
- What was the worst thing about your operation?

From Mashour GA, Tremper KK, Avidan MS. Protocol for the Michigan Awareness Control Study: a prospective, randomized, controlled trial comparing electronic alerts based on bispectral index monitoring or minimum alveolar concentration for the prevention of intraoperative awareness. *BMC Anesthesiol.* 2009;9:7.

Surprising cases of awareness have been recently cited by Mashour et al.,[55,56] in a large study (n = 22,885) of patients who did not undergo general anesthesia, but received monitored anesthesia care 1:3269 (0.03%). This provocative finding indicates that awareness is not simply related to pain, but awareness itself was a source of distress. Several patients reported hearing unwanted conversations and remembered bright lights during their procedure inconsistent with their expectations, making them distraught. Therefore, it might be prudent to spend more time preparing patients for such experiences in order to avoid disparities in expectations that could lead to complications of awareness discussed later in this section.

The concept of consciousness involves not simply brain arousal and recall, but also subjective experience involving higher-order processes including memory. Explicit recall requires

TABLE 53-8 Risk Factors for Awareness

Situation Posing Increased Awareness Risk	Examples
Unsafe to administer sufficient anesthesia	• Trauma with severe hypoperfusion/hypotension • Cardiac cases using cardiopulmonary bypass • Obstetric emergency under general anesthesia
Mistake/failure in anesthesia delivery	• Inhalational agent not turned on/empty vaporizer • TIVA not begun or failure of device • Provider abuse of anesthetic drugs • Discontinuation of anesthesia too early
Anesthetic technique results in inadequate anesthesia	• Failed neuraxial technique • Use of neuromuscular blockade results in underappreciation of light anesthesia • Difficult airway with prolonged intubation attempts • TIVA techniques (e.g., IV infiltration, dosage miscalculation)
Patient needs are underappreciated	• Pharmacodynamic resistance (e.g., opioid, benzodiazepine tolerance) • Altered P450 metabolism (e.g., chronic alcohol use) • Increased P450 3A activity caused by efavirenz, nevirapine, barbiturates, carbamazepine, glucocorticoids, phenytoin, rifampin, St. John's wort • Mutations of melancortin-1 gene associated with red hair phenotype

From Mashour GA, Orser BA, Avidan MS. Intraoperative awareness: from neurobiology to clinical practice. *Anesthesiology*. 2011;114(5):1218-1233.
TIVA, Total intravenous anesthesia; *IV*, intravenous.

not only consciousness, but also involves memory. One of the most potent actions of general anesthetics is memory blockade or amnesia. Intravenous and inhalation anesthetics cause amnesia at doses considerably lower than those required for loss of consciousness and immobility. Propofol and midazolam cause greater memory blockade than fentanyl at equisedative doses. Retention of memory (studied after 24 hours) is also impaired by all anesthetics at relatively low concentrations (e.g., 0.2% isoflurane, 0.3% sevoflurane, 0.44% desflurane, 20% nitrous oxide). Finally, most anesthetics cause anterograde amnesia (i.e., loss of memory for a period after administration of the drug) but not reliable retrograde amnesia (i.e., loss of memory for events before administration of the drug). Intravenous anesthetics, including propofol and etomidate, cause anterograde amnesia and can also interfere with memory consolidation, or stabilization of memories after the initial acquisition.[56]

Awareness is often associated with a high rate of post-traumatic stress disorder (PTSD), increases patients' apprehension of future surgery, enhancing medicolegal risks associated with anesthesia. The B-Aware trial, one of the most recent randomized controlled trials studying awareness, reported a 71% incidence of post-awareness PTSD.[59] Not all patients who have documented intraoperative awareness develop PTSD, but initial emotional distress and the experience of paralysis have been cited as most predictive of developing PTSD. Postoperative sequelae reported related to PTSD include sleep disturbances (19%), nightmares (21%), fear of future anesthetics (20%), and daytime anxiety (17%).[58]

Preventing intraoperative awareness may appear straightforward: give patients adequate anesthesia doses, keep them deep, and ensure that patients receive more-than-sufficient doses of intravenous and inhalational anesthetic agents. Unfortunately, there are no fail-safe methods for what constitutes sufficient dosing for each individual patient. It could be argued that routine administration of muscle relaxants is inhibiting observation of voluntary movement and should be minimized or avoided when possible. Nonetheless, patients who are distressed or in pain can be expected to manifest pain with sympathetic stimulation if anesthesia is light, thereby alerting the anesthesia provider to deepen the anesthetic. Vigilance is imperative.

Brain monitoring using bispectral index (BIS) values has become relatively common during general anesthesia to detect light anesthesia and decrease risk of awareness, although it does not ultimately prevent intraoperative awareness. BIS monitoring theoretically serves as an alert and to guide the titration of anesthesia along with other hemodynamic parameters. Currently, all available brain-monitoring technologies have a nonlinear dose-response relationship, plateauing as doses reach higher levels. Therefore, titration of anesthesia according to these devices may not be reliable. The risk of postoperative recall appears to be low if patients become light only briefly (less than 30 seconds), but increases if patients are awake for more than 30 seconds.[56]

Studies hypothesizing that BIS monitoring protocols decrease intraoperative awareness have produced conflicting results. The B-Aware trial, involving 2500 patients, demonstrated that administration of anesthesia using a BIS monitoring protocol (maintaining BIS values between 40 and 60) compared with traditional anesthesia practice (end-tidal anesthetic concentrations) decreased intraoperative awareness by 0.74 percentage points in patients at high risk for awareness.[58] However, the B-Unaware trial demonstrated no reduction between a BIS monitoring protocol and using end-tidal anesthetic concentrations.[54] Both studies had lower than average incidences of awareness. A more recent trial, the BAG-RECALL trial, also demonstrated no significant differences in intraoperative awareness in high-risk populations related to monitoring for awareness or not.[60]

Incidence and consequences of pediatric intraoperative awareness data have been limited. Three recent studies evaluated awareness using semi-structured interviews modified for use in children with reported incidences between 0.6% and 2.7%.[61-63] Forty-three percent of children reported feeling scared, and 21% reported hurting during their surgery. Psychological follow-up was deemed unnecessary in all cases, and none of the children or parents expressed concern. Additionally, 14% of children with possible/probable awareness stated they would feel worse if they had to undergo another anesthetic procedure in the future, which was similar to reports from children who did not experience awareness (15%). Data seem to suggest that children with awareness do not develop PTSD, but a child's report of intraoperative recall should not be readily dismissed and should be addressed with appropriate follow-up.[64]

MANAGEMENT OF COMPLICATIONS

The aftermath of critical incidents and complications is equally as important as the incident itself, because incident investigation is a prerequisite for learning about the actions and events

surrounding the critical incident and prevention.[65,66] It is important to view the critical incident from an organizational point of view after it has occurred. There are many documented systematic approaches for handling critical incidents. One approach is discussed in this chapter. It would be helpful for anesthetists to explore their individual institution's approach to handling critical incidents.

Organizational learning is an important strategy for improving patient safety. For quite some time, the focus on medicolegal risks has diverted attention from the system-wide improvements with the potential to meet the needs of patients, families, and healthcare providers. Patients, their families/supporting individuals, and healthcare professionals involved are all affected and suffer from a critical event or complication. Taking care of the spectrum of these individuals is an important element of handling adverse events. Every healthcare organization should have a framework for handling critical events and complications embedded in effective communication between all parties involved, while also supporting the healthcare provider in the process.[65,66]

Incident Reporting

Not all critical incidents lead to adverse outcomes or complications. Once a critical incident has occurred, it must be reported and investigated systematically. Any death occurring within 48 hours of an anesthetic should be evaluated for potential relevancy.[10] Effective risk management depends crucially on establishing a reporting culture.[66] All critical incidents should be reported whether or not the outcome is negative.[67] Each hospital or healthcare institution should have a written, accessible policy to guide individuals in how to best support patients and families and also how to learn in a systematic way from the critical incident to minimize the likelihood of recurrence.

When a critical incident occurs, the anesthesia provider's first obligation is to protect the patient from further harm, providing the care required and mitigating further injury. Continuation of patient care, by the same team, for at least a short period of time is up to the individuals involved in the critical incident.[65,66,68] After the critical incident is stabilized, actions to secure the area, brief the team, and analyze the incident should be taken. First, secure implicated drugs, equipment, and records for further investigation. Brief all members of the care team as soon as possible so all members are fully aware of the issues and all subsequent communications are consistent with the patient and family. Decide immediately who will have primary responsibility for communicating with the patient and family about the event. Determine the circumstances surrounding the adverse events and factors contributing to it as quickly as possible while memories of those involved are fresh. This information can be crucial to the immediate clinical treatment plan for the patient, as well as for analysis of the situation. Report the event to the appropriate institutional officer.[69]

Root Cause Analysis

A retrospective analysis of the critical incident should ensue. One common example of this is called a *root cause analysis* (RCA). Root cause analysis is based on the premise that adverse events are caused, not by individual human errors, but by combinations of factors linked to organizational processes and structures by which errors are missed and adverse events are not prevented.[70] The objective of an RCA is to systematically uncover multiple factors or causal chains that contribute to a critical incident, developing systems changes to make it less likely that the incident will recur. During this process, the importance of unbiased investigation and blame avoidance is important. The RCA process is organized in sequential steps including: (1) identifying the incidents/problem statement, (2) organizing a multidisciplinary team to conduct the RCA, (3) exploring processes involved, (4) collecting facts and written statements from all involved, (5) performing an evidence-based literature review, (6) identifying possible causes, (7) analyzing the data, (8) proposing possible actions, (9) writing a report, and (10) reevaluating actions taken.[71-73] There is also broad consensus that RCA represents a toolbox of approaches rather than a single method, but a commitment to using a systematic and disciplined approach should remain.[73]

TABLE 53-9 Components of a Problem Statement When Conducting a Root Cause Analysis

What	What happened or should not have happened, or what change in performance is desired?
Where	Where specifically was the problem? This can be geographic, where in a process, and/or location on a piece of equipment.
Who	Who does this problem directly affect, either individual or group?
When	When was the problem first found or when did it begin?
How much	The frequency or magnitude of the problem: numbers provided should be absolute values plus percentages.

From Okes D. *Root Cause Analysis: The Core of Problem Solving and Corrective Action*. Milwaukee: American Society for Quality: Quality Press; 2009.

The first vital step in any RCA process is to identify the problem. Okes[72] has five components that should be answered when developing a problem statement, as shown in Table 53-9. The problem statement should represent cogent thinking and contain definitive, straightforward terminology that is well recognized and not misunderstood.

Step 2 calls for assembling a multidisciplinary group that will facilitate the process.

Step 3 seeks to understand the processes involved in and around the critical event. Why focus on process? Because everything individuals do on a daily basis is a process. Understanding the process is about stepping back and taking a broad view of the problem before jumping to possible causes. This step is especially important if the problem was thought to have been solved previously, but has recurred.[72] Keep the process boundaries internal to the organization, and limit them to those circumstances over which there is control. A flowchart diagram can be helpful for understanding the steps. An example scenario would be a 48-year-old male undergoing a redo 3-level laminectomy who awakens with bilateral blurry vision, only barely able to see shadows. Previous medical history includes secondary hypertension and dyslipidemia. Vital signs are 145/88, heart rate 78 beats/min, respiratory rate 14 breaths/min, and room air saturation is 96%. Recent laboratory results include sodium 136 mEq/L, chloride 108 mEq/L, potassium 3.8 mEq/L, hemoglobin/hematocrit 14.3/44%, and platelets 240. The surgical procedure lasted 5.5 hours and the total anesthesia time was 6.2 hours. Estimated blood loss was 850 mL. Figure 53-5 shows a sample flowchart diagram related to the postoperative visual loss.

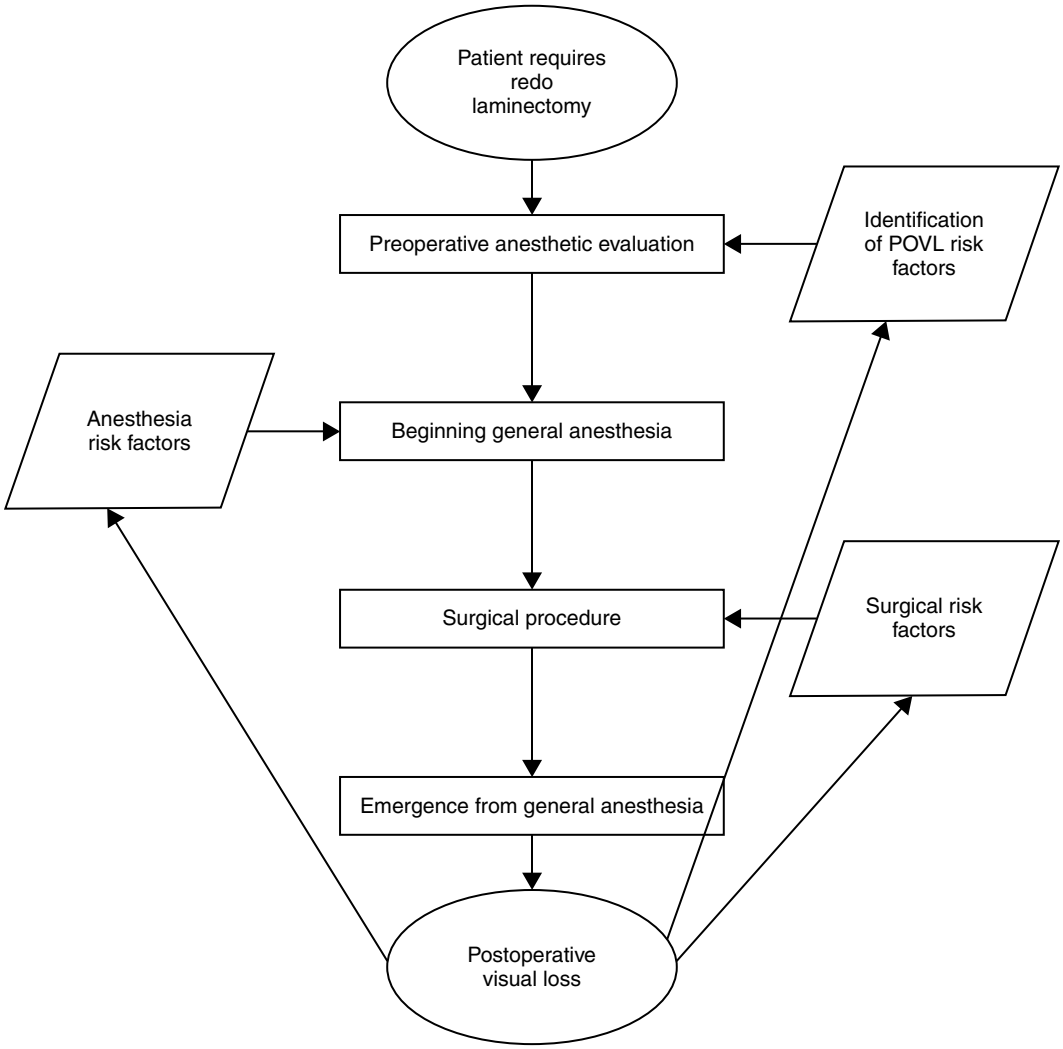

FIGURE **53-5** Sample flowchart diagram for Step 3, understanding the process, in a root cause analysis.

Step 4 involves collecting factual information and perspectives from individuals involved. This should be performed by one individual and compiled for future use by the multidisciplinary group.

Step 5 involves developing a search strategy to locate meaningful, quality evidence to support, refute, or reveal new evidence for the critical event being studied. The essence of evidence-based decision making includes locating the latest and highest-quality information combined with practitioner experience and skill, and incorporating the patient's desires as much as possible.[74] Locating needed information can be easily achieved by visiting the National Center for Biotechnology Information (NCBI) web-based database, which provides access to the National Library of Medicine and PubMed at http://www.nlm.nih.gov. The user should click on PubMed/MEDLINE and search using relevant terms. This website has multiple tools to help with searches. The Cochrane Library of Systematic Reviews and the Cumulative Index of Nursing and Allied Health Literature (CINAHL) databases are also helpful, quality web-based resources that can facilitate an evidence-based search. Other quality web-based resources exist, but the databases mentioned provide a solid, evidence-based foundation.

Once all pertinent data have been accumulated, brainstorming for all possible causes occurs in Step 6. Each brainstormed cause from the multidisciplinary group should ask the question "Why?" in order to form a connection to the critical event. A logic tree is helpful for depicting this thought process and for formulating relationships between each potential cause. An example of a logic tree related to the topic of postoperative visual loss in the scenario described earlier is shown in Figure 53-6.[72] Notice that the tree is hierarchical; the top level of the logic tree is the problem statement (or shorter description), and the next level below lists potential causes across on the same level. Then each level below should describe the causes. Each level of the tree is developed by asking "Why?" or how the step above could have occurred.

Step 7, data analysis, examines which of the causal theories appear plausible and which do not. Being clear about the theory (problem) to be tested and the data acquired to test whether it is true or not is important in analyzing each of the potential causes. Ask questions such as the following: What would the data look like if the theory (problem) were true? Do data collected support or deny the theory (problem) being tested? It is important to consider other conclusions the data might support, other ways to look at the same data, and other data that might confirm or deny the same conclusions. This is where the multidisciplinary group becomes very helpful. There are many ways to analyze data using a variety of diagrams and tools that

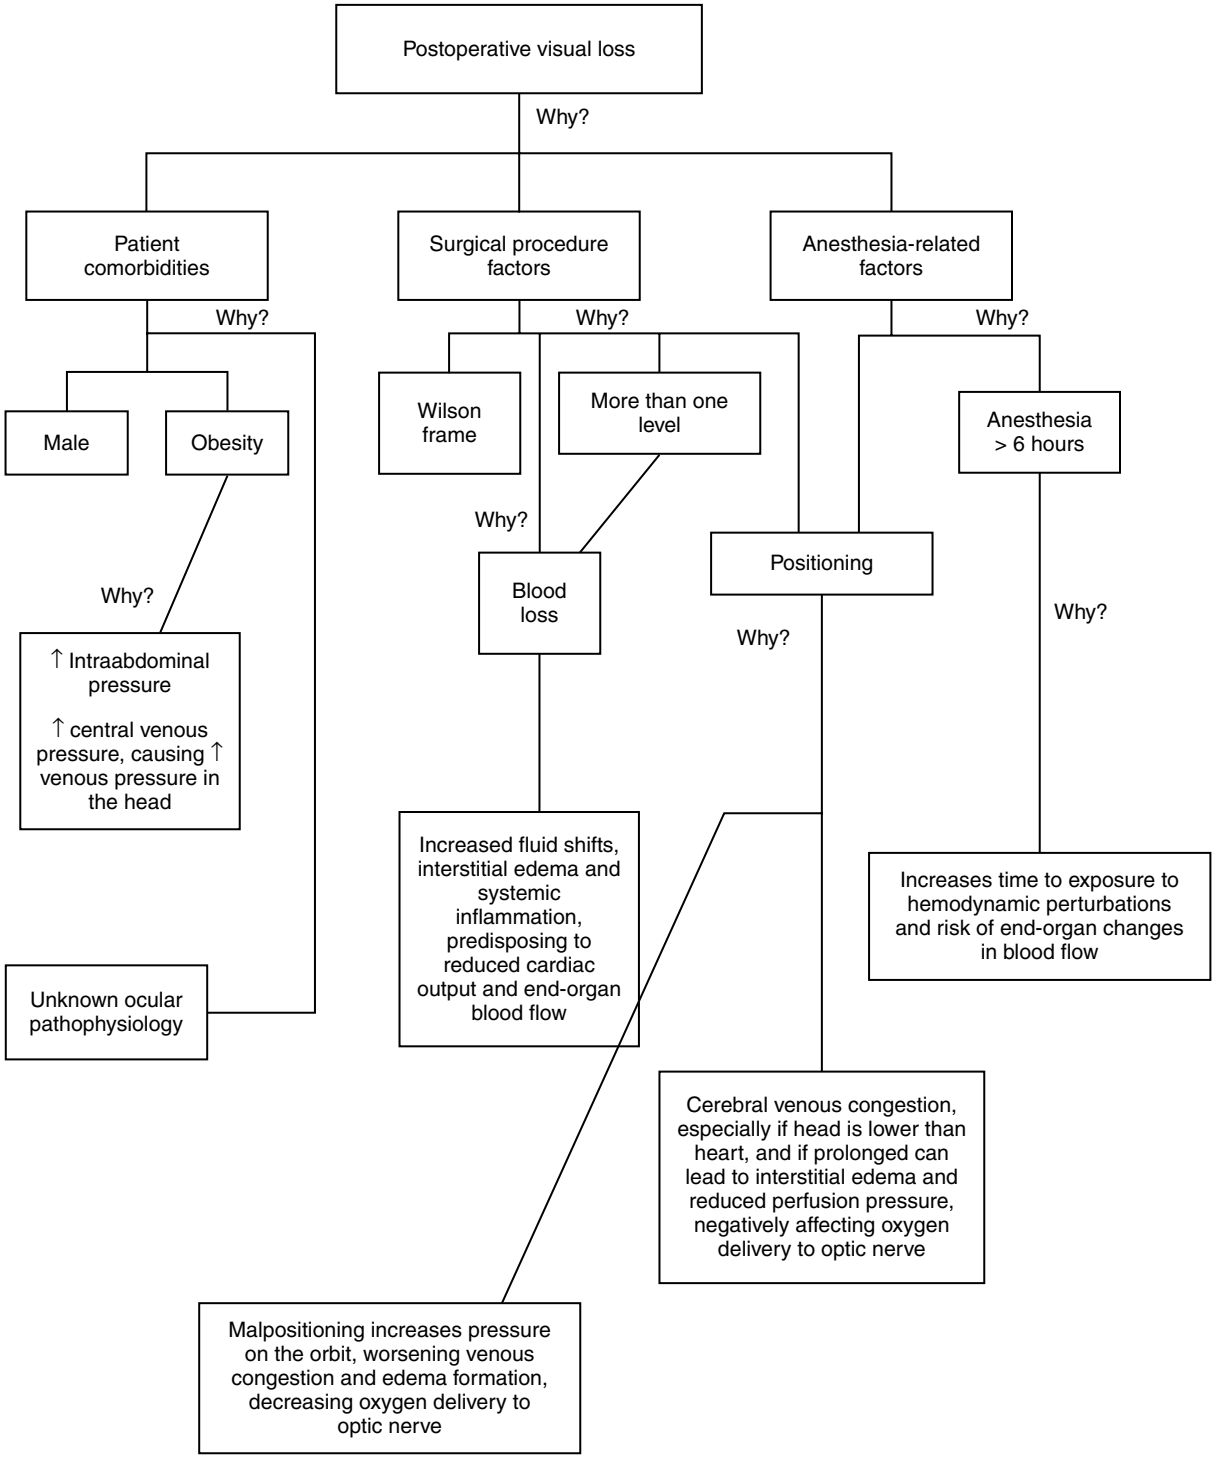

FIGURE **53-6** Sample logic tree diagram for Step 6, identifying potential cause, in a root cause analysis.

are beyond the scope of this chapter. Please see the References section of this chapter as an excellent source for a more detailed approach to data analysis.[72]

Step 8 involves proposing possible actions, which can engender a tendency to formulate only one idea that everyone thinks will work and then immediately implement it. Many tend to think that doing otherwise wastes time, but what is likely to happen is that the institution misses the opportunity to identify and implement breakthrough ideas. If a central idea has emerged, create a concept map, expanding on that idea. The central idea is in the center of the diagram with lines connecting it to expanded or related concepts.

Writing a formal report related to the RCA process is vital. This encompasses Step 9. There are many methods for constructing a report, but primarily the report must be logical, cogent, and factual and devoid of emotion or blame (Box 53-7).

Step 10 calls for reevaluation of actions taken within a certain predetermined time frame. Taking action without checking

BOX **53-7**

Elements of an Root Cause Analysis Report

Executive Summary

- Incident description and consequences
- Pre-investigation risk assessment
- Background and context
- Terms of reference
- Members of the investigation team
- Scope and level of investigation
- Involvement and support of patient and relatives
- Involvement and support for staff involved
- Information and evidence gathered
- Chronology of events
- Detection of incident
- Notable practice
- Care and service delivery problems
- Contributory factors
- Root causes
- Lessons learned
- Recommendations
- Arrangements for shared learning
- Distribution

to see whether the process improvement worked is like shooting in the dark.[72]

A vital aspect of RCA is that during discussions of adverse events, the focus on the individual is removed. Therefore, it is less likely that defensive behavior will occur and more likely that reflection on practice will occur openly. RCA can be used to reinforce good practice, support individuals involved in incidents so that they can come to terms with the event, and to explain to patients and families why care was suboptimal and what staff will do to prevent the event from recurring.[70]

Disclosure

Open disclosure of a critical incident and timely communication with patients and families is increasingly being emphasized and is largely responsible for decisions regarding legal action.[65,66] Open disclosure includes accurate information about the critical incident, immediate consequences and remedial action, expression of regret, and other information about preventing such an incidence from occurring again. A survey of 958 adults (31% reported experience with medical errors involving either themselves or another family member) revealed that not disclosing information was associated with lower patient satisfaction, less trust, and stronger negative emotional responses. Patients and families have interpreted healthcare provider silence as hiding information, covering up errors, or showing a lack of respect. Patients and families who take legal actions related to critical incidents do so in an effort to prevent that incident from ever happening again; they want an explanation and feel abandoned, and they desire to make the physicians/healthcare providers realize what they had done.[65,66] A recent interview study (n = 23) using open disclosure after a critical incident supported the positive aspects of open disclosure. All interviewees appreciated the opportunity to meet with staff to receive an explanation of the incident.[75] More research needs to be conducted in this area related to the full impact and techniques of open disclosure

BOX **53-8**

Process for Effective Disclosure

- Continuation of care
- Acknowledgement of incident and patient consequences
- Information on what happened and what to expect
- Apology (when appropriate)/expression of regret
- Advice about necessary treatment
- Information about preventing recurrence
- Tangible support regarding physical, psychological, social, and financial consequences

From Iedema R, et al. Practising Open Disclosure: clinical incident communication and systems improvement. *Sociol Health Illn.* 2009; 31(2):262-277.

on patients, families, and healthcare providers. It is imperative that anesthesia providers comply with state law and/or institutional policies regarding disclosure and not view disclosure as an individual endeavor (Box 53-8).

THE SECOND VICTIM

Complications, in the healthcare provider's eyes, have been described as the darkest hour of one's professional career.[76] Involvement of healthcare providers in critical incidents and the emotional turmoil that ensues is often regarded as taboo and to be avoided at all costs. No one wishes to be involved in the drama. Psychological stress and negative emotional responses can engulf the practitioner, creating serious health and performance deficits.[65,66,76,77] This practitioner is called *the second victim*, or a healthcare provider involved in an unanticipated adverse patient event who becomes victimized. The second victim is traumatized by the critical/adverse event. Frequently these individuals feel personally responsible and believe they have failed their patients and begin second-guessing their clinical skills and knowledge.[65,66,76] Some healthcare providers even report developing post-traumatic stress disorder, sleep disturbances, and problems with irritability. As a result, it becomes harder to work clinically and have job satisfaction. Published evidence addressing emotional and health-related effects of critical incidents on healthcare providers have looked only at short-term outcomes. However, a recent prospective longitudinal study examining medical errors by residents (n = 184) over a 3-year period found that self-perceived errors were common among trainees. These errors were associated with significant personal distress, burnout, loss of empathy, and increased risk of making another error.[78] Time to recovery from these symptoms can last for several months.[77]

Stages of Recovery

Participants develop their own unique way of coping, yet each describes a predictable recovery trajectory. Six stages of recovery are listed in Box 53-9.[76] At the moment the critical incident occurs, the involved clinician can usually describe chaotic and confusing scenarios of external and internal turmoil that ultimately lead to a realization about what happened. There is a period immediately after the incident of rapid inquiry to verify exactly what happened. Additional clinicians are summoned to provide support. The victim is frequently distracted, immersed in self-reflection, while also trying to manage a patient in crisis. The second stage is characterized by haunted reenactments, often accompanied by feelings of internal inadequacy.

BOX **53-9**

Stages of Second Victim Recovery

1. Chaos/accident response
2. Intrusive reflections
3. Restoring personal integrity
4. Enduring inquisition
5. Obtaining emotional first aid
6. Moving onward

From Scott SD, et al. Caring for our own: deploying a systemwide second victim rapid response team. *Jt Comm J Qual Patient Saf*. 2010; 36(5):233-240.

The victim reevaluates the situation repeatedly with "what if" questions. Stage 3 is entered when the victim seeks support from a trusted individual, usually a colleague or supervisor, friend, or family member. One of the biggest challenges in this stage is an inability to move forward and introspection related to "what will others think of me" and "will I ever be trusted again." Then in Stage 4 the individual wonders what the ramifications from the institution will be and "will I ever practice again." Second victims in Stage 5 seek out respected and safe colleagues to confide in. Litigation issues are often discussed. Stage 6 is a unique stage describing the second victim as moving on—dropping out, surviving, or thriving.[76]

What do practitioners need emotionally and professionally after a critical incident involvement? Little evidence exists to address this issue, but four primary needs have been identified after a critical incident involvement: (1) talking to someone about what happened, (2) validation of decision-making process, (3) reaffirmation of professional competence, and (4) personal reassurance.[65,66] Colleagues and supervisors are perceived as being the most helpful people with whom to discuss the situation. However, evidence suggests that little support is obtained at an organizational level. This lack of support after a critical incident often causes the negative emotional responses and psychological stress to be sustained.[76] Along with emotional needs, there are definite professional needs that should be met as well. The anesthetist should consider speaking with the appropriate hospital administrators and possibly an attorney if there is litigation or expected litigation.[79]

THE HUMAN FACTOR IN COMPLICATIONS

Human Error

Human error is inevitable. The most important component of anesthesia is the anesthesia provider, the human performance embedded in a larger system of care. Human failures have been identified in 51% to 77% of anesthesia-related deaths.[9] Most cases are related to lack of experience or competence observed in 89% of human failures–related deaths. Less frequently, errors of judgment or analysis were detected in 11% of these deaths.[4]

The topic of human error is rich in myths, such as error is intrinsically bad; bad people make bad errors; and errors are random and highly variable.[67] Errors are not intrinsically bad, but instead are essential for coping with trial-and-error learning in novel situations. One of the basic rules of error management is that the best people can make the worst errors. Many times the best people tend to push at the limits of existing practice by trying out new techniques. Errors do not occur "out of the blue," but do take on recurrent and predictable forms. Different errors occur in different situations. Errors happen when individuals know what they are doing, but actions do not go as planned, taking the form of absent-minded slips and memory lapses. Errors also can happen when individuals think they know what they are doing, as in dealing with what appears to be a trained-for problem, but then misapply a normally good rule, apply a bad rule, or fail to apply a good rule. Errors are certain to occur when the individual is not sure what he or she is doing.[67]

Past concepts related to human error in health care have not embraced the statement that human error is inevitable, but tried to avoid or prevent human error, doing so without success.[80] It has been argued that judgments of human error should form the starting point of accident investigations, not be the explanation for the failure.[80,81] Human involvement in complex systems is necessary and beneficial, because of our ability to adapt, our creativity, and our ability to be flexible.[80] This relevance of human factors in improving safety cannot be overstated. Even though we cannot change the human condition, we can change the conditions under which humans work.[67]

The aviation industry realized, embraced, and acted upon human factors more than 20 years ago. A systematic approach to safety at an organizational level is currently in practice in the aviation industry and has been recommended as an approach to dealing with human factors in anesthesia. This type of safety culture possesses certain features such as standard operating procedures, operations manuals, and checklists that could be incorporated into anesthetic practice; however, there is a certain amount of reluctance to embrace these tools, perhaps for fear of being constrained in exercising clinical judgment and critical thinking as well as being forced to forego practical long-standing techniques.[80]

A key concept related to human factors is the concept of resilience. Resilience is an everyday word synonymous with *buoyant*, *elastic*, and *flexible*, and it can describe an individual's ability to recover readily from illness, depression, or some other life adversity. A human factors perspective of resilience refers to the ability to understand how failure is avoided and how to learn from successes and error avoidance rather than simply conduct a reactive search for causes and remedies. It offers a systems-based approach to understanding how to stay safe proactively. Resilience is a positive human attribute that can be used to bounce back from errors made, learn from mistakes, and move forward. Resilience has the potential to provide significant advances in patient safety by shifting focus from an emphasis on human error and error counting to preventing these errors from being repeated.[82,83]

Human factors that contribute to complications often include nontechnical skills and behaviors. Lack of communication and teamwork have been shown to contribute to 43% to 65% of sentinel events occurring in the operating room (e.g., wrong side, transfusion error). Poor team performance has been the trigger for the development of crew resource management, which has been adapted to health care and anesthesia in the form of crisis resource management.[84] Communication is fundamental to workplace efficiency and safety. Elements of good communication are not just verbal, but nonverbal as well (Box 53-10). Good communication is a major part of good teamwork. Teamwork represents a distinguishable set of two or more people who interact dynamically, interdependently, and adaptively toward achieving a common goal, who have each been assigned specific roles or functions to perform, and who have a limited life span of membership (Box 53-11). Effective teamwork and communication do not happen alone, but must be developed through training. Training individuals working in a team is based upon developing competence, knowledge, skills, and attitude of individuals as well as training objectives. Teams should develop identity, in which team

BOX 53-10

Elements of Good Communication

- Send information clearly and concisely
- Include context and intent during information exchange
- Receive information, especially by listening
- Identify and address barriers to communication

members learn their own roles and tasks and understand those of other team members.[67,85] Simulation provides a teaching and learning methodology that allows team members to practice crisis resource management and develop nontechnical skills and behaviors to improve teamwork and communication.[4]

Fatigue

Fatigue is the largest identifiable and preventable cause of accidents. The aviation industry estimates that fatigue may involve 4% to 7% of civilian aviation accidents, and anywhere between 4% to 25% of military aviation accidents. Fatigue, anesthesia, and complications have not traditionally been discussed together, but are an expanding science of interest and a significant safety concern. Anesthesia care is a 24-7 profession, and consequently this can require long working hours, sustained vigilance, unpredictability of stressful situations, and production pressure.[85] Currently no quantitative data exist regarding the incidence of complications in anesthesia related to the fatigued provider. Reducing work hours and allowing 24 hours of sleep time between shifts significantly impacted attentional failures (i.e., intrusion of slow rolling eye movements into confirmed episodes of wakefulness during work hours) in a small prospective study with interns.[86] The Joint Commission has published evidence-based actions that healthcare organizations can incorporate to help mitigate the risks of fatigue (Box 53-12).[87]

Stress

Every anesthesia provider knows what it feels like to be under stress, both professionally and personally. Stress can have both acute and chronic effects. Acute stress in humans can be related to the classic fight, flight, or freeze response.[85] Chronic stress is related to conditions in the workplace and the individual's reaction to these over a period of time. Stress has been linked to safety outcomes, such as accident involvement. Because stress has been linked to accident involvement and safety outcomes, the ability to recognize and manage stress in self and others is an important nontechnical skill. Job demands, control over work activities, support or lack thereof from managers or coworkers, poor relationships, uncertain work

BOX 53-12

The Joint Commission Action Suggestions for Healthcare Provider Fatigue

1. Assess organizational fatigue-related risks (e.g., shift hours)
2. Assess patient handoff processes
3. Invite staff input for schedule design to promote less fatigue
4. Create and implement a fatigue management plan to help fight fatigue
   a Conversation
   b Strategic caffeination
   c Short naps (less than 45 minutes)
5. Educate staff about sleep hygiene and effects on patient safety
6. Provide opportunities for expressing concerns about fatigue
7. Encourage teamwork as a strategy to support staff working extended hours
8. Consider fatigue potentially contributing to adverse events

From Jeffcott SA, et al. Improving measurement in clinical handover. *Qual Saf Health Care*. 2009;18(4):272-277.

roles, uncertainty about change, and family-personal problems are all considered stressors. How each individual handles these with the resources available to them using prior experience, training, personality, fitness, social support, and coping strategies will indicate whether the stress will have a positive or negative effect on the individual. The effects of stress on behavior are generally the most readily observable by work colleagues (Table 53-10). For example, a placid coworker becomes irritable, or a colleague who generally has a neat appearance begins to take less interest in how he or she looks.[85]

Patient Handoff/Communication

Communication issues and breakdowns in communication have been estimated to contribute between 15% and 67% to the development of critical incidents.[88] In particular, communication at organizational interfaces (e.g., care transitions, shift changes) with changing responsibility for care is a key target for improvement.[89] A surgical patient undergoing elective surgery can have direct patient care change a minimum of at least four times (e.g., admission area to surgery/anesthesia to postanesthesia care area to unit/floor).

A clinical handover/handoff or transfer of care is by definition, "the transfer of professional responsibility and accountability for some or all aspects of care for a patient, groups of patients to another person or professional group on a temporary or permanent basis."[65,66,89,90] The Joint Commission defines handoffs as the real-time process of passing patient-specific information from one caregiver to another or from one team of caregivers to another for the purpose of ensuring the continuity and safety of patient care.[91]

Historically, patient handover has not been studied systematically, which is in stark contrast to other high-risk industries where handovers have received considerable attention. Qualitative studies and surveys across different healthcare settings cite that handover processes are highly variable with widespread dissatisfaction among physicians and nurses.[65,66,88] As a result, patient handover has been recognized as a safety initiative by the World Health Organization (WHO) Alliance for Patient Safety and the WHO Collaborating Center for Patient Safety for over 5 years and is listed as one of the National Patient Safety Goals by The Joint Commission.[91] There has been a substantial increase in research activity and literature reviews across healthcare disciplines focusing on a specific type of handover in a specific clinical setting (e.g., nursing, physicians, perioperative care area)[88,92,93] (Figure 53-7).

TABLE 53-10 Indicators of Chronic Stress

Behavioral	Emotional	Somatic	Thinking	Organizational
• Absenteeism • Abuse of drugs • Hostile behavior • Apathy • Reduced productivity • Distracted • Careless errors	• Anxiety • Hopelessness • Cynicism • Resentfulness • Depression • Irritability	• Decline in physical appearance • Chronic fatigue • Frequent infections • Health complaints (e.g., headache, stomach)	• Lack of concentration • Reduced attention • Difficulty in remembering • Impaired decision making • Failures in planning	• High staff turnover • Absenteeism • Poor timekeeping • Decreased productivity • Increased client complaints • Increased employee compensation claims • More near-misses and accidents

From Flin R, O'Connor P, Crichton M. *Safety at the Sharp End: A Guide to Non-Technical Skills*. Burlington, VT: Ashgate Publishing Ltd; 2008.

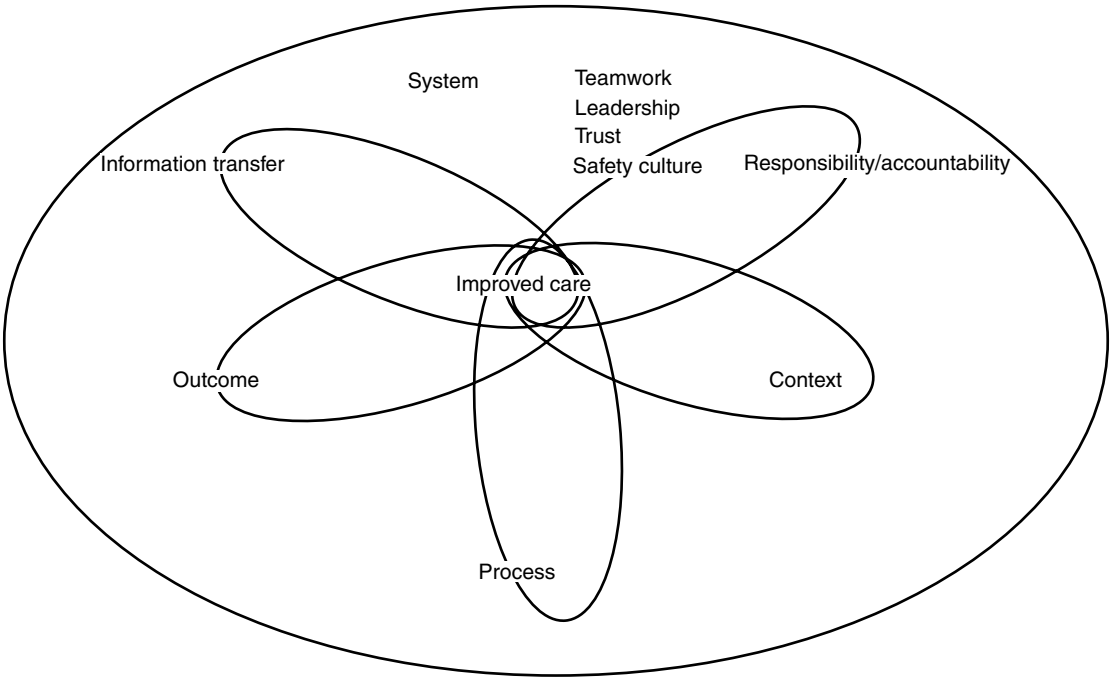

FIGURE **53-7** Conceptual model of handover elements. (From Jeffcott SA, et al. Improving measurement in clinical handover. *Qual Saf Health Care*. 2009;18[4]:272-277.)

Certain handoff attributes contribute to potential complications such as truncated handoffs and omission of information due to work demands or time constraints, unfinished diagnostic and care activities, or a perceived lack of trust or familiarity with the participating individual.[94,95] A self-reporting survey among 133 residents found that 31% had experienced an issue for which the handover had not prepared them.[96] Another recent study reviewing 2729 critical incidents found that the most frequent type of handover incident reported besides an incomplete handover (45.2%) was no handover at all (29.3%).[97]

Nagpal et al.[92,93] studied information transfer and communication (ITC) across the entire surgical care pathway in patients undergoing major gastrointestinal procedures. Most ITC failures were observed during the preoperative phase (61.7%) and postoperative handover (52.4%). Seventy-five percent of patients had clinical incidents or adverse events because of ITC failures.

So what constitutes a handover that contributes to the quality and safety of patient care? Quality of the handover depends on the perception as to what is the primary function of the handover (e.g., information or responsibility transfer, shared decision making).[65,66,89,90] Handover quality measures can be grouped into five areas: (1) information delivery or transfer, (2) responsibility/accountability, (3) context and environments, (4) the handover process, and (5) handover outcome.[83,88] For a conceptual model of handover elements, see Figure 53-7.

Measures of handover content appear to be straightforward, but which items should be included in a list for a quality handoff can vary depending on the clinical setting, timing, and individual perceptions and experience.[65,66] The list can often become lengthy and generate heated discussions. Most handover content should concentrate on completeness and accuracy of information and related errors. Purely verbal handovers have been found to be the most incomplete when compared with information available in the patient record or located in a predefined protocol.[89,90,94] A noisy operating room and an anesthetist that is in a hurry may not create the optimal handover process, leaving a gap for crucial information to be missed. The generation of evidence in this area is extremely limited, and there is still an open question regarding how various process measures translate into safe care.[65,66,89,90]

Handover outcome measures usually include healthcare provider satisfaction. An observational study conducted in three different clinical settings (e.g., paramedic to emergency room, anesthetist to

postanesthesia care unit [PACU], and PACU to floor/unit nurse) found that although information transfer was the key characteristic, overall handover quality was predicted by three factors: information transfer, shared understanding, and working atmosphere.[65,66,89,90]

Professional organizations have published guidelines for handover communication, and standard approaches do exist that can improve handover communication. Study outcomes evaluating adherence to a protocol for handovers demonstrated statistically significant improvement in handover quality and improved teamwork.[98] Another approach focuses on general interaction structures and does not define actual content, but instead focuses on an order of topics to be covered. Both approaches have demonstrated improvements in teamwork and communication, which are factors that have translated into a significant reduction in morbidity and mortality in surgical patients.

An emerging area related to communication and handovers is incorporating a shared understanding among a healthcare team during a handover so that a handover is not a one-person–one-way process. An ideal patient handover conducted as a team-based activity would comprise an episode of shared cognition and understanding among healthcare providers and an opportunity for collaborative cross-checking. In this view, handovers represent a source of resilience for healthcare systems.

Standardized handovers in anesthesia have been proposed. One approach to handover content defines specific content to be included and also an order in which the information should be presented using a checklist-type format. A second approach focuses on the environment and general interaction structures without any defined content.[65,66]

The electronic medical record (EMR) system has been proposed as one solution that provides a handover sheet that can easily be extracted to improve completeness of handover information. Arora et al.[89,90] systematically reviewed studies reporting interventions for improving patient handovers and found that technology solutions were associated with a reduction in preventable adverse events and improved satisfaction with handoff quality and also improve provider identification. Technology, however, ignores behavioral and cultural aspects of communication and does not necessarily improve communication.

SUMMARY

It is important to recognize the effect of local culture as a key underpinning for processes for improvement. A culture of blame is no longer acceptable and should not be supported.[65,66] Learning from a critical incident can be both prospective (deliberating in advance of process changes and how they might affect safety) and retrospective (learning from events that have already transpired). It is important in these educational interventions to reinforce that errors are not always the cause of accidents, and blaming an individual may hinder uncovering a latent error or problem in the system. If reporting is safe and provides useful information from expert analysis, then it can measurably improve safety. Transfer of care is complex—much more involved than one-way communication—and is a major source of error, yet specific contribution to these errors and their evaluation remain unclear. A more complete understanding of the processes involved is needed. Safety is a dynamic "non-event" when individuals employ foresight, coping, and recovery to bridge gaps, thereby avoiding failure.
