on the patient in a standardized sequential configuration (or montage) that examines known electrical potentials. This configuration was internationally standardized by Jasper in 1958 as the 10-20 system and is usually used to record the spontaneous EEG. With this system, 21 electrodes are placed on the surface of the scalp. The positions of the electrodes are determined by following three primary reference points: (1) the *nasal-frontal angle*, which is the depression at the top of the nose; (2) the level aligning with the eyes; and (3) the *inion*, which is the bony lump at the base of the skull on the midline at the back of the head. These reference points allow the practitioner to measure the skull perimeters in the transverse and median planes. Electrode locations are determined by dividing these perimeters into 10% and 20% intervals.[6] Freeman[7] suggested that the electrodes should be placed in areas that emit similar signals to concentrate and better record the electrical activity.

Generally, the basic parameters of the EEG include frequency, amplitude, shape (amplitude and shape constitute morphology of the wave), and time of each of these electrical discharges. The waveforms are then arranged in the following manner. Four common types of brainwaves are noted on the EEG; they are alpha, beta, delta, and theta waves. There are also several variants or subgroups of waves noted during specific activities. Some of these waveform variants are gamma, mu, and lambda waves. Gamma waves are typically seen with high-order activity such as problem solving and analytic thinking. The amplitude of the mu wave is about one half that of the beta wave and is seen more frequently over the motor areas of the brain.[8-10] Lambda waves occur in the awake

TABLE 18-1 Brain Monitoring Methods

Method	Spatial Resolution	Temporal Resolution	Purpose	Advantages	Disadvantages
ICP	Global	Continuous	Measure intracranial compliance	Reliable Quantitative Allows monitoring of CPP	Invasive Risk of infection Risk of hemorrhage
Jugular oximetry ($SjvO_2$)	Global	Continuous	Measure adequacy of hemispheric oxygenation	Quantitative Allows monitoring of $AVDo_2$ and O_2ER	Susceptible to artifacts Local complications (e.g., infection, thrombosis)
EEG	Global	Continuous	Monitoring electrical brain activity Detection of seizures	Technique well standardized Only method to diagnose nonconvulsive seizures	Qualitative Relatively insensitive to secondary insults
SSEP	Global	Continuous	Monitoring integrity of sensory pathways	Technique well standardized Simple	Qualitative Fairly insensitive to secondary insults
MEP TES-MEP	Global	Continuous	Monitoring integrity of motor pathways	Technique well standardized Multimodality monitoring when combined with SSEP (the standard for spinal surgery)	Fairly insensitive to secondary insults
Bedside Xe-133 CBF	Regional	Discontinuous	Measure hemispheric CBF	Quantitative	Only accurate if radiotracer injected into carotid artery Radioactivity
Laser Doppler flowmetry	Local	Continuous	Measure cortical CBF	Accurate Dynamic information	Qualitative Invasive Susceptible to artifacts Only monitors 1-2 mm^3 of tissue
Thermal diffusion flowmetry	Local	Continuous	Measure cortical CBF	Simple Dynamic information	Qualitative Invasive Monitors small volume of tissue
TCD	Regional	Continuous	Measure CBF velocities	Simple Noninvasive Allows measuring PI, VMR	Qualitative and indirect assessment of CBF Difficult to keep probes in place
Brain tissue Po_2	Local	Continuous	Measure cerebral oxygenation	Quantitative Sensitive Probes also measure brain temperature	Invasive Susceptible to artifacts Monitors small volume of tissue
NIRS	Local	Continuous	Measure cerebral oxygenation	Noninvasive	Measures only relative changes Susceptible to artifacts
Microdialysis	Local	Discontinuous	Measure cerebral metabolism	Sensitive Quantitative	Invasive Complicated technique Labor intensive Unclear which is the best parameter to monitor

$AVDo_2$, Arteriovenous oxygen difference; *CBF*, cerebral blood flow; *CPP*, cerebral perfusion pressure; *EEG*, electroencephalogram; *ICP*, intracranial pressure; *NIRS*, near-infrared spectroscopy; *O_2ER*, oxygen extraction rate; *PI*, pulsatility index; *Po_2*, partial pressure of oxygen; *TCD*, transcranial Doppler; *SSEP*, somatosensory evoked potentials; *MEP*, motor evoked potentials; TES-MEP, transcranial electrical stimulation motor evoked potentials; *VMR*, vasomotor reactivity.

patient and are usually present when staring, reading, or looking at objects for long periods, as happens with videogames and TV.[11] It can be difficult to distinguish artifact and normal variations of the EEG from the four common types of known brainwaves.[12-14]

The head and much of the scalp may be inaccessible during intracranial surgical procedures so the standard 16-channel EEG is rarely used. Intraoperative monitoring during craniotomy is usually accomplished with a 2- to 4-channel recording, with computer processing to simplify the interpretation. To interpret an EEG properly, it is necessary to remember that an EEG reflects how "awake" or metabolically active the brain is. Electrical activity in the brain is a process that requires energy that is dependent on certain substrates, such as oxygen or glucose. Depression of EEG activity and characteristic changes in the EEG can be seen with reduction in cerebral blood flow, oxygen, or glucose delivery. During an awake-state, the high-frequency and low-amplitude beta waves are most prominent. There is a transient increase in the beta waves with the onset of ischemia or hypoxia, with eventual development of large-amplitude theta and delta waves. With the increase in ischemia or hypoxia, the beta waves begin to disappear and there is an appearance of low-amplitude delta waves. This progresses to electrical activity suppression with occasional bursts of activity. The onset of irreversible damage can be seen when there is complete electrical silence with a flat EEG.

Monitoring the EEG intraoperatively for the development of delta waves allows for the recognition of an increased risk of ischemic damage to the brain. To simplify EEG interpretation, the anesthetic delivery should ideally be "stable" and not changing during the critical surgical portions of the case. Also, any changes in anesthetic delivery should be communicated to the EEG technician. The EEG can only provide information of the cerebral cortex function, and not much information on the subcortical brain, spinal cord, or the cranial and peripheral nerves.[3,15,16]

Anesthetic Effects on EEG

Induction Agents

Induction doses of etomidate and propofol all cause similar effects on the EEG by increasing the frequency of beta waves and decreasing their amplitude. This beta-rhythm EEG activity correlates with the patient losing consciousness after drug administration; a dose-related depression is seen with anesthetic drugs.[17,18]

One difference noted with the administration of etomidate is that myoclonus, frequently seen with its use, is not reflected on EEG signals.[19] Coincidently, the EEG frequency decreases as the serum levels of etomidate rise, thereby leading to burst suppression. Burst suppression can be achieved with both of these induction agents in their higher dosage ranges. *Burst suppression* is an alternating high-frequency activity with 0.5- to several-second periods of electrical suppression. This type of electrical activity is unpredictable, and the duration constantly varies. Burst suppression is also typically seen with a decrease in cerebral circulation and oxygenation, as well as with hypothermia, particularly during cardiopulmonary bypass surgery. Many of these effects can be additive. Burst suppression EEG patterns remain somewhat controversial relative to cardiopulmonary bypass surgery. However, to reduce cerebral oxygen requirements and provide neuroprotective properties, burst suppression may be desirable during manipulation of brain tissues.[20-22] Burst suppression can be achieved during anesthesia using a variety of anesthetic agents. These agents include etomidate, propofol, and the inhalation agents, which all provide varying levels of suppression of electrical activity with increasing depth; effects usually remain bilateral and uniform.[17,19,23] Unilateral burst suppression is usually indicative of ischemia or injury to the brain. Forethought should be given to the use of sevoflurane in patients with known epileptiform EEG activity; the activity may be accentuated by these inhalation agents in their lower concentrations.[18,24,25]

PROCESSED EEG WAVEFORMS

The interpretation of a raw EEG can many times be difficult and depend on the quality of the waveform, lead placement, any artifact or electrical interference that might be present, and the skill level of the clinicians in interpreting the waveforms. To further analyze the EEG, multiple methods are used, including compressed spectral array (CSA) and density spectral array (DSA). The CSA and DSA are obtained, calculated, and displayed by collecting, assessing, and providing a summary of each of the waves (alpha, beta, theta, delta) over a period of time. A mathematical description for the timeframe, using the amplitude and frequency of the waves, is accomplished by using a fast Fourier transform (FFT) algorithm. Applying an FFT algorithm is typically thought of as breaking down a signal into a variety of components and then reconstructing the useful information into an analysis of the complex signals. The cell phone, TV, and radio are examples of devices in which this technology is best known. The Fourier analysis also results in a compressed view of EEG waveforms. The compressed data are presented in a two- or three-dimensional graph. Depending on the display used, these data appear as either a compressed spectral array (CSA) or a dot matrix called a *density spectral array* (DSA), as seen in Figure 18-1.[26]

The processed information collected and displayed for the CSA and DSA is analyzed for the waveform relationships using the amplitude and frequency and illustrated in two- or three-dimensional graphs. These relationships are expressed as the spectral edge frequency (SEF), median frequency (MF), and relative delta power (RDP). Most commonly, the SEF is used and represented by the EEG frequency and power activity, which falls below 90% (SEF90).[27,28] Figure 18-2 shows an EEG power spectrum demonstrating the SEF of waveforms within 90% of power and frequency. As frequency declines below a predetermined power, the spectral edge changes. In the presence of general anesthesia or injury, frequency and power decline, thereby causing a change in the spectral edge. The modern EEG calculates the computerized spectral array, which is then used during anesthesia to determine the "depth of anesthesia" or unilateral injury, based on the processed results. The compressed spectral array (CSA) in Figure 18-3 shows the spectral edge shifted to the right, indicating lower power and frequency in brainwave activity. This pattern is typically found during deep sedation and sleep, and in Figure 18-3 is produced by the presence of 0.2% isoflurane anesthesia, indicating the patient's brainwave activity is suppressed. General anesthesia produces a reduction in high-frequency waves and an increase in low-frequency amplitudes. In Figure 18-2, the spectral edge is positioned well to the left, indicating a higher power and frequency, suggesting that the patient is awake.[29-31]

Considerations for Inhalation Anesthetics and EEG Interpretation

Interpreting the EEG in the presence of anesthetic drugs can be confounding because the different drug classes used for anesthesia may affect the EEG in different ways. Instead, generalized assumptions can be made from the interpretation of the EEG. There are two major reasons the EEG remains difficult to correlate with the course of the anesthetic and patient outcomes. The first major

variable preventing exact correlation between the EEG and anesthetic depth is the combination of the many different drugs used to induce and maintain general anesthesia. Dose-related effects are seen with each general inhalation and intravenous anesthetic. The inhalation agents affect the frequency and amplitude of the EEG waveforms (Table 18-2).[29-34] Alpha waves seen primarily in the occipital and posterior lobes are increasingly abolished with inhalation anesthesia. Beta activity is usually seen in the frontal lobe and typically increases slightly with general anesthesia. The second major variable involves environmental factors and manipulation of the brain intraoperatively, adding to the complexity of interpretation. Extensive research with bispectral analysis (BIS) has sought to clarify EEG interpretation by analyzing the EEG electrical signals, processing them, and displaying the result as a final numeric value of 0 to 100. BIS measurement is effective in determining the level of anesthesia produced with inhalation agents but remains less predictable with pediatric patients and during regional and intravenous anesthesia.[35]

Processing Devices

Several devices on the market today use a combination of processed EEG signals to determine the depth of anesthesia. The BIS machine (Aspect Medical Systems) is the most widely used and relies on a combination of bispectral analysis, power spectral analysis, and time domain analysis in combination with a mathematical algorithm that produces an index of the hypnotic state of the patient. Other available monitors include the following:

- S/5 Entropy module (GE Healthcare)
- Cerebral state monitor (Danmeter)
- SNAP II monitor (Stryker)
- AEP Monitor/2 (Danmeter)
- SEDLine/patient state analyzer (Hospira)

The most frequently used monitor for assessing anesthetic depth based on the processed electroencephalogram is the bispectral index (BIS) monitor. The BIS monitor processes a single frontal electroencephalographic signal to calculate a dimensionless number that provides a measure of the patient's level of consciousness.

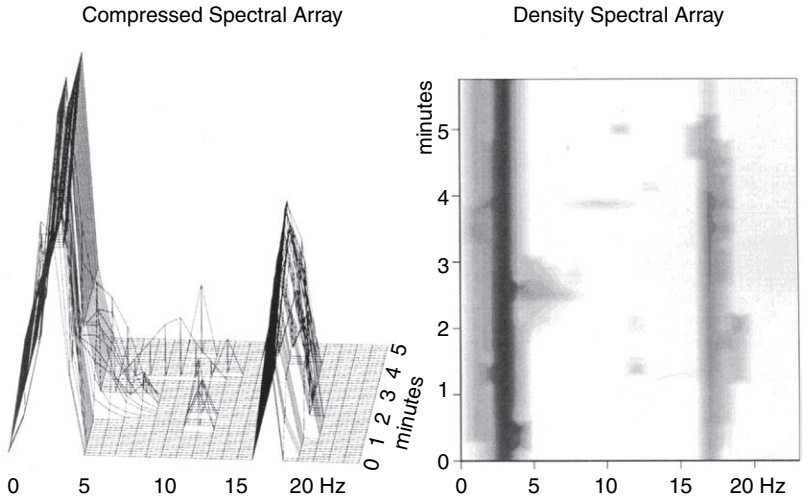

FIGURE **18-1** The compressed spectral array (CSA) histogram on the left is the compression and transformation of raw EEG waveform data and plotted over time. The density spectral array (DSA) on the right is created by converting each brainwave value into a shade of gray and then plotting them on the DSA graph. (From Rampil IJ. A primer for EEG signal processing in anesthesia. *Anesthesiology.* 1998;89[4]:980-1002.)

FIGURE **18-3** **A,** The solid line indicates a compressed spectral edge with the administration of isoflurane 0.2%. **B,** The solid line indicates the compressed spectral edge with no anesthesia. (Adapted from Heyer EJ, et al. Erroneous conclusion from processed electroencephalogram with changing anesthetic depth. *Anesthesiology.* 2000;92[2]:603.)

BIS values range from 100 (awake) to 0 (no brain activity). BIS values between 40 and 60 suggest adequate general anesthesia for surgery. Values below 40 indicate a deep hypnotic state. Targeting a range of BIS values between 40 and 60 is advocated to prevent anesthesia awareness while still allowing a reduction in the administration of anesthetic agents.[36] The success of the BIS monitor to prevent awareness remains a matter of controversy. BIS-guided anesthesia reduces the incidence of awareness with recall in high-risk patients.[37] A recent study comparing BIS-guided anesthesia to measurement of the end-tidal anesthetic concentration (ETAC) found that ETAC, which is already routinely monitored, was superior in preventing recall.[38] It has been suggested that deep anesthesia as defined by a sustained BIS value less than 40 for greater than 5 minutes is associated with increased postoperative mortality (B-Aware trial).[39] The concern was that with additional risk factors such as hypotension, high concentrations of anesthetic gases and patient co-morbidities, adverse outcomes are increased. Other studies do not support the B-Aware trial results.[40] Several large-scale trials are ongoing that address these important issues.[41]

These devices have their limitations. Most important is a time delay that is steadily being remedied by faster processors. The intraoperative gold standard is still the 16- to 32-channel analog EEG monitored by an experienced technician. Studies evaluating whether systems with processing software using fewer channels are comparable to 16- to 32-analog EEG encephalography are not available.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is a relatively new method of analyzing brain hemodynamics, especially hemoglobin oxygenation and blood volumes, by using the near-infrared spectrum of electromagnetic waves from approximately 600 to 2500 nanometers (nm). Near-infrared spectroscopy can better penetrate deep into thick tissues, allowing noninvasive physiologic interpretation of oxygenation by evaluating, in real time, the transmission and absorption of infrared light in the hemoglobin in brain tissue. As each area of the brain is evaluated with NIRS, the local blood volume is also analyzed, thus determining flow to that area.

Constant monitoring with NIRS allows the anesthetist to quickly determine regional volume and hemoglobin changes in the brain tissue. Not only is NIRS used to evaluate oxygenation and blood volume during anesthesia, it can also facilitate motor-function monitoring of patients, with strong clinical correlations.

Contamination of the NIRS signal is an issue that has recently been studied and arises with the use of the unit. The contamination of the oxygenation signal occurs with increased levels of hypoxia in the tissues on the scalp, leading to distorted signals and readings of brain oxygenation. When using the NIRS monitor, the nurse anesthetist must be careful to consider the peripheral oxygenation of the scalp or the NIRS signal may not fully or solely reflect the oxygenation of the brain.[42,43] Because NIRS devices differ, some caution in their use and interpretation is encouraged.[44-46]

EVOKED POTENTIALS

Evoked potentials (EPs) are electrical potentials that are measured in response to some type of stimulus. These stimuli can be changed or completely depressed with the administration of anesthesia. In the operating room, EPs are used to help alert surgeons and aid adjustments to surgical strategy, to confirm their decisions, and help them improve subsequent procedures and outcomes, therefore avoiding neurologic damage. This is all done to preserve or improve neurologic structures at risk and prevent irreversible damage. It is also sometimes effective in localizing anatomic structures. Auditory, visual, motor, and somatosensory stimuli are commonly used for clinical EP studies during surgical procedures. Attempting to preserve neural function with EPs can be daunting. Once the basic science of measurement is understood, interpretation and diagnosis can be challenging, owing to harsh operating room environments. Injuries to neural structures can arise from heat (electrocautery), mechanical stress (retraction), ischemia (ligation and vessel damage), and loss of functional integrity (transection). Some if not most nerves encountered during surgical procedures lack perineurium, which protects against longitudinal retraction, and epineurium, which protects against retraction. The "elastic limit" of such nerves is around 20%, suggesting that stretching the nerve farther may produce irreversible damage to the nerve itself.[47] Evoked potentials also can be affected by hypothermia, hypotension, positioning, and anesthetic agents themselves. These systemic effects usually develop slowly and show more potential to be reversible defects rather than permanent.

It is important to remember that some injuries may be reversible, but early detection is the key to reducing more serious complications. Early detection must then be paired with good communication among the anesthesia provider, surgeon, and neurophysiologist. Adequate understanding of EPs is essential if anesthesia providers are to have productive dialogue to guide care for

TABLE 18-2 Effects of Inhalation Anesthetics on EEG

Inhalation Agent	Low-Dose Inhalation Anesthesia	Moderate-Dose Inhalation Anesthesia	High-Dose Inhalation Anesthesia	EEG Amplitude	Dose for Burst Suppression
Desflurane	<Alpha waves >Beta waves	>Beta waves	Diffuse delta and theta	↑Low dose ↑Anesthetic dose ↑ or 0 High dose	>1.2 MAC
Isoflurane	<Alpha waves >Beta waves	>Beta waves	Diffuse delta and theta	↑Low dose ↑Anesthetic dose ↑ or 0 High dose	>1.5 MAC
Sevoflurane	<Alpha waves >Beta waves	>Beta waves	Diffuse delta and theta	↑Low dose ↑Anesthetic dose ↑ or 0 High dose	>1.2
Nitrous oxide (alone)	>Beta waves	>Beta waves	>Beta waves	↑Low dose ↑Anesthetic dose ↑ High dose	Not seen in clinical concentrations

↑, Increase; *0*, no effect; *MAC*, minimum alveolar concentration; *EEG*, electroencephalogram.

the patient. There currently is no set standard for the amount of change in latency or amplitude that necessitates warning the surgeon. A rule of thumb offered by several sources states that a 50% decrease in amplitude or a 10% decrease in latency should exist before a warning is needed.[42] A better plan of care would be to ask the surgeon and neurophysiologist prior to surgery what they deem an acceptable amount of change in the EP before warning.

One important question all anesthesia providers should ask is this: What are the best anesthetic agents to use for surgical procedures when using evoked potentials? A fine balance must be established between adequately anesthetizing patients while at the same time optimizing conditions that monitor neurologic structures and preserve them. Each different type of EP has a unique interaction with the anesthetics delivered. However, there are some generic rules to help guide the clinician. The first rule is that lipophilic agents that interfere with neuronal membrane conduction also interfere with subcortical conduction. Therefore these agents cause an increase in both interpeak latencies and control conduction time. The second rule is that anesthetic agents that interfere with EEG also interfere with EP. Changes occur because the component frequencies of the EP are the same as the EEG. Lastly, intravenous agents, at equipotent doses to inhalation agents, will have less effect than inhaled agents. However, when combinations of drugs are used for anesthesia, like those used in balanced anesthesia techniques, they too can have additive effects.

Somatosensory Evoked Potentials

Somatosensory evoked potentials (SSEPs) are used to monitor a number of neural structures along both the peripheral and central somatosensory pathways. Stimulation for SSEPs is created by stimulating peripheral nerves electrically. These stimulations can be induced through mechanical devices, but electrical stimulation gives a more robust response and may be better controlled. A supermaximal electrical stimulation is not required to elicit a response from the nerve. SSEPs are usually induced by stimulation of a peripheral nerve, which contains both a sensory and motor component combining to provide a mixed signal. Typically, the lower extremities can be monitored by stimulating the posterior tibial nerve located between the Achilles tendon and medial malleolus of the ankle. The upper extremities are monitored by placing the stimulus at the median nerve located between the tendons of the flexor carpi radialis and the palmaris longus. If these common sites cannot be accessed, two alternate sites are the common peroneal in the popliteal fossa (may be used for the lower extremity) and the ulnar nerve (either at the wrist or ulnar notch) for the upper extremities.

Recording electrodes used for SSEPs are placed at C2, C3, and C4, referencing to F2 of the montage for cortical SSEPs. An electrode placed over cervical spine C7 is used for subcortical SSEPs. For upper limb SSEP studies, electrodes are placed over Erb's point both ipsilateral and contralateral to the stimulus. Erb's point is located on the side of the neck, 2 to 3 cm above the clavicle and in front of the transverse process of the sixth cervical vertebra. Pressure over this point elicits the Duchenne-Erb paralysis, and electrical stimulation over this area elicits various potentials measured in the arm. For lower limb studies, the electrode is placed at the iliac crest. Several different characteristics of SSEPs can be measured. Peak latencies are the easiest to measure and standardize, but like other characteristics, they can vary with age, tissue mass, electrical stimulus, and limb length. Spinal SSEP electrodes are placed over the spinal cord. SSEPs usually are *processed* signals, meaning they are processed as an average, with electrical filters to remove background noise, instead of providing real-time electrical waveforms. Interpretation of the compound action potential depends on the site of stimulus and distance to the recording electrodes.

Almost all anesthetic agents produce change in latency or amplitude, with the exception of ketamine, etomidate, and opiates.[48] Anesthesia and SSEPs provide a challenge for the anesthetist; the less anesthesia one administers, the better the SSEP monitoring results. Many researchers report that better monitoring conditions for SSEPs are obtained with narcotic-based anesthetics, less than 1 MAC (minimum alveolar concentration) total end-tidal inhaled concentration of inhalation agent, and nitrous oxide. If monitoring SSEPs alone, use of paralytic agents is acceptable, and potentials can be measured. However, in the absence of paralytics, motor responses can be elicited, and the nurse anesthetist needs to make sure that adequate anesthesia is provided for the operative procedure to prevent recall and extreme catecholamine responses.

Although sometimes limited in their evaluation of neurologic diseases, the value of SSEPs in the operative setting is high.[49] Because changes in SSEPs are sensitive to cerebral ischemia, they have multiple uses in vascular surgery. During carotid endarterectomy procedures, SSEPs can help determine the need for shunting intraoperatively. If changes are immediate, SSEPs can indicate high-risk or neurologic injury during aortic cross-clamping. During cerebral aneurysm surgery, changes in SSEPs can possibly indicate occlusion of parental vessels, directing the positioning of important aneurismal vascular clips.

Brainstem Auditory Evoked Potentials

Brainstem auditory evoked potentials (BAEPs) are used to monitor the entire auditory pathway from the distal auditory nerve to the midbrain, inadvertently allowing monitoring of basic brainstem function. The stimulus used is typically a standard broadband repeating click. Repetition is generally around 10 Hz, and the intensity is around 65 to 70 decibels (dB) above the click-perception threshold. The stimulus is delivered via earphone. Because an external earphone is impractical, an earphone placed in the auditory canal, or "insert earphone," is used. For best results, care must be taken (1) to place the transducer after the head is positioned so as not to cause abrasive injury to the ear canal and (2) that the internal auditory canal is free of any built-up cerumen or fluid. Such things as fluid, saline, cerebrospinal fluid, and soap can dampen or change the sound and delay responses. Recording electrodes are determined by the type of evoked BAEPs performed on the patient. There are several common evoked responses used as BAEPs that will be discussed further.

Brainstem auditory evoked potentials have five main peaks represented by roman numerals (Figure 18-4). Peak I relates to the peripheral portion of the cochlear nerve inside the internal auditory canal. Peak II relates to the cochlear nucleus and the area where the eighth cranial nerve enters the brainstem. Peak III correlates to the area of the brainstem at the level of the cochlear nucleus and potentially the ipsilateral superior olivary nucleus. Peaks IV and V relate to the brainstem along the ascending auditory pathway between the cochlear nucleus and the inferior colliculi. Measured peaks must be compared with relative norms for age, sex, intensity, polarity, and repetition rate.

Brainstem auditory evoked potentials are clinically useful in that they are very resistant to alteration by anything other than structural pathology in the brainstem. This means that BAEPs are not significantly affected by barbiturates, benzodiazepines, ketamine, nitrous oxide, propofol, or muscle relaxants. There is one reported case of abolishment of the wave with the use of lidocaine infusion.[50,51] However, inhalation agents can mildly affect BAEPs'

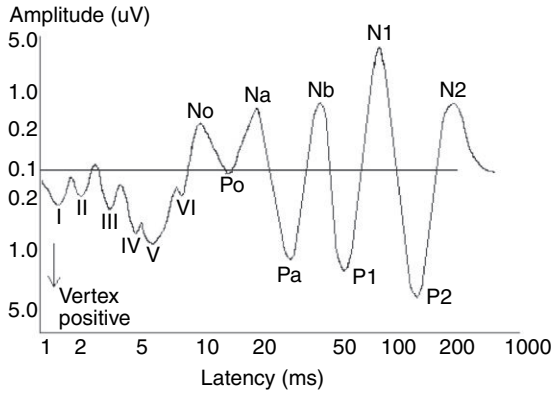

FIGURE **18-4** Auditory evoked potentials—common labeled potentials *(Roman numerals)* that can be measured to assess different areas of the auditory and brainstem pathways. Peak I relates to the peripheral portion of the cochlear nerve inside the internal auditory canal. Peak II relates to the cochlear nucleus and the area where the 8th cranial nerve enters the brainstem. Peak III correlates to the area of the brainstem at the level of the cochlear nucleus and potentially the ipsilateral superior olivary nucleus. Peaks IV and V relate to the brainstem along the ascending auditory pathway between the cochlear nucleus and the inferior colliculi. Peak VI relates to the medial geniculate body and VII (not shown) relates to auditory radiations. (Modified from Barlow HB, Mollon JD. *The Senses*. Cambridge, England: Cambridge University Press; 1982.)

latency and amplitude, and their effect is proportional to the dose of inhalation agent administered.[50]

A common effect on BAEP during anesthesia and in the operating room environment is hypothermia. Even mild hypothermia (patient temperature less than 35° C) has been associated with decreased latency and prolonged interpeak intervals during BAEP.[52] BAEPS can also be exaggerated, as demonstrated by an increase in latency with low P_{CO_2} seen during hyperventilation.[42]

The auditory nerve can be directly monitored during the surgical procedure by the surgeon. The monitoring electrode is placed on the nerve itself after surgical exposure, and its response is measured as an *auditory nerve compound action potential* (AN-CAP). When the eighth nerve is involved, the AN-CAP is referred to as the *eighth nerve potential* (8NP). The AN-CAP, like the BAEP, can be used to determine auditory nerve insult or injury.

For auditory brainstem responses (ABRs), the noninverting (positive) electrode is placed at C2 or high on the forehead. The inverting (negative) electrode is typically placed on the mastoid or earlobe. However, if neither of these sites is practical, owing to surgical exposure, then the tragus of the ear may be used as an alternate site.

Electrocochleography (ECochG) is a specific test used to provide information about the cochlea and the distal section of the auditory nerve. It is typically used to evaluate and/or verify blood supply to the cochlea. The measure itself is called the *ECochG-CAP*. The inverting electrode is placed near the cochlea, tympanic membrane, or the cochlear promontory. The noninverting electrode is placed on the opposite ear.

Otoacoustic emissions (OAEs) are sometimes used, but this test is not an evoked potential. Because a stimulus is not used, there is only a recording device. No stimulus is required because the normal cochlea does not just receive sound but can produce low-intensity sounds called *OAEs*, produced specifically by the cochlea and most probably by the cochlear outer hair cells as they expand and contract. These sound transmissions can be recorded; they are typically used to assess auditory hair-cell function and not internal structure of the ear.

Motor Evoked Potentials and Electromyography

Motor evoked potentials (MEPs) are used to monitor the functional integrity of motor tracts, particularly in the corticospinal tract. Stimuli used for MEPs can be either electrical or magnetic. Either the motor cortex or spinal cord can be used for sites of stimulation. Magnetic stimulation of the motor cortex can be accomplished using a rapidly changing magnetic field (compared with a constant field from magnetic resonance imaging [MRI]). Based on the Faraday law, electrical current is created in a nearby conductor, generating the stimulus. Although useful, magnetic stimulation is cumbersome in the operating room because of the interference of magnetic fields with other operating-room equipment, as well as the size and position of equipment during the procedure. Magnetic stimulation also generates intense heat that needs to dissipate to safe levels and therefore can prolong procedures. Magnetic fields also produce a high-intensity noise, however brief, so ear protection is recommended. Contact with magnetic stimulation is contraindicated in patients with pacemakers, spinal or bladder stimulators, epilepsy, metallic foreign body, or previous craniotomy. Direct stimulation of the motor cortex may also be produced by cutaneous electrodes on the scalp or electrodes placed directly on the brain after surgical exposure. Electrical stimulation is more commonly used for spine cases.

Potentials are recorded as neurogenic potentials in the distal spinal cord or peripheral nerve. They also can be recorded as myogenic potentials of innervated muscle. While SSEP can assess the dorsal column (fasciculus cuneatus and gracilis) and the lateral sensory tract of the spinal cord, it also can make assumptions on changes in anterior motor tracts because the stimulation is a mixed nerve (motor and sensory) signal. However, because they are not directly measured, motor deficits have been seen in spinal cord cases in which SSEPs have been normal. Advances in technology and the refinement of methodologies are significantly changing intraoperative neurophysiologic monitoring of the spinal cord. The clinical application of spinal D wave and muscle MEP recordings is becoming standard in many procedures. D wave changes have proven to be the strongest predictors of maintained corticospinal tract integrity and therefore of motor function/recovery. Combining the use of muscle MEPs with D wave recordings provides the most comprehensive approach for assessing the functional integrity of the spinal cord motor tracts during select surgeries. MEPs are now considered the gold standard for monitoring the motor pathways; SSEPs continue to be valuable for assessing the integrity of the dorsal column. Multimodal monitoring combining SSEP and MEP monitoring is rapidly approaching the standard for spinal surgery.[53]

Stimulation and monitoring of motor components of nerves are important in the operating room, but they require an active stimulus to produce an action potential. Electromyography (EMG) can be both passive and active. EMG has the capability to stimulate a motor nerve and monitor the known innervated muscle groups, as well as passively "listen" to all muscle groups. The ability to passively monitor nerves allows the surgeon to become more aware of what nerve is being stimulated with surgical manipulation.

EMG analysis of the facial nerve for related surgeries has been used and researched extensively. Other cranial nerves can and have been used for monitoring purposes as well. Monitoring needle electrodes are typically placed in the orbicularis oculi and the orbicularis oris muscles. To assess the cervicofacial and temporofacial divisions of the facial nerve as it divides from the posterior aspect of the parotid gland, both of these muscles require monitoring. Frequency and density of discharges elucidate the type of damage to the actual nerve. Simple benign contact with the nerve causes few random discharges. A response train is associated with more significant

TABLE 18-3 Monitoring of Cranial Nerves

Cranial Nerve		Monitoring Site or Method*
I	Olfactory	No monitoring technique
II	Optic	Visual evoked potentials
III	Oculomotor	Inferior rectus muscle
IV	Trochlear	Superior oblique muscle
V	Trigeminal	Masseter muscle and/or temporalis muscle (sensory responses can also be monitored)
VI	Abducens	Lateral rectus muscle
VII	Facial	Orbicularis oculi and/or orbicularis oris muscles
VIII	Auditory	Auditory brainstem responses
IX	Glossopharyngeal	Stylopharyngeus muscle (posterior soft palate)
X	Vagus	Vocal folds, cricothyroid muscle
XI	Spinal accessory	Sternocleidomastoid and/or trapezius muscles
XII	Hypoglossal	Genioglossus muscle (tongue)

From Sloan, et al. Evoked potentials. In Cottrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia*. 5th ed. Philadelphia: Mosby; 2010:115-130.
*Unless otherwise specified, monitoring is performed via electromyographic activity of the muscle(s) listed.

TABLE 18-4 Nerve Roots and Muscles Most Commonly Monitored

Spinal Cord Nerve(s)		Muscle(s)
Cervical	C2-C4	Trapezoids, sternocleidomastoid
	C5, C6	Biceps, deltoid
	C6, C7	Flexor carpi radialis
Thoracic	C8-T 1	Adductor pollicis brevis, abductor digiti minimi
	T5-T6	Upper rectus abdominis
	T7-T8	Middle rectus abdominis
	T9-T11	Lower rectus abdominis
	T12	Inferior rectus abdominis
Lumbar	L2	Adductor longus

nerve irritation. Neurotonic discharges are associated with nerve irritation, as well as impending nerve damage. Elimination of environmental factors should be considered prior to diagnosing nerve damage. Trains of stimulation also can be caused by thermal changes (electrocautery or cold irrigation), drilling, traction, and/or nerve ischemia. The choice of anesthesia is essentially unrestricted, with the exception of avoiding paralytic agents. Additionally, the efficacy of partial paralysis has not been studied extensively. Monitoring methods for cranial and spinal nerves are shown in Tables 18-3 and 18-4.

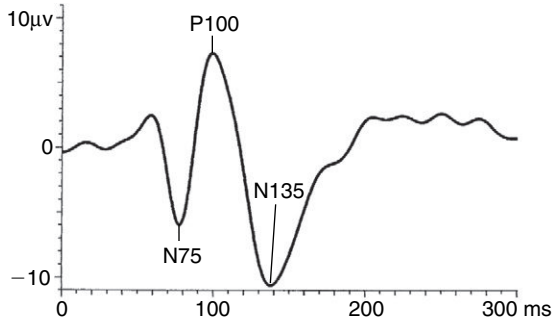

FIGURE **18-5** Pattern reversal visual evoked potentials. The three peaks that characterize the potential and are subsequently measured are denoted as *N75*, *P100*, and *N135*. (Adapted from Odom J, et al. Visual evoked potentials standard. *Doc Ophthalmol*. 2004; 108:115-123.)

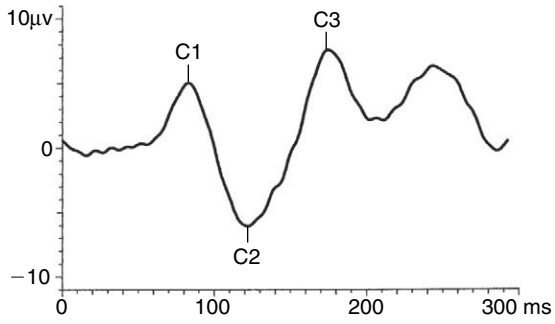

FIGURE **18-6** Pattern onset/offset visual evoked potential. The three peaks that characterize the potential and are subsequently measured are denoted as *C1*, *C2*, and *C3*. (Adapted from Odom J, et al. Visual evoked potentials standard. *Doc Ophthalmol*. 2004;108:115-123.)

Visual Evoked Potentials

Visual evoked potentials (VEPs) are used to monitor the function of the visual pathway, which comprises the retina to the occipital cortex and everything in between, including the optic nerve and optic chiasm. A visual stimulus is presented to the subject for a selected number of times, and the cerebral responses are amplified, averaged by a computer, and displayed. The two major classes of VEP stimulation are patterned and unpatterned (luminance). Typically, awake tests consist of a pattern stimulus. The two most common pattern stimuli are pattern reversal and pattern onset/offset stimuli. Pattern reversal stimulus consists of black-and-white checks (checkerboard) that change phase (same luminescence) at a predetermined number of reversals per second (Figure 18-5). Pattern onset/offset stimulus consists of a black-and-white checkerboard that exchanges with a diffuse background with the same luminescence (Figure 18-6).

Because such stimulation cannot be used in conjunction with anesthesia or even sedation, a stroboscopic flash (luminescence) stimulus must be used in such cases. The flash VEP is created from a flash that has a predetermined strength against a dim background of certain luminance. Recording electrodes are fixed to the scalp and, as always, placed relative to bony landmarks. The active electrode is placed on the scalp over the visual cortex at Oz, with the reference electrode at Fz. The ground electrode can be placed at the forehead, vertex (Cz), mastoid, earlobe (A1or A2), or linked earlobes.

Monocular stimulation is typically used to avoid masking of unilateral conduction abnormality. Care should be taken to ensure

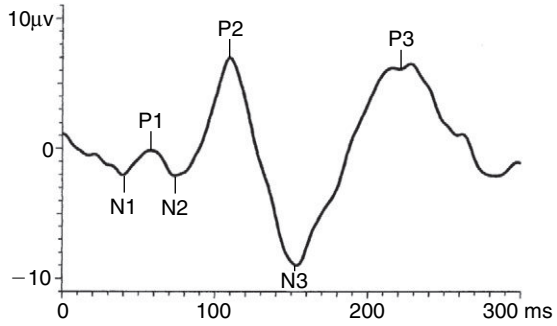

FIGURE **18-7** Flash visual evoked potential. The three positive deflections that characterize the potential and are subsequently measured are denoted as *P1*, *P2*, and *P3*. The three negative deflections that characterize the potential and are subsequently measured are denoted as *N1*, *N2*, and *N3*. (Adapted from Odom J, et al. Visual evoked potentials standard. *Doc Ophthalmol*. 2004;108:115-123.)

that no light enters the eye not being stimulated. Closure with a patch and tape are usually sufficient to block light. Close assessment must be made of the eyes preoperatively and should be noted in the record because they may affect recorded outcomes. Examples of such consideration include extreme pupil size or anisocoria (inequality of pupil diameter). Pupils do not need to be dilated for flash VEPs, and the cornea may need to be carefully moistened from time to time to prevent the cornea from drying. Mydriatics and miotics should not be used with awake tests. It is also important to compare VEPs with appropriate age- and sex-related normal values.

The action potential of VEPs varies, depending on the type of stimulus used. Flash VEPs consist of a series of negative and positive waves, with the earliest detectable response occurring around 30 ms post-stimulus. For flash VEP, the N2 and P2 peaks are the most robust components, peaking around 90 and 120 ms, respectively (Figure 18-7). Unfortunately, flash VEPs are more variable between subjects than between pattern responses. Some question the usefulness of intraoperative VEPs because in anesthetized patients, stable recording was either not obtainable or not consistent across subjects.[54,55] Indications for monitoring evoked potentials are noted in Box 18-2.

SUMMARY

The use of neurologic monitors does not guarantee prevention of neurologic injury. However, the use of neurologic monitors adds one more tool to aid the nurse anesthetist in patient assessment. Several factors contribute to intraoperative EEG changes, making the monitoring device more challenging to interpret. Some of these factors include hypothermia, hyperthermia, volatile and intravenous anesthetic agents, surgical intervention, previous neurologic injury, and excessive auditory and visual stimulation. Providing anesthesia for neurologic surgical procedures requires knowledge in both basic and advanced anesthesia techniques. The anesthetist should not only use all the usual techniques for safe anesthesia practice but also many times must apply these principles while being at a distance from the airway, particularly in cranial cases. Postoperative neurologic changes can occur, so continued monitoring is essential to reduce the incidence of preventable permanent changes. Cooperation and communication between the surgeon and the nurse anesthetist remains a vital key for safe neurologic monitoring and surgical outcomes.

BOX 18-2

Indications for Monitoring Evoked Potentials

- Spinal fusion/deformity surgery (e.g., tethered cord surgery, scoliosis repair, meningomyelocele surgery)
- Spinal instrumentation or hardware placement (e.g., pedicle screws, rods)
- Spinal tumor resection
- Spinal trauma/fracture repair
- Spinal vascular surgery
- Plexus surgery
- Peripheral nerve surgery
- Thoracoabdominal aortic aneurysm surgery
- Epilepsy surgery
- Brainstem or posterior fossa surgery
- Aneurysm repair
- Aortic cross-clamping
- Carotid endarterectomy
- Cerebral tumor resection
- Cortical mapping and/or regional cortical function
- Probe localization during stereotactic neurosurgery
- Facial nerve monitoring during acoustic neuroma resection

Preoperative Evaluation and Preparation of the Patient

CHAPTER 19

◆ *Rex A. Marley, Troy Calabrese, and Kimberly J. Thompson*

A crucial element of the perioperative care of the patient includes a timely and thorough preoperative assessment. A fine-tuned approach to patient evaluation then enables appropriate interventions when required to properly prepare the patient for the upcoming anesthesia and surgery. For any patient scheduled to undergo anesthesia, preoperative evaluation is compulsory to help identify factors that increase the risk associated with anesthesia and the status of the patient relative to the proposed surgery. Essential goals of preoperative assessment and preparation of the patient include the following:

- Optimize patient care, satisfaction, comfort, and convenience.
- Minimize perioperative morbidity and mortality by accurately assessing factors that influence the risk of anesthesia or might alter the planned anesthetic technique.
- Minimize surgical delays or preventable cancellations on the day of surgery.
- Determine appropriate postoperative disposition of the patient (i.e., given the patient's status, whether the procedure is best performed on an ambulatory, inpatient, or intensive care basis).
- Evaluate the patient's overall health status, determining which if any preoperative investigations and specialty consultations are required.
- Formulate a plan for the most appropriate perianesthetic care and postoperative supportive patient care.
- Communicate patient management issues effectively among care providers.
- Educate patient regarding surgery, anesthesia, and expected intra- and postoperative care, including postoperative pain treatments, to reduce patient anxiety and increase patient satisfaction.
- Ensure time-efficient and cost-effective patient evaluation.

During the preoperative visit, patient assessment begins with a thorough review of the patient's medical records and patient interview, followed by the physical examination. A comprehensive medical history and physical examination are the cornerstones of a systematic approach to continued patient preparation. Information gathered from this evaluative process guides further individualized assessment (e.g., obtaining diagnostic tests, specialist consultation). The extent of this preoperative workup depends on the existing medical condition of the patient, the proposed surgical procedure, and the type of anesthesia. Significant findings from this initial evaluation enable the anesthesia provider to make adjustments in the patient's care (i.e., initiate specific treatment modalities to optimize the patient's condition for the proposed surgery and anesthesia).

Important strategies for achieving high-quality, cost-effective patient evaluation include the following[1]:

- Educating the practitioner (e.g., regarding the cost of diagnostic tests) and thereby modifying practice patterns
- Developing and implementing evidence-based practice guidelines
- Using clinical pathways (interdepartmental teamwork required)
- Disseminating information regarding protocols, thereby avoiding duplication of services
- Performing economic analyses of services, including cost-effectiveness, and cost-benefit studies
- Rendering efficient resource management
- Providing for outcomes measurement

PREANESTHESIA ASSESSMENT CLINIC

The preanesthesia assessment clinic has emerged as the most effective means of providing convenient "one-stop shopping" designed to (1) permit patient registration, (2) obtain a medical history and perform a physical examination, (3) promote patient teaching, (4) meet or schedule appointments with medical consultants, and (5) complete any required preoperative diagnostic testing. Successful preanesthesia assessment clinics have realized a reduction in patient anxiety, direct cost, last-minute surgical cancellations, overall length of hospitalization after surgery, and diagnostic testing, as well as improvement in patient education and a shift from inpatient to outpatient surgery status.[2] The preanesthesia assessment clinic allows patients scheduled for elective surgery to be evaluated and their condition optimized sufficiently in advance of the surgery.

Timing of Patient Assessment

To allow ample time for necessary risk assessment, preoperative testing, and specialty consultations, ideal preoperative assessment for surgery and anesthesia should take place well in advance of the proposed surgery. Patients with complex medical conditions should be evaluated at least 1 week before the scheduled procedure. Because of the present economic realities, patients undergoing more complex procedures and those who have complicated medical conditions (Box 19-1)[3] are frequently not admitted to the hospital before the day of surgery. Preoperative evaluation on the day of surgery can result in last-minute discoveries (e.g., of inappropriate fasting, suspected difficult airway, preexisting medical condition) that may result in surgical delay or cancellation. The timing of the preanesthesia assessment does not appear to influence outcome of anesthesia.[4] In one study, no difference in the cancellation rate for ambulatory patients was observed between groups seen within 24 hours and groups seen within 1 to 30 days of the scheduled surgery.[5] Governmental requirements may mandate that the preanesthesia evaluation be completed and documented by a qualified anesthesia practitioner within 48 hours prior to surgery.[6] This focused evaluation must be performed by a practitioner qualified to administer anesthesia.

BOX **19-1**

Conditions That Would Benefit from Early Preoperative Evaluation

General
- Medical conditions inhibiting ability to engage in normal daily activity
- Medical conditions necessitating continual assistance or monitoring at home within the past 6 months
- Admission within the past 2 months for acute episodes or exacerbation of chronic condition
- Use of medications (e.g., anticoagulants or monoamine oxidase inhibitors) for which modification of schedule or dosage might be required

Cardiocirculatory
- History of angina, coronary artery disease, myocardial infarction, symptomatic arrhythmias
- History of cardiac rhythm device in case device interrogation or reprogramming by appropriate personnel will be necessary
- Poorly controlled hypertension (diastolic greater than 110 mmHg, systolic greater than 160 mmHg)
- History of congestive heart failure

Respiratory
- Asthma or chronic obstructive pulmonary disease that requires chronic medication; acute exacerbation and progression of these diseases within the past 6 months
- History of major airway surgery, unusual airway anatomy, or upper or lower airway tumor or obstruction
- History of chronic respiratory distress requiring home ventilatory assistance or monitoring

Endocrinologic
- Diabetes treated with insulin or oral hypoglycemic agents (unable to control with diet alone)
- Adrenal disorders
- Active thyroid disease

Hepatic
- Active hepatobiliary disease or compromise

Musculoskeletal
- Kyphosis or scoliosis causing functional compromise
- Temporomandibular joint disorder with restricted mobility
- Cervical or thoracic spine injury

Oncologic
- Patients receiving chemotherapy
- Other oncologic process with significant physiologic residua or compromise

Gastrointestinal
- Morbid obesity (greater than 140% ideal body weight)
- Hiatal hernia
- Symptomatic gastroesophageal reflux

Modified from Barash PG (ed). *ASA Refresher Courses in Anesthesiology.* Vol 24. Philadelphia: Lippincott, Williams, & Wilkins; 1996.

CHART REVIEW

To provide the basis for and direction of the patient interview and physical assessment, the patient's past and current medical records should be reviewed preoperatively. Ideally the anesthesia provider will have the opportunity to review the patient's medical records before the interview with the patient or caregiver.

Past Medical Records

For a patient who has undergone surgery at the same institution in the past, previous anesthesia records should be retrieved and reviewed, especially if complications are suspected. If past medical records are not available, the patient must provide details of significant anesthetic experiences. If this information suggests that the patient has an unusual condition (e.g., atypical plasma cholinesterase, susceptibility to malignant hyperthermia), surgery may be delayed so that medical records can be obtained for review to provide further information that might affect patient care, or measures should be taken (e.g., avoidance of succinylcholine; provision of trigger-free anesthetic technique) to avoid consequences associated with the condition.

Patient Chart or Electronic Medical Record

A review of the current medical record includes verifying that the surgical and anesthesia consents are accurate and complete. The names of the patient and surgeon, the date, and the proposed procedure should be matched with those on the operating room schedule. Demographic or baseline data, such as the age, height, and weight of the patient, can often be obtained from the admitting record. Vital-sign trends and input-output totals are transcribed from graphic flow sheets, which may also contain pertinent data (e.g., daily blood glucose values for the diabetic patient).

Progress notes and consultation reports provide a valuable overview of the health history and physical status of the patient. Medical treatments, such as drug dosages and schedules, may be derived from these materials, but diagnostic test results should be obtained directly from their original sources. This retrieval of primary data prevents the possible misinterpretation of data that were transcribed incorrectly. Knowledge gleaned from a review of progress notes and consultative reports enables the anesthesia provider to formulate supplementary questioning, seek further specialist consultations, or obtain additional diagnostic testing as needed.

Baseline data concerning the patient, such as cultural diversity, coping mechanisms, or patient limitations (e.g., hearing impairment), can often be derived from nursing notes and can effectively guide the anesthesia provider in conducting a thorough preoperative interview. Increasingly the anesthetist must be able to appropriately interact with culturally diverse populations to properly evaluate and educate patients.

A preanesthesia questionnaire is included on the patient's chart (Figure 19-1). This questionnaire should be part of the admission paperwork to be completed by the patient or the patient's caregiver and consists of a concise checklist regarding the patient's health history and medical care. When properly completed and readily available on the chart, the preanesthesia questionnaire enables the anesthesia provider's visit with the patient to be accomplished more efficiently. Interview questions and physical assessment are appropriately directed toward abnormal findings and areas of concern.

PATIENT INTERVIEW

The preoperative interview may be conducted in person or by telephone. The in-person patient interview is preferred, but for

FIGURE **19-1, cont'd** Preanesthesia questionnaire.

patients who are unable to visit the hospital setting (e.g., who live far from the hospital or have transportation constraints), an opportunity to participate in a telephone interview should be made available. Regardless of the location or approach used, the interview promotes a trusting relationship between the patient and anesthesia provider. When the interview is performed in a caring and unhurried manner, the patient's degree of trust and confidence in anesthesia care is enhanced. Furthermore, compliance with perioperative instructions is increased when the patient is treated with respect; an example of such respect is using the surname (Mr. Smith, Mrs. Jones) unless instructed differently by the patient.

The title of the anesthesia provider and his or her specific role in the patient's perioperative care should also be defined. The patient is entitled to know whether the interviewer is a Certified Registered Nurse Anesthetist, student registered nurse anesthetist, anesthesiologist, or medical resident in anesthesiology. The professional appearance and attitude of the anesthesia provider also can create a positive impression during the preoperative visit.

The environment of the preoperative interview should be staged to maximize the quality and effectiveness of the interaction. Adequate lighting enhances effective communication with the patient. Distractions such as an operating television set can be eliminated. The anesthesia provider should ensure that the time and location of the interview, whether it occurs in person or by telephone, are convenient and private for the patient. A return visit or call may be necessary if the patient is eating or receiving medical therapy.

Because the preoperative interview is a private interaction between the patient and the anesthesia provider, a tactful request that visitors remain outside the interview area, unless the patient wishes family members to be present, will be necessary. Otherwise, the patient may not volunteer confidential health information, such as a history of substance abuse or sexual history. In certain

situations, however, assistance from a family member or caregiver is required. The health history may be provided, for example, by the parent of a pediatric patient or by an interpreter for a patient with cognitive or language barriers.

The patient interview is designed to achieve specific objectives (Box 19-2).[7] The interview process, along with patient education, yields beneficial consequences of reduced patient anxiety and increased patient satisfaction. A valuable step in preparing the patient or responsible caregivers (e.g., family members, legal guardian) for the scheduled surgery includes an educational process during which the staff counsels the patient concerning fundamental perioperative issues (Box 19-3).[7] Reinforcing information to the patient verbally and in writing is essential to gaining patient compliance. Coordinating the patient's visit to the preanesthesia assessment clinic to include educational time is ideal for the patient.

Medical History

The extent of a patient's health history depends partly on the amount of information available in the chart before surgery. If the surgeon has already documented a thorough medical history and physical examination, the interview can focus on confirming major findings and obtaining information that directly relates to the anesthetic management of the patient. The anesthesia provider must obtain and document a detailed health history, however, if the history is unavailable in the chart during the preoperative visit.

The health history should be obtained in an organized and systematic way, as with the preanesthesia questionnaire, to minimize possible omission of important data. Open-ended and direct questions targeting each category of the checklist can be posed. With this approach, more detailed and graded responses are elicited from the patient. To avoid overwhelming or confusing a patient, questions are asked separately and formulated in comprehensible or layperson's terms.

Surgical History

The surgical history of a patient may be learned from the chart or preoperative interview. Most patients only vaguely recall surgical experiences, even from childhood operations. Information regarding complications related to previous operations, such as a peripheral nerve injury or uncontrolled blood loss, should be elicited to determine the need for further investigation.

Anesthetic History

Past anesthetic experiences are often not as easily defined as the surgical history. It is vitally important to determine the reaction of a patient to previously administered anesthetics. Adverse reactions to anesthetic agents and techniques (e.g., prolonged vomiting, difficult airway, malignant hyperthermia, postoperative delirium, anaphylaxis, and cardiopulmonary collapse) may have simply been an annoyance to the patient or could have been life threatening. Preoperative knowledge of these complications allows the anesthetic approach to be modified and the recurrence of the complication thereby prevented. Causative factors are also thoroughly investigated in patients who note that a previous operation was aborted. Difficulties with airway management can alter the approach to endotracheal intubation, if indicated. Vague reports of fever and convulsions merit further investigation to rule out an episode of malignant hyperthermia.

Familial Anesthetic History

Numerous inherited diseases involving metabolic derangements may affect a patient's reaction to stress and certain drugs, including anesthetic agents. The patient is specifically asked whether any family member ever experienced an adverse reaction to anesthesia during surgery. Familial tendencies for diseases such as atypical plasma cholinesterase, malignant hyperthermia, porphyria, or glycogen storage diseases (e.g., glucose-6-phosphate dehydrogenase deficiency) are then investigated. A diagnosis should be established before the surgery proceeds, because adjustments in the anesthetic management of the patient may be required.

Drug History

A preoperative drug history provides an excellent guide for the direction and depth of the patient interview and assessment. Drug

BOX 19-2

Objectives of the Preoperative Interview

- Ensure that the goals of preoperative assessment are met.
- Provide preoperative education to the patient and family.
- Obtain written documentation of informed and witnessed consent.
- Acquaint the patient and family with the surgical process (to reduce stress and increase familiarity).
- Evaluate the patient's social situation with respect to surgery (e.g., support network).
- Motivate the patient to comply with preventive care strategies (e.g., smoking cessation, improvement of cardiovascular fitness).

Modified from Cassidy J, Marley RA. Preoperative assessment of the ambulatory patient. *J Perianesth Nurs*. 1996;11(5):334-343.

BOX 19-3

Patient Education Objectives

- Promote interactive communication between patient and care provider.
- Encourage patient participation in making decisions about perioperative care.
- Maximize and enhance patient self-care skills and participation in continuing care during the postoperative phase.
- Increase the patient's ability to cope with his or her health status.
- Increase patient compliance with perioperative care.
- Provide individualized preoperative instructions regarding the following:
  - Where and when laboratory tests, consultations, and diagnostic procedures will be completed
  - Appropriate time at which the patient should cease ingestion of food and drink
  - Personal considerations (e.g., comfortable clothes to wear; no jewelry or makeup; what personal items to bring; leave valuables at home; bring favorite toy, comforter, or book)
  - Postoperative considerations and instructions (e.g., anticipated recovery course, discharge instructions, how to deal with complications)
  - Person to contact if the patient's physical condition changes (e.g., upper respiratory tract infection, cancellation)
- Detail the process of arrival and registration on arrival to the surgical facility (i.e., time and location of arrival).
- Review advance directive information as required by law in some states.
- Explain the surgical facility policies to the patient and family.

Modified from Cassidy J, Marley RA. Preoperative assessment of the ambulatory patient. *J Perianesth Nurs*. 1996;11(5):334-343.

dosages, schedules, and durations of treatment are reviewed and the patient questioned about the purpose and effectiveness of these medications. An interview with a patient receiving β-adrenergic blockers, for example, can focus in greater detail on the cardiovascular system. Patients on medications for hypertension or angina pectoris require further investigation and possibly specialty consultation if they have not been recently evaluated.

Adverse Drug Effects and Interactions. During the preoperative evaluation, current drug therapy must be carefully reviewed for side effects and potential interactions with anesthetic agents. Table 19-1 lists selected drugs and their potential anesthetic interactions.[4,8-17] One drug-management strategy is to discontinue particular drugs preoperatively in the hope of reducing the potential for adverse interactions. The therapeutic benefits of these drugs

TABLE 19-1 Potential Drug Interactions Affecting Perianesthesia Care

	PERIANESTHESIA CONCERN		
Drug Category	**Intraoperative Concerns**	**Management**	**Discontinuation Issues**
Drugs Affecting the Cardiovascular System			
Angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers	Hypotension, especially on anesthesia induction, with or without bradycardia; intolerance to hypovolemia; vasoplegic syndrome	Optimize hydration; moderate doses of vasopressor as needed; withhold on morning of surgery if indication for use is for hypertension only, otherwise continuation may improve regional blood flow and oxygen delivery and preserve renal function; consider withholding in patients taking amiodarone, on multiple (three or more) antihypertensives, or in whom even a brief period of hypotension is unacceptable; cautious ambulation after position change; omit AM dose on day of surgery	Increased risk of atrial fibrillation and rebound hypertension if discontinued
β-adrenergic blockers	Hypotension; bradycardia	Optimize hydration; β-adrenergic blockers should be continued in patients undergoing surgery who are receiving β-blockers to treat angina, symptomatic arrhythmias, or hypertension	Discontinuation may increase perioperative cardiovascular morbidity and development of withdrawal symptoms (e.g., increased nervousness, tachycardia, headache, nausea, exacerbation of myocardial ischemia, or sudden death)
Calcium channel blockers	Decrease systemic vascular resistance and blood pressure via peripheral vasodilation; exhibit a negative inotropic effect by slowing sinus automaticity and arterioventricular conductivity; demonstrate a negative chronotropic effect by slowing the sinoatrial and arteriovenous (AV) nodes and prolonging AV nodal conduction	Optimize hydration; phenylephrine as needed to maintain atrial pressure; continue chronic calcium channel blocker therapy preoperatively in patients with normal or slightly impaired heart function; exercise caution in patients with left ventricular dysfunction (ejection fraction <40%)	
Diuretics	Hypokalemia; hypovolemia	Monitor potassium levels preoperatively; maintain hydration; consider need for urinary drainage catheter for moderately long cases	Patients rarely become symptomatic if morning dose withheld; patients appreciate lack of urinary urgency while awaiting surgery; it might be desirable to continue in patients for whom diuretics are part of treatment for chronic renal failure or congestive heart failure
Antiarrhythmics	Cardiac depression; prolonged neuromuscular blockade; amiodarone—hypotension and atropine-resistant bradycardia requiring ventricular pacing	Monitor serum drug levels as needed; amiodarone—large doses of vasopressors or inotropes and pacemaker capability	Discontinuation rarely recommended, because usually not prescribed for benign arrhythmias; amiodarone—impractical to discontinue because half-life is 58 days; withhold concurrent medications (e.g., ACE inhibitors)

Continued

TABLE 19-1 Potential Drug Interactions Affecting Perianesthesia Care—cont'd

	PERIANESTHESIA CONCERN		
Drug Category	**Intraoperative Concerns**	**Management**	**Discontinuation Issues**
Drugs Affecting Hemostasis			
Antiplatelet drugs and nonsteroidal antiinflammatory drugs (NSAIDs)	Increased bleeding; impaired platelet function; altered renal function; gastrointestinal bleeding	Cardiology consultation for patients with coronary stents previously placed less than 1 year ago; continue aspirin perioperatively in patients previously treated; antiplatelet drugs, e.g., clopidogrel (5-7 days), ticlopidine (7-10 days) , should be discontinued prior to high-risk surgery; unless surgery puts patient at particular risk for increased or catastrophic bleeding or impaired renal function, it is reasonable to continue NSAIDs up to morning of surgery; if desirable to discontinue NSAIDs preoperatively, short-acting NSAIDs should be withheld for at least 1 day, longer-acting agents for 2-3 days	Increased risk of blood clot formation and embolism with discontinuation
Anticoagulants (heparin, Coumadin, low-molecular-weight heparins [LMWH])	Increased hemorrhage	Baseline hemoglobin and hematocrit; may reverse heparin with IV protamine; may reverse Coumadin with vitamin K or fresh frozen plasma	Heparin—discontinue IV 6 hr before surgery and check PTT; Coumadin—discontinue 3-5 days (5 days if INR <1.5 is required) before surgery and check INR or PT; LMWH—discontinue 12 hr before surgery
Fibrinolytic drugs (streptokinase, urokinase, tissue plasminogen activator)	Hemorrhage	Antifibrinolytic agent (aprotinin) may be indicated	Discontinuation usually not an option when administered for treatment of life-threatening conditions (e.g., acute myocardial infarction, massive pulmonary embolus)
Hypoglycemic Agents			
Insulin	Hyperglycemia; hypoglycemia	Monitor serum glucose; use insulin-supplementation protocol	Morning dose either withheld or reduced and adjustments in therapy based on periodic serum glucose determinations
Oral hypoglycemic agents	Hyperglycemia; hypoglycemia	Monitor serum glucose; avoid dehydration	Withhold oral hypoglycemic agents beginning on day of surgery
Drugs Affecting the Central Nervous System			
Monoamine oxidase inhibitors (MAOIs)	Hypertension secondary to indirect-acting sympathomimetic drugs causing release of norepinephrine; excitatory state (from meperidine) or depressive phenomena secondary to opioid administration	Avoid known triggering agents such as meperidine (may precipitate seizure and hypertensive crisis), pentazocine, dextromethorphan, anticholinergics, and indirect-acting sympathomimetic agents (e.g., ephedrine)	Older, nonselective, irreversible monoamine oxidase inhibitors—discontinue for 2 wk with risk of serious psychiatric consequences (serious depression, suicidality, paranoid delusions) or provide MAOI-safe anesthesia if drugs continued; newer, reversible inhibitors of monoamine oxidase A—have short half-life (1-3 hr); therefore discontinue drug on morning of surgery; consider changing irreversible MAOIs to a reversible MAOI in the weeks prior to surgery, then only discontinuing reversible MAOI on morning of surgery
Tricyclic antidepressants	α-Adrenergic blocking activity and potentiation of sympathomimetic effects of epinephrine and norepinephrine, resulting in hypertensive crisis; cardiac arrhythmias; lowers seizure threshold	Consider baseline ECG; norepinephrine should be considered the vasopressor of choice for related hypotension	Discontinuation can lead to cholinergic symptoms (i.e., GI), movement disorders, and cardiac arrhythmias; relapse rate is higher when discontinued

TABLE 19-1 Potential Drug Interactions Affecting Perianesthesia Care—cont'd

	PERIANESTHESIA CONCERN		
Drug Category	**Intraoperative Concerns**	**Management**	**Discontinuation Issues**
Selective serotonin reuptake inhibitors	Serotonergic potentiation with GI symptoms, headache, agitation	Continue to avoid withdrawal syndrome	Withdrawal may induce psychosis, agitation, dizziness, palpitations, etc.
Lithium	T-wave smoothing, ventricular arrhythmias, myocarditis; sinus dysfunction can lead to extreme atropine-resistant sinus bradycardia; dehydration will lead to increases in lithium blood levels	Continue pre- and perioperatively; check serum levels prior to surgery; obtain thyroid function tests if indicated; monitor serum sodium, avoid sodium wasting diuretics; optimize hydration	No withdrawal effect after abrupt discontinuation; high risk of recurrence of depression and total affective relapse
Antiparkinsonian agents		Carbidopa/levodopa: continue until the morning of surgery and restart as soon as possible after surgery to avoid withdrawal syndrome; Selegiline: stop 2 wk prior to surgery when possible; Bromocriptine, amantadine, pergolide: continue; Entacapone, tolcapone: Continue to avoid withdrawal syndrome (check liver enzymes before surgery)

are weighed against the risks of abrupt discontinuation. Abrupt discontinuation of long-standing medication may lead to the development of undesirable withdrawal symptoms. With occasional exceptions, the majority of medications are continued preoperatively. Should a decision be made to withhold a particular drug before surgery, sufficient time should be allowed for metabolic clearance (ideally three to five half-lives).[8]

Drug Allergies

A patient's drug history should include information regarding allergic reactions to certain foods and medications. Prior allergic responses are investigated so they can be differentiated from adverse drug reactions. Use of certain antibiotics and opioids may be avoided because of gastrointestinal side effects. These do not represent a true allergic response, however. A distinction between allergic reactions and adverse effects is crucial, because an allergy to a drug is an absolute contraindication to its use. Medications within the same classification of a drug allergy should be avoided, and heightened awareness of a potential allergic reaction is required during the perioperative period.

Latex Sensitivity

Patient sensitivity to latex products has recently been identified as a frequent basis of allergic reaction. Up to 20% of intraoperative anaphylactic reactions have been attributed to latex sensitivity.[18]

The preoperative questioning of patients should include inquiry regarding specific latex sensitivity or allergy. Patients at increased risk for latex sensitivity should be cared for in a no-latex setting and scheduled as the first case of the day to reduce the likelihood of aeroallergen latex exposure. The diagnosis of latex allergy is based on the findings of the history and physical examination and if necessary, in vivo (skin-prick test is the most sensitive) and in vitro testing. Preoperative testing is indicated only when there is a family history of reactions or when patients report experiencing symptoms such as a rash, swelling, or wheezing when exposed to latex.[19] Patients at high risk for latex sensitivity include those with a history of the following[18]:

- Chronic exposure to latex-based products (e.g., industrial workers using protective gear; occupational exposure to latex)
- Spina bifida, urologic reconstructive surgery
- Repeated surgical procedures (more than nine)
- Intolerance to latex-based products (e.g., balloons, rubber gloves, condoms, dental dams, rubber urethral catheters)
- Allergy to food and tropical fruits (e.g., avocado, banana, buckwheat, celery, chestnut, kiwi, mango, papaya, passion fruit, peach)
- Intraoperative anaphylaxis of uncertain cause
- Healthcare professionals, especially with a history of atopy or severe dermatitis, hand eczema

Social History

The addictive nature of tobacco and alcohol, as well as illegal drugs, exerts a detrimental influence on several aspects of life in the United States.

- Approximately 22.6 million Americans aged 12 years of age or older (9%) were classified as illicit drug users in 2010.[20]
- Nearly one quarter of all deaths (75,000 annually)[21] in the United States are caused by addictive substances.[22]
- The economic burden of addiction (e.g., healthcare expenditures, missed work, crime) is estimated at more than $400 billion annually.[22]

Certain drugs, despite their social or recreational application, may be associated with adverse and life-threatening consequences with long- or short-term use or overdose. The social history provides an excellent opportunity to explore the extent of self-medication. Open-ended questions, posed in a professional and nonjudgmental manner, are most likely to elicit detailed information from the patient. At this time, the patient can also be educated about the adverse consequences of substance abuse; especially as such substances affect anesthetic care.

Tobacco Use

Many patients arrive for anesthesia and surgery with a history of tobacco smoking. In the United States, some disturbing statistics are associated with this form of substance abuse:

- One in five deaths in the United States is related to smoking. Cigarette smoking is the leading cause of preventable premature death in the United States (approximately 443,000 premature deaths annually).[23]
- In 2010, 27% (70 million) of Americans aged 12 or older smoked.[20]
- Teen smoking rates have declined from 15.2% in 2002 to 10.7% in 2010.[20]
- Smokers die 14 years earlier than nonsmokers.[24]
- Exposure to secondhand smoke causes 3400 deaths a year from lung cancer and 46,000 deaths from coronary heart disease; 776 newborns a year die from sudden infant death syndrome attributed to secondhand smoke.[25]

The inhaled components of tobacco smoke lead to multiple pathophysiologic changes within the body. Nicotine and carbon monoxide are just two of the more than 6000 noxious components that have been identified in tobacco smoke.[26] Nicotine, a toxic alkaloid, produces ganglionic stimulant effects and is the tobacco component that affects the cardiovascular system.[27] Acute side effects of nicotine include increased heart rate, blood pressure, myocardial contraction, myocardial oxygen consumption, myocardial excitement, and peripheral vascular resistance. Net effects of nicotine's cardiovascular influence include impaired coronary blood flow and an adverse myocardial oxygen supply/demand ratio.[28] Carbon monoxide readily occupies the oxygen-binding sites of hemoglobin (approximately 250 to 300 times greater affinity for hemoglobin than oxygen).[29] Oxygen transport to the tissues and resultant oxygen use is thereby drastically reduced. In the heavy smoker, carboxyhemoglobin may be as high as 15%, which effectively reduces the patient's oxyhemoglobin percentage accordingly. The adverse effects of nicotine on the cardiovascular system and carbon monoxide on oxygen-carrying capacity are short lived (half-life of nicotine is 40 to 60 minutes[30]; half-life of carbon monoxide if room air is breathed is 130 to 190 minutes).[31]

Patients should be instructed to stop smoking at least 12 to 48 hours before surgery. *Short-term (e.g., 12 hours) preoperative abstinence from tobacco smoke reduces the deleterious effects of nicotine and carbon monoxide on cardiopulmonary function.*[32] Smoking cessation for even 1 night before surgery reduces heart rate, blood pressure, and circulating catecholamine levels[33] and allows carboxyhemoglobin values to return to normal levels.[34]

Patients who smoke have a higher incidence (a nearly sixfold increase[35]) of postoperative pulmonary complications (pneumonia and atelectasis).[36] A smoking history of more than 20 pack years equates to an increased risk of perioperative complications.[37] Smoking cessation of less than 4 weeks does not reduce the risk of postoperative respiratory complication.[4,38] Longer periods of smoking cessation (8 weeks or longer) result in a marked improvement in pulmonary mechanics (e.g., enhanced ciliary function, decreased mucous secretion and small airway obstruction, and enhanced immune function).[39] Patients who stopped smoking less than 2 months before surgery had nearly four times the pulmonary complications (e.g., purulent sputum, secretion retention, bronchospasm, pleural effusion, pneumothorax, segmental pulmonary collapse, pneumonia) of those who abstained from smoking for longer than 2 months.[40] However, even short-term smoking cessation is effective in reducing postoperative complications when compared with patients who continued to smoke up until the time of surgery.[39] A reduction in postoperative wound-related complications occurs in patients who stop smoking preoperatively.[41] Patients who smoke should be advised to quit even immediately prior to surgery, without fear of worsening pulmonary outcomes or increasing psychological stress as a result of acute abstinence.[42] Effective interventions, including behavioral support and nicotine replacement therapy, should be made available to smokers considering abstinence at this time.[43]

The influence of environmental tobacco smoke (also known as *secondhand* or *passive smoke*) on children has been found to produce disturbing respiratory consequences, including increased reactive airway disease, abnormal results of pulmonary function tests, and increased respiratory tract infections.[44,45] The perioperative complications in children exposed to smoke include laryngospasm, coughing on induction or emergence, breath holding, postoperative oxyhemoglobin desaturation, and hypersecretion.[46]

Alcohol Intake

An estimated 14 million Americans are dependent on alcohol, with 105,000 deaths annually attributed to alcohol abuse.[47] Perioperative complications, such as arrhythmias, infection, and alcohol withdrawal syndrome, are increased two- to fivefold in chronic excessive alcohol users.[48] Postoperative complications can by reduced with 4 or more weeks of abstinence prior to surgery.[49] Information regarding the type and amount of alcohol regularly consumed and the frequency of consumption is important in the evaluation for anesthesia and surgery. Often an accurate assessment of a patient's alcohol intake may be difficult to obtain. The Alcohol Use Disorders Identification Test (AUDIT), a self-reporting questionnaire designed to identify problem drinkers, can be incorporated into the preoperative interview of suspected problem drinkers.[50] A less confrontational and a reliable approach to evaluating a patient's potential for an alcohol problem uses the mnemonic *CAGE*, which refers to the following four questions[51]:

1. Do you feel you should *c*ut down on your alcohol consumption?
2. Have people *a*nnoyed you by criticizing your drinking habits?
3. Have you felt guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (*e*ye-opener)?

A patient reporting more than two positive responses is at high risk for alcoholism and an increased likelihood of experiencing withdrawal symptoms.[52] Both AUDIT and CAGE have been shown to be effective in identifying the abusive alcohol consumer.[53]

In the heavy drinker, it is important to determine whether the patient has experienced seizures, abrupt withdrawal syndrome, or delirium tremens as a consequence of alcohol abuse. Clinical signs suggestive of alcohol withdrawal include increased hand tremors, autonomic hyperactivity (e.g., sweating, tachycardia, systolic hypertension), insomnia, anxiety, restlessness, nausea or vomiting, transient hallucinations (visual, tactile, or auditory), psychomotor agitation, and grand mal seizures.[52]

Chronic alcohol abuse results in the development of tolerance, physical dependence, and multisystem organ dysfunction. Tolerance to alcohol is evidenced by a resistance or cross-tolerance to other central nervous system (CNS) depressants. For example, the anesthetic requirement of hypnotics, opioids, and inhalation agents is increased in the chronic alcoholic; however, exaggerated responses to anesthetic agents are likely during periods of acute intoxication or advanced alcoholism. This effect is attributed to the additive depressant effects of alcohol and anesthetic agents. Enzymatic function and plasma albumin concentrations may also be reduced in patients with alcoholic hepatic insufficiency. As a result, greater circulating concentrations of unbound intravenous agents may result in an exaggerated and prolonged drug effect.[54] This enhanced drug response has not been shown to occur with propofol in patients with moderate liver cirrhosis.[55]

An insidious progression of multisystem organ dysfunction is also characteristic of long-term alcohol abuse. Numerous illnesses are attributable to the toxic adverse effects of advanced alcoholism on overall health and nutrition. Predictably, postoperative morbidity and mortality rates are increased in alcoholic patients as a result of poor wound healing, infection, bleeding, pneumonia, and further hepatic deterioration.[56,57]

Illicit Drug Use

Use of illicit drugs (e.g., cocaine, cannabis, "crack," lysergic acid diethylamide-25 [LSD], amphetamines, heroin, hallucinogens, inhalants, prescription-type psychotherapeutics used nonmedically) is a significant healthcare issue in the United States. The most popular recreational drugs continue to be cocaine and marijuana. Monthly drug abuse among Americans include 17 million marijuana users, 7 million prescription-type psychotherapeutic nonmedical drug users, 1.5 million cocaine users, 1.2 million hallucinogen users, and 731,000 methamphetamine users in 2010.[20] Americans use 80% of all opioids available in the world.[58] The use of these substances increases the risk for adverse consequences and drug interactions during anesthesia. An accurate illicit drug history is often difficult to obtain because of the patient's fear of legal reprisal or refusal to believe a drug problem exists. During the physical examination, the anesthesia provider should look for signs that indicate illicit drug use by the patient. A diagnosis of recent or continuing drug abuse should be suspected in patients exhibiting the following on physical examination[59]:

- Evidence of drug injection (e.g., track marks or scarring), thrombotic veins, phlebitis, tattoos (may be used to mask the sites), ablation of venous return leading to unilateral edema of the nondominant hand, subcutaneous skin abscesses
- Ophthalmologic changes, such as pupillary constriction from opioid use, pupillary dilation with amphetamine use, nystagmus from phencyclidine (PCP) use
- Lymphadenopathy secondary to nonspecific activation of the immune system as a result of repeated injections of impurities
- Malnourishment as a result of amphetamine abuse (opioid users tend to be well nourished)
- Poor dental care and bruxism (involuntary grinding and clenching of teeth) from amphetamine use
- Nasal perforation from cocaine abuse

BOX 19-4

Signs and Symptoms of Acute Substance Abuse

Cannabis (Marijuana or Hashish)
- Tachycardia, labile blood pressure, headache
- Euphoria, dysphoria, depression, occasional anxiety and panic reactions, psychosis (rare)
- Poor memory and decreased motivation with chronic use

Cocaine and Amphetamines
- Tachycardia, labile blood pressure, hypertension, myocardial ischemia, arrhythmias, pulmonary edema
- Excitement, delirium, hallucinations to psychosis
- Euphoria: feeling of excitation, well-being, and enhanced physical strength and mental capacity
- Hyperreflexia, tremors, convulsions, mydriasis, sweating, hyperpyrexia, exhaustion, coma with overdose

Hallucinogens: LSD, PCP
- Sympathomimetic and weak analgesic effects
- Altered perception and judgment; high doses may progress to toxic psychosis
- PCP produces dissociative anesthesia with increasing doses

Opioids
- Respiratory depression, hypotension, bradycardia, constipation
- Euphoria (most marked with heroin)
- Pinpoint pupils with overdose; decreased level of consciousness to coma

From Cheng DCH. The drug addicted patient. *Can J Anaesth*. 1997;44(5 Pt2):R101-R111; Cavaliere F, et al. Anesthesiologic preoperative evaluation of drug addicted patient. *Minerva Anestesiol*. 2005;71(6):367-371. *LSD*, Lysergic acid diethylamide-25; *PCP*, phencyclidine.

Primary concerns for the anesthesia provider are the likelihood of the patient exhibiting acute abuse or possible withdrawal syndrome.[60] Signs and symptoms of acute abuse of the more common substances are listed in Box 19-4.[59,60] Elective surgery should be delayed or canceled in patients suspected of being under the influence of an illicit drug until further patient evaluation can be performed. Suspicion of acute substance abuse should be followed up with a urine screen for drug identification. Abstinence syndrome typically exhibits increased sympathetic and parasympathetic responses resulting in hypertension, tachycardia, abdominal cramping and diarrhea, tremors, anxiety, irritability, lacrimation, mydriasis, algid sweat, and yawning.[61]

Synthetic Androgens

Anabolic steroids are self-administered in an attempt to increase muscle mass, strength, and growth, and improve athletic performance, but such actions can result in hepatic and endocrine system dysfunction. Risks associated with long-term androgen steroid supplementation include impaired liver function, cholestatic jaundice, hepatic adenocarcinoma, peliosis hepatis, myocardial infarction (MI), atherosclerosis, hypercoagulopathy, stroke, hypertension, dyslipidemia, and psychiatric and behavioral disturbances in susceptible patients.[62-65] The hepatotoxic effects have important implications for the anesthetic management of a chronic steroid abuser, particularly with agents metabolized by the liver, and such patients should undergo preoperative liver function testing.

TABLE 19-2 Clinically Important Effects and Perioperative Concerns of Selected Herbal Medicines and Recommendations for Discontinuation of Use Before Surgery

Herb: Common Name(s)	Relevant Pharmacologic Effects	Perioperative Concerns	Preoperative Discontinuation
Echinacea: purple coneflower root	Activation of cell-mediated immunity	Allergic reactions; decreased effectiveness of immunosuppressive actions of corticosteroids and cyclosporine; potential for immunosuppression with long-term use; inhibition of hepatic microsomal enzymes may precipitate toxicity of drugs metabolized by the liver (e.g., phenytoin, rifampin, phenobarbital)	No data
Ephedra: ma huang	Increased heart rate and blood pressure through direct and indirect sympathomimetic effects	Risk of myocardial ischemia and stroke from tachycardia and hypertension; ventricular arrhythmias with halothane; long-term use depletes endogenous catecholamines and may cause intraoperative hemodynamic instability (control hypotension with direct vasoconstrictor, e.g., phenylephrine); life-threatening interaction with monoamine oxidase inhibitors	At least 24 hours before surgery
Garlic: ajo, *Alium sativum*	Inhibition of platelet aggregation (may be irreversible); increased fibrinolysis; equivocal antihypertensive activity	Potential to increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	At least 7 days before surgery
Ginkgo: duck foot tree, maidenhair tree, silver apricot	Inhibition of platelet-activating factor	Potential to increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	At least 36 hours before surgery
Ginseng: American ginseng, Asian ginseng, Chinese ginseng, Korean ginseng	Lowers blood glucose; inhibition of platelet aggregation (may be irreversible); increased PT-PTT in animals; many other diverse effects	Hypoglycemia; potential to increase risk of bleeding; potential to decrease anticoagulation effect of warfarin	At least 7 days before surgery
Kava: awa, intoxicating pepper, kawa	Sedation, anxiolysis	Potential to increase sedative effect of anesthetics; potential for addiction, tolerance, and withdrawal after abstinence unstudied	At least 24 hours before surgery
St John's wort: amber, goat week, hardhay, *Hypericum*, klamatheweed	Inhibition of neurotransmitter reuptake, monoamine oxidase inhibition is unlikely	Induction of cytochrome P-450 enzymes, affecting cyclosporine, warfarin, steroids, protease inhibitors, and possibly benzodiazepines, calcium channel blockers, and many other drugs; decreased serum digoxin levels	At least 5 days before surgery
Valerian: all heal, garden heliotrope, vandal root	Sedation	Potential to increase sedative effect of anesthetics; benzodiazepine-like acute withdrawal; potential to increase anesthetic requirements with long-term use	No data

Perioperative anesthesia clinical considerations of alternative medicines. *Anesthesiol Clin North America*. 2004;22:125-139; Hogg LA, Foo L. Management of patients taking herbal medicines in the perioperative period: a survey of practice and policies within anaesthetic departments in the United Kingdom. *Eur J Anaesthesiol*. 2010;27(1):11-5.
PT-PTT, Prothrombin time–partial thromboplastin time.

Herbal Dietary Supplements

Patients should be questioned regarding their use of nonprescription herbal medications to determine the herb's name, the duration of herbal therapy, and the dose taken. If patients are in doubt as to the herbal medications they are taking, they should be encouraged to bring the herbal products with them to their preoperative workup. Certain herbal products are known to influence blood clotting, affect blood glucose levels, produce CNS stimulation or depression, or interact with psychotropic drugs (Table 19-2).[66,67]

PATIENT EVALUATION: OVERVIEW OF SYSTEMS

Upper Airway

Assessment of the airway should be performed preoperatively in every patient, regardless of the plan of anesthetic management. It is important to evaluate the patient before anesthesia to identify those patients at risk for difficult airway management. The initial physical examination of the patient includes careful inspection of the teeth, inside of the mouth, mandibular space, and neck in a

TABLE 19-3 Components of the Preoperative Airway Physical Examination

Airway Examination Component	Cautionary Findings
Length of upper incisors	Relatively long
Relation of maxillary and mandibular incisors during normal jaw closure	Prominent "overbite" (maxillary incisors anterior to mandibular incisors)
Relation of maxillary and mandibular incisors during voluntary protrusion of the jaw	Patient mandibular incisors anterior to (in front of) maxillary incisors
Interincisor distance	Less than 3 cm
Visibility of uvula	Not visible when tongue is protruded with patient in sitting position (e.g., Mallampati class greater than II)
Shape of palate	Highly arched or very narrow
Compliance of mandibular space	Stiff, indurated, occupied by mass, not resilient
Thyromental distance	Less than three ordinary fingerbreadths
Length of neck	Short
Thickness of neck	Thick
Range of motion of head and neck	Patient cannot touch tip of chin to chest or cannot extend neck

From American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology*. 2003;98(5):1269-1277.

sequential fashion to determine predictors of airway management difficulties (Table 19-3).[68] Certain body structural features, metabolic disease states, and congenital or acquired structural anomalies are associated with difficult airway management (Box 19-5).[69] The combination of subtle or minor physical anomalies may result in a difficult tracheal intubation, even when each factor individually is not expected to pose a problem.

Tests for Prediction of Difficult Intubation

Several screening tests for predicting difficult endotracheal intubation are recommended as part of the preoperative patient evaluation. No single test should be relied on exclusively when the airway is evaluated; a combination of evaluative criteria should be used to increase the predictive value for difficult intubation.

Mallampati Classification. A popular technique for airway assessment is the modified Mallampati airway classification, which entails examination of tongue size relative to the oral cavity.[70] During the assessment for the Mallampati classification, the patient is seated upright with the head in neutral alignment, while the examiner sits opposite the patient at eye level. The patient is asked to open the mouth as wide as possible and maximally extrude the tongue. The patient is encouraged not to phonate during this maneuver because phonation may inappropriately elevate the soft palate. The airway is then classified based on the structures visible on direct examination of the oropharynx (Figure 19-2).[70] Endotracheal intubation is generally easy in a patient with a Mallampati class I airway and can be expected to be difficult in a patient with a Mallampati class III or IV airway. Mallampati airway classification has been criticized as not being a reliable or sensitive predictor of difficult intubating conditions.[71] Because of the unusually high incidence of false-positive and false-negative findings associ-

BOX 19-5

Conditions Associated with Difficult Airway Management

Head
- Mass defects (e.g., encephalocele, soft-tissue sarcoma)
- Macrocephaly (e.g., severe hydrocephaly, Dandy Walker syndrome, mucopolysaccharidoses [Hurler syndrome])
- Interference with airway access (e.g., thoracopagus conjoined twins, stereotactic frame)

Facial Anomalies
- Maxillary and mandibular deformities
- Maxillary hypoplasia (e.g., Apert's syndrome, Crouzon's disease)
- Mandibular hypoplasia, microgenia, micrognathia (e.g., Pierre Robin syndrome, Treacher Collins syndrome, Goldenhar's syndrome, cri du chat syndrome, Nager syndrome)
- Mandibular hyperplasia (e.g., cherubism)
- Temporomandibular joint anomalies
- Reduced mobility (e.g., arthrogryposis multiplex congenita, diabetes, Dutch-Kentucky syndrome, Hecht-Beals syndrome), ankylosis (inflammatory, congenital, traumatic, infectious)

Thoracoabdominal
- Morbid obesity, sleep apnea syndrome, Prader-Willi syndrome
- Kyphoscoliosis
- Prominent chest or large breasts
- Full-term or near-term pregnancy

Mouth and Tongue Anomalies
- Microstomia
- Congenital anomalies (e.g., Freeman-Sheldon [whistling face] syndrome)
- Acquired anomalies (e.g., burn)
- Stomatitis (e.g., noma)
- Tongue disease
- Macroglossia
- Congenital (e.g., Beckwith-Wiedemann syndrome, Down syndrome, congenital hypothyroidism, Pompe's disease)
- Swelling (e.g., burns, trauma, Ludwig angina)
- Tumors (e.g., hemangiomas, lymphangioma)
- Protruding upper incisors (e.g., Cockayne's syndrome)
- Foreign body

Nasal Pathology
- Choanal atresia
- Tumors (e.g., encephaloceles, gliomas, foreign body)

Palate Pathology
- Arch and cleft defects
- Soft-palate swelling and hematomas

Pharynx
- Adenoid and tonsillar disease
- Hypertrophy
- Tumors and abscesses
- Lingual tonsils
- Pharyngeal wall pathology
- Retropharyngeal and parapharyngeal abscesses
- Inflammatory disease (e.g., epidermolysis bullosa, erythema multiforme bullosum)
- Scarring (e.g., Behçet's syndrome)

Continued

BOX **19-5—cont'd**

Conditions Associated with Difficult Airway Management

Laryngeal Pathology
- Supraglottic
- Laryngomalacia
- Supraglottis (epiglottitis)
- Glottic
- Congenital lesions (vocal cord paralysis, laryngeal web, cyst, laryngocele)
- Papillomatosis
- Granuloma formation
- Foreign body
- Subglottic
- Congenital stenosis
- Infectious (croup)
- Inflammatory (edema, traumatic stenosis)

Tracheal and Bronchial Tree Pathology
- Tracheomalacia (e.g., Larsen syndrome)
- Croup
- Bacterial tracheitis
- Mediastinal masses
- Vascular malformation
- Foreign body aspiration
- Other (e.g., tracheal stenosis, webbing, fistula, diverticulum)

Neck
- Mass lesions
- Lymphatic malformation, hemangioma, teratoma, goiter, abscess
- Skin contracture (postburn, inflammatory [scleroderma, epidermolysis bullosa, erythema multiforme bullosum])
- Webbed (e.g., Turner syndrome)

Spine
- Limited cervical spine mobility
- Congenital (e.g., Klippel-Feil syndrome)
- Acquired (e.g., surgical [fusion], trauma [vertebral fracture], inflammatory [ankylosing spondylitis])
- Cervical spine instability
- Congenital (e.g., Down syndrome, Larsen syndrome, Möbius syndrome, Morquio syndrome)
- Acquired (e.g., trauma [subluxation, fracture], inflammatory [rheumatoid arthritis])

BOX **19-6**

Calculation of Ideal Body Weight and Body Mass Index

Ideal Body Weight (IBW)
IBW (male) = 105 lb + 6 lb for each inch >5 ft
IBW (female) = 100 lb + 5 lb for each inch >5 ft

To Calculate Body Mass Index (BMI):
BMI = Weight in kg/(height in meters)^2

Example 1:

70 kg/1.7 m^2 = 70 kg/2.89 m = 24 kg/m^2

Example 2:

125 kg/1.7 m^2 = 125 kg/2.89 m = 43 kg/m^2

ated with the system, it should not be used as the only means of screening for the difficult airway.

Thyromental Distance. Thyromental distance can be quantified to enable prediction of difficulties with laryngoscopy. Thyromental distance represents the straight distance, with the neck fully extended and the mouth closed, between the prominence of the thyroid cartilage and the bony point of the lower mandibular border. In adults, a thyromental distance of less than 7 cm, which is approximately three adult fingerbreadths, is associated with difficult endotracheal intubation because the pharyngeal and laryngeal axes may not properly align, and difficult laryngoscopy can be anticipated.[72]

Interincisor Distance. The degree of mouth opening, largely a function of the temporomandibular joint, is a vital component of airway assessment. Limited temporomandibular joint movement is a well-recognized contributor to difficult endotracheal intubation. An adult should be able to open the mouth at least 4 cm, allowing two large fingers to be placed between the upper and lower incisors. An interincisor gap of less than two fingerbreadths is associated with difficulty in endotracheal intubation.[73] Some patients who are able to open their mouths sufficiently while awake experience limitations in temporomandibular joint mobility after anesthesia is induced. This limited movement renders the visualization of laryngeal structures difficult. In this situation, forward protrusion of the mandible can be attempted for opening the mouth adequately to allow direct laryngoscopy.[74]

Head and Neck Movement (Atlantooccipital Function). Moderate flexion of the neck on the chest and full extension of the atlantooccipital joint aligns the oral, pharyngeal, and laryngeal axes into the McGill, or "sniff," position. In this position, less tongue obscures the laryngeal view during laryngoscopy. Limitations to atlantooccipital joint extension, which are frequently attributed to cervical arthritis or a small C-1 gap, enhance the convexity of the neck and push the larynx anteriorly. This situation can impair laryngoscopy and render endotracheal intubation difficult.

Mandibular Mobility. Have the patient demonstrate the ability to move the jaw forward and bite their upper lip. Being able to protrude the mandible in front of the central incisors indicates relative ease for maneuvering the laryngoscope.

BOX **19-7**

Obesity-Related Comorbidities

Cardiovascular
- Hypertension
- Coronary heart disease
- Hypertrophic cardiomyopathy
- Peripheral vascular disease
- Thromboembolic disease
- Stroke

Dermatologic
- Dermatitis
- Cellulitis
- Panniculitis
- Hirsutism (presence of excess body and facial hair)

Endocrine
- Dyslipidemia (e.g., high total cholesterol, low levels of high density lipoprotein [HDL] cholesterol, or hypertriglyceridemia)
- Liver dysfunction
- Type 2 diabetes
- Gout

Gastrointestinal
- Gallbladder disease (cholelithiasis)
- Hiatal hernia, heartburn
- Gastroesophageal reflux disease (GERD)

Genitourinary
- Complications of pregnancy
- Menstrual irregularities
- Stress incontinence

Malignancies
- Some cancers (e.g., endometrial, uterine, cervical, ovarian, breast, prostate, esophagus, liver, pancreas, kidney, gallbladder, and colorectal)

Maternal
- Pregnancy-induced hypertension (PIH)
- Induced labor, prolonged labor, difficult delivery
- Increased primary cesarean section rate (greater than 50%)
- Increased perinatal mortality
- Pulmonary embolism
- Wound infection
- Maternal death

Musculoskeletal
- Osteoarthritis
- Degenerative joint disease

Psychological
- Depression
- Anxiety disorders

Pulmonary
- Chronic obstructive pulmonary disease (COPD)
- Restrictive pulmonary disease
- Reactive airway disease
- Obstructive sleep apnea
- Pulmonary hypertension

Dentition

The incidence of perianesthetic dental injury in patients undergoing general anesthesia involving endotracheal intubation ranges from 0.02% to 0.07% and is associated with patients who have preexisting poor dentition and characteristics linked with difficult laryngoscopy and intubation (e.g., limited neck motion, previous head and neck surgery, craniofacial abnormalities, history of previous difficult tracheal intubation). Because dental injuries are the most common reason for anesthesia-related medicolegal claims (accounting for one third of all claims in the United States),[75] a preanesthesia inspection of the teeth should be performed and documented for each patient. Otherwise, fractured or missing teeth may be falsely attributed to damage occurring during airway instrumentation. The patient with protuberant or loose maxillary incisors should also be informed of the increased risk of tooth injury or loss with laryngoscopy. An informed consent to proceed with the anesthetic plan, despite this dental risk, must then be documented. If the patient is properly informed of the likelihood of dental damage, the anesthesia provider may not be held liable should dental injury occur.[76]

The location and condition of crowns, braces, and other significant dental work are also noted. Prosthetic devices such as partial plates and dentures are removed before surgery, unless they significantly improve the mask fit. An extremely loose tooth may be extracted before laryngoscopy to prevent its aspiration during anesthesia.

Musculoskeletal System

Obesity

Evaluation of the musculoskeletal system usually begins with a general assessment of the size and stature of the patient. Baseline height and weight information can be obtained from the admission data or by direct questioning of the patient during the health history interview. Body weight is then compared with normal values for a given height in relation to the patient's age and gender. Ideal body weight, for example, can be determined for men and women (Box 19-6). The actual weight of the patient is compared with the calculated ideal body weight. Body weight that is 20% in excess of the ideal body weight at a particular height constitutes obesity. A body weight that is twice the ideal body weight is deemed morbidly obese.

A more scientific approach to describing weight in relation to height uses the measure of body mass index (BMI). Box 19-6 presents the formula for calculating BMI and incorporates it into examples for an average and an overweight individual of the same height. The adult patient weight classification based on BMI is as follows: overweight, 25 to 29.9 kg/m^2; moderate obesity, 30 to 34.9 kg/m^2; severe obesity, 35 to 39.9 kg/m^2; and morbidly obese, greater than or equal to 40 kg/m^2.[77] Two thirds of the adult population in the United States are overweight or obese.[78] Obese patients are at risk of illness from a multitude of conditions (Box 19-7) that require detailed workup.[77]

The morbidly obese patient is at greater risk for cardiopulmonary aberrations, sleep-disordered breathing, and abnormal airway issues. Preoperative assessment scheduled in advance of the surgery should reflect careful attention to these concerns.[77] Appropriate diagnostic testing prior to bariatric surgery has been proposed (Box 19-8).[79,80] Much of this testing centers around the likelihood of patients presenting for bariatric surgery with preexisting metabolic complications or nutritional deficiencies. The extent of preexisting comorbid medical conditions needs to be thoroughly evaluated

BOX **19-8**

Recommended Diagnostic Testing of Candidates for Bariatric Surgery

- 12-lead electrocardiogram—if at least one risk factor for coronary heart disease, poor functional capacity, or both
- Chest radiograph (posteroanterior and lateral)— if BMI 40 kg/m^2 or greater
- Complete blood cell count
- Glycosylated hemoglobin
- Serum chemistries with parameters for liver and kidney function
- Fasting blood glucose
- Lipid profile (total cholesterol, triglycerides, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol)
- Thyroid function (thyrotropin)
- Coagulation studies
- Ferritin
- Vitamins ($B_{12,}$ 25-Hydroxyvitamin D, other fat-soluble vitamins if considering a malabsorptive procedure)
- Minerals and trace elements, for example, zinc, selenium, calcium, magnesium

Adapted from Eldar S, et al. A focus on surgical preoperative evaluation of the bariatric patient—the Cleveland Clinic protocol and review of the literature. *The Surgeon*. 2011;9(5):273-277; Poirier P, et al. Cardiovascular evaluation and management of severely obese patients undergoing surgery: a science advisory from the American Heart Association. *Circulation*. 2009;120(1):86-95; Thompson J, et al. Anesthesia case management for bariatric surgery, *AANA J*. 2011;79(2):147-160.

preoperatively, typically by internal medicine physicians. Serious or life-threatening comorbid conditions associated with obesity are noted in Box 19-9.[79] Patients should receive cardiac assessment in accordance with the American Heart Association guidelines.[81] Asymptomatic patients should be screened for coronary disease if they have an abnormal baseline electrocardiogram; a history of coronary artery disease/valvular disease; or are more than 50 years of age with at least two of the following: metabolic syndrome, diabetes, hypertension, smoking, dyslipidemia, or family history of coronary disease.[82] Patients without comorbid conditions may not require further preoperative workup because diagnostic testing should be individualized based on identified needs.[83]

Obstructive sleep apnea is a breathing disorder distinguished by periodic, partial, or complete obstruction of the upper airway during sleep.[84] More than 70% of patients presenting for bariatric surgery have obstructive sleep apnea.[83] Particular attention is given to a history of snoring, apneic episodes, frequent arousals during sleep (vocalization, shifting position, extremity movements), morning headaches, and daytime somnolence. The physical examination would include airway evaluation, nasopharyngeal characteristics, neck circumference, tonsil size, and tongue volume.[84] A concise, easy to use screening questionnaire for undiagnosed obstructive sleep apnea, known as STOP-Bang (Box 19-10),[85,86] has been shown to be highly sensitive for categorizing obstructive sleep apnea severity.[87,88]

Polysomnography is the current "gold standard" test for establishing a clinical diagnosis of obstructive sleep apnea. If the findings of the history and physical examination are suggestive of obstructive sleep apnea, a decision in consultation with the surgeon should be made regarding obtaining a preoperative sleep study. If the diagnosis of obstructive sleep apnea is confirmed, the patient will be evaluated to determine optimal levels of continuous positive airway pressure (CPAP) therapy. Patients already receiving CPAP therapy will be asked to bring their cleaned home CPAP units to the hospital for postoperative application as needed. If the hospital is to provide the CPAP device, the patient needs to be queried as to the type of interface device the patient uses, pressure settings, and whether supplemental oxygen is required.

Particular attention is given to airway evaluation to determine the likelihood of difficult endotracheal intubation. Patients who

BOX **19-9**

Comorbid Conditions Associated with Obesity

- Known sleep apnea in which patient is noncompliant with continuous positive airway pressure (CPAP)
- $HbA1_C$ (glycosylated hemoglobin) greater than 8% (average blood sugar greater than 200 mg/dL)
- Diabetic nephropathy, retinopathy, or neuropathy
- Cirrhosis
- Pulmonary hypertension
- Pseudotumorcerebri (with severe headaches or impending vision loss)
- Significant coagulopathy (including history of pulmonary embolus, bleeding diathesis, hypercoagulable syndrome, excessive bleeding, more than one deep venous thrombosis, taking Coumadin or clopidogrel medication)
- Chronic steroid therapy
- Oxygen dependent (does not necessarily have to be constant)
- Wheelchair-bound most of the time
- Systemic disease and poor functional capacity (including multiple sclerosis, inflammatory bowel disease, scleroderma, lupus, cancer)
- Severe venous stasis ulcers
- Recent complaint of chest pain (undiagnosed)

STOP-Bang Questionnaire for Obstructive Sleep Apnea Screening

STOP

1. Snoring—Do you *snore* loudly (louder than talking or loud enough to be heard through closed door)?	Yes	No
2. Tired—Do you often feel *tired*, fatigued, or sleepy during the daytime?	Yes	No
3. Observed—Has anyone *observed* you stop breathing while you sleep?	Yes	No
4. Blood Pressure—Are you now being or have you been treated for high blood *pressure*?	Yes	No

BANG

BMI—greater than 35 kg/m^2?	Yes	No
Age—greater than 50 years?	Yes	No
Neck circumference greater than 40 cm?	Yes	No
Gender—male.	Yes	No

A high risk of obstructive sleep apnea is defined as a score of 3 or more; low risk of obstructive sleep apnea, a score of less than 3.

Adapted from Seet E, Chung E. Obstructive sleep apnea: perioperative assessment. *Anesthesiol Clin*. 2010;28(2):199-215.

are obese or have short, thick necks or have obstructive sleep apnea have a higher incidence of difficult or failed endotracheal intubation (1:20) than the general population (1:2200).[77] If a problem is anticipated and an awake or fiberoptic tracheal intubation is planned, proper patient preparation, which includes a drying agent and proper upper airway anesthesia, should be instituted.

The patient should be questioned about the use of antiobesity drugs such as amphetamines, nonamphetamine Schedule IV appetite suppressants, and antidepressants (e.g., fluoxetine, sertraline).

Ankylosing Spondylitis and Rheumatoid Arthritis

Disorders of the musculoskeletal system include degenerative disk disease (osteoarthritis), ankylosing spondylitis, and rheumatoid arthritis. The chronic pain and inflammation of spinal or extraspinal joints associated with these diseases limit the degree of patient mobility. Tolerance for positions required during surgery and regional anesthesia techniques should therefore be ascertained preoperatively. Traditional ankylosing spondylitis treatments (nonsteroidal antiinflammatory drugs, sulfasalazine, methotrexate, and local corticosteroid injections) and biologic therapies (tumor necrosis factor [TNF]-alpha antagonists) may be included in pharmacologic regimens for such patients.[89,90] A thorough family history and previous dental, obstetric, surgical, traumatic injury, transfusion, and drug histories should be elicited from patients taking these drugs to evaluate the propensity for bleeding. A history suggestive of a bleeding disorder (e.g., excessive bruising or prolonged bleeding) should lead to a patient work-up that may include measurement of international normalized ratio (INR), platelet count, prothrombin time, and activated partial thromboplastin time.[91]

If the dosage and duration of corticosteroid therapy are considerable in patients with rheumatoid arthritis, perioperative supplementation also may be necessary to avoid hemodynamic instability. Patients considered at risk for adrenal insufficiency include those who received the hydrocortisone equivalent of more than 20 to 30 mg daily for longer than 2 weeks during the previous year and those who are receiving replacement corticosteroid treatment for adrenal insufficiency.[92] Patients with proven or suspected adrenal insufficiency or suppression should be evaluated for perioperative steroid coverage (Table 19-4).[93-96]

Although less common than osteoarthritis, ankylosing spondylitis and rheumatoid arthritis have greater implications for anesthetic management. Systemic manifestations are extensive during the advanced stages of both disorders. Patients frequently have pain, inflammation, and limited mobility in affected joints, such as those in the back and hands. Extreme ankylosis and joint deformity often make peripheral venous access and intraoperative positioning a challenge. On physical examination, limited range of motion of the temporomandibular joint and cervical spine, and reduced mouth opening, can make tracheal intubation more difficult.[97] In rheumatoid arthritis, this limitation is compounded by restrictions in vocal cord movement or tracheal stenosis caused by cricoarytenoid arthritis. These changes may be evidenced by preoperative hoarseness, stridor, painful speech, or dysphagia. Restrictive lung disease, polychondritis, pleural and pericardial effusions, and cardiac conduction abnormalities may be present during advanced stages of ankylosing spondylitis or rheumatoid arthritis.[98,99]

Neurologic System

Preoperative evaluation of the neurologic system includes the determination of CNS or peripheral nervous system dysfunction.

TABLE 19-4 Recommendations for Perioperative Glucocorticoid Coverage

Degree of Surgical Stress	Recommended Dose
Minor (inguinal hernia repair)	Preoperative corticosteroid dose + hydrocortisone 25 mg or equivalent
Moderate (lower extremity revascularization, total joint replacement)	Preoperative corticosteroid dose + hydrocortisone 50-75 mg or equivalent
Major (cardiac surgery, aortic aneurysm repair)	Preoperative corticosteroid dose + hydrocortisone* 100-150 mg or equivalent every 8 hr for 48-72 hr

From Nagelhout J, Elisha S, Waters E. Should I continue or discontinue that medication? *AANA J.* 2009;77(1):59-73.
*Hydrocortisone has mineralocorticoid activity at doses above approximately 100 mg per day. The mineralocorticoid activity of hydrocortisone may produce undesirable side effects including fluid retention, edema, and hypokalemia. It is preferable to use a glucocorticoid without mineralocorticoid activity, such as methylprednisolone, when the total dose of hydrocortisone exceeds 100 mg per day. Methylprednisolone 4 mg is equivalent to hydrocortisone 20 mg.

An initial neurologic examination consisting of the following should be performed[100]:

- *Musculoskeletal (motor) system:* Observe the patient's gait, ability to perform toe-and-heel walk, ability to maintain the arms held forward; evaluate the patient's grip strength
- *Sensory system:* Physical distinction of vibration, pain, and light touch on the patient's hands, feet, and limbs
- *Muscle reflexes:* Deep, superficial, and pathologic
- *Cranial nerve abnormalities*: Obtained by patient medical history and observation
- *Mental status and speech pattern:* Appearance, mood, thought processes, cognitive function

Knowledge of clinical manifestations of neurologic disease is essential for the preoperative evaluation of patients with CNS or peripheral nervous system disorders. Signs and symptoms of increasing intracranial pressure and cerebral ischemia, for example, may include papilledema; unilateral mydriasis; headaches, made worse by coughing; nausea and vomiting; slurred speech, disorientation, and altered levels of consciousness; flaccid hemiplegia or hemiparesis; abducens or oculomotor palsy; neck rigidity; and respiratory disturbances. Hypertension, with corresponding decreases in heart rate, represents a physiologic attempt to enhance cerebral perfusion when intracranial pressure is high. The appearance of Q waves, deep and inverted T waves, prolonged QT intervals, and ST-segment elevations on the electrocardiogram (ECG) may reflect hypothalamic ischemia and sympathetic overactivity. These abnormalities are most often attributed to vasospasm after a subarachnoid hemorrhage, but myocardial ischemia should be ruled out before surgery.[101] Fever and leukocytosis also can follow a subarachnoid hemorrhage as a result of meningeal irritation by subarachnoid blood. The progression of neurologic dysfunction to coma, obtundation, and decerebrate rigidity worsens the overall prognosis of the patient with an intracranial mass or hemorrhage. This prognosis mirrors that of a patient who has sustained an acute head injury. The patient with an initial Glasgow Coma Scale (Table 19-5)[102] score of less than 8 is considered comatose. Patients with a score of 8 or less usually require tracheal intubation and mechanical hyperventilation.[103]

Diagnostic reports should be reviewed so that the extent of neurologic and coexisting disease can be determined. These

BOX 19-11

Active Cardiac Conditions for Which the Patient Should Undergo Evaluation and Treatment Before Noncardiac Surgery

Unstable Coronary Syndromes
- Unstable or severe angina
- Recent myocardial infarction (MI) within 30 days

Decompensated Heart Failure
Significant Arrhythmias
- High-grade atrioventricular block
- Symptomatic ventricular arrhythmias
- Supraventricular arrhythmias with uncontrolled ventricular rate (greater than100 beats/min at rest)
- Symptomatic bradycardia
- Newly recognized ventricular tachycardia

Severe Valvular Disease
- Severe aortic stenosis (mean pressure gradient greater than 40 mmHg, area less than 1 cm^2 or symptomatic)
- Symptomatic mitral stenosis

Clinical Risk Factors
- History of ischemic myocardial disease
- Currently stable but history of heart disease
- History of cerebrovascular disease
- Diabetes (insulin dependent)
- Renal failure (serum creatinine [SCr] greater than 2 mg/dL)

From De Hert S, et al. Preoperative evaluation of the adult patient undergoing non-cardiac surgery: guidelines from the European Society of Anaesthesiology. *Eur J Anaesthesiol*. 2011;28(10):684-722.

reports include the results of electromyography, conduction velocity studies, electroencephalography, computed tomography (CT), magnetic resonance imaging (MRI), and cerebral arteriography studies. Consultation with a neurologist and obtaining preoperative electromyography, for example, are recommended for patients with complaints of extremity weakness, pain, or paresthesia. This screening is especially important in patients at greater risk for peripheral neuropathy (e.g., patients with long-standing diabetes, patients with uremia, chronic alcoholics with nutritional deficits).

Documentation of symptoms and reports of abnormal preoperative neurologic findings is important in these patients. Preoperative CT that reveals a 0.5-cm midline shift of the brain is significant and can confirm suspicions of intracranial hypertension. The size and location of an intracerebral aneurysm are represented on cerebral arteriography. This information can facilitate the prediction of the surgical approach and guide the evaluation of neurologic involvement. The degree of collateral circulation in the patient with cerebrovascular occlusive disease can be determined from arteriographic films. In a patient with vertebral artery involvement, for example, extremes in head flexion, extension, and rotation are avoided. Because of the associated risks of perioperative myocardial ischemia and infarction in patients undergoing a carotid endarterectomy procedure, a thorough cardiac evaluation by a cardiologist, including 12-lead ECG and stress testing, is advised.[104]

Information gained from the preoperative evaluation of neurologic function can enlighten the management of a patient with a CNS or peripheral nervous system disorder. For example, sedatives are avoided in patients with intracranial hypertension, especially when an altered level of consciousness accompanies the hypertension. Affected patients may be extremely sensitive to the CNS-depressant effects of such drugs as opioids.

Doses, schedules, and adverse effects of therapeutic regimens should also be considered before surgery. Serum concentrations of anticonvulsants such as phenytoin and phenobarbital are measured to determine whether levels are therapeutic. A complete blood cell count is obtained for patients receiving prolonged phenytoin therapy because of the risk of agranulocytosis associated with this drug. As with anticonvulsant therapy, corticosteroid therapy is continued perioperatively in patients with a CNS tumor. Although the exact mechanism of the beneficial effects of corticosteroids is unknown, it is theorized to involve the reduction of cerebrospinal fluid production or cerebral edema as a result of capillary membrane stabilization. Blood glucose levels are also determined for the patient treated with either dexamethasone or methylprednisolone, because hyperglycemia frequently accompanies the use of these drugs. Heightened risks of pulmonary infection and gastrointestinal irritation are unlikely in the patient undergoing perioperative therapy.[105]

Cardiovascular System

Preanesthesia patient evaluation for cardiovascular risk includes the determination of (1) preexisting cardiac disease (e.g., hypertension, ischemic heart disease, valvular dysfunction, cardiac arrhythmias, and cardiac conduction abnormalities, with or without evidence of ventricular failure); (2) disease severity, stability, and prior treatment; (3) comorbidity (e.g., diabetes mellitus, peripheral vascular disease, chronic pulmonary disease); and (4) surgical procedure. The prevalence and adverse consequences of cardiovascular disease make it a prime consideration in the overview of systems. Major cardiovascular risk factors that correlate with increased perioperative morbidity and mortality have been described by the European Society of Anaesthesiology (Box 19-11).[4] The type of surgery for which the patient is scheduled impacts on the likelihood of developing perioperative adverse

BOX 19-12

Surgical Risk Estimates

High Risk (Cardiac risk greater than 5%)
- Aortic surgery
- Major vascular surgery
- Peripheral vascular surgery

Intermediate Risk (Cardiac risk 1%-5%)
- Intraperitoneal
- Transplant (e.g., renal, liver, pulmonary)
- Carotid
- Peripheral arterial angioplasty
- Endovascular aneurysm repair
- Head and neck surgery
- Major neurologic/orthopedic (e.g., spine, hip)
- Intrathoracic
- Major urologic

Low Risk (Cardiac risk less than 1%)
- Breast
- Dental
- Endoscopic
- Superficial
- Endocrine
- Cataract
- Gynecologic
- Reconstructive
- Minor orthopedic (e.g., knee surgery)
- Minor urologic

TABLE 19-6 Exercise Tolerance in Metabolic Equivalents (METs) for Various Activities

Estimated Energy Expenditure	Physical Activity
1 MET*	*Poor functional capacity*
	Self-care Eating, dressing, or using the toilet Walking indoors and around the house Walking one to two blocks on level ground at 2 to 3 mph[2]
4 METs	*Good functional capacity*
	Light housework (e.g., dusting, washing dishes) Climbing a flight of stairs without stopping, or walking up a hill longer than 1 to 2 blocks Walking on level ground at 4 mph Running a short distance Heavy housework (e.g., scrubbing floors, moving heavy furniture) Moderate recreational activities (e.g., golf, dancing, doubles tennis, throwing a baseball or football)
Greater than 10 METs	*Excellent functional capacity*
	Strenuous sports (e.g., basketball, cross-country skiing [> 8 km/hr][3], rope skipping, running, soccer, swimming [> 3.5 km/hr], weight training)

Modified from Jetté M, Sidney K, Blümchen G. Metabolic equivalents (METS) in exercise testing, exercise prescription, and evaluation of functional capacity. *Clin Cardiol.* 1990;13(8):555-565; Fleisher LA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. *Circulation.* 2007;116(17):1971-1996.
*MET is defined as the amount of oxygen consumed while sitting at rest and is equal to 3.5 mL oxygen/kg/min.
mph, Miles per hour; *km/hr*, kilometer per hour.

cardiac events (cardiac death, MI) within 30 days following surgery (Box 19-12)[4,14]

The patient's functional capacity, measured in metabolic equivalents (METs), can be simply and accurately assessed preoperatively by asking a set of questions (Table 19-6)[106,107] and is recommended as part of cardiac risk assessment.[14] Patients with good functional capacity (more than 4 METs) may proceed for surgery provided patients with cardiac risk factors are properly managed with statin and beta-blocker therapy.[14] Good functional capacity (more than 4 METs) may be determined by an affirmative answer to two simple questions: (1) Are you able to walk four blocks without stopping regardless of limiting symptoms? (2) Are you able to climb two flights of stairs without stopping regardless of limiting symptoms?[108] The inability to climb two flights of stairs or walk a short distance is indicative of poor functional capacity and is associated with an increased incidence of postoperative cardiac complications in noncardiac surgery.[109,110] Patients with moderate to poor functional capacity (less than 4 METs) should be further assessed to identify cardiac risk factors.[14]

A standard means of categorizing the degree of cardiovascular disability is the New York Heart Association classification tool (Table 19-7).[111] When the patient interview is conducted, specific inquiry should be made regarding the presence of dyspnea, chest pain, fatigability, syncope, palpitation, and the factors that predispose to angina. Lee et al.[112] developed a Revised Cardiac Risk Index (Box 19-13), which offers an improved predictive risk index for major postoperative cardiac complications. Whenever a patient has signs of significant cardiovascular disease, referral to a cardiologist is indicated for assessment and possible intervention.[4]

Hypertension

Hypertension, defined as a systolic blood pressure greater than 140 mmHg or a diastolic pressure greater than 90 mmHg,[113] is the most common circulatory derangement to affect humans (approximately 65 million in the United States; 45% to 50% of adults older than 70 years) and is a major risk factor for coronary artery disease[110,114] and increased perioperative mortality.[115] Increasingly, patients undergoing surgery have stage 2 hypertension and accompanying target-organ damage, or uncontrolled stage 3 hypertension (systolic blood pressure greater than 180 mmHg, diastolic pressure greater than 110 mmHg, or both). This problem can be attributed to the lack of or inadequacy of medical treatment or to patient noncompliance. In such a situation, elective surgery may be postponed for further patient assessment and normalization of the preoperative blood pressure.[116,117] Consultation with an internist can be pursued for the medical evaluation and treatment of the patient with uncontrolled or newly diagnosed hypertension. These recommendations are aimed at reducing the occurrence of perioperative hemodynamic instability and consequently the incidence of myocardial ischemia. Both complications are more likely to occur when hypertension is not effectively treated before surgery.[118] With the goal of reducing perioperative risk, delaying surgery is justified in hypertensive patients with target-organ damage (or suspected damage) such as ischemic heart disease, heart

TABLE 19-7 New York Heart Association Functional Classification of Cardiovascular Disability

Classification	Cardiovascular Status
Class I	*Patients with cardiac disease*
	No functional limitations to physical activity, such as walking or climbing stairs. Ordinary physical activity is not associated with undue fatigue, palpitations, dyspnea, or anginal pain.
Class II	*Patients with cardiac disease who are comfortable at rest*
	Slight functional limitations to physical activity, such as walking or climbing stairs rapidly, or during emotional stress. Patients are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.
Class III	*Patients with cardiac disease resulting in marked limitations to physical activity*
	Patients are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain.
Class IV	*Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort*
	Symptoms of cardiac insufficiency or anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.

Modified from Kaplan JA, Reich DL, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*, 6th ed. Philadelphia: Saunders; 2011.

BOX 19-13

Revised Cardiac Risk Index

Risk Categories

- High-risk surgery (aortic, major vascular, peripheral vascular)
- Ischemic heart disease (previous myocardial infarction; previous positive result on stress test, use of nitroglycerin; typical angina; ECG Q waves; previous PCI or CABG)
- History of compensated previous congestive heart failure (history of heart failure; previous pulmonary edema; third heart sound; bilateral rales; evidence of heart failure on chest radiograph)
- History of cerebrovascular disease (previous TIA; previous stroke)
- Diabetes mellitus (with or without preoperative insulin)
- Renal insufficiency (creatinine greater than 2.0 mg/dL)

Estimated Rates for Postoperative Major Cardiac Complications per Number of Risks

- 0 Risk Factors: 0.4%
- 1 Risk Factor: 0.9%
- 2 Risk Factors: 7%
- 3 or more Risk Factors: 11%

From Lee TH, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation*. 1999;100(10):1043-1049; Freeman WK, Gibbons RJ. Perioperative cardiovascular assessment of patients undergoing noncardiac surgery. *Mayo Clin Proc*. 2009;84(1):79-90.
ECG, Electrocardiogram; *PCI*, percutaneous coronary intervention; *CABG*, coronary artery bypass grafting; *TIA*, transient ischemic attack.

failure, renal damage, and cerebrovascular diseases if either of the following scenarios is probable[119]:

- Conditions can be improved by such postponement to the extent that the perioperative risk would be considerably decreased.
- Care may be influenced by further preoperative examination.

Delaying elective surgery in patients with mild to moderate hypertension only for the purpose of blood pressure control may not reduce perioperative risk.[119] A systolic blood pressure below 180 mmHg and diastolic blood pressure below 110 mmHg is not an independent risk factor for perioperative cardiovascular complications.[107]

The practitioner taking the medical history should focus on identifying comorbid diseases, such as diabetes mellitus, and social risk factors (i.e., tobacco use, alcohol or caffeine consumption, illicit drug use [especially cocaine or amphetamines]). What medications the patient takes to manage hypertension should be established. In general, the substances used affect the central and peripheral components of the sympathetic nervous system by altering the synthesis, release, biotransformation, or end-organ action of norepinephrine. Because the circulatory-depressant effects of general anesthesia may be additive, the combination of antihypertensive drugs and anesthetics is of concern. Complaints of syncope and dizziness also are investigated. These symptoms may be the clinical manifestations of cerebrovascular insufficiency, although a diagnosis of drug-induced orthostatic hypotension should be considered preoperatively. This diagnosis can be confirmed by measuring a significant decrease in the blood pressure as the patient rises from the supine position. The lack of hemodynamic compensatory responses that normally accompany positional changes may then predict their absence during anesthesia and surgery.

The physical examination of the patient includes the following[120]:

- *Overall appearance:* Truncal obesity with purpura and striae suggestive of Cushing disease
- *Vital signs:* Measurement of blood pressure in both arms
- *Funduscopic examination:* Hypertensive retinopathy
- *Neck:* Carotid bruits, distended veins, or enlarged thyroid gland
- *Heart:* Abnormal rhythm or size, murmurs, or heart sounds
- *Lungs:* Rales or bronchospasm
- *Abdomen:* Bruits, masses, enlarged kidneys, or abnormal aortic pulsation
- *Extremities:* Delayed or absent femoral pulses secondary to aortic coarctation; evidence of atherosclerosis, peripheral edema
- *Neurologic evaluation:* See the discussion of the neurologic system earlier in this chapter

Ischemic Heart Disease

Myocardial ischemia occurs secondary to insufficient oxygen and nutrient supply (increased demand, reduced blood supply, or both) to meet the metabolic requirements of the myocardial cells. Nearly one third of the estimated 30 million patients undergoing surgery annually in the United States is at high risk for coronary artery disease or factors for cardiovascular disease.[121] Risk factors for ischemic heart disease include advanced age, smoking, diabetes mellitus, hypertension, pulmonary disease, previous MI, left ventricular wall motion dysfunction, and peripheral vascular disease.[122] The preoperative evaluation of a patient with known or suspected ischemic heart disease is aimed at determining the severity, progression, and functional limitations imposed by

cardiovascular disease. Myocardial ischemia, cardiac arrhythmias, and left ventricular dysfunction are usually precipitating factors for patient symptomatology. Complaints of undue fatigue, angina pectoris, palpitations, syncope, or dyspnea should be thoroughly investigated. A 12-lead ECG is reviewed for evidence of myocardial ischemia or infarction, cardiac arrhythmias or conduction abnormalities, and ventricular hypertrophy. Signs and symptoms of myocardial ischemia may not be apparent at rest, however. Therefore the response of the patient to various activities, such as walking a certain distance or climbing several stairs, must be determined (see Tables 19-6[106,107] and 19-7[111]).

Anginal symptoms can also be classified according to the stability of precipitating factors, the frequency of the events, and the duration of pain. Stable angina (characterized as substernal discomfort brought on by exertion, relieved by rest or nitroglycerin or both in less than 15 minutes, and having a typical radiation to the shoulder, jaw, or the inner aspect of the arm)[111] poses no greater threat of MI perioperatively than the absence of anginal symptoms.[123] Unstable angina is defined as newly developed angina occurring within the past 2 months; angina that has progressively worsened, that occurs with increased frequency, intensity, or duration, that is less responsive to medicine, or that occurs when the patient is at rest; or angina that lasts longer than 30 minutes, exhibiting transient ST- or T-wave changes without development of Q waves or diagnostic elevation of enzymes.[111] *Unstable angina is associated with the highest risk for perioperative MI*.[124] In the patient with unstable angina, elective surgery is canceled until the cardiovascular status of the patient has been thoroughly evaluated and optimized. Advanced diagnostic techniques such as coronary angiography and exercise ECG may be used for determination of the extent and functional impairment of ischemic heart disease.

The overall risk of MI after general anesthesia is approximately 0.3% in the population at large.[125] In patients known to have had an MI in the remote past (more than 6 months previously), the risk of perioperative reinfarction increases to approximately 6%. If MI occurred 3 to 6 months previously, the risk of reinfarction is 15%; within 3 months previously, 30%. If reinfarction occurs, the mortality rate is approximately 50%. The highest at-risk period appears to be within 30 days after an acute MI; therefore the ACC/AHA (American College of Cardiology Foundation/American Heart Association) guidelines recommend waiting at least 4 to 6 weeks after an MI before a patient undergoes elective surgery. Patients who have survived coronary revascularization and are asymptomatic are at lower risk of reinfarction when undergoing noncardiac surgery.[107] The new clinical classification of myocardial infarction is noted in Table 19-8.[126]

Coronary Stents. Approximately 528,000 coronary stents are placed annually in United States patients to open clogged coronary arteries.[127] Coronary stents (either bare metal or drug-eluting) were designed to prevent arterial restenosis after percutaneous coronary intervention with balloon angioplasty. Bare metal stents, while beneficial over balloon angioplasty in reducing the incidence of restenosis, experience a restenosis rate of 20%.[128] Drug-eluting stents were developed to further reduce the incidence of stent thrombosis, and restenosis rates approaching 5% after 2 years are reported.[129] Postprocedure pharmacotherapy involves long-term oral dual antiplatelet therapy, consisting of aspirin (continue indefinitely) and clopidogrel (typically continue for at least 1 year) to prevent in-stent coronary artery restenosis.[130] Approximately 5% of these patients will require noncardiac surgery within 1 year after placement of coronary stents.[131] There is an increased risk of coronary stent thrombosis, perioperative MI, hemorrhagic complications, and death in patients having noncardiac surgery performed early after stent placement.[132,133] Box 19-14[134-138] and Figure 19-3[135,139] describe preoperative assessment and management considerations for patients presenting for surgery in which coronary artery stents have been placed.

TABLE 19-8 New Clinical Classifications of Myocardial Infarction

Classification	Description
1	Spontaneous MI related to ischemia due to a primary coronary event, such as plaque erosion and/or rupture, fissuring, or dissection
2	MI secondary to ischemia due to an imbalance of O_2 supply and demand, as from coronary spasm or embolism, anemia, arrhythmias, hypertension, or hypotension
3	Sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggesting ischemia with new ST-segment elevation, new left bundle branch block, or pathologic or angiographic evidence of fresh coronary thrombus—in the absence of reliable biomarker findings
4a	MI associated with PCI
4b	MI associated with documented in-stent thrombosis
5	MI associated with CABG surgery

From Thygesen K, et al. Joint ESC/ACCF/AHA/WHF Task Force for the Redefinition of Myocardial Infarction: universal definition of myocardial infarction. *J Am Coll Cardiol*. 2007;50(22):2173-2195.
MI, Mycocardial infarction; *PCI*, percutaneous coronary intervention; *CABG*, coronary artery bypass graft.

Left Ventricular Dysfunction

Active left ventricular failure is the prominent cardiovascular risk factor for patients undergoing noncardiac surgery.[140] Patients with ischemic cardiomyopathy are at even greater risk for perioperative MI and ventricular dysfunction.[141] Heart failure is defined by the presence of any of the following: history of congestive heart failure, pulmonary edema, or paroxysmal nocturnal dyspnea; physical examination showing bilateral rales or S_3 gallop; or chest X-ray showing pulmonary vascular redistribution.[107] Prominent signs include moist rales in the lungs, often associated with tachypnea. These extraneous sounds may be confined to the bases, with mild degrees of left ventricular failure, or they may be generalized throughout the lungs, with acute pulmonary edema. As a result of sympathetic nervous system stimulation, resting tachycardia may also be present. A third heart sound (S_3) or ventricular gallop, jugular vein distention, and peripheral edema are significant. In the presence of congestive heart failure as confirmed by a chest radiograph, elective surgery should be postponed until optimal ventricular performance can be achieved.

Patients exhibiting dyspnea of unknown origin or current or prior heart failure with worsening dyspnea or other relevant change in clinical status should undergo preoperative evaluation of left ventricular function if an assessment has not been performed within the previous 12 months.[107] Tests of resting left ventricular function include cardiac magnetic resonance,[142] radionuclide angiography, two-dimensional echocardiography, and contrast ventriculography. Systolic left ventricular dysfunction is defined as a left ventricular ejection fraction less than 50%, with and without accompanying diastolic dysfunction.[143] A left ventricular ejection fraction of less than 35% as determined by

BOX **19-14**

Preoperative Considerations for the Patient with Coronary Stent

Stents
- Type of stent (s) (e.g., BMS, DES)?
- When were stent(s) placed?
- Complications during the revascularization, such as malposition, longer length, overlapping?

Antiplatelet Therapy
- What is antiplatelet regimen?
- What is the recommended duration of antiplatelet therapy?
- Consult interventional cardiologist or patient cardiologist regarding antiplatelet management.

Elective Surgery
Delay until completion of dual antiplatelet therapy (aspirin and clopidogrel) with resultant complete stent endothelialization
- *BMS:* 6 weeks minimum after PTCA
- *DES:* 12 or more months if patient is not at high risk of bleeding after PTCA

Nonelective Surgery
- *Determine risk for surgical bleeding:* If not at high risk, continue dual antiplatelet therapy. Discontinuation of dual antiplatelet therapy, in patients with incomplete stent endothelialization, markedly increases the risk of stent thrombosis, myocardial infarction, and death.
- *High risk for bleeding:* Risk primarily associated with closed space surgeries (i.e., medullary canal spine surgery, intracranial surgery, posterior chamber eye surgery) where increased tissue pressure would be deleterious. If dual antiplatelet therapy must be interrupted, aspirin should be continued, when possible. An evolving treatment option involves "bridging therapy" anticoagulation in which drugs of short duration (glycoprotein inhibitor, e.g., tirofiban, eptifibatide; direct thrombin inhibitor, e.g., bivalirudin; unfractionated heparin; low molecular weight heparin; nonsteroidal antiinflammatory drugs, e.g., flurbiprofen; COX-1 inhibitors) are administered for up to 6 hours during the surgery, with the goal of preventing stent thrombosis while dual antiplatelet therapy is interrupted. Restart dual antiplatelet therapy as soon as possible after the surgery.
- Surgery should be performed in an institution where higher-acuity care and an interventional cardiologist are available when possible. Consult prior to surgery to determine procedural complexities, and determine optimal antiplatelet therapy and requisite patient management.

echocardiography is associated with greater incidence of postoperative heart failure and death.[144]

Valvular Heart Disease

Basic lesions of valvular heart disease may involve stenosis, incompetence, or both. In adults, aortic and mitral valve lesions are more common than those involving the tricuspid or pulmonic valve. Despite decreasing incidence, rheumatic heart disease is still the most common cause of adult valvular disease. Degenerative disorders (sclerosis, fibrosis) and congenital diseases are less common causes. With stenosis, the chamber proximal to the obstruction must increase the work of maintaining a stroke volume; this eventually results in hypertrophy. Normal valves can episodically accommodate up to seven times the normal cardiac output—for example, in intense physical exercise in the normally active patient. Valvular stenosis usually is chronic and severe before cardiac output decreases. In valvular incompetence, the chambers both proximal and distal to the lesions are involved, because regurgitant flow during one phase of the cardiac cycle is added to forward flow during subsequent systole. Because lesions are almost never entirely unitary, in stenosis some regurgitation is common, and vice versa. It is important to identify the type of valvular lesion before surgery. Evaluation of the clinical symptoms and cardiac catheterization data regarding valve area and gradients, combined with assessment of data from any surgical history (e.g., correction of congenital heart lesions), is an important component of the preoperative evaluation of patients with valvular heart disease.

Severe aortic stenosis poses the greatest patient risk for noncardiac surgery,[107] especially when the cross-sectional area of the aortic valve is less than 1 cm^2. Severe aortic stenosis is associated with a 14-fold greater incidence of perioperative sudden death.[145] For patients in whom aortic stenosis is symptomatic, elective noncardiac surgery should be postponed until after cardiac surgical consultation.[107] Chapter 23 describes the perioperative care of patients with valvular heart disease.

Arrhythmias

Patients with cardiac arrhythmias must have an adequate preoperative evaluation to ascertain the nature of the arrhythmia, associated underlying heart disease, and type of antiarrhythmic therapy. Whether symptoms of palpitations or dizziness have been relieved may be a sign of successful therapy or continuing problems. Other cardiac symptoms such as dyspnea, angina, or syncope may suggest worsening of associated cardiac disease. Treatment of the underlying disease preoperatively may aid in control of arrhythmia in the perioperative period. All patients with a history of symptomatic arrhythmias should undergo electrocardiography with rhythm strip before surgery. Other preoperative laboratory evaluations should include measurement of potassium and magnesium levels, determination of antiarrhythmic drug levels (if possible), and chest radiography (in the presence of structural cardiac disease).

Ventricular arrhythmias are classified into three categories: benign ventricular arrhythmias (unifocal premature ventricular

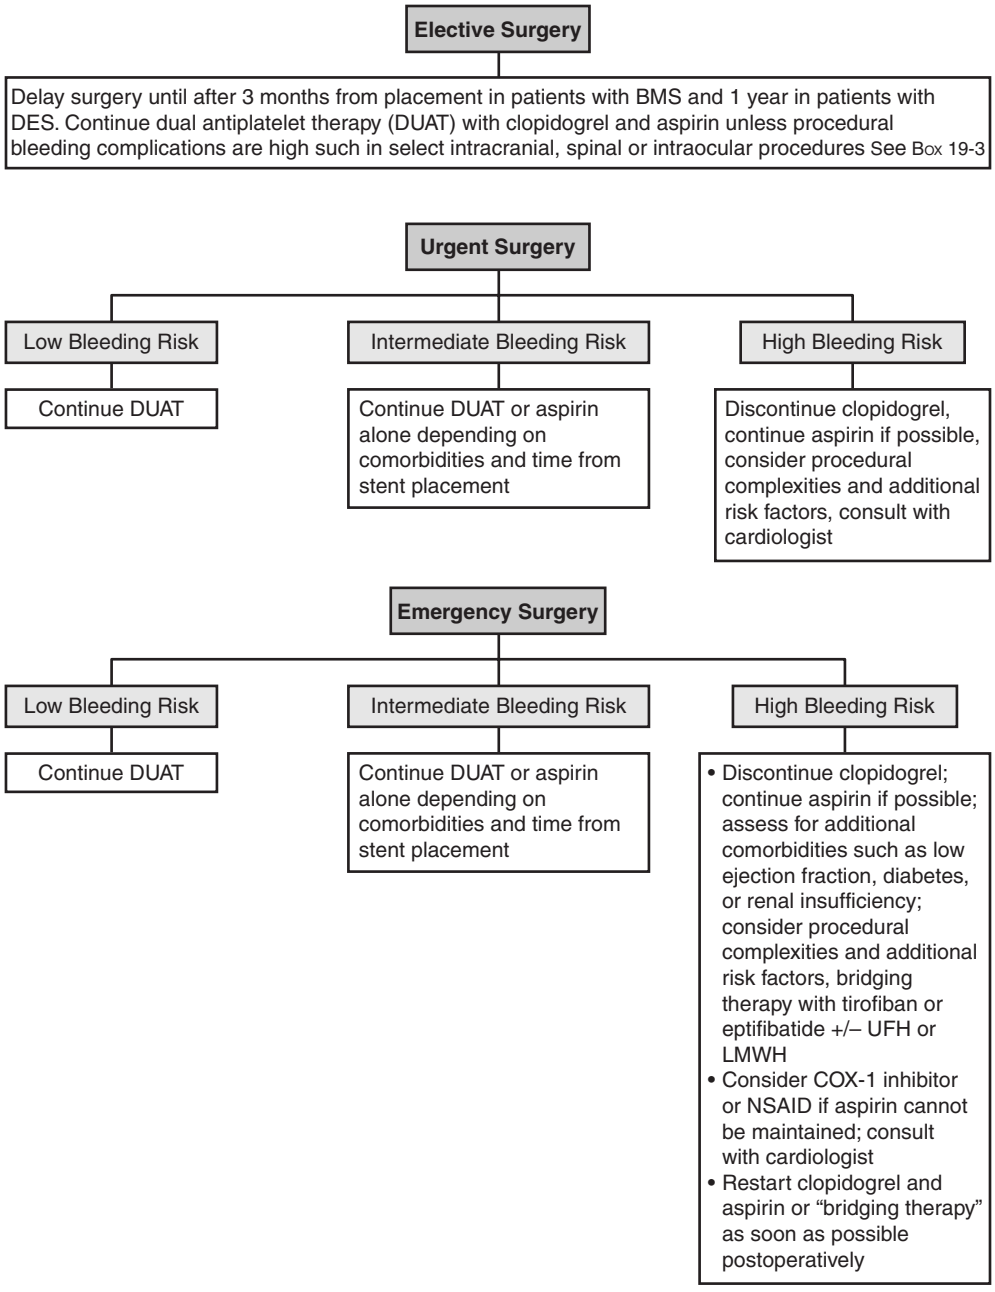

FIGURE **19-3** Perioperative management of patients with coronary stents. (Modified from Newsome LR, et al. Coronary artery stents: II. Perioperative considerations and management. *Anesth Analg*. 2008;107:570-590; Abualsaud AO, Eisenberg MJ. Perioperative management of patients with drug-eluting stents. *J Am Coll Cardiol Intv*. 2010;3:131-142; American Society of Anesthesiologists Committee on Standards and Practice Parameters: Practice alert for the perioperative management of patients with coronary artery stents: a report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology*. 2009;110[1]:22-23.)

contractions); potentially malignant ventricular arrhythmias (patient has known organic heart disease and is on antiarrhythmic therapy); and malignant ventricular arrhythmias (patient has organic heart disease, hemodynamic compromise, and possibly a family history of sudden death).[146] Few data are available to help correlate the risk of arrhythmias and perioperative risk.[111] In the absence of cardiac disease, benign ventricular arrhythmias do not carry a significantly increased surgical risk.[147] In patients with severe coronary artery disease, recent MI, or peripheral vascular disease, arrhythmias may increase perioperative risk.[148,149]

Cardiovascular Implantable Electronic Devices (Pacemaker, Implantable Defibrillators)

When a patient presents for surgery with an implanted cardiac device, preprocedural planning must be employed to minimize risk to patient, and the device. This planning includes knowledge of the device, its indication for use, and functional assessment (Box 19-15).[150-153] Because of the evolving complexity of these devices, direct interrogation by a qualified member of the cardiovascular implantable electronic device (CIED) management team remains the only trustworthy method for evaluating battery status, lead performance, and adequacy of current settings.[154]

BOX **19-15**

Perioperative Guidelines for the Patient with a Cardiovascular Implantable Electronic Device

Preoperative Key Points

- Establish the indication for the permanent pacemaker, for example, symptomatic third-degree heart block, type II second-degree heart block, sinus node dysfunction, recurrent neurally mediated syncope, some forms of cardiomyopathy.
- Establish the indication for the implantable defibrillator, for example, history of cardiac arrest not secondary to a temporary condition.
- Identify device and manufacturer (available from manufacturer's identification card).
- Notify the cardiovascular implantable electronic device (CIED) management team of the planned procedure, including anatomic location of surgery, whether monopolar electrosurgery will be used, and whether other sources of electromechanical interference (EMI) will be present. Have the pacemaker or defibrillator interrogated by a qualified member of the CIED management team (physicians or staff) who monitor the device function shortly before the anesthetic. Pacemakers should be routinely interrogated annually and implantable cardioverter devices (ICDs) every 3 to 4 months. Pacemakers should be assessed within 12 months of elective surgery. ICD function should be assessed within 6 months of surgery.
- Obtain a copy of this interrogation, including current settings. Ensure that the device will pace the heart with appropriate safety margins.
- A prescription for the perioperative management of the patient with the CIED should be communicated to the procedure team from the CIED team.
- Consider replacing any device near the end of its elective replacement period in a patient scheduled to undergo either a major surgery or surgery within 25 cm of the generator.
- Is the patient device dependent for antibradycardia? Determine the patient's underlying rhythm/rate to evaluate the need for backup pacing support.
- Evaluate effect of magnet on pacemaker function. Identify the magnet rate and rhythm if a magnet mode is present and magnet use is planned. Will device automatically reset to preoperative settings when a magnet is removed?
- Program minute ventilation rate responsiveness to "Off," if present.
- Program all rate enhancements to "Off."
- Consider increasing the pacing rate to optimize oxygen delivery to tissues for major cases.
- Inactivation of ICD tachyarrhythmia detection is recommended for all procedures using monopolar electrosurgery or radiofrequency ablation above the umbilicus. ICD arrhythmia detection can be suspended by placement of a magnet over the pulse generator.

Intraoperative Key Points

- Is electromagnetic interference (EMI) likely during the procedure? Interference is unlikely if the device is less than 10 years old and bipolar cautery is greater than 15 cm (below the umbilicus) from device lead or generator.
- Have a magnet immediately available for patients with CIEDs who are undergoing a procedure that may involve EMI.
- Monitor cardiac rhythm/peripheral pulse with pulse oximeter or arterial waveform.
- Disable the "artifact filter" on the electrocardiogram (ECG) monitor.
- Avoid use of monopolar electrosurgery.
- Use bipolar electrocautery system or ultrasonic (harmonic) scalpel if possible; if not possible, then pure cut (monopolar electrosurgery) with short bursts of 5 seconds or less is better than "blend" or "coag."
- Position the electrosurgical unit (ESU) current return pad in such a way that it will prevent electricity from crossing the generator-heart circuit, even if the pad must be placed on the distal forearm and the wire covered with sterile drape.
- If the ESU causes ventricular oversensing, pacer quiescence, or tachycardia, limit the period(s) of asystole or reprogram the device.

Postoperative Key Points

- Have the device interrogated by a qualified member of the team (physician or staff) who monitors the device function postoperatively. Some rate enhancements can be reinitiated, and optimum heart rate and pacing parameters should be determined. The ICD patient must be monitored until the antitachycardia therapy is restored.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011 Feb;114(2):247-61.

Pacemakers can mask the toxicity of antiarrhythmic drugs, electrolyte disorders, and myocardial ischemia and irritability. In general, the ECG should be examined for pacemaker malfunction, as evidenced by unexpected pauses. If the patient's heart rate is slower than the pacing rate, pacing spikes should appear on the ECG. To determine whether these pacing impulses are associated with myocardial contractions, the clinician should palpate a peripheral pulse. Evaluation of a pacemaker becomes more difficult when the patient's heart rate is faster than the pacing rate. A Valsalva maneuver slows the patient's rate so that pacing impulses appear on the ECG. Generally, because sensing is lost before pacing, the pacemaker is probably functioning normally if (1) it has been in place for fewer than 2 years, (2) chest radiography demonstrates that leads are intact, and (3) impulses do not appear on the ECG.[155] Chest radiography should provide information on electrode placement, the presence of electrode fracture, and even battery depletion.[156]

If each pacing impulse is not associated with a pulse or if the symptoms that led to pacemaker implantation have returned, cardiology consultation should be considered.[155] Anesthesia providers sometimes must decide whether a transvenous, temporary pacing wire should be inserted preoperatively. Persistent bradycardia not responsive to intravenous administration of atropine or exercise is one indication. Bifascicular block in a patient with a history of

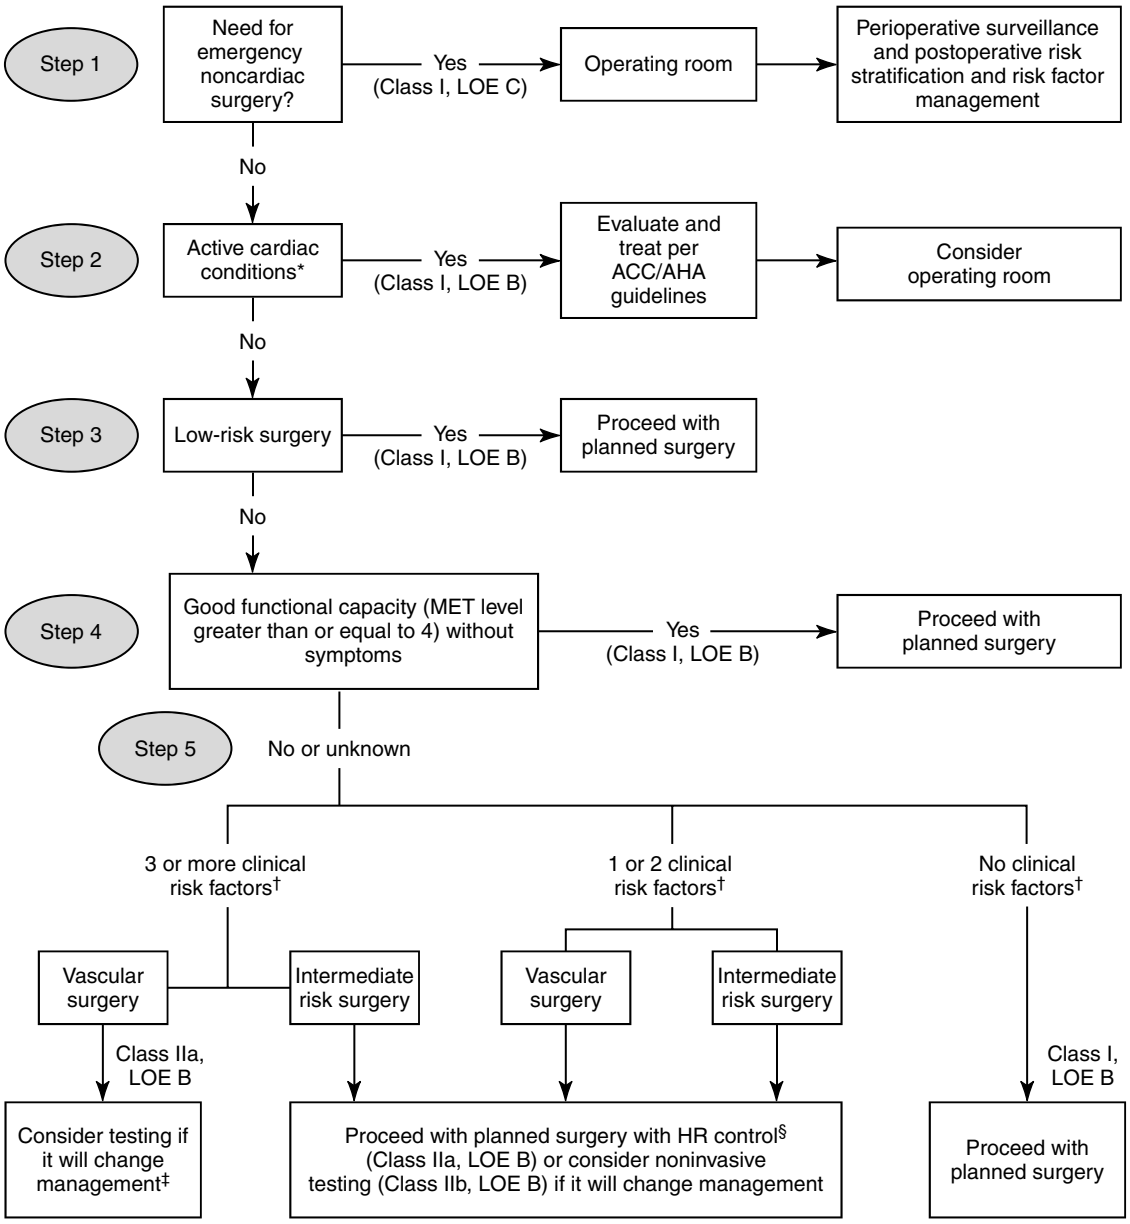

FIGURE **19-4** Cardiac evaluation and care algorithm for noncardiac surgery, based on active clinical conditions, known cardiovascular disease, or cardiac risk factors for patients 50 years of age or older. *See Box 19-11 for active clinical conditions. †Clinical risk factors include ischemic heart disease, compensated or prior heart failure (HF), diabetes mellitus, renal insufficiency, and cerebrovascular disease. ‡Consider perioperative beta blockade for populations in which this has been shown to reduce cardiac morbidity/mortality. *ACC/AHA*, American College of Cardiology/American Heart Association; *HR*, heart rate; *LOE*, level of evidence; *MET*, metabolic equivalent. (From Fleisher LA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. *Circulation*. 2007;116:1971-1996.)

syncope suggests underlying, unrecognized complete heart block. Such patients can benefit from the availability of transvenous pacing.

It also must be determined whether exercising the muscles adjacent to the generator causes dizziness. The presence of this symptom, indicating that myopotentials may be inhibiting the pacemaker, implies that muscle fasciculations caused by succinylcholine and shivering should be avoided.

Diagnostic Testing to Assess Cardiovascular Disease

Multiple tests are available to define the presence of cardiac disease. Preoperative cardiac testing should not be performed unless the results are likely to influence patient management. The ACC/AHA guidelines include an algorithm for determining the appropriateness of preoperative testing (Figure 19-4).[107]

Several noninvasive tests are available for preoperative assessment of the high-risk patient (i.e., three or more risk factors and poor functional capacity). The exercise stress ECG is preferred.[142] Stress testing with exercise or pharmacologic stress agents is designed to increase myocardial work and permit measurement of myocardial response to the increased workload. The exercise stress test not only is a standardized means of obtaining a functional history of angina but also provides excellent documentation

of how ischemia manifests its effects on the cardiovascular system. By examining the stress test report, one can learn the extremes of blood pressure and heart rate the patient can tolerate while awake (although exactly how these correlate with the anesthetized state is a matter of debate), the location of ischemic leads, and whether arrhythmias are associated with ischemia. Significant coronary disease is likely if ST-segment depression is greater than 0.2 mV, if ST depression occurs early in the test, if little increase in blood pressure or heart rate occurs at the time of ST depression, or if hypotension occurs. Hypotension is considered an ominous finding and usually prompts cardiac catheterization.

Perioperative risk is considered low if exercise stress testing does not produce signs of myocardial ischemia at a reasonable workload (greater than 85% of predicted maximum heart rate).[157] Although it is useful in diagnosing coronary artery disease, its value as a preoperative test has been questioned,[112] even in patients undergoing major vascular surgery.[158] Stress testing is not indicated in patients with intermediate risk factors (i.e., fewer than three risk factors), even if major vascular surgery is planned, provided the patient has complete heart rate control with beta-blocker therapy.[108] Patients who are able to tolerate a good exercise stress workload, even those with stable angina, are unlikely to have myocardial dysfunction.[159]

Pharmacologic stress testing can be performed in patients unable to exercise or in those who take digoxin. Two pharmacologic techniques, which incorporate either echocardiography or radionuclide scintigraphy, are used: (1) dipyridamole or adenosine, both of which cause a coronary steal phenomenon by redistributing coronary blood flow without direct negative inotropic effects and (2) dobutamine for inotropic stress testing.[160]

Additional noninvasive studies are available for preoperative testing, such as stress myocardial perfusion scintigraphy (MPS), stress echocardiography, resting transthoracic echocardiography, pharmacologic stress echocardiography, cardiac computed tomography, cardiac magnetic resonance (CMR), and adenosine stress CMR.[142,161] There is insufficient evidence to support the clinical utility and development of appropriate guidelines for these tests at this time.[142]

Cardiac catheterization provides definitive information about the distribution and severity of coronary artery disease and may be indicated for patients with New York Heart Association class III or IV criteria who are undergoing high-risk surgical procedures.[157] Significant stenosis means narrowing of a major coronary artery by more than 70% or narrowing of the left main coronary artery by more than 50%. However, it is important to look beyond the coronary anatomy and concentrate on other findings that can guide perioperative decision making.

Three readily identifiable findings that indicate poor ventricular function are a cardiac index of less than 2.2 L/m^2, a left ventricular end-diastolic pressure of greater than 18 mmHg, and an ejection fraction of less than 40%.[162] Taking note of ischemia-induced dysfunction of the papillary muscles can help in avoiding later confusion about the configuration of the pulmonary wedge pressure waveform and the significance of intraoperative changes in wedge pressure. Wall motion abnormalities should be noted. Areas of akinesis (no movement during systole) usually represent nonviable regions of myocardium and are relatively fixed deficits. In contrast, areas of hypokinesis (reduced contraction during systole) may represent ischemic but nonetheless viable regions of myocardium. This should alert anesthesia providers to a potentially dynamic situation in which alterations in the balance of myocardial oxygen supply and demand can either improve or worsen regional ischemia and associated contractility.

Cardioprotective Pharmacotherapy

Appropriate pharmacologic therapy should be instituted preoperatively in patients exhibiting clinical risk factors (e.g., angina pectoris, prior MI, heart failure, stroke/transient ischemic attack, renal dysfunction, diabetes mellitus requiring insulin therapy) and moderate to poor functional capacity. Patients having up to two clinical risk factors should be managed with statin and beta-blocker therapy preoperatively.[14] If stable left ventricular dysfunction is present, angiotensin-converting enzyme (ACE) inhibitor therapy is recommended.

Statins. In addition to their lipid-lowering benefit, statins are valuable for enhancing endothelial function, improving atherosclerotic plaque stability, decreasing oxidative stress, and reducing vascular inflammation. Common statins used perioperatively include atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin.[163] Recommendations are as follows[14]:

- Institute therapy between 30 days and at least 1 week before high-risk surgery.
- Continue statin therapy perioperatively.

Beta Blockers. Low-dose titration of beta blockers restores the oxygen supply/demand mismatch, reduces perioperative ischemia, redistributes coronary blood flow to the subendocardium, stabilizes plaques, increases ventricular fibrillation threshold, and may reduce the risk of MI and death in high-risk patients.[14] Common beta blockers used perioperatively include atenolol, bisoprolol, nadolol, and metoprolol. Recommendations are as follows[13,164,165]:

- Indicated for patients with high cardiac risk, known ischemic heart disease, or stress-induced myocardial ischemia who present for high-risk surgery such as vascular procedures.
- Continue beta blockers in patients previously treated with beta blockers for ischemic heart disease, symptomatic arrhythmia, or hypertension.
- Institute therapy between 30 days and at least 1 week before high-risk surgery. Avoid acute initiation of high-dose beta-blocker therapy.
- Titrate beta blocker to achieve a resting heart rate of 60 beats per minute.
- Continue beta-blocker therapy postoperatively for approximately a month to maintain a heart rate of 60 to 65 beats per minute with systolic blood pressure greater than 100 mmHg.
- Beta blockers are not recommended in patients scheduled for low-risk surgery without risk factors, or who have absolute contraindications.

ACE Inhibitors. ACE inhibitors are beneficial in reducing heart failure, myocardial infarction, and death when administered in the perioperative period in patients with left ventricular dysfunction.[166] Common ACE inhibitors used perioperatively include captopril, enalapril, lisinopril, benazepril, and ramipril. Recommendations are as follows[14]:

- Recommended in cardiac stable patients with left ventricular dysfunction for intermediate- to high-risk surgery and considered for those scheduled for low-risk surgery.

Respiratory System

A detailed evaluation of the respiratory system is crucial because of the relative frequency of and complications associated with respiratory disease. From an epidemiologic perspective, some form of lung disease is present in nearly 25% of the adult population. The most common problems are chronic obstructive pulmonary diseases (COPDs), such as chronic bronchitis, emphysema, and asthma, which are major predictors for postoperative pulmonary disorders.[167] In their acute or chronic forms, the lung diseases are

second only to coronary artery disease as a cause of death. Patients with COPD are twice as likely to have postoperative pulmonary complications.[168] Risk factors associated with increased postoperative respiratory morbidity and mortality rates include preoperative sepsis, emergency operations, age (older than 60 years), history of smoking, comorbid diseases (e.g., cardiovascular disease, congestive heart failure, diabetes, American Society of Anesthesiologists [ASA] physical status class III or greater), chronic bronchitis, obesity (as little as 20% overweight), type of surgery (abdominal, thoracic), prolonged duration of anesthesia (3 to 4 hours or longer) and elevated creatinine.[168,169] The surgical site (aortic and thoracic surgeries) has been found to be the most important risk factor for the development of postoperative pulmonary complications.[170]

Emphysema and Chronic Bronchitis

The preparation of a patient with two forms of COPD—emphysema and chronic bronchitis—depends largely on the severity of the respiratory disease, as reflected by the preoperative history, physical examination, and diagnostic testing. Elective surgery is postponed when severe dyspnea, wheezing, pulmonary congestion, or hypercarbia ($PaCO_2$ greater than 50 mmHg) is evident. The risk of postoperative respiratory failure in such circumstances is drastically increased. Consultation with a pulmonologist may be necessary for further evaluation and optimization of the respiratory status of the patient before anesthesia and surgery. Interventions to improve the pulmonary status of the patient with chronic bronchitis are the primary focus before surgery. Prophylactic measures that may reduce pulmonary risk are cited in Box 19-16.[171-173] Specific antibiotic therapy is initiated in patients with thick, purulent sputum and pulmonary infiltrates on the chest radiograph.

BOX 19-16

Therapeutic Maneuvers to Decrease Risk of Pulmonary Complications

Preoperative

- Instruction in respiratory maneuvers
- Smoking cessation
- Antibiotic treatment of pulmonary infection
- Antibiotic treatment of chronic bronchitis
- Expectorants
- Psychologic preparation
- Bronchodilator therapy for asthmatics
- Maintenance of good nutrition
- Chest physiotherapy
- Weight reduction

Postoperative

- Adequate pain control with minimization of postoperative opioid analgesia
- Maximal inspiration maneuvers, incentive spirometry, chest physiotherapy
- Mobilization of secretions
- Early mobilization of elderly patients
- Cough encouragement
- Heparin prophylaxis in selected cases

Data from Mohr DN, Lavender RC. Preoperative pulmonary evaluation. Identifying patients at increased risk for complications. *Postgrad Med.* 1996;100(5):241-244,247-248,251-252; Marienau MES, Buck CF. Preoperative evaluation of the pulmonary patient undergoing nonpulmonary surgery. *J Perianesth Nurs.* 1998;13(6):340-348; Wang JS. Pulmonary function tests in preoperative pulmonary evaluation. *Resp Med.* 2004;98(7):598-605.

Administration of prophylactic antibiotics to "sterilize" the sputum is not recommended, because secondary resistant infections may develop and complicate the perioperative management of the patient. To enhance the mobilization and clearance of pulmonary secretions, chest physiotherapy and adequate hydration can be instituted. There is a lack of quality studies demonstrating the benefit of chest physiotherapy for noncardiothoracic surgery. Incentive spirometry may be beneficial in reducing postoperative pulmonary complications after upper abdominal surgery.[4]

The most reliable way to reduce the incidence of perioperative pulmonary complications is to have patients stop smoking cigarettes. Eight weeks after smoking cessation, the pulmonary complication rate correlates with that of nonsmokers.[40] This intervention may not be feasible when initial meetings with the patient occur within days or hours of the scheduled procedure.

Several diagnostic tests are used for clinically differentiating bronchitis and emphysema in patients in the advanced stages of COPD. Arterial blood gases, for example, may document the presence of preoperative hypoxemia or hypercarbia. An abnormally low partial pressure of arterial oxygen (PaO_2) value (less than 60 mmHg), with or without partial pressure of arterial carbon dioxide ($PaCO_2$) retention, often reflects a state of chronic bronchitis. Over time, the patient develops cor pulmonale because of the adverse effects of chronic hypoxemia on pulmonary vasculature. The chest radiograph may suggest a diagnosis of COPD if slight abnormalities on the chest radiograph, including emphysemic bullae and pulmonary hyperlucency (which reflect vascular deficiencies in the lung periphery) are apparent. Diaphragmatic flattening and a vertical orientation of the cardiac silhouette also are characteristic. Chronic bronchitis, on the other hand, is rarely recognized through chest radiography unless secondary infections are present. Preoperative chest radiographs seldom change patient management and have not been shown to impact on the incidence of postoperative pulmonary complications.[4]

In addition to their role in categorizing patients with COPD, pulmonary function tests are occasionally used as diagnostic adjuncts for confirming the severity of airflow obstruction and its reversibility with bronchodilator therapy. In both chronic bronchitis and pulmonary emphysema, a decrease of the forced exhaled volume in 1 second (FEV_1) occurs in comparison with the forced vital capacity (FVC). FEV_1/FVC ratios of less than 80% indicate the presence of an obstructive process. Individual values of pulmonary function test results may be misleading. The FEV_1, for example, may already be low if the vital capacity is also decreased or the patient is uncooperative with the spirometric tests.

Numerous studies have found routine preoperative pulmonary function studies to be poor indicators of postoperative pulmonary complications and are not recommended.[4,174] All patients scheduled to undergo lung resection should have spirometric assessment preoperatively to estimate postoperative FEV_1 and suitability for resection.[168,175] It is not necessary to routinely obtain spirometric data prior to high-risk noncardiothoracic surgery. The value of pulmonary function testing prior to noncardiothoracic surgery is unproven and should be reserved for symptomatic patients suspected of having COPD.[176]

Asthma

Unlike other COPDs, asthma is characterized by reversible airflow obstruction. Inflammation of the airways is the hallmark of asthma. Distal bronchoconstriction results from airway hyperreactivity to stimuli that have little or no effect on normal airways. Precipitating factors include allergens, exercise, upper respiratory tract infections (URTIs), emotional stressors, and unidentified

triggers.[171] Pertinent data obtained from the medical history are detailed in Box 19-17.[177,178]

Information gleaned from these questions will help establish the nature and stability of the disease process. Patients with a history of coexistent cardiovascular disease, copious sputum production, previous perioperative complications from asthma, recurrent nocturnal awakenings from asthma, frequent or continuous systemic corticosteroid requirement, or a recent hospitalization or emergency visit for asthma are considered to be at greater risk for perioperative aggravation of their asthma. Asthma should be under optimal medical management before a patient undergoes elective surgery and anesthesia. If the patient has a persistent cough, dyspnea, wheezing, or tachypnea on the day surgery is scheduled, it is best to reschedule surgery to allow for additional treatment of the asthma.[174]

The need for diagnostic testing is based on the clinician's assessment of the severity of the disease and magnitude of the operative procedure. An ECG is indicated if right ventricular hypertrophy is presumed, typically implying long-standing insufficient therapy. A chest radiograph is considered only if the patient is suspected of having an acute infiltrative process (e.g., pneumonia, pneumothorax in an acute exacerbation) or if a recent change in the patient's physical status is suggestive of a worsening pulmonary condition.[179] Arterial blood gases are usually indicated only when signs of chronic respiratory insufficiency (e.g., hypoxia, hypercarbia) are suspected or in patients with acute asthma who require emergency surgery. If age appropriate, spirometric evaluation consisting of a peak expiratory flow rate should be performed the morning of surgery if active disease is suspected. The results should be compared with the patient's best value in recent weeks. Findings will be as follows:

- *Normal:* 80% to 100% of baseline
- *Moderate exacerbation:* 50% to 80% of baseline
- *Severe episode indicating the need for delay of surgery and more intensive therapy:* Less than 50% of baseline

Peak expiratory flow is of limited use in assessing asthma preoperatively, because other symptoms or clinical signs of poor asthma control are usually present.[179]

Early preoperative patient assessment promotes optimizing pharmacotherapy in the days prior to the scheduled surgery (Table 19-9).[178] Patient medications should be continued up to and on the day of surgery. Prophylactic β-adrenergic metered-dose inhalers should be used on the morning of surgery and accompany the patient to the operating room. Oral medications (e.g., theophylline) may be taken with a sip (1 to 2 oz) of water up to 1 to 2 hours before surgery. Therapeutic serum theophylline levels, 10 to 20 mcg/mL, should be confirmed if theophylline is used. Supplemental stress doses of corticosteroids may be appropriate if the patient has recently taken corticosteroids. Antianxiety premedication should be considered; psychologic triggers such as anxiety are common.

Ensure adequate hydration (e.g., minimize the fasting interval) to reduce airway desiccation and improve mobilization of secretions. If signs and symptoms of infection are present, surgery may be postponed while antibiotic therapy, based on sputum Gram stain and cultures, is initiated.

BOX 19-17

Pertinent Data Obtained from the Medical History

Asthma Control and Current Therapy

- The frequency of asthmatic attacks
- The time interval since the last attack
- Recent asthma exacerbation? How long since the patient was last hospitalized or treated in the emergency department for an asthmatic attack?
- Increased use of inhaled short-acting β-agonists? Use per week?
- Current or past use of inhaled corticosteroids?
- Most recent course of oral corticosteroids?
- What works best for treating an acute asthmatic event?

Asthma History and Complicating Conditions or Factors

- Recent upper respiratory tract infection or sinus infection?
- Recent pneumonia? Was this documented on chest radiograph?
- What triggers an asthmatic attack?
- The severity of attacks: Was endotracheal intubation or intensive care unit admission required?
- History of pulmonary complications with prior surgical procedures?
- History of long-term corticosteroid use or corticosteroid-dependent asthma?

Modified from Karlet M, Nagelhout J. Asthma: an anesthetic update. *AANA J.* 2001 Aug;69(4):317-24; Tirumalasetty J, Grammer LC. Asthma, surgery, and general anesthesia: a review. *J Asthma.* 2006;43(4):251-254.

TABLE 19-9 Guidelines for Preoperative Asthma Pharmacotherapy

Clinical Characteristics of Asthma	Corresponding Preoperative Pharmacologic Therapy
No asthma symptoms	No additional asthma therapy preoperatively
Not on any asthma medications	
No flares in asthma symptoms over past year	
Spirometry does not show significant obstruction	
On bronchodilators only	Initiate therapy with inhaled corticosteroid, beclomethasone 320 mcg per day or equivalent dose, 1 week before surgery
No history of oral corticosteroid use	
Spirometry is not below baseline	If spirometry is below baseline or patient is having flare of symptoms, consider adding prednisone 0.5 mg/kg for 5 days before surgery
Already on inhaled corticosteroid	Continue treatment with inhaled corticosteroid
Spirometry at or below baseline	Treat with prednisone 0.5 mg/kg for 5 days before surgery
	Treat with hydrocortisone 100 mg IV every 8 hours the morning before surgery and postoperatively until stable
Patient is already on oral steroids	Increase dose of oral steroids for 5 days before surgery
	Treat with hydrocortisone 100 mg IV every 8 hours the morning before surgery and postoperatively until stable

From Tirumalasetty J, Grammer LC. Asthma, surgery, and general anesthesia: a review. *J Asthma.* 2006;43(4):251-254.

Upper Respiratory Tract Infection

Children with URTIs, particularly those younger than 1 year, have an increased risk (twofold to sevenfold increase) of respiratory-related adverse events intraoperatively and postoperatively (e.g., bronchospasm, laryngospasm, hypoxemia, atelectasis, croup, stridor). Signs and symptoms of URTI include sore throat; inflamed and reddened nasopharyngeal and oropharyngeal mucosa; sneezing; rhinorrhea (clear secretions) or mucopurulent nasal secretions; nasal congestion, including watery eyes; malaise; bulging, tender eardrums with associated inflammation; nonproductive cough; fever of 37.5° to 38.5° C (greater than 38° C associated with lower respiratory tract involvement); laryngitis or tonsillitis; viral ulcers in the oropharynx; and white blood cell count greater than 12,000 cells/mm^3 with a left shift. Positive chest findings such as pulmonary congestion and rales are usually associated with lower respiratory tract involvement.

Each case should be reviewed individually. The decision to operate frequently depends on the urgency of the surgery, the duration and complexity of the surgery, and the need for instrumentation of the airway (Figure 19-5).[180] Children with uncomplicated URTIs may undergo elective procedures without significantly increasing anesthesia complications.[181] It is important to obtain a specific history to distinguish a chronic state from an acute, superimposed infectious process, which has predictive value for morbidity. Parents will be the best resource for establishing baseline conditions. If the parents state that the child typically has a cold or chronic runny nose (clear rhinorrhea) and is in his or her optimal state (afebrile, without respiratory distress), short elective procedures may be considered. If the child has a productive cough from lower respiratory tract involvement or an infectious-appearing runny nose, elective surgery should be postponed. However, it may be necessary to schedule children who have chronic URTIs for procedures such as myringotomy with ventilation tube placement or tonsillectomies, because URTIs are commonly associated with these conditions. Exercise caution with children younger than 5 years (consider postponing the procedure for children less than age 1 year) because risks are increased. If the child is older than 1 year with a resolving URTI, it is reasonable to proceed with minor procedures not requiring endotracheal intubation (intubation with URTI increases risk 11-fold).

Infectious nasopharyngitis (without lower respiratory tract involvement) requires postponing the surgery for 2 weeks after peak symptoms.[182] If the child exhibits signs and symptoms of lower respiratory tract involvement, it is prudent to postpone an elective surgical procedure for 4 to 6 weeks, the time necessary to minimize airway hyperactivity.

Laboratory testing may consist of a complete blood count, including differential. The value of obtaining a preoperative white blood cell count has been questioned because it is of little value and rarely is a factor in determining whether to proceed with the surgery.[183] Nasal or throat cultures may be obtained if signs of an infectious process are observed. A chest radiograph is not warranted, especially if chest sounds are clear. Pulmonary function tests and arterial blood gas analysis rarely offer any useful information.

Gastrointestinal System

Evaluation of the gastrointestinal system includes preoperative determination of the presence of nausea and vomiting, diarrhea, occult or overt gastrointestinal bleeding, abdominal or referred pain, abdominal distention, palpable masses, dysphagia, or gastric hyperacidity, with or without reflux. The fluid and electrolyte status of the patient is reviewed, especially when gastrointestinal symptoms are associated with weight loss or malabsorption. Active bleeding requires preoperative hemoglobin concentration measurement. The hematocrit value may be falsely elevated as a result of hemoconcentration in patients with acute or chronic bleeding. Radiographic and CT scans of the abdomen are reviewed for evidence of obstruction or masses. The presence of peptic ulcer disease or esophageal hiatal hernia is also ascertained. For affected patients, prophylactic measures to reduce the risk of aspiration and its adverse pulmonary sequelae (e.g., aspiration pneumonitis) are instituted before surgery.

Hepatobiliary System

Preoperative evaluation of the hepatobiliary system includes screening for the presence of acute or chronic liver parenchymal disease, such as hepatitis or cirrhosis, or cholestatic liver disease. Because of the tremendous reserve of the liver, progression of hepatic disease is often insidious. Signs and symptoms may be inapparent or vague until physiologic functions of the hepatobiliary system (Box 19-18) are markedly affected. Liver function tests are also limited in their ability to reflect the acuity and extent of hepatobiliary disease.[184] Considerable damage to the liver may be evident before laboratory test results are altered.

During the early stages of hepatitis or cirrhosis, the clinical presentation ranges from one in which the patient is asymptomatic with normal liver function tests to one in which the patient has malaise, weight loss, abdominal discomfort, and mild jaundice with mild elevations in bilirubin levels. In cases of unexplained jaundice or elevated transaminase levels, suspicions of hepatobiliary dysfunction should be thoroughly investigated by a preoperative consultation with a gastroenterologist. Elective surgery is postponed until a definitive diagnosis and treatment are established and indicators of active inflammation (e.g., transaminase levels, cellular infiltration on liver biopsy, etc.) have subsided.[185] Further decompensation of hepatic function may follow anesthesia and surgery, notably after intraabdominal procedures. Figure 19-6 offers an algorithm for the preoperative assessment of the patient with known or suspected liver disease.[186]

Progression of hepatobiliary disease to overt hepatic failure may be evidenced by gross abnormalities of liver function test results, including coagulopathies; extreme jaundice with or without cyanosis; generalized tremors and increased deep tendon reflexes; ascites, spider nevi, and hepatosplenomegaly; hepatorenal failure; and signs of hepatic encephalopathy.[187] Elective surgery is avoided at this time because surgery on a patient with hepatic failure is associated with an extremely high incidence of morbidity and mortality. Anesthesia may be required, however, for a patient who requires a palliative or emergent procedure. Placement of a portocaval shunt and the surgical control of hemorrhage from esophageal varices are common procedures, given the growing number of patients with advanced liver disease. Anesthetic management is supportive in such situations and is focused on minimizing the risk of further hepatobiliary deterioration. Administration of phytonadione (AquaMEPHYTON) and transfusion of fresh frozen plasma and cryoprecipitate may be required for the correction of preoperative coagulopathies. Sedative premedicants are avoided in the disoriented or somnolent patient in whom hepatic encephalopathy has been diagnosed. Because of the rapid development of hypoglycemia, the patient's blood glucose level is checked preoperatively. The acid-base balance, electrolyte status, and extent of hepatorenal reserve may be determined by arterial blood gas analysis, serum multiphasic profiles, and liver function tests.[187]

The interpretation of liver function tests should be approached cautiously. Differential diagnosis of parenchymal versus cholestatic liver disease is limited by the insensitivity and nonspecificity

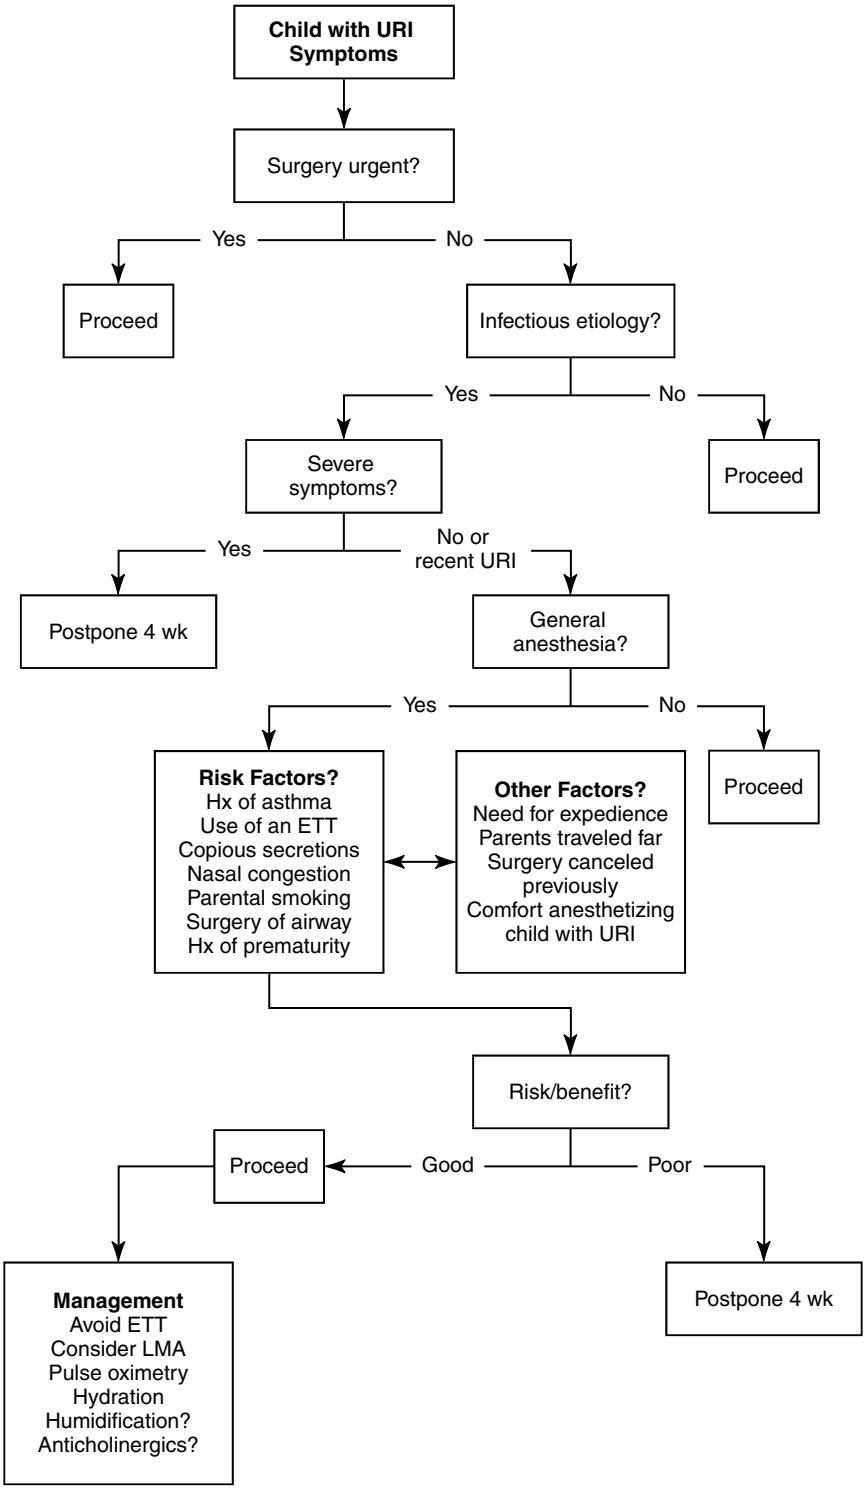

FIGURE **19-5** Suggested algorithm for the assessment and anesthetic management of the child with an upper respiratory infection. *Hx*, History; *ETT*, endotracheal tube; *LMA*, laryngeal mask airway; *URI*, upper respiratory infection. (From Tait AR, Malviya S. Anesthesia for the child with an upper respiratory tract infection: still a dilemma? *Anesth Analg.* 2005;100:59-65.)

of current laboratory analysis, especially serum transaminase and alkaline phosphatase levels.[188] Aspartate transaminase (AST), or serum glutamic oxaloacetate transaminase (SGOT); alanine transaminase (ALT), or serum glutamic pyruvic transaminase (SGPT); and lactate dehydrogenase (LDH) are commonly measured hepatocellular enzymes also distributed throughout cells of the lungs, heart, kidneys, and skeletal muscles. Increases in their serum concentrations are therefore not always indicative of hepatobiliary disease. Greater specificity can be derived from isoenzyme-5 fractions of the enzymes, such as LDH.[189]

In cases of biliary obstruction or irritation, alkaline phosphatase enzymes may be released from the cells of bile ducts. Increases in serum concentrations of these enzymes also help differentiate hepatic dysfunction caused by parenchymal disease from that

BOX **19-18**

Physiologic Functions of the Hepatobiliary System

Bilirubin Formation and Excretion
- Conjugation of free bilirubin and secretion into bile

Carbohydrate Metabolism
- Glycogenesis
- Gluconeogenesis
- Glycogenolysis

Fat Metabolism
- Lipogenesis
- Lipolysis

Protein Metabolism
- Formation of proteins, such as albumin, prothrombin, transferrin, and glycoprotein
- Synthesis of plasma cholinesterase
- Deamination of proteins, such as hormones, into ammonia and urea

Hormone Metabolism Drug Detoxification
- Conversion of lipophilic drugs into inactive hydrophilic substances
- Hydrolysis of ester linkages by plasma cholinesterase

Vitamin Storage
- Storage of fat-soluble vitamins A, D, E, and K
- Storage of antipernicious anemia factor, vitamin B_{12}

Synthesis of Coagulation Factors and Inhibitors
- Synthesis of most clotting factors, including prothrombin, fibrinogen, factors V, VII, IX, and X
- Synthesis of antithrombin
- Mast-cell production of heparin

Phagocytosis
- Filtration and destruction of bacteria and debris in blood circulating through hepatic sinusoids by Kupffer cells

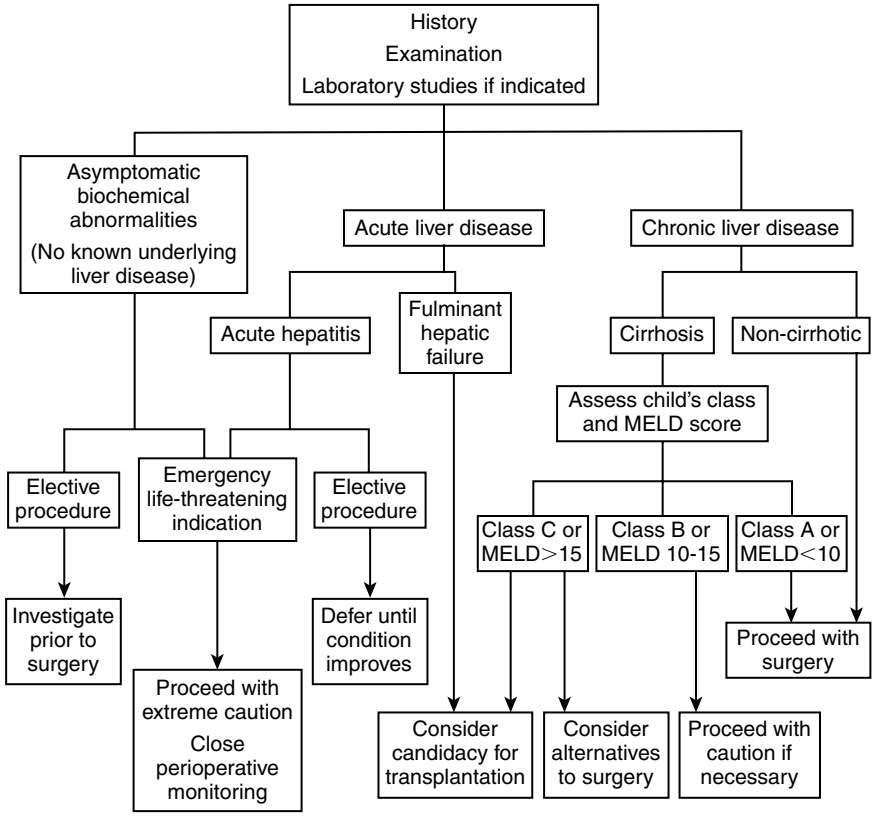

FIGURE **19-6** Suggested algorithm for assessing the patient with known or suspected liver disease—the MELD (Model for End-stage Liver Disease) scoring system to objectively assess liver disease severity. (From Keegan MT, Plevak DJ. Preoperative assessment of the patient with liver disease. *Am J Gastroenterol.* 2005;100:2116-2127.)

caused by cholestasis. The interpretation of these results is again limited by the presence of extrahepatic stores of alkaline phosphatase. In this situation, cholestatic liver disease can be confirmed by high serum levels of conjugated (direct) bilirubin.[190] Causative factors are then determined from discussions with a gastroenterologist and the results of ultrasound, CT, and endoscopic retrograde cholangiopancreatographic scans.

When acute parenchymal injury is evident, prolongation of prothrombin time offers the most rapid and reliable hallmark of liver dysfunction and is shown to have prognostic significance. It reflects the inability of the acutely damaged liver to synthesize clotting factors. Although the production of albumin is also affected, its plasma half-life exceeds that of prothrombin. Hypoalbuminemia may then be inapparent for days after an acute hepatocellular insult.[191]

Once a functional impairment of the liver has been established, the cause is investigated as part of the preoperative evaluation. Cirrhosis and hepatitis, for example, are frequently associated with long-standing alcohol abuse. The increasing consumption of alcohol in the United States parallels the rising incidence of liver disease. Exposure to hepatotoxic agents in the workplace, such as carbon tetrachloride or vinyl chloride, should be ruled out. Hepatotoxic drugs may then be discontinued or avoided before surgery. These drugs commonly include acetaminophen and other nonsteroidal antiinflammatory drugs, aspirin, methyldopa, isoniazid, and rifampin.[192,193] Finally, a diagnosis of infectious hepatitis should be pursued in patients with hepatobiliary disease of unknown cause and in patients considered to be at high risk, which includes those with a history of hemodialysis, multiple blood transfusions, or intravenous drug abuse. Because of the virulent nature of the hepatitis viruses, care of an infected patient also poses an occupational hazard for anesthesia providers.[194] Maximum precautions must be consistently exercised, and vaccination with the hepatitis B virus, as recommended by the Centers for Disease Control and Prevention, should be performed.[195]

The Child-Pugh score was developed to predict surgical mortality in patients with cirrhosis. It assigns points for five variables: total bilirubin level, serum albumin level, international normalized ratio (INR), ascites, and hepatic encephalopathy. Patients are categorized into Child-Pugh class A, B, or C. The predicted perioperative mortality for intraabdominal surgery in these patient groups is Class A (10%), Class B (30%), and Class C (80%). Patients in Child-Pugh classes A and B are suitable candidates for surgery with preoperative optimization. Patients in Child-Pugh class C are usually treated medically. Surgery, if necessary, is delayed until liver function improves.[190]

TABLE 19-10 Common Renal Function Tests

Test	Reference Range
Urea nitrogen	5-25 mg/dL
Creatinine	0.5-1.5 mg/dL
Sodium	133-147 mmol/L
Potassium	3.2-5.2 mmol/L
Chloride	94-110 mmol/L
CO_2	22-32 mmol/L
Uric acid	2.5-7.5 mg/dL
Calcium	8.5-10.5 mg/dL
Phosphorus	2.2-4.2 mg/dL
Urinalysis, routine	
Color	Straw-amber
Appearance	Clear-hazy
Protein	0 mg/dL
Blood	Negative
Glucose	0 mg/dL
Ketone	0 mg/dL
pH	4.5-8
Specific gravity	1.002-1.030
Bilirubin	Negative
Urinalysis, micro	
Red blood cells	0-3/high-power field
White blood cells	0-5/high-power field
Casts	0-2/low-power field

Modified from Brenner BM, et al, eds. *Brenner and Rector's The Kidney*. 9th ed. Philadelphia: Saunders; 2012.

Renal System

Evaluation of the kidneys and urinary tract includes preoperative determination of the patient's volume status and presence of polyuria; urinary incontinence or retention; microscopic or frank hematuria; recurrent infections in the form of glomerulonephritis, pyelonephritis, or cystitis; dysuria; and oliguria or anuria. Fluid balance is calculated from the patient's intake and output during the hospital stay. Preoperative dehydration may be evident, for example, in a patient receiving long-term diuretic therapy. Polyuria, when not attributed to diuretics, may reflect glycosuria or, rarely, inadequate secretion of antidiuretic hormone (diabetes insipidus). Urinary retention and other signs of neurogenic bladder may be caused by a spinal cord injury or long-standing diabetes mellitus. Frequent catheterizations are often necessary in such situations, increasing the patient's risk for developing chronic urinary tract infections. Preoperative urinalysis and culture are therefore required so infection can be ruled out. Treatment and resolution should be accomplished before elective surgery is performed, especially for procedures involving the placement of a prosthetic graft for a mitral valve or total hip replacement. Problems with intraoperative bladder catheterization can be anticipated in patients with dysuria or voiding difficulties. In older men, these problems are frequently attributed to chronic prostatism. Untreated prostatic hypertrophy, as well as renal calculi and congenital malformations of the ureters, results in obstructed urinary outflow. Over time these conditions may lead to a state of chronic renal insufficiency or failure.

Any suspicion of renal dysfunction should be investigated before surgery. Unfortunately, clinical evidence of renal insufficiency may not be apparent until at least 70% of nephrons are nonfunctional. Accurate diagnosis of renal insufficiency is further limited by the insensitivity of laboratory tests (Table 19-10).[196] Blood urea nitrogen (BUN) concentrations, for example, do not accurately reflect glomerular filtration rate (GFR). Although urea is freely filtered at the glomerulus, it is reabsorbed to a large and variable extent through the tubules. BUN levels are also affected by the amount of protein ingested in the gastrointestinal tract and the amount of urea metabolized by the liver, as well as by the catabolic state of the patient. Because tubular reabsorption of creatinine does not occur, creatinine levels correlate more with the rate of glomerular filtration than do BUN concentrations. The serum levels of creatinine, a by-product of skeletal muscle metabolism, can reflect the muscle mass and catabolic state of each patient. This characteristic limits its precision in determining the magnitude of nephron loss. Normal serum creatinine levels may be higher, for example, in a muscular man than in a woman. Conversely, serum creatinine levels can remain within the normal range in the elderly patient, despite a progressive decline in glomerular function,[197] because of the decrease in muscle mass associated with aging.

The most accurate reflection of renal reserve or GFR is creatinine clearance, which reflects the ability of glomeruli to excrete creatinine into the urine at a given blood concentration.[4] The drawbacks of this assessment lie in the cost and time required for the collection of urine samples. As a general principle, urine is collected over a 24-hour period and the creatinine clearance rate is measured by the following equation:

$$\text{GFR (mL/min)} = \text{UV} \div \text{P}$$

where U is the urinary concentration of creatinine (mg/dL), V is the volume of urine (mL/min), and P is the plasma concentration of creatinine (mg/dL).

Accurate measures of GFR also can be calculated from a 2-hour specimen.[198] Creatinine clearance or GFR values between 50 and

80 mL/min are indicative of mild renal dysfunction. Renal failure is otherwise evident when creatinine clearance levels decrease to less than 10 mL/min.

Practically all surgical patients with chronic renal failure are undergoing dialysis, usually hemodialysis performed at the hospital or renal facility. Others undergo continuous ambulatory peritoneal dialysis. The goal of dialysis therapy is to maintain a reasonable degree of homeostasis, although BUN and creatinine concentrations remain abnormal. The preoperative evaluation and preparation of the patient with chronic renal failure should therefore focus on fluid and electrolyte balance, as well as on the extent of concomitant diseases.[199] Estimates of volume status are derived from the amount of weight gained between periods of dialysis. Fluid overload may also be evidenced by jugular vein distention, peripheral and periorbital edema, and bibasilar rales.

Preoperative measurement of serum potassium concentration is recommended within 6 to 8 hours of surgery, regardless of whether dialysis is performed, because unexpected hyperkalemia, with its adverse cardiac effects, is known to occur rapidly. In cases in which the serum potassium level exceeds 5.5 mEq/L and congestive heart failure is apparent, elective surgery should be delayed until after dialysis. When postponement is not feasible, as with emergency surgery to relieve a pericardial effusion or procedures to revise a hemodialysis shunt, measures to reduce the serum potassium concentration are then instituted (see Table 20-6).

Although hemoglobin ranges from 5 to 8 mg/dL are not unusual in patients with chronic renal failure, a hemoglobin level should also be obtained as part of the preoperative evaluation. Chronic anemia is predominantly caused by decreases in renal erythropoietin production and enhanced fragility of red blood cells in the presence of uremia. It is further exacerbated by blood loss experienced with hemodialysis and chronic gastrointestinal bleeding. When extreme fatigue and pallor, limited exercise tolerance, and persistent tachycardia are evident before major surgery, the transfusion of packed red blood cells may be necessary. Because repeat transfusion and immunosuppression therapy are often required during the course of chronic renal failure, the patient is at greater risk for being infected with the hepatitis virus, human immunodeficiency virus (HIV), or both. Coagulopathies are also suspected. The most likely cause is a decrease in platelet adhesiveness secondary to the chronic state of metabolic acidemia. Hemodialysis can be effectively used for the correction of prolonged bleeding times before surgery in this situation.

Throughout the perioperative period, most therapeutic regimens for patients with chronic renal failure can be continued, including the administration of antihypertensives, digitalis preparations, corticosteroids, and insulin.[200] Requirements for preoperative sedation may be less than anticipated, and medications with prolonged durations, such as diazepam, are avoided.[201] Peripheral arteriovenous shunts should be assessed for patency and infection. Measurement of noninvasive blood pressures and application of intravenous lines are avoided in the limb of the graft. Administration of gastrointestinal preparations (e.g., antacids and gastrokinetic agents) and drainage of peritoneal dialysate, aimed at reducing the risks of regurgitation and pulmonary aspiration, are instituted when preparing the patient with chronic renal failure for anesthesia and surgery.

Endocrine System

Endocrine diseases of concern in the preoperative evaluation include diabetes mellitus, thyroid gland disorders, and adrenocortical dysfunctions. End-organ effects of each of these diseases increase perioperative risk substantially. For example, morbidity and mortality rates are 5 to 10 times greater in diabetic patients with renal and autonomic nervous system involvement.[202]

TABLE 19-11 Distinguishing Features of Diabetes Mellitus

	Type 1	Type 2
Previous name	Insulin-dependent diabetes	Non–insulin-dependent diabetes
Age of onset	Childhood	Middle age or elderly
Timing of onset	Abrupt	Gradual
Predisposing factors	Genetic	Obesity, pregnancy, drugs
Prevalence	0.2%-0.3%	2%-4%
Insulin requirement	Always	Infrequent
Ketoacidosis	Common	Rare
Systemic complications	Frequent	Frequent

Diabetes

Diabetes mellitus is the most common of endocrine disorders, affecting more than 20.8 million people—8.3% of the population—in the United States. Twenty-seven percent of people ages 65 years or older report having diabetes.[203] It represents a dysfunction in glucose metabolism caused by impaired synthesis, secretion, or insulin resistance.

Most patients with diabetes (90% to 95%) are not dependent on exogenous insulin for the regulation of blood glucose levels. As shown in Table 19-11, the patient with non–insulin-dependent (also known as adult onset or type 2) diabetes often benefits from diet modification, weight control, and exercise alone. An oral hypoglycemic agent (Table 19-12) may also be added to the patient's therapeutic regimen.[204] The remaining 5% to 10% of patients with diabetes are dependent on insulin preparations listed in Table 19-13 and are therefore classified as having insulin-dependent, or type 1, diabetes mellitus.[205,206] These patients are susceptible to periods of hyperglycemia and ketoacidosis. Patients may be on a transitional continuum between the two types. As a result of microvascular changes, they are also prone to the development of severe end-organ complications, including diabetic retinopathy and cataract formation, somatic and autonomic insufficiency (e.g., orthostatic hypotension, bradycardia, gastroparesis), and nephropathy. Because of acquired abnormalities in the macrovasculature, patients with type 2 diabetes are more likely to have hypertension, coronary artery disease (which frequently is asymptomatic), and peripheral vascular disease. Death in the majority of patients with diabetes is secondary to complications of atherosclerosis (MI, stroke).[207]

The aim of an evaluation of a patient with diabetes, notably one with type 1 diabetes mellitus, is ascertaining the degree of preoperative blood glucose control and the presence of major organ system dysfunction. Renal and cardiovascular complications of diabetes substantially heighten perioperative morbidity and mortality. Particular attention should be paid to the following:

- *Diabetes*: Type of disease, method of home monitoring and usual metabolic control
- *Drugs*: Antidiabetic medication, medication for associated diseases

TABLE 19-12 Oral Hypoglycemic Therapy

Drug Class	Drug Name	Onset	Duration of Action
Second-generation sulfonylureas	Glyburide	30 min	24 hr
	Glipizide	IR 30 min	IR 24 hr
		ER 2-4 hr	ER 24 hr
	Glimepiride	2-3 hr	24 hr
DPP-4 Inhibitors	Sitagliptan	1 hr	8 hr
	Saxagliptan	1 hr	8 hr
	Linagliptan	1 hr	8 hr
GLP-1 Analogs	Exenatide	1-2 hr	24 hr
	Liraglutide	1-2 hr	24 hr
Biguanides	Metformin	1-3 hr	17 hr
Thiazolidinediones	Rosiglitazone	1-3 hr	4 hr
	Pioglitazone	2 hr	N/A
Non-sulfonylurea secratogues (glinides)	Repaglinide	30-90 min	4 hr
	Nateglinide	30-60 min	4 hr
Alpha-glucosidase inhibitors	Acarbose	2 hr	4 hr
	Miglitol	1 hr	4 hr

ER, Extended release; *IR*, immediate release; *N/A*, not available; *DPP-4*, dipeptidyl peptidase-4; *GLP-I*, glucagon-like peptide 1.

- *Cardiovascular disease*: Including an assessment of exercise tolerance
- *Renal disease*: Electrolyte assessment, hemodialysis regimen if applicable
- *Neuropathy*: Peripheral and autonomic, in particular gastric paresis
- *Airway*: diabetics with stiff joint syndrome (due to glycosylation) often have limited mobility of the upper cervical spine and are more likely to have a poor view on direct laryngoscopy, and they may therefore present difficulties with tracheal intubation.[208] Patients with a long-standing history of diabetes require a close look at the airway to assess for potential difficulties.[4]

Early preoperative evaluation and workup of diabetic patients are important. This is especially true in patients who are noncompliant, patients whose blood glucose level is poorly controlled, and patients with newly diagnosed diabetes, because modifications in their care may be necessary before surgery. Early assessment of a patient allows for consultation with a medical internist to optimize the patient's preoperative condition before anesthesia and surgery. Elective surgery is also postponed in cases of extreme hyperglycemia and ketoacidosis. Aggressive fluid, electrolyte, and insulin therapy are initiated, and the cause of ketoacidosis must be investigated before surgery.

Consultation with a cardiologist may also help a practitioner evaluate and improve the preoperative cardiac status of a patient with diabetes, especially if the patient is undergoing a procedure associated with a greater risk of perioperative myocardial ischemia, such as a carotid endarterectomy or an abdominal aortic aneurysm resection. Because of the high incidence of ischemic heart disease in this population, exercise stress testing and a 12-lead ECG may be performed. Orthostatic hypotension, resting tachycardia, and lack of respiratory variability in cardiac rhythm may reflect

TABLE 19-13 Insulin Preparations and Guidelines

Insulin Type	Onset	Peak (hr)	Duration (hr)	Comments
Very Rapid				
Lispro; Aspart	IV immediate; subcut 5-15 min	Subcut 0.5-1.5	Subcut 3-4	Usually administered immediately prior to a meal; use subcut or via an insulin pump, but not recommended for continuous infusion
Short-Acting				
Regular	IV immediate; subcut 30-60 min	Subcut 2-3	Subcut 3-6	Usually administered 30-60 min before meals; most common in continuous IV infusions
Intermediate-Acting				
NPH	Subcut 2-4 hr	Subcut 6-10	Subcut 10-16	Often combined with regular insulin
Lente	Subcut 3-4 hr	Subcut 6-12	Subcut 12-18	
Long-Acting				
Ultralente	Subcut 6-10 hr	Subcut 10-16	Subcut 18-20	Perioperative use uncommon
Glargine	Subcut 4 hr	Minimal peak activity	Subcut 24	May be administered as usual to provide basal insulin levels during surgery
Combinations				
75/25 (75% protamine lispro, 25% insulin lispro)	Subcut 30-60 min	Dual	10-14	
70/30 (70% NPH, 30% regular)	Subcut 30-60 min	Dual	10-16	Usually given before breakfast
50/50 (50% NPH, 50% regular)	Subcut 30-60 min	Dual	10-16	Usually given before dinner

autonomic neuropathy. Abnormalities in autonomic function may also result in bladder atrophy and delayed gastric emptying times in nearly 50% of diabetic patients.[209] A gastrokinetic agent, such as metoclopramide, should be considered before surgery to reduce the incidence of regurgitation and pulmonary aspiration during general anesthesia.

It is best to schedule surgery as early in the day as possible to minimize the fasting period. Just before surgery, diabetic patients who require insulin or oral hypoglycemic agents should have blood glucose checked. Depending on the type and length of surgery and the lability of diabetes, blood glucose levels are checked intraoperatively and in the postanesthesia care unit at 1-hour intervals. There continues to be discussion as to optimal levels; however, a safe goal of perioperative insulin therapy is to maintain the serum glucose level at less than 180 mg/dL while avoiding hypoglycemia.[210] Efforts to reduce the $HbA1_c$ to as close to normal as possible are desirable. Levels less than 5.7% are normal, 5.7 to 6.4 are high risk, and 6.5% or more are diabetic.

Preoperative management of antidiabetic medications is based on the principle that therapies aimed at providing basal insulin can, with careful management, be continued in the fasting patient. Therapy includes adjustment of routine dosing regimens and provision and careful monitoring of blood glucose. Correction therapy (i.e., sliding scale insulin) may be needed, but should not be relied upon as the sole therapy for long periods. Prandial therapies should be held in the fasting patient. Specific recommendations for preoperative management generally call for a reduction in the dose of insulin the evening before surgery and the omission of insulin or administration of a decreased dose the morning of surgery.

The insulin analog glargine warrants special attention. Glargine has a prolonged duration of 20 to 24 hours, but is unique in that its activity is without a significant peak. Because of an absence of peak activity, some experts believe that glargine is well suited for the perioperative period although a reduction in dose may be warranted. Recommendations for management of patients on insulin pumps include decreasing the insulin dose delivered to the patient the evening before and the morning of surgery with the patient being converted to an IV insulin drip for glycemic control during the procedure. If the patient is undergoing a short, simple case under local anesthesia, continuation of the insulin pump is safe.[8]

Several different regimens are available for the treatment of diabetic patients undergoing surgery and anesthesia. Consultation with the physician responsible for managing the diabetes is helpful in determining an acceptable range of serum glucose and when and what type of insulin therapy may be appropriate. Considerations for managing the diabetic patient are as follows[1,8,96]:

Night before the procedure:

- Continue usual dose of PM (afternoon/evening) glargine/NPH (neutral protamine Hagedorn) or mixture (can recommend two-thirds usual dose if tightly controlled) as long as patient allowed usual diet.
- Insulin pumps should continue at usual basal rate.

Morning of procedure:

- Patients undergoing short, simple procedures early in the morning can be managed by delaying the patient's normal diabetes treatments until the patient is ingesting food in the early postoperative period. It should be noted that procedures requiring a patient with diabetes to fast are customarily scheduled early in the morning to minimize disruption of routine diabetic treatments.
- The biguanide metformin is associated with increased risk of lactic acidosis, especially in settings in which glomerular filtration rate is decreased (as in surgery or radiologic procedures involving the injection of iodinated dyes). Published recommendations for the discontinuation of metformin vary. Some experts advise holding the medication for as long as 48 hours prior to surgery, whereas others suggest holding metformin only on the day of surgery.[8]
- Patients taking oral hypoglycemic agents should withhold the short half-life agents (e.g., repaglinide) on the day of surgery and withhold the longer-lasting agents (e.g., chlorpropamide and glimepiride) for up to 48 hours.
- Fasting patients who are receiving insulin should have intravenous access established. A crystalloid solution containing 5% glucose should be available to infuse for maintenance of optimal blood glucose levels. The intravenous route still has the risk of making the patient hyperglycemic or hypoglycemic if the glucose or insulin infusions become unbalanced. The tighter the control of glucose levels, the more frequent the glucose monitoring. The subcutaneous route of insulin administration has been criticized as being too unpredictable in its absorption, especially perioperatively, with alterations in blood pressure and cutaneous blood flow.[211]
- Patient should not take short-acting insulin bolus the morning of procedure unless blood glucose level is greater than 200 mg/dL and more than 3 hours preoperatively.
- In the patient with type 1 diabetes, a common approach, especially for brief procedures, is to subcutaneously administer a fraction (50% of usual dose) of the patient's usual morning dose of intermediate- or long-acting insulin and institute continuous 5% glucose infusion.
- Insulin pumps should be continued, but only to provide basal insulin coverage, and institute continuous 5% glucose infusion.
- For patients with either insulin-dependent or non–insulin-dependent diabetes, the most important goal of perioperative management is the prevention of hyperglycemia and especially hypoglycemia, as well as their adverse consequences, during surgical stress.

Thyroid Gland Disorders

Although disorders of the thyroid gland are relatively uncommon, the anesthesia provider may still encounter patients with hyperthyroidism or hypothyroidism who require surgery. Most have undergone adequate medical therapy before anesthesia and surgery are performed. Nevertheless, the anesthesia provider should be aware of the clinical manifestations of thyroid gland dysfunctions (Table 19-14).[95,212]

Hyperthyroidism. Hyperthyroidism is caused by an excess secretion of thyroid hormones, 3,5,3′-triiodothyronine (T_3) and tetraiodothyronine (thyroxine or T_4). It is evident in such conditions as Graves' disease, toxic goiter (multinodular, single), thyroid carcinoma, and pituitary tumors that oversecrete thyroid-stimulating hormone (TSH). Signs and symptoms reflect a hypermetabolic state with sympathetic overactivity (e.g., tachycardia, atrial fibrillation, fever, tremor) resulting from the primary effects of thyroid hormones on the adenylate cyclase system.[96]

The preoperative preparation of the hyperthyroid patient is aimed at attaining a euthyroid state. This may be accomplished through administration of antithyroid drugs such as methimazole or propylthiouracil for 6 to 8 weeks, followed by iodine for 7 to 14

TABLE 19-14 Clinical Features of Thyroid Gland Disorders

	Hyperthyroidism	Hypothyroidism
General	Heat intolerance; weight loss; tremor; sweating; warm, moist skin	Cold intolerance, thinning hair, arthralgia, alopecia, "strawberries and cream" complexion, gruff voice
Cardiovascular	Tachycardia, cardiac arrhythmias, wide pulse pressure, elevated systolic blood pressure, decreased diastolic blood pressure, increased left ventricular contractility and ejection fraction, atrial fibrillation and heart failure in elderly	Bradycardia, cardiomegaly, cardiac failure, increased peripheral resistance, pericardial effusions
Respiratory	Dyspnea	Hypoventilation, sleep apnea
Gastrointestinal	Diarrhea, nausea, vomiting	Decreased gastrointestinal motility, constipation
Neurologic	Anxiety, irritability, hyperactive reflexes, insomnia; depression, withdrawal, and apathy in elderly	Fatigue, lethargy, slow mental function, hypoactive reflexes, myxedema coma
Musculoskeletal	Goiter, weight loss, proximal myopathy, bone resorption	Goiter, lethargy, large tongue, amyloidosis, peripheral neuropathy, muscle stiffness
Ophthalmic	Exophthalmos, lid lag, lid retraction, reduced blinking	
Renal		Impaired free water clearance
Hematologic	Hypercalcemia, thrombocytopenia, mild anemia	Anemia, coagulopathy

Modified from Connery LE, Coursin DB. Assessment and therapy of selected endocrine disorders. *Anesthesiol Clin North America*. 2004; 22(1):93-123; Barash PG, et al, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009; Elisha S, et al. Anesthesia case management for thyroidectomy. *AANA J*. 2010;78(2):151-160.

days.[212] Not only does propylthiouracil decrease the overall synthesis of thyroxine, it also lessens its conversion into the more potent T_3. Reversible agranulocytosis is infrequently seen with long-term therapy.[213] A complete blood cell and platelet count should be determined preoperatively. Beta-antagonist drugs, such as propranolol and esmolol, are also useful adjuncts in the management of hyperthyroidism. They ameliorate signs of sympathetic nervous system overstimulation such as tachycardia, diaphoresis, and tremors.

All drugs used to manage hyperthyroidism, including propylthiouracil and propranolol, should be continued perioperatively, including the morning of surgery, and elective surgery is postponed until the patient is rendered euthyroid. If emergency surgery cannot be delayed for a patient with symptomatic hyperthyroidism, a continuous infusion of esmolol (100 to 300 mcg/kg/min) may be initiated to control unwanted tachycardia (goal heart rate less than 90 beats/minute).[214] Higher doses of preoperative anxiolytics and sedatives, such as benzodiazepines, may also be required. Anticholinergics are avoided because of their interference with normal heat-regulating mechanisms and their potentiation of tachyarrhythmias.

Hypothyroidism. Hypothyroidism represents several conditions, such as chronic thyroiditis or Hashimoto disease, in which tissues are exposed to decreased circulating concentrations of T_3 and T_4. The cause of hypothyroidism may be primary, resulting from the destruction or hypofunction of the thyroid gland, or secondary, resulting from insufficient TSH production. The diagnosis of hypothyroidism is confirmed by decreased serum concentrations of T_3 and T_4, with or without secondary increases in TSH levels.[215]

The treatment of hypothyroidism consists of administration of T_4, levothyroxine sodium (Synthroid) replacement therapy, with the restoration of intravascular volume and electrolyte status. Elective surgery need not be delayed for patients with mild to moderate hypothyroidism. No difference in perioperative outcome has been noted between untreated hypothyroid patients and patients who are euthyroid.[95]

Adrenocortical Disorders. Disorders of the adrenal cortex, ranging from hyperadrenocorticism to hypoadrenocorticism, are the result of primary disease of the adrenal cortex or pituitary gland, ectopic production of adrenocortical hormones by malignant tissue, or most commonly treatment with exogenous corticosteroids. Steroids are commonly used to treat bronchial asthma, autoimmune diseases, and connective tissue disorders such as rheumatoid arthritis. Their high-dose administration for prolonged periods or their excess levels in circulating glucocorticoid hormones characteristically results in a syndrome referred to as *Cushing syndrome*. This syndrome is clinically manifested as hypertension and hypovolemia, truncal obesity with an accumulation of interscapular fat ("buffalo hump"), abdominal and gluteal striae, plethoric facial appearance ("moon facies"), easy bruising, osteoporosis, personality changes, and menstrual irregularities and hirsutism. Hyperaldosteronism—an excess of mineralocorticoid hormones—may be manifested as hypertension in association with marked hypokalemia (plasma potassium [K] less than 3 mmol/L). Its major alterations involve sodium and water retention, potassium depletion, and metabolic alkalosis.

Adrenocortical insufficiency may be of a primary origin (Addison disease) or caused by the secondary inhibition of adrenocortical function by prolonged exogenous steroid therapy. Clinical signs are less obvious than those of Cushing disease and include skin hyperpigmentation, weight loss, muscle wasting, hypotension, intravascular volume depletion, hypoglycemia, hyponatremia, and hyperkalemia.[216]

The preoperative preparation of a patient with adrenocortical dysfunction includes the correction of fluid and electrolyte disturbances and the treatment of coexisting disorders, such as hypertension and diabetes mellitus. Glucocorticoid or mineralocorticoid replacement therapy is also continued perioperatively. Patients are at risk for depression of the hypothalamic-pituitary-adrenal (HPA) axis if they have (1) received 20 mg or more of prednisone, or equivalent, for 5 or more days, or (2) have been treated for 1 month or more. HPA axis suppression may persist for 6 to 12 months after discontinuation of treatment.[96] A reliable test to assess adrenocortical function, the short adrenocorticotropic hormone (ACTH) stimulation test, may be performed to evaluate the need for supplemental steroid.[217] If the patient presenting for surgery is at risk for HPA axis depression, or if findings (i.e., hyponatremia, hyperkalemia, hypotension, eosinophilia) are consistent with adrenal insufficiency, then need for exogenous corticosteroid

supplementation should be assessed (see Table 19-4).[96,218] For patients currently receiving high-dose steroid therapy, such as those with chronic hypoadrenocorticism or Addison disease, further supplementation of the daily maintenance doses may be required based on the surgical stress. This recommendation, although controversial regarding the need for additional supplementation,[219,220] is based on concerns that additional cortisol may not be released from the adrenal cortex as a result of its primary hypofunction or secondary suppression in response to surgical stress. Unexplained hypotension in spite of intravenous fluid repletion or cardiovascular collapse may then ensue during major surgical procedures.

DIAGNOSTIC TESTING

Appropriate laboratory evaluations and diagnostic procedures should be obtained and the results considered to determine the patient's surgical and anesthetic risk, as well as the need for appropriate healthcare modifications. The controversy lies in which tests are necessary and appropriate for specific settings. The rationale for performing "routine" tests has been under intense scrutiny, primarily because of recent and ongoing changes in healthcare economics. A protocol that delineates the indications for testing should be established by each surgical facility and approved by the medical staff. When protocols are followed for ordering preoperative laboratory tests, the total number of tests performed has been reduced 50% to 60%, and the appropriateness of the tests has improved.[221] A necessary step in the implementation process for preoperative testing guidelines is the education of the medical staff. Centralizing the test-ordering process, such as in the preoperative assessment clinic, makes standardization and compliance more attainable.

Routine Diagnostic Testing

It has been traditional practice, even within the past decade, to order a "battery" of routine evaluative tests before a patient undergoes surgery and anesthesia. Routine ordering of preoperative diagnostic tests remains a common practice in many institutions. Until the early 1990s, the rationale for obtaining preoperative diagnostic tests was rarely questioned. Tests were frequently ordered for a variety of reasons but were often unrelated to findings based specifically on the patient's history and physical examination. Reasons cited for ordering the standard battery of preoperative tests included the following[222-224]:

- To follow customary practice at an institution
- To adhere to institutional or legislative mandates that dictate the tests be performed
- To further evaluate and determine the progress of a known disease or condition, because preexisting medical conditions have a greater risk for intraoperative and postoperative complications
- To detect asymptomatic yet modifiable conditions that could alter anesthetic and surgical care
- To detect asymptomatic but unmodifiable conditions that could alter anesthetic and surgical risk
- To screen for conditions unrelated to the planned surgery
- To acquire baseline results that might be useful in the perioperative period
- To protect against medicolegal involvement

When considering the value of preoperative tests, the following must be considered:

1. The diagnostic procedure should be cost-effective—that is, the costs saved from knowing the results exceed the expense of performing the test.
2. The diagnostic procedure should have a positive benefit-risk ratio—that is, the benefit derived from conducting the test outweighs the harm that might ensue from a false-positive result.
3. Test results are available for interpretation and recuperative intervention before surgery.
4. Test results will yield information that could not be obtained from the history and physical examination.
5. Abnormal test results in an asymptomatic patient would influence the patient care, the surgery, or the anesthesia management.

Without any clinical sign, the likelihood of observing a significant anomaly is very small for diagnostic procedures such as ECG,[223] chest radiography,[223,225,226] or laboratory tests.[223,227] Asymptomatic disease is rarely of clinical concern in perioperative surgical care. In addition, unexpected abnormal findings from preoperative testing tend not to affect the upcoming surgery.[228] When a battery of routine preoperative tests are conducted, abnormal test results potentially alter patient care only 0.22% to 0.56% of the time.[223,227] A consistent conclusion of most studies is that routine preoperative laboratory screening is not cost-effective or predictive of postoperative complications[222,229] and is unnecessary when an extensive history and physical examination do not suggest any patient abnormalities.[1,230-234]

Limitations to Routine Preoperative Diagnostic Testing

Studies estimate that at least 10% of the more than $30 billion spent on laboratory testing annually in the United States goes to preparing patients for surgery.[235] Although added healthcare costs are the most apparent limitation to performing the routine battery of preoperative tests, additional factors can negatively affect the patient and care providers. The indiscriminant ordering of tests for diagnostic evaluation increases the likelihood that at least one test will be abnormal in a healthy patient.[224] False-positive, or even false-negative, test results can lead to additional medical evaluation and the potential for increased morbidity. Abnormal laboratory tests for continuous data are defined in probabilistic terms and assume a normal patient population distribution.[223,224] The end points of the bell-shaped distribution curve are arbitrarily set at 2.5%; therefore 5% of test results in normal patients are reported as abnormal. False-positive test results may lead to additional follow-up tests, which can place the patient at risk of increased morbidity.[236] Abnormal test results that were not further pursued and lack of documentation of the rationale for not investigating abnormal test results have increased the medicolegal risk for physicians.[237]

Timing of Diagnostic Testing

In general, diagnostic testing results are deemed current within 6 months of the scheduled surgery if the test results are normal and if the patient's current health status indicates no change has occurred since the test was performed.[238] However, specific tests require more current data analysis. A serum potassium level should be obtained within 7 days of surgery for patients receiving diuretics or digitalis, and blood glucose level determinations should be obtained on the day of surgery for patients with diabetes controlled by medication. An electrocardiogram, when indicated, within 30 days prior to elective surgery is considered adequate for patients with stable disease.[107] Chest radiographs taken within 6 months are generally acceptable if the patient's pulmonary condition is stable.[239]

Indications for Diagnostic Testing

A continuing point of controversy relates to disagreement about which tests are appropriate for specific patients, surgeries, and

BOX **19-19**

Indications for Diagnostic Procedures

Chest Radiograph

- Previous abnormal results on chest radiography
- History of malignancy in which pulmonary metastasis might alter the surgical therapy
- History of tuberculosis (TB) or a positive skin test result for TB and no history of treatment
- History suggestive of pulmonary infection (e.g., new or chronic productive cough or blood-tinged or purulent-appearing sputum)
- Suspected intrathoracic pathologic condition (e.g., tumors, vascular ring)
- History of congenital heart disease
- History of prematurity associated with residual bronchopulmonary dysplasia
- Severe obstructive sleep apnea (patient may have cardiomegaly)
- Down syndrome (patient may have asymptomatic subluxation of the atlantoaxial junction)
- Symptomatic or debilitating asthma, chronic obstructive pulmonary disease, or cardiovascular disease

Electrocardiogram

- Patients at risk for cardiovascular disease (e.g., because of cocaine abuse, hypertension, chest pain, renal insufficiency, peripheral vascular disease, thyroid disease, diabetes mellitus [age 40 years or older], inability to exercise, significant pulmonary disease, smoking (more than 40 pack years), history of ischemic heart disease, history of compensated or prior heart failure, history of cerebrovascular disease
- History of previously unevaluated pathologic-sounding murmur or palpitation
- Family history reveals possibility of inherited prolonged QT syndrome
- Patients with history of morbid obesity, moderate to severe sleep apnea, or chronic anatomic airway obstruction (e.g., Pierre Robin syndrome) may be at risk for right-sided heart strain

Adapted from Zaglaniczny K, Aker J, eds. *Clinical Guide to Pediatric Anesthesia*. Philadelphia: Saunders; 1999; Institute for Clinical Systems Improvement. *Health Care Guidelines: Preoperative Evaluation*. 9th ed, June 2010. Accessed June 21, 2012 at http://www.icsi.org/preoperative_evaluation/preoperative_evaluation_2328.html.

conditions. Difference of opinion exists among and within medical specialties regarding which tests are appropriate. Suggested guidelines for ordering various diagnostic tests based on results of the patient's history and physical examination have been offered for ordering diagnostic procedures (Box 19-19) and laboratory tests (Box 19-20).

Pregnancy Testing

Routine preoperative pregnancy testing in women of childbearing age remains controversial. If a patient is concerned about possible pregnancy, uncertain of her pregnancy status, or if the physical examination or medical history suggests the possibility of pregnancy (e.g., because of information regarding sexually active status, time of last menstrual period, presence or absence of birth control methods), a preoperative pregnancy test should be performed with the patient's consent on the evening prior to or morning of the surgery.[1,240] A serum human chorionic gonadotropin (hCG) measurement performed either the day prior to surgery or on the morning of surgery (realizing the potential for delay while awaiting the hCG result) should be considered for patients less than 1 month past the expected date for their initial missed period. Currently available urine pregnancy tests may yield falsely negative results until week 5 of the pregnancy.[241] Issues to address when deciding whether to test include the following:

- Policies of the hospital or healthcare facility based on medical staff bylaws. The medical facility should have established guidelines, supported on ethical, legal, financial, and scientific relevance that delineate when testing for pregnancy is appropriate.[242]
- All women should be advised of the potential fetal risk (e.g., premature labor, spontaneous abortion) secondary to the underlying surgical condition and surgical uterine stimulation that is unrelated to anesthesia.[240] The incidence of congenital abnormalities is no greater in pregnant women who undergo surgery, however, than it is in those with a surgery-free pregnancy.[243,244] Despite this finding, patients are advised to postpone elective surgery until postpartum or at the least well after the first trimester, when fetal organogenesis is complete.
- Patients should be privately questioned about the possibility of pregnancy. Female staff should interview adolescent patients in the absence of family members.
- Patients should be offered pregnancy testing despite history, except in patients with a history of hysterectomy or bilateral salpingo-oophorectomy.[245]

Chest Radiography

A preoperative chest radiograph is of minimal predictive importance and is not cost-effective as a screening test for postoperative respiratory problems, so it is not to be recommended without specific indications, that is, new or unstable cardiopulmonary disease, from the medical history and physical examination.[1,4,246,247] The risk of performing a routine preoperative chest radiograph in asymptomatic patients less than 75 years of age is greater than the benefit.[237]

Electrocardiography

A routine preoperative electrocardiogram is not necessary unless a specific indication is present.[1,233] Many medical facilities continue to use an age-specific criterion for acquiring a preoperative ECG, regardless of indications—or lack of indications—based on the patient's medical history and physical examination. The recommended minimum age for routinely conducting a baseline ECG, if deemed necessary by the facility, has gradually increased to 65 years or older and is considered current if tested within I year of the procedure provided no changes in the patient's condition have occurred.[107,248] Inquiry has even been raised regarding the appropriateness of an age-only basis for preoperative ECG testing, especially since the Centers for Medicare and Medicaid Services (CMS) no longer reimburse for routine, age-based testing.[233]

The value of obtaining a routine preoperative 12-lead ECG in asymptomatic, low-risk patients, that is, having cataract surgery,[249]

BOX **19-20**

Indications for Laboratory Testing

Complete Blood Count
- Hematologic disorder
- Vascular procedure
- Chemotherapy
- Unknown sickle cell syndrome status

Hemoglobin and Hematocrit
- Age less than 6 months (less than 1 year if born prematurely)
- Hematologic malignancy
- Recent radiation or chemotherapy
- Renal disease
- Anticoagulant therapy
- Procedure with moderate to high blood loss potential
- Coexisting systemic disorders (e.g., cystic fibrosis, prematurity, severe malnutrition, renal failure, liver disease, congenital heart disease)

White Blood Cell Count
- Leukemia and lymphomas
- Recent radiation or chemotherapy
- Suspected infection that would lead to cancellation of surgery
- Aplastic anemia
- Hypersplenism
- Autoimmune collagen vascular disease

Blood Glucose Level
- Diabetes mellitus
- Current corticosteroid use
- History of hypoglycemia
- Adrenal disease
- Cystic fibrosis

Serum Chemistry
- Renal disease
- Adrenal or thyroid disease
- Chemotherapy
- Pituitary or hypothalamic disease
- Body fluid loss or shifts (e.g., dehydration, bowel prep)
- Central nervous system disease

Potassium
- Digoxin therapy
- Diuretic therapy
- ACE inhibitors or angiotensin receptor blockers

Creatinine and Blood Urea Nitrogen
- Cardiovascular disease (e.g., hypertension)
- Renal disease
- Adrenal disease
- Diabetes mellitus
- Diuretic therapy
- Digoxin therapy
- Body fluid loss or shifts (e.g., dehydration, bowel prep)
- Procedure requiring radiocontrast

Liver Function Tests
- Hepatic disease
- Exposure to hepatitis
- Therapy with hepatotoxic agents

Coagulation Studies
INR, Prothrombin Time, and Partial Thromboplastin Time
- Leukemia
- Hepatic disease
- Bleeding disorder
- Anticoagulant therapy
- Severe malnutrition or malabsorption
- Postoperative anticoagulation to establish a baseline

Platelet Count and Bleeding Time
- Bleeding disorder
- Abnormal hemorrhage, purpura, history of easy bruising

Urinalysis
- Not indicated as a routine screening test

Pregnancy Test
- Possibility of pregnancy

Medication Levels
- Monitor for medications (e.g., theophylline, phenytoin, digoxin, carbamazepine) if patient exhibits signs of ineffective therapy, potential drug side effects, or poor drug compliance or has recently changed medication therapy without documentation of the drug level

ACE, Angiotensin-converting enzyme; *INR*, international normalized ratio (prothrombin time).

has been questioned.[250,251] This rethinking of indications for when to order a preoperative ECG has been challenged for the following reasons:

- It has not been shown to be cost-effective.[228,252,253]
- It is a poor predictor of perioperative complications.[251,253,254]
- It is of limited value in detection of ischemia in asymptomatic individuals.[255,256]
- Abnormal preoperative ECGs rarely lead to alteration in patient care.[228,252,257]
- No evidence supports the value of a "baseline" ECG.[250,251,258]

FASTING CONSIDERATIONS

Part of the anesthesia provider's role in patient preparation involves establishing an appropriate fasting interval for the patient. This requires knowledge of risk factors for pulmonary aspiration of gastric contents weighed against the consequences of prolonged fasting. The risk of perioperative pulmonary aspiration of gastric contents that results in morbidity or mortality is relatively low, so the recommendations for withholding oral feeding before elective surgery have recently become much more liberal. When studies were conducted challenging the traditional fasting times (7 hours or greater) for clear liquids, the results appeared to show that a reduced fasting interval does not increase the risk of pulmonary aspiration in normal, healthy individuals.[259]

The traditional policy of fasting after midnight fails to address three variables that influence gastric emptying for surgery: (1) the time of the scheduled surgery, (2) the time at which the patient retired for the night, and (3) the variability in gastric emptying for solids and fluids among individuals. Prolonged fasting, especially in children, can be highly distressing in addition to causing physiologic alterations. Periods of long preoperative fasting have been shown to contribute to the following:

- Dehydration[260]
- Hypoglycemia (in smaller children)[261]

BOX 19-21

Conditions That Increase the Risk of Regurgitation and Pulmonary Aspiration During Anesthesia

- Age extremes (less than 1 yr or older than 70 yr)
- Anxiety
- Ascites
- Collagen vascular disease (e.g., scleroderma)
- Depression
- Esophageal surgery
- Exogenous medications (e.g., opioids, premedication)
- Failed intubation or difficult airway history
- Gastroesophageal junction dysfunction (e.g., hiatal hernia)
- Mechanical obstruction (e.g., pyloric stenosis, duodenal ulcer)
- Metabolic disorders (e.g., hypothyroidism, chronic diabetes, hepatic failure, hyperglycemia, obesity, renal failure, uremia)
- Neurologic sequelae (e.g., those of developmental delays, head injury, hypotonia, seizures)
- Pain
- Pregnancy
- Prematurity with respiratory problems
- Smoking
- Type and composition of gastric contents (e.g., solid foods and milk products)

- Hypovolemia
- Increased irritability[261]
- Enhanced preoperative anxiety[262]
- Reduced compliance with preoperative fasting orders[260]
- Thirst[263] and related discomforts (e.g., hunger, headache, unhappiness)

Pulmonary Aspiration Risk

Recent ingestion of food and liquid before surgery does contribute to an increased risk of pulmonary aspiration. Solid foods must be digested to a bolus diameter of less than 2 mm before the food can pass through the pylorus.[264] This process normally takes several hours for solids, whereas liquids pass through the pylorus in 1 to 2 hours. Historically, patients have been required to fast for extended periods in an attempt to ensure an empty stomach. However, sustained fasting does not guarantee that the stomach will be empty at the time of surgery.[265]

Part of the preoperative evaluation process identifies patients who are at risk for aspirating gastric contents into the lungs and developing aspiration pneumonitis. Factors associated with an increased risk of pulmonary aspiration of gastric contents are listed in Box 19-21.[266-277]

Fasting Interval

When the fasting interval is minimized, patients (especially children) are reported to be less irritable, less thirsty, and less hungry; to have fewer headaches; to be more comfortable; and generally to tolerate the preoperative phase better than patients who have fasted for longer periods of time. Modest amounts of clear liquids taken orally 2 hours[278-280] to 3 hours[281,282] preoperatively, when compared with a conventional fasting interval of "7 to 8 hours" or "after midnight," are acceptable and have been shown to lower residual gastric volume (stimulation of the gastric emptying reflex) and raise gastric pH in a majority of patients. Acceptable clear fluids (e.g., water, apple juice, black coffee, black tea, clear juice drinks, clear Jell-O, clear broth, ice, Popsicles, Pedialyte) may be given to healthy, unpremedicated patients. Chewing gum or sucking on candy does not warrant delay or cancellation of the operation.[283] In light of these findings, recommended fasting guidelines for otherwise healthy individuals have been liberalized (Box 19-22).[277,283,284]

BOX 19-22

Fasting Guidelines for Healthy Patients (All Ages) Undergoing Elective Surgery

- No chewing gum (nicotine gum allowed with patient counseling) or candy after midnight (foreign body aspiration concern)
- Clear liquids up to 2 hours before surgery*
- Breast milk until 4 hours before surgery
- No infant formula, nonhuman milk,† or light meal‡ for at least 6 hours before surgery
- Prescribed medications (e.g., premedication) administered with a sip of water or prescribed liquid mixture (up to 150 mL for adult; up to 75 mL for children) up to 1 hour before anesthesia

From American Society of Anesthesiologists Committee. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: an updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters, *Anesthesiology.* 2011;114(3):495-511.

*Consider the possibility that the case may proceed earlier than scheduled.

†Because nonhuman milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.

‡A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period.

AMERICAN SOCIETY OF ANESTHESIOLOGISTS PHYSICAL STATUS CLASSIFICATION SYSTEM

With the conclusion of the preanesthesia assessment, assignment of an ASA physical status classification is made for each patient. The classification ideally represents a reflection of the patient's preoperative status and is not an estimate of anesthetic risk. For greater accuracy to be attained from its interpretation, the ASA status should also remain independent of the proposed surgical procedure.[285-288]

Advent and Purpose

In 1940 the ASA developed a system "to classify the physical condition of a patient requiring anesthesia and surgery." This six-category classification was then revised by the ASA in 1961 to the current system of five categories (Table 19-15).[289] The purpose of the ASA classification, then and now, is to provide a consistent means of communication to anesthesia staff, within and among institutions, about the physical status of a patient.[289] Furthermore, it allows for a standardized interpretation of anesthesia outcome based on one criterion.

Despite rough correlations between patient physical status and postoperative outcome, *the ASA classification system does not represent an estimate of anesthesia risk.*[285-288] Although a patient in poor physical health is known to be at greater risk for negative outcome, this does not account for other factors that influence perioperative morbidity and mortality. These factors include the duration and involvement of the surgical procedure, the degree of perioperative monitoring, and unfortunate circumstances, such as human error or equipment failure.

TABLE 19-15 American Society of Anesthesiologists Physical Status Classification

Classification	Physical Status
ASA Class I	No organic, physiologic, biochemical, or psychiatric disturbance
	Example: Healthy patient
ASA Class II	Mild to moderate systemic disturbance
	Examples: Heart disease that slightly limits physical activity, essential hypertension, diabetes mellitus, chronic bronchitis, anemia, morbid obesity, age extremes
ASA Class III	Severe systemic disturbance that limits activity
	Examples: Heart or chronic pulmonary disease that limits activity, poorly controlled essential hypertension, diabetes mellitus with vascular complications, angina pectoris, history of previous myocardial infarction
ASA Class IV	Severe systemic disturbance that is life threatening
	Examples: Congestive heart failure; persistent angina pectoris; advanced pulmonary, renal, or hepatic dysfunction
ASA Class V	Moribund patient undergoing surgery as a resuscitative effort, despite a minimal chance for survival
	Example: Uncontrolled hemorrhage from a ruptured abdominal artery aneurysm
ASA Class E	Emergency surgery is required
	Example: An otherwise healthy 30-year-old woman who requires a dilation and curettage for moderate but persistent hemorrhage is classified as ASA IE

Modified from American Society of Anesthesiologists. New classification of physical status. *Anesthesiology.* 1963;24:111.
ASA, American Society of Anesthesiologists.

Definition

The current ASA classification system ranges from class I through V, with E denoting an emergent procedure. At some institutions, a classification of ASA status VI also may be assigned to postmortem patients undergoing organ procurement procedures. By definition, a patient classified as ASA status I is a healthy individual except for the condition that has necessitated surgery. A healthy young woman about to undergo an emergency dilation and curettage for vaginal bleeding, for example, is classified as ASA status IE. At the other end of the spectrum, a 74-year-old man with hypertension, uncontrolled diabetes, and unstable angina who is scheduled for a coronary artery bypass graft procedure is classified as ASA status IV.[289]

Limitations of the Current System

Despite the numerous benefits of the ASA classification system, it has its shortcomings. Namely, the current system is not explicit enough in its categorization to account for every patient, and this can result in patient misclassification.[290] If the physical status classification system is used for statistical or reimbursement purposes within a department, overclassification is often the consequence. Overclassification of a patient also occurs when the proposed surgical procedure is incorporated into the assignment of ASA physical status. This improper classification, or overclassification, of patient status thereby limits the degree of accuracy attained from its original interpretation. As a result, correlations between preoperative status and postoperative outcome are skewed. Despite the shortcomings of the system, ASA physical status continues to be assigned to each patient as a summary of the preoperative evaluation.

PREVENTING OPERATIVE ERRORS

The Joint Commission has endorsed a universal protocol for eliminating wrong site, wrong procedure, wrong patient surgeries. It has been endorsed by more than 40 of the leading medical, nursing, and healthcare leadership organizations. The guidelines are to be used in all hospitals, ambulatory care surgery centers, and office-based surgery sites, as shown in Box 19-23.

BOX 19-23

Guidelines for Implementing the Universal Protocol for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery

Conduct a Pre-Procedure Verification Process

Address missing information or discrepancies before starting the procedure.

- Verify the correct procedure, for the correct patient, at the correct site.
- When possible, involve the patient in the verification process.
- Identify the items that must be available for the procedure.
- Use a standardized list to verify the availability of items for the procedure. (It is not necessary to document that the list was used for each patient.) At a minimum, these items include:
  - Relevant documentation. Examples: History and physical, signed consent form, preanesthesia assessment
  - Labeled diagnostic and radiology test results that are properly displayed. Examples: Radiology images and scans, pathology reports, biopsy reports
  - Any required blood products, implants, devices, special equipment
- Match the items that are to be available in the procedure area to the patient.

Mark the Procedure Site

At a minimum, mark the site when there is more than one possible location for the procedure and when performing the procedure in a different location could harm the patient.

- The site does not need to be marked for bilateral structures. Examples: tonsils, ovaries
- For spinal procedures: Mark the general spinal region on the skin. Special intraoperative imaging techniques may be used to locate and mark the exact vertebral level.
- Mark the site before the procedure is performed.
- If possible, involve the patient in the site marking process.
- The site is marked by a licensed independent practitioner who is ultimately accountable for the procedure and will be present when the procedure is performed.*
- Ultimately, the licensed independent practitioner is accountable for the procedure – even when delegating site marking.
- The mark is unambiguous and is used consistently throughout the organization.
- The mark is made at or near the procedure site.

Continued

BOX **19-23—cont'd**

Guidelines for Implementing the Universal Protocol for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery

- The mark is sufficiently permanent to be visible after skin preparation and draping.
- Adhesive markers are not the sole means of marking the site.
- For patients who refuse site marking or when it is technically or anatomically impossible or impractical to mark the site (see examples below): Use your organization's written, alternative process to ensure that the correct site is operated on. Examples of situations that involve alternative processes:
  - Mucosal surfaces or perineum
  - Minimal access procedures treating a lateralized internal organ, whether percutaneous or through a natural orifice
  - Teeth
  - Premature infants, for whom the mark may cause a permanent tattoo

Perform a Time-Out

The procedure is not started until all questions or concerns are resolved.

- Conduct a time-out immediately before starting the invasive procedure or making the incision.
- A designated member of the team starts the time-out.
- The time-out is standardized.
- The time-out involves the immediate members of the procedure team: the individual performing the procedure, anesthesia providers, circulating nurse, operating room technician, and other active participants who will be participating in the procedure from the beginning.
- All relevant members of the procedure team actively communicate during the time-out.
- During the time-out, the team members agree, at a minimum, on the following:
  - Correct patient identity
  - Correct site
  - Procedure to be done
- When the same patient has two or more procedures: If the person performing the procedure changes, another time-out needs to be performed before starting each procedure.
- Document the completion of the time-out. The organization determines the amount and type of documentation.

*In limited circumstances, site marking may be delegated to some medical residents, physician assistants (PA), or advanced practice registered nurses (APRN).

SUMMARY

An important feature of patient care is a timely and thorough preoperative assessment to identify factors that increase the risk of anesthesia and surgery. The preoperative evaluation and preparation of the patient involve integration of information obtained from the patient interview, chart review, physical examination, and interpretation of the results of necessary diagnostic tests. The anesthesia provider can then assimilate the assessment data and devise and implement the most appropriate anesthetic plan for the patient.

CHAPTER 20

Fluids, Electrolytes, and Blood Component Therapy

◆ *Russell R. Lynn and Lori Ann Winner*

In the clinical practice of anesthesia, an important priority in patients experiencing the stresses of surgery and anesthesia is maintenance of homeostasis. Maintaining a physiologic balance of body fluids in both volume and composition is critical to maintaining overall homeostasis. The following discussion focuses on factors of fluid and electrolyte management and transfusion therapy that are of greatest consequence to patients in the perioperative period.

FLUID COMPARTMENTS

A prerequisite to understanding clinical fluid management is an appreciation of the role of fluids in the human body and the distribution of fluids and electrolytes among the fluid compartments. The body is in large part composed of fluid, ranging between 46% and 80%, depending on the age and gender of the individual and the body's composition of fat relative to muscle. Compared with muscle, fat contains less fluid as a percentage of weight. Total body fluid as a percent of body weight is the highest in newborns (70%-80%) and declines with age to approximately 50% at age 50.

Total body water is partitioned into two principal compartments: the intracellular fluid (ICF) and the extracellular fluid (ECF). The extracellular compartment is further subdivided into intravascular fluid (IVF) and interstitial fluid (ISF) spaces. The fluid compartments are divided by water-permeable membranes[1]; the intracellular space is separated from the extracellular space by the cell membrane, and the extracellular space is divided into intravascular and interstitial spaces by the capillary membrane.

The ICF compartment contains approximately two thirds of the body's total fluid volume[2] and is characterized by high concentrations of potassium, phosphate, and magnesium. The adenosine triphosphatase (ATPase)–driven sodium-potassium pump (Na-K–ATPase pump) located in the cell membrane maintains the high concentration of potassium found in ICF[3] (Figure 20-1 and Table 20-1). The Na-K–ATPase pump exchanges three sodium ions for two potassium ions and offsets the tendency for sodium to diffuse into the intracellular space.

The ECF compartment contains approximately one third of the body's fluid volume[2] and contains high concentrations of sodium and chloride compared with the ICF compartment. The IVF (also known as *plasma*) space contains approximately one quarter of the ECF volume and has essentially the same composition and concentration of electrolytes as the ISF. The presence in the IVF of relatively high concentrations of osmotically active plasma proteins, of which albumin is most important, is a significant difference distinguishing ISF from IVF.[4] The capillary membrane is relatively impermeable to the plasma proteins contained within the vascular space, unless a disease state such as trauma or sepsis alters the capillary permeability.

The properties of the membranes that separate the fluid compartments, as well as the relative concentration of osmotically active substances within each compartment, are the factors primarily responsible for the movement of fluid (water and electrolytes) among compartments in the body. Because the intravascular space is the fluid compartment accessible to the clinician and the chief focus of fluid therapy, it is useful to understand the motion of fluid from the IVF space to the ISF space across the capillary membrane. Four forces known commonly as *Starling forces* determine the motion of fluids across the capillary membrane. The four forces that govern fluid dynamics in the microcirculation are capillary pressure, ISF pressure, ISF colloid osmotic pressure, and plasma colloid osmotic pressure.[2]

The plasma colloid osmotic pressure is significant because this force is determined primarily by plasma protein concentration and serves to maintain the circulating fluid volume within the intravascular space. Plasma protein concentrations can be increased or decreased, depending on the types and volumes of intravenous (IV) fluids administered.

INFLUENCES OF SURGERY AND ANESTHESIA ON FLUID BALANCE

Illness, surgery, and anesthetics can profoundly alter the fluid and electrolyte balance of patients during the perioperative period.

Preoperatively, patients can become volume depleted and experience alterations of electrolyte balance due to several processes. Burns, vomiting, diarrhea, fever, and gastric suction can lead to hypovolemia before surgery.[5] If a large volume of fluid is lost from the gastrointestinal (GI) tract, careful evaluation of electrolytes and appropriate replacement is indicated.[4] Quite often, preoperative hypovolemia is at least in part an iatrogenic phenomenon secondary to bowel preparation and preoperative fasting. Unless surgery is of the greatest urgency, to reduce the risk of hypotension and complications resulting from electrolyte imbalances, preoperative fluid deficits and electrolyte abnormalities should be corrected before anesthetic induction.[6]

During the intraoperative period, the effects of surgery and anesthesia combine to challenge fluid and electrolyte homeostasis. Surgery can lead to hemorrhage and a need to replace fluids or blood. Surgery can also lead to evaporative loss; loss from exposed viscera is composed entirely of water (without electrolytes) and is most appropriately replaced with free water (water available for dissolving substances). Manipulation of tissues during surgery can lead to "third spacing," which is the redistribution of fluid from the intravascular space to the interstitial space. Replacement of fluid lost from the intravascular space in the phenomenon of third spacing is best carried out by balanced salt solutions that have an electrolyte composition similar to ECF.[1,6] Absorption of electrolyte-free irrigation solutions during transurethral prostate surgery

or endometrial ablation can result in a life-threatening hypo-osmolar state that must be addressed appropriately by the clinician.[7]

Anesthesia in and of itself can lead to derangements of fluid balance in surgical patients. The vasodilatory effects of both regional and general anesthesia can result in a relative hypovolemia, which may lead to hypotension on induction. General anesthesia increases the release of antidiuretic hormone, causing increased retention of water,[1,8] which can predispose the patient to hyponatremia.[9] Mechanical ventilation can increase evaporative loss of water and decrease the release of atrial natriuretic peptide, leading to renal conservation of sodium.[1]

The effects of surgery on fluid balance can persist into the postoperative period. Third-spaced fluids are typically mobilized (returned to the intravascular space) on the third postoperative day. The increased circulating volume may be poorly tolerated by patients with marginal renal or cardiovascular performance and can result in congestive heart failure or pulmonary edema.[4,10]

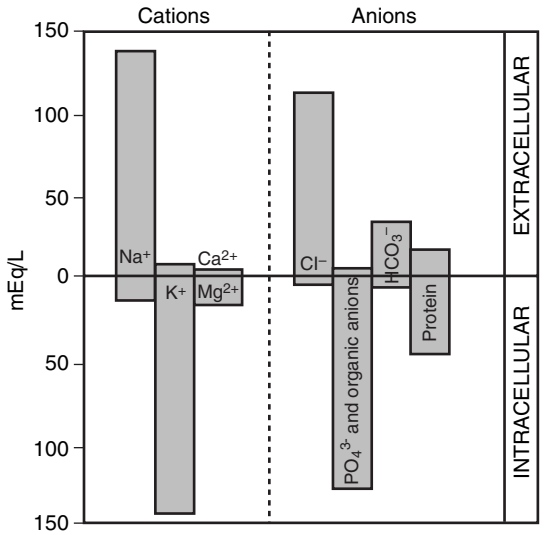

FIGURE **20-1** Major cations and anions of the intracellular and extracellular fluids. The concentrations of calcium and magnesium represent the sum of these two ions. The concentrations shown represent the total of free ions and complexed ions. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:288.)

FLUID VOLUME DISORDERS

Fluid volume disorders, particularly hypovolemia, are often encountered in patients undergoing surgery. Discussion of disorders of concentration and volume of body fluids is facilitated by careful consideration of the concepts of osmolarity, osmolality, and tonicity. Osmolarity is an expression of the number of osmoles of solute in a liter of solution, whereas osmolality expresses the number of osmoles of solute in a kilogram of solvent. Because of the dilute nature of body fluids, the difference between osmolarity and osmolality is minimal. Tonicity, a concept related to osmolarity and osmolality, describes how a solution affects cell volume. Isotonic solutions have an effective osmolality close to that of body fluids (approximately 285 mOsm/L)[3]; therefore cells placed in an isotonic solution are not expected to swell or shrink.

Volume depletion, or *hypovolemia*, refers to the loss of ECF and is not to be confused with *dehydration*, which refers to a concentration disorder in which insufficient water is present relative to sodium levels.[3] Hypovolemia can result from an absolute loss of fluid from the body or a relative loss of bodily fluids in which water is redistributed within the body, leading to a reduced circulating volume. Causes of absolute fluid loss include loss of fluid from the GI tract, polyuria, and diaphoresis. Decreased intake of fluids is a common cause of absolute fluid deficit in surgical patients because

TABLE **20-1** Osmolar Substances in Extracellular and Intracellular Fluids

	Plasma (mOsm/L H_2O)	Interstitial Fluid (mOsm/L H_2O)	Intracellular Fluid (mOsm/L H_2O)
Na^+	142	139	14
K^+	4.2	4	140
Ca^{2+}	1.3	1.2	0
Mg^{2+}	0.8	0.7	20
Cl^-	108	108	4

Total mOsm/L	301.8	300.8	301.2
Corrected osmolar activity (mOsm/L)	282	281	281
Total osmotic pressure at 37° C (mmHg)	5443	5423	5423

From Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:288.

of intolerance to oral fluids and prolonged preoperative fasting. Relative fluid losses can be caused by conditions such as burns and third-space losses resulting from surgery. It should be noted that patient weight does not decrease in cases of relative fluid loss.

Because most cases of hypovolemia are caused by the loss of ECF, replacement with isotonic crystalloids (which have a composition similar to ECF) is appropriate.[3] Determining the appropriate volume of fluids to administer for maintenance and replacement needs is discussed later; however, in certain circumstances such as oliguria or hemodynamic instability, a fluid bolus (also known as *fluid challenge*) may be warranted. Four components of a fluid challenge are the type of fluid, rate of administration, critical end points, and safety factors. (Table 20-2). Estimated fluid and blood requirements based on the clinical presentation of a patient have been classified into four stages of shock (Table 20-3).

Hypervolemia is an excess of fluid volume in an isotonic concentration. Hypervolemia is not usually encountered in surgical patients but can be seen if diseases such as congestive heart failure, renal failure, or cirrhosis of the liver are present. Iatrogenic causes of fluid overload include administration of steroids and excessive IV administration of isotonic fluids. Excessive consumption of sodium in the diet or in medications can lead to retention of water and hypervolemia. Treatment of hypervolemia may include sodium restriction, diuretics, and in cases of renal failure, hemodialysis or ultrafiltration.

TABLE 20-2 Successful Fluid Challenge

Critical components of the fluid challenge: a hypothetical patient with hypotension mean arterial pressure (MAP) of 65 mmHg and a central venous pressure (CVP) of 15 mmHg

Example	Baseline	+10 Minutes	+20 Minutes
1. Type of fluid: Ringer's lactate			
2. Rate of infusion: 500 mL/30 minutes			
3. Clinical end points: MAP of 75 mmHg	MAP 65	MAP 70	MAP 75
4. Pressure safety limits: CVP of 15 mmHg	CVP 12	CVP 13	CVP 14

DISORDERS OF SODIUM BALANCE

Disorders of sodium balance may be encountered in anesthetic care and are of great clinical significance. Sodium is the most abundant electrolyte in the ECF; along with its accompanying chloride anion (NaCl), it is responsible for most of the osmotic activity of the ECF. The physiologic significance of sodium can be appreciated when one considers that gain or loss of sodium is accompanied by a gain or loss of water, respectively.[3] Because sodium concentration in the ECF is much higher than in the intracellular space (as a result of the action of the Na-K–ATPase pump in the cell membrane), alteration of sodium levels in the extracellular space greatly affects the osmotic relationship between intracellular and extracellular spaces, leading to movement of water across the cell membrane.

The clinical importance of sodium disorders is due largely to the influence of sodium on the water content in brain cells. The blood-brain barrier, unlike peripheral capillary beds, has only limited permeability to ionic solutes. The result of this limited permeability in the blood-brain barrier is the prevention of equilibration of osmotically active ionic solutes between intravascular and interstitial spaces. This lack of permeability to sodium (and consequent failure to equilibrate osmotically active solutes between the intravascular and interstitial spaces) changes the osmotic gradients between fluid compartments, leading to the precedence of sodium over plasma proteins as the most important osmotically active substance influencing the water content of the brain tissues.[10,11]

Because sodium imbalances reflect impaired concentration between water and sodium, evaluation of sodium imbalance should take into consideration both the volume of the solvent (water) and the amount of solute (sodium) present in the solution. Likewise, treatment of sodium imbalances can involve restriction or expansion of water volume and enhanced elimination or supplementation of sodium.

Hyponatremia may have multiple causes (Box 20-1). Of particular interest to anesthetists is hyponatremia resulting from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), which is discussed in Chapter 33. Water intoxication resulting from the absorption of electrolyte-free irrigation solution during procedures such as transurethral resection of the prostate and endometrial ablation is discussed in Chapter 29. Water intoxication and SIADH lead to hyponatremia from an excess of water, not loss of sodium.[1,12]

Hyponatremia results in a condition in which the intracellular environment is hyperosmolar relative to the ECF, leading to an

TABLE 20-3 Four Classes of Hemorrhagic Shock

	CLASS			
Parameter	**I**	**II**	**III**	**IV**
Blood loss (mL)	<750	750-1500	1500-2000	≥2000
Blood loss (%)	0-15	15-30	30-40	>40
Central nervous system	Slightly anxious	Mildly anxious	Anxious or confused	Confused or lethargic
Pulse (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Respiratory rate	14-20/min	20-30/min	30-40/min	>35/min
Urine (mL/hr)	>30	20-30	5-15	Negligible
Fluid	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

influx of water into the intracellular space. One of the most significant consequences of hyponatremia is cerebral edema. Because the brain is contained within the fixed confines of the skull, cerebral edema is poorly tolerated.[13] Compensatory mechanisms can forestall the development of symptomatic cerebral edema for a period of time.[14] Brain cells can maintain osmotic equilibrium by extruding intracellular solutes, thereby reducing intracellular osmolality.[9,13] However, if the extrusion of solute by brain cells is inadequate to compensate for the hypo-osmolar influence of the ECF, an intracellular influx of water may lead to symptomatic cerebral edema.[13]

Clinical studies have demonstrated that compared with men or postmenopausal women, menstruating women are at increased risk of brain damage resulting from hyponatremia.[3,13] It is believed that estrogen and progesterone inhibit the efficiency of the Na-K–ATPase pump, which is essential to the extrusion of intracellular solutes to maintain osmotic equilibrium in hyponatremia; female sex hormones may facilitate movement of water into the brain through the mediation of antidiuretic hormone (ADH).[13]

Hyponatremia is the most common electrolyte abnormality in hospitalized patients. The development of hypervolemic hyponatremia in patients with congestive heart failure (CHF) or cirrhosis is associated with an increased risk of death. Even mild stable euvolemic hyponatremia due to SIADH has been associated with cognitive defects and gait disturbances. Overly rapid correction of serum sodium, particularly in patients with chronic hyponatremia, can cause neurologic complications such as seizures, spastic quadriparesis, and coma due to osmotic demyelination.[15] There are two drugs available for the treatment of hypervolemic or euvolemic hyponatremia due to CHF, cirrhosis, or SIADH. Tolvaptan (Samsca) and conivaptan (Vaprisol) are vasopressin receptor antagonists. Tolvaptan is an oral preparation and conivaptan is available for intravenous use. Treatment of hyponatremia usually includes fluid restriction and diuresis. IV conivaptan has been used for short-term treatment of euvolemic hyponatremia. Oral treatment with tolvaptan can increase serum sodium concentrations in patients with hypervolemic or euvolemic hyponatremia due to cirrhosis, heart failure, or SIADH, but has not been shown to reduce mortality. Overly rapid correction of serum sodium, which can cause osmotic demyelination, has not been reported to date with tolvaptan.[15-17]

Controversy exists as to how aggressively hyponatremia should be treated (Figure 20-2). In chronically hyponatremic patients, rapid correction of serum sodium can lead to the neurologic disorder known as *myelinolysis*. Myelinolysis, originally known as *central pontine myelinolysis*, can lead to disorders of the upper neurons, spastic quadriparesis, pseudobulbar palsy, mental disorders, and in some cases death.[14] Patients at particular risk for myelinolysis are those who have been hyponatremic for more than 48 hours[9,14] and individuals who have had orthotopic liver transplantation or a history of alcohol abuse.[14] Optimal treatment of hyponatremia must balance the risks of cerebral edema against the risks of myelinolysis.[12]

The risk of myelinolysis can be reduced by correcting serum sodium levels in a deliberate manner. It has been suggested that serum sodium concentrations should be increased by no more than 1 to 2 mEq/L/hr. In symptomatic patients, this is accomplished by infusing 3% saline at a rate of 1 to 2 mL/kg/hr. Once the patient is clinically stable, sodium administration should be slowed to raise serum sodium not more than 10 to 15 mmol/L in 24 hours.[9,12,14]

Hypernatremia can result from several causes (Figure 20-3, Box 20-2, and Table 20-4) but is usually the result of impaired water intake.[12] Inadequate administration of free water to hospitalized patients can lead to an iatrogenic hypernatremia. Debilitated, mentally impaired, and intubated individuals are at particular risk for developing hypernatremia.[4,12] In cases of slow-onset hypernatremia, the brain can adapt by conserving intracellular solutes, which allows maintenance of normal intracellular volume. Rapidly occurring hypernatremia can be accompanied by rapid shrinking of the brain and concomitant traction on intracranial veins and venous sinuses, leading to intracranial hemorrhage.[7]

As with hyponatremia, overly aggressive treatment of chronic hypernatremia can lead to unwanted effects. In the case of hypernatremia, rapid correction of serum sodium with solutions containing large amounts of free water may lead to cerebral edema.[7]

Correction of hypernatremia is carried out by replacement of the water deficit, which can be calculated by the formula shown in Box 20-3. If the hypernatremia is acute (i.e., less than 24 hours' duration),

BOX 20-1

Hyponatremia*

Causative Factors and Classification

Isotonic Hyponatremia (Pseudohyponatremia)

Serum osmolality 275-295

Causes: Hyperlipidemia, hyperproteinemia, multiple myeloma, infusion of isotonic nonelectrolytic substances (e.g., glucose, mannitol glycine)

Hypertonic Hyponatremia

Serum osmolality greater than 295

Causes: Hyperglycemia, mannitol excess glycerol therapy

Hypotonic Hyponatremia

Serum osmolality less than 275

Hypovolemic hypotonic hyponatremia

Causes: Diuretics, salt-losing nephropathy, ketonuria, Addison's disease, vomiting, diarrhea, third spacing of fluids, excessive sweating

Isovolemic hypotonic hyponatremia

Causes: SIADH, renal failure, hypothyroidism, drugs, water intoxication, porphyria, pain, stress, positive pressure ventilation

Hypervolemic hypotonic hyponatremia

Causes: Nephrotic syndrome, cirrhosis, congestive heart failure, renal failure

Clinical Features

Seizure
Coma
Agitation
Confusion
Headache
Cerebral edema
Anorexia
Nausea and vomiting
Cramps
Weakness

*Serum sodium less than 135mEq/L.
SIADH, Syndrome of inappropriate secretion of antidiuretic hormone.

TABLE 20-4 Clinical Signs of Hypernatremia at Increasing Serum Osmolality

Osmolality (mOsm/kg)	Neurologic Symptoms
350-375	Confusion, restlessness, agitation, headache
375-400	Ataxia, tremors, weakness
400-430	Cramps, hyperreflexia, twitches, spasms
> 430	Coma, seizures, death

water deficits can be replaced relatively rapidly with hypotonic solutions. If chronic hypernatremia accompanied by volume depletion is present, the volume disorder is corrected first with isotonic crystalloids. Once the circulating volume has been restored, hypotonic solutions are used to correct the water deficit. Correction of chronic hypernatremia, like treatment of chronic hyponatremia, calls for prudence. Plasma sodium should be decreased by 1 to 2 mEq/hr until the patient is clinically stable, and correction of serum sodium to normal levels should gradually progress over the subsequent 24 hours.[12]

DISORDERS OF POTASSIUM BALANCE

Potassium is the principal electrolyte of the ICF, where 98% of the body's supply of potassium is located. The difference between intracellular and extracellular potassium concentration is in large part responsible for the resting membrane potential of the cell.[18] Potassium exists in a dynamic balance between the intracellular and extracellular compartments. Abnormal serum potassium levels may be the result of disturbances in the balance between intracellular and extracellular distribution of potassium or an abnormality in the total body store of potassium. Evaluation and treatment of disorders of potassium homeostasis should address factors that can shift potassium into the cell and total body levels of potassium. The symptoms associated with disorders of potassium homeostasis are largely a reflection of disorders of resting membrane potential.

Hypokalemia, defined as plasma potassium of less than 3.5 mEq/L, can result from an absolute deficiency caused by GI loss, renal loss, or from a poor intake of potassium (Box 20-4). Redistribution of potassium from the extracellular to the intracellular compartment can also lead to hypokalemia. β-Adrenergic stimulation, insulin, and alkalosis all promote movement of potassium into the intracellular space.[19]

Treatment of hypokalemia depends on the severity of the symptoms accompanying the potassium deficit. In the face of malignant dysrhythmias, aggressive IV administration of potassium is warranted.[18] IV replacement of potassium should be accomplished with the patient under continuous electrocardiographic (ECG) monitoring. Rates of IV administration as fast as 40 mEq/hr have been reported,[19] although a maximum rate of 10 to 20 mEq/hr is usually recommended to avoid an iatrogenic hyperkalemia.[4,7]

Once serious symptoms of hypokalemia such as respiratory muscle weakness or dysrhythmias have ceased, IV replacement can be discontinued in favor of oral supplementation.[19] It is recommended that IV potassium be replaced as a chloride, because the hypochloride state makes it difficult for the kidney to conserve potassium.[4] Furthermore, potassium chloride should be mixed in a dextrose-free solution to prevent stimulation of insulin, leading to increased redistribution of potassium to the intracellular space.[7,20]

Some clinicians have questioned whether surgery should be canceled because of low serum potassium. In a study of 447 patients scheduled for cardiovascular surgery, Hirsch and co-workers used continuous ECG monitoring to evaluate the preoperative and intraoperative incidence of ectopy. They found no significant difference in frequent or complex ventricular ectopy among patients with normal serum potassium and those with mild to severe hypokalemia. The authors concluded that cancellation of surgery based on low serum potassium was not warranted.[21]

Hyperkalemia is less common than hypokalemia if renal causes are excluded.[19] In addition to impaired renal excretion of potassium, causes of hyperkalemia include a high intake of potassium and a shift of potassium from the intracellular to the extracellular space. Movement of potassium from the intracellular to the extracellular compartment can result from lysis of cells, as well as from acidemia and the administration of β-adrenergic blockers, which inhibit the Na-K–ATPase pump and disrupt movement of potassium into the cell (Box 20-5). Electrocardiographic changes associated with increased levels of potassium are outlined in Table 20-5.

BOX **20-4**

Causes of Hypokalemia*

Decreased Intake
- Decreased dietary potassium
- Impaired absorption of potassium
- Clay ingestion
- Kayexalate

Increased Loss
Renal
- Hyperaldosteronism
  - Primary: Conn syndrome; adrenal hyperplasia
  - Secondary: Congestive heart failure; cirrhosis; nephrotic syndrome; dehydration
  - Bartter syndrome
- Glycyrrhizic acid (licorice, chewing tobacco)
- Excessive adrenocorticosteroids
  - Cushing syndrome
  - Steroid therapy
  - Adrenogenital syndrome
- Renal tubular defects
  - Renal tubular acidosis
  - Obstructive uropathy
  - Salt-wasting nephropathy
- Drugs
  - Diuretics
  - Aminoglycosides
  - Mannitol
  - Amphotericin B
  - Cisplatin
  - Carbenicillin

Gastrointestinal
- Vomiting
- Nasogastric suction
- Diarrhea
- Malabsorption
- Ileostomy
- Villous adenoma
- Laxative abuse

Increased Losses from Skin
- Excessive sweating
- Burns

Transcellular Shifts
Alkalosis
- Vomiting
- Diuretics
- Hyperventilation
- Bicarbonate therapy

Insulin
- Exogenous
- Endogenous response to glucose

Beta$_2$-agonists (albuterol, terbutaline, epinephrine)
Hypokalemic Periodic Paralysis
- Familial
- Thyrotoxic

Miscellaneous
- Anabolic state
- Intravenous hyperalimentation
- Treatment of megaloblastic anemia
- Acute mountain sickness

*Serum potassium less than 3.5 mEq/L.

Treatment of hyperkalemia should be preceded by exclusion of pseudohyperkalemia, which is a laboratory artifact. Pseudohyperkalemia results from hemolysis of the blood sample, leukocytosis, thrombosis, or prolonged fist clenching during blood drawing. Treatment of hyperkalemia is based on the severity of the patient's presenting signs and symptoms (Table 20-6).

DISORDERS OF CALCIUM BALANCE

Calcium is a divalent cation, 99% of which is found in bones. Calcium has an important structural function, but perhaps most important to anesthetists is its role as a second messenger that couples cell membrane receptors to cellular responses. The action of calcium as a second messenger is critical to functions such as muscle contractions and release of hormones and neurotransmitters.[2,22] In addition to the second messenger function, calcium plays an important role in coagulation of blood and in muscle function.

Although most of the body's calcium is found in the bones, a small percentage is freely exchangeable with the ECF. Calcium in the ECF is found in three distinct fractions. Ionized calcium accounts for 50% of the calcium in the ECF and is the physiologically active portion of circulating calcium.[1] The remainder of the circulating calcium is bound either to anions (10%) or plasma proteins, primarily albumin (40%).[23] Changes in pH alter the extracellular distribution of calcium, with acidemia decreasing the protein-bound fraction and increasing the ionized fraction.[4]

Because the ionized fraction of calcium is the most clinically significant form, and total serum calcium levels are largely dependent on albumin levels, direct measurement of ionized calcium is the preferred method in critically ill patients.[3] Mathematical formulas to "correct" total calcium measurement for albumin concentration are available but have been characterized as inaccurate.[4,23]

Hypocalcemia has numerous causes (Box 20-6). In the intraoperative period, the most likely causes of hypocalcemia are hyperventilation and massive transfusion of citrated blood. Hyperventilation leads to an increased pH and an increased protein-bound fraction of calcium. Massive transfusion of citrated blood is discussed later in this chapter.

Treatment of acute hypocalcemia involves the infusion of calcium salts. Calcium chloride is the most bioavailable parenteral preparation of calcium and results in the most rapid correction of hypocalcemia; however, it is more irritating to the vein than calcium gluconate.[23] One technique for treatment of hypocalcemia calls for administration of 10 mL of 10% calcium gluconate (93 mg of elemental calcium) over 10 minutes, followed by an infusion of 0.3 to 2 mg/kg/hr of elemental calcium.[4]

Hypercalcemia typically results from a situation in which the movement of calcium from the bone to the ECF exceeds the ability

of the kidney to excrete calcium (Box 20-7). Primary hyperparathyroidism accounts for more than half of all cases of hypercalcemia, with malignancy being the second most common cause.[23] Treatment of hypercalcemia involves volume expansion with normal saline (NS) (severely hypercalcemic patients are typically hypovolemic), which in and of itself increases renal excretion of calcium. The addition of a loop diuretic further enhances the renal excretion of calcium. Bisphosphonates, mithramycin, calcitonin, glucocorticoids, and phosphate salts also have been used in the treatment of hypercalcemia.[3]

DISORDERS OF MAGNESIUM BALANCE

Magnesium is the second most abundant intracellular cation, second only to potassium. The physiologic importance of magnesium lies in its role as a cofactor in more than 300 enzymatic reactions, including those involving energy metabolism and the function of the Na-K–ATPase pump.[22]

Hypomagnesemia is common in hospitalized patients, especially critically ill patients.[1,7] Magnesium deficiency is usually the result of increased renal or GI loss or poor intake of the electrolyte[3] (Box 20-8). Thirty percent of alcoholics admitted to the hospital are hypomagnesemic because of poor dietary intake.[7] Severe hypomagnesemia can be treated with administration of 1 to 2 g of magnesium sulfate over 5 minutes while the ECG is monitored, followed by administration of 1 to 2 g/hr of magnesium sulfate.[3]

Hypermagnesemia is most commonly the result of iatrogenesis (Box 20-9). Hypermagnesemia can result from the treatment of preeclampsia, preterm labor, ischemic heart disease, and cardiac dysrhythmias.[24] The symptoms of hypermagnesemia tend to reflect depression of the peripheral and central nervous systems and are dose related. Because magnesium potentiates the action of nondepolarizing neuromuscular relaxants, their use should be carefully monitored in patients with hypermagnesemia.[1] Treatment of hypermagnesemia involves discontinuing the administration of magnesium; in urgent situations such as bradycardia, heart block, and respiratory depression, calcium should be used as an antagonist.[7,25]

PARENTERAL FLUIDS

Intravenous fluids are the primary means to address a patient's need for fluid and electrolytes. Parenteral fluid therapy serves three principal purposes: provision of maintenance fluids, replacement of fluids lost as a result of surgery and anesthesia, and correction of electrolyte disturbances.[3] In anesthesia practice, IV fluids fall into two main categories: crystalloids (Table 20-7) and colloids.

Crystalloid solutions, which consist of fluids and electrolytes, are the most commonly used fluids in the surgical setting. Balanced salt solutions are crystalloids formulated to consist of an electrolyte concentration similar to ECF.[1] Two balanced salt solutions commonly administered to patients undergoing surgery include

TABLE 20-6 Guidelines for Treatment of Hyperkalemia

Clinical Feature	Therapy	Onset	Duration	Mechanism of Action
Electrocardiographic Evidence of Pending Arrest				
Loss of P wave and widening QRS; immediate effective therapy indicated	1. IV infusion of calcium salts*: 10 mL of 10% calcium chloride over 10-minute period *or* 10 mL of 10% calcium gluconate over 3-5 minutes	1-3 min 1-3 min	30-60 min 30-60 min	Membrane stabilization Membrane stabilization
	2. IV infusion of sodium bicarbonate: 50-100 mEq over 10- to 20-minute period	5-10 min	1-2 hr	Shifts potassium intracellularly
Electrocardiographic Evidence of Potassium Effect				
Peaked T waves; prompt therapy needed	1. Glucose and insulin infusion: IV infusion of 50 mL of $D_{50}W$ and 10 units of regular insulin; monitor glucose 2. Immediate hemodialysis	30 min	4-6 hr	Shifts potassium intracellularly
Biochemical Evidence of Hyperkalemia and No Electrocardographic Changes				
Effective therapy needed within hours	1. Potassium-binding resins in the gastrointestinal (GI) tract	1-2 hr	4-6 hr	GI excretion
	2. Promotion of renal potassium excretion: diuretic—Furosemide 40 mg IV	15-30 min	2-3 hr	Renal excretion

*Calcium chloride yields three times the ionized calcium as calcium gluconate; calcium chloride = 27 mg/mL; calcium gluconate = 9 mg/mL.
$D_{50}W$, 50% dextrose in water.

NS (also known as *0.9% normal saline* or *0.9% NS*) and lactated Ringer's (LR) solution.

Isotonic solutions such as NS and LR are commonly used to correct the hypovolemia resulting from surgery and anesthesia because the bulk of fluid lost is isotonic. Excessive volumes of NS have been associated with hyperchloremic metabolic acidosis.[26] A study by Scheingraber et al.[27] revealed that a significant acidosis was noted when NS but not LR was administered at a rate of 35 mL/kg/hr over a 2-hour period during the perioperative period. Although large-volume administration of LR may not result in acidosis, metabolic alkalosis may result when lactate is metabolized into bicarbonate by the liver[6]; furthermore, the potassium in LR can accumulate in patients with renal failure.

Hypertonic saline solutions (3% or 5% NaCl), or saline solutions containing Na concentrations exceeding 154 mEq/L, have been used as low-volume solutions for fluid resuscitation. Because of its hyperosmolar characteristics, hypertonic saline draws water from the interstitium into the vascular space. However, hypertonic saline carries with it a risk of unwanted hyperchloremia, hypernatremia, and cellular dehydration, as well as a limited intravascular duration. In the past, the principal role for hypertonic saline was the treatment of hyponatremia.[1] Current research suggests that isotonic saline solutions are preferred when treating hemorrhagic shock, in patients with traumatic brain injury (TBI).[28] Isotonic crystalloid solutions are the first choice for volume resuscitation of trauma patients with head injuries. Normal saline is a good choice because it is inexpensive, can be given with packed red blood cells, and is mildly hyperosmolar in comparison with normal plasma. A disadvantage is the development of hyperchloremic acidosis in large-volume resuscitation settings. Some trauma centers use other balanced salt solutions. Fluids to be avoided include hypotonic solutions such as 0.45% saline and any solution containing dextrose.[29]

Dextrose is often added to crystalloid parenteral solutions for a variety of reasons. Dextrose 5% in water (D_5W) is mildly hypotonic and is often used to provide free water that is available to the body once the dextrose has been metabolized. Dextrose also can be used as a metabolic substrate but is not usually administered intraoperatively because of the risk of hyperglycemia. Intraoperative dextrose administration is warranted in patients such as neonates, who have limited glycogen stores,[30] and diabetic patients who have received insulin and are at risk of hypoglycemia and protein catabolism.[1]

Colloids are solutions containing osmotically active substances of high molecular weight that do not easily cross the capillary membrane and therefore draw fluid into the intravascular space and expand circulating volume.[3] Colloids can be manufactured from human blood or synthesized from nonanimal substances.

Normal human serum albumin is manufactured from pooled donor plasma and is available in 5% and 25% (commonly called *salt-poor albumin*) solutions. Albumin 5% replaces plasma loss in a 1:1 ratio and remains in the vascular space for a prolonged time because of the presence of high-molecular-weight protein molecules. Albumin 25% can expand intravascular volume up to five times the volume infused, owing to its high osmotic pressure. Albumin 25% is well suited for use in patients with excessive ECF who need intravascular expansion.[1] Colloids formulated from human blood have at least a theoretical risk of disease transmission via pathogens such as prions,[31] and availability can be limited by donor supply.[32]

Synthetic colloids include dextran, gelatins, and hetastarch. Gelatins are generally not available for use in North America.[32] Dextrans are polysaccharides that are useful for volume expansion but are also associated with anticoagulation, which limits their application to settings such as vascular surgery, in which

prevention of thrombosis is desired. Dextran is also associated with risk of anaphylaxis.[3]

Hetastarch is a synthetic colloid made from plant starch. It has fluid expansion properties similar to those of albumin[3] but is far less expensive than albumin. Use of hetastarch 6% in saline has been limited by its effect on coagulation. It can produce a dilutional dysfunction of coagulation like other colloids and crystalloids. Hetastarch also directly inhibits clot formation by movement into fibrin clots.[1] Because of the effect of this colloid on coagulation, it is generally not administered in volumes exceeding 20 mL/kg. Another formulation of hetastarch, Hextend, is a solution containing 6% hetastarch with balanced electrolytes, a lactate buffer, and physiologic glucose. A study by Gan et al.[32] evaluated hetastarch in saline versus the hetastarch in the buffered solution and found that patients with the newer formulation could receive the colloid in volumes exceeding 20 mL/kg without coagulopathy. Hydroxyethyl starch (HES) 130/0.4 (Voluven) is a new colloid solution indicated for the treatment and prophylaxis of hypovolemia. Because the Voluven molecule is smaller than those of other available hydroxyethyl starch products, it is associated with less plasma accumulation and may be safer for use in patients with renal impairment. Previous studies have demonstrated that Voluven has comparable effects on volume expansion and hemodynamics as other available HES products. Voluven is also associated with fewer effects on coagulation and may be an acceptable alternative to albumin for volume expansion in situations in which other starches are contraindicated secondary to risk of coagulopathy.[33] Several studies have been reported that questioned the use of Voluven for fluid resuscitation. They note that there is no convincing evidence that third-generation HES 130/0.4 is safe in surgical, emergency, or intensive care patients despite publication of numerous clinical studies.[34,35]

The amount of fluid replacement is an important clinical question. Traditional infusion concepts, also known as liberal, often aimed at keeping the patient "wet"; however, other studies indicate that a more restrictive infusion regimen of "dry" may be preferable. The terms *restrictive*, *conservative*, *standard*, or *liberal* have no clear definitions, and sometimes imply the same, sometimes contradictory approaches.[36] Current evidence suggests that the patient should be treated according to the principles of goal-directed therapies that compensate for individual needs. The primary objective of perioperative infusion therapy is maintenance of normovolemia. To achieve this target, it is crucial to discriminate between fluid substitution such as replacement of sensible and insensible fluid losses and volume therapy to replace intravascular volume losses, until individual transfusion triggers are met.[37]

In the past, patients undergoing major surgery were often administered large volumes of crystalloid, based on a preoperative dehydration from long fasting intervals and theoretical "third space" fluid loss. However, positive perioperative fluid balance, with postoperative fluid-based weight gain, is associated with increased major morbidity. The concept of "third space" fluid loss has been refuted, and preoperative dehydration has been minimized by reduced fasting times and the allowance of oral fluids up to 2 h before the operation. A "restrictive" intraoperative fluid regimen, avoiding hypovolemia but limiting infusion to the minimum necessary may improve outcomes after major surgery.[38]

Goal-directed therapy is based on the assumption that maximizing cardiac flow parameters as a surrogate for oxygen delivery improves outcome. The use of minimally invasive esophageal Doppler technology may assist in further individualizing fluid guidance from goal-directed fluid therapy. This technology may become routine practice in the years to come. Esophageal Doppler monitoring uses Doppler ultrasound technology to asses the blood flow in the descending aorta. A disposable probe is inserted into the esophagus and aligned with the blood flow to produce a flow velocity profile for each heartbeat. The stroke volume can be used to indicate volume responsiveness. Modern evidence-based practice suggests that intraoperative fluid therapy should be tailored to two broad clinical contexts: In healthy patients undergoing low-risk or ambulatory surgery, high-volume crystalloid infusions of the order of 20–30 ml/kg (e.g., 2 liters over 30 min to the average adult) improves ambulatory anesthesia outcomes such as pain, nausea, and dizziness, and increases street readiness. High-risk patients undergoing major surgery seem to benefit from a "restrictive" fluid regimen. This remains to be clearly defined, but in a patient with normal renal function the restrictive fluid amounts should maintain intraoperative urine output between 0.5 and 1.0 ml/kg/hour. Fluids given early in the case seem to improve outcome as compared to later administration.[37-39]

Estimation of intraoperative fluid requirements is an imperfect science and is based on an understanding of patient fluid needs as well as the dynamics of fluid compartments. Fluid therapy in surgical patients should include administration of fluids to compensate for preoperative fluid deficit, maintenance fluids to compensate for evaporative losses and provide solute for excretion of waste, and fluids to replace surgical fluid losses (e.g., third-space loss and blood loss).[30] Recently clinicians have questioned whether the classical third space exists. Instead they theorize that perioperative fluid shifting predominantly represents losses toward the interstitial space. Crystalloids should be suitable to replace extracellular losses through insensible perspiration and urinary output. Colloids are the therapy of choice to replace acute blood losses above the blood transfusion border. As far as possible, hypervolemia and hypovolemia should be avoided. If clinical signs of intravascular hypovolemia occur, despite sufficient replacement therapy of measured and estimated losses, two explanations are possible. Either blood loss has been underestimated or a pathologic protein-rich shift is accruing that is related to an alteration of the vascular barrier. In both cases, intravascular application of further isooncotic colloid, not of crystalloid, should be considered.[39]

Traditional hourly maintenance fluid requirements are estimated according to the 4-2-1-formula (Table 20-8). A shortcut for estimating hourly maintenance fluid requirements in patients who weigh more than 20 kg is to add weight in kilograms to 40 to arrive at an hourly infusion volume in milliliters. Fluid deficit is estimated by multiplying the hourly maintenance requirement by

TABLE 20-8 Maintenance Fluid Requirement Calculation

Weight	Rate
The first 10 kg	4 mL/kg/hr
The next 10-20 kg	Add 2 mL/kg/hr
For each kg above 20 kg	Add 1 mL/kg/hr
Sample calculation for a 45-kg patient: 10 kg × 4 mL/hr = 40 mL/kg 10 kg × 2 mL/hr = 20 mL/kg 25 kg × 1 ml/hr = 25 mL/kg	Total maintenance rate 85 mL/kg/hr
Sample calculation for a 75-kg patient: 10 kg × 4 mL/hr= 40 mL/kg 10 kg × 2 mL/hr = 20 mL/kg 55 kg × 1 mL/hr = 55 mL/kg	Total maintenance rate 115 mL/kg/hr

TABLE 20-9 Fluid Losses from Various Types of Surgical Cases

Invasiveness and Surgical Trauma	Additional Fluid Requirements
Minimal Short superficial procedure	0-2 mL/kg
Moderate Uncomplicated intraabdominal or orthopedic procedure	2-4 mL/kg
Severe Prolonged highly invasive procedure	4-8 mL/kg

the number of hours the patient has been without oral or parenteral fluids. Calculation of the fluid deficit also should account for fluids lost through preoperative events such as nasogastric suctioning and bowel preparation.

Surgical fluid loss consists of blood loss, evaporative loss resulting from an open wound, and possible third-space losses resulting from fluid redistribution. Estimation of third-space loss is based on the degree of tissue trauma expected during the surgical procedure (Table 20-9) and can be substantial (e.g., as in major abdominal surgery). Estimation of blood loss is discussed in the section on transfusion therapy; blood volume loss can be replaced by crystalloids in a 3:1 or 4:1 ratio of crystalloid to blood. The 3:1 or 4:1 ratio has come into question because of the understanding that as crystalloids are infused, plasma osmotic pressure decreases, which leads to an increased loss of fluid from the intravascular to the interstitial space. Traditional rules of thumb indicating the need for three to four times the amount of crystalloids for the plasma volume to be replaced are probably erroneous and might have contributed to association of overly aggressive crystalloid resuscitation with poor outcome. Significant progress has been made in the last few years with respect to the understanding of basic principles of volume resuscitation in the critically ill. Isotonic crystalloids are safe and effective for use and the amount of crystalloid required to restore circulating blood volume is substantially less than assumed in the past.[40] Replacement of blood with crystalloid or colloid solutions replaces volume only and does not replace lost oxygen-carrying capacity or coagulation factors.

The rate at which fluids are administered intraoperatively is determined after summation of fluid requirements for surgical loss, deficit, and maintenance. Typically, maintenance and replacement fluids are administered to meet the hourly needs of the patient, and the deficit is replaced within the first 3 hours after induction. In clinical practice, induction of anesthesia frequently requires a fluid bolus to maintain blood pressure and often results in an initial infusion of IV fluids that exceeds what might be suggested by calculations.

The subject of much discussion, selection of IV fluid for therapy is based in large part on the purpose of the fluid. Maintenance needs are ideally met by fluids such as 5% dextrose and ¼% NS (D_5-¼ NS), which provide free water to facilitate excretion of waste and replace evaporative loss.[30] IV therapy in the operating room is principally focused on replacement of fluids lost during surgery and uses balanced salt solutions such as NS or LR. Replacement needs can also be met by colloid solutions such as hetastarch.

The relative merits of LR versus NS as a replacement solution for trauma resuscitation were explored in an animal model by Healey et al.[41] They found that in cases of moderate hemorrhage, NS and LR were both acceptable solutions. However, in cases of massive hemorrhage, LR was found to be superior to NS because of an absence of hyperchloremic metabolic acidosis. The treatment of hypovolemia in patients with non-cerebral trauma should begin with Ringer's lactate solution. Normal saline (0.9% sodium chloride) is appropriate for patients with head injury, alkalosis, or hyponatremia, but in large volumes may lead to metabolic acidosis. Base deficit and lactate levels can be used to guide resuscitation.[42]

TABLE 20-10 Advantages and Disadvantages of Crystalloid and Colloid Solutions for Fluid Resuscitation

Crystalloid	Colloid
Advantages	
Inexpensive	Causes sustained increase in plasma volume
Promotes urinary flow	Requires smaller volume for resuscitation
Restores third-space loss	Causes less peripheral edema
Used for extracellular fluid replacement	Tends to remain intravascular after repletion
Used for initial resuscitation	Causes more rapid resuscitation
	Useful in conditions of altered vascular permeability
Disadvantages	
Dilutes plasma proteins	Expensive
Causes reduction of capillary osmotic pressure	Can cause coagulopathy (dextran > hetastarch > Hextend)
Causes peripheral edema	Can cause anaphylactic reaction (dextran)
Has transient effect	Decreases Ca^{2+} (albumin)
Has potential for pulmonary edema	Can cause renal failure (dextran)
Can cause osmotic diuresis	
Can cause impaired immune response (albumin)	

Whether crystalloids or colloids are superior as replacement fluids has been debated for decades. The relative merits and disadvantages of each fluid are well known (Table 20-10). Data to support the choice of either crystalloids or artificial and natural colloids in the critically ill are tipping the scales toward crystalloids for reasons of safety, side effects, and containment of costs.[40] The Saline versus Albumin Fluid Evaluation (SAFE) study, a multicenter, randomized, double-blind trial, compared the effect of fluid resuscitation with albumin or saline on mortality in a heterogeneous population of patients.[43] A subgroup analysis evaluated patients with traumatic brain injury (TBI).[44] Almost 7000 patients who had been admitted to the intensive care unit (ICU) were randomly assigned to receive either 4% albumin or normal saline for intravascular-fluid resuscitation. At 24 months, 33.2% in the albumin group compared to 20.4% of patients in the saline group had died. Patients with a history of TBI also showed an unfavorable effect of albumin. A recent Cochrane review noted that there is no evidence that resuscitation with colloids reduces the risk of death compared to resuscitation with crystalloids in patients with trauma, burns, or following surgery. Because colloids are not associated with an improvement in survival, and are more expensive than crystalloids, it is hard to see how their continued use in these patients can be justified.[45] Another recent review suggested that evidence from clinical studies shows that comparable resuscitation is achieved with

TABLE 20-11 Average Blood Volumes

Age	Blood Volume
Neonates	
Premature	90-100 mL/kg
Full-term	80-90 mL/kg
Infants	80 mL/kg
Adults	70 mL/kg

considerably less crystalloid volume than frequently suggested, namely, less than twofold the volume of colloids. The use of colloidal solutions for resuscitation of patients with acute hypovolemia is not supported by clinical evidence. Synthetic colloids are not superior in critically ill adults and children and may be harmful depending on the cumulative dose administered. Crystalloids are safe and equally effective as compared to colloids; therefore the use of synthetic colloids should be avoided.[46]

BLOOD COMPONENT THERAPY

For the purpose of volume replacement, perioperative blood loss can be replaced with crystalloids and/or colloids, but if hemorrhagic losses are significant, transfusion therapy involving the administration of blood or blood components may be necessary to increase oxygen-carrying capacity, increase intravascular volume, and restore hemostasis. Decisions regarding transfusion therapy must take into account several factors, including perioperative blood loss, the clinical condition of the patient, and access to the patient blood type.

Estimation of blood loss, patient-specific blood volume, and calculation of allowable blood loss for that patient are important factors to consider when making decisions about blood component therapy. Estimating blood volume (EBV) takes into account patient age and weight, and is summarized in Table 20-11.

Once blood volume has been estimated, a clinician can, by a simple calculation, determine the volume of blood loss that would decrease hematocrit to a target value. The formula for maximum allowable blood loss (MABL) is as follows:

$$\text{MABL} = \frac{\text{EBV} \times (\text{Starting hematocrit} - \text{Target hematocrit})}{\text{Starting hematocrit}}$$

Unfortunately, estimation of intraoperative blood loss is fraught with error because of a lack of practical objective measures. Rapid intraoperative measurement of hemoglobin and hematocrit has become widespread with the introduction of easy-to-use, point-of-care monitors.[47] They do not measure the amount of blood loss.[48] Measuring net suction volume (amount of fluid suctioned minus amount of irrigant) and counting or weighing sponges are common methods used to determine the volume of blood lost during surgery. A study by Orth et al.[49] examined the accuracy of conventional, subjective techniques for estimation of blood loss by comparing the results of conventional techniques to those derived from an objective technique (sodium fluorescein dye). The investigators found a significant difference between subjective and objective techniques; in general, blood loss was underestimated by an average of approximately 300 mL when subjective techniques were used.

In addition to estimating blood loss, patient response to intraoperative hemorrhage should be taken into consideration when making decisions regarding transfusion therapy. Tachycardia and decreased mixed venous oxygen saturation are suggestive of anemia, especially in the setting of intraoperative hemorrhage. A useful metric in decision making for transfusion therapy involves the measurement of systemic oxygen delivery (DO_2), which integrates cardiac index, oxyhemoglobin saturation, and hemoglobin concentration to produce a global measure of DO_2, rather than one isolated parameter such as hemoglobin. Survival in high-risk patients is associated with a DO_2 greater than or equal to 600 mL O_2/min/m^2.[10]

TABLE 20-12 Relationship Among Blood Groups, Antigens, Antibodies, and Blood Compatibility

Blood Group	Antigen on Red Blood Cell	Antibodies in Serum	Blood Group Compatibility
A	A	Anti-B	A, O
B	B	Anti-A	B, O
AB	A and B	—	AB, A, B, O
O	—	Anti-A and Anti-B	O only
Rh-positive	D	—	Rh-positive and Rh-negative
Rh-negative	—	Anti-D if sensitized	Rh-negative

A further prerequisite of blood component therapy is establishing blood compatibility. Because of the presence of antigens in red blood cell (RBC) membranes and circulating antibodies, a blood recipient can receive red cells only from a compatible donor (Table 20-12). Two blood groups deserve special attention. Individuals with group AB blood possess both A and B antigens on their RBCs and lack anti-A and anti-B antibodies; therefore such individuals can receive blood from any ABO group and are known as *universal recipients*. Individuals with type O blood are known as *universal donors* because their RBCs are devoid of any of the ABO antibodies.

The most important tests of blood compatibility are those used to determine ABO and Rh (also known as *type D*) blood groupings; transfusion of ABO- or Rh-incompatible blood can result in serious hemolysis. Patients at risk for needing a transfusion and the banked blood stored for transfusion are "typed" to determine ABO and Rh status. To further reduce the risk of a transfusion reaction, patients and banked blood are screened for clinically significant antibodies other than ABO and D. The ultimate test of blood compatibility is a type and crossmatch, during which donor blood and recipient blood are mixed together in what is essentially a trial transfusion. In contemporary clinical practice, patients are often prepared for surgery with only a type and screen, which predicts compatible transfusions 99.94% of the time. The addition of crossmatching increases the possibility of a compatible transfusion only one hundredth of 1%.[50]

In an emergency situation in which a patient's blood group is unknown, uncrossmatched type O, Rh-positive blood can be given to males or females of non-childbearing years who have never received a previous type O Rh-positive blood transfusion. Type O Rh-negative should be reserved for females of childbearing years, or when clinicians are unsure of the patient's previous blood transfusion history in order to avoid any hemolytic reaction. However, if two or more units of O-negative whole blood have been given, the patient may not be able to receive transfusions of his or her own type (A, B, or AB) because of the risk of hemolysis. It is preferred that type O Rh-negative uncrossmatched packed RBCs (PRBCs) should be used because packed erythrocytes have smaller plasma volumes and are almost free of hemolytic anti-A and anti-B antibodies. The patient may not be transfused with his or her respective blood type until the blood bank determines that the transfused anti-A and anti-B antibodies have decreased to levels that permit safe transfusion of type-specific blood.[50]

Currently in the United States, most donor blood is fractionated into its component parts (i.e., RBCs, plasma, platelets, and individual factor concentrates). Because of fractionation, blood component therapy can be targeted to a specific patient need (e.g., diminished oxygen-carrying capacity and/or hemostasis). Red blood cell transfusions are used to treat hemorrhage and to improve oxygen delivery to tissues. Indications for transfusion include symptomatic anemia in high-risk patients, acute blood loss of more than 30% of blood volume, or in hemodynamically unstable patients where blood loss continues. Fresh frozen plasma infusion can be used for reversal of anticoagulant effects. Platelet transfusion is indicated to prevent hemorrhage in patients with thrombocytopenia or platelet function defects. Cryoprecipitate is used in cases of hypofibrinogenemia, which most often occurs in the setting of massive hemorrhage or consumptive coagulopathy. Transfusion-related infections are less common than noninfectious complications. Acute complications occur within minutes to 24 hours of the transfusion, whereas delayed complications may develop days, months, or even years later.[51]

Storage of blood as components rather than as whole blood has distinct advantages[52]; however, banked blood does undergo undesirable changes during storage (Box 20-10). The deleterious effect of storage on RBCs in particular has been well known for some time and has been referred to as "the storage lesion." The clinical effects of the functional and morphologic changes observed in banked blood are not fully understood at present and continue to be the subject of intense investigation.[53] A recent observational study of almost 6000 cardiac surgery patients found an association between transfusion of blood stored longer than 14 days and increased postoperative morbidity and mortality when compared with patients receiving blood stored for less than 14 days.[54] Similar findings were noted in intensive care units.[55,56]

Deciding when to administer blood components is an important clinical judgment that should be based on sound evidence, not custom. In recent years, critical attention has been directed to transfusion practices because of concerns regarding the expense, availability, and risks of transfusions. In 1996 and 2006, the American Society of Anesthesiologists (ASA) convened task forces on blood component therapy to develop guidelines to help inform clinicians of the best practices in transfusion therapy.[57,58]

A single threshold for transfusion, a so-called *transfusion trigger*, has been the subject of much discussion and study. The literature, based largely on clinical experience with Jehovah Witnesses, records the survival of patients with hemoglobin values as low as 1.8 g/dL, although significant mortality is associated with hemoglobin values of less than 5 g/dL.[31] During anemic episodes, oxygen delivery to the tissues can be improved by increased cardiac output and improved microvascular blood flow resulting from the decreased viscosity of diluted blood.[59] The current consensus is that no single transfusion threshold exists and that decisions regarding RBC transfusions should be based on the specific clinical situation.

In practice, packed RBCs (PRBCs) are the component of choice for improving oxygen-carrying capacity. PRBC infusions are generally administered in a ratio of 1 mL for each 2 mL of blood loss (along with crystalloids or colloids for volume). The 1 to 2 ratio is due to the higher hematocrit of packed red blood. A commonly used rule of thumb states that each unit of PRBCs increases hemoglobin 1 g/dL and hematocrit 2% to 3%.[48]

The ASA Task Force concluded that transfusion is "usually unnecessary" in patients with hemoglobin greater than or equal to 10 g/dL and should "usually be administered" when hemoglobin is less than 6 g/dL.[58] Transfusing patients with a hemoglobin level of 6 to 10 g/dL is based on specific clinical factors. Factors that affect the selection of a transfusion threshold in individual patients include consideration of cardiopulmonary reserve, experienced and expected blood loss, O_2 consumption (reflected in indices such as arterial oxygen saturation and mixed venous oxygen saturation), and the presence or absence of atherosclerotic disease.[31,57,58]

BOX 20-10

Changes in Banked Blood

- Depletion of 2,3-diphosphoglycerate (DPG)
- Depletion of ATP (adenosine triphosphate)
- Oxidative damage
- Increased adhesion to human vascular endothelium
- Acidosis
- Altered morphology of red blood cells (change in shape, decreased flexibility, membrane loss)
- Accumulation of microaggregates
- Hyperkalemia (as high as 17.2 mEq/L)
- Absence of viable platelets (after 2 days of refrigerated storage)
- Absence of factors V and VIII
- Hemolysis
- Accumulation of proinflammatory metabolic and breakdown products such as lysophospholipids

From Corazza ML, Hranchook AM. Massive blood transfusion. *AANA J*. 2000;68(4):311-314; Tinmouth A, et al. ABLE Investigators Canadian Critical Care Trials Group: clinical consequences of red cell storage in the critically ill. *Transfusion*. 2006;46(11):2014-2027; Shander A, et al. Patient blood management in Europe. *Br J Anaesth*. 2012;109(1):55-68.

Outcomes in patients whose transfusions were guided by restrictive transfusion triggers have been studied. The Cochrane Injuries Group conducted a systematic review of 17 studies examining restrictive transfusion triggers and concluded that in patients without cardiovascular disease, renal failure, or hematologic disorders, withholding transfusions in those with hemoglobin as low as 7g/dL was a justifiable practice.[60]

The most common surgical procedures that require transfusion are orthopedic, especially hip and knee replacement, colorectal, cardiac, major vascular, liver transplant, and trauma. Because most of these procedures are elective, careful preoperative planning is possible. Patient Blood Management (PBM) has been adopted worldwide as a strategy to reduce unnecessary transfusions and maximize patient outcomes. PBM is a multidisciplinary, multimodality care strategy for timely use of safe, effective medical and surgical techniques designed to prevent anemia and decrease bleeding in an effort to improve outcomes.[61-63] Three strategies of PBM include optimizing the patient's own red blood cell mass, minimizing blood loss, and optimizing the patient's physiologic tolerance of anemia. Major goals for PBM are listed in Box 20-11. The Joint Commission has developed transfusion performance measures as accreditation goals (Table 20-13).[61]

The American Association of Blood Banks (AABB) has recently issued four recommendations for transfusions: (1) adhere to a restrictive transfusion strategy (7 to 8 g/dL) in hospitalized, stable patients; (2) adhere to a restrictive strategy in hospitalized patients with preexisting cardiovascular disease and consider transfusion for patients with symptoms or a hemoglobin level of 8 g/dL or less; (3) no recommendation for or against a liberal or restrictive transfusion threshold for hospitalized, hemodynamically stable patients with the acute coronary syndrome; and (4) transfusion decisions should be influenced by symptoms as well as hemoglobin concentration.[64] A common strategy for management of transfusions is given in Table 20-14. Restrictive triggers

BOX **20-11**

Patient Blood Management Strategies

Preoperative Suggestions

- Screen for and treat anemia. Manage any underlying disorders that may lead to anemia.
- Treat iron deficiency and administer erythropoiesis-stimulating agents as indicated.
- Identify and manage any bleeding risks such as medications or chronic diseases.
- Assess patient reserve and optimize patient-specific tolerable blood loss.
- Formulate management plan with evidence-based transfusion strategy.
- Preoperative autologous blood donation in select situations.
- May require preoperative visit up to 30 days prior to elective surgery to accommodate therapy.

Intraoperative Suggestions

- Perform elective surgery when hematologically optimized.
- Use meticulous blood-sparing surgical techniques.
- Continually measure and assess hemoglobin and hematocrit.
- Plan and optimize fluid management of nonblood products.
- Optimize cardiac output, oxygen delivery, and ventilation.
- Use blood salvage and autologous transfusion when possible.

Postoperative Suggestions

- Treat anemia with erythropoiesis-stimulating agents and iron deficiency as indicated.
- Vigilant monitoring and management of postoperative bleeding.
- Maintain normothermia to minimize oxygen consumption.
- Avoid and/or treat infections promptly.
- Carefully manage anticoagulant medications.

Adapted from Shander A, et al. Patient blood management in Europe. *Br J Anaesth*. 2012 Jul;109(1):55-68; Goodnough LT, Shander A. Patient blood management. *Anesthesiology*. 2012 Jun;116(6):1367-76; Shander A, Javidroozi M. TABLE **20-13** Patient Blood Management

TJC* Performance Measures	Principles
Preoperative anemia screening	Formulate a plan of proactive management for avoiding and controlling blood loss tailored to the clinical management of individual patients, including anticipated procedures
Preoperative blood type and antibody screen (blood compatibility testing)	Employ a multidisciplinary treatment approach to blood management using a combination of interventions (e.g., pharmacologic therapy, point-of- care testing)
Transfusion consent	Promptly investigate and treat anemia
Blood administration	Exercising clinical judgment, be prepared to modify routine practices (e.g., transfusion triggers) when appropriate
RBC transfusion indication	Restrict blood drawing for unnecessary laboratory tests
Plasma transfusion indication	Decrease or avoid the perioperative use of anticoagulants and antiplatelet agents
Platelet transfusion indication

may be harmful in patients with signs and symptoms of low blood volume or other risk factors such as in patients experiencing acute myocardial infarction or unstable angina. Most hospitals have developed general transfusion guidelines to assist decision making.

Massive transfusion of RBCs, variously defined as (1) replacement of estimated blood volume within 24 hours, (2) ≥ 10 units of RBCs over 24 hours, or (3) 50% of blood volume within 3 hours or less[65] presents special concerns to anesthetists. Replacement of lost blood volume by PRBCs, often accompanied by crystalloids and colloids, does not provide coagulation factors and can lead to a dilutional coagulopathy or dilutional thrombocytopenia. Banked blood is commonly anticoagulated by a solution containing sodium citrate, which binds calcium, thereby inhibiting coagulation. Very rapid infusion of blood can reduce the level of ionized calcium.[50] This phenomenon, sometimes referred to as *citrate intoxication*, presents as acute hypocalcemia. Fortunately, normothermic patients with normal kidney and liver function can metabolize the amount of citrate present in 20 units of banked blood per hour and are not likely to display citrate intoxication.[4]

Fresh-frozen plasma (FFP) contains all coagulation factors[66] and is administered to provide coagulation factors that may be inadequate because of dilution or dysfunctions of coagulation. Indications for administration of FFP include reversal of the effects of warfarin, correction of known coagulopathy, correction of microvascular bleeding in the presence of elevated prothrombin time (PT) or partial thromboplastin time (PTT) that is > 1.5 times normal, and correction of microvascular bleeding in patients suspected of dilutional coagulopathy. For the reversal of warfarin, FFP is usually administered in doses of 5 to 8 mL/kg; 10 to 20 mL/kg is the guideline for all other purposes and should increase coagulation levels 20-30%.[57,58,66] The majority of FFP is transfused for the management of acquired bleeding disorders. The PT and the international normalized ratio (INR) are the most common tests to detect these disorders. Studies have shown that the PT correlates poorly with clinical bleeding and that transfusion of plasma often achieves no measurable change in the INR and has no known clinical benefit. The use of FFP is being discouraged if the INR is less than 2.0 in the absence of active bleeding, and the use of vitamin K is encouraged if the patient is on warfarin.[67]

Platelets are essential for adequate hemostasis and may need to be transfused because of thrombocytopenia or abnormal function.[52] Platelets are available as platelet concentrates separated from one unit of whole blood or as apheresis platelets, which originate from a single donor and are the equivalent of approximately six platelet concentrates.[68] Transfusion of platelets is usually indicated when the count is less than $50 \times 10^3/\mu L$ but not more than $100 \times 10^3/\mu L$. Platelet transfusions in patients with platelet counts of $50 \times 10^3/\mu L$ to $100 \times 10^3/\mu L$ are indicated when the patient displays microvascular bleeding or if the patient is at risk for platelet dysfunction or continued bleeding. The usual dose of platelets is one platelet concentrate per 10 kg of body weight; transfusion raises the platelet count for 6 to 7 days.[52,57,58]

TABLE 20-14 Decision Criteria for Transfusion

Class of Hemorrhage	Reduction of Volume (%)	Blood Loss (mL)*	Hemoglobin	Indication for Transfusion of PRBC
Class I	<15%	<750	≥ 10 g/dL	Not necessary if no preexisting anemia
Class II	15-30%	750-1500	8-10 g/dL	Not necessary, unless preexisting anemia and/or cardiopulmonary disease
Class III	30-40%	1500-2000	6-8 g/dL	Probably necessary
Class IV	>40%	>2000	≤ 6 g/dL	Necessary

PRBC, Packed red blood cells.
From Liumbruno GM, et al. Recommendations for the transfusion management of patients in the peri-operative period. II. The intra-operative period. *Blood Transfus*. 2011;9(2):189-217.
*In an adult person weighing 70 kg and with a circulating blood volume of 5000 mL.

A less frequently used blood component, cryoprecipitate, contains factor VIII, von Willebrand factor, and fibrinogen.[52] Cryoprecipitate is recommended for treatment of patients with von Willebrand disease and in patients with probable or documented deficits in fibrinogen (e.g., fibrinogen less than 80 to 100 mg/dL).[57,58] Cryoprecipitate should be administered through a filter and as rapidly as possible. The rate of administration should be at least 200 mL/hr, and infusion should be completed within 6 hours of thawing.[50]

An adjuvant therapy that has been used in cases of massive transfusion is recombinant factor VIIa (rFVIIa). This therapy was approved in 1999 for the treatment of congenital or acquired hemophilia A or B, for inhibitors of coagulation, or for congenital factor VII deficiency. Currently, 90% of rFVIIa use is off-label, meaning that its usage is for treatment of conditions other than what was approved by the FDA. The exact mechanism of action is not fully understood; however, it is believed that rFVIIa induces coagulation by binding to platelets and exposed tissue factor at the site of injury, which initiates a thrombin burst. This thrombin-burst amplifies the activation of clotting factors and the generation of thrombin-enhancing hemostasis. According to two recent meta-analyses, there is limited evidence that demonstrates a mortality reduction when compared to the risk of thromboembolism with the use of rFVIIa.[68,69]

Benefits of transfusion include increased oxygen-carrying capacity and improved coagulation. Unfortunately, transfusion of blood and blood products is not without risk. Infectious and noninfectious complications are possible, and the risk of complications is increased by massive transfusion, as well as by transfusion of blood that has been stored for a prolonged period.

COMPLICATIONS OF BLOOD TRANSFUSION

Some of the most common serious complications of blood transfusion are due to incompatibility. In a survey of hematologists in the United Kingdom and Ireland (the Serious Hazards Of Transfusion [SHOT] initiative), reports of transfusion reactions have been assessed on an ongoing basis. The most recent report noted 300 serious transfusion reactions, 262 of which were "incorrect blood component transfused" incidents. (Incorrect transfusions in the SHOT study were typically the result of procedural errors that led to the misidentification of patients.[70,71]) The result of transfusion to an incompatible recipient is an immune reaction, with the risk of intravascular hemolysis because of an interaction between the circulating antibodies of the recipient and the RBCs of the donor. Approximately half of all deaths from acute hemolytic reactions are caused by ABO-incompatible transfusions resulting from procedural or administrative error. Volumes of donor blood as small as 10 mL may lead to hemolytic reactions that may result in death for 20% to 60% of patients.[50] The clinical picture is complicated by the fact that general anesthesia may obscure the symptoms associated with a hemolytic reaction.[57]

Other life-threatening complications seen in the context of transfusion include transfusion-associated graft-versus-host disease and transfusion-related acute lung injury (TRALI). Transfusion-associated graft-versus-host disease results when donor lymphocytes incorporate themselves into the tissues of the recipient, leading the recipient's immune system to attack the embedded recipient tissues. Rash, leukopenia, and thrombocytopenia occur, with sepsis and death usually ensuing.[50]

Since 2003, TRALI has been recognized by the U.S. Food and Drug Administration (FDA) as the leading cause of transfusion-related death in the United States and is believed to occur as frequently as once in every 432 units of platelets or as infrequently as one in every 7900 units of FFP.[72,73] It is likely that TRALI is underreported because the syndrome may be confused with other forms of acute lung injury (ALI) and was without a clear definition until 2005. TRALI has been defined as ALI occurring within 6 hours of transfusion in individuals who were previously free of ALI and without other risk factors for ALI.[72]

The etiology of TRALI has not been fully explained, but two theories have been proposed to describe the syndrome. One explanation proposes that antibodies in donor plasma activate recipient neutrophils, leading to pulmonary capillary leakage. An alternative explanation puts forward a two-event model in which a physiologic stressor such as sepsis leads to sequestration of neutrophils in the lungs, then the transfusion of biologically active mediators (the second event) leads to activation of the neutrophils and capillary leakage. Treatment of TRALI is supportive and should include notifying the blood bank that a transfusion reaction suspected to be TRALI has occurred.[72-74]

Several undesirable effects of transfusions have been linked to the presence of leukocytes in allogenic blood. Homologous transfusions, which invariably contain some leukocytes, have been implicated in immunosuppression of recipients, leading to unexpectedly early recurrences of cancer and higher than expected rates of postoperative infection—a condition known as *transfusion-related immunomodulation* (TRIM).[52,57,69]

Nonhemolytic transfusion reactions are relatively common, occurring in 1% to 5% of all transfusions, and are associated with symptoms such as fever, chills, and urticaria. Like hemolytic reactions, these reactions are difficult to detect during general anesthesia.[57] Although not usually life threatening, febrile nonhemolytic and allergic reactions can cause concern and may lead to interruption of the transfusion.[50] According to the FDA, the most common causes of transfusion-related deaths are TRALI followed by hemolytic transfusion reaction, transfusion-associated sepsis, transfusion-related circulatory overload, babesiosis, anaphylaxis, and graft-versus-host disease.[75]

Leukoreduction, the use of filters to reduce the level of white blood cells (WBCs), is one technique used to reduce the incidence of certain adverse events related to transfusion. Leukoreduction has proven

BOX 20-12

Clinical Benefits of Leukoreduction

Proven clinical relevance
- Reduced frequency and severity of NHFTRs
- Reduced risk of CMV transmission
- Reduced risk of HLA alloimmunization and platelet refractionness

Likely clinically relevant
- Reduced infectious risk associated with immunomodulation (TRIM)
- Reduced organ dysfunction and mortality
- Reduced direct risk of transfusion-transmission bacteria

Unproven clinical relevance
- Avoidance of vCJD transmission
- Avoidance of HTLV I/II, EBV, and similar viruses
- Reduced risk of GVHD

From Blajchman MA. The clinical benefits for the leukoreduction of blood products. *J Trauma*. 2006;60(suppl 6):S83-S90; Friese RS, et al. The use of leukoreduced red blood cell products is associated with fewer infectious complications in trauma patients. *Am J Surg*. 2008;196(1):56-61; Phelan HA, et al. CMV, Cytomegalovirus; *EBV*, Epstein-Barr virus; *GVHD*, graft-versus-host disease; *HLA*, human leukocyte antigen; *HTLV*, human T-lymphotrophic virus; *NHFTRs*, nonhemolytic febrile transfusion reactions; *TRIM*, transfusion-related immunomodulation; *vCJD*, variant Creutzfeldt-Jakob disease.

to be effective in reducing the incidence of nonhemolytic transfusion reactions and is likely to be effective in the reduction of TRIM. One hypothesis for the mechanism behind this storage lesion centers on the role of leukocytes in the donor units. Leukocytes exert a variety of immunomodulatory effects on the recipient in a magnitude that is proportional to the length of time the donor unit is stored. The effects of universal leukoreduction have been so promising (Box 20-12) that several nations, including Canada and France, have mandated universal leukoreduction for their nations' blood supply.[76-78]

Despite enhanced safety of the blood supply, infectious complications remain a real, although perhaps overemphasized, possibility (Table 20-15).[79-81] The current rates of transmission of viral illness by transfusion are so low that mathematical models are now used to estimate risk.[69] Even with improved testing, transmission of viral disease can still occur during a period of time commonly called the *window period*, during which the donor blood is infectious, but screening tests used by blood banks are insensitive. Polymerase chain reaction (PCR) assays have improved testing for antibodies and shortened the window period to approximately 11 days for human immunodeficiency virus (HIV) and 8 to 10 days for hepatitis C virus (HCV).[82] Although hepatitis and HIV continue to be the subjects of considerable attention, other newly emerging viral diseases in the United States threaten the safety of the blood supply. West Nile virus is one example of a newly recognized transfusion-related illness. Fortunately, rapidly developed testing procedures for the virus have greatly reduced the risk of transmission by transfusion.[83]

One of the most recently identified transfusion-related diseases is variant Creutzfeldt-Jakob disease (vCJD). Theories suggest that this disease is contracted by blood donors through the ingestion of beef from cattle infected with bovine spongiform encephalopathy (BSE). The infectious agent responsible for BSE—believed to be an abnormal prion protein—can be passed from blood donor to transfusion recipient and become manifest in the recipient as vCJD,

TABLE 20-15 Risks and Side Effects of Allogenic RBC Transfusion

Type of Risk	Incidence (per Unit Transfused)
Infections	
Viruses	
Human immunodeficiency virus (HIV)	1:1,468,000 – 1:4,700,000
Hepatitis B virus (HBV)	1:31,000 – 1:205,000
Hepatitis C virus (HCV)	1:1,935,000 – 1:3,100,000
Bacteria	
All	1:28,000 – 1:143,000
Parasites	
Malaria	1:4,000,000
Prions	
New variant Creutzfeldt-Jakob disease	Possible
Immunologic Reactions	
Hemolytic Transfusion Reactions	
Acute hemolytic TR	1:13,000
Delayed hemolytic TR	1:9000
Alloimmunization	1:1600
Immunosuppression	1:1
Transfusion-related acute lung injury	1:70,000
Mistransfusion	
All RBC mistransfusions	1:14,000 – 1:18,000
Increased mortality	
Increased length of hospital stay	

From Spahn DR, Kocian R. Artificial 0_2 carriers: status in 2005. *Curr Pharm Des*. 2005;11(31):4099-4114; Spahn DR, et al. More on transfusion and adverse outcome: it's time to change. *Anesthesiology*. 2011;114(2):234-6; Glance LG, et al. Association between intraoperative blood transfusion and mortality and morbidity in patients undergoing noncardiac surgery. *Anesthesiology*. 2011;114(2):283-92.

leading to degeneration of the central nervous system. Fortunately, vCJD remains a rare disease, with the majority of cases confined to the United Kingdom. Measures to protect the integrity of the blood supply include careful donor screening and leukodepletion.[84]

Bacterial contamination of blood remains a risk and increases with the length of time the blood is stored.[69] Contamination of platelets is of particular concern. Platelets are stored for a maximum of 5 days[85] at room temperature and carry a risk of bacterial contamination of 1 in 12,000.[69]

Concerns regarding cost, availability, and complications associated with blood and blood products have led to strategies to reduce the risk of intraoperative blood loss, such as careful preoperative evaluation of the patient focusing on conditions that place the patient at increased risk of hemorrhage. In the surgical setting, these factors generally include medications that affect coagulation and inherited and acquired defects of coagulation. An important tool to reduce the risk of significant intraoperative blood loss is the preoperative administration of agents to promote coagulation or reverse anticoagulants. The ASA transfusion practice guidelines recommend judicious preoperative administration of reversal agents such as vitamin K, prothrombin-complex concentrate, recombinant factor VII, and FFP. Antifibrinolytic agents should be considered in cases in which

large amounts of blood loss are anticipated. This may lead to the administration of agents such as tranexamic acid G.[58,86]

In the event that blood transfusion becomes unavoidable, alternatives to blood transfusion from anonymous donors have been developed in the hope of reducing patient risk. One option involves the use of directed donors. Donor-directed blood transfusions are homologous blood transfusions from a donor selected by the recipient and believed by some to decrease the risk of transmission of disease. Studies comparing the safety of donor-directed blood with blood from anonymous donors, however, fail to demonstrate any advantage to using donor-directed blood.[48,68]

A widely used alternative to allogenic blood transfusion is the use of autologous transfusion. Autologous transfusion techniques can be divided into three main categories: intraoperative and postoperative blood salvage, preoperative blood donation, and acute normovolemic hemodilution.[87] Autologous transfusion is a valuable tool when used in select patients.[88]

Intraoperative red-blood-cell (RBC) salvage involves the aspiration of blood shed into the surgical field into a specialized apparatus that concentrates the RBCs and washes the shed blood to remove debris, after which the RBCs are reinfused. Cell salvage may be used in surgical cases in which significant blood loss is likely, as well as in cases of unexpected massive blood loss (Table 20-16). Generally accepted contraindications to cell salvage include surgery involving wounds contaminated by bacteria, sepsis, bowel contents, amniotic fluid, or malignant cells, as shown in Table 20-16.[89] Cell-washing devices can provide a volume equivalent to 10 units of blood per hour for transfusion in cases of massive blood loss.[90] Prolonged use of cell salvage of large volume autotransfusion may be associated with dilution of clotting factors and thrombocytopenia, and regular laboratory or point of care monitoring is required. Cell salvage should be considered in all cases where significant blood loss (greater than 1000 mL) is expected or possible. The use of cell salvage in combination with a leukocyte depletion filter appears to be safe.[71]

Preoperative blood donation consists of the collection and storage of a potential recipient's own blood for possible reinfusion of the blood at a later date, the intraoperative period. Although this procedure may eliminate certain risks associated with transfusions, some risks remain, and other risks arise (Box 20-13).[87] The process of autologous preoperative blood donation and transfusion carries with it the risks of preoperative anemia and resultant myocardial ischemia, the risk of bacterial contamination, and the risk of clerical error leading to the administration of the wrong blood.[50] In addition to these patient risks, approximately half of autologously donated blood is discarded,[90] which contributes to waste. Other disadvantages include a possible reduction in preoperative hemoglobin and anemia tolerance, and the donated blood requires storage so the usual concerns with banked blood remain.[88]

Acute normovolemic hemodilution is a transfusion alternative involving the removal of whole blood from a patient immediately before or after the initiation of anesthesia and surgery and replacing volume with crystalloid or colloid solutions. Blood lost during surgery will have a low hematocrit. Reinfusion of the whole blood (with a normal hematocrit as well as clotting factors) is initiated when intraoperative loss of blood has stopped, or earlier if the patient's condition warrants it. Advocates of acute normovolemic hemodilution suggest that hemodilution, compared with autologous donation, eliminates the expense of testing, the risks of bacterial contamination, and opportunity for wrong unit transfusion because the whole blood remains in the operating room.[90]

The search for a "blood substitute" has evolved over time into efforts to develop "oxygen therapeutics," which involves the use of technology to increase the oxygen-carrying capacity of the circulating volume.[91] Main areas of concentration in this field include the development of cell-free hemoglobin solutions to carry oxygen and perfluorochemicals to carry dissolved oxygen in a manner similar to that of plasma.[80,86,90-92]

SUMMARY

Surgery and anesthesia challenge the body's ability to maintain the dynamic balance of fluids and electrolytes necessary for proper function. Skillful management of fluids and electrolytes in the perioperative period is one of the most challenging and important tasks of the anesthetist and requires knowledge of both basic sciences and clinical research.

A subject intimately related to fluid and electrolyte management is transfusion therapy. An expanding body of evidence addressing transfusion therapy is better informing the clinician, who must evaluate risks versus benefits in the process of clinical decision making.

TABLE 20-16 Cell Salvage

General Indications for Cell Salvage

Specialty	Surgical procedure	Comments
Cardiac	Valve replacement Redo bypass grafting	
Orthopedics	Major spine surgery Knee replacement Hip replacement	
Urology	Radical retropubic prostatectomy Cystectomy Nephrectomy	Individualized by surgeon Limited to patients with prior radiation therapy When tumor involves major vessels
Neurosurgery	Giant basilar aneurysm	
Vascular	Thoracoabdominal aortic Aneurysm repair Abdominal aortic aneurysm repair	Should be individualized by surgeon and patient's characteristics
Liver transplant		
Other	Jehovah Witnesses Unexpected massive blood loss Red cell antibodies	When accepted by patient

TABLE 20-16 Cell Salvage—cont'd

Relative Contraindications to Cell Salvage
Pharmacologic Agents
Clotting agents (e.g., Avitene, Surgicel, Gelfoam) Irrigating solutions of disinfectants for topical use (e.g., oxygenated water, betadine, distilled water, alcohol, antibiotics meant for topical use)
Anticoagulant drugs
Synthetic resins such as methylmethacrylate Catecholamines (pheochromocytoma) Oxymetazoline (Afrin) Papaverine
Contaminants in the Operating Field
Urine Bone chips Fat Bowel contents Infection Amniotic fluid
Malignant Tumors or Neoplastic Cells
Hematologic Disorders
Thalassemia Sickle cell disease
Miscellaneous
Carbon monoxide (electrocautery smoke)

Adapted from Esper SA, Waters JH. Intra-operative cells salvage: a fresh look at the indications and contraindications. *Blood Transfus*. 2011;9(2):139-147.

BOX 20-13

Autologous Blood Donation

Advantages

- Prevents transfusion-transmitted disease
- Prevents red-cell alloimmunization
- Supplements the blood supply
- Provides compatible blood for patients with alloantibodies
- Prevents some adverse transfusion reactions
- Provides reassurance to patients concerned about blood risks

Disadvantages

- Does not affect risk of bacterial contamination
- Does not affect risk of ABO incompatibility error
- More costly than allogeneic blood
- Results in wastage of blood not transfused
- Increased incidence of adverse reactions to autologous donation
- Subjects patient to perioperative anemia and increased likelihood of transfusion

Positioning for Anesthesia and Surgery

CHAPTER 21

◆ *Jennifer Lynn Thompson*

The act of positioning a patient for surgery is a group endeavor that requires teamwork, timing, communication, and knowledge of measures that protect against injury. The goal of patient positioning is to allow optimal surgical access while minimizing potential risk to the patient. Every surgical position carries some degree of risk that is magnified once an anesthetic is administered, which renders the patient unable to make necessary changes in positioning as needed. To prevent patient injury, clinicians must be knowledgeable about possible hazards associated with various surgical positions.

PHYSIOLOGIC EFFECTS OF SURGICAL POSITIONS

Anesthesia providers are intimately involved in coordinating and directing patient positioning and are also continually monitoring and assessing the subsequent changes in the patient's physiologic status. Numerous factors have an effect on these changes: the surgical position; the length of time; the padding and positioning devices used; the type of anesthesia given; and the operative procedure. These changes most frequently involve (1) the cardiovascular system, (2) the respiratory system, (3) the nervous system, and (4) other vulnerable areas such as the skin, eyes, breasts, and genitalia.

Cardiovascular System

Cardiac output and blood pressure are generally decreased under general anesthesia in response to central nervous system and myocardial depression and vasodilation induced by volatile anesthetics. As a result, blood pools in dependent body areas, reducing preload and decreasing stroke volume. Administration of neuromuscular blocking agents also contributes to decreased venous return because normal muscle tone is abolished. Additionally, opioids and volatile agents slow the heart rate, further decreasing cardiac output and blood pressure. In healthy patients, mean arterial pressure (MAP) is maintained by compensatory increases in heart rate and systemic vascular resistance (SVR), but elderly patients and those with preexisting diseases can be less adaptive. Compensatory mechanisms to increase heart rate when hypotension occurs are blunted by general anesthetics, rendering cardiac output and blood pressure more susceptible to gravitational forces.

Hemodynamic changes are usually minimal in the supine and lateral positions.[1,2] However, cardiac output and blood pressure are often decreased in the sitting, prone, and flexed lateral positions, where the lower extremities are dependent.[1,3] Although central venous pressure (CVP) is increased in the prone position, left ventricular volume is reduced, probably due to decreased venous return and increased intrathoracic pressure.[4] Cardiac index (CI) may be decreased[5,6] or unchanged[5] in the prone position compared with the supine; the effect may be frame dependent.[6] In the lateral decubitus position with the kidney rest elevated, hypotension is likely because the legs are dependent, venous return is reduced by extreme flexion, and the kidney rest may compress the great vessels.[1,3] Conversely, blood pressure may appear normal or higher in the lithotomy position, in which elevation of the legs above the trunk provides an autotransfusion of 100 to 250 mL per leg.

Mean arterial pressure increases or decreases by approximately 2 mmHg per inch for each change in height between the heart and a body region.[7] Therefore regions elevated above the heart in the head-up, sitting, and lithotomy positions may be at risk for hypoperfusion and ischemia, particularly if hypotension occurs. The decrease in hemodynamic parameters depends on the degree of elevation of the torso. Hemodynamic changes are minimal if the patient is placed in a 45-degree, head-up sitting position, but cardiac output decreases 20% if the patient is raised to 90 degrees, because venous blood pools in the extremities. When the patient is in the seated position, as compared with supine, CI, CVP, and pulmonary capillary wedge pressure (PCWP) decrease significantly and SVR increases.[8] In procedures in which the head is elevated and cerebral perfusion is a concern, invasive arterial blood pressure monitoring should be instituted, with the transducer placed at the level of the circle of Willis.[9]

Positioning devices and mechanical ventilation may contribute to decreased cardiac output and hypotension. In the lateral decubitus position, elevation of the kidney rest under the flank may cause vena cava compression. When the patient is in the lateral decubitus position, the kidney rest should lie under the dependent iliac crest.[1] Extreme flexion of the hips in some variations of the prone or lithotomy positions may occlude the femoral vessels and contribute to decreased venous return. Large tidal volumes and positive end-expiratory pressure (PEEP) may generate high intrathoracic pressures, with a subsequent reduction in atrial filling and cardiac output.

A variety of methods have been suggested for attenuating the hemodynamic changes associated with surgical positioning. Slow assumption of the surgical position allows the cardiovascular system time to compensate for position-induced hemodynamic alterations. Because hemodynamic changes may be influenced by anesthetic technique, using a nitrous-narcotic technique or a lighter level of anesthesia (less than 0.5 minimum alveolar concentration) or gradually attaining a deeper level of anesthesia may attenuate position-induced hypotension.[3] Intravascular volume loading before positioning can reduce or eliminate hypotension.[1,6] However, volume replacement must be done judiciously because excessive fluid administration can lead to volume overload in susceptible individuals when the patient is returned to the supine position, or when the vasodilatory effects of general anesthetics are terminated.[3]

The Trendelenburg position is often used to treat hypotension, because it is assumed to increase venous return and MAP. When placed in a head-down position, normotensive individuals compensate for increases in CVP and pulmonary artery pressure (PAP) with vasodilation and a decrease in heart rate from stimulation of baroreceptor reflexes. However, hypotensive individuals may

not respond in the same manner. Investigators have demonstrated variable effects of the Trendelenburg position on cardiovascular parameters. Changes in intrathoracic blood volume of 2% to 3% in unanesthetized normovolemic individuals are reported with the Trendelenburg position.[10] CVP, mean PAP, and pulmonary artery occlusion pressure can be increased in the head-down position, but this increase may not reflect changes in CI, stroke volume, or MAP.[10,11] Others have shown no increase in MAP, an increase in SVR, and a decrease in CI in hypotensive patients placed in Trendelenburg position.[12]

Hypovolemia can be unrecognized in the lithotomy and Trendelenburg positions, because MAP can appear normal despite volume deficit. Volume replacement can be assessed as adequate until acute hypotension occurs when the patient is returned to the horizontal position. An additive effect can occur if the Trendelenburg position is used to supplement the lithotomy position.

Patients with comorbidities may be susceptible to the detrimental effects of various positions. The combination of the lithotomy position and a head-down tilt can have a detrimental effect on myocardial function in patients with coronary artery disease, because CVP, PAP, and PCWP are increased, whereas cardiac output is decreased.[13] The Trendelenburg position may increase myocardial work by increasing central blood volume, cardiac output, and stroke volume. Individuals with very poor cardiac function can have decreased cardiac output if the increased central blood volume moves them to a worse position on the Frank-Starling curve. The lower extremities of individuals with peripheral vascular disease may be at risk of ischemia in the lithotomy and Trendelenburg positions because a relative state of hypoperfusion exists when the lower extremities are elevated above the heart.

The prone and Trendelenburg positions may increase venous pressure in the head, with resultant swelling of facial, pharyngeal, and orbital structures. Intracranial pressure can be elevated when the head is dependent, because venous pressures are transmitted to the head and intracranial structures through the valveless jugular system. Cerebral blood flow can be decreased when inflow is limited by venous congestion in intracranial structures. Postoperative visual loss (POVL) may result from an increase in ocular venous pressures and concomitant decrease in ocular perfusion pressure. Facial edema, macroglossia, and airway edema are reported following the prone and head-down positions.[14] A 10-degree head-up tilt may prevent the development of facial edema.

Respiratory System

During spontaneous respiration in awake patients, contraction of the diaphragm and intercostal muscles causes expansion of the thoracic cavity in both an anterior-posterior and lateral direction. Downward displacement of the diaphragm generates a negative intrathoracic pressure and allows lung expansion as gas flows inward. Lung elastance and chest-wall compliance affect the amount of pressure necessary to expand the alveoli for a given change in volume. Gravitational factors affect the distribution of ventilation and perfusion within the lung, as well as the shape of the thoracic cavity and movement of the diaphragm and abdominal contents.

Postural changes may significantly alter compliance, lung volumes, and the distribution of ventilation and pulmonary blood flow. Positioning devices may cause mechanical interference with movement of the belly wall and abdominal contents, the chest wall, or the diaphragm.[15] Therefore anesthetic-induced depression of ventilation may be worsened by the majority of surgical positions. Individuals with preexisting diseases that alter respiratory function may be more susceptible to the deleterious ventilatory effects of surgical positions.

Effective respiratory gas exchange depends on a balance of ventilation and perfusion throughout the lungs. Traditionally, gravitational effects on gas and blood flow are thought to result in differences in ventilation and perfusion in different lung segments. In both awake and anesthetized patients, gravitational forces are theorized to create a gradient that favors perfusion in dependent portions of the lungs and ventilation in nondependent regions.[16,17] However, new imaging techniques have identified a concentric pattern of blood flow in the lungs, with central regions receiving a greater proportion of flow than the periphery.[18,19] The mechanism for this gradient has not been identified, but the diameters and branching patterns of pulmonary vessels and the distance blood must flow to reach a site are possible factors. Nongravitational factors such as cardiac output, pleural pressures, and lung volumes are also thought to play a factor in regional lung perfusion.[16,19]

Positional changes may result in redistribution of ventilation and perfusion. These changes are less in the sitting position and more evident in the prone and lateral positions. In the prone position, changes in ventilation-perfusion ($\dot{V}/\dot{Q}$) ratios have been postulated as the cause of improved oxygenation.[16] More lung volume is present posteriorly than anteriorly, where anterior mediastinal structures occupy significant space; as a consequence, posterior lung segments are better ventilated. Ventilation is more uniform and $\dot{V}/\dot{Q}$ matching is better in the prone position than in the supine position.[17] In the lateral decubitus position, ventilation and perfusion are greater in the dependent lung than in the nondependent lung in awake, spontaneously breathing patients.[19]

$\dot{V}/\dot{Q}$ mismatching in the lateral decubitus position may affect oxygenation, especially with procedures requiring one-lung ventilation. Hypoxic pulmonary vasoconstriction in the unventilated lung further redistributes blood flow to the dependent lung to improve oxygenation.[19] Patients are susceptible to atelectasis in the lateral position, because closing volumes occur above functional residual capacity (FRC), with closing occurring earlier in the dependent than in the nondependent lung. Tidal volumes of 10 to 12 mL/kg and an F_{IO_2} of 0.5 or higher have been suggested to compensate for $\dot{V}/\dot{Q}$ mismatch in the lateral position; however, excessive tidal volumes can cause barotrauma, decrease hypoxic vasoconstriction, and reduce oxygenation in patients in the lateral position. Tidal volumes of 5 to 7 mL/kg and higher respiratory rates cause smaller declines in oxygenation. Although the application of PEEP to the dependent lung is sometimes used in an attempt to recruit collapsed alveoli and increase compliance, controversy exists regarding its effectiveness in improving patient oxygenation. The administration of oxygen at 2 to 4 L/min to the nonventilated lung may improve hypoxia. Application of 5 to 10 cm H_2O of continuous positive airway pressure (CPAP) to the nondependent lung can significantly improve oxygenation during one-lung ventilation, but the re-expansion of lung tissue may impede surgical access.[19]

Changes in the elastance and resistance of the diaphragm and abdomen occur when shifting between positions. These changes have little effect on movement of the chest wall in healthy individuals but may have an effect in persons with conditions that predispose to abnormalities of lung function.[20] In the prone position, diaphragmatic excursion can be limited by the abdominal viscera if the abdomen is compressed by the weight of the body or positioning devices. If the abdomen hangs free, gravity allows the abdominal contents to shift, reducing interference with diaphragmatic movement.[21,22] In the anesthetized patient in the lateral position, abdominal contents shift cephalad, moving the

hemidiaphragm of the dependent lung upward, thereby decreasing ventilation in the dependent lung and reducing its compliance. In the nondependent lung of the anesthetized patient, ventilation is greater and compliance increased due to the caudal shift of the upper hemidiaphragm allowing unrestricted lung excursion (see Chapter 27). The lithotomy position has little effect on the compliance of the respiratory system in healthy, conscious volunteers.[15] However, extreme flexion of the thighs in the exaggerated lithotomy position compresses the abdomen, shifts the abdominal viscera cephalad, and limits diaphragmatic movement. As a result, compliance and tidal volume are reduced, and airway pressures and dead space–to–tidal volume ratios are increased.[23] This effect may be amplified in obese individuals.

Lung capacities are decreased with most position changes. In the supine position, FRC and total lung capacity are significantly decreased compared with the sitting position due to the cephalad shift of the diaphragm caused by pressure of the abdominal viscera.[15,20] Some investigators have found an increase in FRC with patients in the prone position, when the abdomen hangs free.[16,24] Theories pose that better matching of ventilation and perfusion, rather than changes in lung volumes or capacities, cause improvements in oxygenation in the prone position.[15]

In the awake patient in the lateral position, ventilation favors the dependent lung during spontaneous respiration. With the addition of anesthesia, positive pressure ventilation, and paralysis, the upper lung becomes easier to ventilate. Displacement of the relaxed diaphragm by abdominal viscera and the downward gravity force of the mediastinum result in decreased compliance of the lower lung.[19-21]

Ventilatory changes associated with the lithotomy position are dependent on the extent to which the legs are flexed on the abdomen and the concomitant use of the head-down position. In the normal lithotomy position without Trendelenburg, changes in FRC are similar to those associated with the supine position, and the diaphragm does not shift farther cephalad.[23] However, adding Trendelenburg position to lithotomy can cause an additional decrease in FRC.

The sitting position is more favorable for ventilation and has less effect on lung volumes than other positions. The more the torso is elevated, the smaller the effect on lung mechanics. Forced vital capacity and FRC are within normal parameters in the seated position.[21] The abdominal contents shift caudally and anteriorly, causing less interference with diaphragmatic movement and allowing greater expansion of dependent lung regions.[15] Compared with the supine position, in which the abdominal muscles are used for breathing, in the sitting position, the rib cage contributes more to ventilation.[21] However, respiratory benefits of the sitting position are attenuated when the sitting position is modified to minimize cardiovascular effects. Flexion of the lower extremities at the hip and elevation of the legs causes abdominal contents to shift cephalad against the diaphragm. The sitting position then more closely resembles the supine position, limiting diaphragmatic excursion and decreasing FRC and closing volumes.[9]

The Trendelenburg position exacerbates the deleterious ventilatory effects of the various positions. The diaphragm is displaced cephalad, and its excursion is limited by shifting of the abdominal contents, decreasing the FRC progressively as the degree of Trendelenburg position increases. Movement of the mediastinum toward the head may result in the endotracheal tube migrating into the right mainstem bronchus.[25,26] This complication may also occur upon establishment of the pneumoperitoneum, in which the diaphragm is displaced in a cephalad direction by pressurized gas.[26,27]

PATHOPHYSIOLOGY OF NERVE INJURY

Transection, compression, stretch, and kinking are the primary mechanisms responsible for nerve injuries.[28,29] Nerves may be transected by surgical maneuvers or by trauma. Compression can happen when a nerve is forced against a bony prominence or a hard surface such as an armboard or operating table. In the lateral position, for example, the weight of the superior leg pushes against the dependent extremity and may compress the common peroneal nerve of the dependent leg against the operating table. Stretch or traction injuries occur where nerves such as the sciatic nerve or brachial plexus have a long course across many structures. Peripheral nerves have some laxity that allows a limited amount of elongation. However, excessive elongation or stretch may cause conduction changes, axonal disruption, or interruption of the nerve's vascular supply.[30-32] Kinking injuries happen when a peripheral nerve is pinched between two immovable structures. For example, the femoral nerve can be kinked under the inguinal ligament when the thighs are flexed on the abdomen, as in the exaggerated lithotomy position.

A common component of all peripheral nerve injuries is ischemia. Intraneural blood flow may be compromised by stretch, compression, or disruption of the nerve tissue itself.[33] Other causes include occlusion of major vessels, emboli, tissue edema, or inhibition of perfusion at the capillary level. For example, pressure applied over a body surface may limit venous capillary outflow, causing a rise in venous capillary pressure and a decrease in the hydrostatic pressure gradient between interstitial tissues and the capillary.[34] Ultimately, tissue edema occurs as fluid is sequestered in the cells and interstitial space. As venous capillary pressure rises, the arterial-venous pressure gradient is reduced, decreasing flow to tissues along the capillary. As venous and tissue pressures continue to rise, arterial inflow is eventually obstructed and ischemia results. Low mean arterial blood pressure may augment the development of ischemic conditions.[31]

Tissue metabolism continues even in the absence of blood flow. When ischemia ensues, adenosine triphosphate (ATP) production is decreased, causing failure of the transmembrane sodium-potassium pump and accumulation of sodium within the cell. The resulting osmotic pressure gradient favors the movement of water into the cells. Intracellular volume is increased, and tissue edema occurs.[35] A vicious cycle of ischemia results as tissue pressures increase, preventing the movement of fluid and nutrients from the capillaries into the cells.

The susceptibility of peripheral nerves to ischemia may be partially due to their anatomic structure (Figure 21-1). Peripheral

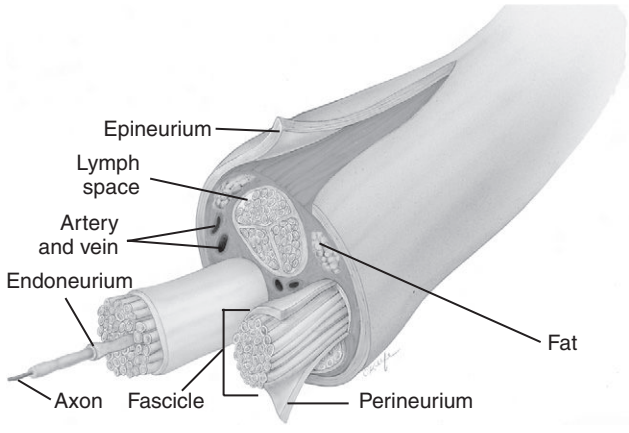

FIGURE 21-1 Cross section of a peripheral nerve trunk showing its components. (From Patton KT, Thibodeau GA. *Anatomy & Physiology*. 8th ed. St Louis: Mosby; 2013:392.)

nerves are composed of bundles of nerve fibers (fascicles) and their vascular supply is encased in protective connective-tissue coverings. Each nerve fiber is composed of one or more axons sheathed by Schwann cells (neurolemma) that are either myelinated or unmyelinated. The axons and neurolemma are covered by a loose connective tissue called the *endoneurium*. The *perineurium* is a tough connective tissue that binds the fascicles into identifiable structures. The *epineurium* consists of two layers: an inner epineurium that supports the fascicles and an outer epineurium that covers the external surface of the nerve.[31,36] The quantity of these protective tissues varies between nerves and even along the same nerve. The entire nerve trunk is covered by a loose layer of connective tissue that allows it to slide across joints and other tissues.[31]

Peripheral nerves have an extensive microvascular supply. Blood vessels in the epineurium run parallel to the nerve and form numerous anastomoses with the perineurium. Collateral connections between the perineurium and the endoneurial capillaries run obliquely between the layers and thus may be more susceptible to compression by increases in tissue pressure. In addition, the endoneurial space lacks lymphatic vessels, so edema and fluid accumulation in this region may obstruct the microcirculation.[31]

FACTORS CONTRIBUTING TO NERVE INJURIES

Postoperative peripheral nerve injuries are frequently attributed to incorrect surgical positioning; however, current evidence indicates that multiple factors are involved in postoperative peripheral neuropathies.[37,38] Perioperative factors that contribute to the development of nerve injuries include ancillary positioning devices, prolonged surgical procedures, and anesthetic technique. Patient-related factors include gender, age, body habitus, and preexisting medical conditions. However, the precise mechanism of nerve injury is often unclear, suggesting that further investigation is needed to identify causative factors.[37,39]

Positioning Devices

Controlled studies of complications related to specific positioning devices are largely nonexistent. Isolated case reports provide much of the evidence that is known about nerve injuries attributable to improper use of positioning devices. Ancillary positioning devices, such as straps used to restrain the patient or an extremity, may cause pressure and temporary injury if excessively tightened. For example, the lateral femoral cutaneous nerve in the thigh is susceptible to injury by tight table straps or the leg-holding device used for knee arthroscopy.[40] Common peroneal nerve injury has been attributed to the use of candy cane stirrups. Brachial plexus injury has been caused by a damaged armboard falling off the operating room (OR) table[41] or the use of shoulder braces with steep Trendelenburg position.[37] Compression injury of the radial nerve has been reported after the intraoperative use of tourniquets and blood pressure cuffs and by compression between the humerus and a firm surface, such as a positioning device.[42,43] Improper placement of an axillary roll may cause compartment syndrome and compression of neural and vascular structures.[44]

Length of Procedure

Prolonged surgical procedures contribute to postoperative positioning complications. Postoperative visual loss, nerve injuries, and compartment syndrome have been associated with a variety of procedures and positions in which the common denominator was a duration of more than 4 hours.[45-48] Rhabdomyolysis and acute renal failure also have been reported after lengthy procedures.[49,50] One possible explanation is that during long procedures, the weight of the body causes external compression of dependent tissues and states of low perfusion.[50] The longer this situation persists, the higher the potential for development of edema and ischemic injury.

Anesthetic Techniques

Anesthetic techniques may contribute to the development of position-related injuries.[51] Patients receiving general anesthesia cannot move in response to painful stimuli generated by uncomfortable body positions. The constraints of the procedure or surgeon may limit movement even when patients are sedated. Muscle relaxation due to neuromuscular blocking drugs or volatile anesthetics may contribute to stretch injuries by allowing increased mobility of joints.[30] For example, limited elbow extension from tight biceps muscles can be overcome by neuromuscular blockade, allowing the arms to be extended flat and subsequently stretching the median nerve.[31] The hypotensive effects of general anesthetics may lower perfusion pressures below acceptable levels in patients who are hypertensive or have other comorbidities. The use of hypotensive techniques to reduce blood loss should be balanced against the risk of possible complications resulting from decreased perfusion pressures, particularly during prolonged procedures and in the sitting, lithotomy, and Trendelenburg positions, in which gravity affects blood flow.

Although neuraxial and peripheral nerve blocks are associated with both permanent and temporary nerve injuries, the majority of injuries are not related to positioning but to block technique, hematoma formation, and needle trauma.[52] However, recognition of compartment syndrome may be delayed when providers attribute the patient's symptoms to the residual effects of regional blocks and local anesthetics.[53,54] Anesthetists must have a high index of suspicion when return of function is delayed beyond what is expected for a particular technique or local anesthetic and when patients complain of severe pain in the presence of a seemingly adequate block.

PATIENT-RELATED FACTORS CONTRIBUTING TO NERVE INJURIES

Body Habitus

Extremes of body habitus are correlated with an increased incidence of positioning complications.[47,49,50] Individuals who are underweight may develop decubiti or nerve damage due to lack of adequate adipose tissue over bony prominences.[47,55] For example, thin patients may be at higher risk for sciatic nerve damage when the opposite buttock is elevated,[28] and thinner women (body mass index [BMI] less than 22) are more likely to develop ulnar neuropathy.[52,55] Individuals with a muscular physique may also be at increased risk for compartment syndrome and ulnar nerve injury.

Obesity increases morbidity from positioning because large tissue masses place increased pressure on dependent body parts. Extreme abduction of the arms may cause stretch injuries to the lower roots of the brachial plexus, whereas the upper roots may be damaged by excessive rotation of the head to the opposite side. Ulnar neuropathy has been associated with an increased BMI.[56] Adipose tissue is poorly perfused and may contribute to this problem. For example, in the lateral position, a heavy superior extremity may interfere with perfusion by exerting substantial pressure on the inferior extremity.

Preexisting Conditions

Preexisting conditions appear to be associated with an increased risk of developing postoperative position-related injuries. Hypertension, diabetes mellitus, peripheral vascular disease, peripheral

BOX 21-1

Factors Associated with Position-Related Injuries

Positioning Devices
- Table straps
- Leg holders and stirrups
- Axillary roll
- Bolsters
- Fracture table post
- Shoulder braces

Preexisting Pathophysiology
- Anemia
- Diabetes mellitus
- Peripheral vascular disease
- Liver disease
- Peripheral neuropathies
- Alcoholism
- Limited joint mobility
- Smoking

Anesthetic Technique
- General anesthesia
- Hypotensive techniques
- Neuromuscular blockade

neuropathies, and alcoholism can exacerbate the physiologic effects of various positions. Nerve injury and preexisting neuropathies are more common in patients with diabetes,[28] and diabetes is the most common metabolic cause of spontaneous isolated femoral neuropathy.[57] A history of smoking within 1 month of the surgical procedure has been identified as a risk factor for nerve injury, as well as for delayed healing.[47,58] Individuals with subclinical ulnar nerve entrapment, which may not be apparent to the patient or anesthetist, are also at risk for nerve injuries.[59,60]

Box 21-1 highlights factors associated with position-related injuries.

PERIOPERATIVE NEUROPATHIES

In the awake patient, pain or discomfort from extreme body positioning would prompt optimization of position for the relief of symptoms. The induction of anesthesia renders a patient unable to make these changes and therefore susceptible to injury. The addition of muscle relaxants may allow body or extremity positioning that the awake patient would not otherwise tolerate, making the patient even more vulnerable to injury.[33] Table 21-1 and Box 21-2 identify specific nerve injuries associated with positioning and recommendations for prevention.

Ulnar Neuropathy

Ulnar neuropathy is one of the most frequently reported injuries after surgery and anesthesia, with a reported incidence ranging from 0.04% to 0.5%.[29,59,61] Ulnar neuropathy is a well-known complication of cardiac surgery, with a prevalence as high as 38%.[62] The American Society of Anesthesiologists (ASA) and American Association of Nurse Anesthetists Foundation (AANA-F) closed-claims studies found that the ulnar nerve was the first (28%) and second (16%) most commonly injured nerve.[61,63,64]

The ulnar nerve traverses the length of the upper extremity from its origins as a branch of the medial cord of the brachial plexus to its terminal branches in the hand. In the upper arm, the ulnar nerve passes along the anterior aspect of the medial head of the triceps muscle and posterior into the groove between the medial epicondyle of the humerus and the olecranon (Figure 21-2). In this region, the nerve is sheathed in the cubital tunnel before exiting and passing between the two heads of the flexor carpi ulnaris.

TABLE 21-1 Potential Position-Related Injuries

Body System or Anatomic Location	Potential Injury
Head, eyes, ears, nose, and throat	Postoperative vision loss Corneal abrasion Facial edema Vocal cord edema
Cardiovascular	Vascular occlusion Deep vein thrombosis Ischemic injuries
Respiratory	Atelectasis Endobronchial intubation
Neurologic	Peripheral neuropathy Quadriplegia Decreased cerebral blood flow Increased intracranial pressure
Genitourinary	Myoglobinuria Acute renal failure
Musculoskeletal	Amputation Backache Compartment syndrome Rhabdomyolysis
Integumentary	Abrasion Alopecia Decubiti

The cubital tunnel retinaculum (CTR) forms the roof of the cubital tunnel (see Figure 21-2), a potential area for nerve compression because fibrous tissue and the elbow capsule form a semirigid canal that changes shape with flexion and extension of the forearm.[47] When the elbow is flexed, the distance between the olecranon and medial epicondyle increases, stretching the CTR, decreasing the size of the tunnel, and increasing pressure on the nerve.[29]

Surgical positioning, age, preexisting diseases, and mechanical factors such as tourniquets and blood pressure cuffs have all been proposed as contributing to ulnar nerve injuries. However, ulnar neuropathy is more frequently associated with male gender,[33,55,59] the presence of a preexisting asymptomatic neuropathy,[59] prolonged hospital stays,[33,59] and extremes of body habitus.[33,52] Median sternotomy and sternal retraction are also proposed as a cause of ulnar nerve injury after cardiac surgery.[65] The incidence of ulnar neuropathy is higher in men—particularly those older than age 50—than in women.[37,55,61,66] Gender-related anatomic variations, such as a larger coronoid process and less subcutaneous tissue over the ulnar region are hypothesized to explain this difference.[55]

Although often blamed on intraoperative positioning, the prevalence of ulnar neuropathy is similar in medical and surgical patients, and prolonged hospital stays are significantly related to the development of ulnar neuropathy. Bedrest is suspected as contributing to ulnar neuropathy, because the initial presentation is often delayed 24 or more hours.[61,67] In addition, clasping the hands on the abdomen causes supination of the hands and rotation of the humerus, allowing the ulnar nerve in the postcondylar groove to be compressed against the bed.[67]

Recommendations for positioning to prevent ulnar nerve injury in anesthetized patients include the use of padding, placing the arms in a supinated position, and abducting the arms less than 90 degrees if armboards are used.[68,69] If the arms are secured on armboards, the forearm should be supinated (palm up), because pronation (palm down) increases pressure over the ulnar nerve.[70] When the patient's arms are tucked at the side of the body, they should be

BOX **21-2**

An Updated Report by the American Society of Anesthesiologists Task Force on Prevention of Perioperative Peripheral Neuropathies

I. Preoperative History and Physical Assessment

- When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position.
- Body habitus, preexisting neurologic symptoms, diabetes mellitus, peripheral vascular disease, alcohol dependency, arthritis, and gender (e.g., male gender and its association with ulnar neuropathy) are important elements of a preoperative history.

II. Positioning Strategies for the Upper Extremities

Arm abduction in supine patients should be limited to 90 degrees. Patients who are positioned prone may comfortably tolerate arm abduction greater than 90 degrees.

- *Supine patient with arm on an armboard:* The upper extremity should be positioned to decrease pressure on the postcondylar groove of the humerus (ulnar groove). Either supination or the neutral forearm position facilitates this action.
- *Supine patient with arms tucked at side:* The forearm should be in a neutral position. Flexion of the elbow may increase the risk of ulnar neuropathy, but there is no consensus on an acceptable degree of flexion during the perioperative period. Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided. Extension of the elbow beyond the range that is comfortable during the preoperative assessment may stretch the median nerve. Periodic perioperative assessments may ensure maintenance of the desired position.

III. Specific Positioning Strategies for the Lower Extremities

- *Stretching of the hamstring muscle group:* Positions that stretch the hamstring muscle group beyond the range that is comfortable during the preoperative assessment may stretch the sciatic nerve.
- *Limiting hip flexion:* Since the sciatic nerve or its branches cross both the hip and the knee joints, extension and flexion of these joints, respectively, should be considered when determining the degree of hip flexion. Neither extension nor flexion of the hip increases the risk of femoral neuropathy. Prolonged pressure on the peroneal nerve at the fibular head should be avoided.

IV. Protective Padding

- *Padded armboards:* Padded armboards may decrease the risk of upper extremity neuropathy.
- *Chest rolls:* The use of chest rolls in the laterally positioned patient may decrease the risk of upper extremity neuropathy.
- *Padding at the elbow:* Padding at the elbow may decrease the risk of upper extremity neuropathy.
- *Padding to protect the peroneal (fibular) nerve:* The use of specific padding to prevent pressure of a hard surface against the peroneal nerve at the fibular head may decrease the risk of peroneal neuropathy.
- *Complications from the use of padding:* The inappropriate use of padding (e.g., padding too tight) may increase the risk of perioperative neuropathy.

V. Equipment

The use of properly functioning automated blood pressure cuffs on the arm (i.e., placed above the antecubital fossa) does not change the risk of upper extremity neuropathy. The use of shoulder braces in a steep head-down position may increase the risk of perioperative neuropathies.

VI. Postoperative Assessment

A simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies.

VII. Documentation

Documentation of specific perioperative positioning actions may be useful for continuous improvement processes, and may result in improvements by helping practitioners focus attention on relevant aspects of patient positioning, and providing information on positioning strategies that eventually leads to improvements in patient care.

From Practice Advisory for the Prevention of Perioperative Peripheral Neuropathies: an updated report by the American Society of Anesthesiologists Task Force on prevention of perioperative peripheral neuropathies. *Anesthesiology.* 2011;114(4):741-754.

in a neutral position with the palms facing inward (Figure 21-3). Anatomic changes in the cubital tunnel with flexion and extension suggest that excessive flexion of the elbow should be avoided when the patient is in the lateral position or if the arms are secured across the chest. Evidence supports the conclusion that ulnar nerve palsy is not always a preventable complication despite the best efforts at careful positioning and padding.[68-70]

BRACHIAL PLEXUS INJURIES

The brachial plexus is vulnerable to injuries in almost every surgical position, particularly if the arms are abducted or the head is rotated (Figure 21-4). When the patient is supine, abduction of the arms greater than 90 degrees stretches the plexus around the humeral head. Turning the head to the side with the arms abducted can cause stretching and compression of the contralateral brachial plexus beneath the clavicle.[71] Even tucking the arms next to the body is not without risk if the head is turned laterally and the shoulders are depressed. When the patient is prone, inadequate support of the shoulders allows them to sag anteriorly, causing traction on the plexus. Also in the prone position, extending the arms over the head may compress the plexus between the clavicle and first rib.

In the lateral decubitus position, brachial plexus injury is most commonly the result of excessive stretching, usually because of arm abduction greater than 90 degrees, external rotation, extension and lateral flexion of the head, and posterior shoulder displacement.[28] In the lateral position, the weight of the chest can compress the lower shoulder and axilla putting pressure on the axillary neurovascular bundle. An "axillary roll" can be placed just caudal to the dependent axilla to relieve this pressure. If the nondependent arm is suspended on an arm holder or with traction, abduction of 45 to 60 degrees should be maintained and less than 10 pounds of traction applied.[72]

Brachial plexus injuries are also associated with positioning devices. Injuries have been caused by a damaged armboard falling off the OR table, causing excessive stretch of the plexus. Sometimes used during steep Trendelenburg position, shoulder braces placed too close to the base of the neck or along the midpoint of the clavicle can compress neurovascular structures and cause brachial plexus neuropathy. If used, shoulder braces are properly placed at the distal end of the clavicle.[41,73]

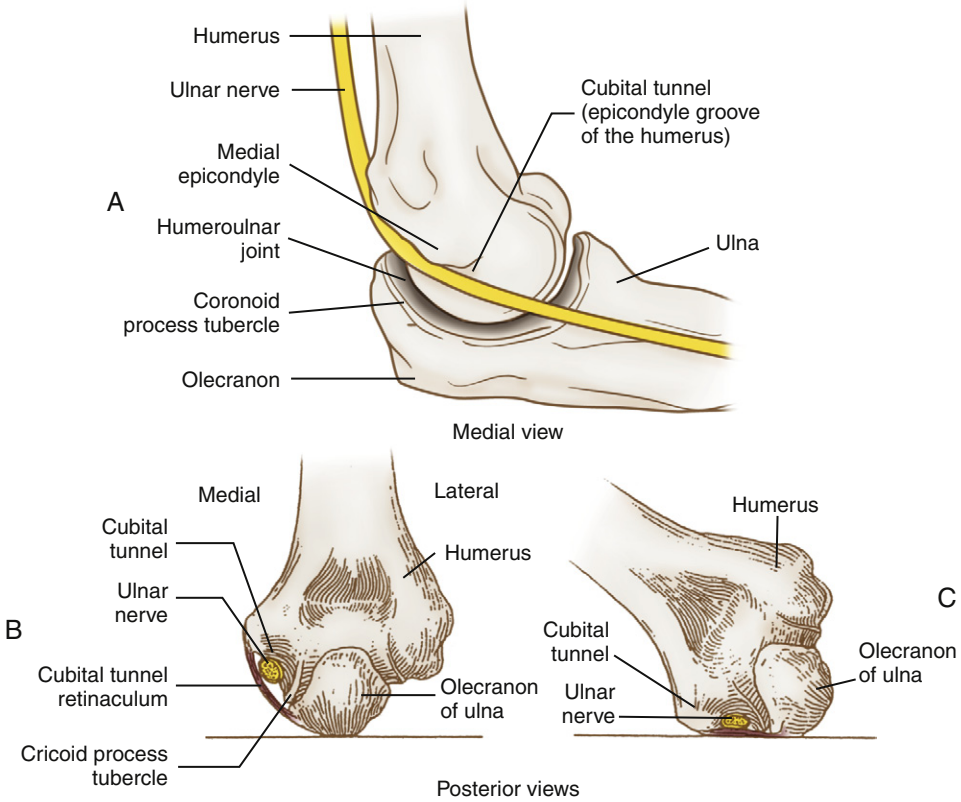

FIGURE **21-2** The ulnar nerve at the cubital tunnel. **A,** Medial view. **B,** Posterior view. Note cubital tunnel retinaculum over the ulnar nerve in the cubital tunnel. **C,** Posterior view with elbow tilted on medial side. Note the ulnar nerve compressed. (From Rothrock JC. *Alexander's Care of the Patient in Surgery*. 14th ed. St. Louis: Mosby; 2011:152.)

Spreading of the sternal retractor during cardiac surgery causes the clavicle to move posteriorly and the first rib to rotate upward, pinching the plexus between the two.[65] Dissection of the internal mammary artery requires wider, asymmetric chest retraction to allow adequate visualization and may predispose to brachial plexus neuropathy.[65,74] To prevent brachial plexus injury during cardiac surgical procedures, caudad placement of the sternal retractor and avoidance of excessive and prolonged asymmetric chest wall retraction are recommended.[65]

SPINAL CORD INJURY

Cheney et al.[37] compared claims documented since 1990 to the outcome claims in the pre-1990 ASA closed-claims database and found that spinal cord injury claims had surpassed ulnar nerve injury claims. However, spinal cord injury claims were primarily associated with neuraxial blocks in anticoagulated patients and with blocks for acute and chronic pain management. Although rare, hemiparesis and quadriplegia are associated with surgical procedures performed in the sitting and prone positions.[75-77] Mid-cervical flexion myelopathy with temporary or permanent quadriplegia may occur when the head is flexed on the neck in the sitting or prone positions. When the head is flexed, the spinal cord moves anteriorly and may be compressed against the posterior vertebral body. Ischemia may result from a combination of compression and stretch, because the spinal cord lengthens with flexion. Like a rubber band, the cord becomes thinner as it stretches, and the caliber of the vessels supplying the cord can be reduced.[77] Increased vertebral venous pressure is also proposed as leading to postoperative spinal cord injury. The absence of valves between the central venous and epidural venous systems allows direct transmission of increased abdominal or intrathoracic pressure to the vertebral venous systems.[78] Congestion in the veins draining the spinal cord, coupled with hypotension, may result in decreased spinal cord perfusion and the onset of new neurologic deficits.[77]

Somatosensory evoked potentials (SSEPs) have been suggested as being useful in identifying position-related changes in spinal cord function.[79] However, neurologic defects have emerged postoperatively despite normal intraoperative SSEP readings.[80-82] A study by Schwarts et al.[80] evaluated the role of transcranial electric motor-evoked potential (tceMEP) and its recommended use for the detection of not only spinal cord injury but also brachial plexus and ulnar nerve injury due to positioning. Hyperflexion of the head on the neck in any position may be avoided by allowing a minimum of two fingerbreadths between the sternum and mandible.[82]

POSTOPERATIVE VISUAL LOSS

Postoperative visual loss (POVL) is a rare but devastating complication of nonophthalmic surgery. It may occur in one or both eyes and refers to a variety of visual defects ranging from decreased visual acuity to total blindness.[83] Visual loss after nonophthalmic surgery is generally attributable to five causes: ischemic optic neuropathy (ION), central retinal artery occlusion (CRAO), central retinal vein occlusion, cortical blindness, and glycine toxicity.[84] In the ASA POVL registry, ION and CRAO accounted for 81% of all cases, with ION accounting for 89% of POVL after prone spinal procedures.[85]

As the name implies, ION is the result of ischemia in a portion of the optic nerve. The optic nerves may be susceptible to hypoperfusion. The central retinal and posterior ciliary arteries are end-arteries

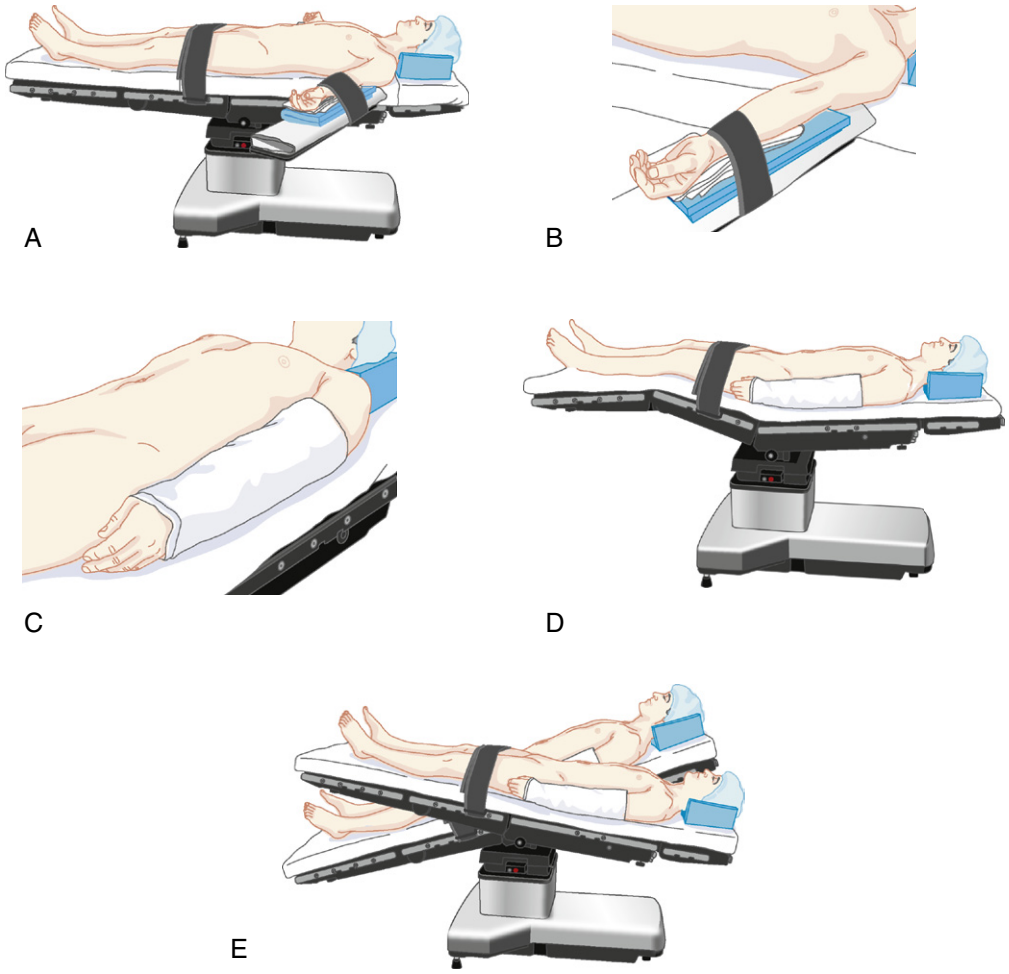

FIGURE **21-3** **A,** Supine. Note the asymmetry of the base of the table, placing the patient's center of gravity over the base if positioned in the usual direction. **B,** Arm position on the armboard. Abduction of the arm should be limited to less than 90 degrees whenever possible. The arm is supinated, and the elbow is padded. **C,** Arm tucked at patient's side. Arm in neutral position with palm to hip. The elbow is padded, and one needs to ensure that the arm is supported. **D,** Lawn-chair position. Flexion of the hips and knees decreases tension on the back. **E,** Trendelenburg position (head tilted down) and reverse Trendelenburg position (head tilted up). Shoulder braces should be avoided to prevent brachial plexus compression injuries. (From Miller RD, Pardo Jr MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Saunders; 2011:302.)

and lack anastomoses with other arteries[86] (Figure 21-5). Thus the structures supplied by these vessels are in a "watershed" region, meaning that the region receives a dual blood supply from the most distal branches of two arteries. Watershed areas are reportedly vulnerable to ischemia if a portion of the blood supply is interrupted.[83,87] Although the ocular circulation lacks autonomic innervation, autoregulation does still occur in the ophthalmic and central retinal arteries.[86] The limits of autoregulation in the ocular circulation are unknown. Preexisting diseases such as diabetes and hypertension that disrupt autoregulatory mechanisms may contribute to ischemic episodes during periods of hypotension.[88]

A variety of patient factors are associated with postoperative ION, including male gender and the presence of coexisting diseases such as hypertension, vascular disease, obesity, and diabetes.[88] Intraoperative factors related to ION include spinal surgery, the prone position, prolonged surgical procedures, large blood loss, low hematocrit, and systolic blood pressure less than 100 mmHg.[88-90] However, ION has occurred in both healthy patients and in the absence of these intraoperative factors.[90,91]

The most common causes of ION are decreased perfusion and increased intraocular pressure.[83] Just as cerebral perfusion pressure equals mean arterial pressure (MAP) minus intracranial pressure, ocular perfusion pressure (OPP) is the difference between MAP and intraocular pressure (IOP).[92,93] Intraoperative and anesthetic events that decrease MAP and thus reduce OPP include general anesthetics, hypotension, hemorrhage, and hypovolemia. Venous pressure and the ratio of aqueous humor production to absorption affect IOP. An increase in venous pressure may impede aqueous humor outflow into the venous system, causing a rise in IOP.[93] As IOP approaches MAP, OPP will decrease. During surgery, ocular venous pressure can be increased by a head-down tilt, increased abdominal and right atrial pressure, and obstruction of jugular venous return.[87] Both steep Trendelenburg position and beds such as the Wilson frame, where the head is positioned much lower than the heart, may exacerbate venous congestion and increase IOP. Unlike CRAO, ION does not seem to be associated with pressure on the globe, because ION has occurred in patients whose heads were secured with pin-type headrests.[85]

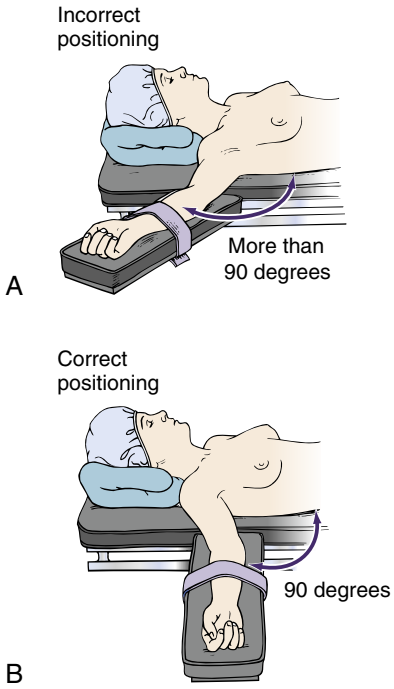

FIGURE **21-4** Position of arm on armboard should not exceed 90 degrees because otherwise injury to the brachial plexus may result. **A,** Incorrect positioning. **B,** Correct positioning. (From Phillips N. *Berry & Kohn's Operating Room Technique*. 12th ed. St. Louis: Mosby; 2013:499.)

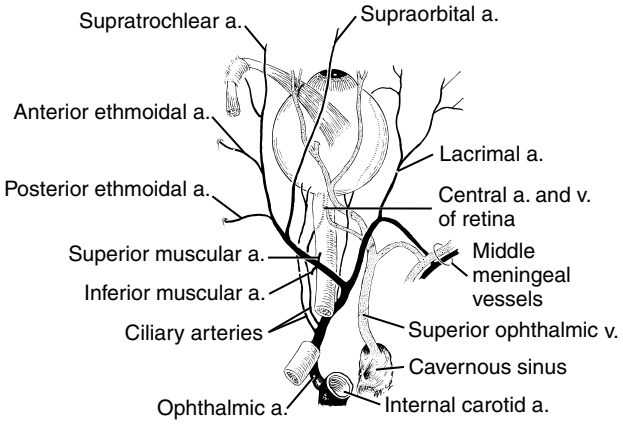

FIGURE **21-5** Superior view of the orbital arteries and veins. *a*, Artery; *v*, vein.

CRAO is a less common cause of POVL than ION. In 93 cases of POVL following prone spinal surgery, only 10 cases were attributed to CRAO.[85] The central retinal artery is one of the first branches of the internal carotid artery and nourishes the internal layer of the retina. Emboli from the ipsilateral carotid can migrate to the central retinal artery and cause unilateral blindness. Perioperative factors associated with CRAO are cardiopulmonary bypass, hypotension, and increased extraocular pressure. Some recovery of vision is possible if blood flow is restored within 4 hours. Although many treatments are recommended for CRAO, few have proven efficacy.[93]

General risk factors for central retinal vein obstruction syndrome include hypertension, cardiovascular disease, increased body mass index, open angle glaucoma, and sickle cell anemia. Because external pressure on the globe may cause central retinal vein obstruction, when the patient is placed prone for procedures on the head and neck, some suggest the use of three-pin headrests that securely immobilize the head rather than the horseshoe headrest.[84] Although the three-pin headrest avoids the potential for external ocular compression, POVL from ION has occurred despite its use.[85] Visual changes caused by central retinal vein obstruction can be subtle or marked, but in either situation, the prognosis for recovery of vision is poor.[84] No definitive treatment is available for central retinal vein obstruction.

Cortical blindness is the result of ischemia or trauma and a subsequent infarction of the visual pathways in the parietal or occipital lobes. Operative causes of cortical blindness include air and particulate emboli, cardiopulmonary bypass, and hypoperfusion resulting from hemorrhage or hypotension. No specific treatment is available for cortical blindness. Vision may improve over time.[84]

Glycine toxicity is a rare syndrome that occurs in patients with a deficiency of L-arginine, the enzyme needed to metabolize ammonia. Ammonia is a by-product of the metabolism of glycine, a nonessential amino acid, to glycolytic acid and ammonia. Temporary vision loss occurs in these patients as a consequence of high blood ammonia levels. Vision returns to normal as blood ammonia levels decrease.[94,95]

Much remains to be learned about POVL. Although factors such as hypertension, vascular disease, obesity, and smoking have been associated with POVL, specific methods for identifying at-risk patients are not available, and reasons that POVL occurs in patients without obvious risk factors are unknown. Patients at high risk of developing POVL include those undergoing lengthy procedures in the prone or steep Trendelenburg position, especially if surgery is accompanied by significant blood loss. During the preoperative interview, high-risk patients should be informed of the risk of POVL. Recently, research has been done regarding the use of intraoperative IOP monitoring, but presently there are no intraoperative monitoring methods that might detect the onset of POVL. Although periodic intraoperative monitoring of hemoglobin or hematocrit is suggested, safe lower limits for hematocrit are unknown. Deliberate hypotensive techniques to prevent blood loss during spine surgery should be avoided in individuals with chronic hypertension or other factors that place them at risk for POVL. Avoidance of direct pressure over the eye is recommended to avoid CRAO. The prone patient's head should be placed in a neutral position (avoid excessive flexion) and level with or slightly elevated above the heart (10-degree head-up tilt) when possible[96] (Figure 21-6). This prone position with the horseshoe adapter is the least preferred head support technique because of pressure on the eye and POVL (Figure 21-6, C and *D*). It should only be used for short procedures. The foam head pillows with cutouts are preferred (Figure 21-6, A). A complete discussion of POVL associated with prone positioning for orthopedic procedures can be found in Chapter 40.

OTHER POSITION-RELATED INJURIES

Position-related injuries range from minor skin abrasions and backache to events with serious morbidity (Table 21-2). Complications of these injuries can lead to tissue necrosis, infection, renal failure, paralysis, loss of limbs, and even loss of life. Although most individuals recover from minor position-related injuries without sequelae, more serious injuries may prolong a patient's hospital stay and recovery, cause psychological trauma, and perhaps even result in permanent disability. Anesthetists must not minimize the physical, psychological, social, and financial impact of transient injuries that resolve over hours, days, or months. Permanent, disabling injuries are even more devastating to patients and providers.

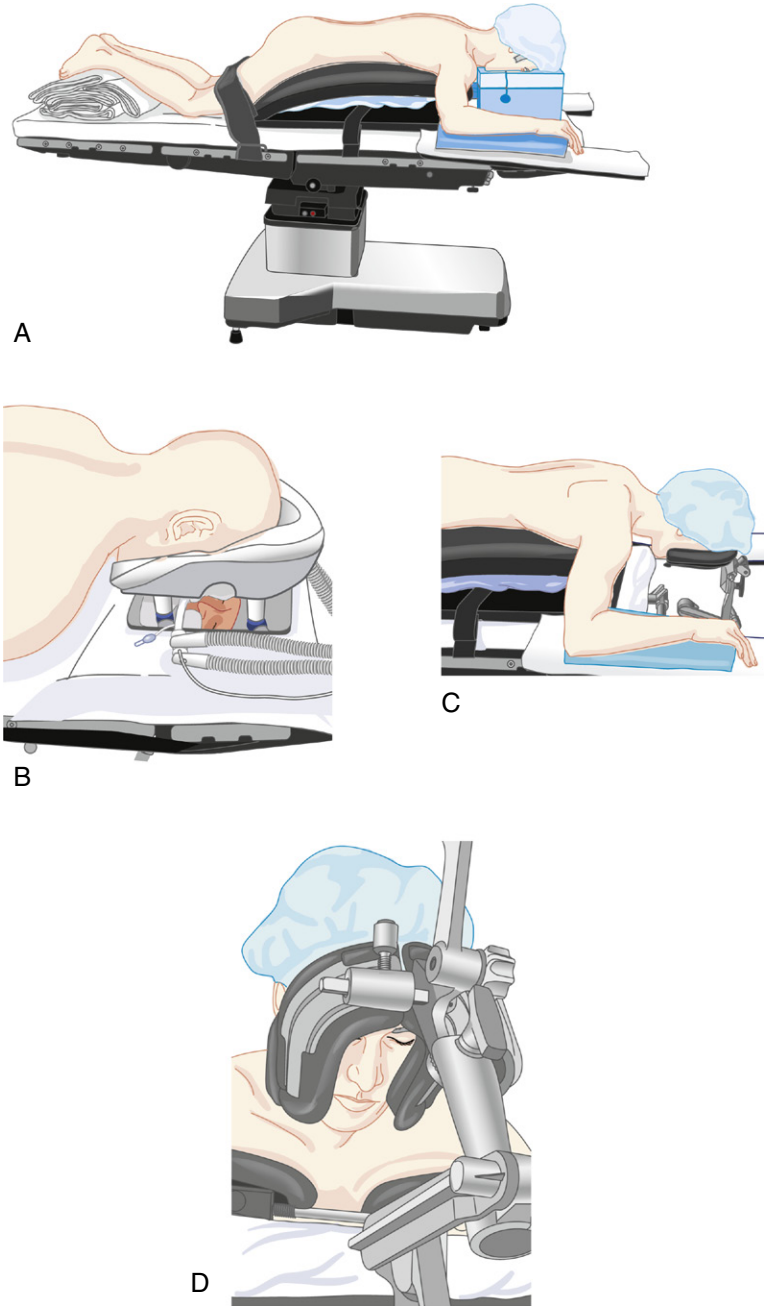

FIGURE **21-6** **A,** Prone position with Wilson frame. Arms are abducted less than 90 degrees whenever possible. Pressure points are padded, and chest and abdomen are supported away from the bed to minimize abdominal pressure and preserve pulmonary compliance. Foam head pillow has cutouts for eyes and nose and a slot to permit the endotracheal tube to exit. Eyes must be checked frequently. **B,** Mirror system for prone position. Bony structures of the head and face are supported, and monitoring of eyes and airway is facilitated with a plastic mirror. **C,** Prone position with horseshoe adapter. Head height is adjusted to position neck in a neutral position. **D,** Prone position, face seen from below. Horseshoe adapter permits superior access to airway and visualization of eyes. Width may be adjusted to ensure proper support by facial bones. (From Miller RD, Pardo Jr MC. *Basics of Anesthesia.* 6th ed. Philadelphia: Saunders; 2011:307.)

Compartment Syndrome

Compartment syndrome is a potentially life-threatening complication that causes damage to neural and vascular structures from tissue swelling as a result of increased pressures and decreased tissue perfusion in muscles with tight fascial borders. Because tissue swelling typically occurs when blood flow returns after a period of ischemia, the syndrome has also been dubbed a "reperfusion injury." Increased compartmental pressure compromises arteriolar supply and results in ischemia with subsequent muscle and nerve infarction.[44,97-99] Although compartment syndrome occurs most often in the extremities, abdominal compartment syndrome also occurs after tight wound closures.[100]

Compartment syndrome takes place as a result of a variety of reasons such as (1) systemic hypotension that falls below perfusion

TABLE 21-2 Common Nerve Injuries: Etiology and Prevention

Nerve/Nerve Group Injured	Potential Cause	Positioning Recommendation
Brachial plexus	*Supine, Trendelenburg, Lithotomy*	
	Arm abducted more than 90 degrees on armboard	Do not abduct arm more than 90 degrees
	Arm falls off table edge and is abducted and externally rotated	Ensure arms are adequately secured
	Arm abduction and lateral flexion of the head to the opposite side	Support head to maintain neutral alignment
	Trendelenburg	
	Shoulder braces placed too medial or lateral	Place well-padded shoulder brace over the acromioclavicular joint Avoid use if possible
	Lateral	
	Thorax pressure exertion on dependent shoulder and axilla	Place roll caudad to the axilla supporting the upper part of the thorax
	Prone	
	Arms abducted more than 90 degrees	Abduct arms minimally
Ulnar nerve	Arm pronated on armboard	Supinate forearm on padded armboard
	Arms folded across abdomen or chest with elbows flexed more than 90 degrees	Do not flex elbows more than 90 degrees
	Arms secured at side with inadequate padding at the elbow	Place sufficient padding around elbow
	Arms inadequately secured at side, elbows extend over table edge	Draw sheet should extend above the elbow and be tucked between the patient and the mattress
Radial nerve or circumflex nerve	Arm pressed against vertical positioning or retractor post or pole securing ether screen	Place adequate padding between or ensure arm is not pressing against vertical posts or pole
Suprascapular nerve	Patient in lateral position rolls semi-prone onto dependent arm with shoulder circumduction	Stabilize patient in lateral position
Sciatic nerve	Malnourished/emaciated patient supine or sitting on inadequately padded table	Generous soft padding under buttock
	Legs straight in sitting position	Flex table at knees
	Lithotomy	
	Legs externally rotated with knees extended	Minimal external rotation of legs; knees should be flexed
Common peroneal nerve	*Lithotomy*	
	Fibular neck rests against vertical bar of lithotomy stirrup	Adequate padding between leg and stirrup
	Knees extended, legs externally rotated	Knees flexed with minimal external rotation
	Lateral	
	Undue pressure on downside leg	Padding under the fibular head
Posterior tibial nerve	*Lithotomy*	
	"Knee crutch" stirrups supporting posterior aspect of knees	Generous padding under knees Avoid use of this stirrup for prolonged procedures
Saphenous nerve	*Lithotomy*	
	Foot suspended outside vertical bar, leg rests on bar	Sufficient padding between legs and vertical bar
	Excessive pressure on medial aspect of leg from "knee crutch" stirrups	Sufficient padding between stirrup and leg
Obturator nerve	*Lithotomy*	
	Excessive flexion of the thigh at hip	Minimal hip flexion
Pudendal nerve	Traction of legs against perineal post or orthopedic fracture table	Generous padding between perineum and post

Modified from Walsh J. AANA journal course: update for nurse anesthetists—patient positioning. *AANA J.* 1994; 62(3):289-298; Phillips N. *Berry & Kohn's Operating Room Technique*. 12th ed. St. Louis: Mosby; 2013:489-525; Heizenroth PA. Positioning the patient for surgery. In: Rothrock JC. *Alexander's Care of the Patient in Surgery,* 14th ed. St. Louis: Mosby; 2011:44-173.

pressure; (2) vascular obstruction of major extremity vessels by intrapelvic retractors, by excessive knee or hip flexion, or (3) external compression of the elevated extremity by a poorly padded positioning device or straps and wrapping that are too tight.[97,98] Other risk factors that might contribute to the development of compartment syndrome include lithotomy position, Trendelenburg position, advanced age, extremes of body habitus, patient history of nerve ischemia or neuropathy, connective tissue disease, anemia, prolonged operative duration, and vasoconstrictive drugs.[98-100] Compartment syndrome can be precipitated

by intraoperative hypotension in conjunction with leg elevation that causes low-flow states. Because blood pressure decreases by 0.75 mmHg per centimeter change in height, elevation of the legs puts the patient at greater risk.[97]

Unless the syndrome is promptly diagnosed and treated, permanent neuromuscular damage will occur. Fasciotomy is generally considered the definitive treatment because less aggressive therapies will not release the constricted compartments. If untreated, the syndrome progresses to tissue necrosis with myoglobinuria and acute renal failure (crush syndrome). Amputation and even death can occur.[100]

Although anesthetic technique has not been implicated as causing compartment syndrome, general and regional anesthesia can contribute to intraoperative hypotension and impaired blood flow. Controversy exists over whether regional anesthesia contributes to delayed diagnosis of the syndrome.[100-102]

Venous Air Embolism

Venous air embolism (VAE) is a well-known consequence of surgery performed in the sitting position. However, VAE may occur in any position where a negative pressure gradient exists between the right atrium and the veins at the operative site.[103-106] The precise incidence of VAE is unknown, but there is an increased incidence in surgeries performed in the sitting position.[107-109] Air that enters the right side of the heart can limit gas exchange in the lungs as it displaces blood in the pulmonary vasculature. Complications of VAE are dependent on both the rapidity and volume of air entrainment. Physiologic effects range from no effect for minimal amounts of air to hypotension, arrhythmias, cardiac arrest, and death with larger volumes.[106-109]

Paradoxical air embolism (PAE) can occur in the patient with a patent foramen ovale (PFO). Studies in vivo and in cadavers indicate that the incidence of PFO can be as high as 35% in the general population.[104,107,108] In the patient with PFO, air can enter the systemic circulation when right atrial pressure is greater than left atrial pressure, a reversal of the normal pressure gradient. Very small amounts of air in the arterial system can result in severe cardiovascular and neurologic complications.

Because VAE and PAE carry the potential for serious consequences, identifying individuals at risk for these complications is important. Preoperative transesophageal echocardiograph (TEE) with contrast is the gold standard for detection of PFO in patients scheduled for surgery in the sitting position.[105,109-111] The cost of TEE is thought to be justified because it is a low-risk, semi-invasive procedure and the sequelae of PAE are severe. However, PFO can be present and PAE can occur despite negative preoperative TEE.[109] Because echocardiography is uncomfortable for patients and has rare but serious complications, transcranial Doppler studies are recommended as an alternative, noninvasive approach for detection of PFO.[109,111]

In addition to the use of standard anesthetic monitoring techniques, patients who are susceptible to VAE should be monitored with devices that detect VAE and allow aspiration of entrained air. TEE, Doppler ultrasonography, capnography, and pulmonary artery catheterization vary in their ability to detect intraoperative VAE. TEE is the most sensitive, having the ability to identify emboli less than 0.2 mL/kg, but it is not specific for gas emboli.[108,111] Although TEE is the gold standard for VAE detection and can be used to position right atrial catheters, it also has its disadvantages. TEE requires specialized training, requires considerable time, comes with risk to the patient, and may not provide a continuous monitor of cardiovascular events.

The precordial Doppler is often used to monitor for VAE when patients are in the sitting position. The probe is placed over the third to sixth intercostal spaces to the right of the sternum. The Doppler is equally as sensitive as TEE and less expensive and cumbersome. However, it does not have the advantage of localizing entrained air within the cardiac chambers, it is sensitive to electrical interference from operating room equipment, and its effectiveness can be reduced by auditory fatigue in the anesthetist.[106,108,111] False positives can be generated by rapid infusion of fluid or flushing transducers. Most frequently used for sitting cases, Doppler devices have not traditionally been advocated for management of VAE during procedures performed in the prone position because of the excessive pressure that it may exert on the chest wall.

VAE increases dead space and contains nitrogen; monitoring capnography will reveal a drop in end-tidal CO_2 and the presence of end-tidal nitrogen. A "mill-wheel murmur" is a characteristic of VAE that can be heard through the esophageal or precordial stethoscope.[111] Air in the coronary arteries can cause ischemic electrocardiographic changes, and air in the pulmonary vessels can result in an increase in PAP and hypoxia. These signs occur later than changes detected by TEE, Doppler, or capnography and are indicative of PAE or large emboli.

Entrained air emboli can be removed from the circulation by aspiration through a multiorifice central venous catheter. For patients undergoing surgery in the sitting position, the catheter is placed in the right atrium at the junction of the superior vena cava.[105,111] Patients who are prone should have the CVP catheter positioned at the junction of the inferior vena cava (IVC) and right atrium because air emboli from spinal surgery enter the venous circulation through the lumbar epidural veins and IVC. The risks of central venous catheter placement, the potential for VAE, and the cardiopulmonary risks of the position must be weighed against the benefits of fluid volume management and air recovery with a CVP catheter. See Chapter 28, Neuroanatomy, Neurophysiology, and Neuroanesthesia for further discussion.

Airway Complications of Surgical Positions

Anesthetized patients in various surgical postures are vulnerable to endotracheal tube displacement, airway edema, and passive regurgitation. The endotracheal tube may become dislodged, kinked, or disconnected when the patient is moved or upon position change. A right mainstem intubation may occur as a result of flexion of the neck or when the patient is placed in steep Trendelenburg position. With neck flexion, the endotracheal tube moves downward and may inadvertently enter the right mainstem bronchus.[112,113] In the Trendelenburg position, pressure of the abdominal contents force the diaphragm cephalad and may cause a similar occurrence.[27] The endotracheal tube can become kinked with extreme degrees of flexion or may compress the arytenoids and epiglottis, resulting in postoperative supraglottic edema.

Extensive edema of the face, tongue, and oropharyngeal structures has been reported after procedures in the prone, head-down, and sitting positions.[114,115] In the prone and head-down positions, gravitational forces or increases in hydrostatic pressures may restrict venous return from the head and neck. Excessive flexion of the head on the neck with patients in the sitting position may obstruct jugular venous return, resulting in macroglossia and airway edema. Oral airways, endotracheal tubes, and esophageal stethoscopes may compress the base of the tongue and limit lymphatic drainage.[114] Macroglossia or upper airway edema may necessitate leaving the patient intubated after surgery until the edema subsides.[115] It may be prudent to verify an air leak around the endotracheal tube or examine the larynx via direct laryngoscopy before extubation in suspected patients.

SURGICAL POSITIONING

The Supine Position (Dorsal Decubitus)

The supine position is most frequently used for surgical procedures on the abdomen, head, neck, extremities, and chest, owing to the favorable exposure it allows. When positioning the patient supine, the head should be maintained in a neutral position on a small pillow or donut. The arms should be either comfortably positioned and secured alongside the trunk or positioned on padded arm boards.[32,82,113] If the patient has severe arthritis, decreased mobility of the head and neck, or neuropathy of the upper extremities, it is best to position the patient to his or her preference prior to the induction of anesthesia. During prolonged procedures, the head should be repositioned at intervals and the occiput massaged to prevent alopecia due to prolonged pressure. Gel-type donuts may more evenly distribute pressure.[38]

The ligaments of the vertebral column relax with anesthesia and can result in postoperative backache. A small support pad may be placed under the lumbar spine to prevent postoperative back pain due to abolition of the normal lumbosacral curve. Placing a pillow under the patient's knees or placing the table in a slight "lounge chair" position, with the patient's hips and knees flexed and the trunk slightly elevated increases patient comfort.[32,113] The legs must remain uncrossed to avoid pressure from the superior extremity damaging the superficial peroneal nerve in the dependent leg and the sural nerve in the superior leg. If prolonged surgery is anticipated, the heels should be elevated off the mattress to prevent pressure sores; however, using too large a support to elevate the heels can cause hyperextension of the knees and pain postoperatively. Gel pads or mattresses more evenly distribute the patient's body weight and prevent reddened areas after lengthy procedures.[32]

If the arms are tucked, the elbow must not be allowed to hang over the edge of the operating table because ulnar nerve damage may occur. When tucked, the hands should be placed in a neutral position, the elbow padded, with the palms facing the hip[66,67,70] (see Figure 21-3). If the arms are secured on armboards, the forearm should be supinated; pronation may result in compression of the ulnar nerve against the armboard. The arms should be abducted less than 90 degrees, and the head should be maintained in a neutral position to avoid brachial plexus stretch injuries.[67,70,71]

Trendelenburg/Reverse Trendelenburg Positions

Trendelenburg position (head-down position) is often used to increase venous return during episodes of hypotension and is also used to supplement the primary surgical position and improve surgical exposure. Physiologic alterations vary greatly depending on the degree of tilt and the primary position. An increase in central venous, intracranial, and intraocular pressures is observed with the Trendelenburg position and may contribute to edema of the face, tongue, oropharynx, and eyes.[10-13,116] Various complications have been observed as outcomes of the Trendelenburg position. Many are the result of devices. Improperly positioned shoulder braces designed to prevent the patient from sliding when in a steep Trendelenburg position can injure the brachial plexus. Placement of the shoulder brace in a position that is placed too medial can result in depression of underlying bony structures and compression of the plexus. Braces placed too lateral may result in a stretch injury of the brachial plexus. The brace should be placed over the acromioclavicular joint and should be avoided if at all possible because nerve injury can still occur despite proper placement.[11-13,70,117] The arms are vulnerable to injury in the Trendelenburg position, particularly if they are positioned on armboards and inadequately restrained. The arms can slip off, hyperextend, and abduct above the level of the shoulder, stretching the plexus.[11,70,82]

The reverse Trendelenburg position (head-up position), often used in laparoscopic surgeries, can also predispose patients to injury. The positioning of the head higher than the heart reduces perfusion pressure to the brain and should be monitored closely. When too tight, table straps used to prevent the patient from sliding in the reverse Trendelenburg position have resulted in lower-extremity neuropathies[70] (see Figure 21-3). The use of a foot board is preferable to the overzealous tightening of the table strap if a steep reverse Trendelenburg position is necessary.

The Lithotomy Position

The lithotomy position is used for surgical procedures that require access to any perineal structure. In the typical lithotomy position, the legs are held in flexion and abduction above the level of the torso by a leg-holding device (Figure 21-7).[38] Depending on the distance the legs are elevated above the torso, the position is identified as *low*, *standard*, *high*, or *exaggerated lithotomy* (Figure 21-8). In low lithotomy position, the legs are almost level with the torso, whereas in exaggerated lithotomy position, the legs are suspended with boots or stirrups so that the feet are well above the body. A hemilithotomy position, with one leg elevated, is also used for some orthopedic procedures.[38,70,113]

The arms are usually positioned either tucked at the sides or abducted on armboards. In the hemilithotomy position, one arm may be secured across the chest. The same cautions for positioning the upper extremity apply as in the supine position. Strict attention must be paid to the fingers, if the arms are tucked at the sides, to avoid a potentially disastrous crush injury or amputation if they become trapped when the foot section is raised.[70,82,113] Many neurovascular complications occur in the lithotomy position because of the position of the leg and hip. Both legs should be elevated and lowered simultaneously when they are placed in a leg-holding device; raising and lowering the legs separately can cause hip dislocation, spinal torsion, or postoperative back pain.[38,70] Acute abduction and external rotation of the hips can also cause femoral nerve or lumbosacral plexus stretch injuries. Flexion of the hips more than 90 degrees in the lithotomy position can cause neural damage by stretching the sciatic and obturator nerves or by direct pressure of femoral neurovascular structures under the inguinal ligament, with subsequent arterial or venous occlusion and nerve palsy.[38,70,117,118] Leg holders that support the leg under the knee can compromise vascular structures in the popliteal space.

Peroneal nerve injury is frequently associated with the lithotomy position because of its anatomic course.[28,30] The nerves crosses the knee joint laterally and wraps around the fibular head before traveling down the lower leg. Depending on the type of leg holder used, the nerve can be injured by compression against the upright bar or against the supporting cradle of the leg holder. The saphenous nerve courses down the medial aspect of the lower leg and is also at risk for compression in the leg holder. Care must be taken to adequately pad any points of potential compression.[70,116]

The Lateral Decubitus Position

The lateral decubitus position is often used for surgeries involving the thorax and kidneys when the supine position cannot provide sufficient exposure. Orthopedic procedures involving the hips, shoulders, or extremities can also require this position for better access to the surgical site. When a nephrectomy is performed using a lateral approach, exposure of the kidney can be facilitated by elevating the kidney rest beneath the dependent iliac crest and flexing the operating table so that the operative flank is higher than the upper torso or legs (Figure 21-9).[38,70,82]

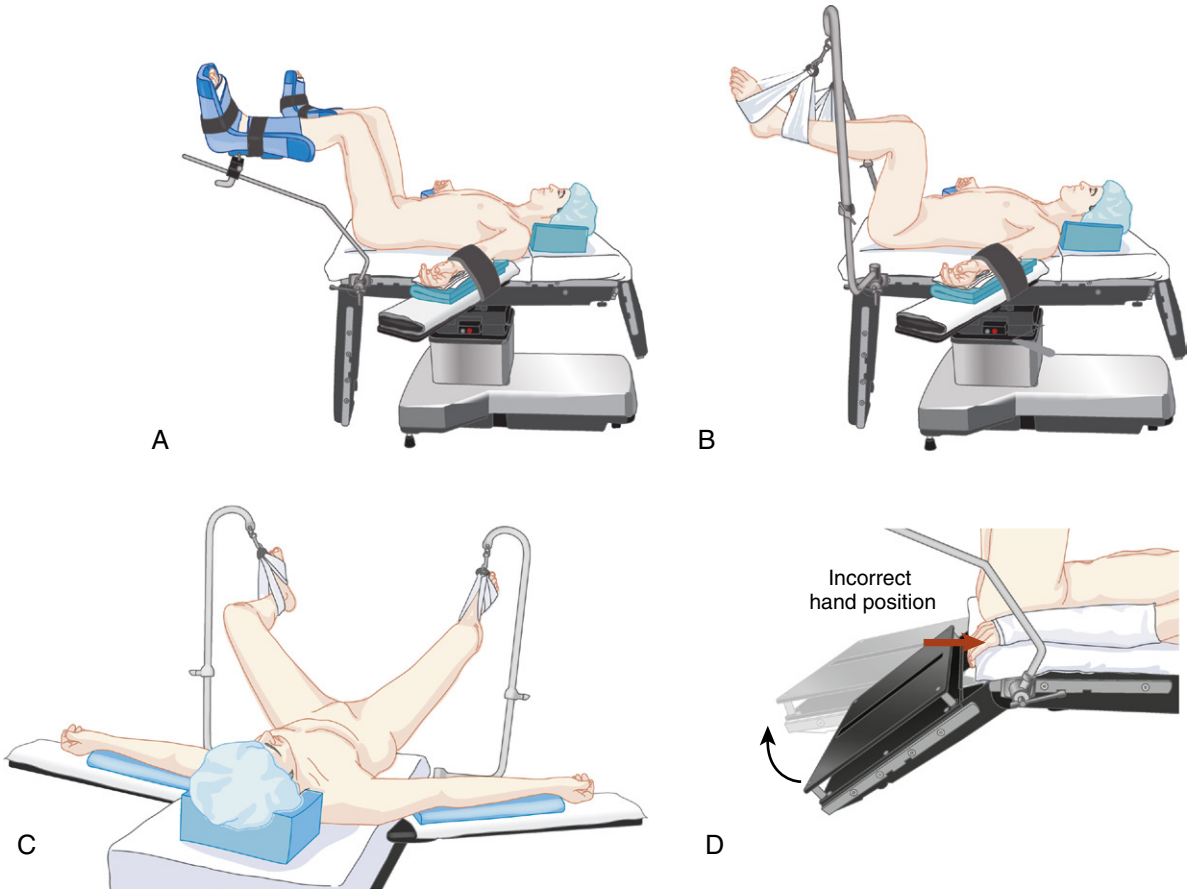

FIGURE **21-7** **A,** Lithotomy position. Hips are flexed 80 to 100 degrees with the lower leg parallel to the body. Arms are on armrests away from the hinge point of the foot section. **B,** Lithotomy position with "candy cane" supports. **C,** Lithotomy position with correct position of "candy cane" stirrups away from lateral fibular head. **D,** Improper position of arms in lithotomy position with fingers at risk for compression when the lower section of the bed is raised. (From Miller RD, Pardo Jr MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Saunders; 2011:304.)

Initially the patient is placed supine for induction of anesthesia and intubation. If a beanbag is used to support the torso, it is placed flat on the operating table prior to the patient's arrival in the OR. Before the patient is positioned, the endotracheal tube, breathing circuit, intravenous and monitoring lines, and any other devices should be secured so that none are beneath the body after the turn. The anesthetist should control the airway, head, and neck, as well as coordinate the turn.

Particular attention should be paid to body alignment in the lateral position. The shoulders, hips, head, and legs are maintained in the same plane and turned simultaneously to avoid stress and twisting of the torso and spine (Figure 21-10). The head and neck remain aligned with the spine in a neutral position. The head should be supported on pillows or a donut and not allowed to hang, tilt laterally, hyperflex, or hyperextend (see Figure 21-9). The dependent eye and ear must be free of pressure. A gel donut is useful for keeping the dependent ear suspended and pressure free.

Once the patient is in the lateral position, flexing the knee and hip of the dependent leg stabilizes the patient. The nondependent leg remains straight and is supported by a pillow placed between the lower extremities. Positioning the legs in this manner prevents bony prominences of the legs from resting on each other and reduces compression of the inferior leg by the superior extremity (see Figure 21-9, A). Padding should be placed along the lateral aspect of the dependent leg, extending from the knee to the heel to protect the peroneal nerve from external pressure against the table or beanbag.[28,68]

The dependent arm is positioned on a padded armboard perpendicular to the torso and flexed less than 90 degrees at the elbow.[28,68] The nondependent arm is placed to avoid interference with surgical exposure—usually parallel to the dependent arm and level with the shoulder on a well-padded arm-holding device. Alternatively, both arms may be positioned on a single armboard with adequate padding between them. Perfusion to the upper extremities, especially the dependent arm, should be periodically assessed by palpating the radial artery and checking capillary refill.[28,82]

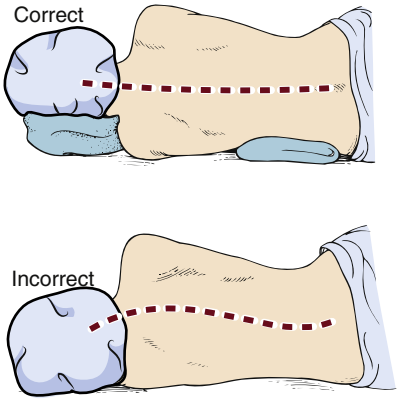

FIGURE **21-10** Proper alignment of spinal column in lateral position. (From Phillips N. *Berry & Kohn's Operating Room Technique*. 12th ed. St. Louis: Mosby; 2013: 507.)

The dependent shoulder and upper extremity are susceptible to compression in the lateral position. A small roll (axillary roll) is placed under the dependent side of the thorax, slightly caudad to, but not directly in the axilla, to lift the thorax and relieve pressure exerted on the shoulder, axillary vessels, and brachial plexus of the dependent arm.[82,119] It is useful to obtain blood pressures in the nondependent arm because of potential for neurovascular compression in the dependent arm from the blood pressure cuff.[82]

Ancillary positioning devices such as beanbags, pillows, sandbags, braces, and adhesive tape aid in securing the patient and preventing rotation of the trunk. If tape or straps are used to stabilize the torso, they should be placed just caudal to the axilla to reduce the risk of brachial plexus injury.[38] Placement across the ribs can impair ventilation. Soft tissue injury may occur if straps or tape is overly tight.

Rhabdomyolysis has been reported after use of the lateral decubitus position.[120,121] Prolonged operating time, hypotension, and pressure of the operating table against gluteal and flank muscles have been described as contributory factors. The anesthetist, as well as the entire operating team, should ensure that the operating table is well padded and that positioning devices are properly placed. Furthermore, prolonged or excessive hypotension should be avoided to ensure adequate tissue perfusion.

The Sitting Position

The term *sitting position* commonly refers to any position in which the torso is elevated from the supine position and is higher than the legs. A true sitting position in which the torso is elevated at 90 degrees to the legs is rarely used. The modified sitting position, in which the torso is elevated 45 degrees, the head is flexed, and the legs are elevated and flexed at heart level, is probably most commonly used. This position is variously described as the *lounging*, *lawn chair*, or *beach chair* position.[38] Although its use is reportedly decreasing in popularity, some neurosurgeons favor the sitting position for posterior fossa and cervical spine procedures because it allows excellent visualization of intracranial structures and facilitates drainage of blood and cerebral spinal fluid from the wound. During shoulder arthroplasty and arthroscopy, the sitting position reduces brachial plexus stretch and aids surgical exposure and manipulation of the arm and shoulder.[122]

Placement of the patient in the sitting position involves flexion of the operating room table, elevation of the backrest and legs, and head-down rotation. The degree of torso elevation desired

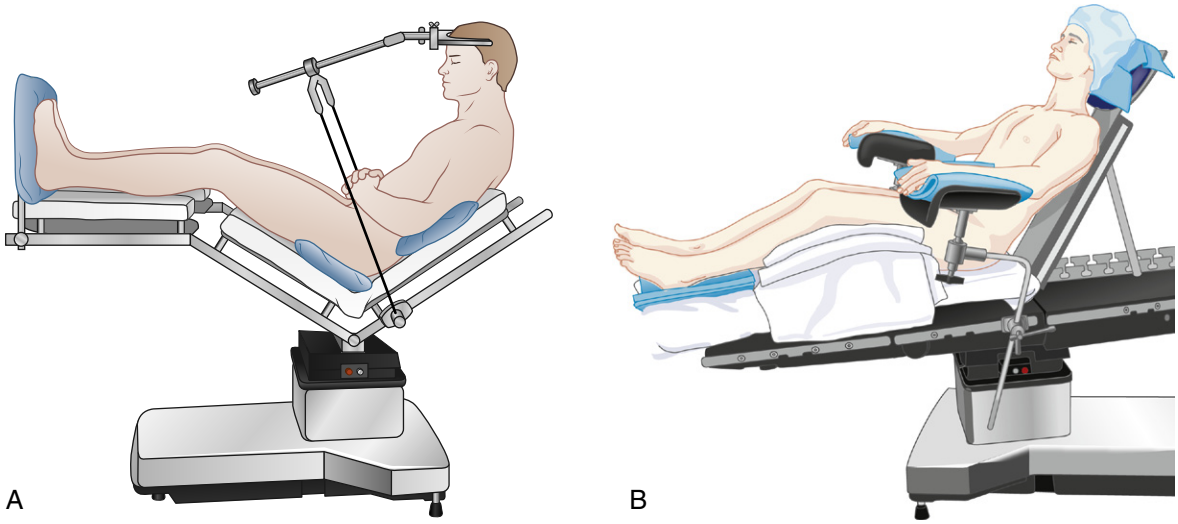

FIGURE **21-11** **A,** Sitting position with Mayfield head pins. The patient is typically semirecumbent rather than sitting because the legs are kept as high as possible to promote venous return. Arms must be supported to prevent shoulder traction. Note that the head holder support is preferably attached to the back section rather than the thigh section of the table so that the patient's back may be adjusted or lowered emergently without first detaching the head holder. **B,** Sitting position adapted for shoulder surgery. Note the absence of pressure over the ulnar area of the elbow. (From Miller RD, Pardo Jr MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Saunders; 2011:309.)

determines the amount of operating table manipulation required. For neurosurgical procedures, a three-pin head holder is generally used to secure the head. The device provides better head stabilization compared with horseshoe-type headrests and avoids eye compression, but jugular venous obstruction can occur if the head is excessively flexed on the neck. At least two fingerbreadths of space should be allowed between the neck and mandible. Incorrect placement of the head holder and direct contact of its metal bars with the nose or skin can cause pressure necrosis[8,9,105,106] (Figure 21-11).

A horseshoe headrest is often used to support the head for shoulder procedures performed in the sitting position. Straps or adhesive tape secure the head to the headrest. Vigorous surgical manipulation of the arm and shoulder can move the patient's body toward the operative side of the table. If the head is firmly secured to the headrest, excessive traction or stretch can be placed on the neck and brachial plexus. If the restraining straps are loose, the head can become partially or completely dislodged from the headrest, introducing the potential for cervical spine injury. Accidental extubation can occur if the endotracheal tube is secured by a supporting device and the head is displaced. Profound hypotension and bradycardia from activation of the Bezold-Jarisch reflex may occur when shoulder surgery is performed in the sitting position under an interscalene block.[112,122]

Serious complications associated with the sitting position are among the reasons that the position is falling out of favor. VAE is the most feared complication, but pneumocephalus, quadriplegia, and peripheral nerve injuries are also possible. Pneumocephalus is a frequent occurrence after neurosurgical procedures performed using the sitting or supine positions and is typically a benign condition. Gravity is the most important factor in the development of pneumocephalus. Opening of the dura, drainage of cerebrospinal fluid, and surgical decompression allow relaxation of the brain and entrance of air, which rises to the top of the cranial vault. Contributing factors are those that decrease brain volume, such as the use of diuretics, hypocarbia, the presence of intraventricular shunts, and gross hydrocephalus.[123,124] Tension pneumocephalus, on the other hand, rarely occurs, but its advent requires immediate intervention to prevent rapid deterioration of the patient. The onset of tension pneumocephalus manifests as restlessness, deterioration of consciousness, convulsions, or other changes in neurologic status. Definitive diagnosis is made by the presence of air on computed tomographic scan. Prompt evacuation of the air collection through twist drill holes is indicated.[125,126]

The Prone Position

The prone position provides optimal exposure for a variety of procedures performed on the spine, certain orthopedic procedures, and some rectal procedures. The prone position has also been advocated for intracranial procedures, owing to the decreased risk of venous air embolism compared with the sitting position. Many modifications of the prone position exist (Figure 21-12). Anesthetists must become familiar with the various methods of securing the patient in the prone position and recognize the potential hazards of each variation or device.

In the prone position, the torso is typically supported on a frame or with rolls that extend from the shoulders to the iliac crests. Alternatively, supports can be placed crosswise at the pelvis and shoulders. The lower legs are supported with pillows, and the upper extremities may be tucked at the sides or supported on armboards with the arms flexed at the shoulders and elbows. Care must be taken to pad pressure points at elbows, knees, and ankles. Breasts and genitalia must be positioned to limit pressure on them.[68,70]

When a prone approach is planned, the patient is anesthetized on the gurney and then log-rolled onto the bed, frame, or rolls with good body alignment maintained. Thoughtful planning of monitor placement allows turning without removal of monitors during this critical period and avoids delays. Typically the patient is disconnected from the breathing circuit to avoid accidental extubation. The anesthetist should control the airway, head, and neck, as well as coordinate the turn.

Head, neck, shoulder, and arm mobility must be assessed preoperatively; arm placement can be limited by ankylosis of shoulder or elbow joints. Depending on the surgeon's preference, the arms

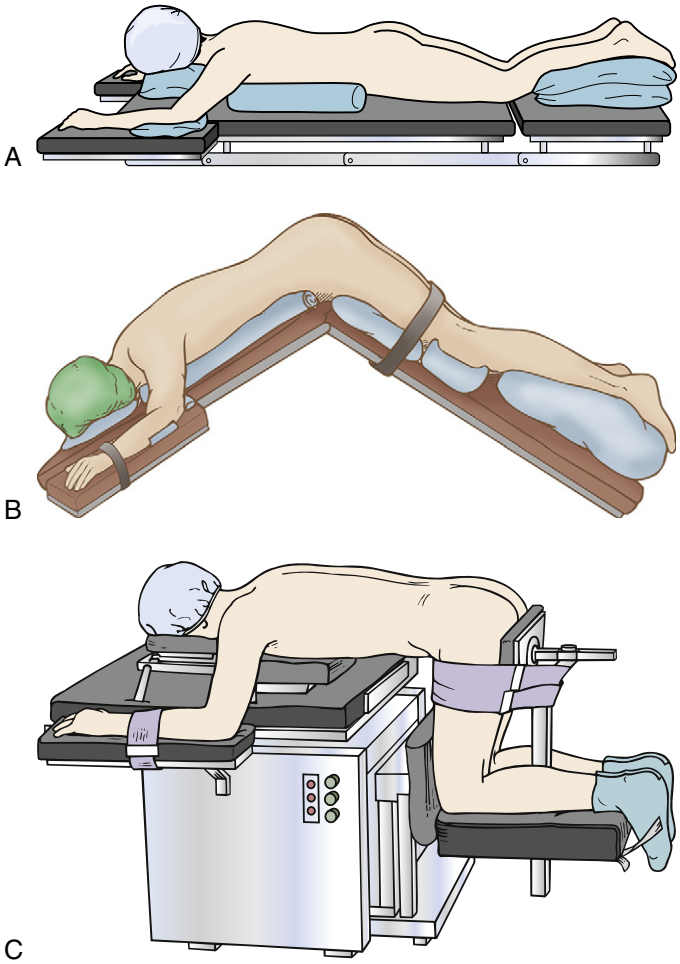

FIGURE **21-12** Variations of the prone position. **A,** Classic prone position with the torso supported on chest rolls. **B,** Jackknife position. **C,** Knee-chest position. (**A,** from Phillips N. *Berry & Kohn's Operating Room Technique*. 12th ed. St Louis: Mosby; 2013:506; **B** and **C** from Rothrock JC. *Alexander's Care of the Patient in Surgery*. 14th ed. St Louis: Mosby; 2011:171.)

may be tucked parallel to the sides with a draw sheet or supported on armboards. If tucked, the arms should be secured in a natural position with the palms facing the thighs. Plastic or metal arm "sleds," with sufficient padding, can be used to protect the arms and vascular access sites from compression by the bodies of the surgical team. If the arms are not tucked at the sides, they should be carefully rotated into position. The preferred arm placement is flexed, slightly abducted, and with the forearms and hands lower than the shoulders and adequately supported. The arms should rest at a comfortable height on the armboards and should not support the weight of the shoulders. Padding should be placed under the shoulders to prevent sagging of the shoulders and stretching of the brachial plexus.[33,68,70]

Particular care must be taken to maintain alignment of the head and neck in the prone position. The head should be supported in a neutral position with a head-holding device. Hyperextension or lateral rotation of the neck should be avoided, because either may compromise spinal cord blood flow, especially in elderly individuals with narrowing of the spinal canal due to osteoarthritis. Also, stretch injuries of the brachial plexus may occur with lateral head rotation.[38,68,80]

A primary goal of positioning the prone patient is to avoid pressure on the abdomen, which can impede venous return, increase venous pressures, and interfere with ventilation by inhibiting movement of the diaphragm.[33,82] Valves are not present in the intervertebral veins that drain the vertebral and spinal cord venous plexuses into the lumbar veins. External abdominal pressure is transmitted to the vena cava and communicated to the lumbar epidural veins.[33,38] Positioning devices that allow the abdomen to hang freely are associated with greater decreases in inferior vena cava pressures than those that compress the abdomen and therefore prevent engorgement of spinal venous plexuses. Engorged epidural veins are fragile and easily traumatized, and the ensuing blood loss will decrease surgical exposure and contribute to hypotension. Studies suggest that in the prone position, the degree to which pulmonary mechanics are altered depends on the positioning device used, not on body habitus.[33,82] The Jackson table resulted in the smallest change in pulmonary compliance and peak airway pressures when compared with the Wilson frame and chest rolls. The investigators hypothesized that the Jackson table allows the abdomen to hang freely, permitting better diaphragmatic excursion and lower intraabdominal and intrathoracic pressures.[82]

Meticulous attention must be paid to protection of the eyes, because corneal abrasions and POVL are complications of the prone position.[85] Several devices including three-point skull fixation, the horseshoe headrest, and foam cushions allow the head to be placed in a neutral position while the eyes are kept free of pressure. However, the head may slip or rotate on the horseshoe headrest, allowing pressure to be applied over the globe and placing the patient at risk of central retinal artery thrombosis. Although three-point skull fixation is often recommended for securing the head and protecting the eyes in the prone position, POVL has occurred despite the use of this device.[85]

CLOSED-CLAIMS STUDIES

Surgical positions are associated with numerous potential complications that can be detrimental to a patient's short- and long-term outcomes. Although the potential for various complications is generally well known, the precise incidence and cause of position-related injuries are often difficult to determine. Because the frequency of these events is low, contributing causes are frequently multifactorial, and uniform reporting of mechanisms does not exist. Position-related injuries are thought to be underreported in the scientific literature.[51,37] Fear of litigation or damage to one's professional reputation may prevent anesthesia providers from reporting such events. However, case reports, closed-claims studies, and retrospective analyses of databases can provide insight into position-related injuries and shed light on precipitating causes and outcomes.

Both the American Association of Nurse Anesthetists Foundation (AANA-F) and the American Society of Anesthesiologists (ASA) have conducted studies of closed malpractice claims from professional liability insurance companies. These studies provide a rich source of data about position-related complications. The ASA Closed Claims Project (ASA-CCP) was initiated in 1985. Since then, this ongoing project has collected data on 9214 anesthesia-related claims filed with more than 35 liability insurance carriers.[127,128] Because the ASA-CCP involves primarily anesthesiologists, the AANA-F conducted a similar study to examine outcomes of care provided by CRNAs. The AANA-F database covers 223 cases that occurred between 1989 and 1997 and is derived from records of the primary insurer of CRNAs at that time.[129,130] Dental claims are excluded from both the AANA-F and ASA-CCP studies.

In 2011, the ASA-CCP contained 5230 claims. An analysis of these claims revealed that death (26%), nerve injuries (22%), and permanent brain damage (9%) were the major causes of liability.[51]

Nerve damage included injuries to both the peripheral nervous system and spinal cord but not to the brain. Nerves most commonly affected were the ulnar (28%), brachial plexus (20%), lumbosacral nerve root (16%), and spinal cord (13%). Injuries to all other nerves accounted for only 8% of the nerve damage claims. Although claims for nerve injury have remained constant over time, claims for ulnar nerve injury have decreased while those from spinal cord injury have increased.[37,51]

Specific causative factors could not be identified in the majority of claims in the ASA-CCP. When the association of anesthetic technique with nerve injury was examined, regional anesthesia was more frequently associated with nerve-injury claims—particularly of the spinal cord and lumbosacral nerve root—than general anesthesia. However, 85% of ulnar nerve injuries were associated with general anesthesia. The quality of anesthesia care was judged as appropriate in 66% of all nerve injury claims, as compared with 42% of non–nerve-damage cases. However, care was deemed appropriate in only 46% of spinal cord damage claims. Other factors associated with nerve damage included positioning and positioning devices, intraoperative trauma, and paresthesias during regional block performance.[37]

The AANA-F closed-claims study compared 151 claims (68%) in which a CRNA was judged to have contributed to the adverse outcome (CRNA-related) with 72 claims (32%) in which the CRNA was judged not to have contributed to the adverse event (non–CRNA related).[130] Death (32%), nerve injury (12%), brain injury (12%), and eye injury (10%) were the primary outcomes of CRNA-related claims. No significant difference in the type of outcome was found between CRNA-related claims and non–CRNA-related claims. Reviewers evaluated the appropriateness of care and found care inappropriate in 52% of CRNA-related cases, appropriate for 30%, and impossible to assess in the remaining cases.

A subsequent analysis was conducted of 44 cases of nerve injury in the AANA-F database.[131] The distribution of nerve injuries was as follows: brachial plexus (15 [34%]), ulnar nerve (7 [16%]), radial nerve (5 [11%]), peroneal nerve (4 [9%]), spinal cord (4 [9%]), and lumbosacral nerves (3 [7%]). A variety of other nerves accounted for the remaining injuries. In the majority of claims filed, documentation of the patient's position and the use of protective padding was inadequate, preventing investigators from identifying possible causative factors. However, a higher percentage of nerve injuries were associated with inadequate positioning, preexisting patient conditions, general anesthesia, extremes of body habitus, and procedures lasting longer than 2 hours.

The AANA-F and ASA-CCP studies highlight the importance of following standards of care and properly documenting perioperative activities. Standards for nurse anesthesia practice identify thorough, complete, and accurate documentation as an expectation of nurse anesthesia practice.[132] In the event of a malpractice claim, thorough documentation assists reviewers in determining the quality of care provided.

Quality of care was judged as inappropriate in 34% of nerve injury claims from the ASA-CCP and 52% of all cases in the AANA-F study.[37,130] In both studies, monetary awards were higher in those cases resulting in more severe outcomes and when anesthesia care was determined to be less than appropriate. Although some suggest that position-related nerve injuries are largely preventable,[33] the ASA analysis of nerve injury claims revealed that payouts were frequently made even when anesthesia care was judged appropriate.[37] This suggests that current knowledge of methods for preventing nerve injury is inadequate and that further research into mechanisms of nerve injury is needed.

Several limitations are inherent in closed-claims studies. First, the purpose of data collected by professional liability insurance companies is to investigate malpractice claims, not to improve patient safety. Not all anesthesia-related injuries result in a liability claim. Therefore data from closed-claims studies are not a random or even representative sample, because only those cases in which a claim was filed and subsequently closed are included. Second, the incidence of various outcomes cannot be described because the total number of cases performed by insured providers is unknown.[130] For these two reasons, closed-claims data are not suitable for calculation of risk. However, analysis of closed-claims data can identify issues confronting practitioners and suggest methods for improving practice or making changes in systems.[130,133]

Other factors limit the conclusions that can be drawn from closed-claims data. Many cases that might be included in the database are eliminated because of inadequate documentation. In addition, closed-claim studies and quality assurance data categorize claims by type of injury rather than cause. Inadequate documentation and inability to determine the role played by various factors can limit the ability of reviewers to determine the cause of injury.[51] Finally, reviewers' knowledge of patient outcomes may bias their opinions on the quality of care provided.[129]

SUMMARY

Surgical positioning disturbs normal cardiovascular and respiratory physiology. These positional changes can be augmented by anesthetic techniques, patient pathophysiology, and body habitus. The implications of physiologic changes associated with each position should be considered when the procedure is planned, when positioning is initiated, and when the patient is returned to the supine posture. Anesthetists must recognize and anticipate both the publicized complications and the potential for damage inherent in each surgical position. Prevention is the best method for decreasing both the incidence of position-related injuries and the associated physical, psychological, and economic costs to the patient.

Airway Management

◆ *Jeremy S. Heiner and Mark H. Gabot*

CHAPTER 22

Effective airway management is a cornerstone of safe anesthesia practice, and it is an essential skill that every nurse anesthetist should possess. Nurse anesthetists are responsible for managing the airway in the operating room as well as other healthcare settings. The maintenance of ventilation and oxygenation are primary goals during airway management for both difficult and routine airways. The best preparation for the management of a difficult airway is through knowledgeable, effective, and regular management of normal airways. Therefore, nurse anesthetists should be familiar with appropriate decision-making strategies and methods for providing adequate ventilation during airway management. These strategies and methods pertain not only to routine (non-difficult) airways but also to anticipated difficult airways, unanticipated difficult intubations or ventilations, failed airways, patients at risk for aspiration of gastric contents, and patients who present with airway obstructions.

An understanding of airway anatomy and appropriate airway assessment techniques will allow the nurse anesthetist to develop a comprehensive airway management plan. Prior to any airway manipulation, the prudent nurse anesthetist should complete a thorough airway examination using multiple airway assessments. The results of these assessments will guide the airway management plan, which may involve placing an airway while the patient is awake or after the induction of anesthesia using a variety of airway adjuncts. Familiarization with the operation of the different airway adjuncts is important so that the nurse anesthetist may become comfortable with their use in a variety of airway management situations and to facilitate safe practices for the establishment of a protected airway.

Removal of an airway management device should be incorporated as part of the overall airway management plan. Nurse anesthetists should consider patient, surgical, and anesthetic risk factors before removing any airway adjunct. When considering an awake or anesthetized extubation technique, the removal of an airway is ultimately determined by the degree of the patient's ability to meet extubation criteria and maintain adequate spontaneous ventilation and oxygenation. Finally, the risk factors and complications of airway management should be understood in order to develop the most appropriate and safe airway management plan for the patient.

ANATOMY AND PHYSIOLOGY OF THE AIRWAY

The airway is divided into upper and lower sections. Anatomic structures above the level of the cricoid cartilage constitute the upper airway and include the nose, mouth, pharynx, hypopharynx, and larynx. Anatomic structures below the level of the cricoid cartilage constitute the lower airway and include trachea, bronchi, bronchioles, terminal bronchioles, respiratory bronchioles, and alveoli. This section reviews primary structures, innervation, blood supply, and normal and abnormal function of the upper airway structures.

Developmental Anatomy

Upper Respiratory Tract

Unlike the structures of the lower respiratory tract, the upper respiratory tract arises from bony structures of the head. Endochondral bone is preformed in cartilage. The bones form initially from the optic, olfactory, and otic capsules. These merge with the midline cartilaginous structures to form the embryologic vestiges of the ethmoid, sphenoid, the petrous portion of the temporal bone, and the base of the occipital bone. Direct ossification of membranous tissue known as the *mesenchyme* occurs during early embryologic development to form membranous bone. The membranous bones include the temporal, parietal, frontal, and portions of the occipital bones and the pharyngeal arches. The pharyngeal arches are complex structures also known as the *branchial arches* that extend anterior to posterior. Development of these structures begins at day 22 (week 4 after fertilization).[1]

Embryologically, there are six arches that develop from five structures. Arches one through four and six go on to develop the airway structures, and the fifth arch disappears with fetal development. The arches all contain a covering of tissue that will eventually become the nerves, muscles, and cartilage of the airway. These will become the tissues of the oropharynx, middle ear, the hyoid bone, and the laryngeal cartilages. Arch one becomes the jaws; arch two becomes the facial structures and the ears; arch three becomes the hyoid bone and structures of the upper pharynx; arches four and six become the structures of the larynx and the lower pharynx; and arch five disappears. The tongue is formed from the mesoderm of multiple arches. The anterior two thirds of the tongue is developed from the first arch. The mesoderm of the third and fourth arches comprises the posterior third of the tongue. Spaces found between the arches are known externally as *clefts* and internally as *pouches*. The cleft between the first two arches becomes the external auditory meatus. The internal pouch between the first and second arches forms the majority of the tympanic cavity and the eustachian tubes. The other clefts disappear as the fetus develops. The pouches contribute to the development of the glandular structures of the head and neck. The palatine tonsils arise from pouch two; the inferior parathyroid glands and the thymus come from pouch three; the superior parathyroid glands arise from pouch four, and the ultimobranchial structures arise from the inferior portion of pouch four.[1]

Nose. The nose and mouth are the external openings to the respiratory tree. The large surface area of the nasal mucosa warms and humidifies inspired air but also provides almost two thirds of the resistance to breathing. The nose is the primary passage by which air enters the lungs. Because of the surface area over the turbinates and the sinuses, the nasal passages are well suited for the task of humidification of air and primary filtration. As air passes through the nose, it meets the turbinates, which cause directional changes in the airflow. Branches of three arteries (e.g., the maxillary [sphenopalatine], ophthalmic, and facial [septal]) provide a rich supply of blood to the

nasal mucosa. The innervation of the nose is from the nasopalatine and ethmoidal branches of the facial nerve. These nerves also supply the nasopharynx, nasal septum, and palate. Sensory-nerve supply to the nasal mucosa is from the ophthalmic and maxillary divisions of the trigeminal nerve. Parasympathetic innervation arises from the seventh cranial nerve and pterygopalatine ganglion. Sympathetic innervation is derived from the superior cervical ganglion. Sympathetic stimulation results in vasoconstriction and shrinkage of the nasal tissue. Depression of the sympathetic nervous system, as occurs with general anesthesia, may cause engorgement of the nasal tissues, increasing the likelihood of bleeding with manipulation from nasal airways or endotracheal tubes.

Mouth. The oral cavity is separated from the nasal passages by the hard and soft palates. The hard palate is stationary and remains in the same position. The soft palate covers the posterior third to half of the oral cavity. The soft palate rises during eating to prevent food and liquids from passing from the mouth into the nose and thereby decreases the chance of aspiration. With age, obesity, and other conditions, this structure may stretch and become more movable. When an individual is asleep or paralyzed, as with general anesthesia, this structure can fall back against the nasal passages, blocking air movement and causing symptoms of sleep apnea. The tongue is a large muscular organ that fills most of the oral cavity and is involved in the tasting and ingestion of food. It relaxes when the individual is either asleep or paralyzed, which increases the potential for airway obstruction. The uvula protects the passageway from the oral cavity into the oropharynx. This pendulous piece of tissue extends from the posterior edge of the middle of the soft palate into the oral cavity. If swollen, enlarged, or injured, it can be a cause of airway obstruction. The tonsils are walnut-shaped structures that sit on both sides of the posterior opening of the oral cavity. They are partially buried in the soft tissue at the base of the tongue and are protected by the anterior and posterior tonsillar pillars.

Pharynx. The pharynx is divided into three compartments: the nasopharynx, oropharynx, and hypopharynx (laryngopharynx). The pharynx extends from the base of the skull to the level of the cricoid cartilage. The nasopharynx lies anterior to C1 and is bound superiorly by the base of the skull and inferiorly by the soft palate. The openings to the auditory (eustachian) tubes and the adenoids are found in the nasopharynx. Sensory innervation of the mucosa is derived from the maxillary division of the trigeminal nerve. The oropharynx lies at the C2 to C3 level and is bound superiorly by the soft palate and inferiorly by the epiglottis. It opens into the mouth anteriorly through the anterior and posterior tonsillar pillars. The hypopharynx lies posterior to the larynx and is bound by the superior border of the epiglottis and the inferior border of the cricoid cartilage at the C5 to C6 level. The upper esophageal sphincter lies at the lower edge of the hypopharynx and arises from the cricopharyngeus muscle. This muscle acts as a barrier to regurgitation in the conscious patient.

Numerous nerves supply motor and sensory fibers to the airway. The glossopharyngeal, vagus, and spinal accessory nerves share nuclei in the medulla and innervate all the muscles of the pharynx, larynx, and soft palate. Afferent (sensory) stimuli elicited when the posterior wall of the pharynx is touched are carried by the glossopharyngeal nerve to the medulla, where they synapse with nuclei of the vagus nerve and the cranial portion of the spinal accessory nerve. The efferent response returns primarily through the vagus nerve, resulting in the gag reflex as the muscles of the pharynx elevate and constrict.

Two branches of the vagus nerve innervate the hypopharynx: the superior laryngeal nerve and the recurrent laryngeal nerve (RLN) (Figure 22-1). The superior laryngeal nerve divides into the internal and external branches. The internal branch of the superior laryngeal nerve provides sensory input to the hypopharynx above the vocal folds (cords). The external branch provides motor function to the cricothyroid muscle of the larynx.

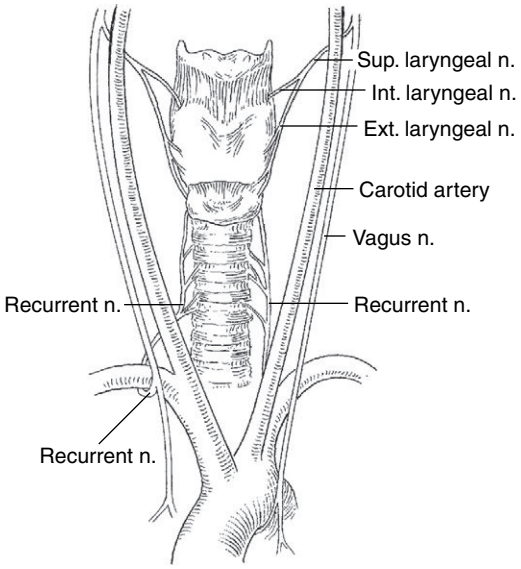

FIGURE **22-1** Anatomy of the right and left, superior and recurrent laryngeal nerves. *n,* Nerve.

The RLN provides sensory innervation to the subglottic area and the trachea. The recurrent laryngeal nerve is so named because it recurs (loops around) other structures. The right recurrent laryngeal nerve recurs around the brachiocephalic (innominate) artery, and the left recurrent laryngeal nerve loops around the aorta. Traction on either of these structures during thoracic surgery can cause injury to the RLN, causing hoarseness or stridor. The motor component of the RLN provides motor function to all the muscles of the larynx except the cricothyroid muscle.

The superior laryngeal nerve and the RLN may be damaged by surgery, neoplasms, and neck trauma. Dissecting aortic arch aneurysms and mitral stenosis place traction on the RLN, causing hoarseness. Unilateral injury to the RLN usually results in hoarseness but does not compromise respiratory status. The vocal cords compensate by shifting the midline toward the uninjured side. In the acute phase of bilateral injury to the RLN, unopposed tension and adduction of the vocal cords result in stridor, which may deteriorate into severe respiratory distress and possibly death. Patients with chronic injury develop compensatory mechanisms that allow for normal respiration and gruff or husky speech. Injury to the superior laryngeal nerve does not usually cause respiratory distress.

Larynx. The larynx begins with the epiglottis and extends to the cricoid cartilage. The larynx is composed of (1) three single cartilages (e.g., thyroid, cricoid, and epiglottis), (2) three paired cartilages (e.g., arytenoid, corniculate, and cuneiform), and (3) intrinsic and extrinsic muscles (Figures 22-2 and 22-3). These structures function in an intricate manner to provide (1) protection to the lower airway from aspiration, (2) patency between the hypopharynx and trachea, (3) protective gag and cough reflexes, and (4) phonation. In the adult, the larynx begins between the third and fourth cervical vertebrae and ends at the level of the sixth cervical vertebra (e.g., cricothyroid muscle). The anterior and lateral larynx is formed by the thyroid cartilage. Anteriorly the thyroid cartilage fuses and forms the thyroid notch. Posteriorly the thyroid cartilage rises toward the hyoid bone at the base of the

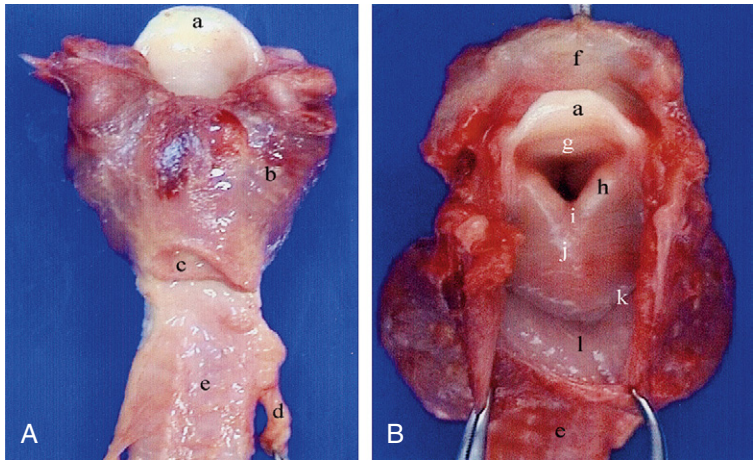

FIGURE **22-2** **A,** Posterior view of the pharyngolaryngotracheal region showing the close relationship between the pharynx, larynx, esophagus, and trachea. The inferior pharyngeal constrictor muscle (b) protects the posterior pharyngeal wall. The esophagus (c) is in close contact with the posterior tracheal wall (e). The laryngeal recurrent nerves (d) ascend in the tracheoesophageal groove. **B,** Superior and internal view of the pharynx and larynx showing the laryngeal cartilages covered by the mucosa (h, i, and j) in the anterior pharyngeal wall, the posterior pharyngeal wall (l), and the pyriform recess (k). (a) Epiglottis. (From Tarrazona V, Deslauriers J. Glottis and subglottis: a thoracic surgeon's perspective. *Thorac Surg Clin.* 2007;17:561-570.)

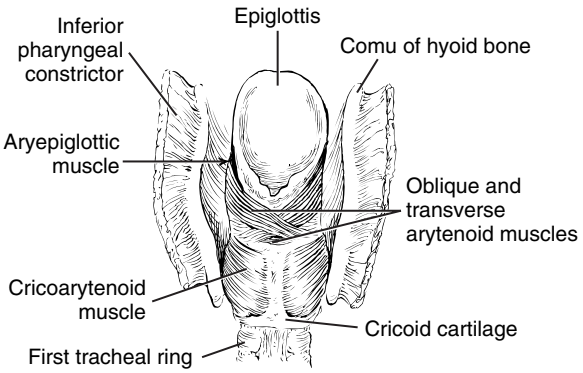

FIGURE **22-3** Posterior view of the larynx showing the laryngeal muscles.

tongue as the posterior cornu. The thyroid cartilage is connected to the hyoid bone by the thyrohyoid fascia and muscles of the larynx.

The posterior portion of the cricoid cartilage forms the posterior border of the larynx. Internal to the larynx are the epiglottis and three paired cartilages. The epiglottis exists as a single leaf-like cartilage. The epiglottis rests above the glottic opening where it closes the glottic aperture during swallowing. The superior vallecula is formed by the space between the epiglottis and the base of the tongue. The inferior vallecula is formed by the space between the inferior edge of the epiglottis and the true vocal cords.

The intrinsic muscles of the larynx control the tension of the vocal cords as well as the opening and closing of the glottis (Table 22-1). In contrast, the extrinsic muscles of the larynx connect the larynx, hyoid bone, and neighboring anatomic structures (Box 22-1). The primary function of the extrinsic muscles is to adjust the position of the trachea during phonation, breathing, and swallowing.

Blood supply to the larynx originates from the external carotid, which branches into the superior thyroid artery. The superior thyroid artery eventually gives rise to the superior laryngeal artery, which supplies blood to the supraglottic region of the larynx. The inferior laryngeal artery, a terminal branch of the inferior thyroid artery, supplies the infraglottic region of the larynx.

TABLE 22-1 Intrinsic Muscles of the Larynx

Role	Muscles Involved	Innervation	Main Function
Respiration	Posterior cricoarytenoids	Recurrent laryngeal nerve	Abduction of vocal cords
Phonation	Lateral cricoarytenoids	Recurrent laryngeal nerve	Adduction of vocal cords
	Lateral thyroarytenoids	Recurrent laryngeal nerve	Shortening and adduction of vocal cords
	Medial cricoarytenoids	Recurrent laryngeal nerve	Shortening of vocal cords
	Cricothyroids	External laryngeal nerve	Shortening and increasing tension of vocal cords
Sphincteric function	Interarytenoid		Closing of posterior commissure of the glottis
	Arytenoepiglottics		Closing of laryngeal vestibule

From Tarrazona V, Deslauriers J. Glottis and subglottis: a thoracic surgeon's perspective. *Thorac Surg Clin.* 2007;17(4):561-570.

Lower Respiratory Tract

As the fetus develops, the respiratory system evolves into complex developmental interactions between the endodermal-derived epithelium and the mesoderm. Both contribute to lung development. The lungs and airways develop through a process of five stages. These include the embryonic, pseudoglandular, canalicular, terminal sac phases, and maturation.[2]

During the embryonic phase, the endodermal respiratory diverticulum (laryngotracheal groove) develops. This occurs during week 4 through week 7. The laryngotracheal groove develops from the ventral surface of the foregut. During this period,

fibroblast growth factor (FGF-10) causes stimulation and proliferation of cells that will eventually express fibroblast homologous factor (FHF). As the laryngotracheal groove grows and develops, it becomes the primitive lung bud. By day 28, it has grown caudally to the splanchnic mesoderm. It divides into the right and left bronchial buds. This then progresses through the development and expression of the epithelial lining of the lower respiratory system. Cartilage, muscle, and connective tissue arise from the same tissues that form the smooth muscle of the blood vessels. The bronchopulmonary segments appear by day 42 of fetal development.

During the pseudoglandular stage, there is rapid growth and proliferation of the peripheral airways. This occurs during week 6 through week 16. Repeated branching of the distal ends of the epithelial tubes results in 16 or more generations of the bronchial tubes and the development of the terminal bronchioles. The airways are filled with liquid at this time. The cellular structure is more characterized by tall columnar epithelium.

The next phase of development is known as the *canalicular stage*. This occurs most often during week 16 and week 26. At this time, the airways widen and lengthen. The proliferation of this space will eventually become the large volume of air space in the expanded lung after birth. Terminal and respiratory bronchioles and terminal saccules develop. Cuboidal cells of the terminal sacs differentiate into alveolar type II cells. Secretion of surfactant begins at this time. Type II alveolar cells that are adjacent to a vessel flatten and differentiate into type I cells. As the type II and type I cells develop, vascularization appears. The vascularization is associated with the development of the respiratory bronchioles and the alveoli necessary for air exchange after birth. Along with other growth factors, vascular endothelial growth factor (VEGF) participates in the formation of blood vessels that will surround the alveoli. At the end of this phase, air exchange is possible although inefficient.

The terminal sac phase occurs during week 24 through week 36. Branching of the respiratory bud continues, and further development of the terminal buds is expressed as primitive alveoli. Capillaries begin to develop and proliferate around the terminal buds and proliferate at the same time as the primitive alveoli develop. Cells further differentiate throughout this period, and by week 26, a primitive blood-gas barrier has developed.

By the week 36, mature alveoli are seen. This requires FGF and platelet-derived growth factor (PDGF). Development of alveoli will continue for approximately 3 years after birth. A change in the relative relationship of parenchyma to total lung volume

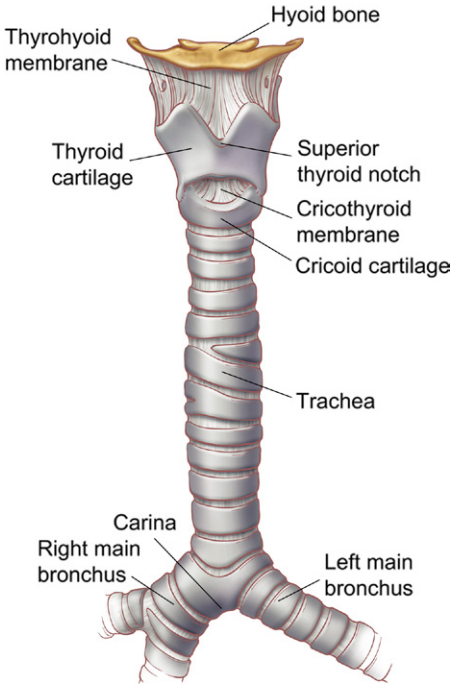

FIGURE **22-4** Principal features of the larynx and trachea. Anterior view. Tracheobronchial angles vary widely. The angle of the right mainstem bronchus is approximately 25 to 30 degrees, whereas the angle of the left mainstem bronchus is 45 degrees. (From Minnich DJ, Mathisen DJ. Anatomy of the trachea, carina, and bronchi. *Thorac Surg Clin*. 2007;17:571-585.)

contributes to lung growth until the second year of life. From the third year of life until adulthood, lung growth continues.[2]

Trachea. The trachea originates at the inferior border of the cricoid cartilage and extends to the carina (Figure 22-4). It is approximately 10 to 20 cm long in adults. The cricoid cartilage is the only cartilage of the trachea that is a complete ring. The remainder of the trachea is composed of 16 to 20 C-shaped cartilaginous rings. The posterior side of the trachea lacks cartilage, thereby accommodating the esophagus during the act of swallowing. The cartilaginous rings and plates continue until the bronchi reach 0.6 to 0.8 mm in size. At this point the cartilage disappears, and the bronchi are termed *bronchioles*. The function of the bronchi is to provide humidification and warming of inspired air as it passes to the alveoli.

The angle of bifurcation of the right mainstem bronchus is approximately 25 to 30 degrees. The bifurcation to the right upper lobe is approximately 2.5 cm from the carina. The angle of the left mainstem bronchus is 45 degrees. The left mainstem bronchus is approximately 5 cm long before it bifurcates into the left superior and inferior lobe bronchi.

The tracheobronchial trees receive sympathetic innervation from the first through fifth thoracic ganglia. Parasympathetic innervation is derived from branches of the vagus nerve. The carina is richly innervated, making it sensitive to sensory stimulation.

Diaphragm

The diaphragm arises from four structures: (1) septum transversum, (2) dorsal esophageal mesentery, (3) the pleuroperitoneal folds, and (4) the body-wall mesoderm. The diaphragm develops in the cephalic region and descends into the position between the abdominal and pleural cavity contents as the embryo develops. The nerve supply for the diaphragm arises from the cords of the third,

fourth, and fifth cervical nerves and travels with the descending diaphragmatic structure as the phrenic nerve. Owing to this process of descent, the phrenic nerves lie within the pericardium as the fetus matures and after birth. Because of the development of the diaphragm in the cephalic position and the merging of four structures, drugs that impair fetal development can result in many potential congenital deformities, including diaphragmatic hernia.[2]

AIRWAY EVALUATION

Evaluation of the airway is central to any airway management plan. A proper airway evaluation should be conducted in a thorough and systematic fashion on every patient to determine potential problems. A substantial amount of research has been conducted over the past 20 years and has identified individual airway assessment examinations as poor and unreliable predictors of difficulty. No single examination has emerged that has a consistently high sensitivity and specificity with minimal false-positive or false-negative reports.[3-6] Instead, many researchers have advocated for a more comprehensive airway management plan that involves the use of multiple airway tests.[6,7] Furthermore, an appropriate airway management plan considers the availability of equipment and personnel needed in the event that difficult airway management is encountered. Additional airway anatomy and physiology can be found in Chapters 26 and 38.

Multiple rating systems have been developed that assist in the assessment and recognition of a difficult airway.[8-11] However, no one rating system has proven to be superior over another. Instead, current recommendations concerning evaluation of the airway are to employ several assessments (Table 22-2). In order to recognize possible difficult airway conditions and to make "sensible airway management decisions," these assessments should be tailored to the patient, operative procedure, and situation (e.g., outside of the operating room [OR]).[6,12,13] It is generally agreed upon that an airway physical evaluation can improve the detection of a difficult airway. Then, after a thorough assessment, the anesthetist can formulate a comprehensive airway management plan that addresses the pertinent identified conditions.

Because of the lack of a system that reliably and consistently predicts airway difficulty with 100% certainty, some authors encourage a more focused approach on "ventilatability" rather than "intubatability."[14] Instead of focusing on conditions that affect the ability to intubate only, Murphy and Walls[15] advocated for a more all-encompassing assessment of the airway and described "four dimensions of difficulty" with airway management. The following four areas of airway management represent a modification of their "dimensions" and focus the airway assessment on conditions that could lead to difficulty with:

1. Bag mask ventilation
2. Direct laryngoscopy with direct tracheal intubation
3. Supraglottic airway ventilation
4. Invasive airway placement (e.g., needle cricothyrotomy, surgical cricothyrotomy)

A series of acronyms was developed to facilitate a thorough and systematic assessment of airway features (Box 22-2) that may lead to difficulty with hand mask, supraglottic device, endotracheal tube, and invasive airway ventilation and placement.[15]

Because a history of a difficult airway is a strong indication for current airway difficulties, an evaluation of the patient's anesthetic history should be included in the airway assessment.[16] A careful review of prior anesthetic records and information obtained directly from the patient or family members can reveal past difficulties and offer insight concerning specific techniques used to previously manage the patient's airway. Clues that may indicate a history of difficult airway management may include chipped or broken teeth, bruised lips, previous sore throat after general surgery, past postoperative dysphonia, a memory of tracheal intubation, an unexpected admission to an intensive care unit, or a pharyngeal, esophageal, or tracheal perforation.[16,17] Weight gain or loss can influence an airway and may not necessarily portray the same airway conditions as in the past. Furthermore, pathologies or conditions such as a tumor or hematoma, which may have previously caused difficulty, but have since been treated or removed, may not influence the current airway to the same degree they once did.

Multiple airway assessments exist that help the anesthetist predict difficulty with bag mask ventilation, direct laryngoscopy and tracheal intubation, supraglottic airway ventilation, and invasive airway placement (see Box 22-2). The following sections consider airway evaluations specific to each of the four areas of airway management.

TABLE 22-2 Components of the Preoperative Airway Physical Examination*

Airway Examination Component	Non-Reassuring Findings
Length of upper incisors	Relatively long
Relation of maxillary and mandibular incisors during normal jaw closure	Prominent "overbite" (maxillary incisors anterior to mandibular incisors)
Relation of maxillary and mandibular incisors during voluntary protrusion (ULBT)	Inability to protrude mandibular incisors anterior to maxillary incisors
Interincisor distance	Less than 3 cm
Visibility of uvula	Not visible when tongue is protruded with patient in sitting position (e.g., Mallampati class III or greater)
Shape of palate	Highly arched or very narrow
Compliance of mandibular space	Stiff, indurated, occupied by mass, or nonresilient
Thyromental distance	Less than three ordinary finger-breadths
Length of neck	Short
Thickness of neck	Thick
Range of motion of head and neck	Patient cannot touch tip of chin to chest or patient cannot extend neck

From Berkow LC. Strategies for airway management. *Best Pract Res Clin Anaesthesiol.* 2004;18(4):531-548.
*This table displays some findings of the airway physical examination that may suggest the presence of a difficult intubation. The decision to examine some or all of the airway components shown in this table depends on the clinical context and judgment of the practitioner. The table is not intended as a mandatory or exhaustive list of the components of an airway examination. The order of presentation in this table follows the "line of sight" that occurs during conventional oral laryngoscopy.
ULBT, Upper lip bite test.

Bag Mask Ventilation Assessment

Every anesthetist needs to possess adequate bag mask ventilation (BMV) skills. An adequate seal between the facemask and patient's face is imperative. Proper BMV can be achieved by placing the left thumb and index finger around the body of the facemask at both the mask bridge and chin curve, while compressing the left side of the mask onto the face with the palm of the left hand (Figure 22-5).

The middle and ring fingers can then be placed on the bony part of the mandible to help compress the mask to the patient's face and to raise the chin. The fifth finger can be placed at the angle of the mandible to provide an anterior jaw-thrusting maneuver. Mask retaining straps can be placed behind the patient's head and then be connected to the collar of the mask to apply pressure at various angles and promote a better mask seal.

If bag mask ventilation is believed to be inadequate, then a series of steps can be performed (Box 22-3) to facilitate ventilation. First, the patient's head and neck can be repositioned into a sniffing position. Second, if the tongue or airway soft tissue is thought to be the cause of obstruction, then the placement of an oropharyngeal airway (OPA) may help bypass the obstruction. However, the placement of an OPA can be considered prior to any attempt at BMV. Third, if BMV continues to remain inadequate, then the anesthetist should perform two-handed mask ventilation by placing both thumbs on either side of the facemask bridge with both index fingers on either side of the mask chin curve on the body of the mask. The middle fingers can then be placed on either side of the mandible at the chin, the ring fingers on the bony part of the mandible, and the fifth fingers on each angle of the mandible to provide a jaw-thrust while maintaining a secure mask seal. A second anesthetist or assistant can then compress the anesthesia bag for ventilation (Figure 22-6). If ventilation continues to remain inadequate, then a supraglottic airway device may be placed while the decision to awaken the patient is considered. In the event that all of these maneuvers fail, then invasive airway ventilation should be considered.

BOX **22-2**

Four Areas of Airway Management with Factors Associated with Difficulty

Bag Mask Ventilation

Mask seal impeded by beards, altered anatomy, or nasogastric tubes
Obstruction of the upper or lower airway
Obesity with redundant upper airway soft tissue and greater chest and abdominal mass compressing the lungs
Age greater than 55 related to loss of upper airway tissue elasticity
No teeth, leading to improper facial structure for the bag mask
Stiff lungs (e.g., increases in airway resistance or decreases in pulmonary compliance)
Sleep apnea or snoring

Direct Laryngoscopy with Tracheal Intubation

Look externally (if it looks difficult it probably is)
Evaluate the 3-3-2 rule*
Mallampati score (classes III and IV indicating increased difficulty)
Obstruction of the upper airway
Obesity with increased neck circumference and redundant soft tissue
Neck mobility that is impaired by disease of immobilization

Supraglottic Device Placement and Ventilation

Restricted mouth opening
Obstruction of the upper airway
Distorted airway preventing seal
Stiff lungs (e.g., increases in airway resistance or decreases in pulmonary compliance)

Invasive Airway Placement

Distortion of neck anatomy (e.g., hematoma, infection, abscess, tumor, scarring from radiation)
Obesity or a short neck limiting cricothyroid identification
Trauma in or around the cricothyroid area
Impediments causing limited access to the neck (e.g., halo device, fixed flexion abnormality)
Surgery causing limited access to anatomic landmarks

*3-3-2 rule = 3 fingerbreadths between incisors; 3 fingerbreadths between tip of the chin (mentum) and chin-neck junction (hyoid bone); 2 fingerbreadths between chin-neck junction (hyoid bone) and thyroid notch.

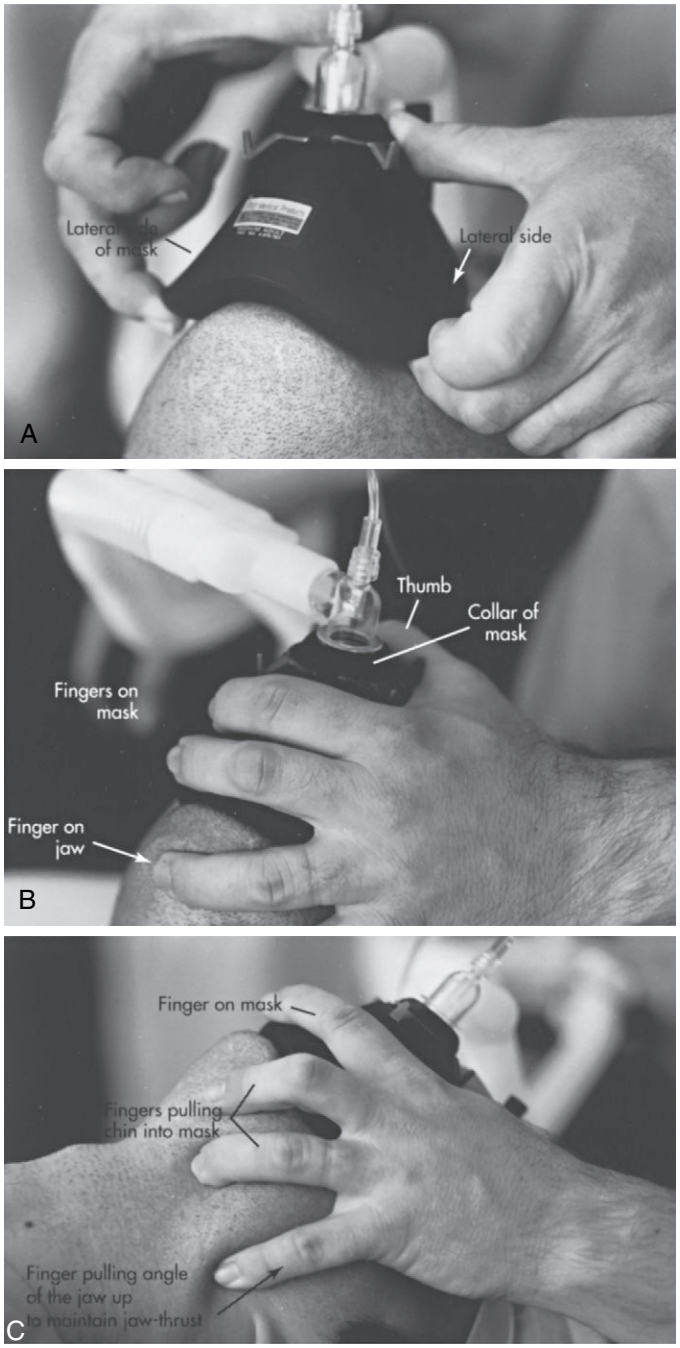

FIGURE **22-5** Proper hand placement for bag mask ventilation. **A,** Application of mask to face. **B,** Standard one-handed grip of mask to face. **C,** One-handed mask grip with jaw thrust. (From Hagberg CA. *Benumof's Airway Management*. 2nd ed. Philadelphia: Mosby; 2007.)

The incidence of difficult BMV has been described as being between 0.9% and 7.8%, and the incidence of impossible BMV as 0.15%.[18-22] Difficulty with BMV can result from problems in establishing an appropriate mask seal (such as with the presence of a beard). Inadequate ventilation during BMV is evidenced by (1) minimal or no chest movement; (2) inadequate or deficient exhaled carbon dioxide (e.g., lack of condensation and spirometic reading); (3) reduced or absent breath sounds; and (4) a decreasing oxygen saturation (e.g., less than 92%).[12,19] If difficulty is believed to be a possibility with BMV, positioning can be improved by elevating the shoulders, neck, and head, which is known as "ramping" the patient (Figure 22-7). Multiple factors have been identified as predictors for difficulty with BMV (see Box 22-2); these include mask seal impediments, upper airway obstructions, obesity, elderly patients, Mallampati scores of III or IV, a short thyromental distance, snoring, and poor lung compliance.[18,19,21,22]

Mask seal impediments such as facial hair, altered facial anatomy, lack of teeth causing the face to cave inward, or a nasogastric tube can cause air leakage out of the mask and prevent adequate positive pressure ventilation. Some of these factors can be modified, such as shaving the patient's beard, delaying removal of dentures, and removing the nasogastric tube. Although shaving a beard may be undesirable and removal of a gastric tube may cause a buildup of gastric secretions in the stomach, these interventions do allow for a better mask seal and more effective positive pressure ventilation upon induction of anesthesia.

BOX 22-3

Proper Sequence for Bag Mask Ventilation When Difficulty Is Encountered

1. Assure proper positioning of the patient.
2. Attempt ventilation with one hand (can consider use of mask strap on opposite side of mask to improve mask seal).
3. Reposition the head into a sniffing position.
4. Place oropharyngeal airway (may consider earlier placement).
5. Proceed with two-hand mask ventilation.
6. Consider placement of a supraglottic device, awaken patient, or proceed with invasive airway access if ventilation becomes impossible.

Obstruction may occur in the upper or lower airway and can severely limit the effectiveness of BMV. Upper airway obstructions should be considered an emergency and managed with extreme care because of the potential to become total airway obstructions. The hallmark signs of an upper airway obstruction in the unanesthetized patient include a hoarse or muffled voice, difficulty swallowing secretions, stridor, and dyspnea. Stridor and dyspnea are ominous signs of severe respiratory obstruction and indicate a 50% decrease in circumference from normal or a diameter reduced to 4.5 mm or less.[15] There are several potential causes of an upper airway obstruction (Boxes 22-4 and 22-5). The management of these conditions is discussed later in this chapter under "Management of the Difficult and Failed Airway." It is important to treat the airway with care because these conditions have the potential to severely impair ventilation and oxygenation, as well as cause difficulty with laryngoscopy and tracheal intubation.

Lower airway obstructions typically manifest with high peak airway pressures, low tidal volumes, and impaired ventilation. These conditions can be caused by pathologic, congenital, or acquired causes (see Boxes 22-4 and 22-5) and should be managed in a way that provides optimal ventilation and oxygenation for the patient.

Obstructive sleep apnea (OSA) and snoring were recognized as predictors of difficult mask ventilation.[18,19,21] Studies have revealed that patients with a history of snoring and sleep apnea are more likely to have difficulty with BMV, and more often these patients require two practitioners to effectively manage the airway.[18,19] An obstructive tongue, as well as posterior oropharyngeal soft tissue collapse, is thought to be the cause of difficulty and obstruction.[23] Patients with a history of OSA should be encouraged to bring their positive pressure device (e.g., CPAP [continuous positive airway pressure] or BiPAP [biphasic positive airway pressure] machine) from home to the hospital for use in the postanesthesia care unit (PACU).

Significant obesity (body mass index greater than 30 kg/m^2) has been identified as a potential risk factor for difficult BMV.[18,19,22] Difficulty with BMV may be the result of excessive weight from both chest and abdominal tissues causing compression on the lungs, especially in the supine position. Pregnant patients in the third trimester may also be difficult to ventilate because the gravid uterus can compress the lungs, creating elevated airway

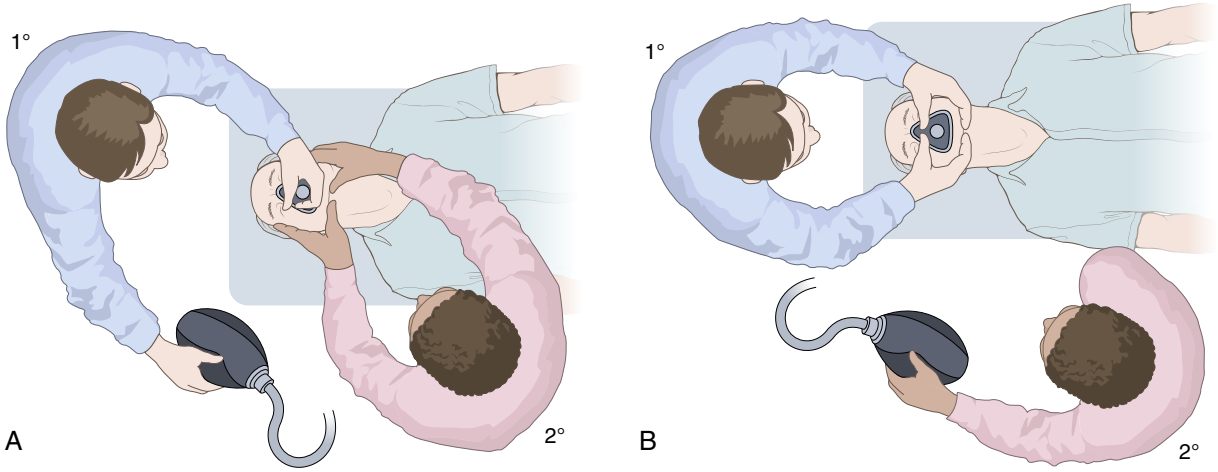

FIGURE 22-6 **A,** Two-person mask ventilation effort with second provider providing a jaw thrust. **B,** Two-person mask ventilation effort with primary provider maintaining a mask seal and performing a jaw thrust while second provider squeezes the anesthesia bag. (Redrawn in Miller RD, Pardo M. *Basics of Anesthesia*. 6th ed. Philadelphia: Saunders; 2011. Originally from Benumof JL. *Airway Management: Principles and Practice*. St. Louis: Mosby; 1996.)

resistance. Furthermore, obese patients tend to have decreased functional residual capacities (FRCs), which predisposes them to desaturate more quickly, even after appropriate preoxygenation periods. One study reported that the time to reach a preoxygenation end-tidal oxygen value of 85% or greater was similar in both obese and lean patients. However, the authors observed that apnea-induced desaturation occurred more quickly, and hypoxemia was more profound, in the obese population.[24] These results should be considered in the overall airway management plan because any time delay after the induction of anesthesia in the obese population may result in significant hypoxemia.

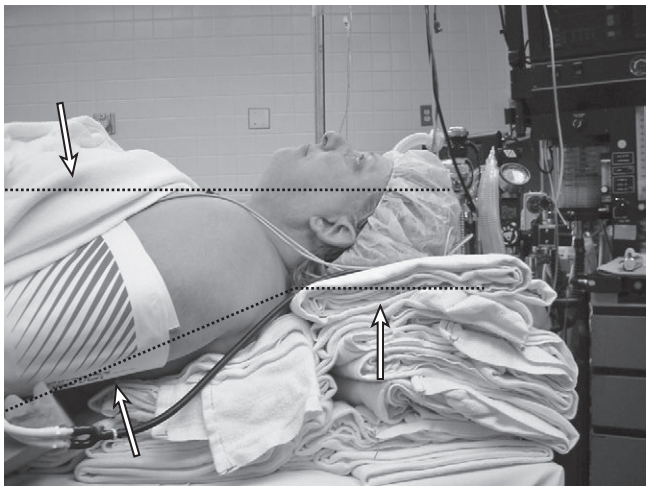

FIGURE **22-7** Example of a ramp created using blankets to improve positioning. Optimal positioning is observed when an imaginary horizontal line can be drawn from the sternal notch and extending just anterior to the ear on the face. Hemorrhage
Tumors or lesions

Bronchial and Alveolar
Acute respiratory distress syndrome (ARDS)
Aspiration pneumonia
Asthma
Bronchospasm
Chronic obstructive pulmonary disease (COPD)
Pulmonary edema

Extrapulmonary
Morbid obesity (BMI greater than 30 kg/m^2)
Pregnancy
Trauma

Redundant tissue of the upper airway may be another factor that leads to difficulty with BMV, because excessive soft tissue in the oropharyngeal and pharyngeal cavities can cause resistance to airflow during positive pressure ventilation.[15] Therefore ideal positioning (e.g., ramping the patient), adequate preoxygenation, a secondary airway management plan with alternative airway adjuncts readily available, and assistance from other anesthesia professionals should be considered prior to the induction of anesthesia in the obese patient.

Researchers have also identified obesity as a risk factor for difficult laryngoscopy and tracheal intubation, because excessive upper airway soft tissue may inhibit direct visualization of the glottis.[18,24] However, some researchers concluded that an increased body mass index (greater than 35 kg/m^2) had no effect on difficulty with laryngoscopy, leaving this to be a somewhat controversial subject.[25,26] Nevertheless, any prudent practitioner should consider multiple patient characteristics when evaluating difficulty.

Advanced age (greater than 55 years) is associated with difficult BMV.[18,19] Older patients may have decreased tone in the upper airway muscles and tissues as a result of inelastic or aged tissue. In addition, elderly patients commonly have loose teeth, missing teeth, or are edentulous; all of which can cause the airway soft tissue to sink inward. These factors contribute to a poor mask seal and the inability to perform adequate BMV. Anesthesia practitioners may consider leaving dentures in place (as long as they are easily removable) in the edentulous patient prior to instrumentation of the airway. This may be done to conserve the facial structure and facilitate a better mask seal.

Decreases in lung compliance can contribute to ineffective BMV because of the inability to effectively move ventilated gases into the alveoli. Conditions such as bronchospasm, pulmonary edema, acute respiratory distress syndrome, or pneumonia (see Box 22-4) can cause peak airway pressures to rise and compliance to decrease, resulting in ineffective BMV and poor oxygenation of the patient. If severe enough, these conditions may necessitate an abortion of the surgical procedure, and they require tracheal intubation and/or intensive care monitoring. Therefore it is important for the anesthetist to recognize potential upper and lower airway problems and realize the time limitations that exist in the event that BMV becomes inadequate.

Direct Laryngoscopy and Tracheal Intubation Assessment

Direct laryngoscopy (DL) and direct tracheal intubation (DTI) are two different procedures. Direct laryngoscopy is the process of airway instrumentation with a laryngoscope in order to acquire a

direct line of sight with the laryngeal opening. In contrast, DTI is the process of placing an endotracheal tube into the trachea proximal to the carina. Usually, when anesthesia professionals perform a DL, it is with the intent of completing DTI, and as a result these two procedures are generally performed together in sequence. Airway assessments specific to both DL and DTI are therefore discussed together in this section.

A primary goal during airway evaluation is to determine factors that predispose a patient to difficulty with DL and DTI. The distinction between these two procedures has not always been clear in the literature; however, the incidence of difficult tracheal intubation has been described to be between 1.5% and 8.5%, and the incidence of failed tracheal intubation has been estimated to be between 0.3% and 0.5%.[6,27-29] As described earlier, although individual airway assessments have demonstrated a decreased ability to reliably and consistently predict difficulty, a prudent practitioner should error on the side of patient safety by using a combination of assessment techniques when determining an airway is potentially difficult.

Shiga et al.[6] conducted a meta-analysis focused on determining the predictors of difficult intubation. They reported that when used alone, current airway evaluation methods had poor predictive values, and they concluded that the combination of Mallampati classification and thyromental distance (TMD) most accurately predicted difficult intubation.

Merah et al.[27] attempted to predict difficult visualization of the larynx in the West African population using a combination of airway predictive indices. They reported that the combination of modified Mallampati test, thyromental distance, and inter-incisor gap was the best predictor of difficult laryngoscopy. Some or all of these predictors have also been identified in Caucasian, Asian, and obstetric populations.[30-33] Prudent airway management aims at predicting the possibility of difficulty to formulate primary, secondary, and even tertiary airway management plans. If an airway turns out to be less difficult than previously anticipated, then the decision to error on the side of patient safety is obviously the better choice.

As stated earlier, there is no single airway assessment that reliably predicts difficulty with DL and DTI all of the time, and there are a myriad of airway evaluation techniques. A significant concern when performing the different airway assessments is the variation in measurements.[6] Inter-practitioner variability in the performance of airway evaluation techniques alters the validity of findings between studies. Therefore it is important that anesthesia practitioners remain consistent and perform the different airway assessments the way they were intended every time. The most commonly cited airway assessments used in combination to evaluate the airway include: (1) the modified Mallampati classification; (2) thyromental distance; (3) inter-incisor gap distance; (4) atlanto-occipital joint mobility and cervical range of motion; (5) mandibular protrusion test; (6) evaluation for obstruction of the upper airway; and (7) obesity (specifically neck circumference).

Mallampati Classification

The Mallampati classification is a commonly used technique of assessing mouth opening, size of the tongue, size of the oral pharynx, and assessment of posterior oropharyngeal structures. First developed by Rao Mallampati, this classification originally described three classes. Later Samsoon and Young[35] added a fourth class, which is now often referred to as the modified Mallampati test (MMT) (Figure 22-8 and Table 22-3). When performing the assessment, the patient is instructed to sit upright, extend the neck, open the mouth as much as possible, protrude the tongue, and avoid phonation. The MMT uses a classification system to evaluate tongue size relative to the oropharyngeal space, and is categorized as follows:

- *Class I:* Full visualization of the entire oropharynx including soft palate, uvula, fauces (archway between oral and pharyngeal cavities), and tonsillar pillars
- *Class II:* Visualization of the soft palate, fauces, and uvula
- *Class III:* Visualization of the soft palate and base of the uvula

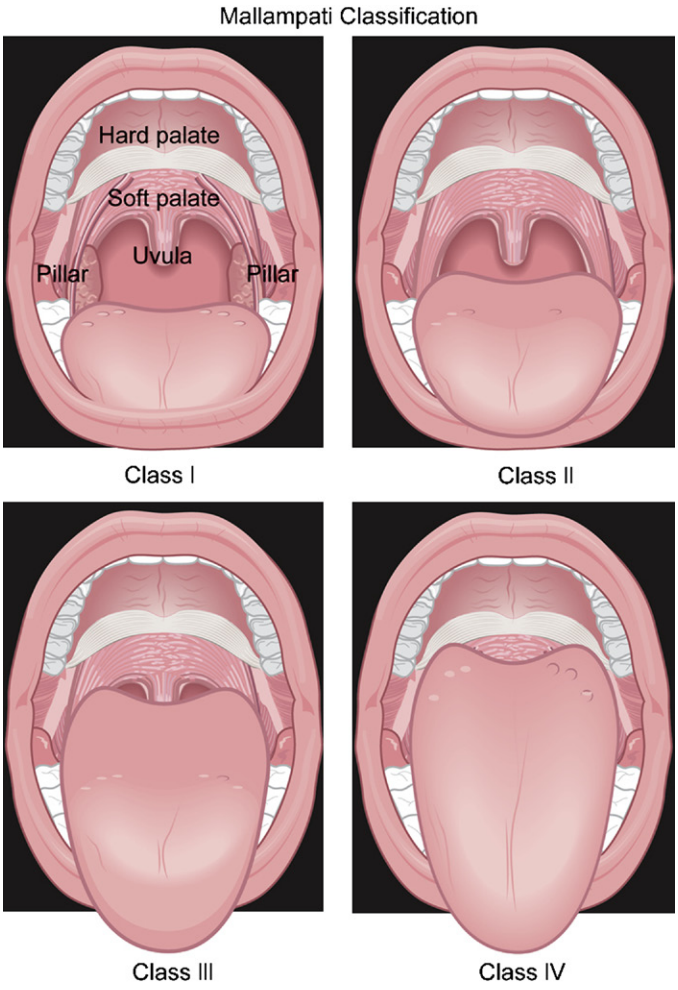

FIGURE 22-8 Modified Mallampati classification. Performed with the patient sitting up and maximally protruding his/her tongue; visibility of the soft palate, fauces, tonsillar pillars, and uvula were noted. Class I described full visualization of all structures. Class II allowed visualization of the soft palate, faucial pillars, and a portion of the uvula. Class III allowed visualization of the soft palate and base of the uvula. With class IV, only the hard palate is visible. (From Cleveland Clinic Center for Medical Art & Photography © 2009-2012. Reprinted with permission. All rights reserved.)

TABLE 22-3 Mallampati Airway Classification

Classification	Description of Visualized Structures
1	Soft palate, faucial pillars, entire uvula
2	Soft palate, faucial pillars, and a portion of the uvula
3	Soft palate and base of the uvula
4	Hard palate visible only

- *Class IV:* Visualization of the hard palate only

Ezri et al.[36] suggested adding a class "zero" to the MMT, which is the ability to see any part of the epiglottis on mouth opening and tongue protrusion, and found a 1.2% incidence. However, most researchers, and likely most clinical practitioners, use the Samsoon and Young I to IV modification of Mallampati's classification.[35]

Evaluations of the MMT have shown some correlations with difficulty when either class III or IV is measured.[34,36] However, by itself the MMT has been unreliable at consistently predicting the presence or absence of a difficult airway.[37,38] Furthermore, anesthesia practitioner variability in the administration of the MMT, years of experience, and subjectivity of assessment can result in the assessment of different classifications between similar patients. However, when used in combination with other airway assessments, the MMT can help increase the predictive ability of both laryngoscopic and intubation difficulties. For example, the combination of increased Mallampati classification levels of III or IV and an increased neck circumference (greater than 43 cm measured at the thyroid cartilage) were predictors of intubation problems.[13,25] Other researchers identified the combination of increased Mallampati classifications, decreased thyromental distances, and limited inter-incisor openings as strong predictors of both laryngoscopic and intubation troubles.[6,27,32]

Cormack and Lehane Grading System

An objective scoring system that is frequently used by researchers to describe laryngoscopic difficulty with intubation is the Cormack and Lehane grading system. The goal of laryngoscopy is to attain the best possible view of the vocal cords and glottic opening. While performing DL, and prior to DTI, different views of the pharyngeal structures and the glottic opening may be observed. These views can be graded using the Cormack and Lehane grading scale (Figure 22-9). This scale offers an objective assessment of the glottic opening, or lack thereof, during laryngoscopy using direct line of site and is rated as follows[39]:

- *Grade I:* Most or full view of the glottic opening
- *Grade II:* Only the posterior portion of the glottic opening can be visualized; anterior commissure not seen
- *Grade III:* Only the epiglottis can be visualized; no portion of the glottic opening can be seen
- *Grade IV:* Epiglottis cannot be seen; only view is of the soft palate

Cormack and Lehane grades I and II are generally associated with easier intubations, whereas grades III and IV correspond with higher degrees of intubation difficulty.[39]

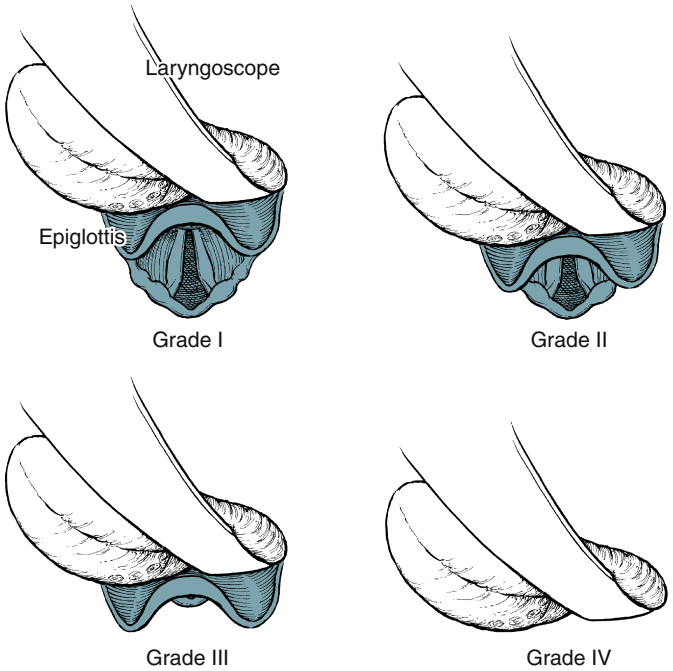

FIGURE **22-9** Cormack and Lehane grading system. Grade I is visualization of the entire glottic opening. Grade II is visualization of only the posterior portion of the glottic opening. Grade III is visualization of the epiglottis only. Grade IV is visualization of the soft palate only. (From Cormack RS, Lehane J. Difficult tracheal intubation in obstetrics. *Anaesthesia*. 1984;39(11):1105-1111.)

Thyromental Distance

The thyromental distance (TMD) is a measurement of the thyromental space. This space is an available pliable compartment, directly anterior to the larynx, where the tongue can be displaced during direct laryngoscopy to improve direct line of site with the glottic opening. The tongue is a noncompressible structure, but is malleable and therefore can be moved to other locations within the oropharyngeal and pharyngeal compartments. The thyromental space is bordered laterally by the neck, superiorly by the mentum, and inferiorly by the hyoid bone, which is semifixed.

The TMD is measured from the thyroid notch to the lower border of the mentum (at the chin) when the patient's head is extended and mouth is closed (Figure 22-10, *B*). A TMD less than 6 cm, or "3" ordinary fingerbreadths, is associated with a higher incidence of difficult intubation. Research has indicated that the thyromental space should accommodate most any tongue size, but that a small space would only facilitate a relatively small tongue.[31,40] Furthermore, if the thyromental space has been rendered noncompliant from radiation or pathologic factors (e.g., tumors), then the tongue may not be able to properly fit, causing it to protrude into the pharyngeal space. A malplaced tongue that does not fit into the thyromental space can obstruct the direct line of site with the glottic opening during laryngoscopy.

A condition that does not allow the tongue to fit into the thyromental space is known as mandibular hypoplasia. Patients with mandibular hypoplasia (e.g., TMD less than three fingerbreadths)

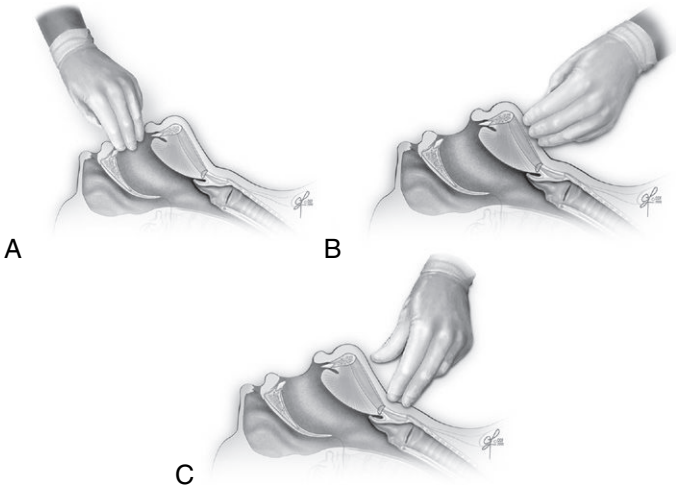

FIGURE **22-10** **A,** Oral access: mouth opening (three fingerbreadths) between upper and lower teeth. **B,** Mentum and hyoid bone, otherwise known as the thyromental distance (three fingerbreadths). **C,** Thyroid notch and hyoid bone (two fingerbreadths). may present with both a difficult laryngoscopic view and a difficult intubation. This is because the tongue cannot be positioned into the small submandibular space. Furthermore, the larynx may be tucked underneath the tongue or be positioned relatively anterior to the base of the tongue in the pharyngeal space, causing difficulty with laryngoscopic views. This condition is commonly called an "anterior larynx," and unless the tongue can be pulled anterior away from the pharyngeal space, little can be done to improve the direct line of site view.

The assessment of a long TMD (greater than 9 cm) may also indicate a potentially difficult airway. The indication for difficulty is due to a large hypopharyngeal tongue, caudal larynx, and longer mandibulohyoid distance (MHD). The MHD measures the vertical distance from the angle of the mandible to the hyoid bone and is usually assessed by radiograph. A long TMD and MHD may position the glottic opening caudally in the neck and beyond the visual horizon. If the larynx is more caudally situated in the pharyngeal compartment, then the tongue is also likely to be positioned lower because the tongue muscle is hinged to the hyoid bone.[41,42] This can lead to both a greater distance to the glottic opening with a laryngoscope and an obstructed view caused by a greater amount of tongue mass in the hypopharyngeal space. In addition, a history of sleep apnea and snoring can provide further evidence of a possible hypopharyngeal tongue, which has been shown to cause difficulty with both mask ventilation and intubation.[42,43] Again, like other airway assessment tests, researchers have found limited predictability when the TMD test was used by itself, and therefore recommend that it be used as part of a multivariable airway assessment.[9,25,29]

The 3-3-2 rule has been described by some authors as a nonscientifically based test to ensure that upper airway geometry is adequately assessed.[44] The 3-3-2 rule is an assessment that evaluates various airway proportions using finger breadths as a measurement (see Figure 22-10). It is a combination of different geometric dimensions that relate mouth opening and the size of the mandibular space to the position of the larynx in the neck.[11,15] The first "3" estimates oral access (inter-incisor gap distance), which should accommodate at least three fingerbreadths. The second "3" assesses the mandibular length (TMD) from the tip of the mentum to the mandible-neck junction and gauges the ability of the tongue to displace within the submandibular space during laryngoscopy. The "2" is a modification of the MHD, which is a nonradiographic measurement from the mandible-neck junction to the tip of the thyroid notch, and assesses the position of the larynx (glottic opening) in relation to the base of the tongue. More than two fingerbreadths indicates that the larynx may be positioned too far down the neck and could be difficult to visualize. Less than two fingerbreadths indicates that the larynx may be tucked under the base of the tongue, which would be indicative of an anterior larynx. This combination of airway assessments allows the anesthetist to perform multiple airway measurements in a rapid and sequential manner.

It may be worth mentioning the sternomental distance (SMD), although it has been described as a poor predictor (even when used as part of a multivariable assessment) of airway management difficulty. The SMD is measured from the sternal notch to the lower border of the mentum at the chin with the head extended and the mouth closed. Normal SMD is greater than 12 cm. Distances of less than 12.5 cm have been described as a preoperative predictor for difficult DTI.[31,45]

Inter-Incisor Gap

As discussed above, the inter-incisor gap is important to assess when performing a DL because mouth opening can affect the ability to create a direct line of sight with the laryngeal opening.[16] If mouth opening is narrow, it may be problematic to introduce the laryngoscope blade's 2-cm flange along with the endotracheal tube (ETT) into the mouth while maintaining good visualization of the vocal cords. An adequate inter-incisor opening is at least 2 to 3 average fingerbreadths, or a minimum of 4 cm.[46] An increase in maxillary incisor length can reduce the inter-incisor gap and create a sharper angle between the oral and glottic openings. Furthermore, prominent incisors or "buck teeth" increase the risk of dental damage from the metal laryngoscope blade. Finally, loose or awkward teeth can either impede the placement of a laryngoscope blade and ETT or create an obstruction in the event a tooth is dislodged and falls into the laryngeal opening or trachea.

Atlanto-Occipital Joint Mobility

The full range of neck flexion and extension varies from 90 to 165 degrees and decreases approximately 20% between ages 16 and 75 years. The atlanto-occipital joint provides the highest degree of mobility in the neck with a normal head extension of up to 35 degrees. Proper atlanto-occipital joint mobility is required for an adequate sniffing position. The sniffing position is important because it helps to improve laryngoscopic views by promoting displacement of the tongue by better aligning the oral, pharyngeal, and laryngeal axes (Figure 22-11). Evaluation of atlanto-occipital joint extension is conducted with the patient seated upright in a neutral face forward position; the patient is then asked to lift the head back with chin up as far as possible. When extension is reduced to 23 degrees, visualization may become difficult.[47] If the patient demonstrates substantial or complete immobility of the atlanto-occipital joint, then significant laryngoscopic compromise should be anticipated. Furthermore, cervical spine diseases such as cervical pathology (e.g., degenerative disease, rheumatic disease, neurologic pathology, trauma, or previous surgical intervention) or spinal abnormalities such as with Down syndrome may lead to difficult laryngoscopy and difficult airway management in general.

Mandibular Protrusion Test

The mandibular protrusion test, also known as the upper lip bite test (ULBT), is an evaluation technique that demonstrates the patient's ability to extend the mandibular incisors anterior past the maxillary incisors. The purpose of this airway test is to assess the mobility of the patient's temporomandibular joint function and forward subluxation of the jaw and to note the patient's maxillary incisor length (e.g., presence of buck teeth). The presence of these indicators can lead to problematic oral airway placement, noneffective relief of soft tissue obstruction from poor mandibular movement, difficulty introducing the laryngoscope blade into the mouth, and an obstructive view of the glottic opening caused by maldisplacement of the tongue. Difficulty with laryngoscopy arises when the patient is unable to protrude the mandibular incisors anterior past the maxillary incisors (Figure 22-12). The test has three classifications[47]:

- *Class I:* Patient can protrude the lower incisors anterior past the upper incisors and can bite the upper lip above the vermilion border (line where the lip meets the facial skin)
- *Class II:* Patient can move the lower incisors in line with the upper incisors and bite the upper lip below the vermilion border, but cannot protrude them beyond
- *Class III:* Lower incisors cannot be moved in line with the upper incisors and cannot bite the upper lip

Assessment of an ULBT class III indicates a potential difficult laryngoscopic view, whereas class I indicates a good view using conventional laryngoscopy.[48]

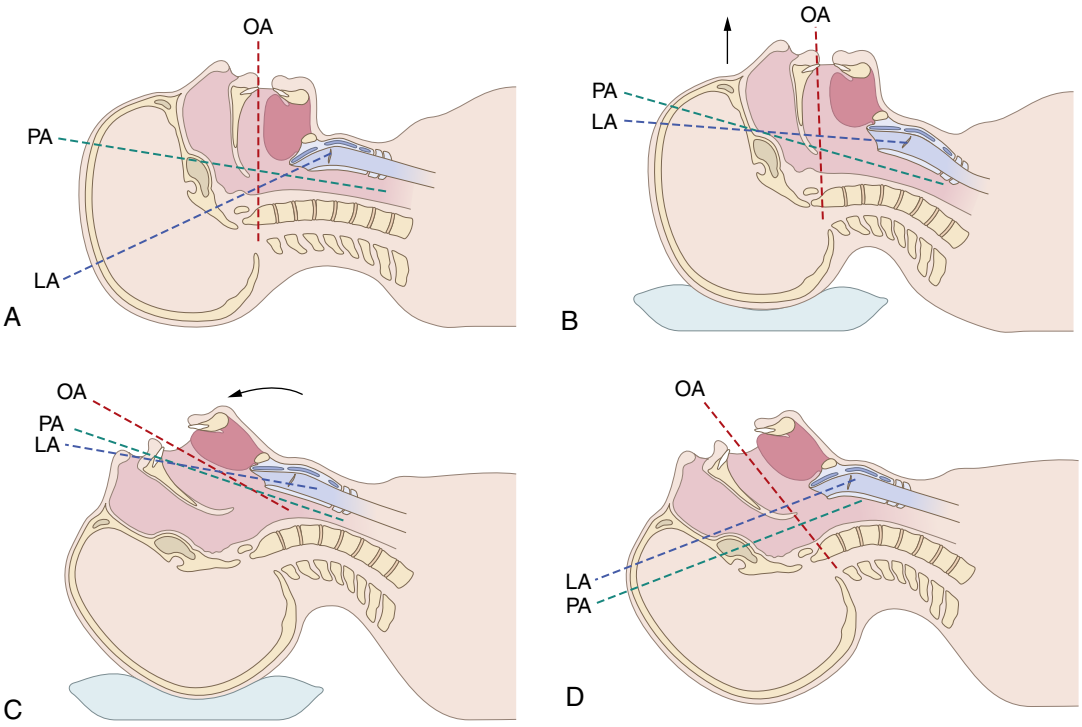

FIGURE **22-11** Oral axis (OA), pharyngeal axis (PA), and laryngeal axis (LA) for intubation. **A,** Nonaligned position. **B,** Head resting on a pad causes flexion of the neck and aligns the PA and LA. **C,** Head resting on pad causes flexion of the neck, with neck extension into sniffing position aligns the OA, PA, and LA. **D,** Extension of the neck without head elevation aligns PA and LA, but not the OA. (From Miller RD, Pardo MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Saunders; 2011.)

The ULBT was found to be a valuable assessment tool for the prediction of difficult ventilation when used in combination with other assessment techniques such as increased neck circumference and a history of snoring.[49] Furthermore, the ULBT has shown to be useful in the assessment of temporomandibular joint function and the prediction of difficult laryngoscopies when used in combination with the modified Mallampati classification.[5,50] However, the ULBT has shown to be an unreliable assessment technique when used in the edentulous population and has demonstrated poor predictability when used as a single screening test for the assessment of laryngoscopic difficulty.[51]

Supraglottic Airway Assessment

Supraglottic airway (SGA) ventilation may be the primary means of managing an airway, or it can be used for rescue ventilation in the event that facemask ventilation is difficult or fails. Similar predictors related to difficulty with mask ventilation, laryngoscopy, and intubation can also indicate difficulty in placing and then ventilating with a SGA device. These predictors include restrictive mouth opening, a distortion in upper airway anatomy, and both upper and lower airway obstruction (see Box 22-2).

The inter-incisor gap is an important assessment to consider when introducing any airway adjuncts into the mouth. As identified earlier, an assessment of less than three fingerbreadths or less than 4 cm indicates a restricted oral access that can make some SGA devices difficult to introduce into the mouth.[16] Furthermore, some researchers have indicated that reductions in atlanto-occipital joint movement from conditions such as ankylosing spondylitis and rheumatoid arthritis may cause difficulty with some SGA placements such as the laryngeal mask airway (LMA).[52,53]

Obstruction at the level of the larynx, trachea, or below can reduce or completely block ventilation from a SGA device (see Box 22-4). In addition, fixed upper airway lesions, such as oropharyngeal tumors or a disruption or distortion in the upper airway anatomy, may make SGA placement difficult and lead to ineffective ventilation from a compromised "seat and seal."[44,54]

Finally, conditions affecting the lower airways resulting in decreases in pulmonary compliance or increases in airway resistance can cause peak airway pressures to rise, which may also make SGA ventilation difficult. For example, bronchospasm or acute respiratory distress syndrome require higher ventilatory pressures for adequate gas exchange within the lungs. Because an SGA device is seated above the larynx, positive pressure ventilation with such a device may not be able to generate the necessary pressures needed to push gases deep within the lungs. Instead, ventilated gases will follow the path of least resistance, and when airway pressures reach 25 cm H_2O or higher, these ventilated gases could overcome esophageal sphincter pressures causing inflation of the stomach, increases in intragastric pressure, and a possible risk of vomiting and pulmonary aspiration.

Invasive Airway Assessment

An assessment of the neck is part of any comprehensive airway examination and should be conducted with the intent of identifying factors that may lead to difficulty with the placement of an invasive airway. The need for an invasive airway usually occurs on an emergency basis. An invasive airway consists of a needle cricothyrotomy, surgical cricothyrotomy, or a tracheotomy. Because surgeons are more likely to perform a tracheotomy, rather than anesthesia personnel, the primary focus here will be on assessments aimed at identifying factors that lead to difficulty with both the needle and surgical cricothyrotomy emergency procedures.

Even though there is no absolute contraindication for the placement of an emergency cricothyrotomy, there are conditions

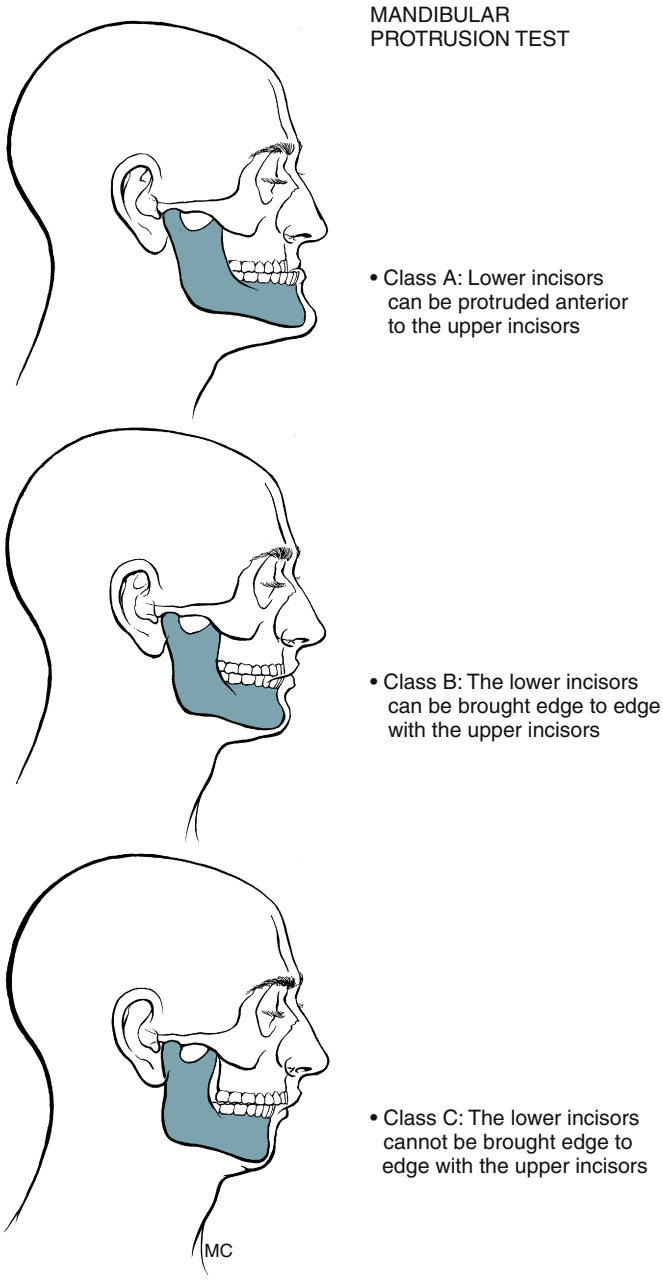

FIGURE **22-12** Mandibular protrusion test classes A, B, and C (also known as the upper lip bite test). (Redrawn from Munnur U, de Boisblanc B, Suresh MS. Airway problems in pregnancy. *Crit Care Med.* 2005;33:S259-68.)

that make performing this procedure difficult to impossible (see Box 22-2). Murphy and Walls[15] described using the pneumonic *SHORT*, as a means for remembering *surgery, hematoma, obesity, radiation,* and *tumors*, which are conditions associated with difficult cricothyrotomy placement. Any condition that causes a distortion of the airway such as trauma, surgery, infection, tumors, or physical impediments in or around the cricothyroid area may cause difficulty with invasive airway access. A hematoma from surgery (e.g., carotid endarterectomy), an infection of the soft tissue around the airway (e.g., Ludwig's angina), an oral or pharyngeal abscess, a tumor in or around the neck, or radiation causing scarring of the neck tissue can distort the neck anatomy and make a cricothyrotomy neck incision challenging. However, none of these factors should be considered a contraindication when emergency airway access is required. In addition, recent or past neck trauma or surgery can alter neck anatomy and cause scarring or acute bleeding, again making invasive airway access difficult. Finally, neck impediments such as a halo device or a rigid cervical collar may impede emergency access or make the procedure technically difficult and should be removed whenever possible.

Patient physical conditions that may also cause difficulty with the placement of a cricothyrotomy include a short neck, obesity, scarring, or fixed flexion abnormality. Both a short neck and excessive soft tissue around the neck can make finding the cricothyroid membrane and surrounding anatomic landmarks challenging. When performing the preoperative airway assessment on patients who exhibit any of these characteristics, practitioners should consider marking the cricothyroid membrane, prior to airway manipulation, in order to save time locating the membrane in the event of an emergency. Scarring from radiation or previous trauma around the cricothyroid area can distort neck anatomy and cause difficulty gaining access to the trachea. Furthermore, any fixed flexion deformity of the cervical vertebra can also lead to difficulty gaining access to the appropriate anatomic landmarks. Therefore the appropriate equipment should be readily available, such as an emergency cricothyrotomy kit, in order to save time when and if emergency airway access is indicated.

Radiologic Imaging

Imaging technologies, such as magnetic resonance imaging (MRI) and computed tomography (CT) can identify pathologies and alterations in airway anatomy and increase the predictive value of anticipated difficulty. These technologies can help anesthetists formulate appropriate airway management plans. An advantage of the CT scan includes the ability to accurately depict pathology involving bones and soft tissues and provides clinicians with the ability to view images in the sagittal, coronal, axial, and three-dimensional views. Furthermore, CT scans have become the "gold standard" for ruling out fractures of the cervical spine.[55]

Whereas CT scans can image both bone and soft tissue, an MRI offers detailed information on soft tissues only. An MRI can help assess the impact the pathologic processes have on soft tissue, such as the altered patency of an airway caused by a tumor in the neck. However, currently both the CT and MRI tests are not used on a routine basis because of the economic costs and time-delaying factors associated with their use, especially if there is no indication to perform them.

When assessing the airway and preparing for manipulation, the anesthetist should perform a multivariable assessment. This assessment is based on patient, surgical, and situational requirements and is crucial for the identification of factors that are associated with difficult bag mask ventilation, direct laryngoscopy and tracheal intubation, as well as difficult SGA ventilation and invasive airway placement.

TRACHEAL INTUBATION

Tracheal intubation remains a cornerstone of traditional airway management. Therefore the anesthetist must be an expert in tracheal intubation and possess the necessary skill and expertise with various equipment and techniques. Tracheal intubation may be performed by traditional methods (e.g., direct laryngoscopy, fiberoptic intubation) or by more novel techniques (e.g., intubating laryngeal mask airway, video-assisted laryngoscopy, retrograde intubation). The technique chosen for tracheal intubation is dependent on the patient's history, physical examination including airway assessment, and previous anesthetic history (e.g., difficult intubation). Indications for tracheal intubation can be found in Table 22-4.

TABLE 22-4 Indications for Tracheal Intubation

Condition	Indication
Anesthesia and surgical	High risk of aspiration of blood (e.g., head and neck trauma, bleeding into respiratory tract) or gastric contents (e.g., severe gastroesophageal reflux disease, inadequate gastric emptying, gastrointestinal obstruction) Anticipated, predicted difficult airway Intraoperative patient positioning that may impede access to the airway (e.g., prone, lateral decubitus) Ineffective oxygenation or ventilation with supralaryngeal airway (e.g., mask ventilation, laryngeal mask airway)
Surgical	Airway access shared with surgeon (e.g., otolaryngologic and head-neck surgery) Surgery requiring paralysis by neuromuscular blocking medications (e.g., intraabdominal surgery) Surgical procedures affecting ventilation and perfusion (e.g., cardiothoracic surgery) Prolonged surgical time
Medical	Inadequate airway protection or suppressed airway reflexes (e.g., Glasgow coma scale less than 10) Ineffective oxygenation or ventilation with supralaryngeal airway (e.g., noninvasive positive pressure respiratory assist device, mask ventilation, laryngeal mask airway) Critical illness (e.g., inadequate respiratory function, acute respiratory distress syndrome, sepsis) Controlled management of arterial carbon dioxide content (e.g,. prevention of hypercapnea for increased intracranial pressure)

Modified from Henderson J. Airway management in the adult. In: Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2009:1573-1610.

The procedure for tracheal intubation is preceded by careful attention to optimal head and neck positioning for laryngoscopy. Flexion of the neck and extension of the atlanto-occipital joint, or "sniffing position," allows for proper alignment of the oral, pharyngeal, and tracheal axis (see Figure 22-11). This can be accomplished using pillows, towels, blankets, or by using the OR table's positioning functions (Figure 22-13). Manipulation of the head and neck must be used with caution in patients with decreased cervical range of motion caused by degenerative disease, rheumatic disease, neurologic pathology, trauma, or previous surgical intervention (Figure 22-14).

Adequate pre-oxygenation is essential prior to the induction of anesthesia because it helps to delay arterial desaturation during subsequent apneic situations. Effective pre-oxygenation increases the oxygen content and eliminates much of the nitrogen (approximately 79% of room air) from the functional residual capacity (FRC) and can theoretically provide oxygen to the blood for up to 12 minutes in a healthy individual. However, without pre-oxygenation the oxygen reserve in the FRC is limited, leading to a decrease in the time an anesthetist has to secure the airway. Adequate pre-oxygenation should include instructing the patient to breathe at normal tidal volumes for 3 to 5 minutes with a fresh gas flow of no less than 5 L using a tight mask fit. The respiratory bag should move with each inspiration/expiration, there should be a good end-tidal CO_2 waveform, and the fraction of expired oxygen should begin to increase. This is easily accomplished by applying the facemask as soon as the patient arrives in the operating room and before the application of other monitors. If time is limited, "fast-track" pre-oxygenation, in which the patient takes four vital capacity breaths in 30 seconds, can be used before induction of anesthesia. This technique can be useful in the emergent situation.[11]

Pre-oxygenation and the induction of general anesthesia (e.g., intravenous or inhalation technique) will assist the anesthetist in minimizing complications of tracheal intubation such as hypoxia and hemodynamic aberrancy. In addition, the administration of muscle relaxants (e.g., depolarizing or nondepolarizing) may provide optimal relaxation of the intrinsic and extrinsic muscles of the larynx to promote both laryngoscopy and passage of the endotracheal tube through the rima glottis.

The technique for direct laryngoscopy is dependent on the type of laryngoscope blade used for the procedure, but the premise of control/displacement of the tongue from right-to-left and elevation of the epiglottis remains the same for both techniques. The use of the curved (e.g., Macintosh) laryngoscope requires the anesthetist to (1) place the tip of the laryngoscope in the vallecula, (2) tension the hyoepiglottic ligament by applying a gentle lifting force, which promotes (3) indirect elevation of the epiglottis. In contrast, the use of the straight (e.g., Miller) laryngoscope requires the anesthetist to (1) place the tip of the laryngoscope posterior to the epiglottis and (2) apply gentle force to directly lift the epiglottis. Levering action should never be applied to the patient's dentition. Such action risks dental damage and diminishes the quality of the laryngoscopic view.

If an adequate laryngoscopic view cannot be achieved after direct laryngoscopy, then strategies and algorithms for the difficult or failed airway should be followed. Maintenance of adequate oxygenation and ventilation is the utmost priority of tracheal intubation and can be facilitated by the use of various adjunctive airway equipment and techniques.

MANAGEMENT OF THE DIFFICULT AND FAILED AIRWAY

Management of the difficult airway is a multilayered process that begins with the airway assessment, considers decision-making strategies suggested by the various difficult airway algorithms, continues with a primary airway management plan, and culminates with an understanding of what to do when initial airway management plans fail. As part of a thorough airway management plan, the anesthetist should consider patient characteristics and conditions that predispose them to difficulty with facemask ventilation, supralaryngeal device use, laryngoscopy, tracheal intubation, and cricothyrotomy. As discussed in previous sections, multiple patient characteristics and conditions are associated with difficult airway management. However, attempts at prediction are much less important than demonstrating the appropriate actions to undertake when difficulty is encountered. No test is likely to be perfect; therefore it remains essential that every anesthetist must be trained and equipped to deal with both identified difficult airways and the less common unexpected failed airway.

The unexpected failed airway, also termed the *unanticipated difficult airway*, consists of an airway that has previously been evaluated with no external identifiers indicating difficulty. In other words, the anesthetist does not "expect" or does not "anticipate" difficulty with facemask ventilation, laryngoscopy, intubation, or other airway management techniques. However, after the patient is anesthetized difficulty with ventilation, intubation, or both occurs. Thankfully, the unexpected failed airway is rare. Researchers have attempted to identify indications to help airway management experts recognize these situations early. A common cause of an unanticipated difficult intubation has been shown to be

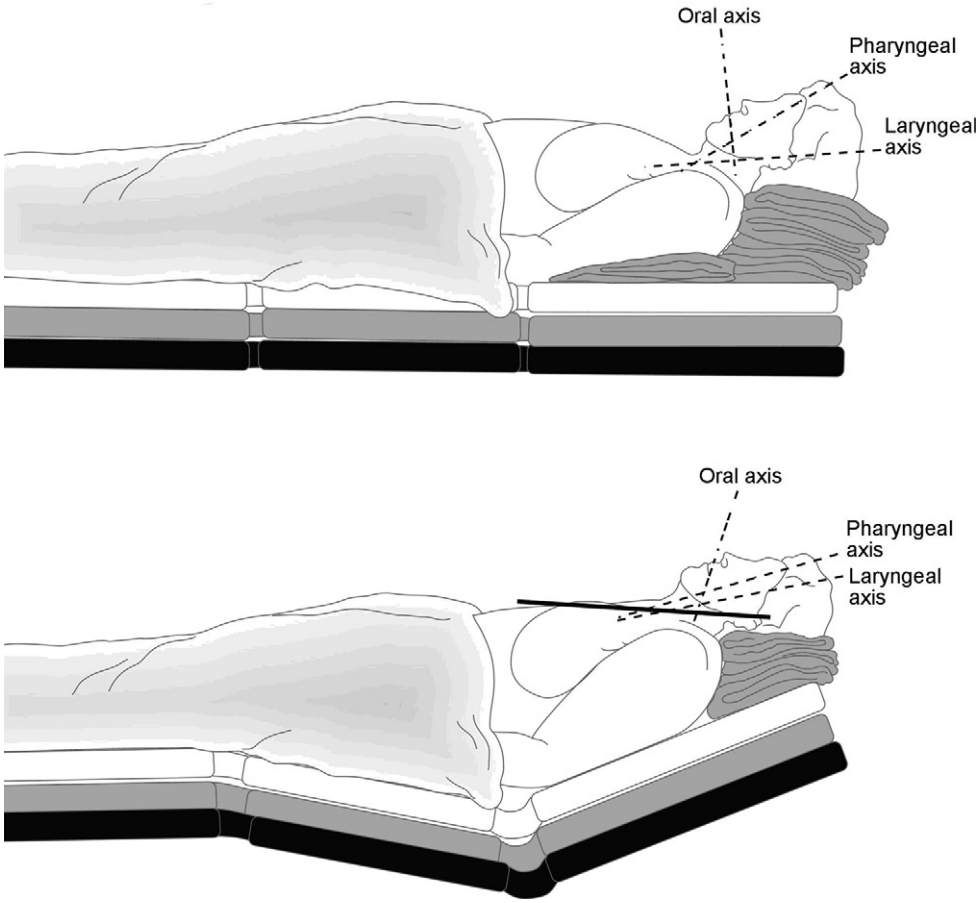

FIGURE **22-13** Improving oral, pharyngeal, and laryngeal axis alignment by raising the head of the operating room (OR) table. **A,** supine position. **B,** Head-up position. (From Thompsen J, et al. Anesthesia case management for bariatric surgery. *AANA J.* 2011;79(2):147-160.)

enlarged lymphoid tissue at the base of the tongue (i.e., lingual tonsil hypertrophy), which cannot be evaluated externally.[56,57] Instead, this condition is discovered during laryngoscopy by a failure to visualize the glottic opening and a description of a grade III or IV airway.

Definition of a Difficult and Failed Airway

The definition of a difficult airway varies within the existing literature, making it challenging to identify the true incidence. However, in broad terms a difficult airway has been described as a clinical situation in which a trained anesthetist experiences difficulty with facemask ventilation, laryngoscopy, intubation, or all of these.[12] A significant amount of subjectivity is possible between observers when performing the different airway assessments leading to various interpretations of predicted airway difficulty. Ultimately, it is not enough to simply identify a difficult airway, but instead to possess the knowledge and skills that guide intervention after difficulty has been identified or when unanticipated difficulty is encountered. Knowing what to do when an airway proves difficult will ensure that proper ventilation is provided in a timely manner.

There are four ways to maintain airway patency and effect ventilation, and thus oxygenation of the tissues. The methods of providing ventilation are as follows:

1. Mask ventilation with an appropriate mask seal with or without a jaw thrust maneuver
2. Placement of a supraglottic airway device such as an LMA
3. Placement of a tube below the vocal cords, such as endotracheal intubation
4. Placement of an invasive airway such as a cricothyrotomy tube

Problems or indications of complexity with one or more of these four methods of providing ventilation would suggest a difficult airway.

When managing an airway, the anesthetist must recognize signs that indicate difficulty with various airway management techniques. Indications of difficult facemask ventilation include (1) gas flow leaks out of the facemask and increasing use of the oxygen flush valve; (2) poor chest rise; (3) absent or inadequate breath sounds; (4) gastric air entry; (5) poor carbon dioxide return and an altered capnographic waveform; (6) a decreasing oxygen saturation of less than 92% as measured by pulse oximetry using a 100% inspired oxygen concentration; and (7) necessity to use an oral or nasal airway and perform a two-handed mask ventilation technique.[19,58] Difficult laryngoscopy and tracheal intubation have been consistently identified in the literature as the inability to visualize any portion of the vocal cords (e.g., Cormack and Lehane grade III or IV) after multiple attempts using a standard laryngoscope. In addition, difficulty with laryngoscopy and intubation has been described as requiring multiple operators in the presence or absence of tracheal pathology. Furthermore, evidence of a failed intubation was identified as a failure to place an endotracheal tube after multiple laryngoscopic attempts.[12] Difficulty with a supraglottic device may also be apparent when placement

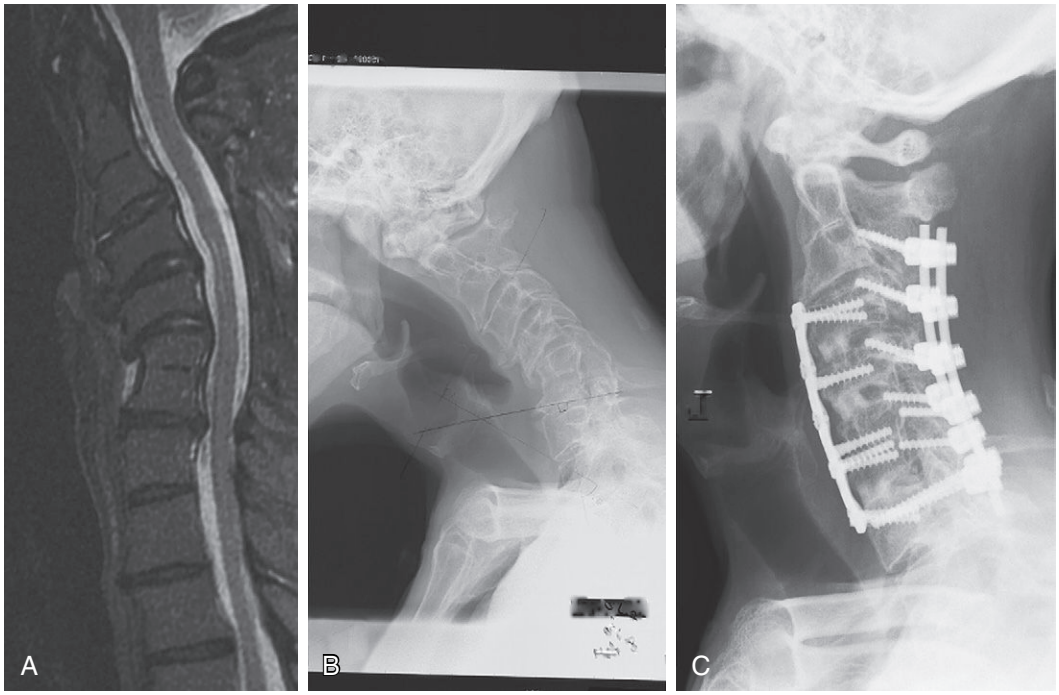

FIGURE **22-14** Sagittal magnetic resonance image (MRI) **(A)** and lateral radiograph **(B)** of a 60-year-old man with a prior laminectomy and Klippel-Feil malformation at C2-C3 shows progressive fixed kyphotic deformity. **C,** Lateral postoperative radiograph after a three-staged procedure, including posterior release, C3-T1 posterior spinal fusion, and C3-T1 correction to anterior cervical discectomy and fusion, shows marked reduction of fixed deformity. (From Chi JH, et al. Complex deformities of the cervical spine. *Neurosurg Clin N Am*. 2007;18(2):295-304.)

requires multiple attempts or requires more than one airway practitioner. Furthermore, objective indications of difficulty with supraglottic ventilation are similar to those described for facemask ventilation earlier, as well as a leak pressure less than 10 to 15 cm H_2O and a poor expired tidal volume.[17] Finally, difficulties with invasive airway device placement, such as a cricothyrotomy, are apparent with bleeding at the site of insertion, an inability to identify the correct anatomic structures, or with difficulty accessing the cricothyroid membrane and puncturing through into the trachea.

Incidence of a Difficult and Failed Airway

Adverse events related to difficulty with airway management continue to occur within the OR, and researchers agree there is continued "room for improvement."[59] In 2008 the Royal College of Anaesthetists in the United Kingdom and the Difficult Airway Society gathered information on administration of 2.9 million general anesthetics in an attempt to identify the incidence of major complications related to airway management. The major complications identified were death, brain damage, emergency surgical airway placement, and unanticipated intensive care unit admission. They found that a major complication occurred at a ratio of 1:22,000 general anesthetics with a mortality rate of 1:180,000.[59] Other researchers have focused strictly on the occurrence of a difficult airway, such as a laryngoscopic view grade II or III, and have reported a 1% to 18% incidence. The incidence of failed tracheal intubation is relatively uncommon and has been reported as 0.05% to 0.35%, with the high end of this range relating to obstetric patients and other surgical patients with known difficulties.[58] As previously mentioned, the incidence of difficult facemask ventilation has been described between 0.9% and 7.8%, with the variation in results occurring as a result of different study parameters. Finally, researchers have reported a supraglottic device complication rate of 0.19%, mostly caused by an inadequate seal and failed placement.[60]

The incidence of difficult intubation and ventilation is much higher in patients with neck or mediastinal pathology, previous surgery, or radiation. For example, Ayuso et al.[61] evaluated 181 patients with pharyngolaryngeal disease and found that 50 (28%) were difficult to intubate, and 4 (2.8%) were impossible to intubate. Ovassapian et al.[62] performed a retrospective analysis on patients with deep neck infections, such as Ludwig's angina, and found a 3.8% incidence of failure to intubate necessitating a tracheostomy. The true incidence of situations in which practitioners cannot intubate and subsequently cannot ventilate (CICV) is difficult to assess because of the failure to consistently and accurately report these occurrences. However, some authors have reported an incidence of 1:2250 in nonparturients and as much as 1:300 in parturients.[14,63] Kheterpal et al.[22] reported four cases of impossible mask ventilation and intubation in 53,041 cases involving anesthetics.

When assessing the frequency of emergency cricothyrotomy placement, Cook et al.[59] reported and incidence of 1 in every 12,500 to 50,000 general anesthetic cases. Other researchers explained that the incidence of emergency cricothyrotomy placement is strongly influenced by the clinical situation and contributing patient factors.[64] For example, the incidence of emergency cricothyrotomy placement resulting from failed tracheal intubation in the emergency department (ED) has been reported as 0.3% to 0.8%, increased to 1.4% in trauma patients, and was reported as high as 11% in the prehospital setting.[65-67] Other research also concluded that difficult airways may be encountered more frequently outside of the OR. A recent audit from the United Kingdom reported that airway-related adverse events, which led to death or brain damage, were 30 to 60 times more likely to occur in the ED or intensive care unit (ICU).[68]

Difficult Airway Algorithms

When considering how to approach airway management, certain issues should be considered prior to the induction of anesthesia. Rosenblatt[16] identified five questions, termed "the airway approach algorithm," which can help the anesthetist initially develop an airway management plan:

1. Is airway management necessary?
2. Will direct laryngoscopy and tracheal intubation be straightforward?
3. Can supralaryngeal ventilation be used?
4. Has the risk for aspiration been minimized or is the stomach empty?
5. In the event of airway failure, will the patient tolerate an apneic period?

If the answer to each of these questions is "yes," then the airway is deemed manageable by conventional means and the anesthetist may proceed with the induction of anesthesia followed by muscle relaxation to provide optimal conditions for laryngoscopy and intubation. If however, the answer to any question is "no," then the anesthetist should either abandon airway management altogether and proceed with an alternative anesthetic option (e.g., monitored anesthesia care, regional anesthesia), or follow the guidelines set forth by various professional associations for the management of anticipated airway difficulty.

Difficult airway management is multifactorial and necessitates an awareness of the interactions between patient conditions, the clinical setting, and the anesthesia provider's experience and skill level. Each of these factors alone or in combination can contribute to poor outcomes during airway manipulation and must be considered when developing airway management strategies. Tools that help the anesthetist formulate plans for safe airway care in the face of both known and unanticipated difficulties are known as difficult airway algorithms. Multiple difficult airway algorithms exist, but perhaps the most notable is the American Society of Anesthesiologist's (ASA) difficult airway algorithm (Figure 22-15).

ASA Difficult Airway Algorithm

The difficult airway algorithm, established in 1991 by the ASA, gave anesthesia practitioners the first standardized approach for the management of the anticipated or unanticipated difficult airway. The practice guidelines were updated in 2003 to reflect current management strategies.[12] The algorithm provides guidelines for dealing with difficult facemask ventilation, difficult laryngoscopy, difficult tracheal intubation, and failed intubation. Assessment of the airway and use of the difficult airway algorithm provide the practitioner with four end-points: (1) intubation awake or asleep, (2) adequate or inadequate facemask ventilation or LMA ventilation, (3) approach to intubation by special means, and (4) surgical or nonsurgical emergency airway access. Each of these end-points entails using specific airway equipment and techniques to facilitate ventilation (Table 22-5). According to the algorithm, an organized plan should be initiated when a difficult airway is encountered. In essence, the philosophy of the ASA difficult airway algorithm has been explained by the following[69]:

1. Plan ahead, and be prepared for failed attempts at intubation.
2. If you are suspicious of airway trouble, intubate awake.
3. If you get into trouble and can still ventilate the patient, wake him or her up.
4. When making intubation choices, do what you do BEST.

Other Difficult Airway Algorithms

An important fact to keep in mind is that many of the guidelines suggested in difficult airway algorithms are based on the opinions of experts in the field of airway management, but lack empirical evidence. Reasons given have included the significant challenges with the design of randomized controlled trials, the infrequency of certain difficult airway events (e.g., failed airway or cricothyrotomy), and an inability to account for confounding variables such as individual practitioner experience.[70] However, the widespread distribution of the different guidelines has resulted in a reduction in airway-related critical accidents.[70,71] Overall, it is important to remember that difficult airway algorithms are simply guidelines that provide structure for decision making and are tools for use when managing difficult airways, but they do not preclude personal responsibility and sound clinical judgment.

There are similarities between the ASA difficult airway algorithm and other airway algorithms. For example, in the event of failed intubation, the ASA difficult airway algorithm reverts to facemask ventilation, and if that proves inadequate, moves to ventilation with an LMA. The Difficult Airway Society's (DAS) algorithm suggests using the LMA as means for ventilation and oxygenation immediately after a failed intubation, and then if the LMA fails, suggests reverting back to facemask ventilation. Both the ASA and DAS algorithms advocate for awakening the patient if initial attempts at intubation fail, but subsequent ventilation attempts succeed. Furthermore, both recommend the placement of either needle or surgical cricothyrotomy if intubation has failed and both facemask and LMA ventilation have proven to be inadequate; this is also termed the CICV situation.[12,72,73]

It is worth noting the important role of the LMA (and perhaps other SGA devices) within the difficult airway algorithms. The LMA is used for rescue ventilation at two points in the ASA difficult airway algorithm: first, in the anesthetized patient whose trachea cannot be intubated but can be ventilated with a facemask (anesthetized nonemergency limb); and second, in the anesthetized patient whose trachea cannot be intubated and whose lungs cannot be conventionally ventilated (anesthetized emergency limb). The DAS algorithm describes a similar strategy, and comparable uses can also be found in other national recommendations from Germany and Italy.[73-76] Brimacombe[77] identified five major considerations that highlight the role of the LMA in difficult airway management:

1. The anatomic and technical factors indicating difficulty with facemask ventilation, laryngoscopy, and tracheal intubation do not generally influence LMA insertion and function; thus the LMA has a high likelihood of success in instances where mask ventilation or tracheal intubation have failed or proven to be difficult.
2. The LMA can be used for both ventilation and as a conduit for intubation.
3. The LMA provides a method of ventilating the lungs, allowing additional time to perform tracheal intubation in an unhurried manner.
4. Usually, LMA insertion is atraumatic, allowing the opportunity to use optic devices that depend on clear unfettered airways for visualization.
5. The LMA is routinely used as an airway management tool, which increases the anesthetist's comfort and skill level.

The number of laryngoscopic attempts and total procedural duration for intubation are quantifiable objective measurements used by multiple airway management guidelines as indications of airway difficulty. Most airway management guidelines allow between 2 to 4 laryngoscopic attempts and between 5 to 10 minutes of total procedural time before they classify the airway as a failed laryngoscopic intubation.[63,70,78] Limiting the number of laryngoscopic attempts is done to prevent excessive airway instrumentation leading to airway trauma and increased difficulty. It has

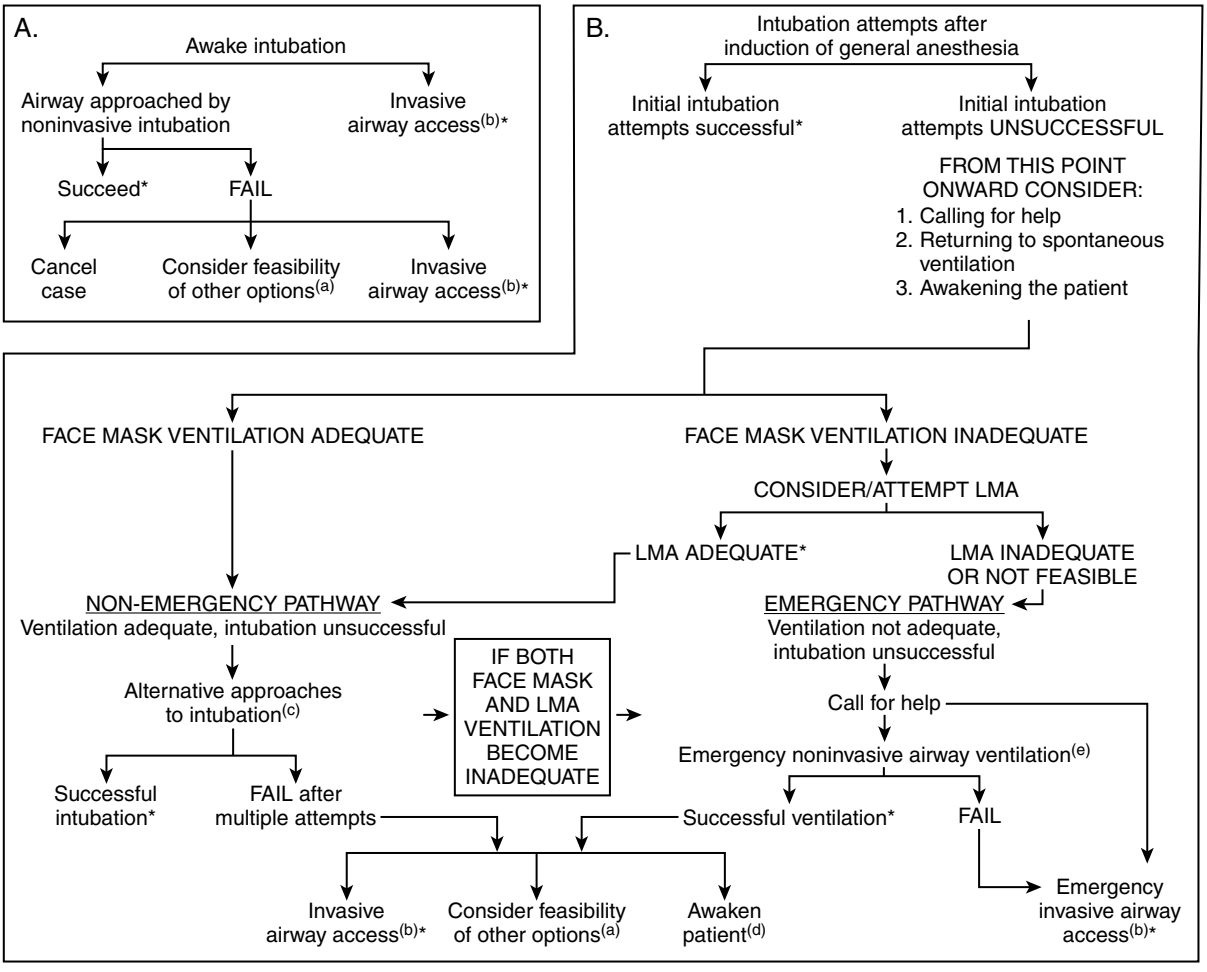
1. Assess the likelihood and clinical impact of basic management problems:
   - A. Difficult ventilation
   - B. Difficult intubation
   - C. Difficulty with patient cooperation or consent
   - D. Difficult tracheostomy

2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management

3. Consider the relative merits and feasibility of basic management choices:

A.	Awake intubation	vs	Intubation attempts after induction of general anesthesia
B.	Noninvasive technique for initial approach to intubation	vs	Invasive technique for initial approach to intubation
C.	Preservation of spontaneous ventilation	vs	Ablation of spontaneous ventilation

4. Develop primary and alternative stategies:



*Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2.

a. Other options include (but are not limited to) surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration, or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.
b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.
c. Alternative noninvasive approaches to difficult intubation include (but are not limited to) use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.
d. Consider re-preparation of the patient for awake intubation or canceling surgery.
e. Options for emergency noninvasive airway ventilation include (but are not limited to) rigid bronchoscope, esophageal-tracheal Combitube ventilation, or transtracheal jet ventilation.

FIGURE **22-15** The American Society of Anesthesiologists (ASA) Difficult Airway Algorithm. (From ASA Task Force on Management of the Difficult Airway: practice guidelines for management of the difficult airway: an updated report. *Anesthesiology.* 2003;98(5):1269-1277.)

been described that when an unanticipated difficult intubation is encountered, the first attempt is usually the "awareness" look, and that the second attempt should be performed under the best possible conditions (e.g., proper head and neck extension, head and shoulders elevated, experienced practitioner). If subsequent attempts are performed, they should be done using alternative approaches (e.g., blade change, introducer usage, video laryngoscope), and possibly performed by a different anesthetist.[79]

Finally many of the airway algorithms advocate for the use of alternative airway techniques, including awake intubation, as long as ventilation is adequate and time permits. The choice of which alternative airway technique or difficult airway adjunct to use should be based on the anesthetist's clinical judgment, which again should consider patient conditions, the clinical setting, and the anesthesia provider's experience and skill level.

Difficult Airway Cart

A dedicated difficult airway cart or box should be made readily available at some location in the OR. This cart should be checked on a routine basis to ensure that all materials are available and all devices are working properly. There is no definitive list of equipment, and the contents of the difficult airway cart should be decided on by the anesthesia department personnel based on the likely caseload and department budget. The recommended basic elements of the difficult airway cart should contain devices for (1) standard laryngoscopy; (2) intubation by alternative means; (3) tube position control; and (4) equipment for anesthetizing the airway (Box 22-6).[70] Some difficult airway carts may also contain video laryngoscopy devices. In addition, the capacity to perform flexible fiberoptic bronchoscopy (FOB) should be immediately available.

BOX 22-6

Suggested Components of the Difficult Airway Cart

Standard Airway Equipment
- Oral and nasal airways of various sizes
- Tongue blades
- Flexible stylets
- Endotracheal tubes (cuffed and uncuffed) from size 2.5 to 8.0
- Miller laryngoscope blades sizes 0, 1, 2, 3, 4
- Macintosh laryngoscope blades sizes 2, 3, 4
- Laryngoscope handles—regular and stubby
- Extra laryngoscope batteries and bulbs
- Magill forceps
- Salem sump—16 and 18 French
- Suction catheters—10, 12, 14 French
- Oxygen mask
- Nasal cannula
- Oxygen with 15 L/min regulator
- Ambu bag

Alternative Airway Equipment
- Laryngeal mask airways—sizes 3, 4, 5
- Intubating laryngeal mask airway
- Combitube
- Lighted stylet (e.g., Trachlite)
- Eschmann stylet (e.g., gum elastic bougie)
- Tube exchanger—small, medium, large
- Ventilating stylet
- Needle cricothyrotomy set
- Retrograde intubation set
- Melker percutaneous dilational cricothyrotomy set
- Transtracheal jet ventilator

Tube Position Control
- Stethoscopes
- CO_2 detectors
- Esophageal detector device

Topical or Infiltration Anesthesia
- Syringes—3, 5, 10, and 20 mL (three or four of each size)
- Angiocatheters—14, 16, 18, 20 gauge (three each)
- Xylocaine jelly 2%
- Lidocaine—4% topical, 2% for injection
- Surgilube
- Nebulizer
- Atomizer
- 4×4 gauze pads

Video Laryngoscopes
- Airtraq
- C-MAC
- GlideScope
- McGrath

Fiberoptic Bronchoscopy Equipment
- Tongue clamp
- Light source
- Endoscopy mask
- Ovassapian intubating airway

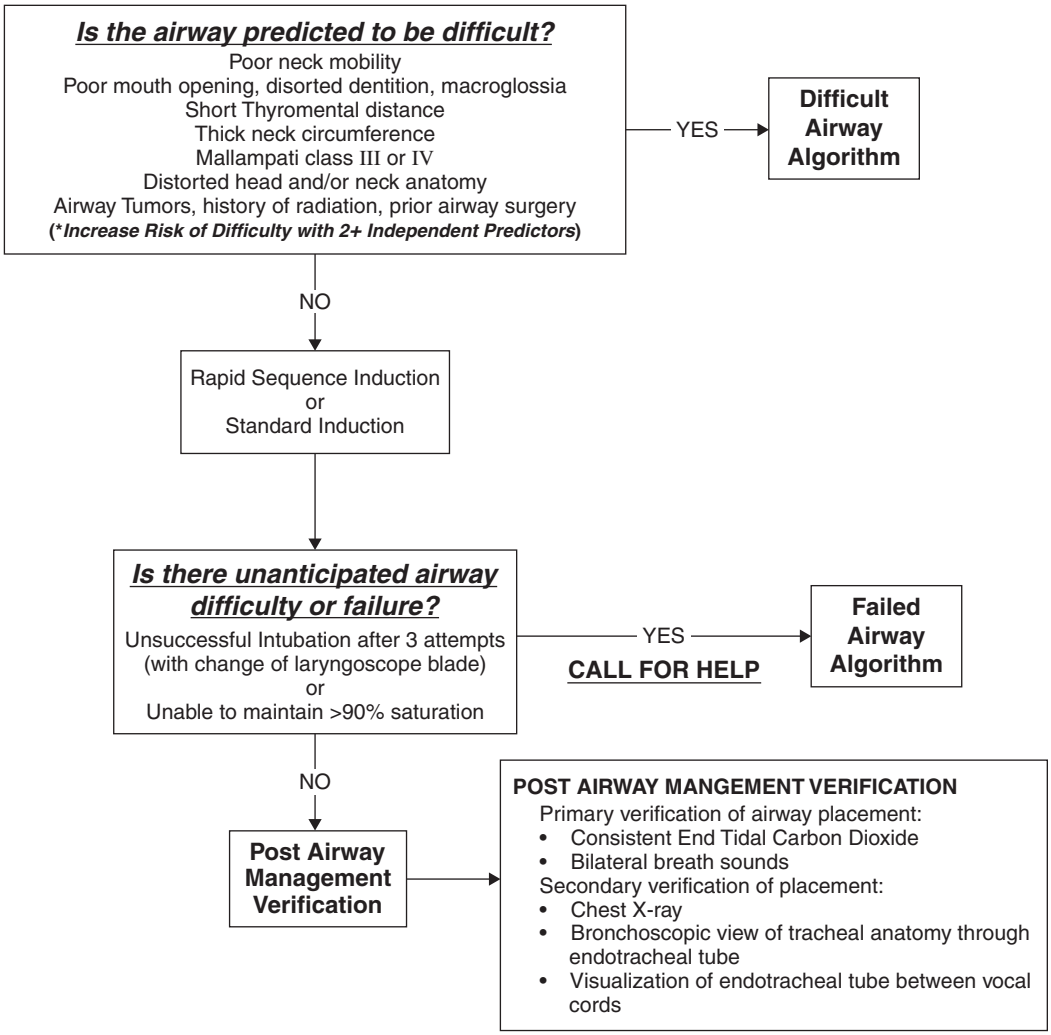

FIGURE **22-16** Standard airway strategy.

Smart Airway Strategies

In an attempt to compile and simplify existing airway management algorithms, and to provide information concerning current alternative techniques for difficult airway management (e.g., video laryngoscopes), the following smart airway strategies have been developed. These airway management strategies were prepared using information from the ASA difficult airway algorithm, the Difficult Airway Society's airway management guidelines, Canadian Airway Focus Group's algorithm for the proposed management of the unexpected difficult airway, the Rush Medical Center approach to emergency airway management, and current literature concerning airway management.[12,73,80-83]

The smart airway strategies are not intended as a minimum standard of practice, nor are they to be used as a substitute for good clinical judgment. Instead, they are guidelines that reflect current opinions by professional associations, airway experts, and research. The smart airway strategies are guided by questions, which help to direct clinical decision making according to either a "yes" or "no" answer. Included at different points within the strategies are considerations with respect to airway assessments, adjunctive airway use, and methods of airway management. The smart airway strategies should be regarded as a tool to help the anesthetist develop a basic airway management plan (Figure 22-16), to provide a structural framework for the management of an identified difficult airway (Figure 22-17), and to assist with decision making after initial attempts at airway management fail (Figure 22-18).

Standard Airway Strategy

The *standard airway strategy* (see Figure 22-16) will be the most commonly followed strategy. It begins by asking the question "Is the airway predicted to be difficult?" Multiple airway examinations are provided to assist with the overall airway examination. As mentioned earlier, the presence of two or more independent predictors increases the risk of difficulty with airway management. If the answer to the initial question is "yes" and airway management is anticipated to be difficult, then the anesthetist should proceed to the *anticipated difficult airway strategy*. If the answer is "no," then the anesthetist should proceed with either an anesthetic standard or rapid sequence induction. The question then becomes "Is there unanticipated airway difficulty or failure?" If the answer is "yes," as demonstrated by unsuccessful intubation after three laryngoscopic attempts (with a change in laryngoscope blades), or difficulty with ventilation as evidenced by the inability to maintain an oxygen saturation greater than 90%, then the anesthetist should call for help and proceed to the *failed or unanticipated difficult airway strategy*.

If no difficulty was encountered and the airway was successfully managed, then the anesthetist should proceed with *post airway management verification*, which consists of primary and

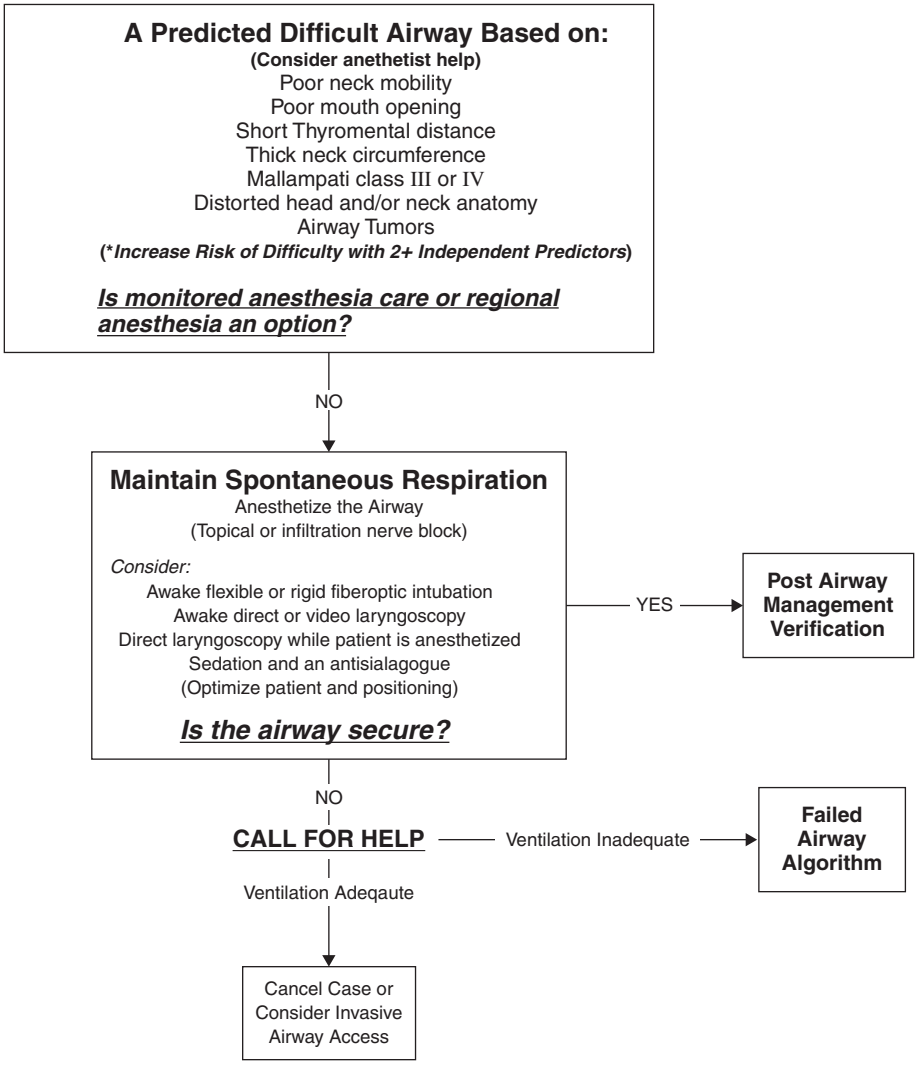

FIGURE **22-17** Difficult airway strategy.

secondary verifications. Primary verification of tube placement is apparent when consistent end tidal carbon dioxide tracing on the end tidal CO_2 monitor is observed and bilateral breath sounds are auscultated. Secondary verification of placement is evident by a chest radiograph confirming ETT placement, a bronchoscopic view through the airway of the tracheal anatomy including the carina, and visualization of the ETT between the vocal cords.

Anticipated Difficult Airway Strategy

The anticipated difficult airway strategy (see Figure 22-17) is used when the airway has been evaluated and predicted to be difficult. Again, multiple airway examinations are provided for review and the presence of two or more independent predictors increases the risk of difficulty with airway management. Anytime the airway is predicated to be difficult, additional anesthesia providers should be present. The strategy then asks "Is monitored anesthesia care or regional anesthesia an option?" If the answer is "no," the strategy then states to employ airway management methods that "maintain spontaneous respiration." Devices that assist with the placement of an ETT while the patient is awake and breathing spontaneously include a rigid or fiberoptic device, a standard laryngoscope, or video laryngoscope. The airway should be anesthetized using either topical or infiltration nerve blocks, and both sedation and an antisialagogue to dry out secretions in the airway should be considered. Techniques for anesthetizing the airway are discussed in subsequent sections. The anesthetist may consider securing the airway after anesthetizing the patient with intravenous or inhalational techniques while maintaining spontaneous ventilation. This method of airway management should be based on the clinical judgment of the practitioners present, the skill of the anesthetist, and patient characteristics (such as an uncooperative patient). Additional airway adjuncts and a cricothyrotomy kit should be readily available.

After attempting to place a definitive airway while the patient is awake or anesthetized, the question then becomes "Is the airway secure?" If the answer is "yes," then proceed to *post airway management verification*. If the answer is "no," then call for help and assess whether ventilation is adequate. If ventilation is inadequate, then proceed to the *failed or unanticipated difficult airway strategy*. If ventilation is adequate, and previous attempts for securing the airway have failed, then cancel the case and consider other anesthetic options. If the case must proceed, then consider placement of an invasive airway.

Failed or Unanticipated Difficult Airway Strategy

The failed or unanticipated difficult airway strategy (see Figure 22-18) is a critical time-sensitive strategy. If help has not already

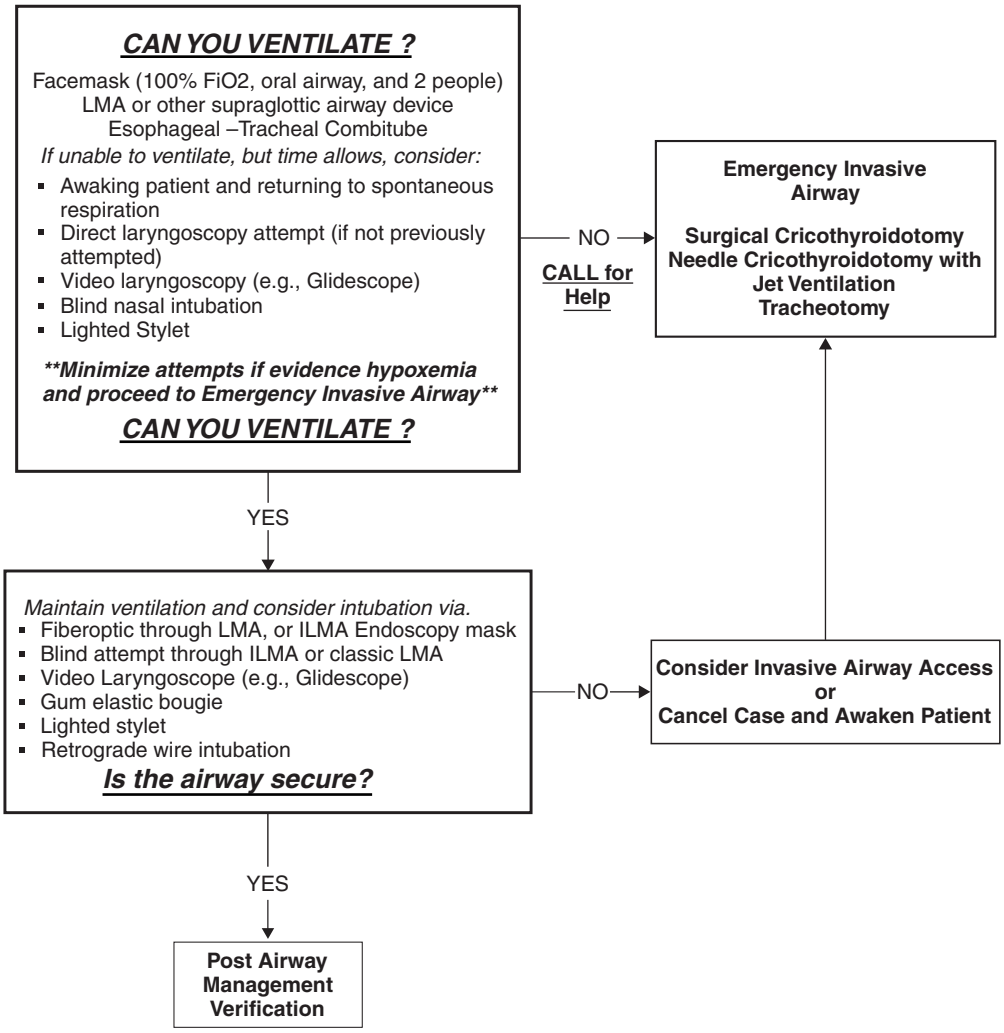

FIGURE **22-18** Failed or unanticipated difficult airway strategy.

arrived, then help should be called for again and confirmed en route. The most important question is "CAN YOU VENTILATE?" Ventilation is essential and must be the primary goal. It should be attempted with either a facemask, SGA device (e.g., LMA), or with an esophageal-tracheal Combitube. At this point in the airway strategy, the anesthetist may consider awakening the patient, attempting a direct or video laryngoscopy (if not already attempted), blind nasal intubation, or lighted stylet intubation. The choice of which technique to use should be based on the patient's condition, criticality of the situation, and skill of the anesthesia provider. However, these considerations should be minimized if there is evidence of hypoxemia, and invasive airway placement must be considered because persistent unsuccessful intubation attempts have been associated with complete airway obstruction, brain damage, and death.[71,84] Again, the question to ask is "CAN YOU VENTILATE?" If the answer is "no," and the anesthetist cannot intubate and subsequently cannot ventilate, then the anesthetist should move to "emergency invasive airway" access and ventilation. Invasive airway placement can be accomplished by a surgical cricothyrotomy, a needle cricothyrotomy with jet ventilation, or a tracheotomy.

If, however, the anesthetist is able to ventilate after other attempts at ventilation or intubation have failed, then additional airway options can be considered. While ventilating the patient, intubation of the trachea can be accomplished using (1) a fiberoptic bronchoscope placed through an LMA, an intubating laryngeal mask airway (ILMA), or an endoscopy mask; (2) a blind intubation attempt through an ILMA; (3) video laryngoscope (e.g., Glidescope); (4) gum elastic bougie; (5) lighted stylet; or (6) retrograde wire intubation. This list is not all-inclusive and other airway adjuncts can be considered; however, trauma to the airway should be avoided and ventilation must be preserved.

After additional attempts at airway management, the question then becomes "Is the airway secure?" If the answer is "no," then the anesthetist should awaken the patient. If awakening the patient is not an option, then the placement of an invasive airway needs to be considered. However, if the answer is "yes," and the airway is secure, then the anesthetist should proceed with *post airway management verification*. In addition, when surgery is finished and airway control is no longer needed, the anesthetist should follow strategies for protected extubation later in this chapter.

Frequent training in the clinical setting, at workshops, or during simulation scenarios can help increase familiarity with difficult airway management strategies and the use of different airway adjuncts, and may play a role in decreasing complications associated with difficult airway management.[85-87] Furthermore, anesthetists should personally prepare a predefined algorithm to use in the event of an unexpected difficult or failed airway. A predefined algorithm is a back-up plan used when ventilation, laryngoscopy, or intubation prove to be difficult. A back-up plan such as a gum elastic bougie followed by the IMLA if needed has shown to be effective in many

unexpected difficult airway situations.[88] Ultimately, the primary goal of difficult airway management is to avoid entering the territory of cannot intubate and cannot ventilate. An awareness and proficiency with the different airway management techniques and strategies, each of which has unique advantages and disadvantages depending on the clinical situation, will assist the nurse anesthetist in safe and effective difficult airway management.

Awake Intubation

When airway management is anticipated to be difficult, many airway guidelines suggest that the airway should be managed while the patient is awake and breathing spontaneously. Because the patient will maintain spontaneous ventilation and pharyngeal/laryngeal muscle tone during airway management, regional anesthesia for the airway (e.g., airway blocks) provides an increased margin of safety and therefore should have a place in every anesthetist's armamentarium.[28] It is imperative to note that the provision of regional anesthesia for the airway can be a time-consuming endeavor and may need to be abandoned if the patient is unwilling or unable to cooperate. Sedation medications are used as an adjunctive therapy to help calm the patient during an awake laryngoscopic intubation attempt. Agents that have been used include midazolam, propofol, etomidate, ketamine, fentanyl, remifentanil, and dexmedetomidine.[89] Agent selection depends on the clinical situation (e.g., an emergency that requires immediate airway access versus an anticipated difficult airway for a scheduled surgery), availability of the medication, and the provider's familiarity with the sedative agent. In addition, combinations of these medications are frequently used in clinical practice to reduce the total amount of any one drug given, especially since most cause respiratory depression in a dose-dependent fashion.

Caution should be exercised in patients with any degree of respiratory compromise or who are at risk for developing respiratory failure, because even small doses of sedative medications may induce apnea. Furthermore, sedative and opioid analgesic agents decrease both pharyngeal and laryngeal muscle tone, which can lead to a total obstruction of the airway. Finally, deep sedation, or sedation levels that approach general anesthesia, defeat the purpose of performing an awake intubation and increase the risk for loss of airway reflexes, upper airway obstruction, and airway failure.[89] Therefore it is important for the anesthetist to remain vigilant during the administration of sedative medications in the anticipated difficult airway and to provide judicious sedation to assist with comfort and decrease anxiety, but to avoid oversedation that may increase the risk of apnea.

Awake Intubation Techniques

An awake intubation is the placement of an endotracheal tube into the trachea in situations where the patient is not under the influence of general anesthesia. Awake is somewhat of a misnomer because it is very challenging to place an endotracheal tube without the use of local anesthesia, sedation, or both because of the strong reflexes that exist in the airway. However, the patient is awake in the sense that they are cooperative and ventilating spontaneously. Awake intubation is an essential component of difficult airway management and should be a primary option any time a difficult intubation is anticipated. There are two awake techniques that can be considered after the patient has been prepared and the airway has been anesthetized:

1. Perform a laryngoscopy with a standard laryngoscope or video laryngoscope to diagnostically determine whether the patient is difficult to intubate.
2. Perform a tracheal intubation using a flexible fiberoptic bronchoscope that has a preloaded ETT and can be passed into the trachea in a known difficult airway.

TABLE 22-6 Medication Considerations for Awake Intubation

	Medication	Indication
Intravenous Medications	Antisialagogue (glycopyrrolate or atropine)	Dry secretions in the airway
	Propofol Midazolam Ketamine Etomidate Dexmedetomidine Fentanyl Remifentanil	Provides sedation, anxiolysis, and assists with patient cooperation *Caution with respiratory depression and decreased muscle tone*
	Bicitra Metoclopramide Histamine 2 blocker (e.g., famotidine, ranitidine, cimetidine)	Aspiration prophylaxis
Topical or Infiltration Medications	Phenylephrine 1%	Vasoconstrictors for nasal intubation
	Lidocaine 2%, 4%	Topical local anesthesia
	Cetacaine	Topical local anesthesia
	Benzocaine 20%	Topical local anesthesia
	Cocaine 4%	Topical local anesthesia and vasoconstrictor
	Lidocaine 2%	Infiltration nerve block

It is generally better to secure the airway on the first visualization; however, there may be situations in which it is best to anesthetize and paralyze the patient for an optimum view of the laryngeal opening. However, these situations will need to be determined by the clinician.

When performing an awake intubation, the anesthetist may elect to place an oral or nasal ETT. The nasal route often has a direct line to the laryngeal opening; however, this route may carry an increased risk of hemorrhage or soft tissue damage. Examples of situations where an awake intubation would be necessary include patients with previous airway difficulty, unstable neck fractures, halo devices, small or limited oral openings, upper airway impingement by a mass, and patients in the critical care setting. An important consideration to remember is that topical anesthesia and instrumentation of an inflamed, compromised airway can produce rapid airway compromise, and the anesthetist must be prepared to quickly intervene, which may include performing an emergency invasive airway.[89] However, with proper patient preparation and a sufficiently anesthetized airway, an awake intubation can be accomplished quickly, safely, and with minimal discomfort to the patient.

Patient Preparation

For maximum patient cooperation, the awake procedure must be clearly explained and consent obtained. It is difficult if not impossible to proceed if the patient is uncooperative or unwilling to participate. Depending on the situation and the patient's condition, judicious use of anxiolytics and narcotics may be considered as previously discussed. Examples of medications that may be considered when anesthetizing the airway are contained in Table 22-6.

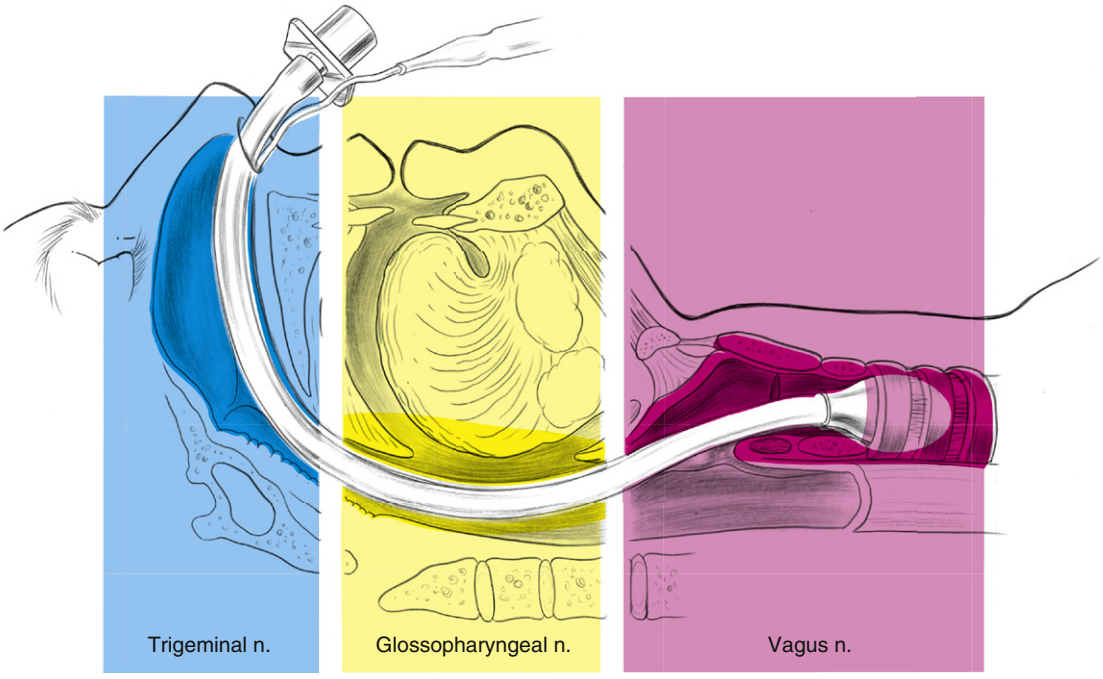

FIGURE **22-19** Cranial nerve innervation of the upper airway. (From Brown DL, et al. *Atlas of Regional Anesthesia*. 4th ed. Philadelphia: Saunders; 2010.)

Administration of an antisialagogue (such as glycopyrrolate) can help dry secretions and maximize the view of the laryngeal structures. Furthermore, an antisialagogue will decrease the secretion of saliva, allowing topical local anesthetics to penetrate the mucosa to a greater degree and enhancing the anesthesia in the oral cavity, tongue, oropharynx, and hypopharynx. However, 20 minutes is usually required to effectively decrease secretions.

The risk of aspiration must always be considered when the airway reflexes have been anesthetized. Therefore medications that decrease stomach acid production and promote gastric emptying should be considered. Vasoconstriction of the nasal passages reduces the risk of mucosal damage and hemorrhage. Solutions containing oxymetazoline 0.05% (afrin), or phenylephrine (Neo-Synephrine) can be sprayed into the nose 2 to 3 minutes prior to application of the local anesthetic.

The most widely used local anesthetic for anesthetizing the airway is lidocaine in various forms and concentrations. Cocaine 4%, benzocaine 20%, and tetracaine are also effective anesthetics. In addition to its local anesthesia–producing effects, cocaine causes vasoconstriction and can be considered for local anesthesia in the nasal cavity. Peak serum lidocaine levels are highest 30 minutes after instillation. Use of lidocaine within the recommended dosage keeps serum lidocaine levels below toxic levels.[90,91] The evidence regarding the maximum safe dose for the topical administration of local anesthetics is controversial. However, an estimate of the maximum safe dose of local anesthesia should be calculated prior to any administration (e.g., lidocaine 4-5 mg/kg). Finally, clinical judgment of the situation is required and the anesthetist should continually assess for signs and symptoms of toxicity.

AIRWAY BLOCKS

Anesthesia for the airway can be provided by either topical anesthesia, infiltration, or a combination of the two. The anesthetic requirements for the airway include sensory inhibition of the nasal, oral, pharyngeal, laryngeal, and tracheal mucosa. Specific branches of three cranial nerves need to be anesthetized to perform an awake oral or nasal intubation. The three cranial nerves include the trigeminal, glossopharyngeal, and vagus nerves (Figure 22-19). Both the ophthalmic and maxillary divisions of the trigeminal nerve provide sensory innervation to the nasal septum and lateral wall. In addition, the mandibular division of the trigeminal nerve forms the lingual nerve, which provides sensation to the anterior two thirds of the tongue. The glossopharyngeal nerve provides sensory innervation to the posterior third of the tongue, the soft palate, and the oropharynx. Finally, the vagus nerve provides sensory innervation to the hypopharynx, larynx, and trachea via the superior and recurrent laryngeal nerves. The internal laryngeal branch of the superior laryngeal nerve provides sensation above the vocal cords, and the recurrent laryngeal nerve provides sensation below the vocal cords (Figure 22-20).

Topical Anesthesia

Anesthesia to the nasal septum, nasal wall, and nasopharynx blocks the anterior ethmoidal, nasopalatine, and sphenopalatine nerves that originate from the ophthalmic and maxillary divisions of the trigeminal nerve. These areas can be anesthetized by insertion of 5 mL of viscous lidocaine down each naris. The solution then liquefies to a greater degree and may coat the back of the throat. The nasal and oral cavities, as well as the nasopharynx and oropharynx, may also be anesthetized by adding 4 mL of 4% lidocaine with 1 mL of 1% phenylephrine to either a handheld nebulizer or a nebulizer attached to a facemask.[89] As the patient breathes through the nose and mouth, small droplets of local anesthetic are deposited on the mucous membranes. This method is also effective for anesthetization of subglottic tissue. However, this procedure requires a minimum of 10 to 20 minutes and may necessitate additional topical anesthesia during the awake procedure.

An alternative approach to nebulization is providing topical anesthesia by atomization using a device such as the DeVilbiss atomizer (Figure 22-21), or mucosal atomization device. Atomization produces larger droplets than nebulization, resulting in an

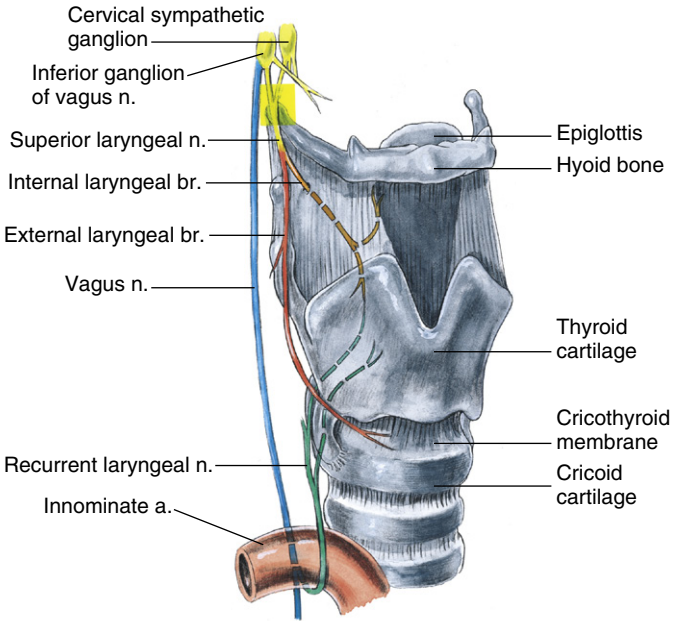

FIGURE **22-20** Laryngeal anatomy and nerve innervation. (From Brown DL, et al. *Atlas of Regional Anesthesia*. 4th ed. Philadelphia: Saunders; 2010.)

FIGURE **22-21** DeVilbiss atomizer.

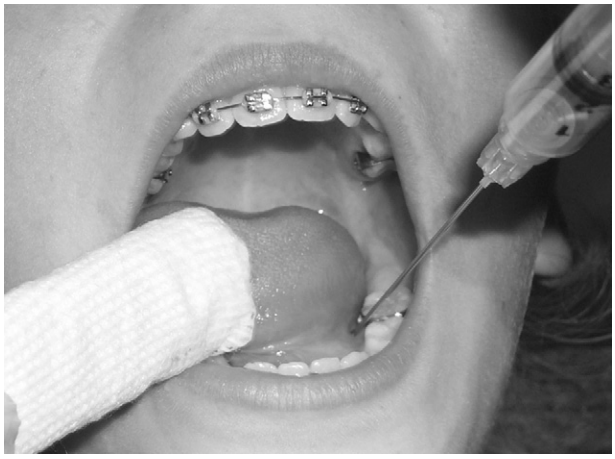

FIGURE **22-22** Glossopharyngeal nerve block.

increase of medication raining onto the upper airway mucosa and producing a denser block. The technique is to have the patient take 5 to 8 deep breaths on the atomizer through both the mouth and nose, which helps the fluid follow the same path as ventilated gases. Like nebulization, a similar dose of 4% lidocaine and 1% phenylephrine can be used for atomization.

Anesthetizing the mouth and oropharynx decreases the gag and coughing reflexes associated with awake intubations. Local anesthesia to this region blocks nerve transmission originating from the trigeminal (anterior two thirds of the tongue) and glossopharyngeal nerve. Topical sprays provide effective anesthesia to the anterior portion of the tongue and mouth. Benzocaine 20% (Hurricaine) spray is a topical anesthetic with a quick onset and short duration. A half-second spray delivers approximately 0.15 mL (30 mg), which is estimated to be approximately one third of the toxic dose (100 mg). Cetacaine spray contains benzocaine 14%, tetracaine 2%, butyl aminobenzoate 2%, benzalkonium chloride, and cetyl dimethyl ethyl ammonium bromide. The combination of these medications shortens the onset time and increases the duration of action.[92] Methemoglobinemia is associated with the use of benzocaine and has been reported after the use of these topical sprays. Therefore only conservative amounts of these sprays should be used. An alternative method for providing anesthesia to the mouth and tongue is to have the patient swish and gargle for 2 minutes with 2% or 4% lidocaine solution. The patient should then spit out the solution.

Topical anesthesia for the oropharynx and posterior tongue can be provided by using a "lidocaine lollipop," which can be made by coating the tip of a tongue blade with lidocaine ointment and then pulling the tongue forward while placing the lidocaine ointment on the back of the tongue. The tongue blade should be held in place for 1 to 2 minutes to allow the lidocaine ointment to liquefy and coat the oropharynx. Additionally, either nebulization or atomization using lidocaine can provide effective topical anesthesia provided adequate time is allowed.

Topical anesthetization of the vocal cords may be accomplished by instilling local anesthetic directly onto the cords. This can be accomplished in one of two ways. After the nasal cavity has been anesthetized, a nasal airway or ETT is passed and positioned in close approximation to the vocal cords. The patient is instructed to take a deep breath. On inspiration, 5 mL of 2% lidocaine is inserted down the lumen of the nasal airway. This causes the patient to cough, indicating that local anesthetic was deposited on the vocal cords. Another option is through the use of a fiberoptic bronchoscope or video laryngoscope. After visualization of the vocal cords is achieved, local anesthetic solution can be deposited directly onto the vocal cords through the injection port of the fiberoptic scope or by using a laryngeal tracheal anesthesia device.

Topical anesthetization of the upper airway can be achieved quickly and safely provided the anesthetist prepares the patient, calculates the appropriate toxic dose of local anesthetic to be used, and becomes familiar with these and other topical anesthesia techniques. Alternative upper airway anesthesia approaches, which can be used alone or in combination with topical anesthesia techniques, are infiltration nerve blocks.

Glossopharyngeal Block

The lingual branch of the glossopharyngeal nerve supplies sensory innervation to the posterior third of the tongue. To block the lingual branch, the practitioner first anesthetizes the tongue with topical anesthesia and then has the patient open his or her mouth and protrude the tongue forward. The anesthetist then displaces the tongue to the opposite side with a tongue blade, and what results is the formation of a gutter (Figures 22-22 and 22-23). Where the gutter meets the base of the palatoglossal arch, a 23- or

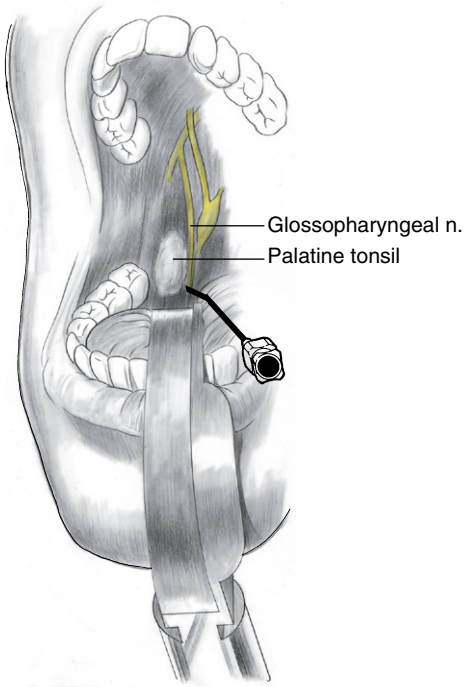

FIGURE **22-23** Glossopharyngeal nerve block anatomy and technique. (From Brown DL, et al. *Atlas of Regional Anesthesia*. 4th ed. Philadelphia: Saunders; 2010.)

25-gauge spinal needle is inserted approximately 0.25 to 0.5 cm and aspirated for air. If air is obtained on aspiration, the needle has been placed too deeply and should be withdrawn until no air is aspirated. If blood is obtained, the needle must be withdrawn and repositioned more medially. After correct positioning, 1 to 2 mL of 2% lidocaine is injected, and the block is then repeated on the opposite side.[89,92] The anesthetist should monitor for signs and symptoms of local anesthetic toxicity because a 5% incidence of intracarotid injection has been reported.[93]

Superior Laryngeal Nerve Block

The superior laryngeal nerve block provides a dense block of the supraglottic region. To perform the block, the practitioner locates the greater cornu of the hyoid bone, which lies beneath the angle of the mandible and can be palpated with the thumb and index finger on either side of the neck as a rounded structure (Figure 22-24). The anesthetist should then displace it toward the side that is being injected to help stabilize the bone and ease identification of structures and injection of the local anesthetic. The needle is inserted perpendicular to the skin to make contact with the inferior border of the greater cornu (Figure 22-25). The needle is then "walked off" the caudal edge of the hyoid bone where it then meets the thyrohyoid membrane. Resistance may be appreciated as the tip of the needle may be felt to "bounce" on the thyrohyoid membrane.[94] This site approximates the area where the superior laryngeal nerve pierces the thyrohyoid membrane. Aspiration should confirm there is no air or blood, and 1 mL of local anesthetic (e.g., 2% lidocaine) is deposited above this membrane. The needle is then advanced an additional 2 to 3 mm through the membrane and 2 mL of local anesthetic is deposited. The block is then repeated on the other side. Again, aspiration is performed before the injection of the local anesthetic. If air is aspirated, the needle has been placed too deep and is in the pharynx, and the tip of the needle should be withdrawn and repositioned.

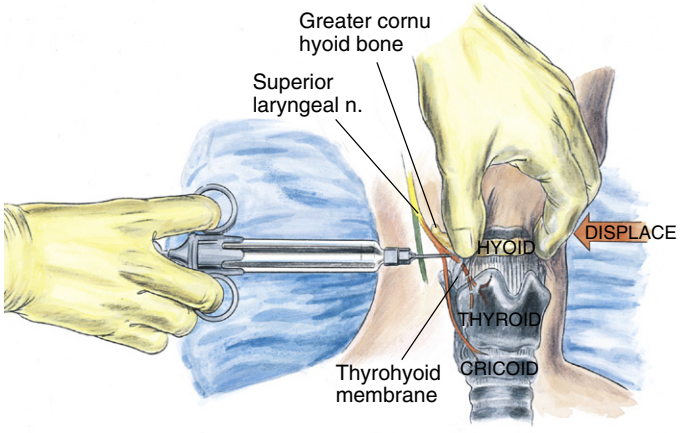

FIGURE **22-24** Superior laryngeal nerve block anatomy and technique. (From Brown DL, et al. *Atlas of Regional Anesthesia*. 4th ed. Philadelphia: Saunders; 2010.)

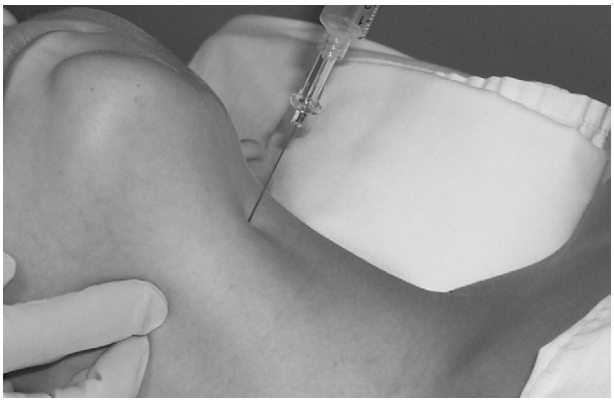

FIGURE **22-25** Superior laryngeal nerve block.

Transtracheal Block

The transtracheal block is accomplished by injecting local anesthetic through the cricothyroid membrane (Figure 22-26). To administer the block, the practitioner first palpates the cricothyroid membrane with the index and middle fingers (Figure 22-27) and the skin is localized. The anesthetist then attaches a 22-gauge needle or a 24-gauge angiocatheter to a syringe containing 3 to 5 mL of 2% lidocaine. The needle is placed midline and advanced in a caudad direction through the cricothyroid membrane while aspiration is continuously performed. When air bubbles are aspirated through the solution, the tip of the needle is in the tracheal lumen. If using an angiocatheter, the catheter is advanced into the tracheal lumen and the needle withdrawn, which may produce coughing.[94] The patient is then instructed to take a deep breath. On inspiration, the local anesthetic is injected into the tracheal lumen. This will cause the patient to cough, spraying the local anesthetic onto the vocal cords. Care must be taken to stabilize the needle so as not to tear the tracheal mucosa when the patient coughs. Use of the softer angiocatheter may decrease trauma.

CRICOID PRESSURE

British anesthetist Brian Arthur Sellick first described cricoid pressure in 1961 as the posterior displacement of the cricoid cartilage against the cervical vertebrae with the patient in a 20-degree head-up position to prevent regurgitation and possible aspiration of stomach contents during the induction of general anesthesia. As such, cricoid pressure (e.g., Sellick's maneuver) has remained a

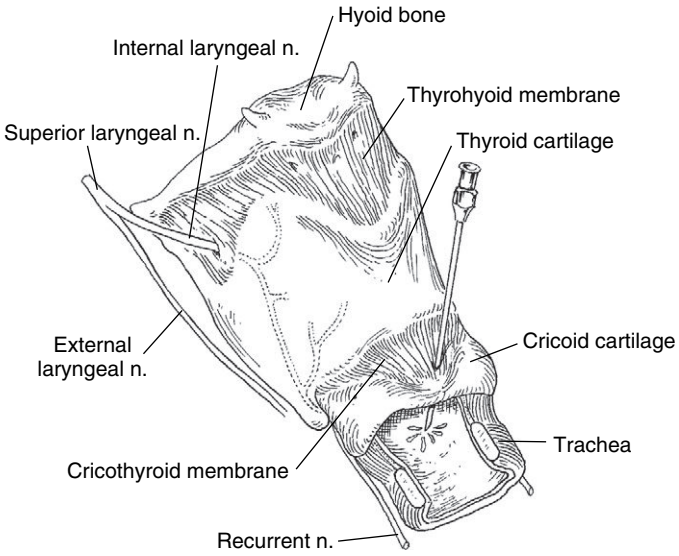

FIGURE **22-26** Transtracheal injection. *n*, Nerve.

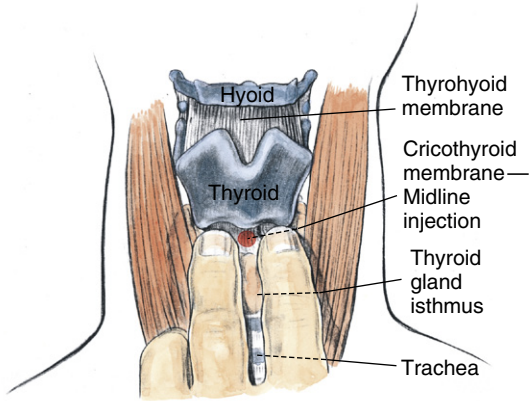

FIGURE **22-27** Transtracheal nerve block anatomy and placement. (From Brown DL, et al. *Atlas of Regional Anesthesia*. 4th ed. Philadelphia: Saunders; 2010.)

mainstay of anesthetic practice, particularly during rapid-sequence induction of general anesthesia in patients at high risk for gastric aspiration. Using a cricoid yolk, studies have shown that the optimal amount of force necessary to effectively occlude the esophagus without obstruction of the trachea is between 30 and 44 Newtons (N). It is recommended that 20 N (e.g., 2 kilogram-force) cricoid pressure be applied prior to loss of consciousness and that the pressure be increased to 40 N (e.g., 4 kilogram-force) after loss of consciousness (Figure 22-28).[95]

Recent evidence has questioned the perceived efficacy of cricoid pressure.[96] After an observational study using magnetic resonance imaging, Smith et al.[97] reported that in more than 50% of subjects, the esophagus can be found lateral to the cricoid ring. In addition, this proportion increases to 90% of subjects after the application of cricoid pressure, theoretically hampering esophageal occlusion during posterior displacement of the cartilaginous cricothyroid ring. A more recent report by Rice et al.[98] found that the anatomic location and movement of the esophagus during the application of cricoid pressure was irrelevant to the efficiency of the Sellick's maneuver in regard to clinical efficacy (e.g., prevention of gastric regurgitation into the pharynx). In a cohort of unsedated volunteers, magnetic resonance imaging showed that compression of the alimentary tract occurs with both midline and lateral displacement of the cricoid

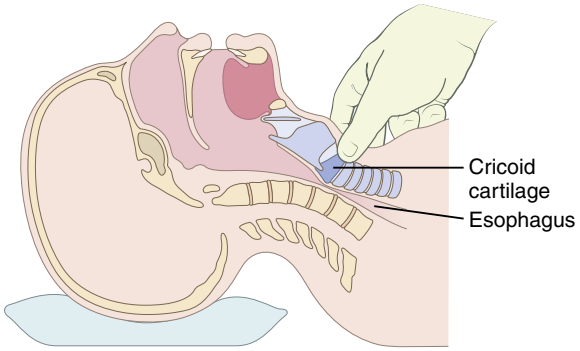

FIGURE **22-28** Application of cricoid pressure. (From Miller RD, Pardo MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Saunders; 2011.)

cartilage relative to the underlying vertebral body. They concluded that the hypopharynx and cartilaginous cricoid ring is an anatomic unit that is essential to the efficacy of cricoid pressure.

The application of cricoid pressure is not a benign procedure. Cricoid pressure of 44 N applied to the awake individual has been associated with laryngeal discomfort and retching. Maintaining cricoid pressure during active vomiting may result in rupture of the esophagus.[99] The application of pressure during rapid-sequence induction has been shown to decrease upper and lower esophageal sphincter tone.[95] Furthermore, complications attributed to the inappropriate application of CP include (1) airway obstruction (e.g., partial or complete), (2) difficulty in placement of the laryngoscope blade, (3) impeding glottic visualization during laryngoscopy, and (4) difficulty with tracheal intubation.[96] Cricoid pressure may be difficult to apply properly; therefore it is imperative that anesthetists and other healthcare providers receive proper training in correctly applying cricoid pressure to minimize complications.[99] When used, cricoid pressure should be applied until correct placement of an endotracheal tube is confirmed through traditional methods.

ADJUNCT AIRWAY EQUIPMENT AND TECHNIQUES

Over the past two decades, multiple adjunctive airway devices have been developed for use in both routine and difficult airway management situations. Adjunctive airway devices include ETT guides, lighted stylets, rigid laryngoscopes, indirect rigid fiberoptic laryngoscopes, flexible fiberoptic bronchoscopes, and supraglottic ventilatory devices. Supraglottic airway ventilation devices include both airway masks (e.g., LMA) and tubes.

Devices and techniques used for difficult intubation and ventilation may include any one or a combination of airway adjuncts. Adjunctive airway equipment should be routinely used in nonemergent or simulated practice situations to increase the anesthetist's familiarity with the equipment and facilitate ease of use in emergent situations.[85-87] Ultimately, the choice of which airway adjunct to use during airway management will be based on the anesthetist's familiarity and skill with the device, as well as (1) the need for airway control; (2) the ease of laryngoscopy; (3) the ability to use supralaryngeal ventilation; (4) aspiration risk; and (5) the patient's tolerance for apnea.[16]

Supraglottic Ventilation Devices

Supraglottic airway ventilation devices consist of those airway adjuncts that provide ventilation above the glottic opening. Different terminology has been used to describe these devices depending on where they are placed. For example, devices that sit above or surround the glottis (e.g., LMA, facemask) are truly supraglottic.

FIGURE **22-29** Classic LMA. (Courtesy LMA North America, Inc.)

In contrast, those devices that pass behind the larynx and enter the upper esophagus (e.g., Combitube, King LT airway) are known as retroglottic or infraglottic devices. However, because ventilation with all of these devices is performed superior to the glottic opening, the term *supraglottic airway (SGA) ventilation* will be the preferred terminology. The choice of which SGA device to use is dependent on the clinical situation and preference of the provider. Indications for the use of these devices include (1) rescue ventilation for difficult mask ventilation and failed intubation; (2) an alternative to endotracheal intubation, in appropriately selected patients, for elective surgery in the OR; and (3) as a conduit to facilitate endotracheal intubation.[100]

Laryngeal Mask Airway

Since its introduction into clinical practice in 1981, the laryngeal mask airway (LMA) has been used extensively in airway management. Its development has been hailed as one of the most significant advances in airway management since the ETT.[101] The LMA can be used as the primary airway device during appropriate surgical procedures and is considered a valuable airway tool in managing the difficult airway. A great deal of literature exists that reports the successful use of the LMA as a primary airway device and as a conduit for intubation of the trachea.[101-103] Indeed, there are over 300 publications involving more than 3000 patients that have described successful usage of the LMA in patients with difficult to manage airways.[104]

The classic LMA (Figure 22-29) was used extensively in Europe, primarily in England, before its introduction in the United States. Several variations of the LMA exist, including the classic, ProSeal, Supreme, and Fastrach models. In daily clinical use, this airway can be used in place of bag mask ventilation during general anesthesia. An appropriately sized LMA is generally based on patient kilogram weight (Table 22-7). Laryngeal mask insertion is usually accomplished using the classic technique, which is fully deflating the cuff and placing a water-soluble lubricant on its posterior surface. The practitioner then inserts the LMA midline into the mouth with the posterior surface pressed against the palate of the mouth and then advances with the index finger along the palatopharyngeal curve. Reports have indicated between an 88% and 95% success rate on the first attempt with an experienced provider.[104,105] If initial attempts at LMA placement are difficult, then the LMA should be removed and attempted with the patient in a proper sniffing position. In addition, if the LMA encounters resistance when it reaches the oropharynx, it is many times due to the distal tip having folded back, and the airway simply needs to be retracted and advanced again. If continued resistance occurs, then the operator can place the right index finger between the superior portion of the LMA and the palate and "flip the tip" back into normal position while advancing the device with the opposite hand. When properly placed, final resistance denotes placement of the LMA's tip in the hypopharynx, and the black line on the tubing will be even with the upper lip. The cuff is then inflated, sealing the airway over the larynx. The esophageal opening at the base of the hypopharynx has no seal. If the cuff is overinflated, it can actually open the upper esophageal sphincter, or potentially cause posterior cricoarytenoid muscle fatigue.[106]

Alternative techniques and maneuvers can be used for LMA placement. The LMA also can be introduced into the mouth with the opening initially facing the palate. It is then advanced until the LMA reaches the oropharynx, when it is rotated 180 degrees counterclockwise and advanced into its final position. Another technique is to partially or fully inflate the LMA cuff with air before insertion. Finally, guided techniques using a gum elastic bougie or a laryngoscope to facilitate placement have been reported.[107]

ProSeal and Supreme LMA

The ProSeal LMA (PLMA) was introduced in 2000, as an alternative supraglottic device to the classic LMA, and comes in the same sizes (Figure 22-30) as the classic LMA. Modifications compared to the classic LMA include: (1) a larger and deeper bowl with no

FIGURE **22-31** LMA Supreme. (Courtesy LMA North America, Inc.)

FIGURE **22-32** Fastrach LMA. (Courtesy LMA North America, Inc.)

grille; (2) the posterior extension of the mask cuff; (3) a gastric drainage tube running parallel to the airway tube and existing at the mask tip; (4) silicone bite block; and (5) anterior pocket for seating an introducer or finger during insertion.[108,109] The PLMA was designed with a second posterior cuff, that when inflated helps to separate the respiratory and gastrointestinal tracts, and a second tube developed for the insertion of a gastric tube into the esophagus without passing through the hypopharynx. The addition of this esophageal gastric drain tube allows the practitioner to identify misplacement, decompress the patient's stomach of air or solid contents, and may vent regurgitated stomach contents. Though not proven in clinical trials, cadaver studies indicate that the PLMA can protect the airway from regurgitated material.[16]

Compared to the classic LMA, insertion of the PLMA takes an additional few seconds, but the overall success is equivalent. In addition, the airway seal is improved by 50% allowing a positive ventilation pressure up to 30 cm H_2O (versus the 20 cm H_2O with the classic LMA). Indications for the use of the PLMA include situations in which the classic LMA may not provide sufficient ventilation or airway protection, and endotracheal intubation would rather be avoided. The PLMA has been used in laparoscopic (though this is controversial), obese, intensive care, trauma, and difficult airway cases.[109] A disposable version of the PLMA, named the LMA Supreme (Figure 22-31), has been developed and comes in rigid preformed sizes to facilitate ease of placement.

Fastrach LMA

The Fastrach LMA (Figure 22-32), also known as the intubating LMA (ILMA), was released in 1997 and was specifically designed for use in difficult airway situations.[103,110,111] The design of the Fastrach LMA provides the anesthetist with the opportunity to ventilate and then to attempt a blind endotracheal intubation through the laryngeal mask channel. It has been used successfully in the cannot intubate and cannot ventilate scenario, as well as in situations where difficult intubation is anticipated. The design of the Fastrach allows for reasonable control of the airway throughout the intubation process, first with the laryngeal mask, then with endotracheal intubation. The primary distinguishing features, as described by the Fastrach inventor, Dr. Archie Brain, include: (1) an anatomically curved rigid airway tube; (2) an integrated guiding handle; (3) an epiglottic elevating bar; and (4) a guiding ramp built into the floor of the mask aperture.[112]

The Fastrach LMA comes in sizes 3, 4, and 5, and involves a series of steps during placement and subsequent intubation (Box 22-7). As with all adjunctive airway equipment, the Fastrach LMA should be used in routine cases to ensure familiarity with the technique before its use is attempted in an emergent situation or with a difficult airway. However, most practitioners who are familiar with the insertion of the LMA adapt readily to insertion of the Fastrach. The Fastrach LMA has been successfully used in the OR for ventilation in 97% to 100% of anticipated and unanticipated difficult airway cases.[76] Successful use of the Fastrach was also demonstrated in prehospital emergency airway situations in which intubation was not possible by direct laryngoscopy. Placement of the ILMA was accomplished in 96% of the study population and successful intubation was performed blindly in 91%.[113]

Visualization of the vocal cords using the Fastrach LMA also can be accomplished with the aid of either a videoscope or fiberscope. The Fastrach LMA can be used as a conduit for intubation using a fiberoptic bronchoscope and preloaded ETT. The preformed ILMA silicone-coated tube provides a direct channel to the vocal cords. This technique provides visualization of the vocal cords and has been successfully documented in the literature.[110,114] An adaptation of the Fastrach is the C-Trach intubation device. This device adds a video screen that is magnetically mounted to the standard Fastrach. The C-Trach allows the anesthetist to visualize the ETT passing through the vocal cords, confirming proper placement of the tube.

LMA Considerations

Familiarity with the different LMA models, their ease and speed of insertion, and their high likelihood of success in difficult airway situations make them an extremely valuable airway rescue device. One of the concerns with the LMA is the possibility of aspiration during insertion or when the LMA is in place. Gastric inflation of the stomach, regurgitation, or aspiration of gastric contents can occur with LMA use. If ventilation is performed using positive pressure greater than 20 cm H_2O with the classic LMA and 30 cm H_2O with the PLMA, the stomach may become inflated. These devices can also be malpositioned or the cuff overinflated, resulting in failure to ventilate the patient. Malpositioning of the LMA in the airway and overinflation of the cuff may result in additional pressure to the sidewalls of the pharynx and pressure on the posterior wall of the larynx. If this occurs, it is possible that the epiglottis can be folded back against the glottic opening, sealing the airway. Pathology at or below the laryngeal level may render the LMA ineffective as a supraglottic device. Indeed, LMA failures have been reported in both obstructions within the hypopharynx and obstructions below the hypopharynx such as subglottic obstructions (e.g., tracheal thrombosis, tracheal stenosis, tumors), Hunter

BOX **22-7**

Fastrach and Blind Endotracheal Tube Placement

PreFastrach LMA and ETT Placement

1. Confirm integrity of LMA and ETT cuff (may use Fastrach reusable silicon-tipped ETT or standard prewarmed polyvinylchloride ETT) and then deflate cuffs.
2. Lubricate ETT with water-soluble lubricant at distal end and pass through to Fastrach lumen lubricate inside the channel.
3. Lubricate anterior and posterior surfaces of Fastrach cuff with water-soluble lubricant.

Fastrach LMA Placement

1. Hold device by the metal handle in dominant hand and open the airway.
2. Insert cuff into mouth with mask tip in contact with the palate (metal tube portion will be in contact with the chin).
3. Maintain firm pressure with the palate and posterior pharynx and rotate while advancing the Fastrach into place until resistance is felt or handle meets face (only metal end of silicone-coated tube will protrude from mouth).
4. Inflate the Fastrach cuff.
5. Confirm adequate ventilation (ventilation confirmation should indicate consistent $ETco_2$ waveform, positive change in color on CO_2-detecting devices, and equal bilateral breath sounds).
6. May manipulate device gently using handle until ventilation is optimized.

ETT Placement Through Fastrach LMA

1. Remove adaptor from ETT and set aside (may place on ventilator circuit for easy placement back onto ETT postintubation).
2. Place ETT through Fastrach LMA lumen until it reaches the 15-cm marking (at this position the ETT is about to push the epiglottic elevating bar up, moving the epiglottis out of the way).
3. Use the Fastrach handle to lift anteriorly and blindly insert ETT into trachea (should not encounter resistance) and inflate ETT cuff balloon.
4. Place ETT adaptor back on ETT and attempt ventilation (ventilation confirmation should indicate consistent $ETco_2$ waveform and equal bilateral breath sounds).
5. Consider leaving Fastrach LMA *in situ* (in emergency situations).

If Decision Is Made to Remove Fastrach LMA

1. Remove adaptor from ETT and set aside (may place on ventilator circuit for easy placement back onto ETT postintubation).
2. Deflate ETT balloon and Fastrach LMA balloon.
3. Place Fastrach stylet on the end of the ETT and provide counter traction caudally as the Fastrach LMA is removed.
4. When the ETT is visualized below the Fastrach cuff at the level of the mouth, hold ETT, remove stylet so that the ETT balloon cuff can pass through the Fastrach LMA lumen, and then remove the Fastrach LMA completely.
5. Replace ETT adaptor and reconfirm correct ETT placement in trachea (ventilation confirmation should indicate consistent $ETco_2$ waveform and equal bilateral breath sounds).

ETT, Endotracheal tube; *LMA,* laryngeal mask airway.

syndrome, obstetric patients, aspiration, or severe rheumatoid arthritis.[16] In obstetric anesthesia, the LMA is used when tracheal intubation has failed and ventilation with a facemask is difficult or impossible. In the cannot intubate and cannot ventilate scenario, the LMA should be attempted prior to a cricothyroidotomy.

Intubating Laryngeal Airways (Cookgas ILA) and Air-Q

Physician inventor Daniel Cook developed an oval-shaped supraglottic intubating airway that allows the anesthetist to maintain ventilation through the airway device or intubate with a standard ETT. The Cookgas ILA (Figure 22-33) comes with a removable stylet to stabilize the ETT while the laryngeal mask is removed. As with most devices, the ILA is able to be re-autoclaved only 40 times. A companion product, the Air-Q, is disposable. The stylet with the ILA cannot be autoclaved but can be sterilized with liquids up to 10 times. The ILA and Air-Q come in varying sizes, and both are usable on patients weighing from 20 to 100 kg.

Several other supraglottic laryngeal masks have been introduced for single airway use. Examples include the Ambu laryngeal mask airway, which combines an anatomic curve and a built-in bite block. The Cobra perilaryngeal airway (PLA) is a single lumen tube with a circumferential distal cuff just proximal to a distal adaptor that looks like a cobra head and is intended to expand hypopharyngeal tissue. Both the I-Gel and the streamlined liner of the pharynx airway (SLIPA) do not have inflatable cuffs, but do have the capacity to ventilate and contain reservoirs to capture regurgitated material.

Supraglottic Tubes

Several supraglottic tubes (also known as retroglottic or infraglottic tubes) have been developed over the past several years. Devices in this class include the Combitube, King Laryngeal Tube (LT) airway, Rusch Easy Tube, and LaryVent. These devices are placed blindly through the mouth and are positioned into the esophagus. These tubes have a distal balloon to occlude the esophagus, as well as a larger proximal balloon to occlude the posterior oropharynx. Between the two balloons is a ventilation port at approximately the level of the trachea. These devices can be used for both rescue and routine management, as well as for prehospital difficult airway situations.

FIGURE **22-33** Intubating laryngeal airway. (Courtesy Mercury Medical.)

Combitube. The Combitube (Figure 22-34) is a double-lumen airway device that is inserted blindly into the hypopharynx. The

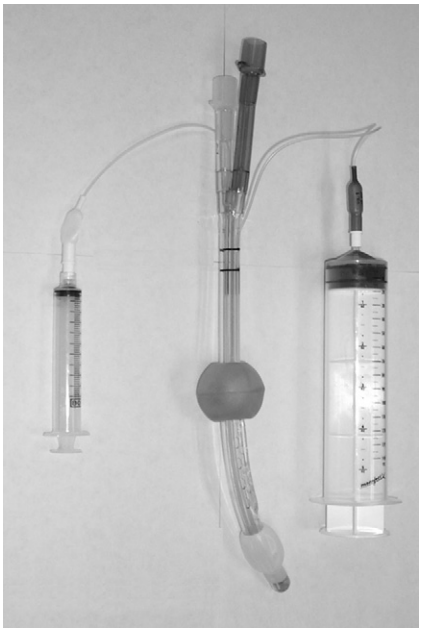

FIGURE **22-34** Combitube.

Combitube can be considered as a secondary rescue device in the event of intubation, gum elastic bougie, and LMA failure.[115] This device contains an esophageal lumen and a tracheal lumen. The esophageal lumen has a blocked distal port and perforations at the pharyngeal level, whereas the tracheal lumen has only an open distal end. Irrespective of where the tip is placed, the lungs may be ventilated.[116] The usual placement of the tip is into the esophagus. This blind insertion is easily accomplished, and the patient's head can be kept in the neutral position. To successfully insert the Combitube, cricoid pressure should be released while the mandible and tongue are lifted anterior. After insertion, the cuffs of both lumens are inflated and ventilation is first attempted with the esophageal lumen and assessed for verification. If there are no breath sounds and air is auscultated over the stomach, then it is probable that the tube was inserted into the trachea and the tracheal lumen is then used for ventilation. Bilateral breath sounds and the presence of end tidal CO_2 should be confirmed and indicate successful placement. The Combitube may offer some protection from aspiration due to the distal cuff occluding the esophagus. The Combitube is a supraglottic device, and pathology at or below the laryngeal level may make the Combitube ineffective. Reported complications include esophageal rupture.

King LT/LTS-D. King Systems introduced the King LT (also known as the laryngeal tube airway) in 2002, which is a minimally invasive airway device similar to the Combitube. This device is a single lumen (Figure 22-35) that has a ventilation outlet between the low-pressure oropharyngeal and esophageal cuffs. The device is inserted in a manner similar to the Combitube but has only one ventilation port. The King LT is a reusable supraglottic airway device created as an alternative to tracheal intubation or mask ventilation. This airway is designed for positive pressure ventilation, as well as for a spontaneously breathing patient, thereby allowing maximum versatility as an airway management tool.

The King LT has the capacity to achieve a ventilatory seal of 30 cm H_2O or higher. It is easy to insert, and a randomized comparison of the laryngeal tube has shown it to be as effective as the classic LMA during anesthesia with controlled ventilation.[102] Furthermore, there is evidence that King LT may be useful in situations where ventilation and intubation are difficult or have failed

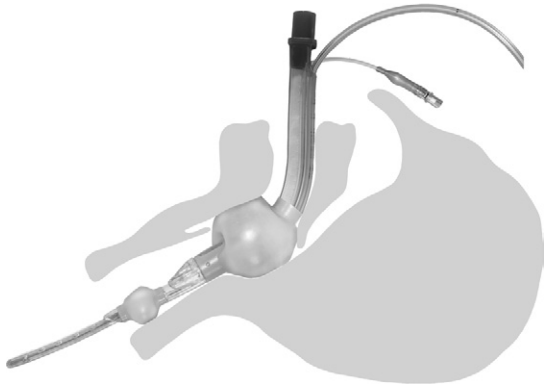

FIGURE **22-35** KING LTS-D. (Courtesy King Systems.)

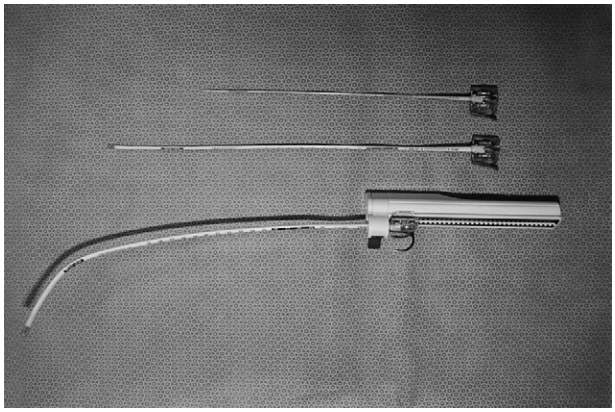

FIGURE **22-36** Trachlite lighted stylet.

altogether.[117] However, the research is limited and further inquiries into its usefulness have been suggested. The King LT is 100% latex free and can be autoclaved up to 50 cycles, or is available in a disposable model. The LT model has a single opening for ventilation. The King LTS-D is a disposable version that contains a second port which accommodates an 18-French nasogastric suction tube for insertion into the stomach.

Intubation Stylets

Trachlite Lighted Stylet

The Trachlite (Figure 22-36) lighted stylet is a recent adaptation of the light wand that uses transillumination of the neck to accomplish endotracheal intubation. Because the placement of the glottic opening is anterior to the esophagus, as the light source enters the trachea, a well-defined circumscribed glow is noticed below the thyroid prominence and can be readily seen on the anterior neck. Placement of the Trachlite in the esophagus results in a much more diffuse transillumination of the neck without this circumscribed glow. The Trachlite has a bright light source that does not require low ambient light for optimum performance. In addition, it has a retractable stylet that increases the success rate for intubation.

The success rate of the Trachlite is similar to that of conventional direct laryngoscopy. It is less affected by anterior placement of the larynx, is less stimulating than conventional laryngoscopy, and is associated with a lower incidence of sore throat. It can be used in both the anticipated and the unanticipated difficult airway when conventional laryngoscopy has failed.[118] The Trachlite also can be used in patients with a small oral opening and minimal neck manipulation.

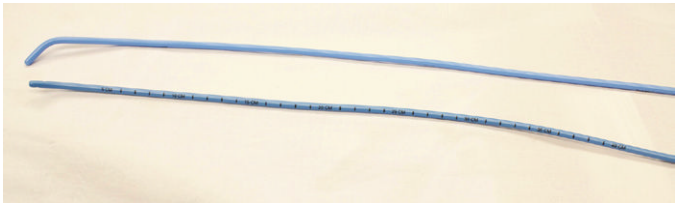

FIGURE **22-37** Eschmann stylet or Gum Elastic Bougie.

Because the Trachlite is inserted blindly using transillumination, risk of injury or failure is increased when the device is used in patients with any upper airway anomaly, such as foreign body, tumor, polyps, or soft-tissue injuries. If these anomalies exist, other airway adjuncts should be used. Furthermore, it may be more difficult to accurately place the Trachlite in patients with short, thick necks or redundant soft tissue. Finally, the Trachlite is not advertised as a rescue adjunct for the cannot intubate, cannot ventilate scenario, but instead has been suggested for situations in which intubation has failed, but time is available because ventilation is still possible.[15]

Eschmann Stylet (Gum Elastic Bougie)

The Eschmann stylet (Figure 22-37) is a flexible stylet with a bent distal tip that can be useful when the glottic opening is difficult to visualize (e.g., Cormack and Lehane grade II or III). Placement first involves visualization of the epiglottis or posterior arytenoid cartilages. The stylet is advanced behind the epiglottis and placed into the glottic opening. Feeling the stylet bounce along the tracheal rings as it is advanced into the trachea is a confirmation of placement, but is not always felt. The stylet should be advanced until the 25 cm marking is at the lip, where the stylet is then held in place. An ETT is inserted over the stylet and slid into place in the trachea. If resistance is felt, the ETT can be rotated 90 degrees and then advanced. An alternative technique is to advance the ETT over the Eschmann stylet until it is in the oropharynx, and then perform a direct laryngoscopy with a laryngoscope while an assistant holds the stylet in place. The ETT is then advanced through the glottic opening and into the trachea. Care should be taken not to advance the Eschmann stylet further into the trachea and risk a bronchial or distal tracheal puncture.

Airway Exchange Catheters

An airway exchange catheter (AEC) can be used during the changing of an ETT, or during the extubation of a difficult airway. These catheters allow gas exchange using either jet ventilation or oxygen insufflation from an adapter and bag mask (Figure 22-38). The AEC is introduced through the existing ETT with the distal tip placed proximal to the carina.[28] The ETT can then be removed and the new ETT placed over the AEC that acts as a stylet. If the new ETT encounters resistance during advancement, an attempt at rotating the ETT 90 degrees may facilitate passage. An alternative technique is to place the new ETT over the AEC and advance until the ETT is in the oropharynx and perform a similar technique as described above with the Eschmann stylet using a laryngoscope. The AEC also can be left in the trachea after the extubation of a difficult airway in the event that the patient requires reintubation. Care should be taken not to advance the AEC distally into either of the mainstem bronchi or to exert excessive force that could result in a tracheal or bronchus perforation.

Flexible Fiberoptic Scopes and Fiberoptic Stylets

Scopes can be either flexible or rigid and allow for the visual placement of ETTs. These devices can be used during routine airway management, but are more frequently employed when the airway exhibits indications of difficulty during the preoperative assessment or during management of an unanticipated difficult airway.

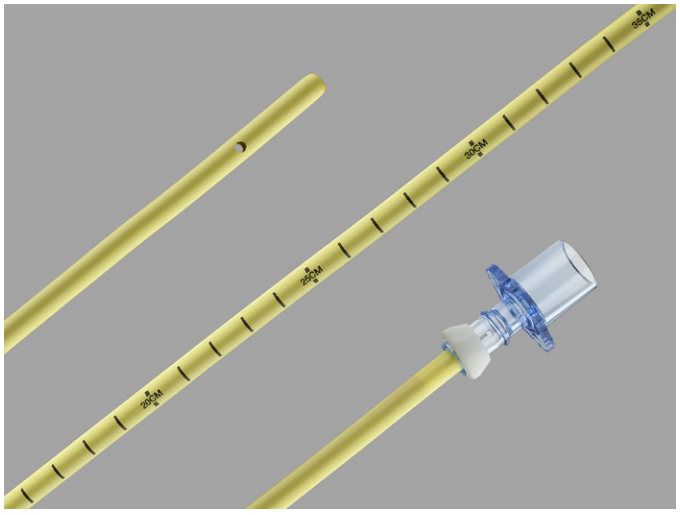

FIGURE **22-38** Cook airway exchange catheter. (From Cook Medical Incorporated, Bloomington, Indiana.)

Flexible Fiberoptic Laryngoscope (Bronchoscope)

The fiberoptic bronchoscope can be used to evaluate the airway, facilitate intubation of the patient with a difficult airway, check ETT placement, change an existing ETT, and perform postextubation evaluations.[119] The flexible fiberoptic laryngoscope consists of multiple strands of tiny glass fibers that transmit light. These fibers are bound together inside a rubberized coating that allows for flexibility. Within the scope are working channels that can carry oxygen, act as suction ports, or be used to instill local anesthetic. The handle contains an eyepiece for viewing and a lever for controlling the distal end of the scope through one plane (either up or down). The second plane is navigated by rotation of the scope by the operator's hand. Light is supplied by an external light source or by battery.

The limitations of fiberoptic laryngoscopy should be considered prior to performing this procedure, but ultimately the decision to proceed is based on the anesthetist's clinical judgment. Limitations with fiberoptic laryngoscopy include the following:

- The scope can become fogged, especially if it is cold. Soaking the scope in warm saline, the use of an antifog liquid, or placing the scope in the buccal mucosa below the patient's lip for 5 seconds before use may help prevent fogging.
- Viewing can be limited when multiple fiberoptic strands are broken or damaged. The scope should never be banged or dropped and should always be stored flat in a protective case or cart.
- Secretions or blood can obstruct the operator's view. This may be prevented with the instillation of oxygen at 10 to 15 L per minute through one of the side channels.
- The fiberoptic bronchoscope should be used with extreme caution in patients with epiglottitis, laryngotracheitis, or bacterial tracheitis, because manipulation of the fiberoptic bronchoscope through the glottis may cause enough stimulation to convert a partial obstruction into a total obstruction of the airway.
- Caution should be strictly exercised in patients with airway burns because of the restricted size and the hyperirritability of the airway.
- The use of the fiberoptic bronchoscope is very limited in airway trauma. The presence of blood and mucus in the

airway obscures the lens and makes visualization impossible. If significant soft-tissue trauma is present, edema of the tissues can prevent adequate visualization of the larynx and trachea.

- In situations in which both intubation and ventilation have failed and immediate airway access is required, it may be prudent to attempt a different airway technique because of time constraints or proceed directly to an invasive airway such as a cricothyrotomy.

Indications for fiberoptic intubation of the patient include the following:

- *An anticipated difficult airway.* These patients usually include a history of intubation difficulty and upper airway obstructions such as angioedema, tumors, abscesses, hematomas, Ludwig's angina, or lingual hyperplasia.
- *Cervical spine immobilization.* For example, patients with traumatic cervical injuries, an unstable cervical spine, or a cervical spine with a severely decreased range of motion may have cervical spine immobilization.
- *Anatomic abnormalities of the upper airway.* Patients with a restricted mouth opening or hypoplastic mandible or who are morbidly obese may fall into this category.
- *Failed intubation attempt, but ventilation possible with a mask or SGA device.* In these situations, the operator has time to set up and perform the fiberoptic technique using either an endoscopy mask or LMA as a conduit for the scope.

The fiberoptic bronchoscope can be used for oral or nasal intubation, with the patient either awake or asleep. An awake fiberoptic intubation is most commonly performed for an anticipated difficult airway. Preparation for an awake fiberoptic intubation includes educating the patient regarding what to expect, administration of an antisialagogue, anesthetizing the patient's airway, and providing adequate sedation.

The patient's airway should be anesthetized with either topical anesthesia, nerve blocks, or a combination of the two as previously described. Debate and controversy exist regarding the administration of drying agents and sedation. Radiation can cause fibrosis and loss of mucus-producing glands, so drying of the airway can be extensive with the use of an antisialagogue in this patient population. However, either atropine or glycopyrrolate may be administered 5 to 20 minutes before the procedure. Administration of light sedation may help reduce the patient's stress and provide for a more relaxed environment for the practitioner. A common practice is to use a combination sedation-analgesia technique such as the administration of fentanyl and midazolam. However, carefully titrated amounts using small bolus doses should be considered whenever control of the airway is in doubt. A short-acting titratable opioid such as remifentanil is an alternative choice that can be used during the stimulating portion of fiberoptic intubation.[120]

A Yankauer suction device must be accessible whenever the fiberoptic bronchoscope is used. Medications used in airway management should be readily available. These include local anesthetics, resuscitation drugs, induction agents, and muscle relaxants. If the equipment is to be used outside of the OR, the appropriate monitors should be placed in the difficult airway cart. This cart can become the central location for all emergency airway devices, including invasive airway equipment and LMAs.

Success with the fiberoptic scope is dependent on familiarity of the device and skill with its use. This may be accomplished by continued training with intubation manikins, high-fidelity patient simulators, or during routine airway management in the clinical setting.[121,122] With oral intubations, a fiberoptic guide

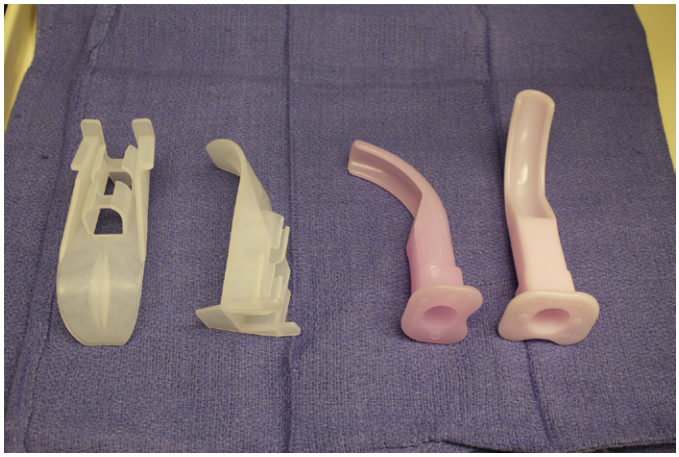

FIGURE **22-39** Williams airway (right) and Ovassapian airway (left).

FIGURE **22-40** Fiberoptic technique (frontal approach).

(such as the Williams, Berman, or Ovassapian airway) functions as a guide to facilitate placement of the scope into the pharyngeal area and also can help prevent damage to the fibers if the patient were to bite the scope (Figure 22-39). The operator can either perform the technique at the head of the bed with the patient in the supine position, or from the side using a frontal approach with the patient in a sitting position (Figure 22-40). The latter technique may help prevent tissues from falling against the airway impeding fiberoptic views, may help to decrease patient anxiety, and has been used in patients in whom upper airway masses have compressed the airway, causing difficulty breathing in the supine position.[123]

An ETT is first loaded onto the fiberoptic scope and is then inserted through either the mouth or the nose and advanced to the posterior pharynx. The anesthetist can manipulate the scope in two planes by adjusting the lever on the handle up or down and by rotating the scope laterally with the wrist. The operator should use the dominant hand to hold the handle with the arm bent and resting on the operator's shoulder or positioned to look through the eye piece on the handle, while the other hand holds the distal portion of the scope to keep it taut (see Figure 22-40). Care must be taken to keep the scope in the midline while the tip is advanced toward the epiglottis. The operator should be able to visualize the different airway structures as the scope is advanced through the oropharyngeal and pharyngeal space (if not using a fiberoptic guide). If at any point the view is lost and the operator is unsure of the scope's location in the airway, it

should be retracted until identifiable airway anatomy is visualized. Instillation of oxygen through the suction port not only aids in the oxygenation of the patient but also helps keep the optics clear. The tip of the scope is slipped through the glottic opening and advanced until the tracheal rings come into view. The ETT is slipped downward, with the scope used as a stylet, and then through the cords into the trachea. If resistance is felt, the ETT should be rotated 90 degrees, but should never be forced into the airway because this may cause airway trauma. After the ETT is advanced into the trachea, the operator can verify placement by visualization of the carina.

Suctioning is difficult through the suction port. A more advantageous use of this channel is to provide the patient with supplemental oxygen. A 2- to 4-L flow through this port can provide additional oxygen to the patient and keeps debris from collecting on or near the port and lens. The administration of local anesthesia through the port or an epidural catheter threaded down the port is another use of this channel.

All personnel who will be using the device should be trained in its care and cleaning. The bronchoscope should be handled with care because the fibers are very fragile and bending, curling, or any other type of kinking could break them. After use, the scope should be flushed with warm sterile water, and all of the channels cleaned thoroughly with the appropriate solutions and equipment. Manufacturers will indicate which detergent and sterilizing solution they recommend. Instructions regarding solution, dilution, soak times, and rinsing must be closely followed to ensure the integrity and longevity of the equipment.

Rigid and Semirigid Fiberoptic Stylets and Laryngoscopes

Though not a regular part of emergency airway management, rigid and semirigid fiberoptic stylets and laryngoscope devices have shown potential for use in difficult airways situations, when intubation has failed, as well as during routine airway management.[119,124,125] However, there is insufficient literature and few comparisons of performance with other airway adjuncts to support any specific recommendations. These devices provide the operator with an indirect view of the glottic opening through a transmitted image via a fiberoptic bundle that is enclosed in a preformed design. The use of both rigid and semirigid fiberoptic stylets allows the operator to see around the tongue and eliminate the need for neck mobility and significant mouth opening. Examples of semirigid fiberoptic stylets include the Shikani optical stylet (SOS) and the Levitan First Pass Success (LFPS) scope. Rigid stylets include the Bonfils Retromolar Intubation Fiberscope™, the airway rigid intubation fiberscope laryngoscope (RIFL), and the Bullard laryngoscope. Indications and limitations with the use of these devices are similar to those described for flexible fiberoptic laryngoscope. Furthermore, as with any airway adjunct, success generally correlates with the degree of skill and familiarity of the operator with the specific device.

Shikani Optical Stylet and Levitan FPS. The Shikani optical stylet (SOS) (Figure 22-41) is a malleable, semirigid, intubating fiberoptic stylet for use in adults and children. It features a battery-operated light source with a high-resolution eyepiece on the handle to which the stylet is attached. The SOS also has the ability to insufflate oxygen into the pharynx via the ETT that is placed over the stylet prior to intubation. The malleable distal end allows configuration for varying intubation angles; this can be particularly useful for patients with a rigid or unstable cervical spine. The SOS can be used alone or in conjunction with direct laryngoscopy or as a conventional light wand.[126] In comparison, the operation of the Levitan FPS scope is similar to the SOS, but is intended to be used with a standard laryngoscope.

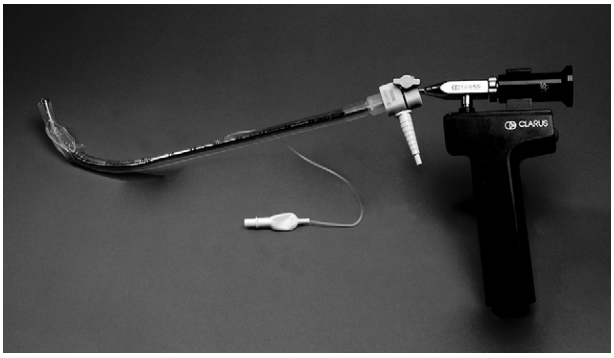

FIGURE **22-41** Shikani optical stylet. (From Marx JA, et al. *Rosen's Emergency Medicine*. 7th ed. St Louis: Mosby; 2010:20.)

Bonfils Retromolar Intubation Fiberscope, Bullard Laryngoscope, and RIFL. These devices have a rigid anatomic shape with fiberoptic bundles that provides an indirect view of the vocal cords. The rigid anatomic shape allows for visualization and intubation of the airway without aligning the oral, pharyngeal, and tracheal axes. These devices can be used on either an awake or an anesthetized patient. Because they do not require the sniffing position, they are ideal for patients with limited range of motion of the neck, such as those in cervical collars. Most have a channel for insufflation of oxygen while performing intubation, and a small combination battery pack that permits portability.

The Bonfils fiberoptic stylet has a rigid shaft that is 40 cm long, has an anterior bend of approximately 45 degrees, and is meant to be advanced in the airway using a retromolar instead of a midline approach. Advancement of the ETT occurs after the stylet has passed through the vocal cords. The RIFL is a hybrid rigid design and incorporates a rigid stylet that ends with a flexible tip that can be adjusted up to 135 degrees with the use of a trigger on the handle as the device is advanced down the airway. The distal tip is manipulated as the operator slowly advances the stylet until it passes through the vocal cords where the ETT is then slid off of the RIFL and placed into the trachea.

The Bullard scope is a rigid fiberoptic laryngoscope with an anatomically shaped blade that is meant to sit proximal to the vocal cords. It also has a detachable stylet to position the ETT along the right side of the blade, which allows the ETT to pass wherever the scope is looking.[127] When advancing the ETT, the arytenoids can obstruct passage through the glottic opening; however, this problem can usually be solved with either gentle cricoid pressure or lifting slightly with the blade. A complication with the use of rigid and semirigid fiberoptic stylets and laryngoscopes is the potential for airway trauma.

Video Laryngoscopy

Video laryngoscopy has been described as the most significant advancement in the way intubation is performed since the development of the laryngoscope in the 1940s.[128] Indeed, some authors believe anesthesia and emergency departments will reach the point where they will not want to be without a video laryngoscope.[129] These devices include a microvideo camera on the laryngoscope blade, which enables the transmission of video images to an external viewing screen. Glottic visualization is indirectly accomplished and tracheal intubation is performed while the operator views the external monitor. Video laryngoscopy is

FIGURE **22-42** GlideScope AVL Single Use in airway. (Used with permission, © verathon. Inc.)

a popular choice for anticipated difficult airways and as a rescue strategy when unexpected difficulty occurs. Furthermore, some authors have advocated for its use as the primary laryngoscopic technique and have found that video-assisted laryngoscopy provides improved visualization of the larynx over standard laryngoscopy.[63,130] Video laryngoscopy can be learned quickly and has several distinct advantages over traditional laryngoscopy such as the following[131]:

- Magnification of the airway allows the operator to visualize airway structures in greater detail.
- Blade design and anterior angulation, along with placement of the video camera on the distal portion of the blade, permit the operator to visualize structures that would otherwise be difficult or impossible to see under direct laryngoscopy.
- The external monitor allows other practitioners to visualize airway anatomy and understand current airway conditions.
- The recording capabilities allow for education, documentation, and research.

Disadvantages of video laryngoscopy include cost, which can reach approximately $10,000 or more. In addition, as with other optic devices, blood and secretions can obscure the viewing of airway structures. No specific device is recommended over another; however, speed, simplicity, reliability, and efficiency are desirable characteristics to be considered.[132]

GlideScope Video Laryngoscope

The GlideScope (Figure 22-42) is a video laryngoscope that provides a laryngoscopic view equal to or better than that of direct laryngoscopy without manipulation of the head into a sniffing position.[133] The device is made of medical grade plastic that is modified to resemble a Macintosh blade. The blade has a 60-degree anterior bend and is 18 mm wide. A camera is located in the middle part of the blade and transmits a signal via a video cable to a separate external liquid crystal display (LCD) monitor.[132] In addition, the GlideScope features an antifog system that heats the lens around the video camera preventing fogging of the device during laryngoscopy. Multiple models have been developed such as the portable GlideScope Ranger intended for prehospital and military field use, and the GlideScope Cobalt, which incorporates a disposable one-time use blade over a lighted video baton.

When performing video-assisted laryngoscopy with this device, the blade should be inserted midline and as soon as the tip of the blade is past the teeth, the operator should begin viewing the LCD monitor to identify the different airway structures and navigate to the glottic aperture. The blade should ultimately be placed into the vallecula followed by a gentle tilt of the handle that allows for visualization of the vocal cords. The ETT should be formed into a shape that is similar to the GlideScope blade to facilitate placement. This can be done using a regular ETT stylet, the rigid stylet provided by GlideScope. An alternative method is to bend the ETT and regular stylet at a right angle just proximal to the cuff. The ETT is inserted into the right side of the mouth by direct visualization and is advanced to the oropharynx. The operator should then view the monitor and use a gentle forward rotation to align the tip of the ETT with the glottic opening. Once aligned, the ETT should be advanced through the vocal cords under video visualization.[131] At this point the stylet may be withdrawn to help facilitate advancement of the ETT. The GlideScope should be cleaned before each use following the manufacturer's recommendations.

FIGURE **22-43** McGrath scope (Courtesy LMA North America.)

Karl Storz C-MAC Video Laryngoscope

The C-MAC video laryngoscope uses a blade design similar to a standard Macintosh blade, but unlike the GlideScope uses a less sharp anterior curve. This facilitates ETT placement, but may be less effective in difficult "anterior" airways.[131] The device includes a distally placed microvideo camera that resists fogging and provides an enhanced field of view. In addition, the C-MAC incorporates a video recording system that can be used for education and documentation. The insertion and technique of the device is similar to direct laryngoscopy, except the operator places the ETT using video visualization. Because the angle of the blade is less acute than that of the GlideScope, the ETT can be formed into a shape consistent with regular direct laryngoscopy.

McGrath Video Laryngoscope

LMA America introduced a video scope in 2007 called the McGrath video laryngoscope (Figure 22-43). This device uses one AA battery and has a rotational 1.7-inch color LCD screen attached to the handle. A one-time use disposable laryngoscope blade fits over the light source and is adjustable to three different positions. The blade is a modification of the Macintosh blade, and like the GlideScope has a similar anterior angle. The McGrath does not have an antifog mechanism. The device is extremely portable because the camera and monitor are both built into the

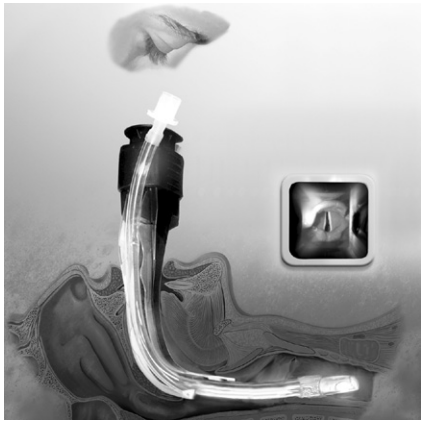

FIGURE **22-44** Airtraq visualization. (Courtesy Prodol Meditec.)

device. Technical use and placement of an ETT is similar to that described with the GlideScope.

Other Video Devices

The Pentax Airway Scope and the Res-Q-Scope II both incorporate a small video screen into the handle of the device. Both use disposable blades with a 90-degree distal bend and allow for preloading of an ETT prior to airway manipulation. Neither has antifog capabilities, though the plastic material on the Pentax is supposed to limit but not eliminate fogging. Both are less expensive alternatives than the previously mentioned video laryngoscopes; however, lens contamination by fogging and blood or secretions severely limit their viewing capabilities.

Airtraq Optical Laryngoscope

The Airtraq (Figure 22-44) is an optically enhanced laryngoscope that uses a series of mirrors, prisms, and lenses to magnify and enhance the laryngeal view and is much less expensive than video laryngoscopes. Like the video laryngoscopes, this device is designed to provide a view of the glottic opening without manipulating the neck into a sniffing position. The blade of the Airtraq has two channels. The first channel has a lighted, heated lens, and the second channel is for passage of an ETT up to a diameter of 8.5 mm. The Airtraq has a unique system that provides antifogging when the LED light is on for at least 30 seconds. There is an optional video camera that clips onto the viewfinder. In simulated difficult laryngoscopy scenarios, the Airtraq was successful in achieving tracheal intubation, required less time to intubate successfully than standard laryngoscopy, and was considered by the anesthetists as easy to use.[127]

Initial set up includes placing the ETT into the side channel until the tip is positioned at the end of the channel. The LED light is turned on for at least 30 seconds prior to placing the device into the mouth to initiate the antifogging system. The tip of the Airtraq is placed in the vallecula in a manner similar to that used with the Macintosh blade. Once in place, the scope is lifted vertically, allowing the epiglottis to flip up onto the blade and the cords to be visualized. Once the cords are visualized, the ETT is advanced through the device's channel and into the trachea. If the practitioner has difficulty visualizing the cords or advancing the ETT through the cords, the scope should be withdrawn slightly.

Subglottic Interventions and Emergency Invasive Airway Access

With the advent of the ILMA and other effective airway rescue devices, there has been less of a need for invasive airway access such as a cricothyrotomy. However, the anesthetist should be familiar with, and maintain regular training in, emergency invasive subglottic airway techniques. This is particularly true if the anesthetist were to encounter a situation in which a failed intubation and subsequent failed ventilation were to occur. In these situations the anesthesia provider must be familiar with and avoid any delay in performing an emergency invasive subglottic airway such as surgical cricothyrotomy or needle cricothyrotomy with transtracheal jet ventilation.

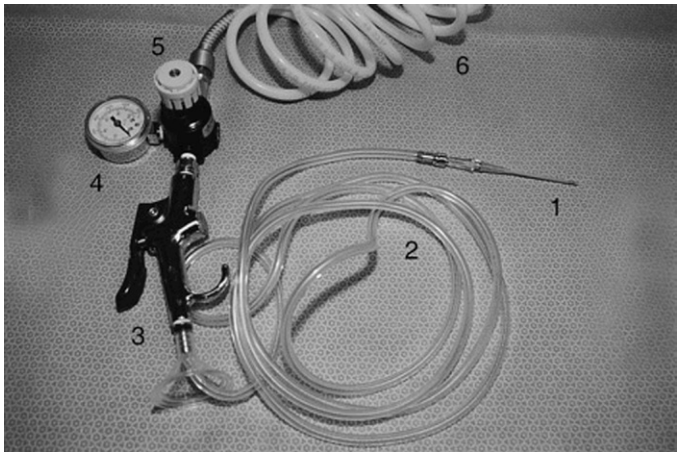

FIGURE **22-45** Transtracheal jet ventilation system assembly: (1) intravenous angio-cath, (2) small-bore tubing assembly with Luer-Lock fitting, (3) manual on/off valve, (4) pressure gauge (e.g., PSI), (5) adjustable pressure regulator, and (6) high-pressure hose assembly with Diameter Index Safety System (DISS) oxygen fitting (not shown).

Needle Cricothyrotomy with Transtracheal Jet Ventilation

Percutaneous transtracheal jet ventilation (PTJV) is attempted after the placement of a needle cricothyrotomy through the cricothyroid membrane. The procedure can be performed using a needle (e.g., 18-gauge or Ravussin needle), or a venous or arterial angiocatheter.[78] Ventilation through the catheter requires a jet injector powered by an oxygen source (Figure 22-45). Needle cricothyrotomy with PTJV may be considered in the cannot intubate and cannot ventilate scenario; however, in the adult patient a surgical cricothyrotomy can be performed quickly and provides a more secure airway with better ventilation. Instead, PTJV should be reserved for those airways where the anatomy is less favorable for placement of a surgical cricothyrotomy (e.g., small children less than 12 years old), or as a temporary means of ventilation.[134]

The procedure can be accomplished quickly using a large-bore intravenous catheter inserted through the cricothyroid membrane (see Figure 22-27) in a caudad direction (Figure 22-46).[135,136] The lungs are ventilated using a high-pressure oxygen source and a regulating valve to control oxygen flow through noncompliant tubing attached to the IV catheter. High-pressure oxygen is delivered reliably through central wall outlets and high-flow (50 to 100 psi) tank regulators. Most jet ventilators have a regulator to allow for a decrease in the inspiratory pressure. Inspiratory pressures should not exceed 50 psi on the regulator, and in most instances, 25 psi is sufficient. A 1-second inspiration at 25 psi with a rate of 20 breaths per minute delivers a 285-mL tidal volume or 5.7 L/min ventilation. Exhalation occurs passively through the upper airway. Obstructions to passive exhalation or excessively large tidal volumes result in hyperinflation and incomplete exhalation of CO_2. Placement of bilateral nasal airways or an oral airway may facilitate exhalation. Use of an in-line pressure gauge and inspiration

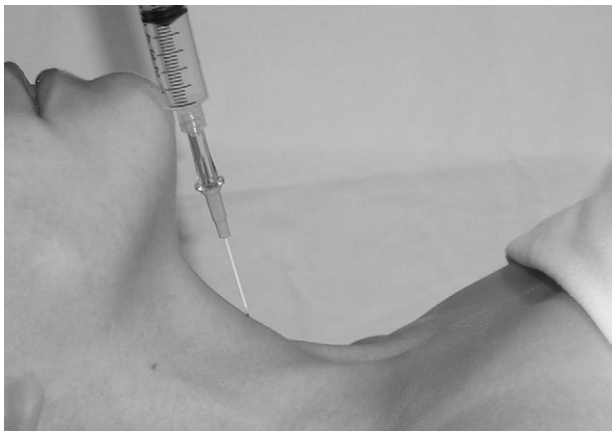

FIGURE **22-46** Insertion of needle for transtracheal jet ventilation.

to expiration ratios of 1:2 or 1:3 help decrease the incidence of barotrauma.

Complications associated with the use of PTJV include barotrauma, subcutaneous emphysema, pneumothorax, pneumomediastinum, hypercarbia, esophageal puncture, airway mucosal damage, blood or mucus obstruction, catheter kinking, and inadvertent removal.[71,134] Bilateral breath sounds should be confirmed frequently to rule out pneumothorax or dislodgement of the catheter.

Retrograde Intubation

A retrograde wire-guided intubation may be considered in a situation in which intubation has failed, but ventilation is possible. A commercial kit is available for retrograde intubation, or the practitioner can choose to insert either a "J-wire" or #2 Mersilene suture via a cricothyrotomy and pass the device cephalad into the oropharynx. This procedure is performed by inserting a 14- to 18-gauge IV catheter or a Cook needle through the cricothyroid membrane and directing it cephalad. After aspiration of air is confirmed, a wire or suture is then inserted through the needle and passed cephalad until it can be visualized in the posterior pharynx. It is then either advanced through the mouth or nose or retrieved using Magill forceps. The distal end of the wire is secured with a clamp at the neck to prevent the wire from being pulled into the trachea prematurely. An ETT is then directed over the wire and passed into the trachea. As the tube enters the larynx, tension is increased on the wire or suture. Once the ETT is through the larynx and cannot pass further, the distal wire is removed at the level of the skin and the ETT is advanced further into the trachea. Placement should be confirmed and the tube secured in place. This procedure is not usually used in an emergency and often can be completed by a skilled practitioner in 5 to 7 minutes.

Surgical Cricothyrotomy

A surgical cricothyrotomy is the establishment of an airway by surgically incising through the cricothyroid membrane and placing a cuffed tracheostomy tube or an ETT. Most airway algorithms and strategies recommend this procedure as a means of providing ventilation for patients who cannot be intubated or ventilated with a facemask or supraglottic airway device.[137] Because of the many surgical cricothyrotomy kits available, this procedure can be performed relatively quickly. One study demonstrated the ability to place a surgical cricothyrotomy in pig tracheas using different cricothyrotomy kits in approximately 1 to 2 minutes.[138] Indications for cricothyrotomy include (1) failed airway (e.g., cannot intubate and subsequently cannot ventilate), (2) traumatic injuries of maxillofacial, cervical spine, head, or neck structures that make intubation through the nose or mouth impossible or difficult and too time consuming, (3) immediate relief of an upper airway obstruction, and (4) the need for a definitive airway for neck or facial surgery, assuming intubation is not possible.

Absolute contraindications are rare; however, the anesthetist should consider avoiding surgical cricothyrotomy in favor of needle cricothyrotomy and PTJV in infants and small children less than 12 years of age. The anatomy of the child's larynx is small, pliable, and movable, which makes cricothyrotomy very difficult.[134] Relative contraindications for cricothyrotomy include preexisting laryngeal or tracheal diseases such as tumors, infections, or abscesses in the location of the cricothyroid membrane, distortion of neck anatomy (e.g., hematoma), bleeding diathesis, and history of coagulopathy.[134]

Complications related to the placement of a surgical cricothyrotomy are similar to those listed under the placement of a needle cricothyrotomy. In addition, initial malplacement (e.g., inferior or superior to the cricothyroid membrane or through the posterior tracheal wall) of a cricothyrotomy is the main complication.[64]

Several cricothyrotomy kits are available, such as the Melker, Quicktrach II, Pertrach, or Portex cricothyrotomy kit (PCK), which can assist the anesthetist with surgical cricothyrotomy placement. The tracheostomy tube is placed percutaneously using these kits by either a cannula over a trocar, or by a Seldinger method. Both the Quicktrach II and PCK devices have a tracheostomy tube loaded over a trocar. The sequence of placing these devices over the trocar includes (1) checking the tube cuff for air leaks; (2) palpation of the cricothyroid membrane and stabilization between the first two fingers (see Figure 22-27); (3) insertion of the trocar/tube through the cricothyroid membrane in a caudad direction; (4) aspiration of air and then advancement of the tracheostomy tube into the trachea; (5) removal of the trocar and inflation of the tube cuff; and (6) securing the tube with a tracheotomy tie and confirming ventilation.

The Melker Universal Emergency Cricothyrotomy Catheter Set (Figure 22-47) by Cook Critical Care is a commonly used technique that contains equipment for both open surgical and Seldinger techniques. The Melker set contains all of the necessary equipment to perform a surgical cricothyrotomy. The set includes an airway catheter (tracheostomy tube) with dilator, scalpel, syringe, introducer needle and catheter introducer needle, stiff guide wire, tracheal hook, forceps, and tie tapes for securing the airway catheter once it is placed in the neck.

The sequence of steps for placing a surgical cricothyrotomy using the Seldinger technique is as follows:

1. Place the patient's head in a neutral position.
2. Open the proper tray and place it in a position that is comfortable and within reach for the person inserting the device. Insert the dilator into the airway catheter.
3. Palpate the cricothyroid membrane, and using the introducer needle with the syringe attached, puncture the neck in a caudad direction while aspirating on the syringe. Once air is aspirated, thread the catheter off of the needle, attach the syringe to the catheter, and again aspirate air (Figure 22-48).
4. Insert the flexible end of the guide wire through the catheter until it is approximately 2 inches beyond the tip of the catheter (Figure 22-49).
5. Using the enclosed scalpel, incise the neck with a single insertion along the guide wire (Figure 22-50).

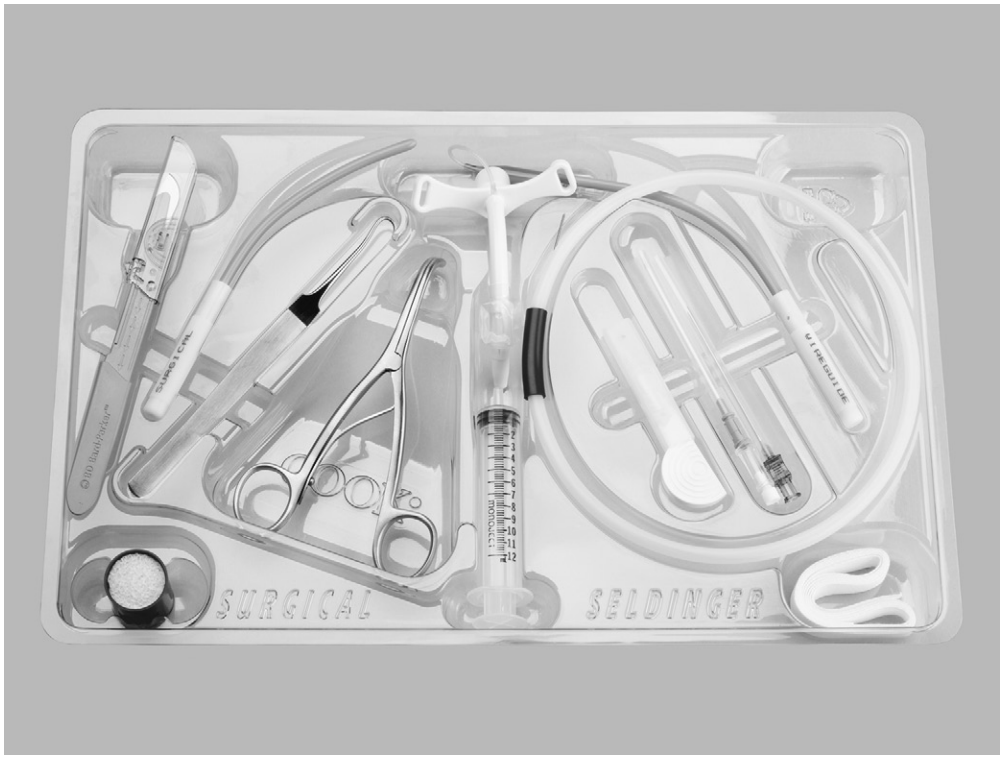

FIGURE **22-47** Melker cricothyrotomy set. (From Cook Medical Incorporated, Bloomington, Indiana.)

FIGURE **22-48** Needle inserted through cricothyroid membrane in caudad direction aspirating for air.

6. Thread the airway catheter/dilator over the exposed guide wire and advance, applying steady pressure by pushing on the dilator. Once there is loss of resistance, usually preceded by a "pop" as the catheter penetrates the cricothyroid membrane, advance the airway catheter off of the dilator until it rests firmly against the neck. Remove the dilator and assess for appropriate ventilation (Figure 22-51).
7. Using suture or the tape ties, secure the airway catheter onto the neck, while continuously ventilating the patient (Figure 22-52).

FIGURE **22-49** Guide wire threaded through catheter in neck.

The decision to place a cricothyrotomy should not be delayed when indications are present.[64] Indeed, a review of closed claims data for injuries related to invasive airway access suggested that failure to apply the technique early enough, and before significant hypoxia developed, resulted in death or brain damage in two thirds of the claims reviewed.[71] Researchers advocate for continued training and practice on a regular basis to maintain proficiency with this critical skill.[139-141]

Tracheotomy

An additional surgical airway technique is the tracheotomy. However, this surgical intervention should not be considered in an emergency and is not a procedure performed by an anesthetist. Instead, this surgical airway technique should be performed under

FIGURE **22-50** Neck incised with scalpel along guide wire.

FIGURE **22-51** Airway catheter/dilator threaded over guide wire, through cricothyroid membrane, and into the trachea.

FIGURE **22-52** Dilator and guide wire removed, allowing ventilation.

ideal conditions by a surgeon because of the potential complications (e.g., recurrent laryngeal nerve trauma, damage to large vessels in the neck). If airway difficulty occurs, such as with facial and neck trauma, and ventilation is compromised, then a surgical cricothyrotomy should be the invasive airway technique of choice in an emergency situation. If a need to perform a tracheotomy exists, the airway should be secured first, or the procedure performed with the patient under a local anesthetic. The standard tracheotomy is performed at the level of the fourth to sixth tracheal ring, below the isthmus of the thyroid gland. This procedure can take up to 30 minutes.

TRACHEAL EXTUBATION

Tracheal extubation and continued control of the airway during recovery are cornerstones of perioperative airway management. Tracheal extubation remains a logical corollary of tracheal intubation, in that almost all intubations are performed with the prospect of tracheal extubation at some point during the course of a hospitalization.[12] During the early postoperative period the plan for tracheal extubation should be considered to (1) minimize alterations in cardiopulmonary physiology; (2) decrease the risk of respiratory infection and complications; and (3) reduce the postoperative length of stay while decreasing cost and resource utilization.

Tracheal extubation is not a benign procedure and is associated with significant complications (Box 22-8).[142] Every tracheal extubation is a trial to determine whether a patient's spontaneous ventilation is adequate enough to support cardiopulmonary function. There is no guarantee that tracheal extubation will be tolerated, especially in patients with marginal cardiopulmonary reserve. Standard criteria for tracheal extubation can be divided into two categories: global and respiratory (Box 22-9).[143] It is often impossible and impractical to fulfill the criteria in its entirety. However, the anesthetist should exercise sound judgment in determining which patients are suitable for postoperative tracheal extubation. In addition, the decision to extubate a patient should be based on a methodical and comprehensive evaluation of patient, surgical, and anesthetic-related risk factors for extubation failure (Box 22-10). Patients that require postoperative mechanical respiratory support should remain intubated until standard extubation criteria are met and risk factors for extubation failure are minimized.

Tracheal Extubation Techniques

The same vigilant care taken to secure the airway should be exercised when control of the airway is returned to the patient. Complications of tracheal extubation are increased when extubation is performed during Guedel's stage II of anesthesia (e.g., excitatory plane). Clinically important reflexes, such as laryngospasm, can be readily elicited during stage II by airway stimulation (e.g., laryngoscopy, intubation, or extubation). Tracheal extubation should be performed with the patient in a surgical plane of anesthesia (e.g., deeply anesthetized or Guedel's stage III) or fully awake. Advantages and disadvantages of deeply anesthetized versus fully awake extubation can be found in Table 22-8. In patients with a history of difficult intubation or who are at high risk of aspiration, it would be prudent for the anesthetist to allow full return of the patient's airway reflexes and extubate fully awake. Increased cardiovascular stimulation during awake tracheal extubation can be minimized using beta-blockers, calcium channel blockers, and vasodilators. Furthermore, coughing and straining can be attenuated by judicious use of local anesthetics (e.g., intravenous, topical, intra-cuff lidocaine) and opioids.

Tracheal Extubation of the Difficult Airway

An American Society of Anesthesiologists' closed claims analysis for perioperative difficult airway management revealed that claims for death or brain damage associated with induction of anesthesia decreased from 62% in 1985 to 1992 to 35% in 1993 to 1999. The development of difficult airway guidelines and new

BOX 22-8

Complications of Tracheal Extubation

Respiratory
- Airway obstruction
- Breath holding
- Clearance of secretions, inadequate
- Coughing and straining
- Hypercarbia
- Hypoxemia
- Laryngeal cartilage damage
- Laryngospasm
- Negative-pressure pulmonary edema
- Postextubation laryngeal edema
- Pulmonary aspiration
- Stridor
- Subglottic or supraglottic edema
- Tracheomalacia
- Vocal cord damage (e.g., edema, paralysis, or dysfunction)

Cardiovascular
- Cardiac dysrhythmias
- Hypertension
- Left ventricular failure
- Myocardial infarction
- Myocardial ischemia
- Tachycardia

Neurologic
- Cervical spine injury
- Increased intracranial pressure
- Increased intraocular pressure

Other Considerations
- Damage to dentition
- Inadvertent removal of equipment (e.g., nasogastric tube)
- Self-extubation
- Unintentional extubation

BOX 22-9

Standard Extubation Criteria

Global Criteria
- Acceptable hemodynamic status
- Normothermia
- Ability to maintain patent airway
  1. Return of laryngeal and cough reflexes
  2. Appropriate level of consciousness
- Adequate muscular strength
  1. Reversal of neuromuscular blockade as indicated by train-of-four ratio greater than 0.9, tetanic response to 100 Hz for 5 seconds, and double-burst stimulation without fade
  2. Head lift for more than 5 seconds and strong, constant hand grip
- Acceptable metabolic function indicators
  1. Electrolytes
  2. Acid-base balance
- Acceptable hematologic function indicators
  1. Hemoglobin level consistent with adequate oxygen delivery
- Adequate analgesia for optimal respiratory effort

Respiratory Criteria
- Adequate respiratory mechanics
  1. Vital capacity greater than 15 mL/kg
  2. Maximal negative inspiratory force greater than –20 cm H_2O
- Ability to maintain adequate oxygenation (with F_{IO_2} less than 50%)
  1. SpO_2 greater than 90%
  2. PaO_2 greater than 60 mmHg
- Ability to maintain adequate alveolar ventilation
  1. $Paco_2$ less than 50 mmHg
- Spontaneous respiratory rate (breaths/minute) to tidal volume (liter) ratio (e.g., rapid shallow breathing index) less than 100 breaths/minute/liter

TABLE 22-8 Tracheal Extubation Techniques

	Anesthetized	Awake
Advantages	Decreased cardiovascular stimulation Decreased coughing and straining	Return of airway reflexes Decreased risk of aspiration Maintenance of airway
Disadvantages	Absent or obtunded airway reflexes Increased risk of aspiration Airway obstruction	Increased cardiovascular stimulation Increased coughing and straining

airway adjuncts (e.g., LMA, ILMA, and video laryngoscopy) has greatly improved the safety of anesthesia induction. In contrast, death or brain damage for difficult airway management during maintenance, extubation, and recovery did not differ significantly between the time periods of 1985 to 1992 and 1993 to 1999.[144] This may be attributed to the paucity of literature and guidelines regarding techniques for tracheal extubation of the difficult airway. Therefore a preformulated airway management plan, based on extubation strategies or algorithms (Figure 22-53), may be helpful in decreasing complications of extubation.[142]

Effective strategies for tracheal extubation in high-risk patients include (1) extubation over a flexible fiberoptic bronchoscope, (2) extubation followed by placement of a supraglottic airway (e.g., laryngeal mask airway), and (3) use of an airway exchange catheter (AEC). The placement of these short-term devices serves as a guide for expedited reintubation in the event that oxygenation or ventilation proves inadequate after extubation (e.g., reversible extubation). The anesthetist should select the most appropriate strategy based on patient characteristics and the anesthetist's own experience, judgment, and skill (Table 22-9). Success of these techniques may be aided by judicious use of antisialagogues (e.g., glycopyrrolate), and/or sedative-analgesics (e.g., dexmedetomidine). It is the responsibility of the anesthetist to ensure accessibility to standard and emergency (e.g., cricothyrotomy) airway equipment in the event that these short-term devices fail.

BOX **22-10**

Risk Factors for Difficult Tracheal Extubation

Patient Risk Factors

- Comprehensive airway evaluation indicating possible difficult reintubation or extubation
- Current and past medical illnesses that affect extubation tolerance or with airway implications (e.g., cardiopulmonary disease)
- Difficult intubation or ventilation (e.g., vocal cord paralysis or dysfunction, morbid obesity, obstructive sleep apnea)
- Generalized airway edema (e.g., drug or systemic reactions, angioedema, anaphylactic reactions, anaphylactoid reactions, sepsis, inhalation injury, burns, SIRS)
- Limited cervical spine mobility injury (e.g., hard cervical collar or halo fixation, ankylosing spondylitis)
- Tracheomalacia

Surgical Risk Factors

- Airway surgery (e.g., uvulopalatopharyngoplasty, laryngeal or tracheal surgery, tracheal resection, or reconstruction)
- Head and neck surgery (e.g., maxillofacial surgery, carotid surgery, thyroid surgery, facial and deep neck infections)
- Neurosurgical (e.g., cranial surgery, posterior fossa surgery, stereotactic brain procedures, and cervical fusion)
- Orthopedic surgery (e.g., close proximity to airway)
- Impingement of head and neck venous drainage
- Postsurgical injury (e.g., hematoma, hemorrhage, nerve injury)
- Prolonged surgical duration and intubation
- Prone or Trendelenburg position

Anesthesia Risk Factors

- Depressed neurologic status, muscular strength, or respiratory effort
- Difficult or traumatic intubation (e.g., failure to visualize glottis, intubation requiring multiple attempts or alternative techniques)
- Excessive head and neck movement during procedure
- Excessive volume resuscitation
- Intubation injury causing laryngeal incompetence or arytenoid dislocation
- Lack of cuff leak
- Laryngotracheal edema (e.g., caused by over sized endotracheal tube or dual-lumen tube, excessive cuff pressure, traumatic suctioning)

SIRS, Systemic inflammatory response syndrome.

BOX **22-11**

Benefits of the Airway Exchange Catheter

- Exchangeable 15-mm external diameter connector for manual ventilation and Luer-Lock adaptor for jet ventilation
- Facilitates removal of endotracheal tube while still maintaining continual access to the airway
- Lumen allows for ventilation, oxygenation, tracheal suctioning, administration of medication (e.g., local anesthetic), and carbon dioxide monitoring
- Lumen and side ports ensure adequate airflow, while blunt tip decreases trauma to airway (see Figure 22-38)
- Radiopaque and depth (cm) markers
- Sufficient length and rigidity guides replacement endotracheal tube into position (e.g., Seldinger technique)

The AEC has received considerable attention because of its potential benefits over other similar devices (e.g., gum elastic bougie) (Box 22-11).[145] There are three AECs currently available on the market: (1) the Endotracheal Ventilation Catheter (CardioMed Industries), (2) the Sheridan Tracheal Tube Exchanger (Hudson Respiratory Care), and (3) the Cook Airway Exchange Catheter (Cook Medical) (see Figure 22-38). For adult patients, 11-Fr (external diameter 3.7 mm) and 14-Fr (external diameter 4.7 mm) AECs are generally well tolerated and allow spontaneous breathing, phonation, and the clearance of secretions. After confirmation of placement and depth, the AEC may be secured in situ until it is determined that reintubation will not be required (e.g., up to 72 hours). It is critical that the internal diameter of the reintubation ETT approximate that of the external diameter of the AEC as much as possible to prevent the leading edge of the ETT from impinging on airway structures, causing trauma and preventing passage through the glottis. A laryngoscope can be used to lift and move supraglottic tissue; this minimizes the angle of approach to the glottis and facilitates ETT passage through the glottis. If the ETT encounters an obstruction at the glottic opening, manual rotation 90 degrees counterclockwise can be used to avoid arytenoid or vocal cord impingement.

Complications After Tracheal Extubation

Laryngospasm is the involuntary protective reflex and contraction of the laryngeal musculature (see Table 22-1 and Box 22-1). Laryngospasm is believed to occur as a result of sensory stimulation of the internal branch of the superior laryngeal nerve and afferent responses from both the external branch of the superior laryngeal nerve and the recurrent laryngeal nerve. Laryngospasm can be caused by a number of factors such as airway manipulation, noxious stimuli (e.g., water, blood, or mucus) within the pharynx, or stimulation of the larynx during inadequate anesthetic depth. Tracheal extubation should therefore be performed with the patient in a surgical plane of anesthesia (e.g., deeply anesthetized or Guedel's stage III) or fully awake to minimize the risk of laryngospasm. See Box 22-9 for standard extubation criteria.

Laryngospasm has been described as having two mechanisms. During "glottis shutter closure," intrinsic laryngeal muscles mediate vocal cord adduction, causing partial airway obstruction. In contrast, during the "ball valve closure," extrinsic laryngeal muscles cause contraction of the false vocal cords and supraglottic soft tissue, causing complete airway obstruction. If left untreated, laryngospasm can result in hypoxia, negative-pressure pulmonary edema, and cardiovascular derangements (e.g., cardiac arrhythmias, tachycardia, bradycardia, and cardiac arrest). Treatment of laryngospasm includes (1) administration of 100% oxygen, (2) the application positive-pressure ventilation (10 to 20 cm H_2O pressure), and/or (3) administration of succinylcholine (e.g., 0.2-0.5 mg/kg intravenously or 4-5 mg/kg intramuscularly).

Laryngotracheobronchitis

Laryngotracheobronchitis, or croup, involves inflammation and edema of the airway below the level of the vocal cords. Subglottic edema may manifest as stridor, which is the high-pitched inspiratory and expiratory sound caused by turbulent airflow through a partially obstructed upper airway. A "barking" cough is another

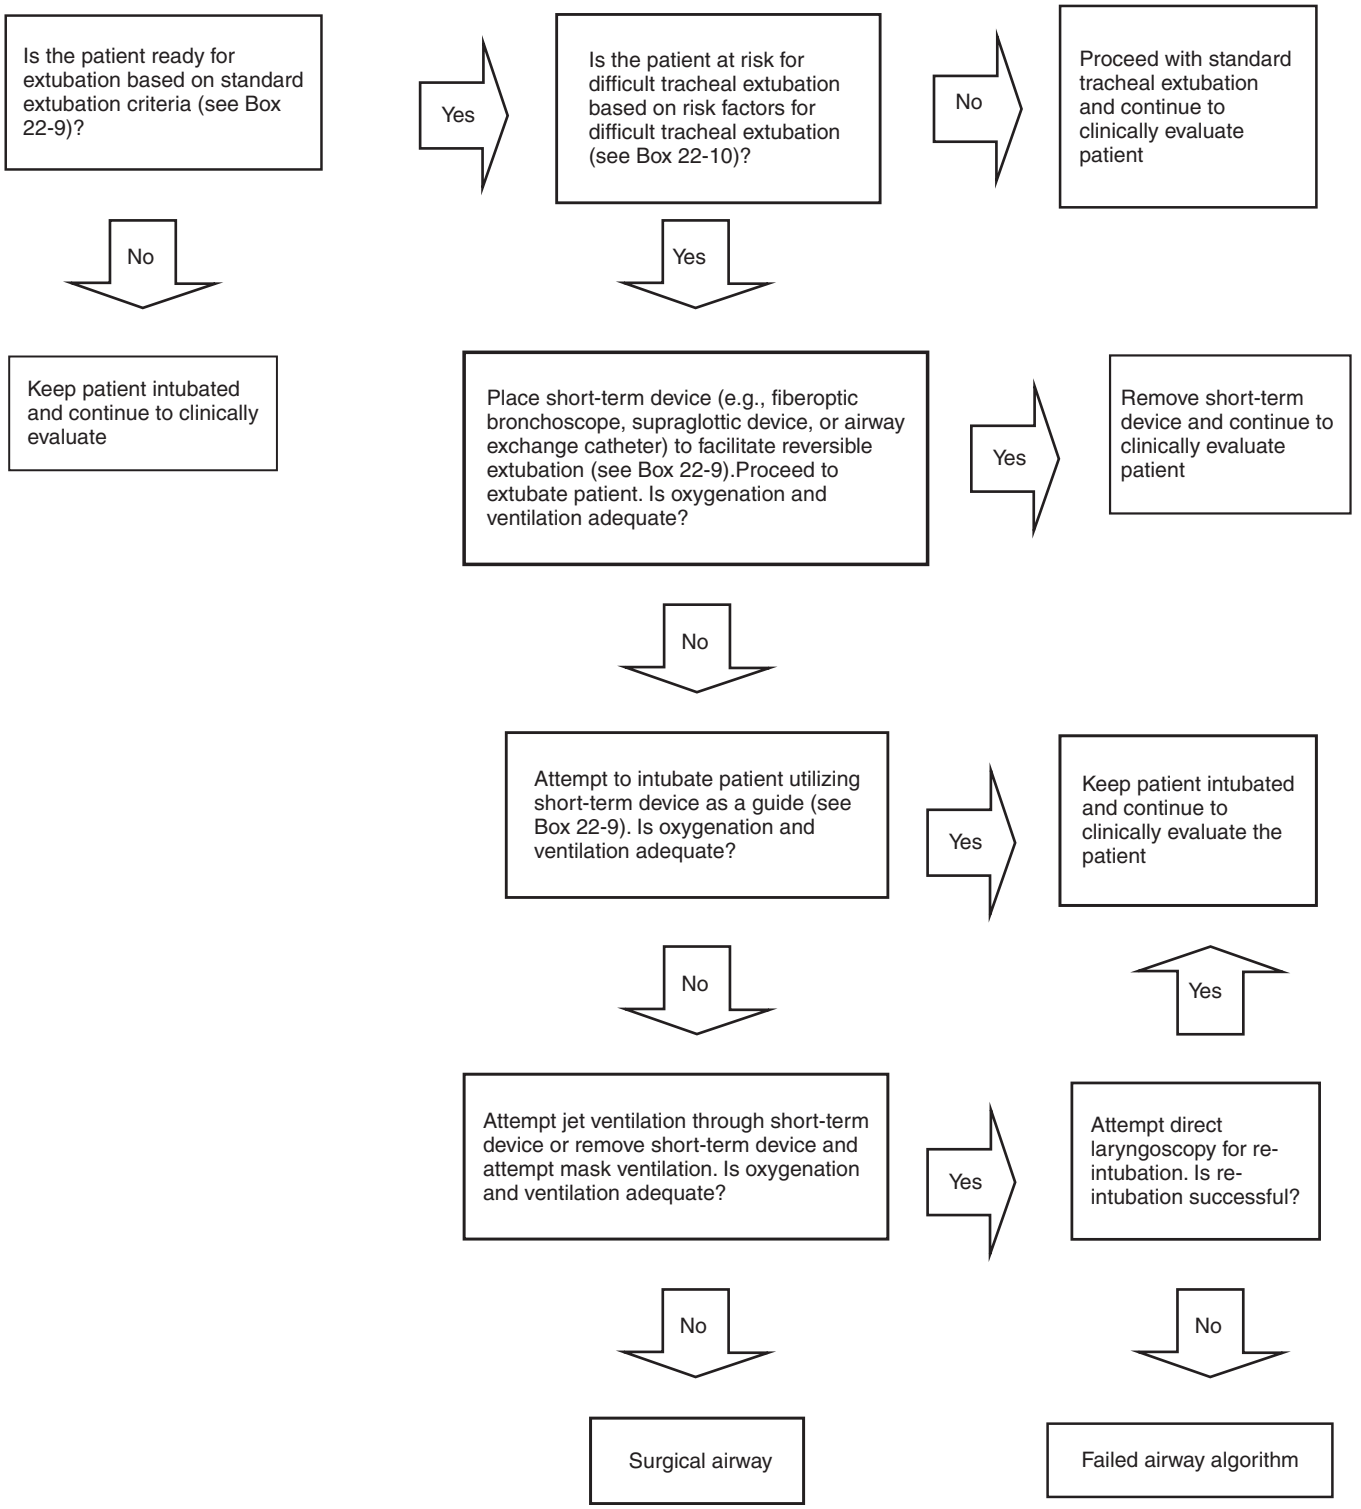

FIGURE **22-53** Extubation algorithm for the difficult airway, using an airway exchange catheter. NOTE: Short-term device refers to fiberoptic bronchoscope, supraglottic device, or airway exchange catheter.

distinctive symptom of croup. Croup can occur in adult and pediatric patients. However, pediatric patients are more vulnerable because of their narrow caliber of airway. Because inflammation greatly increases airway resistance, respiratory failure can occur rapidly. Croup can be caused by (1) postintubation edema around the glottic and subglottic regions, (2) multiple intubation attempts, (3) inappropriately large endotracheal tube, or (4) excessive head and neck movement of the patient. Croup can occur anytime during the postoperative period, but typically occurs within 3 hours of extubation. Treatment of croup is aimed at decreasing inflammation and edema using (1) humidified, supplemental oxygen, (2) racemic epinephrine (e.g., 0.5 mL of a 2.25% solution in 2.5 mL of normal saline), and (3) dexamethasone (e.g., 0.1 to 0.5 mg/kg). Other treatment modalities include the use of a helium-oxygen mixture to facilitate oxygen delivery through narrowed airways.

TABLE 22-9 Tracheal Extubation of the Difficult Airway

	Flexible Fiberoptic Bronchoscope	Supraglottic Airway	Airway Exchange Catheter (AEC)
Advantages	Useful method to evaluate pharyngeal and laryngeal function, injury, pathology, and obstruction	Facilitates fiberoptic bronchoscope evaluation of airway through mask orifice Associated with decreased cardiovascular stimulation, coughing, and straining	Maintains continual access to the airway Lumen allows for ventilation, oxygenation, tracheal suctioning, administration of medication, and carbon dioxide monitoring
Disadvantages	Requires significant skill on the part of the anesthetist May offer only a brief evaluation of the airway May cause carinal irritation	Restricted evaluation of supraglottic and pharyngeal structures if fiberoptic bronchoscope used Periglottic obstruction will impair gas exchange through supraglottic airway	Dislodgement of AEC can occur any time during procedure Complications include trauma from deep placement, barotrauma or pneumothorax with jet ventilation, and carinal irritation
Method for extubation	Tracheal extubation Insertion of bronchoscope prefitted with endotracheal tube Fiberoptic evaluation of airway Bronchoscope is left in place within the trachea and removed when deemed appropriate	Tracheal extubation Insertion of laryngeal mask airway (LMA) LMA is left in place and removed when deemed appropriate	Placement of AEC through endotracheal tube to predetermined depth (e.g., not to exceed 25-26 cm) Tracheal extubation over AEC Confirm depth and tracheal placement of AEC by standard methods, secure with tape AEC is left in place and removed when deemed appropriate
Method for reintubation	Visual confirmation of bronchoscope within trachea Appropriately sized endotracheal tube is passed over bronchoscope Bronchoscope removed Placement of endotracheal tube confirmed by standard methods	Appropriately sized endotracheal tube passed through supraglottic airway tube, blindly or aided by fiberoptic bronchoscope Placement of endotracheal tube confirmed by standard methods	Remove tape and maintain depth of AEC Perform laryngoscopy Appropriately sized endotracheal tube passed over AEC AEC removed Placement of endotracheal tube confirmed by standard methods

COMPLICATIONS OF AIRWAY MANAGEMENT

Complications related to tracheal intubation include (1) airway trauma, (2) aspiration, (3) esophageal intubation, (4) endobronchial intubation, and (5) endotracheal tube complications. Vigilant care must always be undertaken whenever manipulating the airway.

Airway Trauma

Trauma to the airway is a well-recognized complication related to airway management.[142-149] An analysis of the American Society of Anesthesiologists Closed Claims Project (ASA-CCP) indicate that airway trauma was present in 6% of claims. Of these, difficulty with intubation was shown to be a contributing factor in only 38% of claims.[142,148] Structures damaged and sites of injury noted in the analysis included dentition, pharynx, larynx, esophagus, and trachea.[146]

Of the anesthesia-related malpractice claims, dental injury is among the most common with a reported incidence greater than 1:4500.[146] Approximately 50% of dental injuries occur during laryngoscopy and intubation, with the maxillary central incisors most at risk. However, dental injury can also occur after emergence and extubation. Risk factors for dental trauma include: (1) preexisting dental pathology (e.g., carious teeth, periodontitis, paradentosis, or fixed dental work) and (2) one or more indicators of difficult laryngoscopy and intubation (e.g., upper incisor protrusion).

Pharyngeal injury to the airway includes: (1) pharyngeal perforation, laceration, or contusion, (2) localized infection, (3) macroglossia, and (4) edema and necrosis of the uvula.[142,146,147] The cause of pharyngeal injury is often the result of (1) direct trauma (e.g., laryngoscopy or blind pharyngeal suctioning), (2) prolonged mechanical compression and ischemia by an endotracheal tube or oral pharyngeal airway, or (3) pressure-induced nerve injury (e.g., lingual, recurrent laryngeal, or hypoglossal nerve). A malpositioned, oversized, or overinflated laryngeal mask airway (LMA) may also cause trauma to delicate mucosa.[146,147] Lastly, obstruction of the submandibular duct by extreme head flexion, surgical manipulation/trauma, or impingement via endotracheal tube or bike block can cause massive tongue swelling in extreme cases. The incidence of sore throat after intubation is approximately 40% to 65% when blood is observed on the instruments (e.g., laryngoscope) after airway manipulation. Fortunately, pain on swallowing usually lasts no more than 24 to 48 hours.

Trauma to the larynx can be subcategorized into (1) vocal cord paralysis, (2) granuloma formation, and (3) arytenoid dislocation and subluxation. Most susceptible to mechanical injury are the posterior half of the vocal cords, the arytenoids, and the posterior tracheal wall. Unilateral or bilateral vocal cord paralysis can most often be attributed to nerve or mechanical injury and may manifest as partial or complete airway obstruction, respectively. Hoarseness or airway obstruction noted immediately in the postoperative period should be evaluated for possible emergent reintubation or tracheotomy. Granuloma or polyp formation can occur at the vocal process of the arytenoids as well as the posterior wall of the trachea (Figures 22-54 and 22-55), both of which come into intimate contact with the endotracheal tube. Degree of injury and granuloma formation increases with increasing endotracheal tube diameter and with duration of intubation. Arytenoid dislocation (e.g., complete disruption of the cricoarytenoid joint, or malpositioning of the arytenoids cartilages) can be caused by the mechanical force of an endotracheal tube against the arytenoids or by forceful endotracheal tube placement.

FIGURE **22-54** Fiberoptic view of vocal cord polyps.

FIGURE **22-55** Fiberoptic view of granuloma.

Esophageal laceration or perforation can occur with any attempt at intubation, especially in patients with a difficult airway or multiple attempts. Esophageal laceration or perforation may manifest as neck erythema, edema, pneumothorax, and subcutaneous emphysema. Mediastinitis associated with esophageal injury is associated with a high degree of morbidity and mortality despite aggressive treatment with surgical drainage and antibiotics.

Tracheal laceration or perforation may be caused by overinflation of the endotracheal tube cuff, overdistention of endotracheal tube cuff by nitrous oxide, multiple intubation attempts, use of an intubating stylet, repositioning of the endotracheal tube without cuff deflation, or inappropriately large endotracheal tube size. The risk of tracheal injury is increased with tracheal distortion (e.g., neoplasm or enlarged lymph nodes), membranous trachea weakness, corticosteroid therapy, and chronic obstructive lung disease. The anesthetist should exercise extreme caution whenever manipulating the airway.

Aspiration

Pulmonary aspiration has two components: the movement of gastric contents from the stomach to the pharynx, followed by the movement of gastric contents from the pharynx into the lungs. Clinically significant aspiration is an uncommon complication of general anesthesia, with a reported incidence of 1 per 35,000 anesthetics.[96] Less than half of all aspirations lead to pneumonia. An analysis of the ASA-CCP indicated that aspiration pneumonitis was present in 3% of claims.[142,148] Patient, anesthetic, and pathologic risk factors for gastric aspiration are reviewed in Box 22-12. The development of pneumonia, with subsequent ventilation perfusion abnormalities, is dependent on the (1) type of aspirate (e.g., contaminated, acidic, particulate, or nonparticulate), (2) volume of aspirate, and (3) the patient's comorbid conditions. Aspiration

BOX **22-12**

Risk Factors for Gastric Aspiration

Patient-Related Risk Factors
- Ascites
- Cardiac arrest
- Emergency surgery
- Full stomach
- Nausea and vomiting
- Obesity
- Scleroderma
- Severe hypotension
- Trauma or stress

Anesthesia-Related Risk Factors
- Cricoid pressure
- Difficult airway management
- Inadequate depth of anesthesia
- Opioids

Gastrointestinal Pathology
- Decreased esophageal sphincter tone
- Diabetic gastroparesis
- Gastroesophageal reflux disease (GERD)
- Gastrointestinal obstruction
- Hiatal hernia
- Increased gastric pressure
- Peptic ulcer disease

Neurologic Pathology
- Decreased airway reflexes
- Decreased level of consciousness
- Head injury
- Seizures

From Nagelhout JJ. Aspiration prophylaxis: is it time for changes in our practice? *AANA J.* 2003;71(4):299-303.

pneumonitis can be divided into two phases: phase 1 (direct chemical injury) and phase 2 (inflammatory mediator release).[96] Acute gastric aspiration can occur whenever the patient's laryngeal reflexes are inhibited. Gastric aspirate contamination into the lungs causes (1) chemical destruction of pulmonary tissue, (2) alveolar capillary membrane edema and degeneration, (3) alveolar type II pneumocyte destruction, and (4) microhemorrhaging leading to hypoxia. Management of this condition includes positive pressure ventilation and intensive physiologic support.

A number of mechanical and pharmacologic measures can be taken to minimize the risk of gastric aspiration. During airway management and mask ventilation, it is imperative to maintain peak airway pressures of less than 15 to 20 cm H_2O, which helps minimize gastric insufflation. If higher peak airway pressures (e.g., greater than 25 cm H_2O) are used for ventilation, gastric insufflation may occur. The application of cricoid pressure during rapid sequence induction may be beneficial in preventing gastric aspiration provided that it is performed properly and does not impede effective airway management. Realistic adherence to fasting guidelines should be instituted, and these guidelines should include consideration of the type of liquid or food consumed, patient age and characteristics, type of anesthesia and surgical procedure planned, and the presence of risk factors for gastric aspiration.[96]

Pharmacologic methods to reduce the acidity and volume of gastric contents may reduce the risk of gastric aspiration.[96] The administration of nonparticulate antacids (e.g., sodium citrate 30 mL) 10 to 20 minutes before induction of anesthesia effectively raises gastric pH. A histamine-blocking agent (e.g., famotidine, cimetidine, or ranitidine) administered 45 to 60 minutes preoperatively either orally or intravenously is also effective in raising gastric pH. The administration of a gastroprokinetic agent (e.g., metoclopramide 10 mg intravenously) 20 to 30 minutes before induction of anesthesia accelerates gastric emptying.

Esophageal Intubation

Esophageal intubation may occur during any intubation procedure. However, during difficult intubation when inadequate visualization

of the glottis is achieved, the possibility of inadvertently placing the endotracheal tube into the esophagus increases significantly. Unrecognized esophageal intubation can lead to severe hypoxia and catastrophic complications including death. An analysis of the ASA-CCP indicated that that 18% of respiratory-related claims involved esophageal intubation.[142,148] It is imperative that confirmation of endotracheal tube placement includes end-tidal CO_2 monitoring. Fiberoptic bronchoscopy is another sensitive method for confirming endotracheal tube placement. It is important to recognize that other traditional methods of confirming endotracheal tube placement such as equal bilateral breath sounds, symmetrical chest wall movement, epigastric auscultation, and observation of tube condensation lack specificity and are potentially misleading. Esophageal perforation, retropharyngeal abscess formation, subcutaneous emphysema, and pneumothorax have been documented after esophageal intubation. Mediastinitis is a potentially lethal consequence after esophageal intubation with a mortality rate of 50%.[146]

Endobronchial Intubation

Endobronchial intubation may occur during any intubation procedure and is sometimes difficult to identify. An American Society of Nurse Anesthetist closed-claims analysis of respiratory events indicated that 9% of respiratory incidents involved endobronchial intubation, which was believed to contribute to inadequate ventilation. The recommendation from the closed-claims analysis was for anesthesia providers to remain vigilant and be aware of tube markings and recommended depths for common patient populations. Endobronchial intubation occurs most commonly within the right mainstem bronchus. It occurs more commonly in infants and children because of the relatively short distance between the glottis and the carina. Signs and symptoms of endobronchial intubation include: (1) increased peak inspiratory pressures, (2) asymmetrical chest expansion, (3) unilateral breath sounds, and (4) hypoxemia. Endobronchial intubation may occur after initial placement of an ETT or following extreme flexion of the neck. The tip of the endotracheal tube can move an average of 3.8 cm (up to 6 cm) toward the carina when the neck is moved from full extension to full flexion.[142] When endobronchial intubation is discovered, the endotracheal tube should be carefully withdrawn into the trachea and the lungs hyperinflated sufficiently to expand any atelectatic areas.

Endotracheal Tube Complications

Complications regarding the endotracheal tube can occur any time during the administration of general anesthesia. In particular, partial or complete obstruction of the endotracheal tube may occur during surgery of prolonged duration or in a patient with predisposing abnormalities of the airway anatomy. Airway obstruction through an endotracheal tube may be caused by (1) mechanical factors (e.g., sharp bend, kinking, or biting), (2) foreign material (e.g., mucus, blood, tissue, foreign bodies, or lubricant), or (3) the endotracheal tube cuff. The expansion of gas bubbles within the endotracheal tube by nitrous oxide or overinflation of the cuff may cause partial or complete airway obstruction. Wire-reinforced endotracheal tubes may be used to decrease the risk of mechanical obstruction. To clear a partially obstructed endotracheal tube, a suction catheter or a fiberoptic bronchoscope should be placed down the lumen of the endotracheal tube. If the endotracheal tube is totally obstructed, passage of a stylet or airway exchange catheter should be attempted. Total obstruction that cannot be treated quickly requires removal of the endotracheal tube followed by reintubation.

SUMMARY

Airway management is a critical component of anesthesia practice. Knowledge of anatomy, equipment, and techniques is paramount if safe airway management is to be provided. Adherence to established standards and protocols including difficult airway strategies and algorithms can minimize complications. Competence and skill with a variety of airway management techniques will facilitate the appropriate management when a difficult airway situation occurs.

23 CHAPTER Cardiovascular Anatomy, Physiology, Pathophysiology, and Anesthesia Management

◆ *Sass Elisha*

CARDIOVASCULAR SYSTEM

Knowledge of anatomy and physiology of the cardiovascular system is essential to anesthesia practice. Every anesthetic agent has either a direct or an indirect effect on the cardiovascular system. Therefore whether the clinical concern is about a sympathectomy that causes a decrease in blood pressure during neuraxial blockade or about myocardial depression during inhalation anesthesia, a thorough understanding of these effects and their implications with regard to human physiology is vital if excellent anesthesia care is to be provided.

The cardiovascular system is composed of the heart and the vasculature that carries blood to provide nutrients to all cells in the body. In addition, the cardiovascular system transports substances such as hormones and electrolytes from one part of the body to another.

At the center of this network is the heart. The heart pumps unoxygenated blood to the lungs and then supplies oxygenated blood to all parts of the body. This chapter describes the anatomic and physiologic characteristics, as well as pathophysiologic changes, associated with the cardiovascular system.

Heart

Gross Anatomy

The heart is bound anteriorly by the sternum and the costal cartilages of the third, fourth, and fifth ribs and inferiorly by the diaphragm. It is positioned with the apex of the heart projecting anteriorly and inferiorly toward the left fifth intercostal space at the midclavicular line. At this location, the pulsation from the cardiac apex may be palpated. This is known as the *point of maximal impulse*. The first heart sound (S_1) is best auscultated in this area. A third (S_3) or fourth (S_4) heart sound, if present, can also be heard in this location. Heart sounds are generated from the vibrations caused by the closure of the semilunar and atrioventricular (AV) valves.[1]

Cardiac Silhouette

The superior aspect of the cardiac silhouette is formed by the transverse and ascending aortas. The right lateral border is composed of the right atrium (RA), and the mass of the right ventricle (RV) constitutes most of the inferior border. The left ventricle (LV) comprises the majority of the apex and the lower left lateral border. The left atrial appendage lies superior to the LV and to one side of the pulmonary artery. This appendage may be seen radiographically between the LV and the pulmonary outflow tract. The heart is rotated on its base such that the anterior surface is almost entirely made up of the RV. The base of the heart is the most superior portion of the cardiac silhouette.

Pericardium

The heart is situated within the mediastinum and surrounded by a fibrous, double-walled sac called the *pericardium*,[2] which envelops the heart and the roots of the great vessels. It consists of a visceral portion, which is in intimate contact with the outer surface of the heart (epicardium), and an outer parietal portion, and adheres to the fibrous pericardium (Figure 23-1).

The fibrous pericardium is pierced superiorly by the aorta, the pulmonary trunk, and the superior vena cava. The base of the fibrous pericardium is fused with the central tendon of the diaphragm. The visceral pericardium and parietal pericardium are separated by a thin potential space known as the *pericardial cavity*. This space normally contains approximately 10 to 25 mL of serous fluid, which provides lubrication for the free movement of the heart within the mediastinum. In disease states, the pericardial space can fill with blood and or serosanguinous fluid, compress the heart, and decrease cardiac output (CO). In acute cardiac tamponade, the volume rapidly increases, producing myocardial dysfunction. In contrast, in chronic cardiac tamponade, the degree of pressure exerted on the heart increases slowly because the pericardial sac stretches over time to accommodate the blood that accumulates. However, the pressure may eventually increase as much as 10-fold before symptoms of cardiac tamponade occur.[3]

The pericardium receives its arterial blood supply from the branches of the internal thoracic arteries and through the bronchial, esophageal, and superior phrenic arteries. Venous drainage from the pericardium occurs through the azygos system and the pericardiophrenic veins, which anastomose with the internal thoracic veins. Nervous innervation to the pericardium is derived from the vagus nerve, the phrenic nerves, and the sympathetic trunks.

Surface Anatomy

The atria are separated from the ventricles by the coronary sulcus (AV sulcus), as seen in Figure 23-2, *A*. The right coronary artery travels within this sulcus. The circumflex artery arises from the left coronary artery and travels in the coronary sulcus until it branches posteriorly. The RV and LV are separated by the interventricular sulci, which descend from the coronary sulcus to the apex. The interventricular sulci are composed of an anterior interventricular sulcus and a posterior interventricular sulcus. The anterior interventricular sulcus contains the left anterior descending (LAD) artery, which courses over the interventricular septum and continues in the posterior interventricular sulcus.

The crux of the heart is the place at which the coronary and the posterior interventricular sulci meet. Internally, it is where the atrial and ventricular septa meet (Figure 23-2, *B*). This anatomic crux is important in determining coronary artery dominance.

Cardiac Skeleton

Essential to a discussion of the chambers of the heart is a description of the fibrous skeleton, the annulus fibrosus (Figure 23-3). Tough fibrous rings surround the AV valves and act as points of

attachment for the valves. Two additional fibrous annuli develop in relation to the bases of the aorta and the pulmonary trunk. The aortic fibrous annulus is connected to the pulmonary annulus by a fibrous band called the *tendon of the conus*. The aortic annulus is connected to the AV annuli by the small left fibrous trigone and the larger right fibrous trigone, also called the *central fibrous body*. The four annuli and their interconnections constitute the fibrous cardiac skeleton.

The annulus fibrosus is the fixation point for the cardiac musculature and plays an important role in the structure, function, and efficiency of the heart. The annulus acts as an insulator to prevent aberrant electrical conduction from the atria to the ventricles so that AV conduction moves through one pathway only: the AV node to the bundle of His. This element increases the electromechanical efficiency of the heart and helps prevent dysrhythmias.

Chambers of the Heart

Right Atrium. The atria act as the priming chambers for the ventricles. As such, the RA acts as a reservoir for the RV and has unique anatomic characteristics. It has a muscle wall thickness of approximately 2 mm.

The RA receives blood from several sources: the superior vena cava, the inferior vena cava, and the coronary sinus (Figure 23-4). The RA consists of two parts: an anterior, thin-walled trabeculated portion and a posterior, smooth-walled portion called the *sinus venarum*. The sinus venarum receives blood from the vena cava and the coronary sinus. The auricle projects to the left from the root of the superior vena cava and overlaps the root of the ascending aorta.

The superior vena cava returns blood to the RA from the upper body. The inferior vena cava returns blood to the RA from the lower body. The entrance of the inferior vena cava into the RA is protected by a rudimentary valve called the *eustachian valve*.[4]

The entrance from the coronary sinus into the RA is located between the AV orifice and the valve of the inferior vena cava. This opening is protected in part by a rudimentary valve of the coronary sinus called the *thebesian valve*.[5] Other distinguishing structures in the RA include the interatrial septum and the fossa ovalis cordis, which is the remnant of the fetal foramen ovale within the septum.

Right Ventricle. The RV ejects blood into the pulmonary arterial system for oxygenation and removal of carbon dioxide by the lungs. The RV communicates with the RA through the AV orifice, which is separated by the tricuspid valve. The RV also communicates with the pulmonary outflow tract through the pulmonary orifice, which is guarded by the pulmonic valve (see Figure 23-4).

The walls of the RV are much thicker (4 to 5 mm) than those of the RA because of the increased pressures required to generate forward blood flow into the pulmonary circulation. The superior portion of the RV as it approaches the pulmonary orifice has a conical appearance and is called the *conus arteriosus* or *infundibulum*.[6]

The inner wall of the conus is smooth, but the remainder of the right ventricular wall has a rough appearance because of the

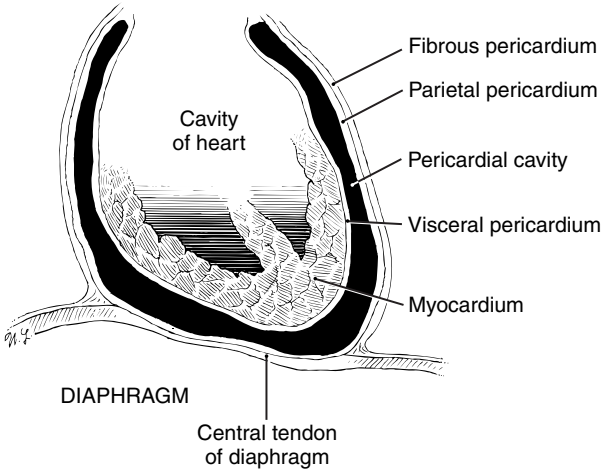

FIGURE **23-1** The pericardium.

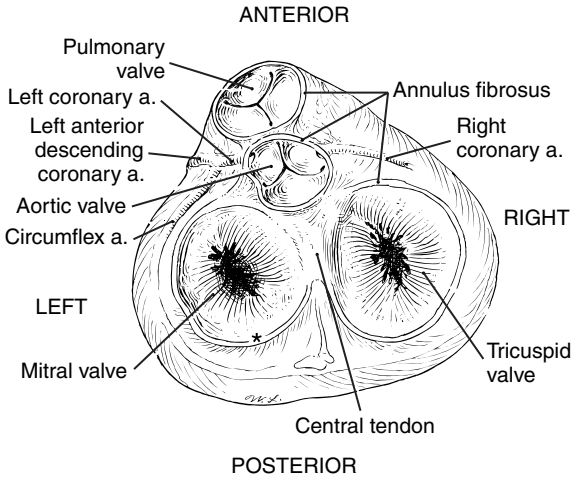

FIGURE **23-3** The annulus fibrosus. *a.*, Artery.

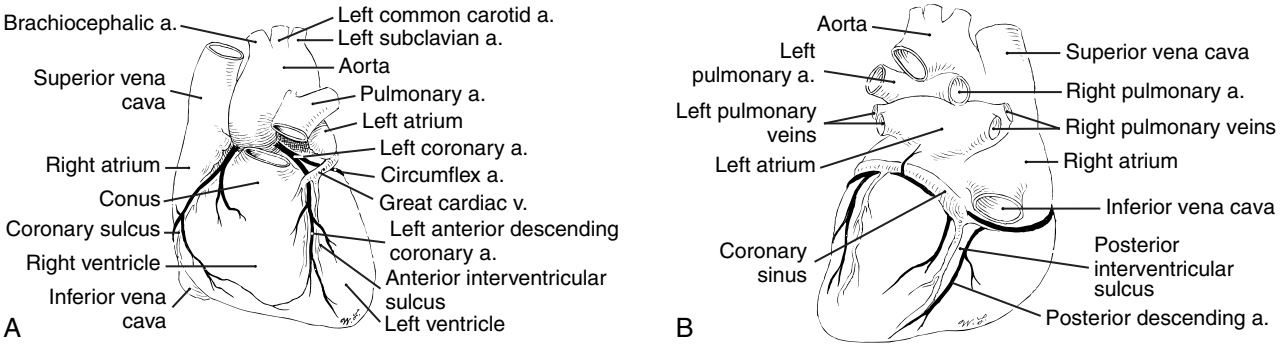

FIGURE **23-2** **A,** Surface anatomy of the heart (anterior view). **B,** Surface anatomy of the heart (posterior view). *a.*, Artery; *v.*, vein.

presence of several irregular muscular bundles called the *papillary muscles* and the *trabeculae carneae*. One of the trabeculae carneae (the moderator band) crosses the cavity of the ventricles and carries the right branch of the AV bundle. The papillary muscles have attachments to the ventricular walls and to the chordae tendineae. The chordae tendineae are attached to the cusps of the tricuspid valve; together with the papillary muscles, they help prevent eversion of the tricuspid valve into the RA during ventricular systole.[7]

Left Atrium. The left atrium (LA) acts as a reservoir for oxygenated blood as it receives blood from the four pulmonary veins and also serves as a pump during atrial systole. It provides a 20% to 30% increase in left ventricular end-diastolic volume (LVEDV), which is known as the *atrial kick*. A person who has normal myocardial performance does not rely on this increase in ventricular filling to achieve adequate CO. However, in certain cardiovascular or respiratory pathologic conditions, compromised patients do rely on this atrial kick to maintain an adequate CO. The LA is located superiorly and posteriorly to the other cardiac chambers. The walls of the LA are slightly thicker (3 μm) than those of the RA. The LA connects to the LV through the left AV orifice, which contains the mitral valve. The atrial septum is smooth but may contain a central depression that corresponds to the location of the fossa ovalis cordis.

Left Ventricle. The apex of the LV is positioned within the mediastinum in an anterior and inferior orientation. The LV receives blood from the LA and ejects it into the aorta. Left ventricular wall thickness is approximately 8 to 15 mm, or two to three times the thickness of the RV. This additional muscle mass is required to overcome the systemic vascular resistance (SVR), or afterload, to maintain CO.

The ventricular septum separates the right and left ventricular cavities.[8] The upper third of the septum is smooth endocardium. The remaining two thirds of the septum and the rest of the ventricular wall are covered with trabeculae carneae.

Two large papillary muscles are present within the LV. The anterior papillary muscle attaches to the anterior part of the left ventricular wall, and the posterior papillary muscle arises from the posterior aspect of the inferior wall. The chordae tendineae of each muscle are attached to the cusps of the mitral valve and prevent eversion of the valve during ventricular systole.

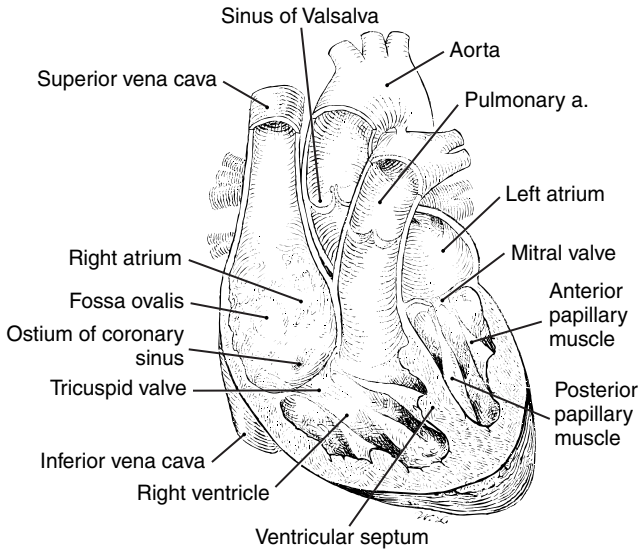

FIGURE **23-4** Internal anatomy of the heart chambers. *a.*, Artery.

Myocardium

The cardiac musculature is arranged in three distinct layers: an outer epicardium, a middle muscular myocardium, and an inner endocardium. The epicardium is composed of mesothelium, connective tissue, and fat. The middle muscular myocardium consists of two muscle layers—a superficial and a deep layer. These layers are arranged in a spiral fashion and appear on cross section to run at right angles to each other. It has been postulated that the superficial and deep layers of the myocardium are not two separate layers but one tortuous and continuous layer. The arrangement of the muscle layers provides strength during contraction of the myocardium and efficient propulsion of blood toward the semilunar valves. The endocardium consists of endothelium and a layer of connective tissue.

Valves

The cardiac valves increase the heart's efficiency by ensuring a one-way flow of blood through the circuit. They open and close in response to pressure gradients that exist above or below the valves. These valves may be categorized as AV or semilunar in configuration.

One of the most accurate ways to determine the presence of valvular pathology is by calculating valve area. The standard method for determining valve area is by cardiac catheterization. A cardiologist is able to determine valve gradients using the Gorlin formula or its correction, which can provide information regarding the degree of pathology that exists.[9]

$$\text{Valve area} = \frac{\text{Flow across valve}}{K \times \sqrt{\text{Mean transvalvular gradient}}}$$

Where valve area is expressed in cm^2, blood flow across the mitral valve is expressed in mL/s, K is a hydraulic pressure constant, and mean transvalvular gradient is expressed in mmHg.

Echocardiography is a noninvasive method of determining valve area and is used in the diagnosis of valvular heart disease. The use of echocardiography is discussed later in this chapter.

Atrioventricular Valves

Tricuspid Valve. The tricuspid valve is situated within the right AV orifice, which lies between the RA and the RV. The tricuspid leaflets are thinner and more translucent than the mitral valve and more easily separated into well-defined leaflets. Three leaflets of unequal size exist: the anterior, septal, and posterior leaflets. The leaflets are attached to the chordae tendineae, which are attached to the papillary muscles.[10] The normal tricuspid valve area is approximately 7 cm^2. Symptoms associated with tricuspid valve stenosis occur when the valve area is less than 1.5 cm^2.

Mitral Valve. The mitral valve is situated in the left AV orifice between the LA and the LV. Two major leaflets, the anteromedial leaflet and the posterolateral leaflet, are connected by commissural tissue. The normal mitral valve area is 4 to 6 cm^2. When the surface area of the valve is decreased by half, clinical symptoms may appear. Like the tricuspid valve, the mitral valve has papillary muscles and chordae tendineae attached to the leaflets to prevent eversion of the valve during ventricular systole.[11]

Semilunar Valves. The configuration of the aortic and pulmonary valves is similar. The cusps of the aortic valve are slightly thicker because it is subjected to greater pressures, which are created by left ventricular ejection. The semilunar valves are situated within the outflow tracts of their corresponding ventricles. Each valve is composed of three cusps. Above the aortic valve is a dilation known as the *sinus of Valsalva*, which allows the valve to open efficiently without occluding the coronary ostia or openings

that communicate with the coronary arteries. Eddy currents form behind the valve leaflets and prevent contact between the valve leaflets and the walls of the aorta. Normal aortic valve area is 2.5 to 3.5 cm^2. Reduction of the valve area by one third to one half is associated with an increase in the symptoms caused by aortic stenosis.

Coronary Circulation

The heart is an aerobic organ that depends on a constant supply of oxygen to meet its high metabolic demand. It requires an elaborate arterial and venous network to ensure that myocytes are adequately supplied with oxygen. The arterial system consists of epicardial and subendocardial vessels. The epicardial vessels are located superficially and most commonly become obstructed at areas of bifurcation where the blood flow is turbulent rather than laminar. Significant obstruction (50% to 70% reduction in luminal diameter) can result in myocardial ischemia or infarction as a result of increased resistance to flow across the stenotic areas.

Coronary Arteries. The coronary ostia are the entrance points by which blood flows through the coronary circulation and they are located behind the aortic cusps near the superior part of the sinus of Valsalva. The ostium of the left coronary artery is superior and posterior to the right coronary ostium. The coronary arteries act as end arteries, and each supplies blood to its respective capillary bed[12] (Figure 23-5).

Left Main Coronary Artery. The left main coronary artery travels anteriorly, inferiorly, and leftward from the left coronary sinus to emerge from behind the pulmonary trunk. Within 2 to 10 mm of its emergence, the left main coronary artery divides into two or more branches of near-equal diameter. The branches include the LAD artery, the left circumflex coronary artery, and possibly the diagonal branch.

Left Anterior Descending Coronary Artery. The LAD is a continuation of the left main coronary artery. The branches of this vessel include the first diagonal branch, the first septal perforator, the right ventricular branches (not always observed), other septal perforators, and other diagonal branches. The LAD provides blood flow to the anterior two thirds of the interventricular septum, the right and left bundle branches, the anterior and posterior papillary muscles of the mitral valve, and the anterior lateral and apical walls of the LV. The LAD also provides collateral circulation to the anterior wall of the RV.

Left Circumflex Coronary Artery. The left circumflex artery arises from the left main coronary artery at an obtuse angle, and it is directed posteriorly as it travels around the left side of the heart within the left AV sulcus. Branches are variable and may include the sinus node artery (40% to 50% of the population), the left atrial circumflex artery, the anterolateral marginal artery, the distal circumflex artery, one or more posterolateral marginal arteries, and the posterior descending artery (10% to 15% of the population). The circumflex artery supplies blood to the left atrial wall, the posterior and lateral LV, the anterolateral papillary muscle, the AV node in 10% of the population, and the sinoatrial (SA) node in 40% to 45% of the population.

Right Coronary Artery. The right coronary artery supplies blood to the SA and AV nodes, the RA and RV, the posterior third of the interventricular septum, the posterior fascicle of the left bundle branch, and the interatrial septum. In approximately 90% of the population, the right coronary artery leaves the right coronary sinus and descends in the right AV groove. At the crux, the right coronary artery courses inferiorly in the posterior AV groove and terminates as a left ventricular branch.

The branches of the right coronary artery include the conus artery, the sinus node artery (50% to 60% of the population), several anterior right ventricular branches, the right atrial branches, the acute marginal branch, the AV node artery (90% of the population), the proximal bundle branches, the posterior descending artery, and the terminal branches to the LA and LV.

Coronary Artery Dominance. Dominance of one coronary artery is determined by the location of the coronary artery that crosses the crux and provides blood flow to the posterior descending artery. The dominant coronary artery in 50% of the general population is the right coronary. In addition, 10% to 15% of the general population are left coronary dominant, and 35% to 40% of the general population have mixed right and left dominance.

Venous Drainage. An extensive venous system exists in the heart. The three major systems include the coronary sinus, the anterior cardiac veins, and the thebesian veins (Figure 23-6).

The coronary sinus is located in the posterior AV groove near the crux. It collects approximately 85% of the blood from the LV, and for this reason it is catheterized when metabolic studies of the LV are performed. It may also be cannulated during cardiopulmonary bypass to deliver cardioplegia. The coronary sinus receives blood from the great, middle, and small cardiac veins; the posterior left ventricular veins; and the left atrial vein of Marshall.

FIGURE **23-7** Distribution of sympathetic and parasympathetic innervation to the heart.

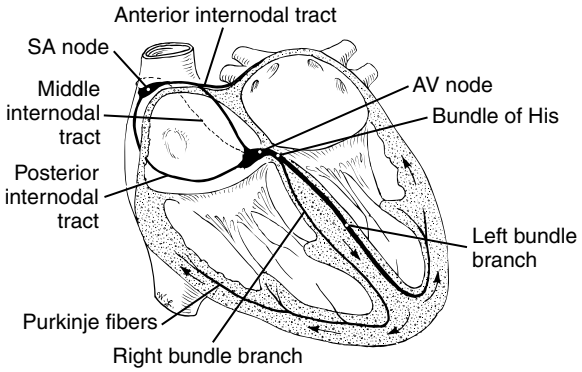

FIGURE **23-8** The cardiac conduction system. *AV*, Atrioventricular; *SA*, sinoatrial.

Two to four anterior cardiac veins drain the anterior right ventricular wall. These veins may enter the RA directly, or they may empty into the coronary sinus.

The thebesian veins traverse the myocardium and drain into the various cardiac chambers, especially the RA, the RV, and to a lesser extent the LV. The thebesian veins may carry up to 40% of the blood that is returned to the RA.

Cardiac Innervation

The autonomic nervous system is divided into the sympathetic and parasympathetic nervous systems. Efferent impulses are transmitted from the brainstem and hypothalamus to numerous body systems, including the heart. The neurologic innervation to the heart originates from the autonomic nervous system, as well as from sensory fibers. The myocardium also has a specialized conduction system that is discussed in this chapter.

Increased sympathetic nervous system tone increases heart rate (chronotropic), force of myocardial contraction (inotropic), and rate of sinus node discharge (dromotropic). Sympathetic nervous system activation results in the mobilization of myocardial fat-free acids and glycogen for energy use by the myocardial cells. The preganglionic sympathetic nervous system fibers originate from the cells in the intermediolateral columns of the higher thoracic segments of the spinal cord and synapse at the first through the fourth or fifth thoracic paravertebral ganglia. These spinal cord segments are known as the *cardioaccelerator fibers*. The postganglionic fibers then travel as the superior, middle, and inferior cardiac nerves and the thoracic visceral nerves. These fibers form an epicardial plexus and are distributed over the entire ventricular myocardium. There is greater distribution of sympathetic nerves that innervate the ventricles, resulting in increased ventricular contractility, as is shown in Figure 23-7. Catecholamines released during sympathetic stimulation bind with adrenergic receptors on the heart (primarily B_1) and change the biochemical properties within the myocyte. This process is discussed later in this chapter.

Some of these postganglionic sympathetic fibers also join with the postganglionic parasympathetic fibers from the cardiac plexus and primarily innervate the SA and AV nodes and the atrial myocardium. Suppression or blockade of this thoracic portion of the spinal cord by regional anesthesia causes bradycardia and hypotension as a result of the blockade of these sympathetic ganglia parasympathetic nervous system predominance.

The preganglionic parasympathetic fibers originate in the dorsal motor nucleus of the medulla. Short postganglionic fibers primarily innervate the SA and AV nodes and the atrial muscle fibers (see Figure 23-7). For this reason, increased parasympathetic tone decreases heart rate (HR). The function of the parasympathetic nervous system is primarily to slow the HR and secondarily to decrease contractility. In fact, maximal vagal (parasympathetic) stimulation reduces contractility by only 30%, whereas maximal sympathetic stimulation increases contractility by 100%. Acetylcholine is the neurotransmitter of the parasympathetic nervous system. Acetylcholine binds to muscarinic receptors on the heart and decreases the rate of sinus node discharge and slows conduction velocity through the AV node. The physiologic effects of parasympathetic nervous system stimulation occur because of increased permeability of cardiac muscle cell membranes to potassium, resulting in hyperpolarization. As a result, SA and AV node cells are less excitable.

Sensory innervation to the heart originates in the nerve endings in the walls of the heart, the coronary artery adventitia, and the pericardium. These nerve endings synapse with ascending fibers in the posterior gray columns of the spinal cord, where the fibers synapse with second-order neurons. From these neurons, the fibers ascend in the ventral spinothalamic tract and terminate in the posteroventral nucleus of the thalamus.

Cardiac Conduction System

Within the myocardium lies the specialized conduction system whose purpose is to automatically initiate and coordinate the cardiac rhythm. The cells of this system differ from the other myocardial cells because they are more variable in shape, contain fewer myofibrils, and have a characteristic pale staining of the cytoplasm. The conductive system consists of the following components: the sinoatrial (SA) node, the internodal tracts, the AV node, the AV bundle, and the Purkinje system (Figure 23-8).

Sinoatrial Node. The SA node (the Keith-Flack node) is a small mass of specialized cells and collagenous tissue located along the epicardial surface at the junction of the superior vena cava and the RA. It has a prominent central artery that is a branch of the right coronary artery. The SA node is derived from the junction of the right horn of the sinus venosus and the primitive atrium. The SA node consists of two cell types: P cells (pacemaker cells), which are pale and ovoid with large round nuclei, and intermediate or transitional cells, which are elongated. These transitional cells are intermediate between ovoid and ordinary cells. They conduct impulses within and away from the SA node.

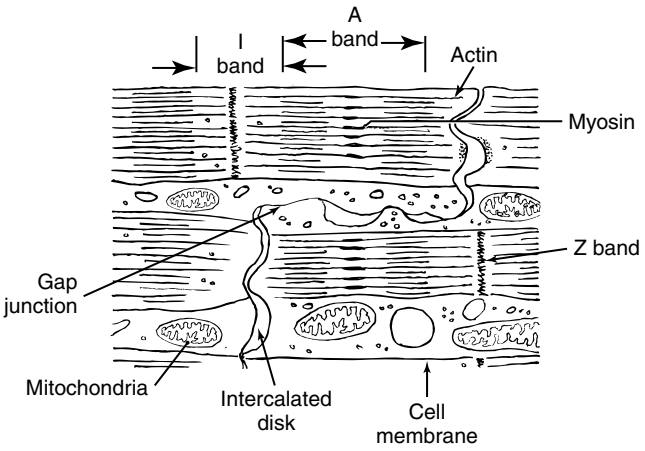

FIGURE **23-9** The myocardial sarcomere.

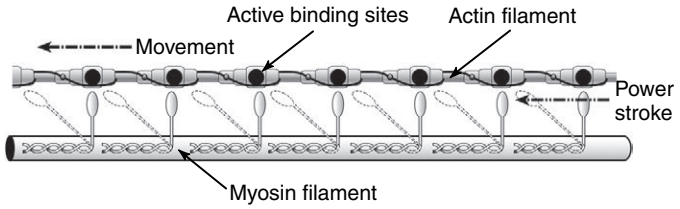

FIGURE **23-10** Interaction between actin and myosin that initiates cardiac muscle contraction.

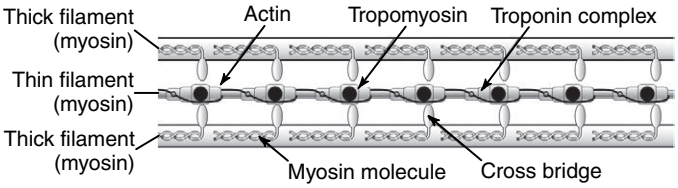

FIGURE **23-11** Arrangement of actin and myosin in cardiac muscle.

Internodal Tracts. The internodal tracts are located within the atria and are the preferential conduction pathways between the SA and the AV nodes. They are composed of a combination of closely packed parallel myocardial fibers and large pale-staining cells with a perinuclear clear zone. They have large nuclei and sparse myofibrils that resemble the Purkinje cells. Like the SA node, the internodal tracts contain P cells and transitional cells.

Three major internodal tracts exist: the anterior, middle, and posterior internodal tracts. The anterior internodal tract, or Bachmann bundle, sends fibers to the LA and then travels down through the atrial septum to the AV node. The middle internodal tract, or Wenckebach tract, curves behind the superior vena cava before descending to the AV node. Finally, the posterior internodal tract, or Thorel tract, continues along the terminal crest to enter the atrial septum and then passes to the AV node.

Atrioventricular Node. The AV node is located beneath the endocardium on the right side of the atrial septum, anterior to the opening of the coronary sinus. The AV node is supplied by an abundance of nerve endings, as well as vagal (ganglionic) cells. The AV node causes a delay in the transmission of action potentials. This delay may be attributed to several factors, such as the size of the AV nodal cells (smaller than the surrounding atrial cells), a decreased distribution of gap junctions between cells, a resting membrane potential that is *more negative* than the normal resting membrane potentials of the surrounding cells, and the paucity of gap junctions. Greater resistance to the transmission of an action potential exists within the AV node.

Atrioventricular Bundle. The AV bundle (bundle of His) extends from the lower end of the AV node and enters the posterior aspect of the ventricle and the Purkinje system. This AV bundle is the preferential channel for conduction of the action potential from the atria to the ventricles.

Purkinje System. The Purkinje system consists of the bundle branch system and its terminal branches. The left bundle branch extends outward under the endocardium and forms several fascicles, which innervate various parts of the LV. The anterior fascicle innervates the anterolateral wall of the LV and the anterior papillary muscle. The posterior fascicle innervates the lateral and posterior ventricular wall and the posterior papillary muscle. The anterior and posterior fascicles join to form the septal fascicle, which innervates the lower ventricular septum and the apical wall of the LV.

The right bundle branch travels under the endocardium along the right side of the ventricular septum to the base of the anterior papillary muscle.

Structural and Regulatory Proteins. The myocardium has characteristics of both skeletal and smooth muscle. Like smooth muscle, cardiac muscle fibers are interconnected (syncytial), which allows for an action potential to rapidly spread to adjacent cells. Because of this characteristic of cardiac muscle fibers, action potential propagation and muscle contraction occur as an "all-or-none" response.

The myocardial cell is similar to skeletal muscle in that it is composed of sarcomeres (Figure 23-9). These sarcomeres contain all the microfilaments and structures that are consistent with the skeletal muscle sarcomere. The sarcomere stretches from Z line to Z line. The A bands consist of the actin filaments, which contain a bilayer filament of F-actin and tropomyosin. Along the actin filament, many active sites exist that can attach to the head of the myosin molecule. A troponin complex is necessary to inhibit actin and myosin from interacting and initiating muscle contraction. The other microfilament in the cardiac muscle is the myosin molecule. This molecule is made up of two major parts: a light meromyosin chain and a heavy meromyosin chain. The heavy meromyosin chain consists of two hinged ends and a head that plays a role in the "ratchet theory" of muscle contraction (Figure 23-10).[1]

During sympathetic nervous system stimulation, catecholamines (primarily epinephrine and norepinephrine) are released from the central nervous system and the adrenal medulla. Increased cardiac conduction velocity, increased force of contraction, and increased heart rate are primarily mediated by beta$_1$ (β_1)-adrenergic receptors. When catecholamine hormones interact with β_1 receptors, they stimulate G protein activation. Adenyl cyclase activity increases and catalyzes the formation of cyclic adenosine monophosphate (cAMP). A specific protein kinase is formed, and phosphorylation occurs, increasing myocardial cell permeability to calcium and sodium. Threshold potential is reached, and depolarization occurs, which increases the concentration of calcium from the sarcoplasmic reticulum and the transverse tubular system. Calcium interacts with the troponin tropomyosin complex to initiate cardiac contraction. The force of myocardial contraction is dependent on the quantity of calcium present in the cardiac cell.

Evidence indicates that the troponin-tropomyosin complex inhibits the binding of the heads of the myosin filaments with the active sites on the actin molecule (Figure 23-11). During the initiation of contraction, calcium is released from the sarcoplasmic reticulum. Calcium binds to the troponin-tropomyosin complex

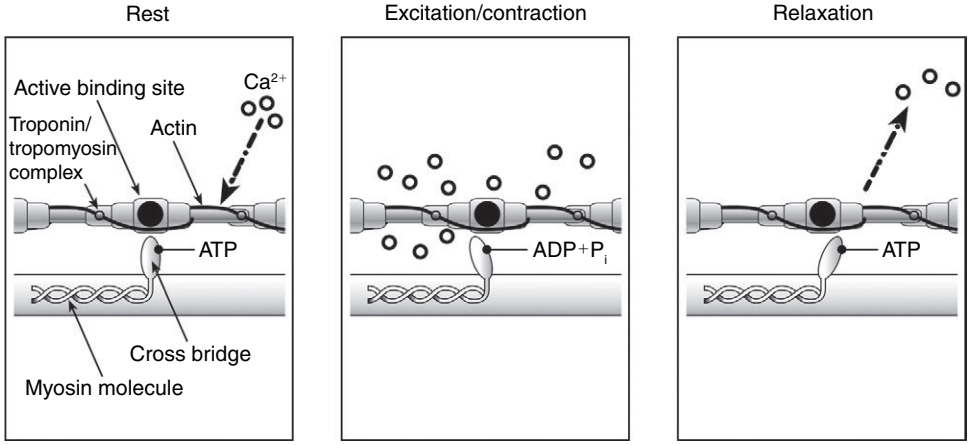

FIGURE **23-12** Phases of cardiac muscle contraction.

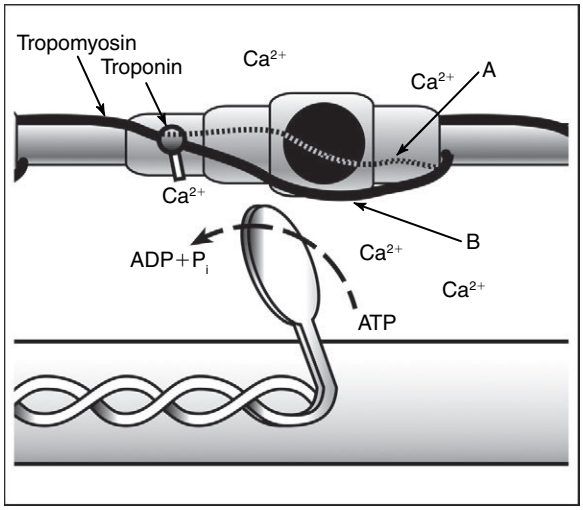

FIGURE **23-13** Letter A *(dotted line)* indicates that the troponin tropomyosin complex blocks the active binding site and inhibits contraction. Letter B *(solid line)* indicates that when calcium interacts with troponin, there is a conformational change. The troponin tropomyosin is displaced, and interaction between actin and myosin initiates muscle contraction. Note that ATP is used during the binding, the power stroke, and the unbinding process. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate.

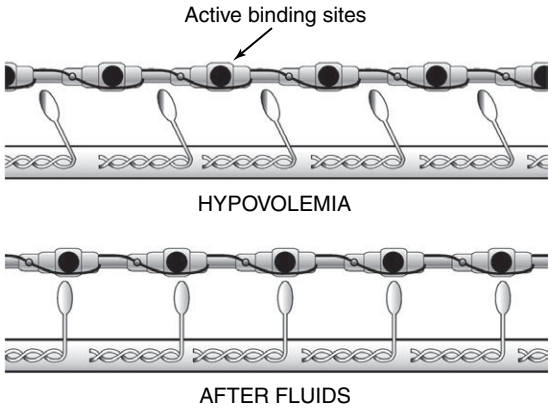

FIGURE **23-14** Greater alignment of actin binding sites and myosin cross bridges causes increased myocardial contractility.

and causes a conformational change so that the active binding sites on the actin filaments become exposed. The myosin cross bridges bind to the active filament and move along the actin filament by alternately attaching and detaching from the active sites, thereby causing shortening of the Z lines (Figure 23-12). This is known as the *sliding filament theory*. When the actin filaments and myosin cross bridges intermingle, muscle contraction occurs. Inhibition of calcium influx into the cardiac muscle cells is the proposed mechanism whereby the inhaled anesthetic agents cause depression of myocardial contractility. Cellular energy or adenosine triphosphate (ATP) is required for this process, known as *excitation-contraction coupling*, to occur, as shown (Figure 23-13). For muscle contraction to cease, calcium reuptake into the sarcoplasmic reticulum occurs as a result of active transport. The troponin-tropomyosin complex reinhibits the interaction between actin and myosin. That this process occurs constantly and within milliseconds is the primary reason for the heart's high metabolic demands (see Figure 23-13). With a limited supply of oxygen and substrate (primarily fatty acids), such as with patients with coronary artery disease or an increased energy demand caused by tachycardia from sympathetic nervous system stimulation, myocardial dysfunction and infarction can occur.

Similar length-force relationships exist within the myocardium and in skeletal muscle. The resting sarcomere length at which the muscle cell is most efficient is 2.0 to 2.4 μm. At greater lengths, the interdigitation of the actin and myosin is compromised, and at shorter lengths the sarcomere is unable to generate an efficient contraction.

Clinically this concept is demonstrated by having the ideal filling pressure of the LV necessary to achieve adequate CO. Filling pressures are used to reflect the filling volumes of the ventricles and (indirectly) the amount of stretch on the ventricular muscle at rest. Filling pressures are measured by the use of the pulmonary capillary wedge pressure (PCWP) or the pulmonary artery diastolic pressure. It has been demonstrated that at excessively high filling pressures (as in congestive heart failure) and at excessively low filling pressures (as in hypovolemia), the CO can be compromised as a result of either excessive or inadequate stretch of the left ventricular myocardium. The greater the degree of stretch of myocardial muscle fibers, the greater the number of actin filaments and myosin cross bridges that are more completely approximated. This will result in an increase in the force of cardiac contraction, as shown in Figure 23-14. This concept is the basis for the Frank-Starling law of the heart, which is discussed later in this chapter.

TABLE 23-1 Equilibrium Potential of Various Ions

Ion	Intracellular Concentration (mmol)	Extracellular Plasma Concentration (mmol)	Equilibrium Potential E_m (mV)
Na^+	10	145	60
K^+	135	4	–94
Cl^-	4	114	–97
Ca^{2+}	10^{-4}	2	132

Differences Between Skeletal and Cardiac Muscle Cells. Several differences exist between myocardial muscle cells and skeletal muscle cells (see Figure 23-9). At the junctions between the fibers in the myocardial muscle mass, many branching, interconnected fibers are intercalated disks and gap junctions, or nexi. Areas of low resistance facilitate the conduction of the action potential from one myocardial cell to another.

The myocardial sarcomeres also contain higher concentrations of mitochondria than do other types of muscle cells. The cardiac cells are aerobic and cannot tolerate oxygen deficiency. Skeletal muscles can function both aerobically and anaerobically.

The myocardial sarcomere system has a rich capillary blood supply (one capillary per fiber) that allows for efficient diffusion and perfusion. The T-tubular system and the sarcoplasmic reticulum are extensive within the cardiac sarcomere. This situation allows for the rapid release and reabsorption of calcium from the cells. It also serves to highlight the important role extracellular calcium plays in the contractile process of the myocardial cell.

Generation of Membrane Potentials

Resting Membrane Potentials. The myocardial sarcomere is not merely a contractile entity. It also possesses properties common to neural tissue, such as the generation of a resting membrane potential, the ability to generate an action potential, and the conduction of the action potential from one sarcomere to the next.

The resting cell membrane is relatively permeable to potassium and relatively impermeable to both sodium and calcium. The resting membrane potential is caused by a chemical force, an electrostatic counterforce, and the sodium-potassium active transport pump.

The chemical force relies on the potential difference in ion concentration between one side of the cell membrane and the other. The ions primarily responsible for this force are sodium, potassium, and calcium.[13] The electrostatic counterforce results from the negative potential generated by the ion difference of the interior of the cell. This force can pull ions into the cell, especially potassium.

The sodium-potassium pump requires an energy source (active transport) and involves the magnesium-dependent enzyme adenosine triphosphatase located in the cell membrane. Three molecules of sodium are pumped out of the cell into the extracellular fluid for every two molecules of potassium pumped into the intracellular fluid.

Calculation of the equilibrium potential (E_m, measured in millivolts) has been accomplished by examining the concentration of an ion inside the cell versus outside the cell (see the Nernst equation that follows). Table 23-1 lists the equilibrium potentials of the most physiologically important ions. The ion most responsible for the resting membrane potential is potassium.

$$E_m = (-RT/FZ) \times \log [K]_i / [K]_o$$

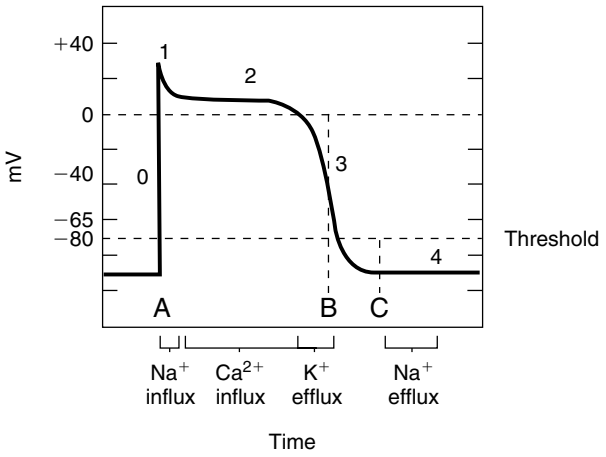

FIGURE 23-15 The ventricular muscle action potential. *A* to *B*, Absolute refractory period; *B* to *C*, relative refractory period; *0*, depolarization; *1*, overshoot; *2*, plateau; *3*, repolarization (rapid); *4*, repolarization (complete).

where R is a gas constant, T is temperature in Kelvin, F is Faraday's constant, $[K]_i$ is the intracellular concentration of potassium, and $[K]_o$ is the extracellular concentration of potassium.

If a temperature of 310° K is assumed for a living human, the Nernst equation reduces to the following in a human heart:

$$E_m = (-61.5/FZ) \times \log [K]_i / [K]_o$$

The Nernst potential is useful only in discussions of a single ion. The membrane potentials are generated because the cell membrane is permeable to several different ions. Three factors affect the calculation of the effect of these different ions on the resting membrane potential: the electric charge of each ion, the permeability of the membrane to each ion, and the concentration gradient across the membrane. The following equation, the Goldman-Hodgkin-Katz equation, is a modification of the Nernst equation that accounts for these factors.

$$EMF = 61.5 \times \log ([Na]_i P_{Na} + [K]_i P_K + [Cl]_o P_{Cl}) / ([Na]_o P_{Na}\ [K]_o P_K\ [Cl]_i P_{Cl})$$

where $[K]_i$ is the intracellular ion concentration of potassium, $[K]_o$ is the extracellular ion concentration of potassium, P_{Na} is the membrane permeability of sodium, P_{Cl} is the membrane permeability of chlorine, and P_K (when calculated) is the membrane permeability of potassium.

Ventricular Muscle Fiber Action Potential

Gate Theory. Several electrostatic gates have been elucidated for the various ions. These gates open (activated) and close (inactivated), depending on the electrical potential of the cell membrane. An electrostatic gate exists for each of the major cardiac ions (sodium, potassium, calcium, and chloride).

Phases of the Action Potential. The action potentials of the various parts of the conduction system vary according to their locations and functions.[14] The action potential of the ventricular muscle fiber is separated into five phases (Figure 23-15). Phase 0, or upstroke, is represented by depolarization and involves the fast sodium channels. The fast sodium channel activation gates (M gates) open between −70 and −65 mV (threshold potential). At 0 mV, both the activation and the inactivation gates (H gates) are open. The rapid upstroke velocity of phase 0 gives a relative

TABLE 23-2 Cardiac Action Potential

Phase	Name	Cation Movement	Effect
0	Upstroke	Na^+ ECF to ICF	Sodium channels open Potassium permeability decreased
1	Initial repolarization	K^+ ICF to ECF	Sodium channels close Potassium channels open
2	Plateau	Ca^{2+} ECF to ICF	Calcium channels open
3	Final repolarization	K^+ ICF to ECF	Calcium channels close Potassium channels open
4	Resting potential	K^+ ICF to ECF	Resting membrane permeability restored, sodium and potassium leak to ICF to increase threshold potential
		Na^+/Ca^{2+} ECF to ICF	

ECF, Extracellular fluid; *ICF*, intracellular fluid.

indication of the conductivity of the myocardial cell. Local anesthetics such as lidocaine have an inhibitory effect on phase 0 by decreasing the influx of sodium. Table 23-2 describes the phases and events of a cardiac action potential.

At *phase 1*, or early rapid repolarization (+2 to +30 mV), the sodium gates close, the rapid influx of sodium stops, and the slower influx of calcium begins. Also, potassium gates open and potassium moves out of the interior of the cell into the extracellular fluid.

One of the characteristics of the action potential unique to ventricular muscle is *phase 2*, or the plateau phase. The plateau phase exists because the slow calcium channels open at −30 to −40 mV and allow an influx of calcium. This inward calcium flux delays repolarization and prolongs the absolute refractory period. Toward the end of phase 2, a decreased permeability to potassium occurs that accounts for a small outward leakage of potassium balanced by the calcium and sodium influx that maintains a membrane potential near 0 mV. Calcium channel blockers exert their pharmacologic effect during phase 2. The physiologic effects include decreased contractility, decreased heart rate, and decreased cardiac conduction velocity.[15]

The terminal repolarization phase, *phase 3*, is initiated as the slow calcium channels become inactivated, and this phenomenon is sustained by an accelerated potassium efflux. These events return the transmembrane potential to its resting membrane value.

The sodium-potassium pump, which is dependent of ATP, reestablishes the proper intracellular-to-extracellular ionic concentrations during *phase 4* (diastolic repolarization phase). Phase 4 lasts from the completion of repolarization to the next action potential. Lidocaine lengthens the duration of phase 4 by decreasing the cardiac cell membrane's permeability to potassium ion, thereby decreasing the efflux of potassium and delaying the onset of the resting membrane potential.[15]

The cardiac glycoside digoxin inhibits the sodium-potassium ATP-dependent pump, decreasing sodium efflux into the extracellular fluid. As intracellular sodium concentrations increase, the exchange between sodium and calcium is decreased. The result is a higher concentration of calcium remains within the cardiac cell, and this effect is believed to be responsible for the increased inotropic effect.[15]

Refractory Periods. The extended duration of the action potential of the myocardial cell protects it against premature excitation. This period of quiescence is known as the *refractory period* and can be divided into absolute and relative periods. The refractory periods are a result of the properties of the sodium channels during the action potential.

The term *effective or absolute refractory period* is used to describe the time during which a conducted action potential may not be evoked, even if an active response is elicited by a stimulus at the cellular level. This period lasts from phase 0 to the middle of phase 3, when the membrane potential drops below −60 mV. The relative refractory period is the time during the action potential when a second stimulus can result only in an action potential with decreased amplitude, upstroke velocity, and conduction velocity. The relative refractory period extends from this middle part of the phase 3 range to the beginning of phase 4, when the membrane potential ranges from −60 to −90 mV. This information can be clinically related to synchronized cardioversion. The shock will not be delivered during the T wave on the electrocardiogram, which represents ventricular repolarization. The relative refractory period occurs during the T wave, and electricity delivered to the chest during this time can cause electrical disorganization in cardiac cells, resulting in ventricular tachycardia or ventricular fibrillation.

Sinoatrial Node Action Potential. The myocardium has among its characteristics contractility, automaticity, and conductivity. Each of the various myocardial masses has its own intrinsic automaticity and rate of action-potential initiation. The SA node is the primary pacemaker of the heart and has several unique characteristics (Figure 23-16). As a result of its higher resting membrane potentials, the SA node membrane is more permeable to sodium than other atrial myocardial cells. This "leakiness" gradually raises the membrane potential closer to threshold potential (−55 to −60 mV), at which point an action potential may be initiated. Therefore the action potential originating within the SA node differs from the action potential generated within the ventricular muscle mass. For this reason, the SA node is the primary pacemaker of the heart.

The SA node and the other automatic cells exhibit only phase 4, phase 0, and phase 3 of the action potential. Because rapid depolarization does not occur, phase 1 or phase 2 (plateau phase) does not occur.

If the SA node fails, the area of the heart with the next highest intrinsic rate, the AV node, replaces the SA node as the pacemaker of the heart. The intrinsic firing rate of the AV node is 40 to 60 beats per minute. If both the SA and the AV nodes fail, the ventricular cells take over and become automatic, firing at a rate of 15 to 30 beats per minute.

Physiology of the Heart

Cardiac Cycle. To understand the cardiac cycle, one must have a firm understanding of the basics of the anatomy of the heart and the pressures and volumes generated within the various chambers during the cardiac cycle. An appreciation for the valves and their positions during the phases of the cycle is essential (Figure 23-17). Additionally, notice that the electrocardiogram impulse generation precedes the mechanical action of the heart. This delay between the electrical impulse and the mechanical event occurs

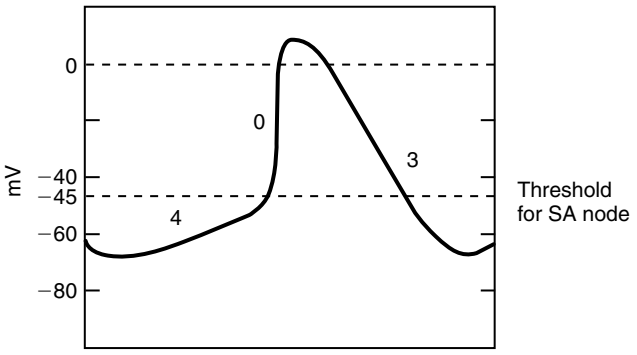

FIGURE **23-16** The sinoatrial nodal action potential.

because time is needed for the wave of depolarization to spread across the myocardium before contraction can begin. In relation to the electrocardiogram, the P wave represents atrial systole, the QRS complex signifies ventricular systole, and the T wave represents ventricular repolarization.

The cardiac cycle extends from one ventricular contraction to the next. It may be divided into two main phases—systole and diastole. Usually the cardiac cycle is described in relation to the left side of the heart. However, similar conclusions about the function of the right side of the heart may be drawn in the absence of cardiopulmonary pathology.

Diastole. During ventricular systole, the atria fill and blood returns from the venous system to the right side of the heart and from the pulmonary circulation to the left side of the heart. The first phase of diastole is the period of isovolumetric relaxation. The ventricular muscle mass relaxes, and the aortic and mitral valves are closed as long as the ventricular pressure remains higher than the atrial pressure. The true filling phase is divided into three periods: (1) rapid inflow, or diastasis, (2) reduced inflow, and (3) atrial systole. Once the ventricular pressure drops below atrial pressure, the mitral valve opens, and the period of rapid inflow to passively fill the ventricle begins. The second period of diastole is diastasis, in which minimal changes occur in volume and in pressure.

Atrial systole provides another period of rapid filling that is commonly referred to as the *atrial kick*. This phenomenon increases ventricular filling by 20% to 30%. In patients who have severe mitral stenosis, the atrial kick may be responsible for up to 40% of the ventricular filling. During periods of strenuous exercise or in patients with many pathologic conditions such as shock or congestive heart failure, the additional ventricular filling is critical to maintaining CO.

Systole. After atrial systole, the isovolumetric phase, or isovolumetric contraction, which is the phase at the beginning of ventricular contraction, occurs. The myocardial fibers shorten, and pressure is generated within the ventricle but only enough to close the mitral valve. Therefore during this period, an increase in left ventricular pressure occurs without a change in ventricular diastolic volume. Isovolumetric contraction begins with closure of the mitral valve and lasts until opening of the mitral valve.

Systolic ejection begins with the opening of the aortic valve and occurs when the ventricular pressure exceeds the aortic pressure. This phase of the cardiac cycle is divided into two periods, with the period of rapid ejection taking the first third of systole and the period of reduced ejection taking the last two thirds of systole. During rapid ejection, ventricular systolic pressures reach their maximum, and the largest amount of volume is ejected. Therefore systole is composed of isovolumetric contraction, rapid ejection, and reduced ejection. The dicrotic notch or incisura on the

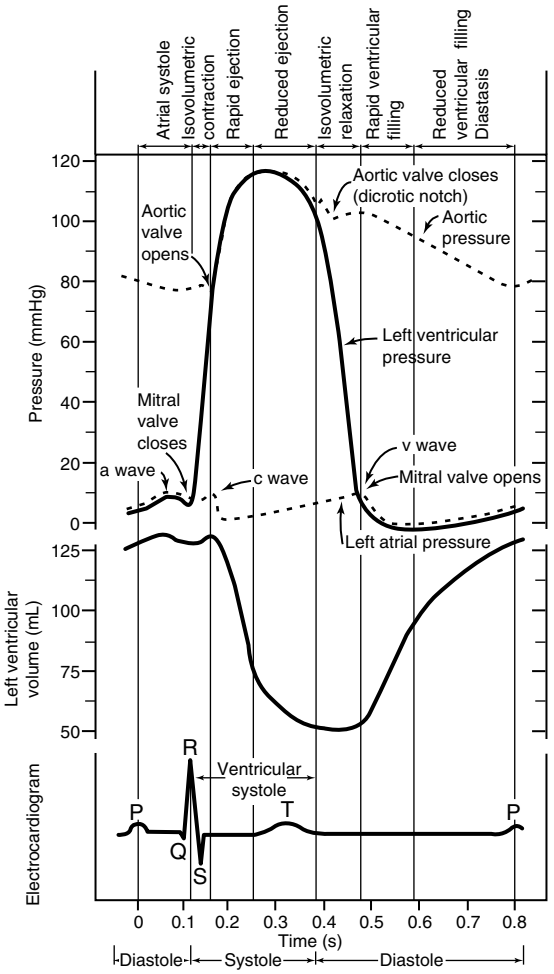

FIGURE **23-17** The cardiac cycle.

arterial pressure tracing occurs within the period of isovolumetric relaxation. This segment represents retrograde blood flow back into the LV before aortic valve closure. Three waveform segments are present on the left atrial pressure tracing: the *a* wave, *c* wave, and *v* wave. The specific waveforms correspond to their position within the cardiac cycle. The *a* wave represents atrial systole as it ends just before mitral valve closure. The *c* wave represents ventricular contraction and is produced by bulging of the mitral valve caused by increasing left ventricular pressure. The *v* wave represents increased pressure in the LA caused by blood return from the pulmonary artery before mitral valve opening.

Physiology of Coronary Circulation. The anatomy of the coronary circulation has already been discussed. A description of the physiologic determinants of coronary blood flow follows.

Coronary Blood Flow. The rate of blood flow is determined by a change in the pressure within the vessel divided by resistance of the system. Alterations of the radius of a vessel change the flow to the fourth power of the radius. This phenomenon is an extension of Poiseuille's law, which determines the flow of a fluid through a tube.

At rest, approximately 4% to 5% of the CO, or 225 mL/min of blood, passes through the coronary vasculature. Phasic changes have been documented during coronary blood flow. A greater amount of coronary flow in the LV occurs during diastole. During systole, left coronary artery blood flow ceases to the subendocardium due to compression of the subendocardial vessels by the myocardium; flow through the epicardial vessels is not affected

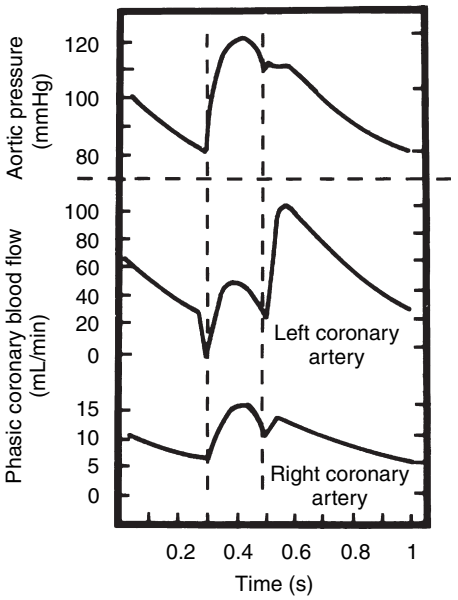

FIGURE **23-18** Blood flow in the left and right coronary arteries. The right ventricle is perfused throughout the cardiac cycle. Flow to the left ventricle is largely confined to diastole. (From O'Brien ER, Nathan HJ. Coronary physiology and atherosclerosis. In: Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia: Saunders; 2011.)

during systole to this extent. The flow to the left coronary artery is greatest during diastole as a result of the decreased resistance to flow from decreased myofibril tension that occurs as the intracavitary pressure decreases (Figure 23-18).

Control of Coronary Circulation and Oxygen Supply and Demand. Coronary blood flow is regulated by intrinsic and extrinsic factors that affect coronary artery tone. Intrinsic factors include the anatomic arrangement and perfusion pressure of the coronary vessels. Extrinsic factors include compressive factors within the myocardium, as well as metabolic, neural, and humoral factors. Blood flow through the coronary circulation is primarily controlled by the factors that determine oxygen demand and oxygen supply. Myocardial oxygen supply is determined by arterial blood content, diastolic blood pressure, diastolic time as determined by HR, oxygen extraction, and coronary blood flow. Myocardial oxygen demand is determined by preload, afterload, contractility, and HR (Figure 23-19).

The factors that increase myocardial oxygen consumption ($M\dot{V}O_2$) are listed in Table 23-3. Notice in Figure 23-19 that heart rate appears on both the supply (diastolic time) side and demand side of the balance. Increasing heart rate not only increases demand but also decreases diastolic time, which is when 80% to 90% of coronary filling and myocardial perfusion occurs. Increased heart rate is the most important factor that negatively affects $M\dot{V}O_2$. Doubling the heart rate doubles $M\dot{V}O_2$.[16] This phenomenon most dramatically affects patients with coronary artery disease, because the supply of blood is compromised and may not be able to meet the oxygen demands caused by tachycardia. As a result, myocardial dysfunction or infarction can occur. By slowing HR and decreasing contractility, β-blocking medications increase supply and decrease demand, protecting the heart from ischemia.[17]

Because at rest the myocardium extracts 65% to 70% of the available oxygen, the only way to increase oxygen delivery to the myocardium is by increasing blood flow. During periods of increased myocardial oxygen demands, flow through the coronary

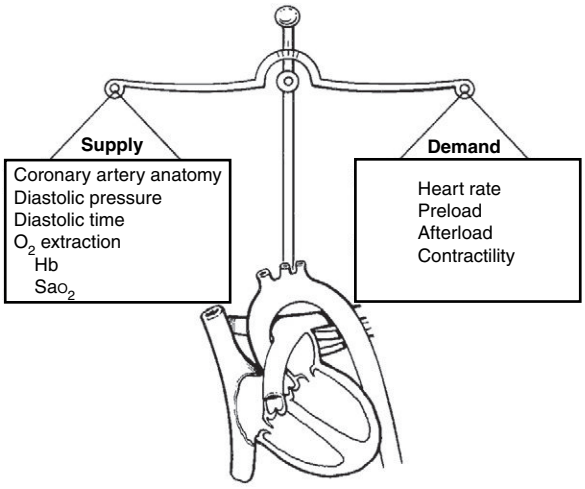

FIGURE **23-19** The heart's oxygen supply and demand must be balanced by the anesthetist, who should increase the former and reduce the latter. *Hgb*, Hemoglobin; *Sao_2*, arterial oxygen saturation.

TABLE 23-3 Components and Effects on Myocardial Oxygen Consumption

A 50% Increase in	Resultant Increase in $M\dot{V}O_2$
Heart rate	50%
Pressure work	50%
Contractility	45%
Wall stress	25%
Volume work	4%

$M\dot{V}O_2$, Myocardial oxygen consumption.

arteries can increase by three to four times. Several vasodilator substances have been identified and are released from the myocardium in response to decreased oxygen delivery or concentration. Among these substances are adenosine, adenosine phosphate compounds, potassium ions, hydrogen ions, carbon dioxide, bradykinin, and prostaglandin. Experts believe that adenosine is the primary substance responsible for coronary vasodilation.

The normal physiologic parameters of the heart are given in Table 23-4. The determinants of $M\dot{V}O_2$ include myocardial contractility, myocardial wall tension (preload), HR, and mean arterial pressure (MAP; afterload). Oxygen extraction is determined by measurement of the difference between the oxygen tension in the pulmonary arterial blood and that in the coronary sinus.

Oxygen supply relies on the blood oxygen content (see following equation), which is affected by both the oxygen carried on the hemoglobin (Hgb) molecule (1.34 mL of oxygen per gram of Hgb) and to a lesser extent the oxygen dissolved in the plasma (0.003 mL of oxygen per milliliter of plasma).

$$O_2 \text{ content (mL } O_2 \text{/ mL plasma)} = (PaO_2 \times 0.003) + (\text{Hgb content} \times \text{Hgb} - O_2 \text{ saturation } \%)$$

Other factors that have an influence on coronary circulation include the direct and indirect effects of the sympathetic nervous system and the effect of certain substrates of cardiac metabolism.

Autoregulation. Under normal physiologic conditions, the coronary circulation, like other tissue beds in the body, exhibits *autoregulation*, which is the ability to maintain coronary blood flow through a range of MAPs by dilating or constricting. Coronary

TABLE 23-4 Normal Physiologic Parameters

Heart size	230-280 g (female) 280-340 g (male)
Coronary blood flow	225-250 mL/min or 4%-7% total cardiac output
Myocardial O_2 consumption	65%-70% extraction 8-10 mL O_2/100 g/min
Normal autoregulation	60-140 mmHg (MAP)
Coronary filling	80%-90% during diastole

MAP, Mean arterial pressure.

blood flow is maintained at a constant rate through a MAP range of 60 to 140 mmHg. When arterial blood pressure is less than or exceeds these pressure limits, coronary blood flow becomes pressure dependent. Therefore during hypotension, when the coronary arteries are maximally dilated, coronary blood flow is determined by the MAP minus the right atrial pressure.

A method for directly estimating coronary perfusion pressure (CPP) can be calculated by subtracting left ventricular end-diastolic pressure (LVEDP) from diastolic blood pressure (DBP)—that is, CPP = DBP − LVEDP. Because under normal conditions LVEDP (10 mmHg) is significantly less than DBP (80 mmHg), the major determinant of CPP is DBP.

Coronary vascular reserve is the difference between the maximal flow and the autoregulated flow. The closer these two values, the lower the coronary reserve of the patient. Factors that increase myocardial oxygen demand and limit supply decrease coronary reserve flow and can result in myocardial dysfunction.

The concept of "coronary steal" has emerged, especially in reference to the use of agents such as adenosine, nitroglycerin, and isoflurane. If vasodilator treatment is used in a patient who has both an ischemic area of the heart that is supplying a stenotic vessel with collateral flow and another area that has an intact autoregulated vessel, only the autoregulated vessel dilates further and has the ability to increase its flow. Constant maximal coronary artery dilation exists in an area where stenosis is present. Therefore only the areas of the heart with intact autoregulation respond to vasodilators and receive preferential flow over the stenotic area. The existence of this phenomenon is questionable. As long as adequate CPP is maintained, coronary steal and myocardial ischemia caused by isoflurane do not occur.[18,19] A second factor that could result in this phenomenon is coronary steal–prone anatomy. This has been defined as complete occlusion of one coronary artery and at least 50% occlusion of a second coronary artery that supplies collateral blood flow to the area in which the complete occlusion exists.[18] In addition, recent evidence suggests that the inhaled anesthetics isoflurane, desflurane, and sevoflurane produce myocardial protection during periods of ischemia in humans by decreasing the formation of free radicals, preserving myocardial ATP stores, and inhibiting increased intracellular calcium.[19,20] This is referred to as *anesthetic preconditioning*.

Cardiac Output. Cardiac output is the amount of blood ejected from the LV during 1 minute. Comparing various CO values among several patients requires a method for calculating output in relation to the size of the patient. The CO is measured in liters per minute. Cardiac output is indexed, because a CO of 3.5 L/min may be adequate for a patient who is 5 feet tall and weighs 95 lb, but it is less than optimal for a patient who is 6 feet 7 inches tall and weighs 300 lb. The average CO is 5 L/min, and the average cardiac index (CI) is 2.5 L/min or more per square meter of body surface area (BSA). The formula for this relationship is CI = CO/BSA.

The primary determinants of CO are stroke volume (SV) and HR. CO is derived by using the equation CO = HR × SV. The SV is the amount of blood ejected from the LV with each beat. The average SV is approximately 70 mL. If the average HR is 70 to 80 beats per minute, a CO of 5 L/min results.

Several key factors affect SV, including preload, afterload, and myocardial contractility. Preload is the effective tension of the blood on the ventricle or the wall tension at the end of diastole. Preload can either be passive (the flow of blood from the atria to the ventricles during diastole) or active (the volume contributed by the atrial kick). With increased preload, there is an associated increase in contractility. This phenomenon is known as the *Frank-Starling law* of the heart, which states that the greater the wall tension (preload), the greater the compensatory increase in myocardial contractility. This mechanism allows the heart to immediately compensate for increased preload and avoid overdistention of the cardiac chambers by increasing SV, which facilitates chamber emptying. However, there is a point at which progressive increases in preload no longer increase contractility but can contribute to decreased myocardial performance. Increased preload increases myocardial oxygen demand. Clinically, preload can be estimated by using the PCWP and the pulmonary artery diastolic pressure. In patients with normal mitral valve and ventricular muscle function, either of these measures provides an estimate of the preload or LVEDP and volume.

Cardiac output can be determined indirectly by applying the Fick principle (see the following equation). Assuming normal respiratory function, CO is equal to the amount of oxygen absorbed by the lungs divided by the arteriovenous oxygen difference.

$$\text{CO (L/min)} = \frac{\text{Oxygen absorbed per minute by the lungs (mL/min)}}{\text{Arteriovenous oxygen difference (mL of blood)}}$$

Right-sided heart pressures (central venous pressure) that are obtained clinically can be estimates of left ventricular volumes in patients with good left ventricular function.[21]

Afterload is the wall tension the myocardium needs to overcome to eject the SV. It is the pressure within the LV during peak systole. Factors affecting LV afterload include the state of the ventricular chamber and the compliance of the arterial vasculature. The shape, size, and wall thickness of the ventricle play an important role in afterload. The vascular component of the afterload includes SVR and MAP because these variables relate to the vascular compliance of the aorta. Thus increases in blood pressure increase afterload.

Afterload is most often estimated clinically by determining the SVR. The SVR may be calculated once the CO and the difference between the MAP and the central venous pressure (CVP) are known (see the following equation). The normal SVR is 800 to 1500 dyn.s/cm^5.

$$\text{SVR} = (\text{MAP} \times \text{CVP}) / \text{CO} \times 80$$

The problem with equating afterload with SVR is that ventricular wall tension, which is an integral part of the afterload, is not considered.

Contractility of the myocardium is the state of inotropy that is independent of either preload or afterload. It may be altered by many cardiovascular disease states. Factors such as rate of pressure changes over time (dP/dt [first derivative of pressure measured over time]), force-velocity or Starling ventricular function curves, pressure-volume loops, ejection fraction (EF), and velocity

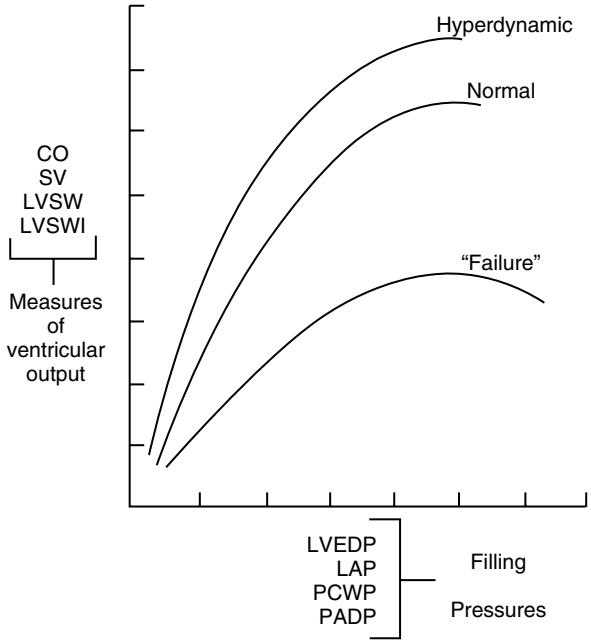

FIGURE **23-20** The ventricular function curve. *CO*, Cardiac output; *LAP*, left atrial pressure; *LVEDP*, left ventricular end-diastolic pressure; *LVSW*, left ventricular stroke work; *LVSWI*, left ventricular stroke work index; *PADP*, pulmonary artery diastolic pressure; *PCWP*, pulmonary capillary wedge pressure; *SV*, stroke volume.

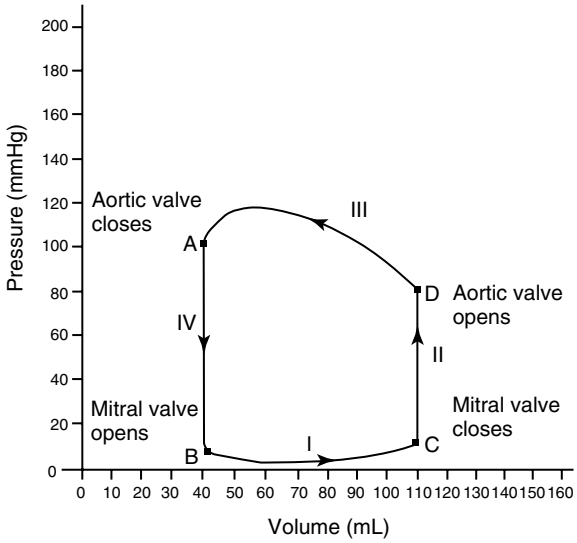

FIGURE **23-21** Phases of the left ventricular (LV) pressure-volume loop, which is a continuous cycle divided into four phases. Phase I represents diastolic filling. Left ventricular filling begins at point *B* and ends at point C. Note the increase in volume of 70 mL and the upward movement of the curve at point C, representing a slightly increased pressure in response to the increased volume. Point C or mitral valve closure represents end-diastolic volume (EDV). Phase II represents isovolumetric contraction. Note there is a significant increase in pressure but no change in volume. Cardiac muscle fibers are shortening and increasing the pressure on the LV volume until point *D*, where the LV pressure exceeds aortic pressure. Phase III represents systolic ejection. Note the decrease in LV volume throughout LV systolic ejection. Phase IV represents isovolumetric relaxation. At point *A* the aortic pressure exceeds LV pressure, and the aortic valve closes. Point A represents end-systolic volume (ESV). The LV relaxes, and the pressure decreases significantly. At maximal LV relaxation, the mitral valve opens and the process starts again.

of circumferential fiber shortening have all been used to estimate contractility.

Left ventricular dP/dt measurements require a high-fidelity recording system, and for this reason these measures are not readily available in the clinical setting. A wide range of normal values exists (800 to 1700 mmHg/sec), making patient-to-patient comparisons difficult. Assessment of the acute change in contractility of a single patient over time is still the common method of using this measurement.

Ventricular function curves[22] (Figure 23-20), define the relationship between the left ventricular filling pressure (left ventricular diastolic pressure, left atrial pressure, PCWP) and the left ventricular stroke work index (LVSWI), which is calculated by use of the following equation:

$$\text{LVSWI (in g/m}^2\text{ per beat)} = 0.0136 \times \text{SVI} \times (\text{MAP} - \text{PCWP})$$

where SVI = CI/HR.

Each left ventricular function curve has a steep upstroke that has a plateau at higher filling pressures. To apply the Frank-Starling mechanism to Figure 23-20, notice in the "normal" and "hyperdynamic" curves that as pressure (horizontal axis) increases, so does LV output (vertical axis). However, at the top of these curves, there is a plateau where increasing the filling pressures no longer increases performance and can then decrease ventricular output. Symptoms may be elicited by either high or low filling pressures. On the "failure" curve, with compromised cardiac function, increases in filling pressures do not dramatically increase myocardial performance and can lead to cardiogenic shock. The clinical determination of LVSWI is worthwhile because it contains many of the factors that contribute to CO, and it gives measures of both systolic and diastolic performance.

Left ventricular pressure-volume loops have been mentioned before as conceptual models depicting phases of the cardiac cycle. They may also be used as tools to determine myocardial performance. Left ventricular pressure-volume loops simultaneously measure chamber pressures and the resultant volumes (Figure 23-21). Movement from left to right on the horizontal axis represents increased volume. Movement from right to left on the horizontal axis represents decreased volume. Movement up and down on the vertical axis represents increases and decreases in pressure, respectively. The distinct phases of the left ventricular pressure-volume loop are represented in Figure 23-22.

The interior of the curve (distance between the two vertical lines of the LV pressure-volume loop) is representative of SV. In this diagram, SV is calculated by subtracting end-systolic volume (ESV) from end-diastolic volume (EDV), or EDV (110 mL) − ESV (40 mL). Thus in this example, stroke volume is 70 mL. Ejection fraction (EF) can then be estimated using the following equations:

$$\text{EF} = (\text{EDV} \times \text{ESV}) / \text{EDV} \times 100$$

or

$$\text{EF} = (\text{SV} / \text{EDV}) \times 100$$

The EF is the percentage of the end-diastolic volume ejected during systole, as seen in Figure 23-23. The normal EF is 60% to 70%. An EF of less than 40% is associated with significant left ventricular impairment.

Deviations from the normal left ventricular pressure-volume loops occur as a result of many causes. Factors that alter the normal loop include increases and decreases in LV preload, LV afterload, and LV contractility. These factors can be acute and transient, such as during the administration of vasoactive medications, or

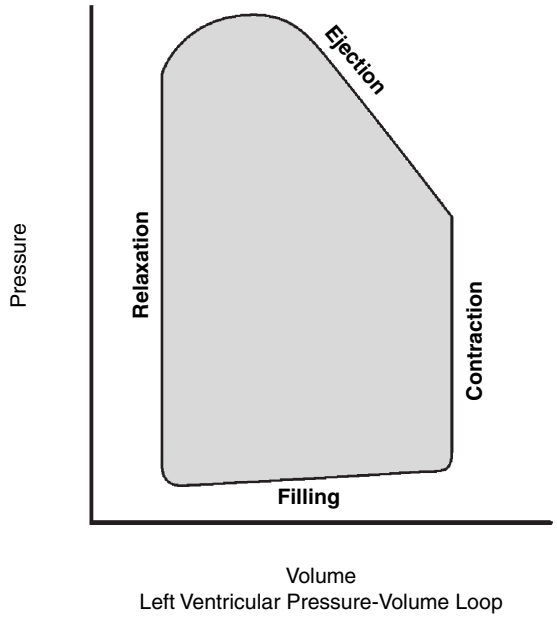

FIGURE **23-22** Phases of the cardiac cycle represented by a left ventricular pressure-volume loop.

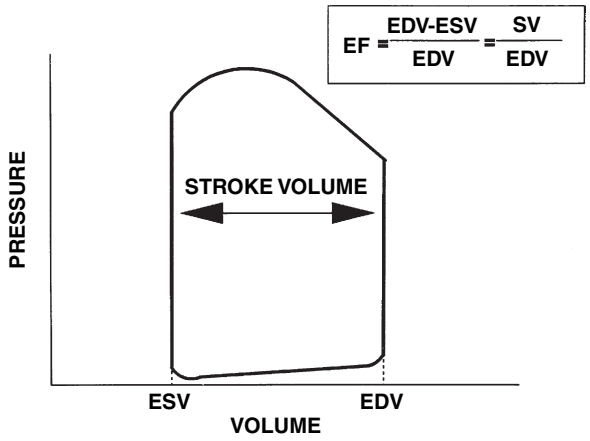

FIGURE **23-23** Pressure-volume diagram indicating end-diastolic volume (EDV), end-systolic volume (ESV), stroke volume (SV), and the equation for ejection fraction (EF). (From Johnson B, et al. Cardiac physiology. In: Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era.* 5th ed. Philadelphia: Saunders; 2006:73.)

chronic as a result of myocardial compensation caused by valvular heart disease. In Figure 23-24, these changes are consistent with valvular heart disease. Because many factors contribute to variations in pressure and volume from beat to beat within the LV, each pressure volume loop is distinct, represents one LV systolic ejection, and is different for each contraction. A discussion of these pathologic curves is presented later in this chapter.

A clinically useful tool is two-dimensional transesophageal echocardiography (TEE). When this technology is appropriately used, real-time movement of all four chambers of the heart, as well as that of the valves, may be visualized.

TEE can be used to detect valvular function and blood flows in both regurgitant and stenotic lesions. It is also useful in determining areas of hypokinesis, dyskinesis, or akinesis caused by myocardial infarction, ischemia, or injury. It can be useful in determining myocardial contractility, and it is a more direct measure of intraventricular volume status than pulmonary artery catheter

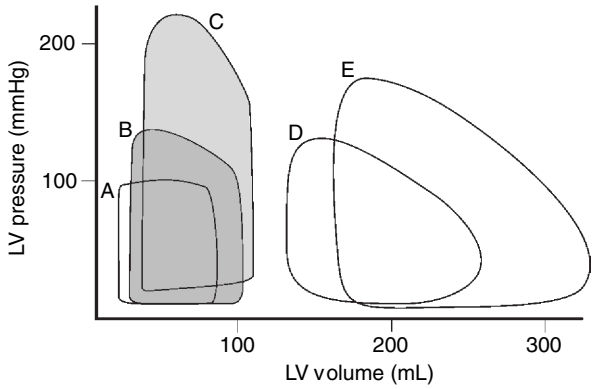

FIGURE **23-24** Pathologic left ventricular pressure-volume loops. *A*, Mitral stenosis; *B*, normal curve; *C*, aortic stenosis; *D*, mitral regurgitation; *E*, aortic regurgitation.

pressure measures. TEE has also proven useful in directing fluid and pharmacologic therapy in patients who have undergone coronary bypass and other surgical procedures. Ventricular dysfunction or reperfusion injury, as well as the presence of intraventricular air, can be determined with TEE. This diagnostic tool is the gold standard for assessing intraoperative myocardial performance. The practical problems associated with the clinical use of TEE entail acquiring the skills necessary for accurate interpretation of the visual data, the possibility of esophageal rupture, and the cost associated with its use.

Cardiovascular Reflexes

Cardiac Output Regulation. A direct interplay exists between CO and venous return. As long as neither the contractility nor the HR is compromised, maintenance of a constant return of blood flow to the heart ensures an adequate CO. The body's regulation of CO depends on its ability to regulate HR and contractility of the myocardium, as well as constriction and distention of the vascular tree.

Many of the factors that affect CO also affect the MAP and are addressed in the section on regulation of MAP. Some of the more common reflexes that can alter the CO are described in this section or in the section on regulation of MAP.

Valsalva Maneuver. The Valsalva maneuver occurs as a result of forced expiration against a closed glottis. The reflex is mediated through the baroreceptors located near the bifurcation of the internal and external carotid arteries (carotid sinus) and the aortic arch. The afferent pathway is directed via Hering's nerve and either the glossopharyngeal nerve (carotid sinus) or the vagus nerve (aortic arch), as shown in Figure 23-25. Stimulation of either of these areas inhibits the vasomotor center in the medulla. The response inhibits the sympathetic nervous system and stimulates the parasympathetic nervous system, producing a decrease in HR, a decrease in myocardial contractility, and vasodilation, resulting in a decrease in blood pressure. The Valsalva maneuver also increases intrathoracic pressure, which decreases venous return and thereby decreases CO.

Baroreceptor Reflex. The baroreceptors respond to fluctuations in arterial blood pressure. Afferent and efferent impulse transmission travels along the same pathway as the Valsalva maneuver. Decreases in arterial blood pressure are sensed by the baroreceptors, increasing sympathetic tone, which results in increased myocardial performance and vasoconstriction. Acute hypertension causes the opposite cardiovascular response. A more in-depth explanation of the baroreceptor response and its role

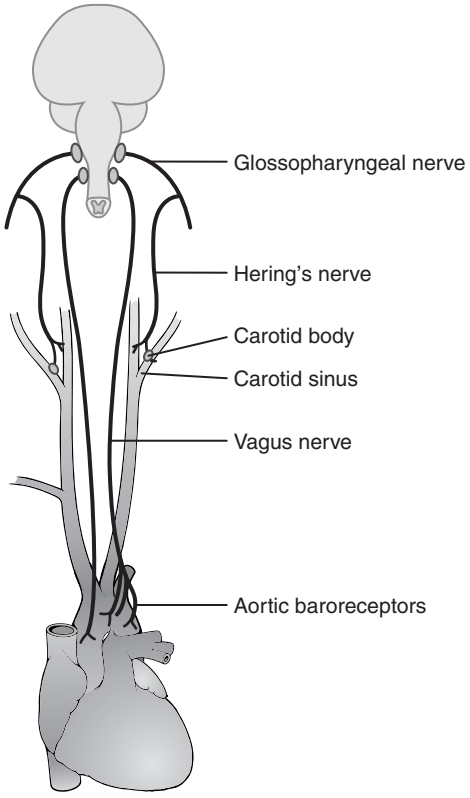

FIGURE **23-25** Afferent and efferent neural pathways from carotid and aortic baroreceptors. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology.* 12th ed. Philadelphia: Saunders; 2011:206.)

in short- and long-term blood pressure control is presented later in this chapter. The baroreceptor response is inhibited by volatile anesthetic agents in a dose-dependent manner and results in decreased ability of the baroreceptors to respond to blood pressure changes when these agents are used.

Oculocardiac Reflex. Traction on the extraocular muscles (especially the medial rectus), conjunctiva, or orbital structures causes hypotension and a reflex slowing of the HR, as well as arrhythmias. The oculocardiac reflex may also be elicited during retrobulbar block, ocular trauma, or pressure on the tissue that remains after enucleation. The afferent path of the reflex is mediated by the long and short ciliary nerves to the ciliary ganglion of the oculomotor nerve and then the ophthalmic division of the trigeminal nerve (cranial nerve V) to the gasserian ganglion. The efferent branch of the reflex is mediated by the vagus nerve (cranial nerve X). This reflex may be blunted by the use of retrobulbar block or the release of the offending stimulus. The resulting vagal response to the heart can be inhibited by an anticholinergic agent (atropine or glycopyrrolate).

Celiac Reflex. The celiac reflex is elicited by traction on the mesentery or the gallbladder or stimulation of the vagus nerve in other areas of the body, such as the thorax and abdominal cavity. Stimulation of this reflex causes bradycardia, apnea, and hypotension. Clinically, the celiac reflex can be initiated indirectly as a result of a pneumoperitoneum. As with the oculocardiac reflex, the celiac reflex is frequently resolved by stopping the initiating stimulus.

Bainbridge Reflex (Atrial Stretch Reflex). The Bainbridge reflex is elicited as a result of an increased volume of blood in the heart, which causes sympathetic nervous system stimulation. Stretch receptors are located in the right atrium, junction of the vena cava, and pulmonary veins. The sinoatrial node is also involved in this process and can increase heart rate by 10% to 15%. This reflex helps to prevent sequestration of blood in veins, atria, and pulmonary circulation. Antidiuretic hormone secretion from the posterior pituitary gland is decreased, resulting in decreased circulating blood volume. Atrial natriuretic peptide is increased, which also promotes diuresis.

Cushing Reflex. This physiologic response to central nervous system (CNS) ischemia caused by increased intracranial pressure is called the *Cushing reflex*. It is triggered as a result of an elevation of intracranial pressure to a value greater than the MAP, thereby decreasing cerebral perfusion and cerebral-causing ischemia. An intense sympathetic nervous system response is initiated by the vasomotor center, resulting in intense vasoconstriction. These compensatory physiologic changes attempt to restore adequate cerebral perfusion. However, if cerebral ischemia is not relieved, cerebral infarction results. When the vasomotor area becomes ischemic as a result of hypotension (MAP less than 50 mmHg), maximal stimulation of the vasomotor center occurs. The Cushing's triad is a late sign of high and sustained intracranial pressure prior to cerebral herniation. The signs include hypertension, bradycardia, and respiratory irregularity.

Chemoreceptor Reflex. The central chemoreceptors are located beneath the ventral surface of the medulla and are directly stimulated primarily by increased hydrogen ion concentrations. The peripheral chemoreceptors are located at the bifurcation of the internal and external carotid arteries (carotid body) and within the aortic arch (aortic body) and are primarily stimulated by decreased arterial oxygen concentration. The response elicited from hypoxia, hypercarbia, and acidosis is increased minute ventilation and increased sympathetic nervous system stimulation, resulting in increased blood pressure. Like the baroreceptor reflex, the chemoreceptor response is inhibited by the volatile anesthetic agents in a dose-dependent manner. Thus if residual volatile agent is present during the emergence from anesthesia, the threshold for breathing will be increased, necessitating a higher $Paco_2$ prior to spontaneous respirations. Table 23-5 provides a summary of the cardiovascular reflexes.

VASCULAR SYSTEM

Anatomy

Vascular Anatomy

The vascular circulation is divided into the pulmonary circulation and the peripheral systemic circulation (Figure 23-26). This vascular system is composed of several functional parts.

Arteries

Arteries transport blood to the tissues under high pressure. Arteries have an average diameter of 4 mm and a wall thickness of 1 mm. They have a thick layer of elastic tissue, smooth muscle, and fibrous tissue. Arteries are able to maintain the flow of blood because of their large internal diameter.

Arterioles

Arterioles are the last small branches of the arterial system, and they act as control valves for the release of blood into the capillary beds. Arterioles have an average diameter of 30 μm and a wall thickness of 20 μm. Like arteries, arterioles have a thick layer of elastic tissue, smooth muscle, and fibrous tissue. Constriction of the arterioles, compared with that of other structures within the vascular system, causes the greatest increase in SVR. Because of this contribution, arterioles exhibit the greatest pressure drop in the vascular system across the length of their vessels.

TABLE 23-5 Cardiac Reflexes

Reflex	Stimulus	Response
Baroreceptor reflex	Hypertension resulting in baroreceptor stimulation; carotid baroreceptors send afferent response via Hering and glossopharyngeal nerves (CN IX); aortic baroreceptors send afferent response via the vagus nerve (CN X)*	Decreased heart rate, decreased contractility, peripheral vasodilation from efferent response via the vagus nerve (CN X)
Valsalva maneuver	Forced expiration against a closed glottis mediated via baroreceptors; see baroreceptor reflex for neural pathways	Decreased heart rate, decreased contractility, peripheral vasodilation from efferent response via the vagus nerve (CN X)
Cushing reflex	Increased intracranial pressure resulting in cerebral ischemia	Sympathetic nervous stimulation resulting in increased blood pressure
Chemoreceptor reflex	Decreased oxygen saturation, increased carbon dioxide, increased hydrogen ion concentration; peripheral chemoreceptors located in the carotid body and aortic arch; see baroreceptor reflex for neural pathways	Increased respiratory drive, increased blood pressure
Atrial stretch reflex (Bainbridge reflex)	Hypervolemia, increased venous return causes stimulation of atrial stretch receptors	Increased heart rate, decreased blood pressure, decreased systemic vascular resistance, diuresis
Oculocardiac reflex	Traction on the extraocular muscles (especially medial rectus) or pressure on the globe causes an afferent response via the trigeminal nerve (CN V) and results in an efferent vagal response via the vagus nerve (CN X)	Bradycardia, hypotension, and arrhythmias
Celiac reflex	Traction or pressure on structures within abdominal and thoracic cavities causes vagal nerve stimulation	Bradycardia, hypotension, and apnea

*Efferent response increases parasympathetic tone via the vagus and sympathetic nerves.
CN, Cranial nerve.

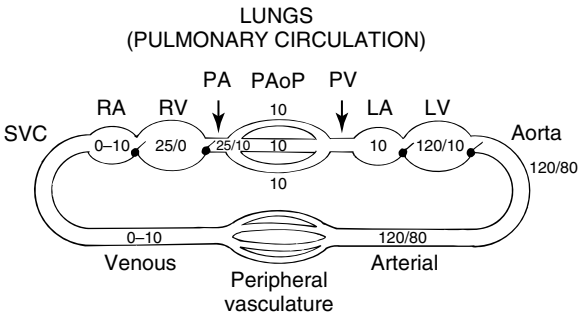

FIGURE 23-26 The vascular circuit. *LA,* Left atrium; *LV,* left ventricle; *PA*, pulmonary artery; *PAOP*, pulmonary artery occlusion pressure; *RA*, right atrium; *RV*, right ventricle; *SVC*, superior vena cava.

Capillaries

The exchange of fluids, nutrients, electrolytes, hormones, and other substances occurs between the blood and the interstitial fluids in the capillaries. Capillaries have an average diameter of 8 μm and a wall thickness of 1 μm. The walls of capillaries are only one cell thick and have no elastic tissue, smooth muscle, or fibrous tissue. The capillary cell membrane is semipermeable to water and other small molecules.

Venules

Venules collect blood from capillaries and gradually coalesce into progressively larger veins. Venules have an average diameter of 20 μm and a wall thickness of approximately 0.5 mm. They do not have an elastic or smooth muscle layer but have a thin fibrous layer.

Veins

Veins act as conduits for the transport of blood back to the heart. They also act as a large reservoir because they are very distensible. They have an average diameter of 30 mm and a wall thickness of 1.5 mm. The venous system contains approximately 60% of the blood volume, as opposed to the 20% contained within the arteries (Figure 23-27). The elastic tissue and the fibrous tissue layers are similar in size to those of the arterioles, but the smooth muscle layer in the veins is smaller than that in the other large vessels.

Arterial Circulation

Knowledge of the anatomy of the arterial circulation is an important part of anesthesia practice. Such information is essential for obtaining intraarterial access, assessing HR and pulse quality, understanding the anatomic relationships for the purpose of regional blocks, and understanding the physiologic implications of blood flow in shock states.

Microscopic Anatomy of the Arterial Circulation. Arteries are classically divided into two types: conducting, or elastic, arteries and distributing, or muscular, arteries. Conducting arteries include the major arteries, such as the aorta, and their major branches, such as the brachial, radial, and ulnar arteries. The walls of the arteries are thicker than the walls of veins and consist of three major layers: the tunica intima, the tunica media, and the tunica adventitia.

Thoracic Aorta. The thoracic aorta is divided into three sections: the ascending aorta is the portion that leaves the LV; the transverse aorta, or arch, is the portion that levels off; and the descending aorta is the portion that descends into the thorax. After the thoracic aorta penetrates the diaphragm, the vessel is called the *abdominal aorta* (Figure 23-28).

The first branches of the ascending aorta are the right and left coronary arteries. From this point, three major branches of the thoracic aorta exist: the brachiocephalic (innominate) artery, the left common carotid artery, and the left subclavian artery.

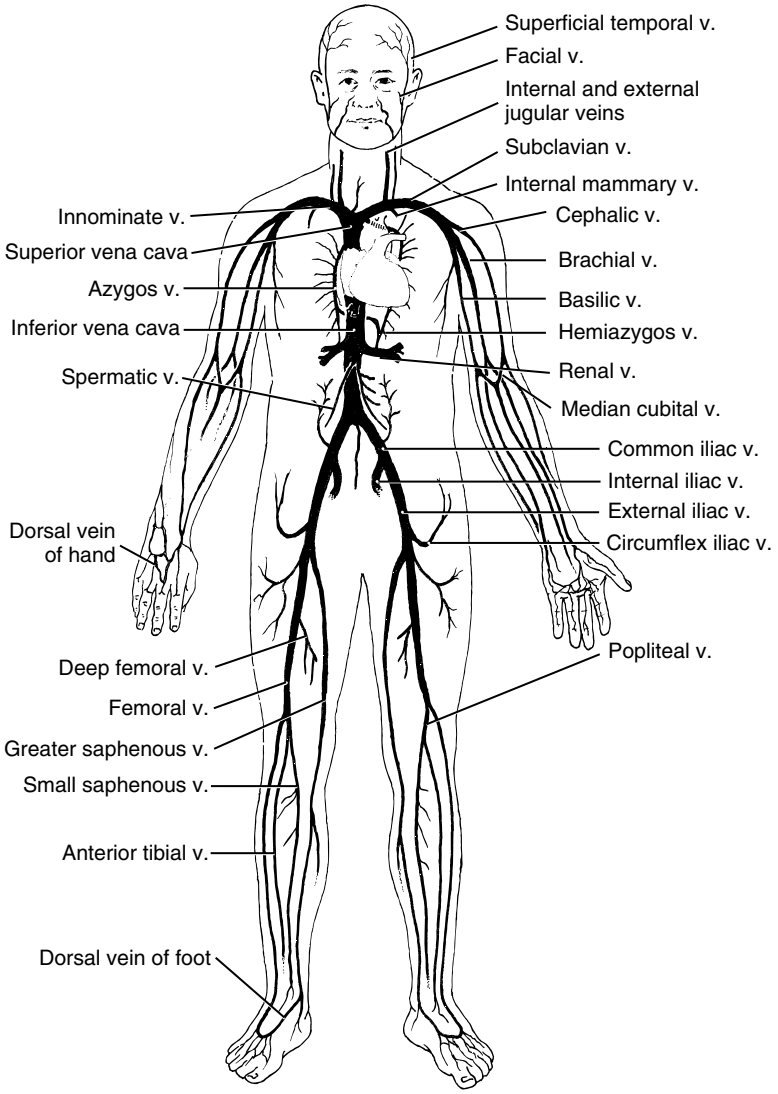

FIGURE **23-27** The venous system. *v.*, Vein.

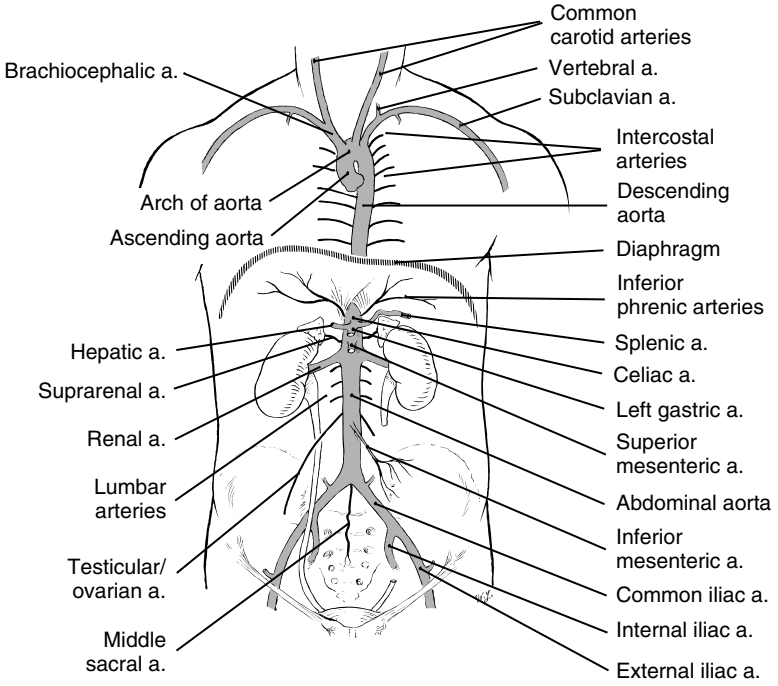

FIGURE **23-28** Thoracic aorta and abdominal aorta and their branches. *a.*, Artery.

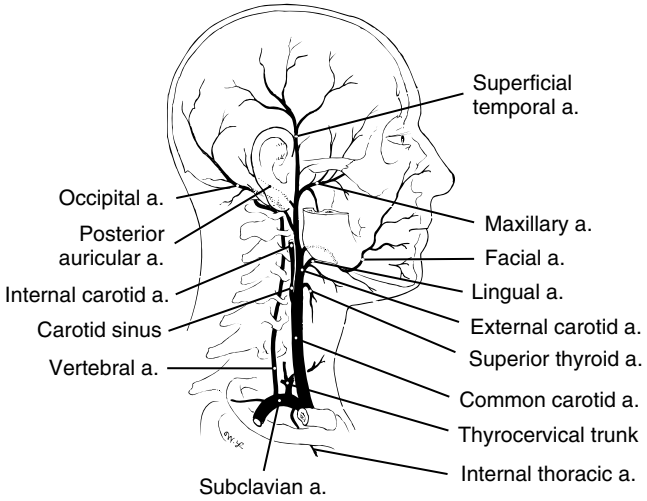

FIGURE **23-29** Arterial supply to the face. *a.*, Artery.

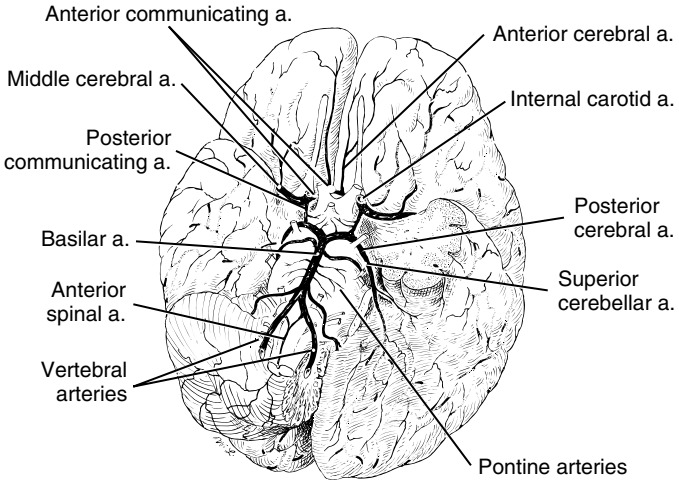

FIGURE **23-30** The circle of Willis. *a.*, Artery.

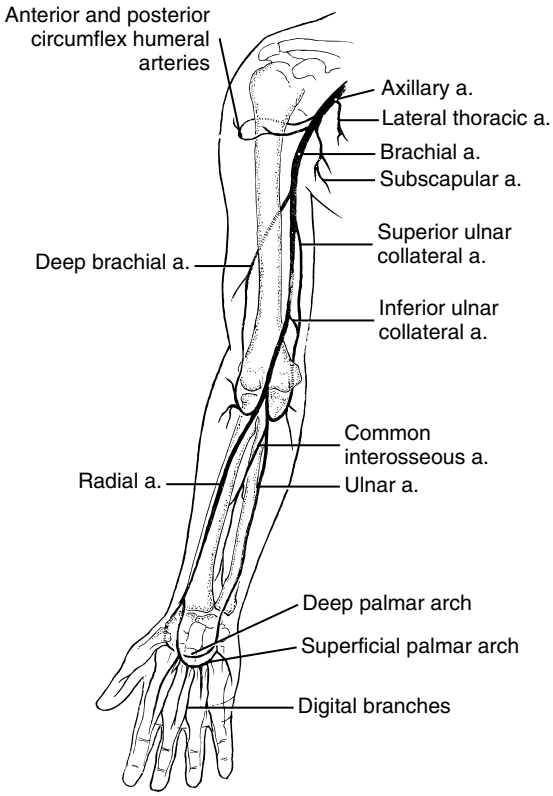

FIGURE **23-31** Arterial supply to the upper extremity. *a.*, Artery.

The brachiocephalic artery branches and becomes the right common carotid artery and the right subclavian artery. The left and right common carotid arteries branch into internal and external carotid arteries. The external carotid arteries supply blood to the face and neck, and the major branches are the superior thyroid artery, the lingual artery, the facial artery, the posterior auricular artery, the maxillary artery, the transverse facial artery, the middle temporal artery, and the superficial temporal artery (Figure 23-29).

The internal carotid arteries supply 80% of blood to the brain via the circle of Willis and to the eyes via the ophthalmic arteries (Figure 23-30). The circle of Willis also receives a major part of its blood supply from the vertebral branches of the subclavian artery.

Upper Extremity Arteries. The subclavian arteries branch before entering the upper arm. These branches include the vertebral arteries, as noted earlier; the thyrocervical trunk, which supplies blood to the thyroid gland as well as other structures in the neck; the internal thoracic artery, which supplies blood to the anterior chest; and the costocervical trunk, which supplies blood to the first two intercostal spaces and the muscles of the neck.

The subclavian artery continues at the border of the first rib as the axillary artery (Figure 23-31). Branches from the axillary artery supply blood to the axillary region and include the highest thoracic artery, the thoracoacromial artery, the lateral thoracic artery, the subscapular artery, and the anterior and posterior circumflex humoral arteries.

The brachial artery begins at the terminal end of the axillary artery at the inferior border of the teres major muscle. The artery continues until the neck of the radius, where it ends by dividing into the radial and ulnar arteries. The radial artery forms the deep palmar arch, and the ulnar artery supplies blood to the superficial palmar arch.

Descending Thoracic Aorta. The descending thoracic aorta passes caudad through the posterior mediastinum on the left side and at the level of the twelfth thoracic vertebra passes through the aortic opening in the diaphragm and becomes the abdominal aorta. Branches of the descending thoracic aorta include the lower nine posterior intercostal arteries, the subcostal arteries, the pericardial arteries, the esophageal arteries, and the bronchial arteries.

Abdominal Aorta. As the thoracic aorta passes through the aortic hiatus of the diaphragm, it becomes the abdominal aorta. The first branches of the abdominal aorta are the inferior phrenic arteries, which supply blood to the underside of the diaphragm and the adrenal glands (see Figure 23-28).

The next major branch of the abdominal aorta is the celiac trunk, which supplies blood to many of the organs in the upper abdomen. Its branches include the splenic artery, the left gastric artery, the gastroduodenal artery, and the hepatic artery. The cystic artery, which supplies blood to the gallbladder, is a branch of the hepatic artery.

Below the celiac trunk of the aorta lies the superior mesenteric artery, which arises at the level of L1. This artery supplies blood to the jejunum, the ileum, and the transverse colon by means of an anastomosis with the middle colic artery. The jejunal and ileal branches unite to form the arterial arcades of the colon.

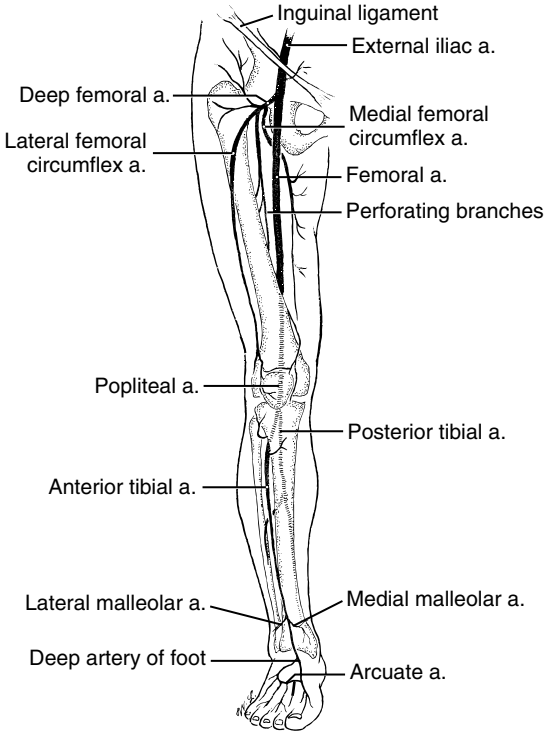

FIGURE **23-32** Arterial supply to the lower extremity. *a.*, Artery.

Below the superior mesenteric artery are the right and left renal arteries. The right renal artery branches to the right adrenal gland, where it is called the *middle suprarenal artery*. Below the renal arteries are the testicular or ovarian arteries. Inferior to the renal arteries lies the inferior mesenteric artery. This artery has branches to the transverse colon, the descending colon, and the sigmoid colon and rectum.

Iliac Arteries. The abdominal aorta terminates at the common iliac arteries in the pelvis. These arteries divide into internal and external iliac arteries. The internal iliac arteries supply blood to structures within the pelvis, whereas the external iliac arteries supply blood to the legs.

Lower Extremities. The external iliac artery continues as the femoral artery and the deep femoral artery (Figure 23-32). The femoral artery becomes the popliteal artery behind the knee and then divides into the anterior and posterior tibial arteries. The anterior tibial artery continues as the dorsal artery of the foot. The posterior tibial artery continues and supplies blood to the plantar arches. Clinically, the dorsal artery of the foot is not only an important landmark for the assessment of lower extremity circulation but can also be used for arterial cannulation if the radial artery catheter insertion is not possible.

Venous Circulation

An understanding of the anatomy of the venous system is essential in the practice of anesthesia, not only for vascular access but also for identification of significant landmarks to help locate nerve bundles when performing nerve blocks. Evaluation of venous distention is an important assessment tool for fluid overload and cardiovascular dynamics.

Head and Neck. In the head and neck, venous drainage returns to the heart via the internal and external jugular veins. The drainage from the brain comes from the sagittal, transverse, and sigmoid sinuses. These sinuses drain into the internal jugular vein, whereas the more superficial structures of the face and head drain into the external jugular vein.

Upper Extremities. Superficial veins of the upper extremities include those that drain into the axillary vein, the cephalic vein laterally, and the basilica vein medially. The axillary vein drains into the subclavian vein on the right and then into the right brachiocephalic vein. The left subclavian vein drains into the left brachiocephalic vein. The right and left brachiocephalic veins empty into the superior vena cava and account for the venous drainage that occurs from the upper extremities. Pressure and occlusion of the superior vena cava from a mass can result in a decrease in venous drainage, causing superior vena cava syndrome.

Thorax. Venous drainage of the chest comes from the branches of the superior and inferior vena cava and the azygos and hemiazygos systems. These systems are an important alternative blood return route if a major obstruction of the inferior vena cava occurs. These vessels include the intercostal vessels, the bronchial veins, and the pericardial veins.

Abdomen, Pelvis, and Lower Extremities. The deep femoral and femoral veins receive superficial and deep venous drainage from the legs and join to form the external iliac veins. The internal iliac veins drain blood from the pelvis. The common iliac vessels receive blood from the internal and external iliac veins and drain into the inferior vena cava. In this region, the common iliac vessels are joined by branches from the abdomen and the hepatic portal system.

Microcirculation

The function of the microcirculation is to control the delivery of nutrients to the capillary tissue beds, remove waste products, maintain ionic concentrations, and transport hormones to the tissues.

Anatomy. In general, a main nutrient artery enters an organ, where it branches six to eight times until the vessels are small enough to be called *arterioles* (less than 20 μm in diameter). Arterioles then branch two to five times and reach diameters of 5 to 9 μm, small enough to supply blood to the capillary bed.

In the capillary bed, the blood enters through an arteriole that has a muscular coat. Arterioles are connected to metarterioles, which have many interconnections to the true capillaries and whose branches are protected by precapillary sphincters. These sphincters can control blood flow through the capillary bed.

The capillary wall is a unicellular layer of endothelium surrounded by a basement membrane. The total wall thickness is 0.5 μm, and the diameter of the capillaries is 4 to 9 μm. In the capillary membrane, intercellular clefts allow the diffusion of water-soluble ions and small solutes. Plasmalemmal vesicles form channels in the cell membrane.

The diffusion of substances through the cell membrane is determined by several factors: lipid solubility, water solubility, size of the molecule, and concentration difference from one side of the membrane to the other.[1]

Movement of fluid volume from the plasma and the interstitial fluid is determined by four factors: capillary pressure, interstitial fluid pressure, plasma colloid osmotic pressure, and interstitial fluid colloid osmotic pressure. Excess fluid from the interstitial space is transported through the lymphatic system, which plays an important role in the prevention of pulmonary edema formation when pulmonary artery pressures are elevated.

Local Control of Capillary Blood Flow. Blood flow to the various capillary beds is regulated by local tissue metabolic requirements. Therefore capillary blood flow may be controlled by the delivery of oxygen and other nutrients, the removal of end products of metabolism, or the maintenance of ionic balance of pH in the tissues.

Two major theories regarding regulation of capillary blood flow are the vasodilator theory and the oxygen-demand theory. According to these theories, the vessels dilate to increase the blood flow as a result of either hypoxemia or release of a vasodilator substance in response to hypoxemia. Some of the vasodilator substances that have been suggested are adenosine, carbon dioxide, lactic acid, adenosine phosphate compounds, histamine, potassium ions, and hydrogen ions. These theories assume an active microcirculatory process exists that responds to tissue metabolic needs.

Certain tissue capillary beds do not function as explained by the vasodilator and the oxygen-demand theories of microcirculatory blood flow. Blood flow to the skin is dependent on external temperature and dissipation of body heat, whereas blood flow to the kidneys is dependent on the amount of fluid and sodium that needs to be excreted.

Autoregulation is another process demonstrated by certain organ tissues; it keeps blood flow through the capillary bed constant, despite the normal changes in MAP. Autoregulation has been demonstrated in such tissues as the brain, the kidney, and the coronary circulation. Autoregulation keeps the blood flow to an organ constant by way of vasodilation or vasoconstriction as occurs in response to fluctuations in MAP.

A substance that causes secondary vasodilation of the large arteries in response to increased flow has been isolated and was once called the *endothelium-derived relaxing factor*.[23] Currently it is referred to as *nitric oxide*. This factor is synthesized by the endothelial lining of the arterioles and the small arteries. Shear stress on the walls of the vessels accelerates the release of this substance and allows larger vessels to dilate when blood flow to the tissues increases.

Growth of Collateral Circulation

Microcirculation is a good example of vascular growth that can occur to provide collateral circulation. The growth of new vessels results in part from angiogenesis and the release of angiogenic factors. These substances are released from ischemic tissues, rapidly growing tissues, and tissues with high metabolic rates.

Several angiogenic factors have been identified, including endothelial cell growth factor,[24] fibroblast growth factor,[25] and angiogen.[26] These factors act by the dissolution of the basement membrane of the endothelial cells, followed by the rapid dissolution of new endothelial cells that stream out of the vessels into cords. The cells in these cords divide and then gradually fold over into a tube. The tubes then connect with other tubes to form a vascular network.

Vascular flow is dependent on neurologic as well as hormonal regulation. Some vasoconstrictor hormones include epinephrine and norepinephrine from the central nervous system (CNS) and the adrenal medulla, angiotensin from the adrenal cortex, and vasopressin from the posterior pituitary. Some vasodilator substances include bradykinin, serotonin, histamine, and the prostaglandins. Various other ionic and chemical factors can produce vasoconstriction and vasodilation as well and have an effect on the flow of blood that is delivered to tissues.

Blood Pressure

Pressure, Flow, and Resistance Interrelationships

Ohm's Law. Ohm's law correlates the flow of electricity (current), the applied electrical pressure (voltage), and the resistance to this flow (resistance). A modification of this law is used in medicine to describe the flow of a fluid (blood) through a tube (blood vessel), even though the vessels are dynamic rather than static. Ohm's law and fluid flow are described by the following equation:

$$Q = (P_1 \times P_2) / R$$

where the flow through a cylinder (Q) is equal to the change in pressure from one end of the tube to the other ($P_1 \times P_2$) divided by the resistance (R) of the tube. Therefore either a decrease in resistance or an increase in pressure change across the tube increases the flow of fluid through the tube.

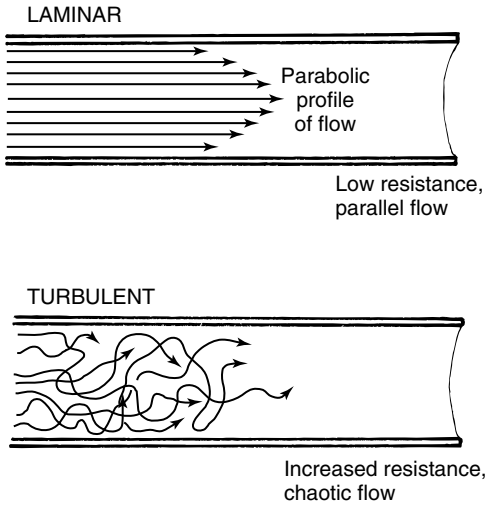

FIGURE **23-33** Laminar and turbulent flow.

Blood Flow. Blood flow is the quantity of blood that passes a given point in a given amount of time. Clinically, CO may be inserted into the equation as blood flow. Two types of flow exist: laminar and turbulent (Figure 23-33).

Laminar flow has a parabolic profile that illustrates the parallel movement of molecules. Conversely, turbulent flow is described as a whirlpool and does not move as easily, thereby increasing resistance to flow. Reynolds number (Re) is a means of determining the type of flow in a tube and uses the diameter of the blood vessel (d) and the velocity (v), density (ϱ), and viscosity (n) of the fluid to determine whether turbulence occurs.

The formula for calculating Reynolds number includes the velocity of blood flow in centimeters per second multiplied by the diameter of the tube in centimeters, multiplied by the density of the fluid in grams per cubic centimeter, divided by the viscosity (see the following equation). A Reynolds number below 200 indicates laminar flow. A Reynolds number of 200 to 400 indicates that turbulence occurs at bends in the tube, and a Reynolds number above 2000 indicates turbulent flow, even in straight, smooth vessels.

$$Re = (v \times d \times \rho) / n$$

Reynolds number demonstrates that in large vessels with high velocities, such as the aorta and large arteries, turbulent flow occurs even in the straight portions of these vessels.

Poiseuille's Law. Poiseuille's law (see the following equation) describes the amount of fluid flowing through a tube (Q) in relation to the pressure drop across the tube ($P_1 - P_2$), the radius of the tube (r), the length of the tube (l), and the viscosity of the fluid (n):

$$Q = ([P_1 - P_2]\, r^4) / (8 \times n \times 1)$$

One of the most important factors in determining fluid flow is the radius of the vessel.

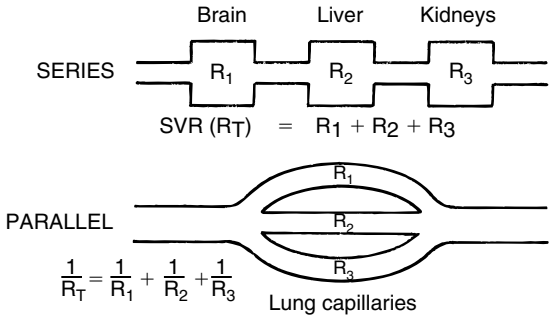

FIGURE **23-34** Resistance in series and parallel systems. *R*, Resistance; *SVR*, systemic vascular resistance. R_T, total resistance.

Clinical applications of Poiseuille's law include selection of intravenous catheter size and endotracheal tube size and determination of vascular distention and constriction in response to pharmacologic agents.

Resistance. Resistance is the impediment to blood flow in a blood vessel. Clinically it cannot be measured directly but is calculated from measures of blood flow (CO) and pressure differences in the vessels.

The units of measure most commonly used in the clinical area are centimeter-gram-second units. The normal SVR is 800 to 1500 dyne/sec per centimeter^{-5}, and the normal pulmonary vascular resistance is approximately one tenth of that number, or between 50 and 150 dyne/sec per centimeter^{-5}.

Resistance of Systems. Resistance is calculated for two major systems (Figure 23-34). In a series system, such as the systemic vasculature, the total resistance (R_T) is equal to the sum of the resistances for the individual tissue beds within the system (see the following equation):

$$R_T = R_1 + R_2 + R_3 + \ldots R_n$$

In a parallel system, such as a capillary bed, the total resistance is less than any of the individual resistances (see the following equation). Therefore the blood flow through a capillary bed such as the pulmonary capillaries is less than the resistance through any of the individual capillaries of the pulmonary system.

$$1/R_T = 1/R_1 + 1/R_2 + 1/R_3 + \ldots 1/R_n$$

Regulation of Mean Arterial Blood Pressure

Regulation of arterial blood pressure is an important function in maintaining homeostasis for patients receiving anesthesia. Mean arterial pressure is an important indicator of perfusion of the tissue beds.

Blood pressure regulation can be categorized as either short term or long term. The choice of category depends on the onset of action, the duration of action, and the intensity of action to return the MAP to normal values.

Short-Term Regulation. The short-term blood pressure regulators are those that respond to rapid changes in MAP and attempt to rapidly (within 30 minutes) return the MAP back to normal range. These reflexes rely on an intact autonomic nervous system, and this interaction is responsible for the rapid onset of action of these blood pressure regulators. The reflexes include the baroreceptor response, the chemoreceptor response, atrial stretch reflex, and CNS ischemic mechanism. All of these reflexes are initiated rapidly in response to acute changes in MAP.

It is important to understand the role of the cardiovascular (vasomotor) center that is located in the medulla and pons. This center regulates four basic actions: vasoconstriction, vasodilation, cardiac excitation, and cardiac inhibition. These areas activate the sympathetic and parasympathetic nervous systems in response to certain stimuli. Under normal conditions, the vasomotor center maintains peripheral vascular tone.

Baroreceptors are located in the internal carotid arteries and the aortic arch and are called the *carotid and aortic sinuses*. They are spray-type nerve endings that increase impulse production when they are stretched. Impulses from the baroreceptors affect the inhibitory centers of the vasomotor center. At MAP of less than 60 mmHg, the baroreceptors do not transmit impulses. However, as the MAP increases to between 60 and 180 mmHg, impulses sent to the inhibitory area of the vasomotor center incrementally increase. The baroreceptors are most efficient in responding to rapid changes in blood pressure. They are not as efficient in long-term blood pressure regulation, because they adapt to the higher pressures, in effect by being reset. Therefore the baroreceptors act as a buffer system to prevent extreme short-term swings in blood pressure. Two clinically significant examples of stimulation of the baroreceptor reflex during surgery include carotid sinus manipulation during carotid endarterectomy and aortic baroreceptor stimulation from pressure exerted on the aortic arch during mediastinoscopy.

Chemoreceptors are chemosensitive cells located within the carotid and aortic bodies. These are known as the *peripheral chemoreceptors*. Each area is supplied by a small nutrient artery and thereby maintains constant contact with the internal environment. Chemoreceptors send impulses to excite the vasomotor center, primarily in response to decreases in Pa_{O_2}. Chemoreceptors play a greater role in respiratory system regulation than in blood pressure regulation.

Low-pressure receptors, or stretch receptors, are located in many areas of the vasculature, especially within the atria and pulmonary arterial tree. They act in conjunction with the baroreceptors to buffer changes in the blood pressure caused by changes in volume status.

The *atrial stretch reflex* is initiated by input from low-pressure receptors. Stretching of the atria caused by an increase in volume results in a dilation of the peripheral arterioles, which decreases SVR, MAP, and CO. Furthermore, hypervolemia causes the release of the atrial natriuretic factor by the atria as a result of increased stretch.[27] This factor causes a reflex dilation of afferent arterioles in the kidney, a phenomenon that increases the glomerular filtration rate and decreases the secretion of antidiuretic hormone via signals to the hypothalamus. The combination of these events causes an increase in urine formation and an attempt to change the MAP by decreasing vascular volume.

The CNS ischemic mechanisms are another rapidly acting blood pressure control system. When hypotension exists, this reflex is initiated in an attempt to restore the MAP to adequate levels for CNS perfusion and especially for perfusion to the vasomotor center. The reflex is most intensely initiated when MAP is less than 20 mmHg and results in one of the most powerful sympathetic vasoconstrictor responses within the human body.[1] The stimulation persists for approximately 10 minutes, by which time either the ischemia has been relieved or the vasomotor center has infarcted, and the stimulation ceases.

Several hormones are instrumental in the short-term regulation of MAP. The onset of action is not as rapid as that of neural control mechanisms, but activation occurs within a short time of stimulation. Norepinephrine and epinephrine are released from the central nervous system and the adrenal medulla during times of sympathetic stimulation and cause vasoconstriction.

Angiotensin I is converted to angiotensin II in the lungs by angiotensin-converting enzyme. This substance is one of the most potent vasoconstrictive substances secreted by the body. It takes approximately 20 minutes to become fully activated. Angiotensin II also plays a role in the secretion of aldosterone from the adrenal cortex. Aldosterone has a role in the long-term regulation of MAP.

The antidiuretic hormone vasopressin has both short-term and long-term effects on blood pressure control. The short-term effect of antidiuretic hormone causes potent and direct vasoconstriction. The long-term control effects of antidiuretic hormone decrease urine output from the kidneys.

Two short-term systems for maintenance of blood pressure that could be classified as intermediate mechanisms are the capillary fluid shift and the stress-relaxation mechanism. Both of these mechanisms depend on an intact vascular system.

The capillary fluid shift is a simple mechanism. As the hydrostatic pressure (MAP) increases within the capillaries, a larger movement of fluid occurs across the capillary membrane as increased pressure. This phenomenon lowers the fluid volume within the vasculature and results in a decrease in MAP.

The stress-relaxation mechanism is an example of the ability of the vasculature to compensate for hypervolemia and hypovolemia as a result of alterations of smooth muscle tone within the vasculature. As intravascular fluid volume increases, tension on the blood vessels results in dilation of the vasculature to compensate for increased volume. Conversely, as the blood volume decreases, the vessels constrict to compensate for the decreased volume in order to maintain MAP.

Long-Term Regulation. Long-term regulation of MAP includes mechanisms that eventually regulate blood volume to within normal range. The renal body fluid system is one of the major long-term regulators of MAP. Renal homeostasis of blood pressure occurs as the kidneys preferentially excrete sodium and water to maintain a normal fluid balance.

It is important to understand the concept of fluid balance and its effect on arterial blood pressure. A chronic increase in blood volume leads to increases in mean filling pressure, venous return, CO, and SVR. The combination of an increased CO and an increased SVR can increase the arterial blood pressure by more than 30%. This causes an increase in myocardial oxygen demand.

Several factors govern the effectiveness of the renal body fluid system, including the renin-angiotensin system, aldosterone secretion, and the nervous system. As fluid intake and blood pressure increase, the secretion of renin by the kidneys decreases. This decreased renin secretion causes a reduced secretion of aldosterone as a result of the decreased production of angiotensin II, which is a potent vasoconstrictor. A decrease in sympathetic nervous system response to the kidney also occurs. The net effect is an increased renal output of sodium and water.

Physiology of the Venous System

In the past, the venous system has been described as simply the return conduit for the arterial system, and it was not thought to play a very active role in the maintenance of circulation and CO. The modern view gives the venous system an integral role in support of the circulation.[28]

The venous system's ability to accommodate large volume changes helps to buffer the intravascular volume during periods of hypervolemia or hypovolemia and thereby helps to maintain CO. In addition, the venous system is well innervated by the autonomic nervous system, and therefore it has the ability to respond to the wide variations in intravascular volume that occur over the course of long surgical procedures and during times of intensive fluid resuscitation.

Knowledge of the anatomy and physiology of the cardiovascular system is essential for safe anesthesia practice. This section discussed issues of concern to the anesthesia provider and offered reference material for the integration of that knowledge into clinical practice.

HYPERTENSION

Extent, Definition, and Etiology

The pathophysiologic cardiovascular condition that is most commonly encountered in patients who require surgery is hypertension. Hypertension affects approximately 70 million people in the United States, and the frequency increases with age. It is vital for the anesthesia provider to understand the pathophysiology of the condition and its relation to the cardiovascular system and other body systems. Only then can a comprehensive anesthesia plan be constructed.[29]

Patients frequently do not exhibit signs or symptoms associated with hypertension. Chronic uncontrolled hypertension affects specific target organs, including the heart, brain, and kidney. Hypertension accelerates and exacerbates the onset of atherosclerotic changes in the arterial vessels of the target organs. It is a primary risk factor for the development of coronary artery disease. Hypertension is a significant cause of congestive heart failure and cardiomyopathy because of increased afterload from chronic vasoconstriction. Because hypertension increases the likelihood of the development of atherosclerosis, it has been implicated as a causative factor responsible for the development of stroke and renal failure.[29]

Hypertension is classified on the basis of its causes. Essential hypertension, also referred to as primary and idiopathic, has no identifiable cause, accounts for 95% of all cases of the disease, and its diagnosis is determined on the basis of exclusion. The relationship between an individual's genetic predisposition and environmental factors most probably influences the potential development and severity of essential hypertension. Theoretic physiologic causes of essential hypertension include sympathetic nervous system hyperactivity and/or increased activity of the renin, angiotensin, and aldosterone system. Remedial (secondary) hypertension has an identifiable and potentially curable cause. Examples of pathophysiologic conditions that cause remedial hypertension include pheochromocytoma, coarctation of the aorta, renal artery stenosis, primary renal diseases (e.g., pyelonephritis, glomerulonephritis), primary aldosteronism (Conn disease), and hyperadrenocorticism (Cushing disease).

Guidelines regarding blood pressure values that constitute hypertension have been published by the National Institutes of Health (NIH). The classification of hypertension is listed in Table 23-6. To determine accurate blood pressure measurements, two readings taken 5 minutes apart with the patient in the sitting position are necessary. The risk of cardiovascular disease doubles with each increment of 20/10 mmHg above 115/75 mmHg. The NIH has coined the term *prehypertension* to refer to those patients who would benefit from lifestyle modifications that decrease the likelihood of developing the pathophysiologic changes associated with hypertension.[30] It is estimated that the implementation of antihypertensive therapy is associated with a 25% decrease in cardiovascular complications and a 38% decrease in stroke.[31] If lifestyle modifications are unsuccessful in decreasing blood pressure to acceptable levels, then antihypertensive therapy should be prescribed.[32] In many instances, patients may have developed advanced atherosclerotic vascular

TABLE 23-6 Classification of Blood Pressure for Adults Age 18 Years and Older

Category	Systolic (mmHg)		Diastolic (mmHg)
Normal	<120	and	<80
Prehypertension	120-139	or	80-89
Hypertension, stage 1	140-159	or	90-99
Hypertension, stage 2	≥160	or	≥100

disease or target-organ dysfunction before the start of treatment for hypertension.[33,34]

Pathophysiology

Systemic blood pressure is regulated by interactive feedback mechanisms involving the sympathoadrenal axis and baroreceptors in the heart and great vessels. It is accepted that some degree of sympathetic hyperactivity is responsible for essential hypertension. Dysfunction of the sympathetic nervous system leads to a state of chronic vasoconstriction. In an attempt to maintain normal intravascular volume, the renal juxtaglomerular apparatus secretes renin. All of the vascular and hormonal effects of renin are caused by its conversion of angiotensin I to angiotensin II. Angiotensin II is the major stimulus for the secretion of aldosterone by the adrenal cortex.

Deposition of collagen and metalloproteinases within the intima of arteries leads to vascular stiffness, and this occurs normally as part of the aging process. Narrowing of the vascular lumen and endothelial dysfunction causing inability of complete vasodilation decreases blood flow, especially within the microvasculature. Furthermore, vascular stiffness increases afterload and myocardial oxygen demand and can cause LV hypertrophy, myocardial ischemia/infarction, and/or congestive heart failure.

Anesthesia Management for the Patient with Hypertension

Preoperative Evaluation

The most important issues to be addressed in the preoperative evaluation of the hypertensive patient are the identification and the adequacy of treatment. A number of otherwise healthy patients scheduled for elective procedures are determined to have hypertension, even though they had no prior need for medical treatment. The goal of antihypertensive therapy is to maintain normotension on a consistent basis. Effective antihypertensive therapy that renders the patient normotensive on a routine basis may not necessarily prevent episodes of perioperative hypertension. However, patients whose condition is optimized before surgery have a more stable perioperative course and a lower incidence of cardiovascular system–related morbidity. Although not ideal, if perioperative diastolic blood pressure is maintained below 110 mmHg, the risk of perioperative cardiac morbidity does not increase significantly.[29,35]

It is imperative for anesthesia providers to have an adequate understanding of the pharmacology and side effects of the drugs used for treating hypertension. For a complete discussion of antihypertensive drugs, see Chapter 13, which discusses some of the drugs used to treat hypertension block or depress homeostatic sympathetic reflexes. The depression of these reflexes may prevent homeostatic compensatory mechanisms from functioning at normal levels during the course of anesthesia. Subsequently, compensatory mechanisms (tachycardia and vasoconstriction) associated with blood loss may be diminished or may not occur. Patients treated with antihypertensive medication do not lose their responsiveness to vasoactive drugs but instead may respond to these substances in an exaggerated manner. Even with depression of the sympathetic reflexes, no predominance of the parasympathetic system occurs.

The clinician should carefully obtain a thorough history of the cardiovascular system to elicit any symptoms of ischemic cardiovascular disease. Hypertension is a major risk factor for coronary artery disease. Any symptoms related to coronary artery disease should be further investigated. In addition to being a risk factor for coronary artery disease, hypertension directly affects myocardial function. The chronic increase in myocardial wall tension caused by long-standing hypertension results in left ventricular hypertrophy (LVH) (Figure 23-35). Ventricular diastolic dysfunction occurs before the development of hypertrophy. This diastolic dysfunction is not clinically apparent, and the patient may appear to have normal cardiac function except under stressful physiologic conditions. A delayed rate of passive ventricular filling is evidence of ventricular diastolic dysfunction. The rate of ventricular filling from atrial contraction becomes predominant in hypertensive patients. This represents the inverse of normal ventricular filling patterns. Other information and results from preoperative tests that will help the nurse anesthetist evaluate and create an individualized anesthetic plan for patients with cardiac dysfunction includes determining exercise tolerance, electrocardiogram (ECG), Doppler ultrasound, stress test, and cardiac catheterization results.

Left ventricular hypertrophy is a consequence of chronic hypertension and increased afterload that results in an enlargement of myocardial mass. This compensatory process increases myocardial oxygen demand. Hypertrophy that occurs in response to chronic increases in intracardiac pressure is termed *concentric hypertrophy*. Ventricular hypertrophy also may produce subendocardial ischemia at perfusion pressures that would normally be adequate in a healthy ventricle. Concomitant development of coronary artery disease coupled with increased myocardial oxygen demand hastens and exacerbates the development of ischemic symptoms. As a rule, all patients with chronic hypertension should be suspected of having some degree of coronary artery disease.

Hypertensive cardiomyopathy and systolic ventricular dysfunction are the direct result of the pathophysiologic changes

associated with chronic hypertension. This hypertensive cardiomyopathy manifests as a decrease in both EF and SV. Increasing diastolic dysfunction results in ventricular dilation in conjunction with systolic dysfunction. The subsequent replacement of myocardial cells with fibrous tissue results in a cardiomyopathy.[4]

Long-standing hypertension that has remained either untreated or inadequately controlled has adverse consequences on brain, kidney, and ocular function, and patients with long-standing disease have a higher incidence of strokes than do patients whose blood pressure has been controlled.[29] Inadequate control of hypertension can lead to alterations in cerebrovascular and coronary artery autoregulation. For example, normal physiologic coronary artery autoregulation occurs at a MAP between 60 and 140 mmHg. However, a patient with chronic hypertension and coronary artery disease may develop ischemic changes at a MAP of 60 mmHg or greater. The cerebral and coronary autoregulation curves are shifted to the right in patients with chronic hypertension, necessitating higher perfusion pressures to ensure adequate organ blood flow. Therefore cerebral and myocardial ischemia may occur with significant decreases in MAP in patients with hypertension and coronary artery disease. This phenomenon makes patients with uncontrolled hypertension more susceptible to cardiac and cerebral ischemia, compared with normotensive individuals.[34] Chronic untreated hypertension can cause nephrosclerosis, which can impair renal function. Nephrosclerosis can produce proteinuria and a gradual decrease in renal function. Early treatment of hypertension results in little change in renal function and spares the kidneys. Signs of target organ involvement must be investigated in the hypertensive patient who is to undergo anesthesia.

Anesthesia Management

An individualized anesthetic plan must be created by taking into account the type and extent of cardiac pathophysiology, other disease states, and the surgical procedure. To maintain a stable intraoperative course, administration of antihypertensive medications should be continued on schedule until the time of surgery. All oral medications can be given with one or two sips of water without increased risk of aspiration.[33] It should be noted that acute hypertensive rebound can occur with abrupt cessation of antihypertensive medications. Tachycardia, hypertension, angina, and myocardial infarction can result from interruption of therapy with β-blockers, clonidine, and other cardiac agents. All cardiac drugs should be continued up to and including the day of surgery.

Determining whether to proceed with elective surgery in a patient in whom hypertension is untreated and poorly controlled remains controversial. However, evidence suggests that patients with diastolic blood pressures greater than 110 mmHg have a significantly increased risk of perioperative cardiac morbidity.[34] This caveat may be modified in patients with hypertension in whom diastolic blood pressures greater than 110 mmHg occur frequently, despite aggressive antihypertensive drug therapy (e.g., patients with end-stage renal disease).

To attenuate sympathetic responsiveness, preoperative sedation may be indicated for patients with hypertension. Establishing control of the blood pressure before induction should result in a more stable hemodynamic course during the induction, maintenance, and emergence from anesthesia. A fluid bolus and incremental titration of anesthetic induction agents may help decrease the degree and duration of hypotension.

Induction of Anesthesia

Patients with hypertension may react in an exaggerated manner to induction agents and the stimulation associated with laryngoscopy and tracheal intubation. This response is highly variable and may result in hypertension or hypotension. It is dependent on the individual's physiology, degree of stimulation, adequacy of preoperative antihypertensive therapy, and amount and type of induction agents administered. Hypertensive patients are hypovolemic, either as a result of renal-compensatory mechanisms, extreme vasoconstriction, or pharmacologic therapy (diuretics). Increased vasoconstriction as a consequence of hypertension results in volume contraction and a greater susceptibility to hypotension from the vasodilating and cardiac-depressant effects of anesthetic agents. Of the anesthetic induction agents, etomidate, propofol, or dexmedetomidine can be used in patients with hypertension. Etomidate offers an advantage in patients with cardiac pathology, as compared to propofol, because it preserves stroke volume and cardiac output.[15] Due to the sympathomimetic response that occurs with the administration of induction doses of ketamine, this drug should be not be used routinely for patients with cardiovascular disease.

The stimuli of laryngoscopy and tracheal intubation can result in an exaggerated hypertensive response, despite postinduction hypotension. An existing hypertensive state is further compounded by intense stimulation caused by airway manipulation. Suppressing the exaggerated hypertensive response to intubation requires that a greater depth of anesthesia be achieved. However, the depth of anesthesia at induction necessary to suppress this response may produce a more profound hypotensive state. Administration of adjunct medications before induction (e.g., β-blockers or arterial dilators) can reduce the hyperdynamic sympathetic response to tracheal intubation. Hypotensive episodes can be treated with fluid administration, decreasing anesthetic depth, and administration of vasoconstrictors. Numerous strategies have been suggested for the management of this hyperdynamic response. The pressor response to laryngoscopy and intubation could be significantly reduced by laryngotracheal or intravenous administration of lidocaine.[36] Reducing the duration of airway manipulation to 15 seconds or less may be helpful. Use of a β-blocker before induction has been shown to reduce the hyperdynamic sympathetic responses.[33] Administration of fentanyl (2 to 3 mcg/kg) just before induction also helps attenuate the pressor response.

With regard to suppression of marked hemodynamic responses, a smooth induction followed by a rapid and atraumatic intubation is imperative. Maintaining an adequate depth of anesthesia at induction that produces extreme hypotension may be more detrimental to both coronary and cerebral perfusion than the hypertensive response it was intended to prevent. Because the hypertensive patient is frequently hypovolemic as compared with the normotensive patient, adequate hydration before induction may help prevent postinduction hypotension.[29,33]

Most intravenous induction agents are appropriate for the hypertensive patient. The propensity for these agents to cause vasodilation in a comparatively hypovolemic patient is a concern. In light of this, a combination of low doses of more than one agent in addition to titration of medications may prove a better choice than a full dose of a single agent. In emergency cases in which rapidly securing the airway is of paramount importance, the choice of agents may be limited, and hyperdynamic pressor responses become a secondary issue.

Maintenance of Anesthesia

A general hemodynamic goal during anesthetic management for the hypertensive patient undergoing general anesthesia is to maintain blood pressure stability within 20% of the normal mean arterial pressure (MAP). Intraoperative events that cause wide

TABLE 23-7 Hemodynamic Goals for Management of Coronary Artery Disease

Parameter	Goal
Preload	Decrease/Maintain
Afterload	Maintain
Contractility	Decrease/Maintain
Heart rate	Slow
Heart rhythm	Normal sinus rhythm

fluctuations in blood pressure should be anticipated and treated immediately. The most common event that precipitates intraoperative hypertension includes surgical stimulation. This induces increased sympathetic tone causing release of catecholamines, cortisol, and aldosterone, which is representative of the physiologic stress-induced response caused by surgical stimulation. Volatile and opioid agents given alone and in combination have the ability to attenuate this response.[2,33,34] Altering the depth of anesthesia to suppress maximal surgical stimulation may not be adequate for achieving rapid and complete control of hypertensive responses. The adjunct use of drugs such as β-antagonists, nitroprusside, angiotensin-converting enzyme inhibitors, and others may be necessary for achieving control. These drugs offer the advantage of continued control of hypertensive response in the immediate postanesthesia recovery period. Table 23-7 lists hemodynamic goals for patients with coronary artery disease.

The onset of profound hypotension during anesthesia maintenance should be immediately recognized, diagnosed, and treated. Prolonged severe hypotension has predictive significance in perioperative cardiac morbidity.[35] Treatment of hypotension may require reduction of the amount of volatile agent used and infusion of adequate volume. Should these measures prove inadequate or untimely, a rapid-acting vasopressor such as phenylephrine or ephedrine may be administered as a temporizing measure until the cause of the hypotension can be diagnosed. It is important to realize that hypertensive patients may have exaggerated responses to vasopressor agents. The goal of intraoperative anesthesia management is maintenance of hemodynamic stability, which includes anticipation of intraoperative events that may affect cardiovascular stability and thereby prevent extreme fluctuations in blood pressure.

Postoperative Considerations in the Hypertensive Patient

Termination of anesthesia results in hyperdynamic, hypertensive responses, even in patients with well-controlled hypertension. Intraoperative control of blood pressure should continue into the immediate postoperative period. Initiation of adjunct administration of antihypertensive medications should be anticipated at the end of surgery and early in the postoperative period. Adequate control of pain represents a primary antihypertensive consideration. The hypertensive patient is more susceptible to perioperative cardiac morbidity than the normotensive patient during the postoperative period. Adequate control of blood pressure in the postoperative period reduces the incidence of cardiovascular complications.[29,37] Maintenance of normothermia is helpful as well.

Pericardial Disease

In reviewing the anesthetic management of patients with pericardial disease, this section focuses on the pathophysiology, clinical presentation, and anesthetic implications of three primary disease processes: acute pericarditis, constrictive pericarditis, and cardiac tamponade.

The pericardium surrounds the heart and anchors it to its anatomic position, concomitantly reducing contact between it and surrounding structures. It consists of an inner visceral layer, which envelops the surface of the heart, and an outer parietal layer. The pericardial space between these layers usually contains 20 to 25 mL of clear fluid that under normal circumstances can accommodate gradual volume fluctuations. Rapid accumulation of pericardial fluid in the pericardial space can result in cardiac tamponade and cardiovascular collapse.[38]

Acute Pericarditis

Acute inflammation of the pericardium is caused by a number of disorders.[38] The most common cause of acute pericarditis is viral infection. Postmyocardial infarction syndrome (Dressler syndrome), postcardiotomy, metastatic disease, irradiation, tuberculosis, and rheumatoid arthritis represent the remaining primary predisposing conditions that contribute to the development of this process.[39]

Pathophysiology. It is common for a serofibrinous inflammatory reaction associated with a small intrapericardial exudative effusion to evolve. This may result in adherence of the two layers of the pericardium. The sequelae are largely dependent on the severity of the reaction, as well as on the specific cause. Most often when the condition is left untreated or undiagnosed, complete resolution is the end result. Infrequently, however, extended organization of fibrinous exudate within the pericardial sac may lead to encasement of the heart by dense fibrous connective tissue (chronic constrictive pericarditis) or to the accumulation of a large amount of pericardial fluid and consequent cardiac tamponade, usually when fluid levels exceed 1 L. Constrictive pericarditis and cardiac tamponade result in impaired diastolic filling, which results in decreased CO.[38,39]

Clinical Presentation. The principal symptom associated with acute pericarditis is chest pain with sudden onset. Although similar in nature to that experienced during myocardial infarction, this pain is differentiated by the inclusion of a pleural component, which includes increased discomfort associated with postural changes and relief on sitting or leaning forward. Other signs that are characteristic of acute pericarditis include fever with a pericardial friction rub, absence of elevation of cardiac enzymes levels, and diffuse ST-segment elevation in two or three limb leads and in most of the precordial leads. Echocardiography is another reliable method for diagnosing pericarditis and pericardial effusion.

Anesthetic Management. Acute pericarditis in the absence of an associated pericardial effusion or scarring does not alter cardiac function. Specific considerations for anesthetic management are directed toward the underlying illness.

Chronic Constrictive Pericarditis

Chronic constrictive pericarditis results from pericardial thickening and fibrosis. In the past, tuberculosis was the most common cause of pericardial constriction. Currently the most common causes are idiopathic and include complications following cardiac surgery, neoplasia, uremia, radiation therapy, and rheumatoid arthritis.[39,40]

Pathophysiology. Stiff, fibrous tissue encircles the heart and limits its ability to expand during diastole. The fundamental hemodynamic abnormality in chronic constrictive pericarditis is abnormal diastolic filling. Reduced myocardial compliance impairs filling of both ventricles. Consequently, filling pressures increase, and as a result, pulmonary and peripheral congestion

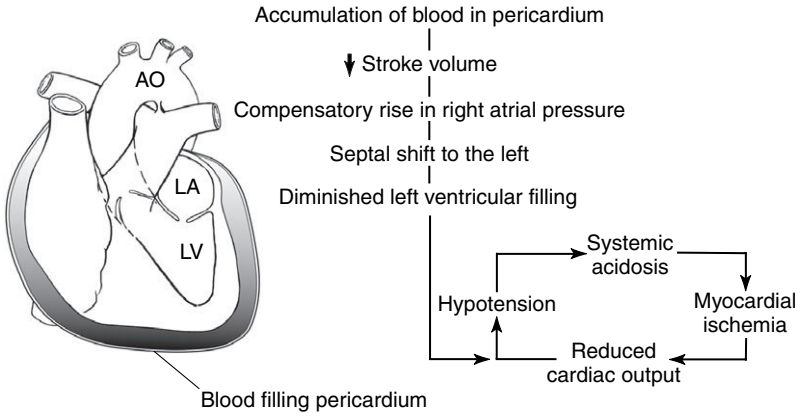

FIGURE **23-36** Pathophysiology associated with cardiac tamponade.

occurs. SV and CO can also be decreased. Equilibration of pulmonary artery diastolic pressure, PCWP, and right atrial pressure commonly occurs. Initially, ventricular systolic function is normal. However, over time the underlying myocardial tissue may atrophy, and systolic function may decrease.

Clinical Presentation. Clinical features representative of chronic constrictive pericarditis include gradually increasing fatigue and dyspnea. Typical signs of increasing venous pressure and congestion are engorgement of neck veins, hepatomegaly, ascites, and peripheral edema. In approximately 50% of patients, the fibrous enclosure becomes calcified and is visible on a chest radiograph.[33] The electrocardiogram may reveal diffuse low-voltage QRS complexes, T-wave inversion, and notched P waves. As many as 25% of patients have atrial dysrhythmias because of the involvement of atrial conduction pathways. Diagnosis is confirmed by demonstration of pericardial thickening with echocardiography or computed tomography.

The treatment used for patients with hemodynamically significant constrictive pericarditis is pericardiotomy. Unfortunately, the surgical removal of adherent pericardium may precipitate malignant cardiac dysrhythmias and massive bleeding. Consequently, pericardiotomy is associated with relatively high perioperative morbidity and mortality rates, ranging from 6% to 19%.[41,42]

Anesthetic Management. Large-bore intravenous lines must be established preoperatively because of the potential for sudden, rapid hemorrhage. A cardiopulmonary bypass circuit should be readily available. Invasive hemodynamic monitoring is essential. Arterial catheterization allows beat-to-beat blood pressure monitoring and assists in the evaluation of significant cardiac dysrhythmias. A pulmonary artery catheter is useful because it permits measurement of filling pressures on both the right and left sides of the heart, as well as determination of CO.

The anesthetic agents chosen for management of patients with constrictive pericarditis should preserve myocardial contractility, HR, preload, and afterload. Among these parameters, HR is of greatest concern. Cardiac output is dependent on HR in patients with constrictive pericarditis. As a consequence of limited ventricular diastolic filling, bradycardia is poorly tolerated and reflects a decrease in SV that can lead to hypotension. Using anesthetic medications that preserve HR and myocardial contractility, such as pancuronium or ketamine, is hemodynamically advantageous. Inhalation agents that cause myocardial depression should be used with caution. Administration of opioids and etomidate and benzodiazepines for the induction and maintenance of anesthesia is suitable in this setting. The clinician should be aware that vigorous positive-pressure ventilation may cause a decrease in venous return to the heart and result in a further decrease in CO.[43]

Immediate hemodynamic improvement may not occur after removal of the constricting tissue. Consistently low CO after pericardiectomy may be secondary to diffuse atrophy of myocardial muscle fibers or myocardial damage from the underlying disease. Intensive postoperative care with inotropic support and awareness of the potential for dysrhythmia or bleeding are integral components of the anesthetic management plan.

Cardiac Tamponade

Cardiac tamponade is a syndrome caused by the impairment of diastolic filling of the heart because of continual increases in intrapericardial pressure.[44] Slow accumulation of fluid in the pericardial space can cause minute increases in intrapericardial pressure. This occurs as a result of the pericardium's ability to stretch to accommodate this increase in volume. If the pericardial fluid accumulates rapidly, the presence of a few hundred milliliters may cause a significant increase in intrapericardial pressure that may result in cardiovascular collapse. Cardiac tamponade is the cause of cardiac compressive shock that can result in inadequate peripheral perfusion, acidosis, and death (Figure 23-36).

Classification of the causes of cardiac tamponade includes: (1) trauma, including sharp or blunt trauma to the chest and dissecting aortic aneurysms; (2) causes associated with cardiac surgery; (3) malignancy within the mediastinum; and (4) expansion of pericardial effusions after any form of pericarditis.[45]

Pathophysiology. Normal intrapericardial pressure is subatmospheric. Accumulation of pericardial fluid leads to an increase in intrapericardial pressure. As a result, diastolic expansion of the ventricles decreases. As in constrictive pericarditis, poor ventricular filling develops and leads to peripheral congestion and a decrease in SV and CO. The decrease in SV decreases peripheral perfusion causing catecholamine release manifested as tachycardia, vasoconstriction, and increased venous pressure, which helps maintain CO. If these mechanisms fail, cardiac collapse can occur.[46] The left ventricular pressure-volume loop associated with cardiac tamponade represents decreased LV volume and decreased SV due to compression (Figure 23-37).

Clinical Presentation. In addition to obvious indications of cardiac distress, specific signs of cardiac tamponade include Beck's triad: hypotension, jugular venous distention, and distant muffled heart sounds.[47] Another common finding is pulsus paradoxus, an exaggerated (i.e., greater than 10 mmHg) decrease in systolic blood pressure that normally occurs with inspiration. Other conditions that may result in pulsus paradoxus are chronic obstructive

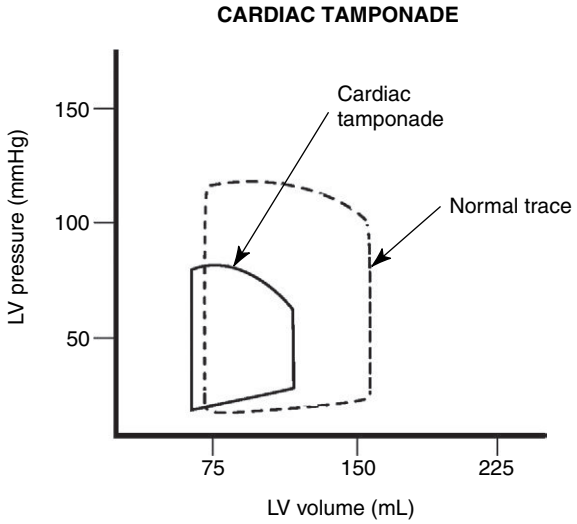

FIGURE **23-37** Left ventricular pressure-volume loop associated with cardiac tamponade.

pulmonary disease, obesity, and congestive heart failure. Jugular venous distention that occurs because of decreased forward blood flow through the heart may also be present.

In cardiac tamponade, chest radiography may show an enlarged cardiac silhouette. The electrocardiogram usually demonstrates a decrease in voltage across all leads or electrical alterations of either the P wave or the QRS complex.[48] Echocardiography is the most sensitive, noninvasive method for detection of pericardial effusion and exclusion of tamponade. Use of a pulmonary artery catheter may reveal equilibration of right and left atrial pressures and right ventricular end-diastolic filling pressures at approximately 20 mmHg.[49]

The definitive treatment for cardiac tamponade is pericardiocentesis, performed either percutaneously by needle decompression, through a subxiphoid incision, or via thoracotomy or video-assisted thoracoscopic surgery to create a pericardial window. In contrast to patients with constrictive pericarditis, in patients with cardiac tamponade, immediate hemodynamic improvement occurs once the pericardium is opened. However, despite this fact, pulmonary edema, acute right and left ventricular dysfunction, and circulatory collapse can occur.[42]

Anesthetic Management. Preoperatively the patient's clinical status should be optimized. This includes expansion of intravascular fluid volume, use of positive inotropic agents, and correction of acidosis. The degree to which these measures are instituted depends on the hemodynamic state of the patient. Severely compromised patients require immediate medical therapy, and therefore emergency pericardiocentesis is indicated. Invasive hemodynamic monitoring should be established before the procedure. Intraarterial and central venous pressure catheters are required for frequent sampling of blood, continuous blood pressure monitoring, and assessment of intravascular fluid status.

Local infiltration anesthesia is the technique of choice for operative correction of cardiac tamponade.[50] Severe hypotension and cardiac arrest after induction of general anesthesia in patients with tamponade can occur.[51,52] The potential for decompensation associated with the use of general anesthetics is attributed to direct myocardial depression and vasodilation in patients with established impairment of cardiac filling. The use of positive-pressure ventilation in such patients may result in a decrease of venous return to the heart and can further decrease CO.[53] After percutaneous pericardiocentesis and the improvement of hemodynamic status, induction of general anesthesia and initiation of positive-pressure ventilation are sufficient for further surgical exploration.

When it is not possible to relieve intrapericardial pressure that causes cardiac tamponade before the induction of anesthesia, the same anesthetic principles that are applied to the anesthetic management of patients with constrictive pericarditis should be used, including the use of anesthetic agents that preserve myocardial contractility, HR, preload, and afterload. Because of the sympathomimetic effects of ketamine, this drug has been advocated for the induction and maintenance of anesthesia.[4,50] However, many combinations of anesthetic agents that preserve the previously mentioned determinants of CO have been used safely.[43,50,52]

Continuous postoperative monitoring of blood pressure, central venous pressure, and chest-tube drainage is necessary. Possible complications after pericardiocentesis include the reaccumulation of pericardial fluid, coronary laceration, cardiac puncture, and pneumothorax. Table 23-8 lists hemodynamic goals for patients with cardiac tamponade.

TABLE 23-8 Hemodynamic Goals for Management of Cardiac Tamponade

Parameter	Goal

Acquired Valvular Heart Disease

The cardiac valves are membranous leaflets that separate the chambers of the heart. When open, they allow blood flow between the chambers and great vessels, and when closed, they prevent regurgitant blood flow between the chambers or backflow from the great vessels. A valve orifice of normal size presents a small degree of flow obstruction and thereby creates a hemodynamically insignificant gradient. Primary dysfunction of the mitral and aortic valves represents the most common and most severe hemodynamic derangement. Acquired primary dysfunction of the tricuspid or pulmonic valves is rare and therefore is not addressed in this chapter.

Valvular disease is classified according to the type of lesion that exists—stenosis, insufficiency, or mixed lesions. Valvular stenosis is a narrowing of the valvular orifice, which restricts flow through the orifice when the valve is open. This situation creates an increase in flow resistance and increases turbulent blood flow. Valvular insufficiency results in regurgitation secondary to incomplete or partial valve closure, which allows blood to flow back through the valve into the previous chamber. In patients with mixed lesions (stenosis with insufficiency or insufficiency with stenosis), one type of dysfunction is considered dominant over the other on the basis of the severity of clinical symptoms.

Valvular dysfunction is classified as either primary or secondary. In primary valvular dysfunction, the valve leaflets or the anchoring and supporting structures are damaged or do not function properly. In secondary valvular dysfunction, the valve is not directly damaged. However, normal valve function is altered secondary to another pathophysiologic entity. Causes of this type of

manifestation include ventricular dilation, which produces mitral insufficiency; retrograde aortic dissection, which creates aortic insufficiency (AI); and papillary muscle infarction, which causes mitral insufficiency.[54,55]

Cardiac Output. The primary components of CO are preload, afterload, contractility, LV compliance, and HR.[55-57] Blood flow may increase due to an increase in HR or an increase in SV. Because blood viscosity decreases with decreasing hematocrit and increasing flow rate, normovolemic anemia reduces cardiac afterload, thereby facilitating the augmentation of CO. This sequence of events occurs so long as intravascular volume is maintained and cardiac reserve is ample. The amount of afterload present determines the degree of tension cardiac fibers must develop before systolic ejection can occur.[58]

Evaluation of the Patient. Evaluation of the patient with valvular heart disease should focus on the pathophysiologic derangements and their effects on cardiac function. The systematic evaluation of primary valvular dysfunction should include the following:

1. *Category of valvular dysfunction*
   - Stenosis (progressive narrowing of the valve orifice)
   - Insufficiency (incomplete valve closure that causes backflow through the valve)
   - Mixed (regurgitant and stenotic dysfunction)
2. *Status of left ventricular loading*
   - Left ventricle (LV) overload from mitral or aortic regurgitation (AR)
   - Pressure overloading from aortic stenosis
   - Volume underloading from mitral stenosis
3. *Acute versus chronic evolution of the dysfunction*
   - Acute lesions have severe and precipitous hemodynamic consequences.
4. *Cardiac rhythm and its effects on ventricular diastolic filling time*
5. *Left ventricular function*
   - Poor left ventricular function places the patient at higher risk for perioperative cardiac morbidity.
6. *Secondary effects on the pulmonary vasculature and right ventricular function*
   - Secondary pulmonary hypertension from valvular lesions can significantly affect right ventricular function.
7. *Heart rate*
   - Changes in HR (either bradycardia or tachycardia) can significantly alter the hemodynamic manifestations of a specific valvular lesion.
   - Bradycardia occurring with regurgitant lesions can result in a significant increase in the regurgitant fraction.
   - Tachycardia is detrimental in patients with stenotic lesions because it shortens the time of ejection and increases myocardial oxygen demand.[27-30,33,34]
8. *Perioperative anticoagulation as discussed in Chapter 34*

Clinical Symptoms. The most frequent clinical signs and symptoms associated with valvular dysfunction are congestive heart failure, dysrhythmias, syncope, and angina pectoris. Symptoms commonly associated with congestive heart failure include dyspnea, orthopnea, and fatigue. The severity of left ventricular dysfunction can be related to the patient's activity level before the onset of cardiac symptoms.[35]

Patient Evaluation: Compensatory Mechanisms. To maintain cardiac function despite progressive valvular dysfunction, sympathetic activity increases to compensate for decreased peripheral perfusion. A decrease in sympathetic tone that occurs during anesthesia can cause severe myocardial dysfunction. Evaluation of the patient should include recognition of sympathetic compensatory mechanisms and strategies to maintain hemodynamic stability. Despite maximum medical therapy, patients with severe valvular dysfunction may remain in congestive heart failure.

The evaluation should also focus on associated organ dysfunction. Cardiac output that is decreased by chronic myocardial failure can cause significant major organ dysfunction, including renal and hepatic insufficiency, as well as poor cerebral perfusion, which can produce an altered level of consciousness, restlessness, agitation, and lethargy.

Diagnostic Modalities. The most valuable diagnostic modalities used to evaluate valvular heart disease include electrocardiography, chest radiography, color flow Doppler imaging, echocardiography, and cardiac catheterization of both the right and left chambers of the heart. Electrocardiography can be used for evaluation of ventricular hypertrophy, atrial enlargement, axis deviation and—most important—determining cardiac rhythm. Chest radiography demonstrates the size of the cardiac silhouette and signs of pulmonary vascular congestion. Color flow Doppler imaging can be used to determine the valvular area, transvalvular gradients, degree of regurgitation, and flow velocity and direction and can measure cardiac function. Cardiac catheterization can be used directly to measure transvalvular gradients, estimate the degree of regurgitation, visualize the coronary arteries, and determine intracardiac pressures.[59-63]

MITRAL STENOSIS

Pathophysiology

In mitral stenosis, the mitral valve orifice becomes progressively narrowed. The normal mitral valve area is 4 to 6 cm^2. This narrowing reduces flow from the LA into the LV during diastole. The narrowing of the mitral valve orifice has two significant hemodynamic consequences. First, a gradient develops across the valve orifice. This change represents a compensatory response directed at maintaining adequate flow. Second, as the cross-sectional area of the orifice decreases and the gradient increases, flow is restricted and left ventricular volume is decreased. The clinical symptomatology of severe mitral stenosis results in pulmonary congestion, decreased CO, and potentially RV overload/failure. Pulmonary congestion occurs as a result of increases in left atrial pressure. Decreased SV is caused by decreased left ventricular volume. Left ventricular filling is dependent on the length of diastole, the gradient between the LA and LV, and the surface area of the mitral valve. As the valve area narrows to 1.5 to 2.5 cm^2, patients frequently develop increased heart rate and cardiac output.[64] At a mitral valve area of less than 1 cm^2, the prolonged diastolic filling time and elevated mean left atrial pressure are incapable of maintaining normal LVEDV, and decreases in left ventricular volume occur, resulting in symptoms that occur at rest.[55] Atrial systole accounts for 20% to 30% of LVEDV. Because mitral stenosis presents a fixed resistance to ventricular inflow, most of the pressure generated during atrial systole is used to overcome the resistance caused by the stenotic valve rather than used for producing forward flow. As the HR increases to greater than 90 beats per minute and diastolic time intervals are shortened, LVEDV is decreased. This is demonstrated by the Gorlin equation, where mitral valve flow (MVF) is estimated using the following equation:

$$\text{MVF} = \frac{\text{Cardiac output}}{\text{Diastolic filling time} \times \text{heart rate}}$$

Any subsequent increase in flow rate or decrease in diastolic filling time reflects an increase in the pressure gradient between the LA and the LV. As the diastolic time interval shortens, the pressure gradient increases by the square of the increase in flow rate. Therefore any marked increase in HR can result in an increase in

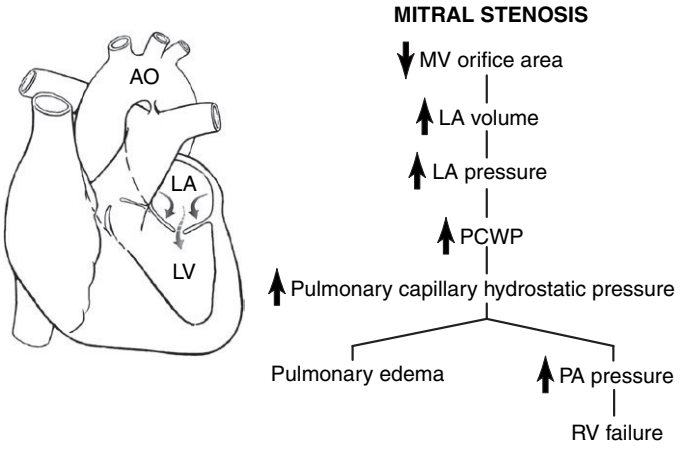

FIGURE **23-38** Pathophysiology associated with mitral stenosis.

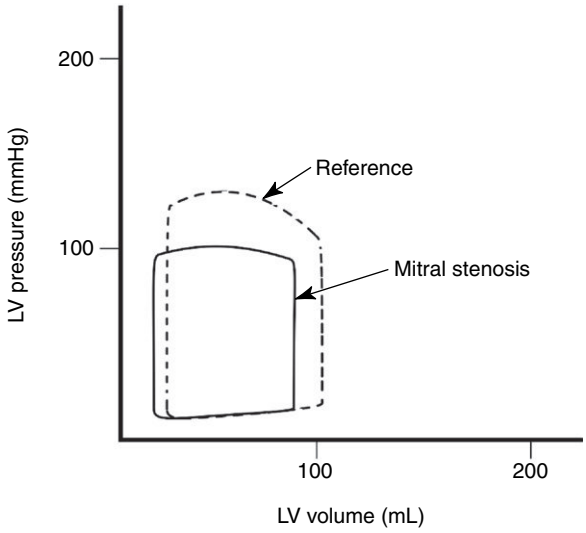

FIGURE **23-39** Left ventricular pressure-volume loop associated with mitral stenosis.

left atrial pressure, which can precipitate a rise in pulmonary artery pressures and ultimately leads to pulmonary edema.[65]

Left atrial hypertrophy and distention are consequences of elevated left atrial pressures. As a result of the increased left atrial pressure caused by mitral stenosis, the pulmonary capillary wedge pressure is artificially high, that is, overestimates the actual left ventricular end-diastolic pressure and left ventricular end-diastolic volume. This distention of the LA can lead to atrial dysrhythmias, most commonly atrial fibrillation. The atrial systolic "kick" is lost during atrial fibrillation; this implies that diastolic filling can be maintained only by a further increase in left atrial pressure. Mean left atrial pressure is limited by the development of pulmonary congestion at pressures greater than 25 mmHg. Elevation of left atrial pressures to greater than 25 mmHg leads to pulmonary congestion and eventually pulmonary edema. In patients with chronic mitral stenosis, pulmonary hypertension develops because of continuous elevations in left atrial pressure (Figure 23-38).

Pulmonary Vascular Changes in Right Ventricular Function

The pulmonary vasculature and eventually the RV are adversely affected by the chronic elevation of left atrial pressure that occurs with mitral stenosis. As mitral stenosis progresses, chronic elevation of left atrial pressure causes increased blood volume in the pulmonary vascular circuit. This can cause perivascular edema, and changes in pulmonary vascular resistance may ensue. These changes in pulmonary vascular resistance result in an increase in RV afterload. As a compensatory response, right ventricular hypertrophy occurs; however, because the RV is not capable of generating high pressures, it eventually begins to fail.[55-57] As the disease progresses, overt signs of biventricular failure such as low CO with poor systemic perfusion become evident. Peripheral edema, hepatic congestion, and marked venous distention are signs of right ventricular failure. The deterioration of right ventricular function decreases adequate left ventricular filling and therefore causes further deterioration in CO (Figure 23-39).

Anesthetic Considerations

Any anesthetic technique should be based on a thorough understanding of the pathophysiology of mitral stenosis, as well as the cardiovascular effects of the anesthetic agents employed. The following goals should be achieved in the anesthetic management of the patient with mitral stenosis:

- Maintenance of sinus rhythm at low normal heart rate.
- LVEDV adequate to maintain adequate CO without increasing pulmonary congestion.
- Avoid extreme decreases in myocardial contractility.
- Reduction in both right ventricular and left ventricular afterload may improve hemodynamics; this must be done in a controlled manner and with careful monitoring. The extent of the surgical procedure and the degree and severity of mitral stenosis determine the level of monitoring necessary.
- Cardioversion as treatment for atrial tachyarrhythmias that cause hemodynamic instability.
- Hypotension treated with small doses of phenylephrine.

The LVEDV is normal in approximately 85% of patients with mitral stenosis. An increased LVEDV in patients with mitral stenosis should alert the anesthesia provider to the presence of mitral or aortic insufficiency or primary coronary artery disease. Most patients with moderate mitral stenosis also have low to normal SV and therefore may have a normal EF. Approximately 33% of patients with mitral stenosis have an EF below normal (normal, 0.67 ± 0.08).[56] When the mitral valve is narrowed to less than 1 cm^2 (severe mitral stenosis), a mean left atrial pressure of 25 mmHg is necessary for maintaining even an adequate resting CO. Owing to the abnormal transvalvular gradient, the pulmonary capillary wedge pressure (PCWP) overestimates LVEDP. On the PCWP, a prominent *a wave* and a decreased *y descent* are present in patients with mitral stenosis.

MITRAL REGURGITATION AND INSUFFICIENCY

Pathophysiology

During ventricular systole, the mitral valve is closed, preventing blood flow from the LV back into the LA. However, if for any reason the two leaflets of the mitral valve are not in opposition to each other, a portion of systolic ventricular flow regurgitates back through this incompetent (insufficient) valve. Therefore the LV has a double outlet for systolic ejection. Ejection into the aorta is a high-impedance outlet, and regurgitation through the mitral valve back into the LA is a low-impedance outlet. This condition is termed *mitral regurgitation* (MR) or *mitral insufficiency*. The degree of regurgitation (quantitatively), called the *regurgitant fraction*, is determined by four factors:

1. Size of the regurgitant valve orifice (surface area measured in square centimeters)

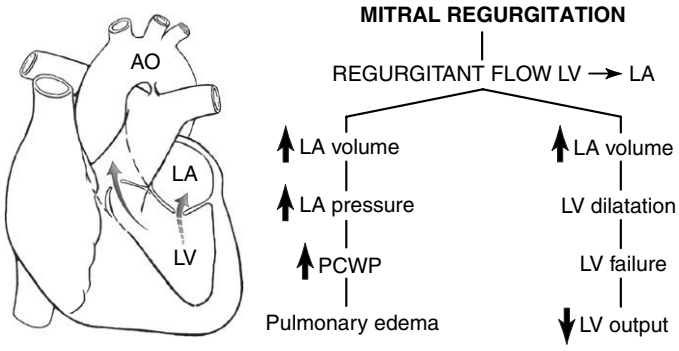

FIGURE **23-40** Pathophysiology associated with mitral regurgitation. *LA,* left atrium; *LV,* left ventricle; *PCWP,* pulmonary capillary wedge pressure.

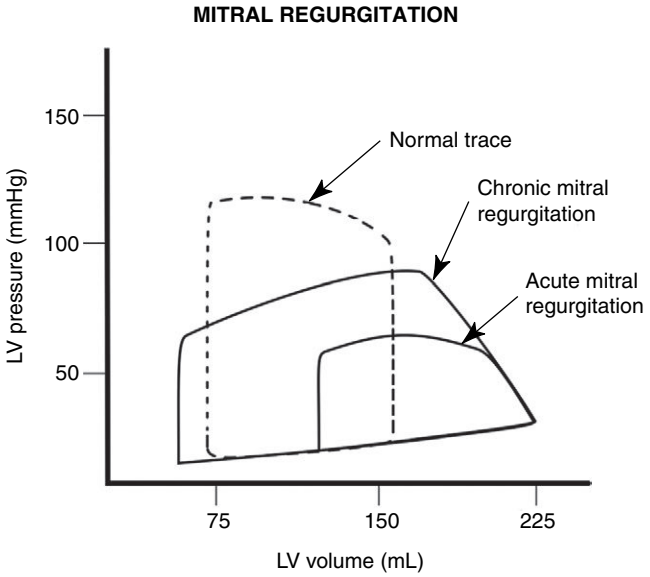

FIGURE **23-41** Left ventricular (LV) pressure-volume loop associated with mitral regurgitation. The large volume and stroke volume associated with chronic mitral regurgitation occur because of LV hypertrophy. Notice that during the isovolumetric contraction phase, LV volume decreases as a result of the incompetent mitral valve.

2. The pressure gradient between the LA and the LV
   - Inotropic state of the LV (peak systolic pressure)
   - Compliance of the LA and pulmonary veins
3. Time available for regurgitation (systole); systolic interval determines length of time during which regurgitation can occur; length of systolic time interval is inversely proportional to HR
4. Aortic outflow impedance SVR; regurgitant fraction can be significantly influenced by changes in impedance to aortic blood flow

The major pathophysiologic derangement associated with MR is volume overload of the LV. This occurs because the regurgitant fraction (retrograde blood flow ejected into the LA during ventricular systole) delivers an increased diastolic volume to the LV. This increase in LVEDV results in ventricular dilation.[44,55,65] Acute MR and chronic MR have substantially different pathophysiologic manifestations. The primary determinant of these pathophysiologic adaptations is left atrial compliance. If acute MR is caused by papillary muscle rupture, the mortality rate approaches 75% within 24 hours and 95% within 48 hours.[66] Chronic MR produces a dilated, compliant LA, whereas the longstanding and gradual elevation of left atrial pressure results in left atrial dilation. This consequently facilitates containment of relatively large end-diastolic volumes while reflecting relatively low increases in LA pressures (Figure 23-40). With chronic MR, compensatory hypertrophic changes occur in response to a continual increased left ventricular volume by increasing the left ventricular chamber size. This type of hypertrophic change is called *eccentric hypertrophy*.

In contrast, in acute MR the LA is small and noncompliant, but over time eccentric hypertrophic changes occur to compensate for progressive increases in volume (Figure 23-41). In this situation, a small regurgitant volume bolus can generate deflections or *v* waves that appear in the PCWP tracing. This *v* wave appears as a result of a systolic jet (ejection) back through the incompetent mitral valve. The pressure wave produced by this jet is transmitted upstream into the pulmonary artery and designated as a *pathologic v wave*. The time delay for this pressure wave to be transmitted results in its appearance at the time interval in which the normal *v* wave (passive atrial filling) occurs.[55] The height of the *v* wave in MR does not represent a measurement of regurgitant volume but rather of left atrial compliance in relationship to the regurgitated volume. The hypertrophic LA accommodates a larger regurgitant volume, which results in small increases in pressure. The dilated and compliant LA allows the pulmonary vascular circuit to be buffered from the excessive left atrial volume. However, chronic MR causes pulmonary venous congestion, which creates pulmonary vascular reactive changes that eventually result in pulmonary artery hypertension. Distention of the LA may lead to atrial fibrillation, a common arrhythmia associated with MR.

Pulmonary Vasculature and Right Ventricular Function

In acute MR, the pulmonary circuit is exposed to immediate and marked elevation of left atrial pressure because of a small and noncompliant LA. Pulmonary vascular congestion is precipitous and results in almost immediate development of pulmonary edema. An acute rise in left atrial pressure and congestion of the pulmonary circuit creates an increased right ventricular workload. This immediate increase in right ventricular afterload results in ventricular dilation and consequently may lead to right ventricular failure. In chronic MR, elevation of baseline pulmonary pressures is much more gradual, occurring over a prolonged period. This allows secondary pulmonary artery hypertension via intimal fibroelastosis generated by chronic perivascular edema. If the patient has coexisting mitral stenosis, pulmonary vascular resistance and right ventricular pressures may be excessively elevated.[44,55,65]

Effects of Afterload Reductions

The path of least resistance for blood flow during left ventricular systole is retrograde into the LA. Reduction of SVR via arterial vasodilation reduces impedance to systolic outflow into the aorta and increases forward flow. Conversely, increases in SVR have marked effects on the reduction in forward flow and the increase in the regurgitant fraction. A 20% increase in MAP raises LA pressure by 50% and reflects a 120% increase in regurgitant flow concurrent with a 16% decrease in forward flow.[55]

Anesthetic Considerations

An otherwise healthy patient with stable and controlled MR undergoing an ambulatory or uncomplicated surgical procedure has a minimal increase in risk of adverse hemodynamic fluctuations. Patients with cardiovascular disease who undergo major vascular, intrathoracic, intraabdominal, neurosurgical, orthopedic, or emergency procedures may have a 25% to 50% higher mortality risk than patients without the disease process. Controversy exists

regarding whether the duration of surgery correlates with perioperative cardiac morbidity.[35,54,55]

Preoperative assessment is essential for evaluating the degree of cardiac compensation (Table 23-9). Anesthetic management of the patient with MR should focus on these hemodynamic goals: decreasing regurgitant blood flow to enhance CO by decreasing afterload, maintaining or increasing preload, and maintaining cardiac contractility. Bradycardia or dysrhythmias that cause a loss of atrial kick can result in pulmonary congestion, left atrial and left ventricular overload, and a significant decrease in CO.[54-56]

Another anesthetic consideration of MR includes decreasing SVR or afterload. Cautiously lowering SVR via an arterial vasodilator such as sodium nitroprusside improves forward flow. However, extreme reductions in blood pressure, and especially diastolic pressure, can lead to decreased coronary artery blood flow and decreased CO.

Selection of the anesthetic technique should take into consideration the adverse effects associated with changes in HR and SVR. General anesthesia is the technique of choice in patients with MR. Regional anesthesia (spinal or epidural) is not contraindicated; however, the potential for profound and precipitous decreases in blood pressure via sympathetic blockade should be considered. Induction of general anesthesia can be safely achieved with any of the presently available agents. Hemodynamic goals include avoiding bradycardia and significant increases in afterload. The use of muscle relaxants does not present a significant risk as long as the resulting changes in HR do not cause severe bradycardia. The vagolytic properties of pancuronium may help to maintain HR. Maintenance of anesthesia can be accomplished with narcotics and a volatile agent. There is no definitive evidence to support that a particular volatile agent yields superior outcomes for patients with MR. Isoflurane may be an ideal choice because of its significant vasodilatory effects, causing an increased HR. Because all volatile agents cause a dose-dependent decrease in myocardial contractility, their use may be detrimental in patients with severe ventricular dysfunction. In this instance, the use of a high-dose opioid technique may provide for a more effective hemodynamic profile. Anesthetic management should focus on avoiding bradycardia or increases in SVR.[55] See Table 23-9 for anesthetic goals for management of mitral lesions.

TABLE 23-9 Hemodynamic Goals for Management of Mitral Valve Lesions

Parameter	Mitral Regurgitation (Insufficiency) Goal	Mitral Stenosis Goal
Heart rate	Increase	Decrease to normal
Rhythm	Maintain normal sinus rhythm	Maintain normal sinus rhythm
Afterload	Decrease	Maintain normal
Pulmonary vascular resistance	Avoid increases	Avoid increases
Preload	Normal to increased	Normal to increased

AORTIC STENOSIS

Etiology and Pathophysiology

The most common causes of aortic stenosis include a congenital defect resulting in a bicuspid aortic valve (especially in males) and the sequelae of rheumatic valvular heart disease. Isolated aortic valvular dysfunction in patients with rheumatic heart disease is rare. Commonly, rheumatic valvular disease is associated with mitral valve involvement. Whatever the cause, the pathophysiology remains the same and results in the need for increased left ventricular systolic pressure to overcome the left ventricular outflow tract obstruction caused by a narrowed aortic valve orifice (Figure 23-42). During auscultation, a low-frequency, systolic ejection murmur is characteristic of aortic stenosis.[67]

An understanding of the flow rates through a normal aortic valve orifice is needed for gaining an appreciation of ventricular pressure overload. A normal aortic valve area of 2.5 to 3.5 cm^2 and SV of approximately 80 mL result in a flow rate of 250 mL/min during the interval of ventricular systole (80 mL/sec × 0.32 sec − systolic time interval). The flow rate through a normal orifice results in a minimal gradient (2 to 4 mmHg). The normal left ventricular systolic pressure of 100 to 130 mmHg is sufficient to generate flow rates of 250 to 300 mL/sec. To ensure normal flow rates and therefore CO through the narrowed orifice, the velocity of systolic ejection must increase. For systolic ejection to be increased, ventricular systolic pressure increases dramatically, depending on the degree of valvular pathology. The LV must compensate for gradually increasing mechanical impedance to ejection. This results in LVH, which allows the heart to generate high ventricular systolic pressure and overcome impedance to ejection. The elevation of systolic ejection pressure produces a gradient between the left ventricular cavity and the aorta. The valve area must be constricted by at least 50% before the gradient becomes

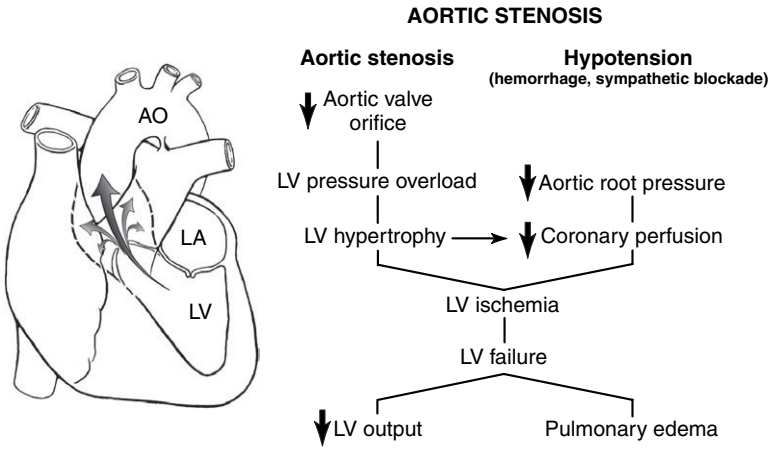

FIGURE 23-42 Pathophysiology associated with aortic stenosis. *LA*, left atrium; *LV*, left ventricle; *AO*, aorta.

significant to the point that symptoms occur at rest. An aortic valve area of less than 1 cm^2 produces a clinical triad of symptoms that include angina (even in the absence of significant coronary artery disease), syncope, and congestive heart failure.[65] An aortic valve area of less than 1 cm^2 represents severe aortic stenosis and should be a cause of concern in planning anesthetic management because of the associated increase in perioperative cardiac morbidity.[35] An aortic valve area less than 0.7 cm^2 is associated with sudden death.[68] For adequate assessment of the degree of valvular stenosis, both the flow rate across the valve and the pressure gradient should be evaluated, either by cardiac catheterization or echocardiography.[62,63]

Left Ventricular Function

Left ventricular concentric hypertrophy is the compensatory change associated with aortic stenosis. It results in several hemodynamic adaptations that are unique to aortic stenosis and present a challenge and a dilemma with regard to anesthesia management. The consequence of LVH in aortic stenosis is a decrease in ventricular compliance, hypertrophic remodeling, and an eventual decrease in the intrinsic contractility of the myocardium.[69] The reduction in ventricular compliance affects normal hemodynamics as follows:

I. Higher filling pressures are needed to produce the same amount of ventricular work.
II. To achieve adequate left ventricular filling, normal sinus rhythm must be maintained to ensure adequate LVEDV from the atrial kick.
III. Concentric ventricular hypertrophy causes alterations in myocardial oxygen balance.
   A. Myocardial oxygen consumption is increased.
      1. Myocardial mass is increased.
      2. Pressure generation (isovolumetric contraction) uses more energy than left ventricular ejection; a high intracavitary pressure must be generated to maintain CO.
      3. The ejection phase is prolonged.
   B. Myocardial oxygen supply is decreased.
      1. CPP is decreased as a result of an increase in LVEDP.
      2. Systolic coronary flow is absent because left ventricular systolic pressure exceeds aortic systolic pressure.
      3. Prolonged systolic ejection reduces the coronary perfusion interval.
      4. Subendocardial capillaries are compressed by hypertrophic myocardium.[44,54,55]

Pulmonary Circuit and Right Ventricular Responses

To maintain CO in the presence of a noncompliant and hypertrophic LV, left atrial pressures increase to accommodate left ventricular filling (Figure 23-43). Left atrial pressures of greater than 18 mmHg can cause an increase in pulmonary artery pressure, resulting in passive pulmonary venous congestion. Eventually, pulmonary fibroelastosis occurs, causing pulmonary artery hypertension. If the ventricular EF is decreased to less than 40% in association with aortic stenosis, CO can be maintained only with increases in left atrial pressures. These pressures increase to 25 to 30 mmHg, which results in increased mean pulmonary artery pressure. Elevated mean pulmonary artery pressure increases pulmonary vascular resistance, which can cause right ventricular failure. Decreasing left ventricular preload in association with significant aortic stenosis can result in decreases in CO.

Anesthetic Considerations

The goals of anesthesia management include maintaining hemodynamic stability without causing significant alterations in compensatory mechanisms. Anesthetic management of patients with aortic stenosis should focus on the following hemodynamic factors:

- Maintain normal sinus rhythm and HR 70 to 80 beats per minute
- Ensure sufficient preload (LVEDV) to maintain CO
- Ensure adequate coronary perfusion by maintaining diastolic blood pressure levels
- Avoid myocardial depression, especially with poor LV function
- Maintain or allow slight increase in afterload

General anesthesia is the preferred technique for major surgical procedures involving patients with aortic stenosis because of the ability to manipulate hemodynamic parameters, especially diastolic blood pressure. Central neural blockade (spinal or epidural) must be used with extreme caution, because precipitous reductions in blood pressure associated with a sympathectomy decrease SVR.[67] Epidural anesthesia offers the advantage of a slower onset of vasodilation. Depending on the degree of compromise, the heart may not be able to compensate for moderate to severe systemic vasodilation. Therefore lower dermatome level blocks decrease the degree of systemic vasodilation and maintain afterload. Successful cardiopulmonary resuscitation is virtually impossible because of the mechanical left ventricular outflow obstruction associated with this type of valvular pathology. The pressure necessary to overcome outflow obstruction and produce adequate coronary artery perfusion and CO cannot be generated with closed-chest compressions. Furthermore, short periods of hypotension may lead to a decrease in coronary perfusion and should be treated with volume and phenylephrine.[70] Because of the increased oxygen demands of the LV, irreversible myocardial ischemia and cardiovascular collapse can occur if hypotension is not promptly and aggressively treated.

Intraoperative control of HR and rhythm is a major goal of the anesthetic management of patients with aortic stenosis. Tachycardia can be detrimental because it decreases diastolic filling time, resulting in a reduction of left ventricular preload. The reduced time interval for coronary artery perfusion reduces oxygen supply to the myocardium. In patients with HRs of greater than 110 beats per minute, systolic ejection time and CO are decreased.[55,56] Bradycardia (fewer than 60 beats per minute) is detrimental in aortic stenosis. Prolonged diastolic filling time, which occurs as a result

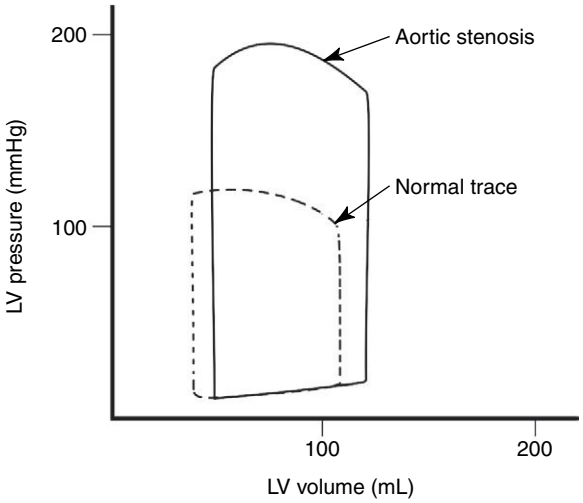

FIGURE **23-43** Left ventricular pressure-volume loop associated with aortic stenosis.

of bradycardia, causes ventricular distention, which can further decrease CPP, especially to the subendocardium.[44,54,55]

Monitoring and Premedication

It is prudent to titrate preoperative sedatives while vital signs can be continuously monitored. In addition to standard intraoperative monitoring, complete invasive monitoring may be required for patients with aortic stenosis, even for routine procedures. Any significant change in basic hemodynamic variables (i.e., HR, heart rhythm, LVEDV, CPP) can rapidly cause irreversible myocardial deterioration. It is imperative that these variables be monitored closely and appropriate interventions be performed to prevent adverse hemodynamic consequences. The complexity of hemodynamic monitoring modalities is dependent on the physical status of the patient, the severity of aortic stenosis, the extent of the surgical procedure, and the ability of the anesthesia provider to use and interpret hemodynamic values.

The use of intraarterial monitoring for direct beat-to-beat blood pressure assessment allows the anesthesia provider to rapidly treat undesirable hemodynamic changes. Pulmonary artery catheterization provides the ability to monitor all the hemodynamic parameters necessary for diagnosing and treating adverse hemodynamic events. Absolute criteria for intraoperative invasive monitoring for patients with aortic stenosis are controversial. However, clinical judgment, experience, and the ability to appropriately use the pulmonary artery catheter should be considered before implementation.[68,71]

Maintenance of Anesthesia

Commonly used induction agents can be given so long as caution to avoid profound hypotension is exercised. Tracheal intubation can be performed with any of the available muscle relaxants, but caution must be exercised to avoid histamine release, which can dramatically increase HR. Anesthetic maintenance can be accomplished with the use of a volatile agent in conjunction with nitrous oxide, opiates, or both. The adverse cardiovascular effects of the volatile agents must be considered before these drugs are used. Higher concentrations of inhaled agent result in greater degrees of myocardial depression and vasodilation. Volatile agents must be used with caution, because the myocardial depressant effect can be deleterious in patients with impaired ventricular function. The use of higher-dose opioid-based techniques is an alternative anesthetic approach that may help achieve cardiovascular stability without causing a significant amount of myocardial depression. Finally, a combination of inhaled agents and narcotics has been used safely to provide anesthesia for patients with aortic stenosis. Whatever the anesthetic technique chosen for patients with aortic stenosis, immediate and aggressive treatment of adverse changes that occur in HR and rhythm, SVR, blood pressure, and LVEDV is paramount if successful anesthetic outcomes are to be achieved.[68,71]

AORTIC INSUFFICIENCY

AI, also known as *aortic regurgitation*, can be classified as acute or chronic and as primary or secondary, depending on the cause. Primary *chronic* AI is caused by rheumatic valvular disease and almost always involves the mitral valve to some degree. Primary *acute* AI usually is caused by infective endocarditis, which is caused by direct damage to the valve cusps. Acute secondary (functional) AI results from aortic root dissection caused either by trauma or aneurysm and results in a mechanical and functional impairment of functional aortic valve closure.

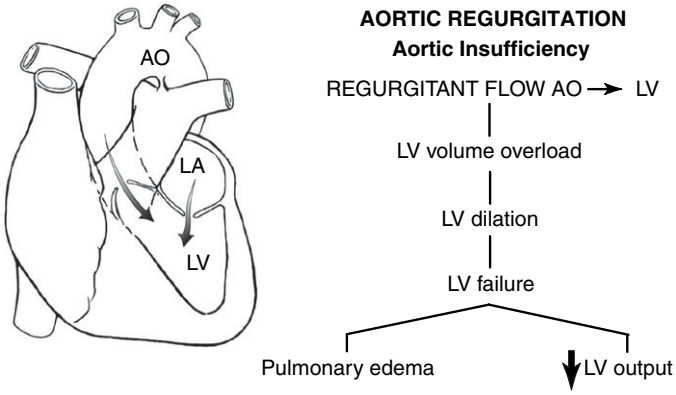

FIGURE **23-44** Pathophysiology associated with aortic regurgitation. *AO*, Aorta; *LA*, left atrium; *LV*, left ventricle.

Pathophysiology

The major hemodynamic aberration related to AI occurs during diastole. A portion of the blood volume ejected from the LV into the aorta regurgitates back into the ventricle because of incomplete closure of the aortic valve. Aortic insufficiency causes volume overload of the LV. Chronic ventricular overload causes eccentric ventricular hypertrophy and chamber dilation (Figure 23-44). The degree of regurgitation depends on three factors: the diastolic time available for regurgitation to occur, the diastolic pressure gradient between the aorta and the LV, and the degree of incompetence of the aortic valve.[65,68]

Diastolic time and diastolic pressure can be manipulated during the course of anesthesia so that the amount of regurgitant flow is decreased and the amount of forward flow is increased. An HR of 90 to 110 beats per minute and decreases in diastolic time interval occur and thereby reduce the time available for regurgitation. Reducing SVR reduces aortic diastolic pressure and decreases the gradient between the aorta and the LV. Unique pathophysiologic adaptations differentiate chronic AI from the acute form. In chronic AI, the LV has had time to compensate for the increased volume. In time, LV hypertrophy allows the LV to tolerate significant increases in volume without dramatic decreases in EF.[44,55] In situations in which the onset of AI is acute, the LV has inadequate time to adapt to volume overload, which renders compensatory mechanisms ineffective (Figure 23-45). Frequently, left ventricular failure, pulmonary edema, and cardiovascular collapse occur. Left ventricular end-diastolic pressure rises precipitously in acute AI because of the inability of the LV to alter its compliance.

Patients with chronic AI can remain asymptomatic for long periods. Except during times of stress, the clinical symptoms associated with chronic AI are usually not incapacitating. End-stage AI is characterized by myocardial failure with decreased CO and precipitous elevation of LVEDV with evidence of pulmonary congestion. As long as ventricular hypertrophy and dilation do not affect the mitral valve, the pulmonary circulation is not affected by the pathophysiologic changes associated with AI. Increased myocardial oxygen consumption occurs because of the development of eccentric hypertrophy. The decrease in aortic diastolic pressure that results from AI reduces coronary flow and can cause subendocardial ischemia. In acute AI, a precipitous increase in LVEDP with a decrease in aortic diastolic pressure can severely compromise coronary blood flow and result in acute myocardial ischemia. The RV and pulmonary vascular circuit usually are spared in chronic AI until secondary (functional) MR occurs. This results in dilation of the mitral valve annulus. A gradual increase in LA pressure and pulmonary artery pressure caused by functional MR eventually causes pulmonary hypertension; right ventricular failure can occur

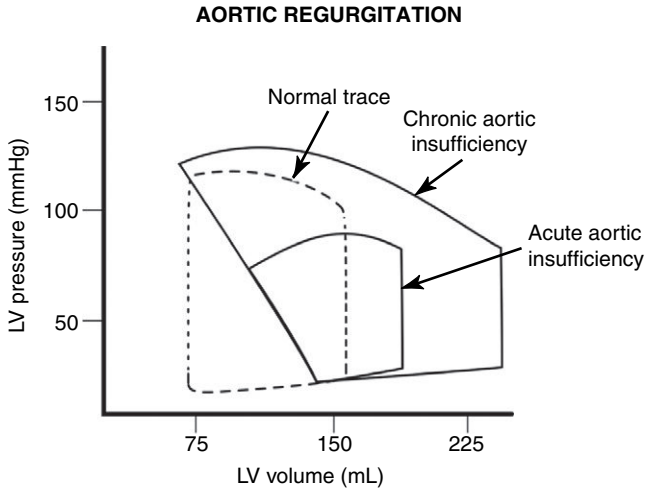

FIGURE **23-45** Left ventricular (LV) pressure-volume loop associated with aortic insufficiency. Increased LV pressure, volume, and stroke volume are associated with chronic aortic insufficiency and are reflective of LV hypertrophy. Notice that during the relaxation phase, as isovolumetric relaxation occurs, LV volume increases as a result of the incompetent aortic valve.

if pulmonary hypertension becomes severe. In acute AI, functional MR is poorly tolerated, owing to a noncompliant LA. This situation leads to immediate pulmonary vascular congestion and pulmonary edema. Patients with asymptomatic AI have a 0.2% annual mortality rate as compared with symptomatic patients, who have a greater than 10% mortality rate per year.[72] Therefore when evidence suggests that increases in left ventricular volume result in left ventricular dysfunction, aortic valve replacement is recommended.

Anesthesia Management

The goals for anesthesia management are to increase forward flow and decrease the degree of regurgitation and therefore should focus on the following hemodynamic factors:

- Heart rate should be maintained slightly higher than normal (80 to 110 beats per minute).
- Afterload (especially diastolic pressure) should be decreased.
- Avoid myocardial depression.
- Maintain normal sinus rhythm (NSR).
- Maintain/increase preload.

Central neural blockade is an appropriate anesthetic choice, depending on the invasiveness of the surgical procedure. Reduction in SVR resulting from sympathetic blockade may reduce the degree of regurgitation. The potential for immediate and uncontrolled hypotension during spinal anesthesia is a concern. However, spinal and epidural anesthesia has been used successfully for patients with AI. Induction of general anesthesia can be accomplished with any of the available intravenous agents. Tracheal intubation can be achieved with the use of available nondepolarizing muscle relaxants. As mentioned in the anesthetic management for patients with mitral regurgitation, the vagolytic properties associated with pancuronium are desirable and may offset the vagotonic effects of narcotics. Succinylcholine may be used, but its potential to cause bradycardia (although rarely) must be considered. Maintenance of anesthesia can be achieved with nitrous oxide and a volatile agent. Isoflurane, with its ability to increase HR and decrease SVR, produces little myocardial depression in lower doses, and therefore its use is preferred over use of other volatile agents. If significant ventricular dysfunction exists, an opioid-based anesthetic technique may be preferable.[52,55,56]

TABLE 23-10 Hemodynamic Goals for Management of Aortic Lesions

Parameter	Aortic Regurgitation (Insufficiency) Goal	Aortic Stenosis Goal
Heart rate	Moderate increase	Normal to slow
Heart rhythm	Normal sinus rhythm	Normal sinus rhythm
Afterload	Decrease	Maintain to slight increase
Pulmonary vascular resistance	Maintain	Maintain
Preload	Normal to increased	Increased

Monitoring and Premedication

Unless end-stage AR or significant preoperative ventricular dysfunction exists, aggressive invasive monitoring is not warranted. However, if the surgical procedure is extensive or if vasodilators or inotropes are being used, then an arterial line and a pulmonary artery catheter should be used for assessing the results and efficacy of these therapeutic agents. Premedication should be tailored to the patient's clinical condition. In elderly or debilitated patients, a conservative amount of premedication in a monitored environment should be titrated until effective.

Appropriate anesthetic management of the patient with valvular heart disease requires a basic knowledge of cardiac physiology and the pathophysiologic changes that occur with valvular dysfunction. The cardiovascular effects of all the agents, techniques, and adjunct pharmacologic agents used during anesthesia must be integrated into the anesthetic plan. A thorough understanding of the use of invasive monitoring along with other sophisticated diagnostic modalities enables the clinician to continuously monitor hemodynamic parameters. Contemporary anesthesia practice has allowed patients with severe valvular dysfunction to undergo surgical procedures that would not have been performed a decade ago.[68] Table 23-10 lists anesthetic goals for management of aortic lesions.

MITRAL VALVE PROLAPSE

Description and Etiology

The incidence of mitral valve prolapse, which was thought to be present in 5% to 15% of the U.S. population, is presently estimated at 1.6% to 2.4% of adults.[72] A familial predisposition exists, and women are three times more likely than men to develop mitral valve prolapse. Other conditions frequently associated with mitral valve prolapse include pectus excavatum and kyphoscoliosis. Symptoms are general and include weakness, dizziness, syncope, atypical chest pain, and palpitations. Atrial and ventricular dysrhythmias are common findings in asymptomatic patients. A diagnosis of mitral valve prolapse is confirmed through echocardiography. Most patients with this condition remain undiagnosed. Despite its benign nature, mitral valve prolapse can produce potentially life-threatening complications. Premature ventricular contractions are the most common dysrhythmia associated with mitral valve prolapse. Prolonged periods of ventricular tachycardia occur in approximately 21% of patients with mitral valve prolapse. Mitral valve prolapse is also the most common cause of isolated MR. Supraventricular tachyarrhythmias and bradycardia associated with AV block may occur. Medical therapy for mitral valve prolapse consists primarily of the use of β-blocking drugs, which are thought to inhibit an autonomic imbalance that exists in women with mitral valve prolapse. Additionally, β-blocking

TABLE 23-11 Hemodynamic Goals for Management of Mitral Valve Prolapse

Parameter	Goal
Preload	Maintain or increase
Afterload	Maintain
Contractility	Maintain
Heart rate	Maintain
Heart rhythm	Normal sinus rhythm

drugs may increase end-diastolic volume and thereby decrease the degree of prolapse. The majority of patients with mitral valve prolapse do not require medical or pharmacologic management, which reflects the asymptomatic nature of this relatively common valvular abnormality (Table 23-11).[33,71]

Pathophysiology and Unique Problems

The pathophysiologic changes that occur in mitral valve prolapse primarily affect the cusps and the chordae tendineae. Involved is a myxomatous degeneration of the valve cusps that replaces normal fibrous tissue. Also, this myxomatous degeneration affects the chordae tendineae and causes them to become pliable and elongated. The valve leaflets become supple and redundant, as the valve everts into the LA during systole.[73]

Mitral valve prolapse is undiagnosed in the majority of patients. A manifestation that commonly occurs in healthy patients who are receiving anesthesia is an unexpected dysrhythmia (e.g., premature ventricular contractions), many of which resolve spontaneously. Lidocaine does not always terminate the premature ventricular contractions for patients with mitral valve prolapse. β-Blockers are the best choice for control of dysrhythmias in patients with mitral valve prolapse. Hemodynamic events and certain positions tend to exacerbate the degree of mitral valve prolapse and dysrhythmias. Hemodynamic changes that cause a decrease in ventricular preload and increase the incidence of eversion of the mitral valve are caused by increased myocardial contractility, decreased SVR, head-up or sitting positions, use of drugs that decrease ventricular preload (e.g., nitroglycerin and sodium nitroprusside), and hypovolemia.

Pharmacology

Preoperative anxiety stimulates the sympathetic nervous system and can increase the degree of mitral valve prolapse and concomitant dysrhythmias. Decreasing anxiety can reduce the sympathetically mediated responses and improve the hemodynamic profile characteristic of mitral valve prolapse. Anticholinergics can cause tachycardia and should therefore be omitted from the preoperative regimen.

Anesthetic Management

Regional anesthesia is an acceptable anesthetic technique for patients with mitral valve prolapse. SVR should be maintained slightly above normal, even in the presence of sympathetic blockade. General anesthesia is an appropriate choice and may be preferred in many instances. Whichever technique is chosen, it is important that preload be maintained. Induction of anesthesia can be accomplished with any of the available intravenous agents. Ketamine, with its ability to stimulate the sympathetic nervous system, should not be used in patients with mitral valve prolapse. Use of a volatile agent alone or in combination with opioids is appropriate for maintenance of anesthesia. Muscle relaxants that have a stable cardiovascular profile can be used. Because of the vagolytic effects of pancuronium, tachycardia and stimulation of the sympathetic nervous system can occur. These cardiovascular effects can be minimized if the drug is administered slowly.[73] Antibiotic prophylaxis is recommended for patients with mitral valve prolapse because of the potential for endocarditis. Currently the American Heart Association has guidelines for antibiotic prophylaxis in surgical patients with valvular disease. All patients who have valvular dysfunction or prosthetic valves are candidates for antibiotic prophylaxis.[74]

CARDIOMYOPATHY

Cardiomyopathy is a general term used to describe specific but distinct cardiac pathology that can ultimately result in fatal dysrhythmias, severely decreased stroke volume, progressive cardiac disability, and sudden cardiac death. All forms of cardiomyopathy can result in congestive heart failure and death. Cardiomyopathy means heart muscle disease and can be categorically differentiated by a general pathologic cause as either extrinsic or intrinsic. Intrinsic cardiomyopathy is described as decreased contractile state of the heart muscle that cannot be attributed to a specific external causative factor. In contrast, the cause of extrinsic cardiomyopathy can be directly attributed to a disease process or toxin that adversely damages cardiac muscle. Factors that can cause extrinsic cardiomyopathy include but are not limited to ischemia, chronic inflammation, congenital heart disease, metabolic diseases (e.g., hemochromatosis), and toxins (e.g., chronic alcohol intake, chemotherapeutic agents). Frequently, histologic findings consistent with cardiomyopathies include myocyte hypertrophy, degradation of the cardiac cytoskeleton, and cellular fibrosis. The four major types of cardiomyopathy include dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), restrictive cardiomyopathy (RCM), and arrhythmogenic right ventricular cardiomyopathy (ARVC). Frequently the discovery of significant cardiomyopathy is accomplished post mortem because sudden cardiac death commonly occurs in those with cardiomyopathy. A discussion of various types of cardiomyopathies, signs and symptoms, and anesthetic implications are included below.

Frequently patients with severe cardiomyopathy have surgery for cardiac procedures such as pacemaker implantation or heart transplantation. A thorough preoperative evaluation is essential to create a comprehensive anesthetic plan that is individualized. In addition to physical examination, a determination of the patient's preoperative medication regimen and assessing the degree of compliance with his or her medications is a component part of medical optimization. A detailed analysis of the invasive and noninvasive cardiac studies including TEE and the cardiologist's impression of the patient's cardiac status is vital. An understanding of the specific cardiomyopathologic differences is necessary for prudent management.

Hypertrophic Cardiomyopathy

Cardiomyopathy is a compensatory enlargement of the heart. Hypertrophic cardiomyopathy, a genetically transmitted disorder, is a form of myocardial dysfunction that can cause coronary artery disease, valvular dysfunction, ventricular remodeling, and hypertension. The incidence in the adult population is approximately 1 in 500 persons.[75] Obstructive HCM has previously been referred to as *idiopathic hypertrophic subaortic stenosis*. Currently the preferred term used to describe this pathologic state is *HCM with or without left ventricular outflow obstruction*.[76]

A summary of the pathophysiology, signs and symptoms, and anesthetic considerations is listed in Table 23-12.

TABLE 23-12 Pathology and Anesthetic Considerations for Various Cardiomyopathies

Cardiomyopathy	Distinctive Features	Signs and Symptoms	Anesthetic Considerations
Dilated	Eccentric left and right ventricular hypertrophy causing systolic and diastolic dysfunction	Chest pain Jugular venous distention Weakness Exercise intolerance Rales Tachycardia Pulsus alternans Atrial fibrillation Atrial and ventricular dysrhythmias Atrioventricular valve regurgitation X-ray–pulmonary venous congestion/spherical appearance of LV/cardiomegaly	Promote afterload reduction Avoid large fluid bolus Choose anesthetic techniques, agents that minimize myocardial depression
Restrictive	Stiff and noncompliant ventricles decrease ventricular end-diastolic volume despite near-normal systolic function	Dyspnea Fatigue Cardiomegaly Atrioventricular valve regurgitation JVD Pulmonary hypertension Rales	TEE and invasive hemodynamic monitoring IV inotropic support may be necessary Choose anesthetic techniques, agents that minimize myocardial depression
Hypertrophic	Left ventricular hypertrophy resulting in decreased LV chamber size and LV outflow tract obstruction	Chest pain Shortness of breath Palpitations Rales Systolic murmur (S_3 and S_4) Ventricular dysrhythmias Syncope	Ensure adequate preload Myocardial depression is desirable Maintenance of normal sinus rhythm Avoid tachycardia Ensure adequate depth of anesthesia
Arrhythmogenic right ventricular	Fatty tissue infiltrates; dilation and outflow tract obstruction of the right ventricle	Tachycardia Ventricular dysrhythmias (ventricular tachycardia, ventricular fibrillation) T wave inversion (leads V_1 and V_3) Bundle branch block Hypokinetic right ventricle Decreased right ventricular ejection Jugular venous distention Syncope Peripheral edema	Treat events that cause moderate to severe sympathetic nervous system predominance Monitor and treat hemodynamically compromising ventricular dysrhythmias with amiodarone

JVD, Jugular venous distention; *LV,* left ventricle; *TEE,* transesophageal echocardiography.

Pathophysiology

Hypertrophic cardiomyopathy is the most common cause of sudden death in the pediatric and young adult populations.[77] The major cardiac changes associated with HCM include: (1) ventricular hypertrophy, (2) decreased ventricular chamber size, (3) increased ventricular wall thickness, and (4) impaired ventricular relaxation. The myocardial defect associated with HCM is related to the contractile mechanism. An increase in the density of calcium channels is one abnormality that appears to lead to myocardial hypertrophy. Asymmetric hypertrophy of the interventricular septum of the LV occurs. It has been determined that there is a genetic predisposition to developing HCM. Patients with HCM and sarcomere myofilament mutations have a greater degree of microvascular impairment, an increased incidence of myocardial fibrosis, and impaired myocardial remodeling.[78] The asymmetric hypertrophy of the intraventricular septum causes a left outflow tract obstruction, and the hemodynamic consequences are similar to those that are characteristic of aortic stenosis. Coronary arterial walls are narrowed because of the presence of collagen. If the entire myocardium is involved, a disproportionate hypertrophy of the intraventricular septum exists. The contraction of the hypertrophic septum bulging into the subaortic area of the left ventricular outflow tract creates a dynamic gradient. The left ventricular outflow tract is bounded anteriorly by the intraventricular septum and posteriorly by the anterior leaflet of the mitral valve. The rapid acceleration of blood traveling through the narrowed outflow tract creates a Venturi effect, which pulls the anterior mitral valve leaflet into the outflow tract. A LV outflow tract obstruction is present in approximately two thirds of patients with hypertrophic cardiomyopathy.[79] The systolic anterior motion of the anterior mitral valve leaflet further obstructs left ventricular outflow. The valve leaflet may even contact the septum and further compromise left ventricular outflow.[67]

The pathophysiologic abnormalities related to HCM include the presence of systolic and diastolic dysfunction. A loss of diastolic compliance results in an abnormally elevated LVEDP in the presence of low-normal end-diastolic volume. Loss of left ventricular diastolic compliance requires a greater contribution of volume from atrial contraction. As a result, congestive heart failure may ensue as left atrial pressures continue to increase.[68] Because as much as 75% of left ventricular preload comes from the LA, maintenance of normal sinus rhythm is critical for adequate SV. The increase in LVEDP, which results from a noncompliant LV, decreases CPP to the hypertrophic LV. Altered coronary perfusion

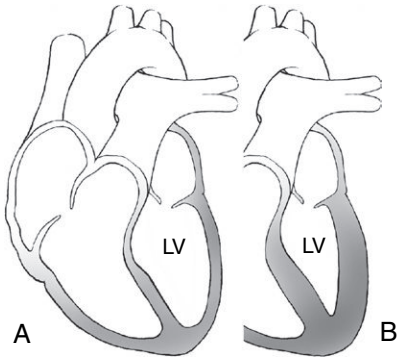

FIGURE **23-46** **A,** Normal left ventricular outflow tract. **B,** Hypertrophic cardiomyopathy with an enlarged interventricular septum and decreased left ventricular chamber size. A further decrease of left ventricular outflow is caused by migration of the anterior mitral leaflet toward the septum.

decreases myocardial blood supply, and the presence of left ventricular hypertrophy increases myocardial oxygen demand. Thickening of the internal lumen of the coronary arteries decreases myocardial perfusion, leading to ischemia.[79]

Hypertrophic cardiomyopathy with obstruction is characterized by its dynamic nature. Three basic hemodynamic parameters can affect the degree of left ventricular outflow tract obstruction. Manipulation of these parameters can exacerbate or ameliorate the hemodynamic consequences of outflow obstruction. These three parameters include preload, afterload, and contractility.[33] Increasing myocardial contractility in patients with HCM exacerbates the obstruction by increasing septal wall contraction and decreasing CO. Increased blood flow velocity causes a greater degree of systolic anterior motion of the mitral valve's anterior leaflet, creating further obstruction. Decreased preload changes left ventricular geometry and thereby brings the anterior leaflet of the mitral valve into closer proximity to the hypertrophic septum. Increases in left ventricular contractility cause the LV to empty more completely and increase the degree of septal contractility, which results in a greater degree of obstruction.[76] A summary of the signs and symptoms is included in Table 23-12.

In HCM with outflow tract obstruction, conditions that impair ventricular function under normal physiologic conditions improve cardiac function. This implies that factors that normally impair contractility (e.g., myocardial depression, increased end-diastolic volume, and increased SVR) improve forward flow and diminish the degree of obstruction. Figure 23-46 illustrates the pathology related to HCM.

Anesthetic Considerations

Anesthetic management should focus on strategies that alleviate and do not increase left ventricular outflow obstruction. It is imperative that adequate or slightly elevated left ventricular volume be maintained. Measures that decrease venous return and interfere with adequate ventricular preload should be avoided. Factors that increase myocardial contractility should be avoided. Inadequate depth of anesthesia that causes sympathetic nervous system stimulation may be detrimental. In the event that hypotension occurs, adequate perfusion pressure should be maintained by increasing preload with fluid administration and increasing SVR with phenylephrine.

Pharmacologic therapy used to treat HCM (including β-blockers and calcium channel blockers) should be continued until the time of surgery.[15] β-Blockers may be administered intraoperatively to reduce HR and contractility. Dysrhythmias must be avoided and immediately treated if they occur; the atrial contribution to left ventricular volume is necessary to maintain CO.[71,76] Table 23-13 lists hemodynamic goals for patients with HCM.

TABLE 23-13 Hemodynamic Goals for Management of Hypertrophic Cardiomyopathy

Parameter	Goal
Preload	Increase
Afterload	Increase
Contractility	Decrease
Heart rate	Maintain
Heart rhythm	Normal sinus rhythm

Anesthetic management must focus on increasing left ventricular preload, decreasing myocardial contractility, controlling HR, and maintaining or increasing afterload. Regional anesthesia is not contraindicated in patients with dilated cardiomyopathy. Decreases in blood pressure must be treated immediately. Hypovolemia must be avoided and expeditiously treated if it occurs. Deep general anesthesia with a volatile agent is preferred in patients with HCM and obstruction.

The potential for hemodynamic deterioration because of increasing subaortic obstruction along with secondary MR necessitates aggressive hemodynamic monitoring. Invasive monitoring via a pulmonary artery catheter allows for maintenance of adequate LVEDV. Because of reduced diastolic compliance associated with HCM, PCWP does not accurately correlate directly with LVEDV. The PCWP should be maintained at approximately 18 to 25 mmHg. If the hemodynamic status deteriorates and exacerbation of outflow obstruction is suspected, β-blocking drugs (propranolol, metoprolol or esmolol) should be administered. In addition, vasoconstrictors such as phenylephrine should be used to increase SVR.[33]

Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is the most common form of cardiomyopathy, and it most often occurs in adults.[80] As with HCM, there is believed to be a genetic link for those people who develop this cardiac pathology. Between 20% and 30% of DCM cases are caused by an autosomal dominant mutation resulting in abnormal cardiac cytoskeleton protein generation.[78] DCM can also occur in patients as a result of autosomal recessive traits, such as in patients with Duchenne muscular dystrophy. When genetic predisposition is not the cause, the specific etiology has not been definitively determined but is not limited to a viral illness, increased inflammation from metabolic abnormalities, autoimmune mechanism, or toxins. It occurs more often in men than in women and is attributed to being a significant risk factor for developing congestive heart failure. For women who develop congestive heart failure during pregnancy, peripartum cardiomyopathy is associated with higher maternal and neonatal mortality.[81] A summary of the pathophysiology, signs and symptoms, and anesthetic considerations is listed in Table 23-12.

Pathophysiology

In DCM, eccentric hypertrophy affects both left and right ventricles. As cardiac cytoskeleton uncoupling occurs, caused by interstitial fibrosis and myocardial cell death, the ventricular chambers increase in size without an associated increase in the diameter of the ventricular walls or interventricular septum. The law of Laplace, as

shown in the following equation, helps us describe why the heart becomes an inefficient pump for patients with DCM. Tension on the ventricular walls is increased due to the decreased size and increased diameter of the ventricular walls. After a period when increased ventricular volumes induce compensatory eccentric hypertrophic changes, impaired systolic function (decreased stroke volume) occurs because of the loss of myocardium causing decreased contractility. Myocardial oxygen consumption is increased as ventricular end-diastolic volume and pressure are increased.

$$T = (P \times R) / M$$

$$T = \text{tension},\ P = \text{pressure},\ R = \text{radius},\ M = \text{wall thickness}$$

This pathologic process does not cause direct damage to the atrioventricular valves. However, as ventricular dilation occurs, changes in ventricular dimensions can cause mitral valve and/or tricuspid valve regurgitation potentially intensifying volume overload, decreased stroke volume, and increased pulmonary congestion.

As the ejection fraction decreases, decreased peripheral perfusion causes increased circulating catecholamines, cortisol excretion, and activation of the renin-angiotensin-aldosterone system, which causes vasoconstriction and increased renal absorption of fluid. Left-sided heart failure resulting in pulmonary venous congestion or biventricular failure leads to fulminant congestive heart failure. These patients are at increased risk of thromboembolism as a result of stasis of blood from inadequate ventricular emptying.

Anesthetic Considerations

Pharmacologic medical treatment for patients with DCM include diuretics, ACE inhibitors, and digoxin. Other interventions for moderate to severe DCM include dual chamber pacing, cardiomyoplasty, or use of a left ventricular assist device. Because of the potential for severely compromised ventricular performance, minimizing myocardial depression is essential. Afterload reduction is important to promote forward blood flow through the heart. As a result, neuraxial anesthesia is an acceptable anesthetic technique for patients with DCM.[82] Narcotics are a common choice for patients with cardiomyopathy because they do not have a direct effect on myocardial contractility. However, patients with DCM who have a severely compromised ejection fraction depend on sympathetic nervous system innervation to augment their cardiac output. Therefore incremental titration of narcotics is warranted. Etomidate is an appropriate choice of induction agent because of the lesser amount of myocardial depression as compared to propofol. Because all inhalation agents cause myocardial depression in a dose-dependent fashion, titration of inhalation agents and adjusting concentrations based on blood pressure, central venous pressure, and pulmonary capillary wedge pressure is indicated.[78]

Restrictive Cardiomyopathy

The term *restrictive cardiomyopath*y (RCM) represents several types of pathologic conditions depending on whether the myocardium or endomyocardial muscle layer is affected. Causes of myocardial RCM include genetic predisposition (e.g., familial cardiomyopathy), infiltrative disease (e.g., sarcoidosis), storage diseases (e.g., hemachromotosis), and endomyocardial dysfunction (e.g., endomyocardial fibrosis). RCM can occur in the pediatric population; however, it is one of the rarest forms of cardiomyopathy that occurs in children. It is associated with a high mortality rate once symptoms begin to develop.[83] A summary of the pathophysiology, signs and symptoms, and anesthetic considerations is listed in Table 23-12.

Pathophysiology

Infiltration of fibrous tissue and deposition into the myocardium and or endomyocardium is the pathologic mechanism by which RCM develops. As a result, one or both ventricles become stiff and noncompliant, which inhibits normal diastolic filling. As a result of reduced end-diastolic volume (reduce ventricular preload) caused by restricted ventricular filling, stroke volume is decreased. An increase in the sensitivity of the troponin and tropomyosin complex of calcium-mediated myofilament is thought to be the cause of genetically derived RCM.[84] Systolic ejection remains relatively normal. The atria become dilated as a compensatory response to volume overload, and left- and/or right-sided heart failure can occur. Significantly elevated RA pressures (15 to 20 mmHg) and pulmonary artery systolic pressure (as high as 50 mmHg) can occur as the disease progresses.[80]

Anesthetic Considerations

Medical management for RCM is similar to DCM and includes use of diuretics, sodium and water restriction, anticoagulation agents, and treatment of dysrhythmias. Maintenance of normal sinus rhythm, adequate preload, and minimal myocardial depression is essential to anesthetic management. As with DCM, an anesthetic technique that minimizes myocardial depression, which is accomplished using higher doses of narcotic as compared to inhalation agents, may be prudent. Results from studies are often conflicting regarding the degree of myocardial depressant effects of modern inhalation agents (isoflurane, sevoflurane, desflurane) in relation to cardiomyopathy and impaired systolic ejection and diastolic relaxation.[85,86] Patients with moderate to severe cardiomyopathy depend on sympathetic nervous system activity to augment myocardial performance. Despite the minimal direct myocardial depressant effects of narcotics, their inhibition of the sympathetic nervous system has an indirect depressant effect on the heart. Thus titration of narcotics and assessment of the patient's hemodynamic status is important.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC), also known as *arrhythmogenic right ventricular dysplasia*, is an autosomal dominant genetically inherited disorder. Diagnosis is often made post mortem in patients with ARVC because sudden cardiac death is a common occurrence with this cardiomyopathy. Signs and symptoms can occur during childhood, but more often manifest during adolescence. During sports-related exercise, severe intolerance caused by increasing myocardial oxygen demand can result in lightheadedness, syncope, and or sudden death. A summary of the pathophysiology, signs and symptoms, and anesthetic considerations is listed in Table 23-12.

Pathophysiology

Fibrous fatty infiltrates invade the right ventricular myocardium and cause myocyte dysfunction and death. As a result, right ventricular cardiac output is decreased. The left ventricle undergoes this type of pathologic change in approximately half of patients with ARVC, and congestive heart failure is a sign of disease progression. Ventricular dysrhythmias are common and range from premature ventricular contractions to ventricular fibrillation. Patients with ARVC may be exquisitely sensitive to increased catecholamine levels, which may further provoke these dysrhythmias.

Anesthetic Considerations

Anesthetic management for patients with ARVC should focus on identification and treatment of fatal dysrhythmias. Many events increase sympathetic nervous system predominance—examples include hypoxia, hypotension, hypercarbia, and surgical stimulation. Excessive catecholamine release can induce fatal dysrhythmias. Amiodarone has been used successfully to treat dysrhythmias in these patients. Prophylactic preoperative administration of antiarrhythmic agents has not been shown to be effective at suppressing ventricular dysrhythmias intraoperatively.[80]

SUMMARY

As the population continues to age and the incidence of obesity rises, the prevalence of cardiovascular disease will increase to reflect the progressive nature of its pathology. Anesthesia providers are nonetheless able to safely manage these extremely critical patients with respect to the full spectrum of surgical needs. A thorough knowledge of cardiac physiology and function is imperative to maintaining administration of high-quality anesthesia care. Improved patient outcomes are consistently being achieved as better assessment, monitoring, and anesthesia management techniques are developed.

24 CHAPTER Anesthesia for Cardiac Surgery

◆ *Margaret A. Contrera, Melissa Patterson, and Mary Cushing*

Despite advances in prevention and treatment, cardiovascular disease (CVD) remains the leading cause of death globally, accounting for 30% of mortality. The World Health Organization estimates that CVD will remain the predominant cause of mortality, resulting in 23.6 million deaths by 2030, mostly from coronary artery disease (CAD).[1] In the United States, CVD causes 1 of every 2.9 deaths, half of them due to CAD.[2] Because of the aging population, degenerative valvular heart disease (VHD) is on the rise. There are currently over 290,000 heart valve operations performed annually worldwide, and that number is expected to triple by 2050, reaching 850,000.[3] Both CAD and VHD lead to heart failure, which impacts more than 5 million Americans. The mortality rate for symptomatic patients is a staggering 45%, worse than that of most cancers.[4] The Centers for Disease Control and Prevention estimates that $444 billion, or $1 out of every $6, in health care costs is spent on cardiovascular disease treatment.[5]

Clearly CVD presents an enormous public health burden. Scientific and medical communities, together with governmental agencies, have worked tirelessly to improve this situation. Consequently, new knowledge about these diseases is accumulating exponentially and technologic advancements have led to the development of cardiac procedures that were once inconceivable. Percutaneous techniques, hybrid operating rooms, mechanical assist devices, robotics, and minimally invasive technology now play significant roles in the practice of cardiothoracic anesthesia. The field has become more diverse, exciting, challenging, and rewarding than ever before.

Care of these high-risk patients in regard to the complex, ever-evolving surgical procedures may at first seem intimidating. But as Richard Morris, a pioneer in the field of cardiothoracic nurse anesthesia advised, "It's simple really; just manage the pump, pipes and volume." Accordingly, the first half of the chapter is about general cardiac surgery. It begins with a brief overview of the key physiologic principles that form the foundation of the evidence-based anesthetic management strategies for cardiac surgery. Next, cardiopulmonary bypass (CPB) is discussed, including a description of the circuit components and the physiologic implications of bypass. Then each phase of the perioperative period is examined and the anesthetic implications detailed. The second half of the chapter covers anesthetic considerations for specific cardiovascular diseases and procedures. The pathophysiology of CAD and VHD is briefly reviewed, and anesthetic management of traditional myocardial revascularization and valvular surgery is detailed. New technologic advancements have changed the landscape of cardiac anesthesia. Consequently, the next sections are devoted to management of first, the innovative, minimally invasive approaches that are now used for both valvular surgery and myocardial revascularization. This is followed by a discussion of the devices and procedures that are bringing new hope to the management of end-stage heart failure. The chapter concludes with the anesthetic management of procedures on the ascending aorta and arch that require CPB, including the considerations for deep hypothermic circulatory arrest.

ANESTHETIC MANAGEMENT OF GENERAL CARDIAC SURGERY

Key Physiologic Principles

Appropriate management of the cardiac surgical patient begins with a comprehensive understanding of normal cardiac anatomy, physiology, pharmacology, and monitoring, as well as the pathophysiologic response to disease. The reader is advised to review the excellent discussions of these topics found in Chapters 13, 16, and 23 as background for the information presented in this chapter. Nevertheless, there are certain key principles that apply to most cardiac surgical patients. An imbalance in myocardial oxygen supply and demand, often as a result of CAD, leads to ischemia or infarction. As a result of the imbalance, the left ventricle hypertrophies by thickening or dilating. The abnormal pressure and volume loads caused by stenotic and regurgitant valves likewise causes the ventricle to compensate by altering its structure, function, and neurohormonal balance. Although each disease starts with a different etiology and pathophysiologic process, with progression of the disease, the limits of compensation are reached and severe decompensated heart failure then ensues.

Myocardial Oxygen Supply and Demand

Myocardial injury and/or infarction are the single most frequent complications after cardiac surgery; they are also the primary cause of complications and death that occur in the hospital setting.[6] Clearly, optimizing the balance between myocardial oxygen supply and demand is of paramount importance (Figure 24-1). Coronary perfusion pressure (CPP) is equal to the aortic diastolic blood pressure minus the left ventricular end-diastolic pressure (LVEDP).

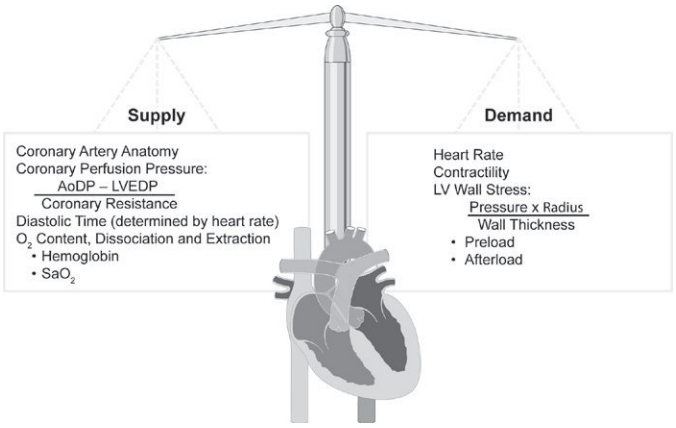

FIGURE **24-1** Myocardial oxygen supply and demand balance. Heart rate and left ventricular pressure affect both supply and demand. *AoDP*, Arterial diastolic pressure; *LVEDP*, left ventricular end-diastolic pressure; SaO_2, arterial oxygen saturation. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)

The subendocardium or inner third of the heart muscle is at greatest risk for ischemia because it is exposed to the highest pressure, especially at the peak of systole. Normally CPP is autoregulated between a mean arterial pressure (MAP) of 60 to 140 mmHg. Consequently, MAP is the most useful measure of coronary perfusion in the clinical setting.[7] However, in patients with CAD, flow is no longer autoregulated after it passes the partial obstruction. Instead, perfusion becomes pressure dependent; especially when the MAP drops below 70 mmHg[8,9] (Figure 24-2). Total coronary blood flow is determined by the perfusion pressure gradient, the time allotted for flow, coronary anatomy, and the resistance. Eighty percent of blood flow to the left ventricle occurs during diastole when the pressure is low (Figure 24-3). Diastolic time progressively shortens as the heart rate increases, resulting in decreased time for coronary perfusion at higher heart rates. Note that elevations in LVEDP and heart rate not only decrease myocardial blood supply but also increase myocardial oxygen demand. An increase in heart rate proportionally increases myocardial oxygen demand and decreases diastolic time.[7] Large epidemiologic studies show that heart rate is an independent predictor for cardiac and all-cause morbidity and mortality in men and women with and without CVD.[8] Heart rate is also the most significant cause of perioperative ischemia.[9] Therefore maintaining an adequate aortic mean pressure and a low heart rate is critical, particularly in patients who have CAD or an elevated LVEDP. The ideal heart rate must be determined on an individual basis, but less than 70 beats per minute (bpm) is a reasonable guide.[10] Patients with concentric left ventricular hypertrophy (LVH) have an elevated LVEDP, so they too are best managed with a higher MAP and lower heart rate. Table 24-1 outlines some of the causes and treatments of alterations in myocardial oxygen supply and demand.

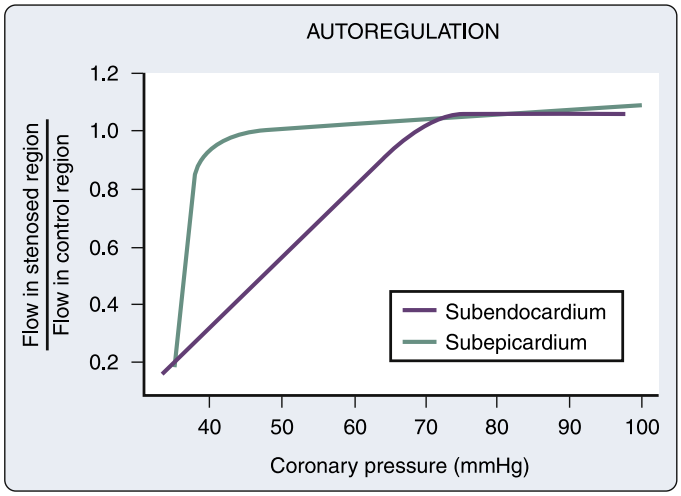

FIGURE **24-2** Pressure-flow relations of the subepicardial and subendocardial thirds of the left ventricle in anesthetized dogs. In the subendocardium, autoregulation is exhausted and flow becomes pressure dependent when pressure distal to a stenosis declines to less than 70 mmHg. In the subepicardium, autoregulation persists until perfusion pressure declines to less than 40 mmHg. Autoregulatory coronary reserve is less in the subendocardium. (Redrawn from Guyton RA, et al. Significance of subendocardial ST segment elevation caused by coronary stenosis in the dog. *Am J Cardiol.* 1977;40:373.)

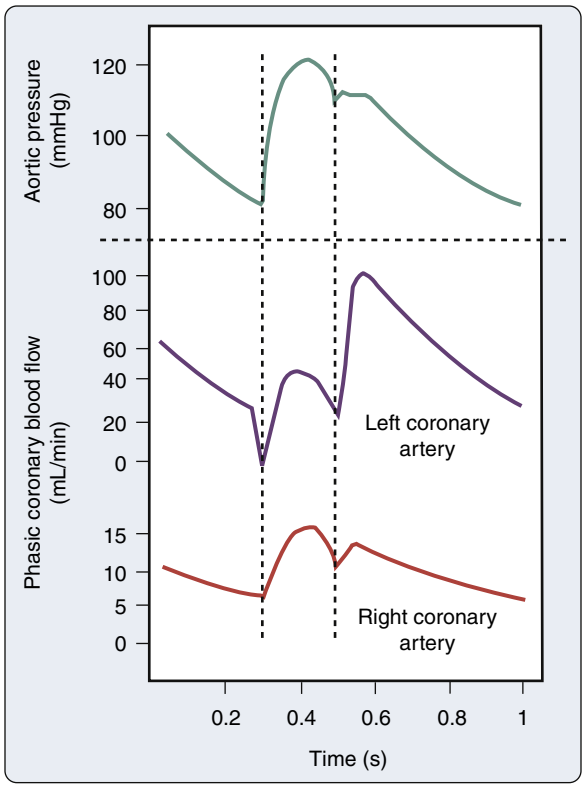

FIGURE **24-3** Blood flow in the left and right coronary arteries. The right ventricle is perfused throughout the cardiac cycle. Flow to the left ventricle is largely confined to diastole. (From Berne RM, Levy MN. Special circulations. In: Berne RM, Levy MN, eds. *Physiology*. St. Louis: Mosby; 2003.)

TABLE 24-1 Perioperative Management of Alterations in Myocardial O_2 Balance

Causes of Decreased O_2 Supply	Perioperative Management Strategy
Tachycardia (↓ diastolic time)	Keep heart rate relatively low (less than 70 bpm) Deepen anesthesia during stimulating periods
Hypotension	Maintain high normal MAP; consider phenylephrine ↓ anesthetic depth during less stimulating periods and surgical manipulation that causes ↓ MAP
↑ PaEDP	Consider nitroglycerin Evaluate LV volume with TEE (PaEDP can be falsely elevated in patients with concentric LVH)
↓ O_2 Content	Maintain Sa_{O_2} at greater than 95%
Anemia	Maintain adequate hemoglobin
Causes of Increased O_2 Demand	**Perioperative Management Strategy**
SNS stimulation	Maintain adequate depth of anesthesia Anticipate stimulating events and treat preemptively.
Tachycardia	Keep heart rate relatively low (less than 70 bpm) Consider β-blockers
↑ Preload	Consider nitroglycerin or diuretic to decrease
↑ Contractility	Consider agents that depress contractility (β-blockers/volatile anesthetics)
↑ Afterload	Avoid hypertension; consider vasodilator

↓, Decreased; ↑, increased; *bpm*, beats per minute; *LVH*, left ventricular hypertrophy; *MAP*, mean arterial pressure; *PaEDP*, pulmonary artery end-diastolic pressure; Sa_{O_2}, saturation of arterial oxygen; *TEE*, transesophageal echocardiography.

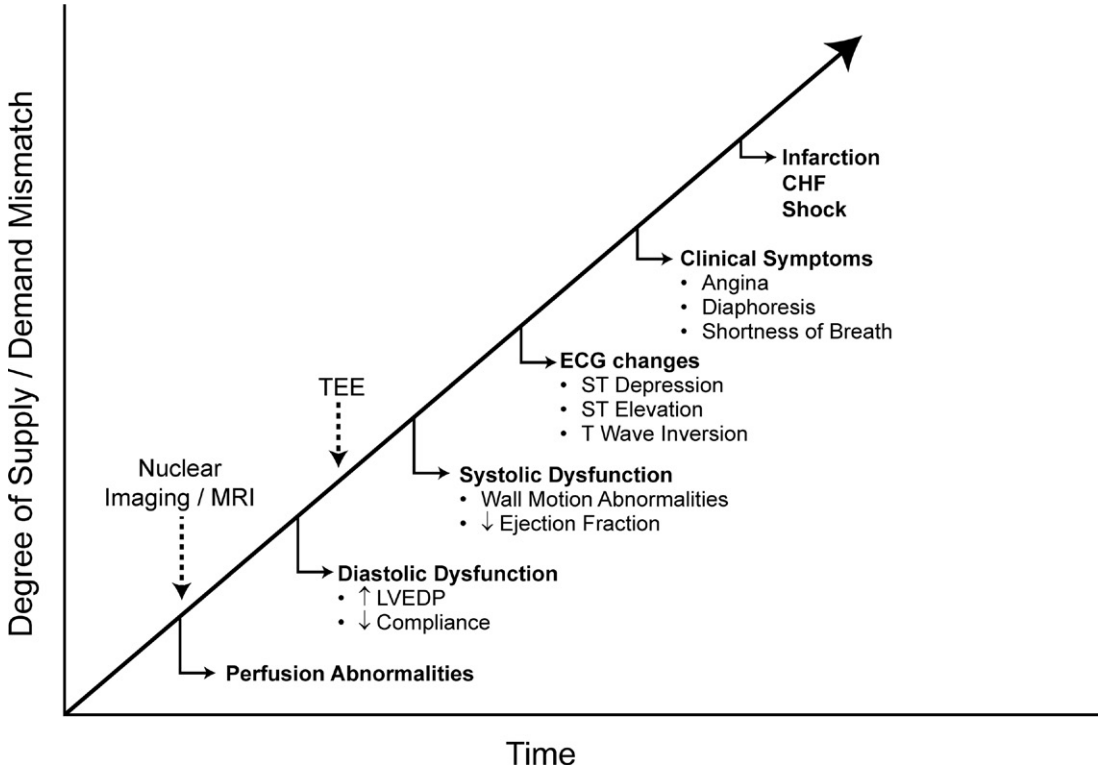

FIGURE **24-4** The ischemic cascade. Pathophysiologic sequence of developing myocardial ischemia correlated with timing of detection using various cardiovascular examinations. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)

Ischemia Cascade

Myocardial ischemia leads to a cascade of events as shown in Figure 24-4.[11] It is important to emphasize that diastolic dysfunction precedes systolic dysfunction, and that regional wall motion abnormalities occur on echocardiography before changes on the electrocardiogram (ECG). An imbalance between myocardial oxygen supply and demand will initially induce diastolic dysfunction, making the ventricle stiff and less compliant. These abnormalities will manifest as an increase in the pulmonary artery end-diastolic pressure (PAEDP); however, multiple studies show that the PAEDP is not specific for ischemia.[12] Systolic dysfunction causes regional wall motion abnormalities that can be readily detected on transesophageal echocardiography (TEE). Consequently, TEE is the most sensitive intraoperative monitor for detecting myocardial ischemia.[13] The single best ECG lead for detecting myocardial ischemia is V_5, which detects 75% of events, so it is important to ensure that the V (brown lead) of the ECG is correctly placed at the fifth intercostal space anterior axillary line. Combining V_4 or V_5 with lead II and using automated ST analysis further improves ECG sensitivity.[11,13,14]

Preconditioning, Stunning, and Hibernation

When the heart muscle experiences brief periods of ischemia that last less than 20 minutes, necrosis or cell death is prevented, but reversible contractile dysfunction, known as *stunning*, can occur and last for several hours.[15-17] As a result of stunning, many cardiac surgical patients may require 12 to 24 hours of inotropic support after cardiopulmonary bypass (CPB).

Ischemic preconditioning refers to the phenomenon whereby a short period of ischemia improves the heart's ability to tolerate subsequently longer periods of ischemic insult.[16] All inhalational anesthetics mimic this preconditioning effect. Consequently, there has been a resurgence of inhalation anesthesia as a primary technique for cardiac surgery, especially in patients with near-normal ventricular function. In past decades, there was a concern that the vasodilatory properties of isoflurane caused coronary steal.[18] However, clinical studies have shown that if blood pressure is controlled, ischemic episodes do not increase and outcomes are unchanged when inhalation agents, including isoflurane, are used.[19-21]

When stable coronary plaque causes chronic reductions in coronary perfusion, steady-state ischemia occurs, which results in left ventricular perfusion-contraction matching or *hibernation*. This phenomenon is considered a self-preservation mechanism whereby left ventricular contractile function is reduced to match the amount of oxygen available.[22,23] Unlike stunned myocardium, patients with hibernating left ventricles (LVs) often have significantly improved function after CPB and coronary artery bypass grafting (CABG). Differentiation of ischemic myocardium that is considered "viable" is important because approximately 20% to 40% of patients with chronically ischemic LV dysfunction will have a significant improvement after revascularization.[23,24] Multiple nuclear imaging tests and dobutamine stress echocardiography are used to help determine the presence of ischemia and viability. Some of the more common cardiovascular tests that are performed to identify ischemia and viability studies are outlined in Table 24-2.

The need to balance myocardial oxygen supply and demand is not limited to patients with CAD. Angina and myocardial infarction in patients with normal coronaries were demonstrated as far back as 1959.[25] Many other patients, such as those with chronic hypertension, aortic stenosis, or obstructive cardiomyopathy, will also benefit from a relatively high perfusion pressure

TABLE 24-2 Significant Findings on Cardiac Preoperative Testing

Diagnostic Tool	Significant Findings	
ECG and/or AECG	ST-T wave changes and presence of significant Q-waves If recent ACS: STEMI vs. NSTEMI vs. unstable angina Presence of *significant* arrhythmia BBB (concern if placing PAC) and LVH Presence of pacemaker	
Chest X-ray	Cardiomegaly Pulmonary vascular congestion/pulmonary edema Pleural effusion Presence of pacemaker or implantable cardioverter defibrillator	
Echo	**Valves**	
	Stenotic	***Regurgitant***
	• Degree (mild, moderate, severe) • Cross-sectional area • Pressure gradient across valve	- Grade (1+ to 4+) - Mechanism
	LV ejection fraction (systolic dysfunction) and RV function Presence and grade of diastolic dysfunction Amount and type of LVH Pericardial effusion/tamponade Presence of PFO (extra concern for air R to L) Presence of plaque on the ascending aorta (problem cannulating and/or clamping)	
Exercise Stress Test	Level and severity of ischemic changes, leads involved Patient characterization of symptoms	
Medications used to induce stress: adenosine and dipyridamole or dobutamine	Adenosine and dipyridamole cause vasodilation in normal coronaries leading to *steal* or *supply* ischemia in areas with CAD; used to identify viable myocardium Dobutamine (β-1 agonist) ↑ HR and contractility inducing *demand* ischemia; used for stress echo as well	
Nuclear Imaging	Radionuclides with varying tracer actions and kinetics are used to evaluate myocardial perfusion and function	
SPECT	Two sets of images are obtained: after stress and after rest. Defects that are initially seen (ischemic area) that fill later indicate viable myocardium, whereas fixed defects indicate scar	
PET	Ischemia shifts metabolism from fatty acids to glucose; an isotope is given that attaches to glucose; the scan can show flow as well as identify areas of uptake; uptake indicates ischemic areas and viable myocardium	
Stress Echo: Exercise or Dobutamine	Segments with new wall-motion abnormalities during stress are considered ischemic and therefore viable	
Cardiac Catheterization	LVEDP, cardiac index Presence of L main, triple vessel disease, or equivalent Quality of targets Type and timing of PCI Type, location, and timing of coronary stents Presence of pulmonary hypertension	

↑, Increase; +, with; − without; *ACS*, acute coronary syndrome; *AECG*, ambulatory electrocardiogram; *BBB*, bundle branch block; *CAD*, coronary artery disease; *ECG*, electrocardiogram; *HR*, heart rate; *L*, left; *LV*, left ventricle; *LVEDP*, left ventricular end-diastolic pressure; *LVH*, left ventricular hypertrophy; *NSTEMI*, Non-ST elevation myocardial infarction; *PAC*, pulmonary artery catheter; *PCI*, percutaneous coronary intervention; *PET*, positron emission tomography; *PFO*, patent foramen ovale; *RV*, right ventricle; *SPECT*, single-photon emission computed tomography; *STEMI*, ST elevation myocardial infarction.

and low heart rate. This is because of the structural, functional, and neurohumoral changes that occur in the ventricle in response to ischemia, infarction, and/or abnormal pressure or volume loads.

Heart Failure

Heart failure is a complex pathophysiologic process that causes a clinical syndrome characterized by pulmonary congestion resulting from the heart's inability to fill with or eject blood in a sufficient quantity to meet tissue requirements.[23] The heart was once thought of as simply the pump of the circulatory system, but it is now known that it evolves into "an endocrine organ" under stress, actively secreting neurohormonal factors in an attempt to meet the needs of the body. For example, atria natriuretic peptide (ANP) is released from the atria in response to volume overload and B-type natriuretic peptide (BNP) is released primarily from the ventricle in response to increased wall stress. These peptides help protect the myocardium by inducing physiologic effects such as diuresis, natriuresis, and vasodilation.[26] In fact, BNP has been recognized as a powerful biomarker for diagnosis, determination of severity, and prognostication of heart failure.[27] Heart failure is caused by an insult that alters perfusion and leads to a state of neurohumoral imbalance. Activation of the sympathetic nervous system (SNS) and the

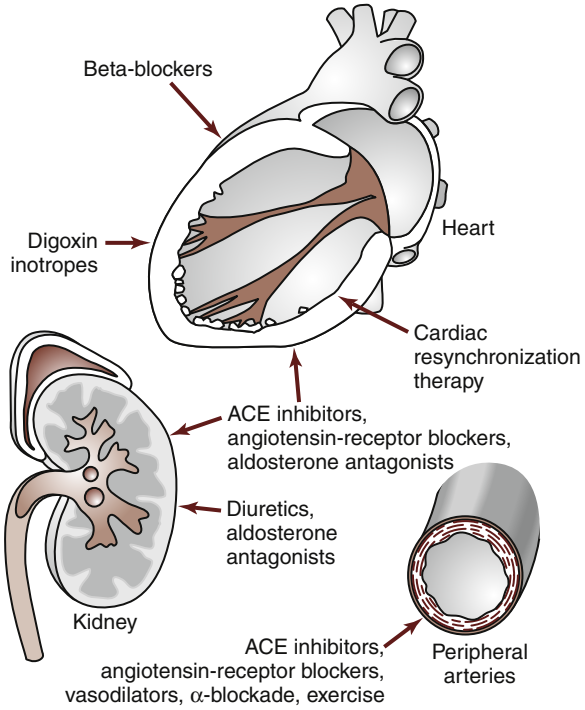

FIGURE **24-5** Pharmacologic treatments target the pathophysiologic changes caused by heart failure. Drug mechanisms produce one or more beneficial mechanisms including decreased preload, afterload, heart rate, blood pressure, deleterious ventricular hypertrophy and remodeling, sodium retention, and sympathetic stimulation. They improve renal and peripheral blood flow, reverse remodeling, and inotropicity. (From Jessup M, Brozena S. Heart failure. *N Engl J Med.* 2003;348:2007-2018.)

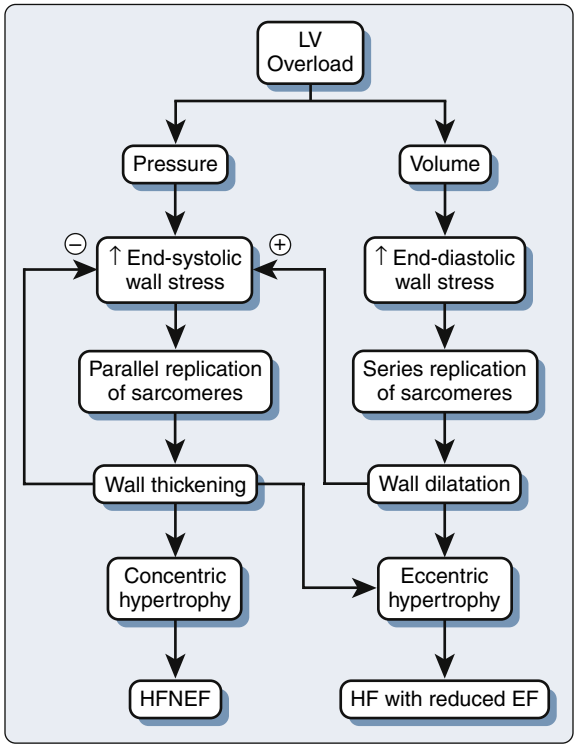

FIGURE **24-6** Left ventricular (LV) pressure and volume overload produce compensatory responses based on the nature of the inciting stress. Wall thickening reduces (−), whereas chamber dilation (+) increases, end-systolic wall stress as predicted by Laplace's law. LV pressure-overload hypertrophy has been linked to heart failure with normal ejection fraction (HFNEF), but LV volume overload most often causes heart failure (HF) with reduced ejection fraction (EF). (From Kaplan JA, Reich JA, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia: Saunders; 2011.)

renin-angiotensin-aldosterone system (RAAS) induces a host of pathologic responses. Consequently, many patients will receive multimodal drug therapy aimed at interrupting the response and slowing disease progression[4] (Figure 24-5). Beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, and aldosterone antagonists can have a synergistic effect when combined with anesthetics. Although dealing with the resulting vasodilation and/or myocardial depression can be challenging for the anesthetist, medications used to control the patient's heart failure should be continued in the perioperative period because their benefit is well documented.[23,26-28] In fact, on the basis of multiple large-scale randomized, controlled clinical trials, it is estimated that 465 lives are saved for every thousand patients treated with a combination of beta-blockers, ACE inhibitors, and aldosterone antagonists.[29]

Left Ventricular Failure and Remodeling. In the face of sympathetic activation coupled with alterations in perfusion, pressure, and volume, the heart changes its size, shape, and function; that is, it *remodels* itself in an attempt to maintain cardiac output. *Supply* ischemia causes an increase in ventricular compliance (dilation) and a decrease in contractility, whereas *demand* ischemia reduces compliance (stiffening) without initially impacting contractility.[22,23] The primary characteristics of remodeling are hypertrophy or dilation, myocyte death, and increased interstitial fibrosis. The clinical impact manifests as a change in systolic and diastolic function. Figures 24-6 and 24-7 help summarize and visualize the process.

Systolic Dysfunction. As demonstrated in Figure 24-7, *A*, *supply ischemia* resulting in myocardial infarction, or chronic volume overload of the left ventricle causes *eccentric* hypertrophy or dilation. The chamber size increases in an attempt to preserve stroke volume. In the dilated state, the heart loses its normal elliptical football shape and becomes more spherical, resembling a basketball.[4] In this shape, the heart is unable to contract effectively (systolic dysfunction) and the mitral apparatus is stretched potentially to a point that results in mitral regurgitation (MR). Of patients with heart failure, 35% to 50% will experience MR.[30] The degree of systolic dysfunction is commonly expressed as ejection fraction (EF). The EF is calculated as stroke volume (SV) divided by end-diastolic volume (EDV). According to the American Society of Echocardiography's guidelines, normal EF is 55% or greater, and dysfunction is graded as mild (45%-54%), moderate (30%-44%), and severe (less than 30%). When SV is reduced, the body compensates by activating the SNS to raise the resting heart rate in an effort to maintain cardiac output. Systolic heart failure (SHF) is caused by CAD, dilated cardiomyopathy (DCM), chronic volume overload (regurgitant valves, high output failure), and the later stages of chronic pressure overload (aortic stenosis and chronic hypertension). Myocardial infarction causes regional defects that can eventually encompass the entire myocardium, whereas other causes of heart failure typically reduce global function from the onset.[26] As shown in Figure 24-6, SHF is associated with a volume overload of the left ventricle that is managed using multiple drug therapies as shown in Figure 24-5.

Diastolic Dysfunction. Diastolic dysfunction is a more difficult concept to explain, but one that is equally important.

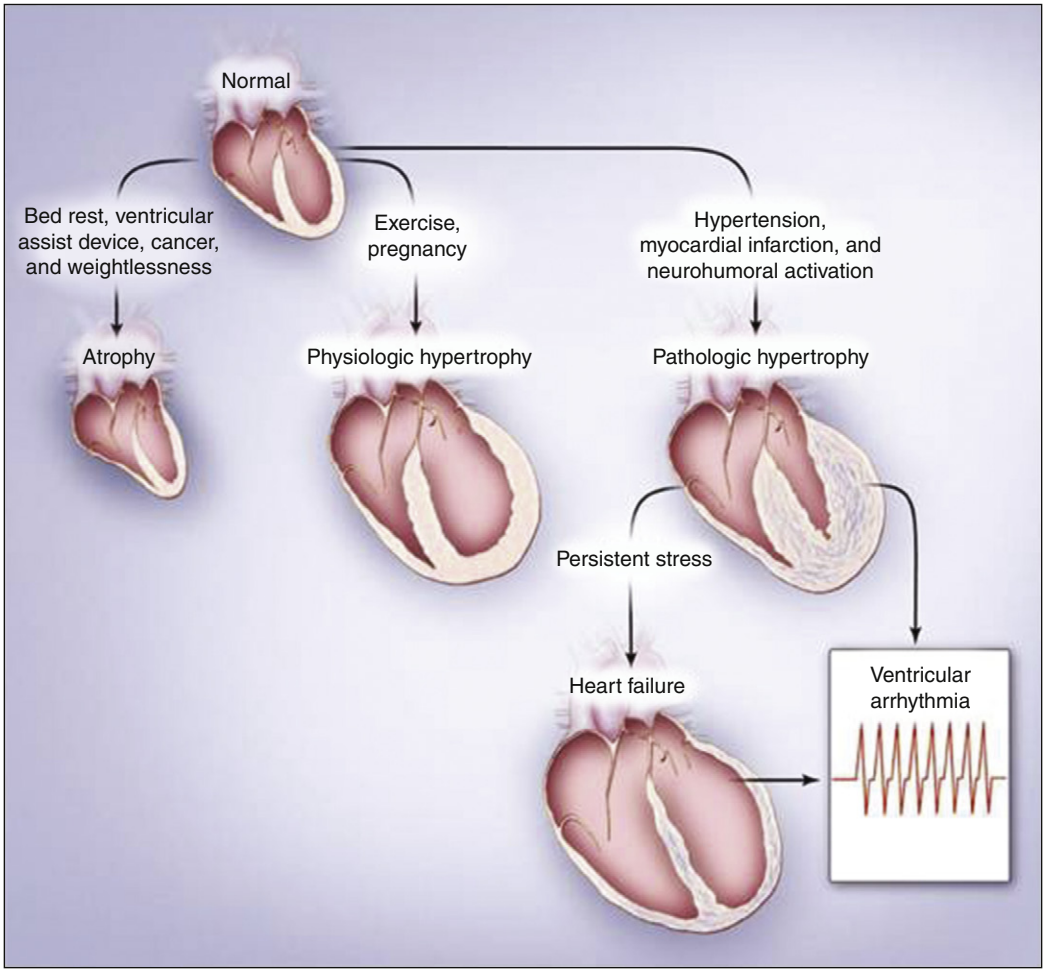

FIGURE **24-7** Conditions leading to remodeling of the heart and resulting in atrophy or hypertrophy. Depending on the circumstances, remodeling can be normal or pathologic. Pathologic remodeling is associated with a propensity toward decompensation, ventricular dilation, systolic dysfunction, and electrophysiologic changes leading to malignant ventricular arrhythmia. (From Hill JA, Olson EN. Cardiac plasticity. *N Engl J Med.* 2008;358:1370-1380.)

Pulmonary congestion and all the symptoms of heart failure can indeed develop with a normal EF. In fact, diastolic heart failure (DHF) is often called *heart failure with preserved EF* (greater than 40%) (see Figure 24-6). *Demand ischemia*, resulting from chronic pressure loads from stenotic heart valves, obstructive cardiomyopathy, chronic hypertension, or obesity, causes the myocardium to thicken (*concentric hypertrophy*) and compliance to decrease (see Figure 24-7).[4,284] Pulmonary congestion develops because the fibrosed, nondistensible LV, with an increased LVEDP, is unable to fill adequately despite near-normal systolic function. Diastolic failure is graded class I to IV based on echocardiographic examination findings.[31] The hypertrophied LV is prone to ischemia; therefore maintenance of a high MAP and slow normal heart rate is crucial.[32] Hypotension should be treated promptly, usually with phenylephrine to avoid rapid decompensation that can potentially lead to cardiac arrest. In the hypertrophied heart, chest compressions rarely generate enough pressure to perfuse the noncompliant LV. The mortality and hospitalization rates are similar in both systolic and diastolic failure. Table 24-3 compares the characteristics of patients with systolic and diastolic failure, and Table 24-4 outlines the anesthetic management strategies for systolic and diastolic dysfunction. Oftentimes, as DHF progresses, SHF will develop and the two will co-exist.[26]

Right Heart Failure. Right heart failure (RHF) is most often secondary to left heart failure (LHF), but can also be caused by pulmonary hypertension or a right-sided infarct. RHF causes systemic venous congestion, hepatomegaly, and peripheral edema.[23,26] Management of RHF can be more difficult to manage than left-sided failure because fewer options exist for unloading and supporting the right ventricle. The goal in managing RHF is to improve contractility while reducing right heart afterload. Thus anything that would increase right heart afterload should be avoided, including hypercarbia, hypoxemia, acidosis, and similar conditions that can potentially cause pulmonary hypertension. Nitrous oxide can cause pulmonary hypertension so it, too, should be avoided. Normally the right heart is perfused throughout the cardiac cycle (see Figure 24-3); however, when the right ventricle is distended, coronary perfusion occurs primarily during diastole as it does in the left ventricle.

Cardiopulmonary Bypass

Principles

Most cardiac surgeries must be accomplished with the aid of cardiopulmonary bypass (CPB). The machine is operated by a perfusionist, but it is imperative that the anesthetist have a clear understanding of the components and physiologic impact of CPB.

The purpose of CPB is to provide a motionless, bloodless heart for the surgical procedure. This goal is achieved by temporarily diverting venous blood away from the heart to an extracorporeal circulation that adds oxygen and removes CO_2 and then filters it before returning it to the body, most often via the ascending aorta. The CPB circuit is continuous with the systemic circulation and provides artificial ventilation, perfusion, and temperature regulation while diverting the blood from the surgical field. The technique results in stopping nearly all blood flow to the heart and lungs. To stop the heart's electrical activity and to protect it during the procedure, the heart is intermittently perfused and cooled with a chemical solution called *cardioplegia*. Although the goal is to provide near physiologic hemodynamics and acid/base balance, the technique is nonphysiologic. A near-normal cardiac index is usually maintained with an arterial flow of 2.0 to 2.4 L/minute/m^2, but it is nonpulsatile. There is some controversy over what is the most appropriate MAP on bypass, but most advocate no less than 50 to 60 mmHg. Older patients or those with known carotid disease should have a higher MAP, closer to 60 to 70 mmHg, to assure that there is adequate cerebral perfusion pressure.[9] The patient's blood and components are exposed to nonendothelial surfaces, which increase the incidence of platelet dysfunction and coagulopathy. CPB incites a host of inflammatory responses; these are outlined after the discussion of the circuit components.

TABLE 24-3 Characteristics of Patients with Diastolic and Systolic Heart Failure

Characteristic	Diastolic HF	Systolic HF
Age	Often in the elderly	Usually 50-70 years
Gender	Often in females	Most often in males
EF	Preserved, greater than 40%	Depressed, less than 40%
LV cavity size	Normal with concentric LVH	Dilated with eccentric LVH
Chest x-ray	Congestion ± cardiomegaly	Congestion + cardiomegaly
HTN	+++	++
DM	+++	++
Previous MI	+	+++
Obesity	+++	+
COPD	++	0
Sleep apnea	++	++
Dialysis	++	0
Atrial fibrillation	+ Usually paroxysmal	+ Usually persistent
Gallop rhythm	4th Heart sound	3rd Heart sound

Basic Circuit

The CPB machine consists of five basic components: a venous reservoir, a main pump, an oxygenator, a heat exchanger, and an arterial filter (Figure 24-8). The following is a simple explanation of full CPB: (1) venous (deoxygenated) blood is drained from the right side of the heart and carried by tubing to a reservoir; (2) a pump then propels the blood to (3) an oxygenator and (4) a heat exchanger; and (5) the oxygenated blood passes through a filter before returning to the arterial circulation to perfuse the rest of the body. The modern bypass machine also performs several other functions, including delivering cardioplegia by means of accessory pumps. The heart is vented and blood is salvaged from the field by means of suction devices.

Cannulae. The CPB circuit includes cannulae and tubing made of medical grade polyvinyl chloride (PVC), with a biocompatible coating to decrease the inflammatory response associated with CPB and to preserve blood components. One or two "staged" (meaning more than one hole to drain the blood) venous cannulae are used to remove the deoxygenated blood from the heart. A large-bore *two-stage* or *multistage* cannula that drains blood from both the right atrium and the inferior vena cava is used for CABG and aortic valve procedures in which the heart is actually closed and small amounts of retained blood will not interfere with the surgery (Figure 24-9). Open-cavity procedures, such as mitral, pulmonic, and tricuspid valve surgery, or procedures that repair defects such as atrial septal defects (ASD),

TABLE 24-4 Anesthetic Considerations for Systolic and Diastolic Dysfunction

	Systolic Dysfunction	Diastolic Dysfunction
Preload	Already ↑, avoid overload, especially coming off pump NTG helps reduce preload and ↑ subendocardial perfusion	Volume will be needed to stretch noncompliant LV Evaluate with echo as LVEDP falsely ↑
Contractility	Reduced →, avoid agents that cause further reductions May need inotropic support	Usually good, but caution with agents that suppress function Does NOT tolerate hypotension
Afterload	Reductions will enhance forward flow as long as coronary perfusion pressure maintained SNP works well if volume is adequate	Already ↑ Higher MAP needed to perfuse thick myocardium Treat hypotension aggressively with phenylephrine
Heart rate	Usually high normal due to sympathetic activation	Slow normal to maximize diastolic time for coronary perfusion and ↓ MvO_2 Prone to ischemia Maintain SR →; cardiovert early
CPB	Expect large pump volumes Consider ultrafiltration, diuretic	Pump volume normal

↓, Decreased; ↑, increased; →, therefore; *CPB*, cardiopulmonary bypass; *LVEDP*, left ventricular end-diastolic pressure; *MAP*, mean arterial pressure; MvO_2, myocardial oxygen consumption; *NTG*, nitroglycerin; *SNP*, sodium nitroprusside; *SR*, sinus rhythm.

patent foramen ovale (PFO) defects, or ventricular septal defects (VSD) all require a bloodless field. For such procedures, two separate venous *single-stage* cannulae are individually inserted into the superior and inferior vena cava, and the vessels are snared with elastic loops to prevent systemic venous blood from entering the heart (Figure 24-10). This technique is also known as *bicaval* cannulation.

Prime. *Prime* is the fluid used to fill the CPB circuit and components. It is composed of an isotonic balanced electrolyte solution, such as lactated Ringer's, Plasmalyte-A, or Normosol-R, that closely matches the principal ionic composition of blood. During setup, the perfusionist must take great care to de-air the circuit. Traditionally the priming volume for the CPB is 1 to 2 L. However, the development of minimally invasive cardiac procedures required the use of smaller cannulae and tubing to enable the surgeon to visualize the field. Medications and other solutions are often added to the prime for a variety of purposes; for example, colloid to decrease postoperative edema, blood to treat anemia, mannitol to promote diuresis, heparin to ensure adequate anticoagulation, and bicarbonate to treat acidosis. When the prime fluid is added to the circulating blood volume, a dilutional anemia occurs, and it is not unusual for the hematocrit to fall to 22% to 25%. The dilution offsets some of the increase in blood viscosity that occurs when the blood cools during CPB.

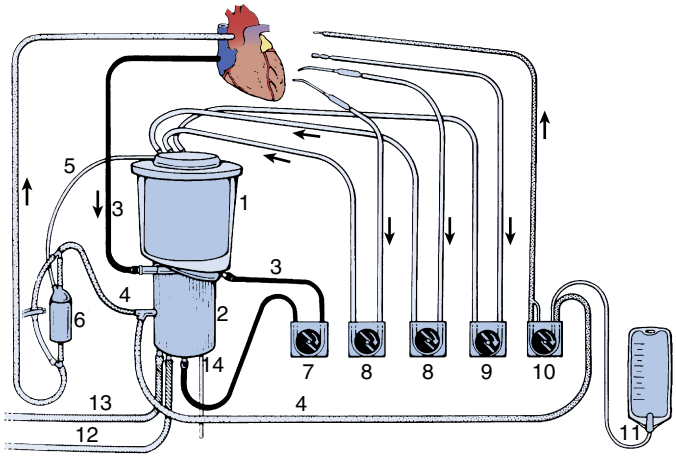

FIGURE **24-8** Components of the extracorporeal circuit. *(1)* Integral cardiotomy reservoir; *(2)* membrane oxygenator bundle; *(3)* venous blood line; *(4)* arterial blood line; *(5)* arterial filter purge line; *(6)* arterial line filter; *(7)* venous blood pump (also called the *arterial pump head*; this pump forces venous blood through the membrane oxygenator and arterialized blood to the patient's aortic root); *(8)* cardiotomy suction pump; *(9)* ventricular vent pump; *(10)* cardioplegia pump; *(11)* crystalloid cardioplegia; *(12)* water inlet line; *(13)* water outlet line; and *(14)* gas inlet line. (From Davis RB, Kauffman JN, Cobbs TL, Mick SL. *Cardiopulmonary Bypass*. New York: Springer-Verlag; 1995.)

Venous Reservoir. Venous reservoir (Figure 24-8 *[1]*) CPB is initiated when the perfusionist removes a clamp that occludes the tubing connecting the venous cannulae to the venous reservoir. The venous reservoir is typically hard-shelled and divided into two compartments, one for the venous drainage from the heart and the other for the blood suctioned or vented directly from the surgical field. This portion of the reservoir is known as *cardiotomy*; it is discussed in detail later. Traditionally blood drains from the patient to the reservoir by gravity. The rate of venous drainage is determined by the size and placement of the cannulae, height of the bed, and the patient's intravascular volume. With the introduction of minimally invasive techniques, gravity drainage was inadequate due to the small cannulae and tubing, so the practice of vacuum-assist venous drainage (VAVD) was established. A vacuum regulator is added to the venous reservoir with a piece of Y tubing and a pressure of −40 mmHg is applied. This Y tubing is used to turn on the suction or open the system to atmospheric pressure. Improved drainage can facilitate surgical exposure and decrease the necessity of adding more crystalloid and/or blood to the CPB circuit. The inherent risks include hemolysis of blood cells and air embolism. VAVD at a suction of −40 mmHg causes less hemolysis than when the suction is increased to −80 mmHg.[33] It is critical that the fluid level in the venous reservoir be kept sufficiently high to prevent air from entering the main pump and causing an air embolism. An alarm is incorporated into the venous reservoir to alert the perfusionist if the fluid level drops

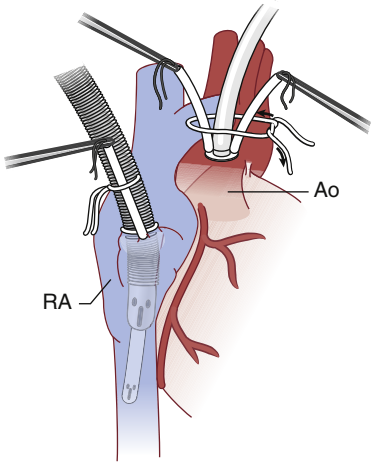

FIGURE **24-9** Aortic (Ao) and single, double-staged, right atrial (RA) cannulation. Notice the drainage holes of the venous cannula in the right atrium and inferior vena cava. (From Connolly MW. *Cardiopulmonary Bypass*. New York: Springer-Verlag; 1995.)

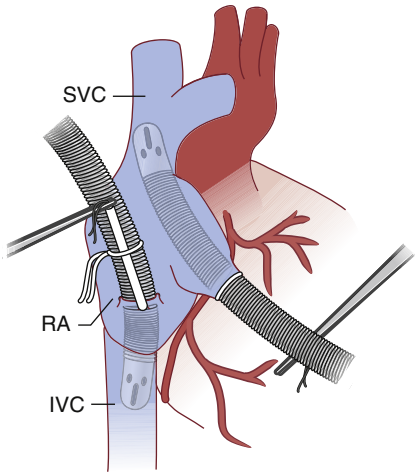

FIGURE **24-10** Position for two-vessel cannulation of the right atrium (RA) with placement of drainage holes into the superior vena cava (SVC) and inferior vena cava (IVC). The aortic cannula is not shown. (From Connolly MW. *Cardiopulmonary Bypass*. New York: Springer-Verlag; 1995.)

below a specific level. The perfusionist may add fluid and medications to the venous reservoir.

Main Pump. Blood is propelled through the CPB machine by an electrical pump (Figure 24-8 *[7]*). Two types of pumps are available. A *roller pump* produces flow by subtotally compressing large bore tubing against a tract and propelling the blood forward. Constant nonpulsatile flow is produced that is directly proportional to the number of revolutions per minute of the roller heads regardless of arterial resistance in the circuit. A *centrifugal pump* uses a magnetically controlled impeller that rotates rapidly, causing a pressure drop that causes blood to be sucked into the housing and ejected. A major difference between the two pumps is that the flow from the centrifugal pump will vary with changes in preload and afterload. For this reason, a flowmeter must be attached to the arterial side of the pump. The roller pump is economical and simple to use; however, unlike the centrifugal pump, it has the disadvantage of increasing the destruction of blood elements. As a result, centrifugal pumps are replacing roller head pumps in contemporary practice. In the event of a power failure, a hand crank can be used to operate either pump.

Oxygenator. The oxygenator performs the functions of oxygenating venous blood and removing carbon dioxide (CO_2) (Figure 24-8 *[2]*). In the past, bubble oxygenators were used, but today only membrane oxygenators are in use. The membrane oxygenator is a coated bundle of hollow microporous polypropylene fibers tightly wound to create a large surface area. Blood flows around the tightly packed fibers and gas flows through the fibers. The gas, consisting of oxygen or a mixture of oxygen and medical-grade air, diffuses passively across the membrane and into the blood. The oxygen level in the blood can be controlled by changing the Fio_2. The amount of CO_2 removed from the blood is controlled by changing the liter gas flow rate or "sweep" of gas through the oxygenator. Volatile anesthetic can also be added to the fresh gas inlet that enters the oxygenator.

Heat Exchanger. The blood enters a heat exchanger either separately or in combination with the oxygenator (Figure 24-8 *[2]*). The heat exchanger is usually made of stainless steel tubes with heated or cooled water flowing through them. Blood flows around the tubes and the temperature is adjusted to the desired level. Traditionally patients were cooled in an effort to protect the heart and other vital organs during CPB. Today, active cooling is less common. Instead the patient's temperature is allowed to naturally drop or *drift* while the surgery is performed. The patient is then actively rewarmed in preparation for the termination of CPB.

For some procedures, the patient is actively cooled to decrease the metabolic rate. This process is discussed later in the chapter under the heading "Surgery on the Ascending Aorta and Aortic Arch." As the patient is rewarmed, gas solubility decreases, and it is possible for air bubbles to form in the CPB circuit. Consequently, the oxygenated blood passes through a filter before it is returned to the patient.

Arterial Filter. Finally, the blood passes through an arterial filter before returning to the arterial cannula and the rest of the body (Figure 24-8 *[6]*). The arterial filter has a pore size of 21 to 40 μm and acts as an air bubble trap and particulate filter preventing thrombi, fat globules, calcium, and tissue debris from entering the circulation. The arterial cannula is most often placed in the ascending aorta, but alternate sites include the femoral or the subclavian artery.

Accessory Pumps and Devices

Cardiotomy and Basket Suction. As illustrated in Figure 24-8, the perfusionist also operates several accessory roller pumps (generally located to the right of the main pump), used to control suction devices and deliver cardioplegia. An assistant helps improve the surgeon's view by aspirating blood from the surgical field using a Yankauer or other suction tip. A "basket" type suction device can be placed in an open cardiac cavity to help drain the blood (Figure 24-8 *[8]*). This *shed* blood can then be returned to the patient in one of two ways. First, the blood can be returned to a portion of the venous reservoir known as the *cardiotomy*. The cardiotomy portion of the venous reservoir has a separate integrated filter that defoams the blood and removes air and debris that is picked up by the suction tip (*pump sucker*) used in the surgical field. Blood returned via the suction may contain fat, bone, and other debris. For that reason some surgeons prefer to return this blood to a separate cell-saver reservoir. Cell-saver blood is later centrifuged, washed, and returned to the patient. Research shows that systemic inflammatory markers decrease when shed blood is not returned to the patient undergoing CABG on CPB.[34,35] Using a cell-saver device instead of returning blood to the venous reservoir reduces the inflammatory response.[36] The disadvantage of this approach is that the volume of blood in the pump is reduced, especially if there is significant bleeding. If bleeding is a problem, the cell-saver blood can be washed and returned to the venous reservoir.

Left Ventricular Vent. The LV vent is a catheter placed in the left ventricle through the right superior pulmonary vein for the purpose of draining blood that accumulated in the cavity (Figure 24-8 *[9]*). Although blood is diverted from the heart during CPB, over time blood enters the LV from the bronchial arteries (which arise directly from the aorta or the intercostal arteries) or Thebesian vessels (coronary veins that drain directly into the heart). Blood and cardioplegia can also fill the LV if the patient has aortic insufficiency. This volume can cause the LV to distend, raise LVEDP, and compromise preservation by opposing the cardioplegia flow into the coronary arteries. Prior to inserting the vent, it is placed in a bowl of water to confirm that it is suctioning rather than blowing because accidental blowing of the vent could lead to an air embolism The vented blood returns to the cardiotomy.

Cardioplegia Pump. The perfusionist controls the infusion of cardioplegia by means of an accessory roller pump (Figure 24-8 *[10]*). A separate heat exchanger allows the temperature, as well as rate and pressure, to be controlled. Cardioplegia is discussed further in the section on myocardial preservation.

Anticoagulation

Systemic anticoagulation is *always essential* prior to cannulation and initiation of CPB. Without anticoagulation, clots can form in the pump that can lead to serious neurologic injury or death. Heparin, derived from porcine intestinal mucosa or bovine lung, is the preferred anticoagulant for cardiac surgery. It is a mucopolysaccharide that potentiates circulating antithrombin (AT III). It binds to AT III and increases its inhibitory action on the procoagulant effect of thrombin by 1000-fold. Heparin increases the speed of the reaction between AT III and multiple clotting factors including II, IX, X, XI, XII, and XIII. The standard cardiac dosage is 300 to 400 units/kg, administered preferably through a central intravenous line. Adequate anticoagulation is measured most commonly with point-of-care testing that includes activated clotting times (ACT) or heparin concentration assays (Hepcon). A baseline ACT is obtained sometime prior to heparin administration. The normal value is approximately 80 to 120 seconds. The ACT is measured 3 to 5 minutes after heparin administration. An ACT of more than 400 seconds (or more than 480 seconds, in some centers) is necessary before CPB is initiated. The lower limit ACT of 400 was determined in 1978 using monkeys on CPB. This level prevented the appearance of fibrin monomers in the CPB circuit.[37]

A heparin concentration monitor (Hepcon) can be used in place of, or in addition to, the ACT measure. The Hepcon generates a heparin dose response (HDR) curve that can then be used to calculate the most appropriate dose of heparin to initiate CPB and maintain an adequate anticoagulation level during bypass. The amount of protamine needed to reverse the heparin after bypass is also calculated. The level of anticoagulation should be checked every 20 to 30 minutes during bypass so that more heparin can be given as needed to maintain a safe level of anticoagulation.

Patients who have been recently exposed to heparin may become "heparin resistant" and require higher doses of heparin to obtain therapeutic anticoagulation. Heparin resistance is defined as an ACT of less than 380 seconds despite administration of 400 units/kg of intravenous heparin.[9] ATT III deficiency should be suspected if the patient does not become anticoagulated with additional heparin administration. ATT III deficiency can be treated empirically with 2 units of fresh frozen plasma, AT III concentrate, or recombinant AT III (rh AT III). Recombinant AT III has been shown to be effective in reducing heparin resistance by increasing circulating AT III without exposing patients to FFP.[38]

Heparin-induced thrombocytopenia (HIT) is an immune reaction that occurs as a direct consequence of exposure to heparin. A comprehensive review of this disorder is found in Chapter 34. The 14C-serotonin release assay (SRA) and an enzyme-linked immunosorbent assay (ELISA) that detects antibodies to the platelet factor 4 (PF4) are used to definitively diagnose the disorder. For patients with a history of HIT, but a negative HIT antibody screen at the time of cardiac surgery, the American College of Chest Surgeons guidelines recommend the use of heparin only during CPB. There is a decreased risk of a patient being rediagnosed with HIT if the prior diagnosis of HIT was greater than 100 days before the scheduled cardiac surgery. Use of an anticoagulant other than heparin is recommended in the preoperative and postoperative period. In all cases, there should be no heparin added to the flush solution or heparin lock intravenous ports, and heparin-bonded catheters are avoided. Surgery should be postponed if feasible in patients with acute HIT and those who are antibody positive (subacute HIT). If urgent surgery is required, an alternative thrombin inhibitor such as bivalirudin or lepirudin is preferred. A secondary alternative is to block platelet activation using aspirin and an antiplatelet drug such as epoprostenol or tirofiban, and then proceed with heparin administration intraoperatively. [39]

Myocardial Preservation

Mild to moderate systemic hypothermia and cold cardioplegia are used for myocardial preservation. The patient can be actively cooled by the CPB circuit or his or her temperature can be allowed to *drift* toward the ambient room temperature. Some surgeons cool the heart topically by packing icy slush around it. The goal is to achieve hypothermic diastolic circulatory arrest to decrease the metabolic rate, oxygen consumption, excitatory neurotransmitter release, and to preserve high-energy phosphate substrates.[9] The brain also benefits from the hypothermia and may be at least partially shielded from neurologic injury as a result. The cerebral metabolic rate decreases 6% to 7% for every degree Celsius decrease in brain temperature.

A hyperkalemic crystalloid solution mixed with blood is the most commonly used cardioplegia solution today. The ratio of the mix varies, but is most often a 4:1 blood to crystalloid solution. The exact composition in the mixture of cardioplegia solution is variable, but the first dose (*induction dose*) is cold (2° C to 5° C) with 20 to 30 mEq/L of potassium. Maintenance doses are also cold and contain 12 to 16 mEq/L of potassium. The goal is to maintain myocardial temperature between 8° C and 10° C.[40] Just before releasing the aortic cross-clamp, many surgeons administer a single terminal dose of warm blood (37° C) cardioplegia (TWBC). This so-called "hotshot" contains metabolic substrates (i.e., glucose, glutamine, and aspartate), which have been found to accelerate myocardial recovery from global ischemia.[41] The amount of cardioplegia given in any single dose can be based on time, volume, or myocardial temperature according to the surgeon's preference. It is generally redosed every 15 to 20 minutes while the aorta is clamped. ECG activity and/or an increase in myocardial temperature indicate that cardioplegia may need to be redosed sooner.

There are two possible approaches to delivering cardioplegia: *antegrade*, that is, down the coronary arteries; or *retrograde*, via the coronary sinus and cardiac veins. The first dose of cardioplegia is usually antegrade, and it is given just after placement of the aortic clamp. A catheter is inserted into the aortic root, just proximal to the aortic clamp, and cardioplegia is administered into the root and flows antegrade down the coronary arteries. Hypothermic diastolic circulatory arrest usually follows in 1 to 2 minutes depending on how well the heart is perfused. Antegrade cardioplegia can also be given directly down the coronary ostia when the aorta is opened for surgeries that involve the aorta or aortic valve. In CABG surgery, it is also infused directly into the new vein or arterial bypass grafts once the distal anastomosis is completed. Maintenance cardioplegia is administered every 15 minutes so the heart remains asystolic. Myocardial preservation is occasionally incomplete because the cardioplegia does not reach the entire myocardium either because the coronaries are blocked by atherosclerotic disease or because the solution has leaked into the left ventricle because of an incompetent aortic valve. When myocardial preservation is inadequate, there may be difficulty achieving diastolic arrest and electrical activity may reappear on the electrocardiogram (ECG) between doses of cardioplegia. Additionally, the fluid that leaks into the left ventricle when the patient has AI can cause the ventricle to distend. The increased pressure caused by the distension opposes the antegrade flow of the cardioplegia in the coronaries, thereby increasing the risk of myocardial ischemia. The purpose of the left ventricle vent is to suction out this fluid and prevent distension. In these cases, retrograde cardioplegia can significantly improve myocardial preservation. In fact, many surgeons choose to maximize myocardial protection by routinely giving both antegrade and retrograde cardioplegia.

In the *retrograde* approach, a catheter is blindly inserted into the right atrium and advanced into the coronary sinus, the largest venous drainage vessel of the heart. To place the catheter, the surgeon often lifts the heart to help locate the sinus and advance the catheter. If this catheter is placed before CPB, lifting and manipulation of the heart frequently results in dysrhythmias and hypotension. It is not unusual for this maneuver to cause atrial fibrillation (AF). Synchronized cardioversion of the AF may be required if the patient becomes hemodynamically unstable. Once the catheter is in place, cardioplegia is administered to the myocardium in a retrograde fashion through the cardiac veins. Retrograde perfusion protects the myocardium that is distal to the coronary obstructions.

Blood Conservation

According to the Society of Thoracic Surgeons (STS) database, 50% of cardiac surgical patients receive a blood transfusion.[42] Currently 10% to 15% of the nation's blood supply is used for patients having cardiac surgery. The risks of transfusion are well documented (see Chapter 20), and blood transfusions during cardiac surgery are associated with worse short-term and long-term

survival.[43,44] Additionally, the donor blood supply is either stable or decreasing.[45,46] Blood is considered a finite, scarce, and expensive resource, and there is a national effort to limit its use. Three preoperative risk factors have been linked to bleeding and blood transfusion: (1) advanced age (70 years or older); (2) low red cell volume either from preoperative anemia and/or small body size; and (3) urgent or complex surgery involving prolonged CPB times.[47]

In 2011 the STS and the Society of Cardiovascular Anesthesiologists (SCA) published instructions for blood conservation in clinical practice guidelines.[47] Practitioners of cardiac anesthesia are encouraged to review this important document; this chapter discusses only the highlights. The recommended techniques that promote the conservation of blood and blood products include the administration of antifibrinolytics, blood salvage, limiting the quantity of pump prime, ultrafiltration when appropriate, and the development of multidisciplinary blood management teams.

Antifibrinolytics. Antifibrinolytics are commonly administered to cardiac surgical patients requiring CPB. Use of antifibrinolytics reduces surgical bleeding and decreases the incidence of blood transfusion.[47] Aminocaproic acid (Amicar) and tranexamic acid (Cyklokapron) are both lysine analogs that inhibit plasmin, the key enzyme in the fibrinolytic cascade. Both drugs form a reversible complex with plasmin that then inhibits fibrinolysis or the natural breakdown of clot. Dosing regimens vary, but a common recommendation for aminocaproic acid is a 50 mg/kg bolus over 20 to 30 minutes followed by an infusion of 25 mg/kg/hr into the immediate postoperative period. A standard dosing regimen of tranexamic acid is 10 mg/kg over 20 minutes followed by 1 to 2 mg/kg/hr maintenance infusion into the immediate postoperative period. Dosing regimens vary among institutions. Tranexamic acid is known to be 5 to 10 times more potent than aminocaproic acid, but also more expensive. The use of aprotinin, a kallikrein inhibitor, was suspended in the United States in 2007 after an increase in mortality was noted in comparison to the other antifibrinolytics in the *B*lood Conservation Using *A*ntifibrinolytics in a *R*andomized *T*rial (BART).[48]

Blood Salvage. Blood that is suctioned from the surgical field while the patient is not on CPB, as well as the residual blood that remains in the CPB circuit at the end of bypass, should be directed into a centrifugal red-cell salvage device. As previously discussed, the blood aspirated from the field during CPB can return to the pump cardiotomy or to the cell-salvage reservoir depending on the surgeon's preference. The *shed* blood is kept in a reservoir until it reaches a quantity specified by the device manufacturer, and then it is washed, a process that removes the serum, coagulation factors, and platelets. The red cells are preserved and placed in a bag that can then be infused into the patient. Cell-salvaged blood has a hematocrit of about 55% to 70%. Infusing large quantities of salvaged blood can contribute to a dilutional coagulopathy, because this blood is devoid of coagulation factors and platelets. Contraindications to the use of salvage include infection and the use of topical hemostasis agents. Malignancy used to be considered a contraindication to salvage. However, the new guidelines state, "In high-risk patients with known malignancy who require CPB, blood salvage using centrifugation of salvaged blood from the operative field may be considered because substantial data supports benefit in patients without malignancy and new evidence suggests worsened outcome when allogeneic transfusion is required in patients with malignancy." Blood shed from mediastinal chest tubes can also be salvaged, washed, and reinfused.[47]

Limiting Pump Prime. Traditionally, the addition of pump prime to the patient's blood volume at the initiation of CPB resulted in significant hemodilution. Several mechanisms have been devised that help limit the volume of pump prime. Minicircuits that require a smaller volume of pump prime are available and should be considered for patients at high risk for anemia. Vacuum-assisted venous drainage in conjunction with these minicircuits has also proved helpful. Retrograde autologous priming (RAP) is a perfusion technique in which the CPB prime is displaced by passive exsanguination (back-bleeding) through the arterial and venous lines back into an empty bag that is out of the main circuit prior to initiating CPB. This means that once the primed CPB circuit is attached to the arterial and venous cannulae, the blood is allowed to back up, filling the circuit, and the crystalloid prime fluid is discarded. A recent meta-analysis found that RAP significantly reduces allogenic blood transfusion for adult cardiac surgery patients that require CPB.[49]

Ultrafiltration. Ultrafiltration is a process in which the perfusionist diverts the patient's blood to a hemultrafilter made of hollow capillary fibers that act as a membrane to separate the aqueous portion of blood from the cellular and proteinaceous elements. The aqueous portion is then discarded while the red cells and coagulation factors are *hemoconcentrated*. Ultrafiltration raises the hematocrit, so the technique is most often performed in an effort to prevent transfusing a patient who has a low hemoglobin level. An adequate pump volume is needed for ultrafiltration. When a patient is volume overloaded preoperatively, there is excess volume in the pump, and ultrafiltration can be used to remove the excess volume.[9]

Of course, the most critical questions are "What to transfuse, and when?" Even the 2011 STS/SCA Blood Conservation Guidelines do not provide clear answers to these complicated questions. Oxygen-carrying capacity is extremely important in cardiac surgical patients, but research has not been able to elucidate what hemoglobin (Hgb) level correlates with organ failure or long-term adverse outcomes. The guidelines suggest transfusion for patients on CPB with a hemoglobin of 6 g/dL or less, but a higher hemoglobin may be justified in patients at risk of decreased cerebral oxygen delivery. If the patient's hemoglobin is greater than 6 g/dL and the patient's clinical situation (including comorbidities, clinical setting, and laboratory or clinical data) warrants transfusion, it is reasonable to transfuse earlier.[47] Based on the increased age and comorbidities of the typical cardiac surgical population, it is generally accepted to keep a patient's hematocrit in the 22% to 25% range. Another recommendation is that a multidisciplinary team be created to manage blood resources.[47]

Physiologic Effects of Cardiopulmonary Bypass

Despite improvements in perfusion, anesthesia, and cardiac surgery, patients are still at risk for developing organ dysfunction after CPB. CPB causes a systemic inflammatory response syndrome (SIRS) that potentially can impact every organ system of the body. The inflammatory response to CPB can be mild and asymptomatic or result in multiple organ dysfunction syndrome (MODS). SIRS and ischemia related to emboli or hypoperfusion at the end organ seem to be the common pathophysiologic mechanisms for organ dysfunction after CPB. The heart, brain, lungs, kidneys, and gastrointestinal system are all at risk for negative impact or trauma. Finally, hemostasis is impaired as related to CPB.

Systemic Inflammatory Response. Systemic inflammatory response syndrome (SIRS) is thought to be activated as a result of CPB when the blood is exposed to the foreign surfaces of the CPB

machine and ischemia-reperfusion injury or embolizations occur that cause the release of endotoxin primarily from the splanchnic hypoperfusion. Endothelium damage occurs and the cellular immune response is activated, as are the complement and coagulation cascades. When bypass is initiated, the body exhibits a marked stress response; cortisol, catecholamines, arginine vasopressin, and angiotensin levels are elevated. Large amounts of oxygen-free radicals are also produced. More research is needed into protective strategies. Some therapies may include corticosteroids, protease inhibitors, (e.g., Aprotinin—not available in United States at this writing), cyclooxygenase inhibitors (i.e., aspirin or nonsteroidal antiinflammatory drugs [NSAIDs]), free radical scavengers, and antioxidants.[50]

Heart. Myocardial injury can occur even when protection strategies seem adequate. The injury can vary from being asymptomatic with only an elevation of cardiac enzymes postoperatively to severe with a marked decrease in cardiac function that results in failure to separate from bypass. Substantial increases in cardiac enzymes resulting from the activation of SIRS and/or ischemic injury can occur from embolization and hypoperfusion during CPB. Due to the very nature of the surgery, cardiac insult and ischemia after CPB may occur even with use of myocardial protection techniques. The extension of myocardial injury may result only in mild elevation of cardiac enzymes postoperatively. However, severe myocardial injury may occur, resulting in failure to wean or separate from CPB. Myocardial injury manifested as increased cardiac enzymes after CABG has been shown to increase the risk of both early and late death.[51] Management strategies and devices that may become necessary after myocardial injury during cardiac surgery and bypass are discussed later in the chapter.

Brain. Injury to the brain or the central nervous system (CNS) after cardiac surgery is a devastating outcome for both the patient and his or her family. Neurologic deficits have been categorized into type 1 outcomes, which include death due to stroke/encephalopathy, stroke, coma, or transient ischemic attack (TIA) and type 2 outcomes, which include new deterioration in intellectual function such as confusion, agitation, disorientation, memory deficit, or seizure. A classic prospective study of 2108 CABG patients found the incidence of type 1 injury was 3.1% and the incidence type 2 was 3.0%. The patients who experienced the type 1 outcomes had a substantial increase in mortality, length of hospital stay, and need for long-term care.[52] Atherosclerotic disease of the ascending aorta is the biggest predictor for type 1 injury, but increased age is also predictive. Most of the type 2 outcomes have been shown to improve in the first 3 months after surgery.[53] Late cognitive decline of CABG patients that was originally attributed by many to CPB, has been shown to occur to the same degree in patients of similar age with CAD who have not undergone CPB.[54] TEE and epi-aortic echocardiography may diagnose atheroma in the aorta, and minimizing manipulation of the aorta may decrease the risk of this neurologic insult. Filters on the CPB circuit decrease embolic debris, and flooding the operative field with CO_2 is thought to decrease gaseous emboli. A wide array of neuroprotective strategies and CNS monitoring have been introduced into practice to combat the causes of post-CPB neurologic dysfunction; however, only the efficacy of hypothermia has been proven.

Lungs. Pulmonary complications after CPB can range from mild atelectasis that develops because the lungs are not ventilated on bypass to severe pulmonary dysfunction that was at one time known as *pump lung* but is now known as acute lung injury (ALI) or acute respiratory distress syndrome (ARDS) depending on the severity. Atelectasis and pleural effusions, which occur in 60% of cardiac surgery patients, are the most common injuries, but hemothorax, pneumothorax, and pulmonary edema may also occur.[40] Patients with chronic obstructive pulmonary disease (COPD) or any other preexisting respiratory disease are at increased risk for exacerbation of their existing pulmonary illness after CPB. Embolic insults, prolonged CPB, and the CPB-induced systemic inflammatory response, which causes an increase in pulmonary endothelial permeability, pose the biggest risk to the development of ALI and ARDS.[50]

Kidneys. Renal dysfunction manifested as acute kidney injury (AKI) is one of the major complications of cardiac surgery and serves as a major predictor of morbidity and mortality for postoperative cardiac surgical patients. Bove et al.[55] found 3.4% of 5068 patients who underwent cardiac surgery with CPB developed acute renal failure (100% creatinine increase) and 1.9% required renal replacement therapy. Hospital mortality was over 40% for the patients with acute renal failure (ARF) and increased to over 63% in patients who required renal replacement therapy. Optimizing cardiovascular volume status and cardiac output as well as limiting CPB time are suggested to decrease the incidence of ARF.

Gastrointestinal. System dysfunction is a relatively rare occurrence but significantly increases the incidence of perioperative myocardial infarction, renal failure, stroke, and even death.[56] Gastrointestinal dysfunction seems to also be affected by hypoperfusion and/or embolic events related to CPB. Splanchnic hypoperfusion causes the release of endotoxins that can initiate SIRS.

Coagulation. Even with adequate heparinization, CPB activates the extrinsic and intrinsic hemostatic pathways as well as fibrinolysis. Contact of the blood with the internal surface of the CPB circuit results in the activation of compliment, the coagulation cascade, platelets, plasminogen, and kallikrein. During CPB, platelets and clotting factors are first diluted and then denatured by the mechanical trauma from the bypass circuit and suction devices. Platelets and leukocytes are also activated by mechanical trauma. The end result is the development of coagulopathies that manifest as increased perioperative bleeding.

Anesthetic Considerations in the Perioperative Period

Preoperative Evaluation

Because of the serious nature of the primary disease and the high prevalence of comorbidities, all patients undergoing cardiac surgery should have a thorough preoperative evaluation, including a history of the patient's medical condition(s) and a complete physical examination. The preoperative assessment should focus on the cardiovascular system, but information must also be gathered and recorded about the airway as well as pulmonary, neurologic, endocrine, renal, hepatic, and hematologic functions.

Cardiovascular System. The medical record should be examined and the results of all cardiovascular tests noted. Table 24-2 summarizes many of the common tests and findings that are used to identify cardiac pathology. Ventricular function and a history of heart failure are important considerations that affect anesthetic choice, hemodynamic management, and requirements for pharmacologic support. The New York Heart Association's (NYHA) functional class of heart failure has prognostic significance and predicts postoperative quality of life. The American Heart Association (AHA) and American College of Cardiology (ACC) stages of heart failure emphasizes disease progression (Table 24-5).

Patients with a history of severe heart failure are likely to have a cardiac electronic implantable device (CEID) including

a pacemaker alone or in combination with implantable cardioverter defibrillators (ICDs). Many patients will have biventricular pacemakers for cardiac resynchronization therapy (CRT). CRT improves cardiac output, hemodynamics, heart failure symptoms, and quality of life.[57] All implantable devices should be evaluated prior to cardiac surgery, and the results of the device interrogation should be readily available.

Antitachyarrhythmia functions on AICDs (if present) and the rate response (if present) on pacemakers is most often suspended in the surgical suite just prior to surgery by reprogramming to prevent electrocautery-induced discharge.[58] Means for pacing and defibrillation are immediately available. Patients with ICDs have defibrillation pads placed prior to induction. The pads are positioned away from the generator to prevent damage to the device should defibrillation be necessary. A magnet must be available and the magnet response identified. In emergency situations, the magnet can most often be used to deactivate ICD devices and place most modern pacemakers in an asynchronous mode. If the programmed backup asynchronous pacing rate is less than 70, it is often advisable to have the pacemaker reprogrammed to a higher rate.[57]

Patients with CAD or aortic stenosis often have carotid disease and/or peripheral vascular disease (PVD) as well. The presence of PVD may limit the locations available for invasive monitoring. The presence of aortic disease can impact the surgeon's ability to cannulate or clamp the aorta. If alternate cannulation sites are selected, this too can impact invasive line placement. The blood pressure is kept within a relatively higher range in patients with carotid disease to ensure adequate cerebral perfusion pressure.

Comorbidities. For elective surgery, patient comorbidities should be optimized prior to the time of the operation. Multiple studies have correlated the following conditions with increased risk in the cardiac surgical population: diabetes mellitus, compromised renal function, depressed ventricular function, and heart failure.[59,60]

Diabetes mellitus and perioperative hyperglycemia are associated with increases in sternal wound infections, extended length of stay, recurrence of angina, postoperative mortality, and decreased long-term survival.[61-64] Given the increased risks associated with hyperglycemia, postoperative glucose control has become a Health and Human Services cardiac surgical care measure associated with Medicare reimbursement.[65] In 2009 the Society of Thoracic Surgeons (STS) developed evidence-based practice guidelines for blood glucose management in the perioperative period.[66] Highlights of the STS recommendations are found in Box 24-1.

Preoperative renal impairment is correlated with increases in morbidity and mortality. Despite research into reducing postoperative risk, thus far, only maintenance of normovolemia has proven effective in preventing further decline in renal function.[67]

Laboratory Studies. Laboratory studies that will assist in the perioperative period include a room-air arterial blood gas, electrolytes, serum blood urea nitrogen (BUN) and creatinine, fasting lipid profile, complete blood count, coagulation profile, hemoglobin A1c, and a fasting blood glucose. Any serum biomarkers drawn to evaluate ischemia, infarction, or failure should be noted. Methicillin-resistant *Staphylococcus aureus* (MRSA) infection has a low prevalence but high mortality associated with cardiac

TABLE 24-5 Comparison of the Primary Heart Failure Classifications

ACC/AHA HF Stage	NYHA Functional Class
A—At high risk for HF but without structural heart disease or symptoms	None
B—Structural heart disease without symptoms	I—Asymptomatic
C—Structural heart disease with prior or current symptoms	II—Symptoms with moderate exertion III—Symptoms with minimal exertion
D—Refractory heart failure requiring specialized interventions	IV—Symptoms at rest

BOX 24-1

Highlights of STS Perioperative Glucose Management Recommendations

Preoperative
- Hold oral hypoglycemic for 24 hours prior to surgery
- Hold nutritional insulin after dinner night before surgery
- Continue basal insulin dose (NPH dose may be cut ½ to ⅓)
- Check glucose level frequently day of surgery
- Maintaining glucose at 180 mg/dL or less is reasonable

Intraoperative
- Intermittent bolus acceptable if nondiabetic and glucose less than 180 mg/dL
- Continuous infusion preferred if glucose 180 mg/dL or greater
- Continuous infusion preferred for diabetics, maintain postoperatively
- Adjust infusion per institutional protocol with a goal of maintaining glucose at 180 mg/dL or less
- Check glucose level every ½ to 1 hour or more frequently

Postoperative in ICU
- Consult endocrinology for diabetic patients
- If glucose persistently greater than 180 mg/dL, continue infusion
- If patient in ICU more than 3 days, target should be 150 mg/dL or less
- Before stopping infusion, transition to subcutaneous insulin

In Step-Down or Floor
- Endocrinology to adjust basal and nutritional insulin doses
- General goal is 180 mg/dL or less after meals and 110 mg/dL or less fasting
- Restart oral hypoglycemic if target achieved and no contraindications

surgery. Preoperatively, nasal swab cultures are taken and those patients colonized with MRSA (≈ 3.9%) have vancomycin added to their antibiotic routine.[68]

Airway Assessment and Pulmonary Function. Airway assessment and pulmonary function deserve special attention. A plan must be developed to safely secure the airway and appropriately ventilate the patient. This is where the *art of anesthesia* care becomes evident. It can be especially challenging for the anesthetist to maintain hemodynamic stability in the face of a difficult airway, severe pulmonary hypertension, lung disease, or compromised ventricular function. A double-lumen tube and a pediatric fiberoptic scope are required for procedures performed through a thoracotomy incision. If prolonged postoperative ventilation is reasonably anticipated, a slightly larger endotracheal tube (ETT) aids mechanical ventilation and pulmonary toileting.

Surgical Risk. After collecting the aforementioned information, the preoperative team can estimate surgical risk. Risk-scoring schemes for cardiac surgery were first published in 1983. Today several validated scoring systems are available. Each system uses different demographic data, laboratory markers, and type of surgery to calculate risk. One of the most widely cited systems is the STS score. The STS maintains a robust national database that estimates the risk of operative mortality and morbidity after adult cardiac surgery on the basis of patient demographics and preoperative clinical variables. The risk calculator is accessible on the internet.[69] Risk can be calculated for primary procedures as well as combined CABG and single valve surgeries. The risk calculation includes overall morbidity and mortality, length of stay, risk of reoperation, and several other quality measures.

A somewhat simpler on-line risk analysis tool is the European System for Cardiac Operative Risk Evaluation.[70] The most recent version was released in October 2011. The validity and utility of one tool over the other is a subject of academic debate, but both are reliable; therefore use is institutionally specific. Seven variables—age, female gender, left ventricular function, body habitus, re-operation, type of surgery, and urgency of surgery—correlate with major risk across very diverse study settings.[66] In addition, the cardiac surgeon must also consider the extent of his or her training and clinical experience, and the breadth of professional support offered by his or her institution because these factors also have been correlated to risk.[71,72] In tertiary care centers specializing in cardiac care, there are likely to be many patients and procedures that exceed any risk model's ability to accurately calculate risk. Procedures such as re-operations for multiple valve replacement in a patient with endocarditis or placement of an assist device are not included in these models.

Management of Preoperative Medications. Cardiac surgical patients are likely to be on multiple medications to manage their primary disease and comorbidities. As a general rule, the patient should receive all of his or her usual long-term medications on the morning of surgery with a sip of water.[73] However, a few medications merit further discussion. Clinical research has demonstrated the benefit of perioperative beta-blocker therapy to improve hemodynamic stability, decrease dysrhythmias, and reduce morbidity and mortality.[74-76] As with postoperative glucose control, preoperative beta-blocker administration is now a Health and Human Services surgical care measure required for Medicare reimbursement.[65]

Medical management of heart failure includes the use of several drugs (see Figure 24-5). Controversy has arisen regarding administering angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) within 10 hours prior to induction. Some studies report moderate to profound intraoperative hypotension in patients who have received these drugs,[77-79] whereas other studies claim that the medications actually improve hemodynamic stability.[79-81] It is generally recommended that these medications be continued[9,73,82] and that hypotension be treated as needed. These medications also have been implicated as a cause of postoperative vasoplegic syndrome. Patients that seem resistant to Neo-Synephrine may exhibit increased responsiveness to small doses of norepinephrine (16 mcg) or vasopressin (1 unit).[83] (See Chapter 13 for a further discussion of vasoplegic syndrome.)

With regard to medications that affect coagulation, most institutions follow the STS recommendations.[47,84] A complete review of these recommendations is beyond the scope of this chapter, but a few important points are addressed as follows. Aspirin (acetylsalicylic acid [ASA]) and heparin are vital in the treatment of CAD, especially in patients with acute coronary syndrome. Heparin and ASA are administered to patients requiring emergency surgery, and heparin is continued until shortly before skin incision. Despite the proven therapeutic benefit of ASA, it is also associated with increased risk of bleeding; therefore the consensus guidelines recommend discontinuing ASA therapy 3 to 5 days before an elective procedure. ASA should be resumed early in the postoperative period because it improves graft patency and reduces mortality.[84] An alternative antiplatelet agent Clopidogrel (Plavix) blocks adenosine diphosphate (ADP)-mediated platelet activation by binding with the P2Y12 receptor. It should be withheld for 5 to 7 days before surgery, but "newer P2Y12 inhibitors are more potent than clopidogrel and differ in their pharmacodynamic properties. Point-of-care testing may help identify patients with incomplete drug response who can safely undergo urgent operations."[47] Because all of these medications increase the risk of bleeding, they should be discontinued 3 to 7 days before surgery depending on the individual pharmacodynamics. GPIIb/IIIa inhibitors also vary in their pharmacodynamics; the intravenous agent eptifibatide (Integrilin) should be discontinued 4 hours before surgery and patients should receive their last dose of abciximab (ReoPro) 12 hours before incision.[85]

Because cardiac surgical procedures are associated with significant blood loss, the anesthesia provider must confirm with all patients their willingness to accept blood products. In patients with specific religious beliefs or personal preferences, specific products that are permissible should be confirmed.[47]

Psychological Preparation and Preoperative Sedation. Because the cardiac operating room (OR) is a fast-paced, high-intensity environment, it is easy for the team to become task-oriented, inadvertently overlooking the emotional needs of the patient. Patients facing major surgery are acutely aware of their mortality and often apprehensive about the procedure and pain. Concerns about the future of their families and others who might be dependent upon them and what those loved ones would do if they (the patients) were not there to support or care for them are common. The preoperative interview provides a unique opportunity to gather needed data and share information to allay their fear. This visit will also help establish rapport and address the patient's and family's concerns. Patients who are mentally prepared will be more calm, confident, and cooperative in the OR and in the intensive care unit (ICU).

Preoperative sedation is selected on an individual basis, considering the patient's functional status and anxiety level. Generally patients with normal LV function and few comorbidities can tolerate heavier sedation, whereas the frail are lightly sedated. Sedation should not be so heavy as to prevent coherent patients from

participating in the identification and interview process. When in doubt, sedation is withheld preoperatively and then administered in the OR while the patient is monitored during line placement.

Preparation for Surgery

Operating Room Preparation. The surgical suite should be readied in preparation for the planned surgical incision before the patient's arrival. Communication with the surgical and perfusion teams is essential to ensure that all parties are ready to act appropriately if the patient should rapidly deteriorate requiring emergent surgical intervention and/or institution of cardiopulmonary bypass. The basic set-up and monitoring is similar to most major cases, with a few additions as outlined in Table 24-6.

Monitoring. Standard and extended monitors for cardiac surgery are listed in Table 24-6. ECG monitoring should include lead II for detection of dysrhythmias and lead V_5 with automated ST analysis for detection of ischemia. The ECG is limited because it cannot detect posterior wall ischemia and is less sensitive than

TABLE 24-6 Typical Anesthesia Preparation of the Cardiac Operating Room

Anesthesia Machine	Routine Check	
Airway	Nasal cannula or mask as needed Facemask, laryngoscope handle and blades Oral airways and appropriate endotracheal tubes Suction (Yankauer and endotracheal) Ambu bag and any anticipated difficult airway equipment	
Vascular Access	Large-bore PIV cathether (14 or 16 gauge preferred) 2nd PIV catheter on a warmer for complex cases or expected blood loss Arterial line (radial or brachial based on institutional preference) R may be preferred for LITA conduit L may be preferred for "redo's" if R subclavian cannulation Avoid side of radial artery conduit and sites distal to prior brachial cut-down for cardiac catheterization Central Venous Access CVP for normal LVF and primary, simple cases PAC with cardiac output for poor LVF and complex surgery	
Monitors	**Standard Monitors**	**Extended Monitors**
	BP (noninvasive + invasive) ECG (II, V_5 + automated ST analysis) Pulse oximetry Capnography Temperature (core ± peripheral) CVP Urine output Intermittent arterial blood gases (ABGs) Neuromuscular blockade monitor Machine with cassettes for monitoring anticoagulation (ACT or HepCon) Paper or electronic medical record	PAC Specialized PACs (pacing, etc.) Cardiac output measurement Mixed venous saturation TEE Left atrial pressure Infrared absorption spectrophotometry BIS monitoring Cerebral oximetry Retrograde coronary sinus cardioplegia perfusion pressure Spinal drain (intrathecal) pressure
Medications	Anesthetic Sedation Line placement (midazolam) Transport to ICU (propofol or dexmedetomidine) Induction (propofol or etomidate) Muscle relaxant (succinylcholine for difficult airway + nondepolarizing) Narcotic (fentanyl, sufentanil, or remifentanil) Inhalation Heparin (300-400 units/kg in a syringe) Vasoactive Bolus: Nitroglycerine, phenylephrine, ephedrine, epinephrine, atropine, ± calcium Infusions on pumps: Aminocaproic acid or tranexamic acid Nitroglycerin (NTG) for patients with CAD or volume overload Sodium nitroprusside (SNP) for patients with HTN, regurgitant valve lesions, or systolic HF Inotrope (epinephrine or dobutamine) for patients with poor left or right ventricular function Vasopressor for septic or vasoplegic individuals Insulin	
Miscellaneous	Pacemaker with battery Warm water mattress or forced-air warming device with appropriate blanket

TEE for detection of ischemia. Core temperature can be recorded using esophageal or nasopharyngeal probes or the pulmonary artery catheter (PAC). If deep hypothermic arrest is planned, the nasopharyngeal recording most accurately reflects brain temperature. To avoid excessive nasopharyngeal bleeding, the probe should be placed at the beginning of the case before heparinization. A peripheral temperature monitor (bladder or rectal) is useful to compare core and shell temperatures during cooling and rewarming.

Arterial Line (A-Line). It is generally safest to place the arterial line (A-line) before induction, using sedation as tolerated and local anesthesia for patient comfort. A noninvasive blood pressure cuff should be placed as a backup monitor in case of arterial line malfunction. The A-line can be used to obtain a blood gas with the patient breathing room air or the supplemental oxygen being used before surgery. This will provide an estimate of lung function and can assist providers when weaning the patient from mechanical ventilation in the postoperative period.

Most importantly, the A-line will provide an instantaneous and continuous monitoring of hemodynamics during induction of anesthesia. This is crucial when the patient has life-threatening cardiac pathology, including severe aortic stenosis, left main coronary artery disease, severe pulmonary hypertension, or moderate to severe decreased left or right ventricular function. In stable patients with less severe disease, the A-line can be placed shortly after induction. The choice between placing a brachial or radial A-line is usually made on a personal or institutional preference. Radial artery cannulation is considered safer secondary to redundant blood flow to the hand via the ulnar artery. However, the radial pressure waveform may dampen during sternal and/or chest wall retraction as a consequence of subclavian artery compression between the clavicle and first rib, especially during dissection of the internal thoracic artery. Additionally, radial A-lines should not be placed below the site of a previous brachial cut-down (for prior cardiac catheterization) because they are prone to thrombosis and waveform distortion. Hence, some providers prefer the brachial artery because it is a more reliable measure of central aortic pressure before and after cardiopulmonary bypass (CPB).[86,87] Although concerns for thrombosis persist, the safety of its use in heparinized patients has been well documented.[87,88] The surgeon may wish to avoid aortic cannulation if the patient has aortic atheroma. As an alternative to aortic cannulation, the right subclavian artery is often cannulated. The right subclavian artery also may be used for redo sternotomy if the surgeon is concerned about inadvertently damaging cardiac structures during opening. In cases of right subclavian cannulation, the A-line is usually placed in the left upper extremity. If the radial artery is being removed as a conduit for CABG, the A-line must be placed in the opposite arm or in the ipsilateral brachial artery proximal to the antecubital fossa. Occasionally other cannulation sites must be considered, most commonly the femoral artery.

Central Venous Access. A central venous access is mandatory in cardiac surgery for volume resuscitation and administration of vasoactive medications. The right internal jugular vein is the preferred cannulation site because it is relatively easy to access and provides a straight, short course to the right atrium. If the left internal jugular vein is used, the anesthetist must be careful to avoid the thoracic duct and the left brachiocephalic vein, which crosses the internal jugular vein at a right angle. Some providers prefer to use a short introducer on the left for this reason. Catheters placed in the external jugular or subclavian vein, especially on the left, are prone to kinking during chest wall retraction. The use of ultrasound to guide placement is becoming increasingly common, especially if the patient has had prior neck surgery or has carotid atherosclerosis. Studies suggest decreased rates of infection and complications when ultrasound is used.[89]

A pulmonary artery catheter (PAC) is frequently placed instead of a central venous pressure (CVP) monitor when more hemodynamic information is desired. Although considered an extended monitor, it is quite useful because changes in intracardiac pressures can be monitored (Table 24-7) and cardiac output measured using thermodilution. The information obtained can then be used to derive several other hemodynamic parameters to assist patient management (Table 24-8). Generally, a PAC is preferred in patients who are undergoing complex surgery or procedures in which large volume shifts are anticipated, or who have left ventricular systolic or diastolic dysfunction, pulmonary hypertension, or right ventricular failure. During CPB, the PAC can advance and become wedged; therefore it is recommended that the catheter be retracted 2 to 3 cm during this time and the baloon inflated slowly after weaning from bypass. To avoid the possibility of pulmonary artery damage or rupture in patients that receive full heparinization, some providers avoid wedging completely and base management on the PAEDP. Special precautions must be taken when a PAC is placed in a patient with a left bundle branch block (LBBB). About 3% of the time, the patient develops complete heart block (CHB) because the catheter causes a right bundle branch block (RBBB) as it enters the right ventricular outflow tract.[90] If a PAC must be placed in a patient with a LBBB, defibrillation/pacing pads should be prophylactically placed before insertion of the catheter. Alternatively, the catheter can be left in the superior vena cava until the chest is open, and then advanced. If CHB does develop, rapid CPB is an option.[91] PACs should generally be avoided in patients that have had pacemaker leads placed in the past 6 weeks because of the possibility of lead displacement.[57] If a PAC is deemed necessary, pacemaker pads for external pacing are placed prior to insertion. Occasionally in cardiac surgery, specialized PACs are useful, including those that can pace or continuously measure mixed venous saturation or cardiac output. In cases in which large blood loss or volume shifts are anticipated, a 9-French two-lumen introducer is useful.

Transesophageal Echocardiography. Transesophageal echocardiography (TEE) requires extensive specialized training, but it has become an invaluable source of information about anatomy

TABLE 24-7 Normal Intracardiac Pressures

Location	Mean (mmHg)	Range (mmHg)
Right atrium	5	1-10
Right ventricle	25/5	15-30/0-8
Pulmonary arterial systolic/diastolic	23/9	15-30/5-15
Mean pulmonary arterial	15	10-20
Pulmonary capillary wedge pressure	10	5-15
Left atrial pressure	8	4-12
Left ventricular end-diastolic pressure	8	4-12
Left ventricular systolic pressure	130	90-140

and function during cardiac surgery. It is the most sensitive clinical monitor for detecting wall motion abnormalities caused by myocardial ischemia. Additional uses include evaluation of right and left systolic and diastolic ventricular function, valvular area, function and pathology, intravascular volume status, intracardiac air, aortic atheroma and dissection, and to guide catheter or cannula placement. Unless there is a contraindication, the 2010 American College of Cardiology (ACC)/American Heart Association (AHA)/American Society of Echocardiography (ACE) practice guidelines recommend TEE for all open chamber (e.g., valvular) procedures and catheter-based valvular procedures. The guidelines also state that TEE should be considered for coronary artery bypass graft surgeries as well.[92] The only absolute contraindications to TEE are pathologic conditions of the esophagus including strictures, diverticula, tumors, traumatic interruption, or recent suture lines. A complete study encompasses at least 20 views and is completed before CPB by a credentialed provider to identify baseline pathology and function. This is then used for comparison after bypass to immediately evaluate the surgical repair(s) and identify new pathology or dysfunction after cardiopulmonary bypass. Although even an introductory discussion of TEE is beyond the scope of this chapter, a basic understanding of TEE is valuable for nurse anesthetists to help them monitor ventricular function and intravascular volume status. More advanced diagnoses are best made by credentialed providers.

The use of other extended monitors is related to personal preference (e.g., bispectral index [BIS] monitor) or case requirement (e.g., spinal fluid pressure in descending thoracic aneurysms). Although the BIS monitor has not been shown to reliably prevent recall,[93] the trend is useful in detecting changes in anesthetic depth. Occasionally during times of hemodynamic instability, the inhalation agent is titrated down during the resuscitation. The BIS can serve as a reminder to the practitioner(s) to administer a medication to prevent recall.

Selection of Medications. An enormous body of information has accumulated regarding the cardiovascular effects of various anesthetic agents. The most significant considerations are highlighted here. Traditionally the choice of anesthetic has been based primarily on preexisting ventricular function and comorbidities, coupled with the desired length of action. However, the same anesthetic combination may cause different responses in patients with similar histories and hemodynamic profiles. Therefore the combination of medications selected for the anesthetic is far less important than the skill and judgment with which they are administered.

Volatile Anesthetics. Volatile anesthetics can potentially cause myocardial depression, vasodilation, and hypotension. They lower the arrhythmogenic threshold to catecholamines[94] and do not provide pain relief in the postoperative period. Consequently, they are often combined with a narcotic in a balanced technique. Inhalation agents are now considered beneficial because of their preconditioning effect. A recent meta-analysis demonstrated for the first time that the choice of an anesthetic regimen based on administration of halogenated anesthetics is associated with a better outcome after cardiac surgery than a total intravenous technique.[95] Most cardiac surgical patients will benefit from the myocardial protection of volatile agents; the exception may be those with severe LV dysfunction who cannot tolerate any further cardiac depression. Desflurane is a potential concern because sudden increases in inspired concentration can lead to tachycardia and hypertension that can be detrimental in patients who have CAD, hypertrophic cardiomyopathy, or stenotic valvular lesions. Desflurane and nitrous oxide raise pulmonary vascular resistance, pulmonary artery pressure, and wedge pressure.[96] Nitrous oxide should be avoided just before, during, and after CPB because of the potential for expansion of air introduced into the circulation during bypass. Nitrous oxide also may cause catecholamine release and LV dysfunction. The use of nitrous oxide in noncardiac surgery was associated with increased long-term risk of myocardial infarction.[97]

The trend today favors fast-track or early extubation in cardiac surgery because decreased length of stay translates into reduced cost without increases in adverse outcomes.[98,99] Thus the goal of early extubation, generally within 6 hours, is now a major consideration in the selection of medications. Early extubation can be achieved using a variety of techniques, including low- to moderate-dose narcotics (fentanyl 5-20 mcg/kg or sufentanil 2-10 mcg/kg) combined with a volatile agent or total intravenous anesthesia with short-acting drugs such as remifentanil, propofol, or dexmedetomidine.

Opioids do not cause myocardial depression, and they maintain stable hemodynamics. Consequently, a high-dose narcotic technique (fentanyl 100-200 mcg/kg) was popularized in past decades. Problems with the technique included significant bradycardia, recall, chest wall rigidity, and prolonged intubation. Today moderate doses of the fentanyl derivatives are most popular, but

morphine, hydromorphone, and other narcotics also can be used effectively. A primary narcotic technique is reserved for hemodynamically unstable patients.

Sedation. Sedation prior to induction can be accomplished with low doses (1-5 mg) of midazolam. Caution is advised because the combination of a benzodiazepine and fentanyl-type drugs reduces systemic vascular resistance (SVR) and myocardial depression leading to hypotension. Sedation for transport to the ICU is often facilitated with infusions of propofol or dexmedetomidine.

Induction Agents. Induction of anesthesia can be accomplished with any of the agents alone or in combination with narcotics, volatile agents, or benzodiazepines. Etomidate causes less myocardial depression than propofol; therefore it may be preferable for patients who have reduced left ventricular function. A large review of studies involving single-dose etomidate induction versus other standard induction agents showed an increase in adrenal insufficiency in critically ill patients.[100] If adrenal insufficiency is suspected, a dose of steroid such as hydrocortisone 100 mg may be administered. Etomidate and propofol may cause pain with injection, but this can be blunted with prophylactic IV lidocaine or narcotic.

Muscle Relaxants. Muscle relaxants are needed to facilitate tracheal intubation, prevent movement during cannulation, and to attenuate shivering and skeletal muscle contraction from defibrillation. Most nondepolarizing muscle relaxants used today lack significant cardiac effects except for pancuronium, which is longer acting and vagolytic. The increased heart rate is potentially detrimental in patients with CAD, hypertrophic cardiomyopathy (HCM), or valvular stenosis, but beneficial in patients with regurgitant valvular lesions. Choice of relaxant is based on the airway examination, patient history, and procedure length. Succinylcholine is often preferred for difficult airways.

Antibiotic Prophylaxis. The STS has published guidelines for antibiotic prophylaxis in cardiac surgery. A beta-lactam antibiotic (cephalosporin) is the prophylactic antibiotic of choice (Class 1A) for cardiac surgical patients who are *not* at increased risk for MRSA. Cefazolin 1 g (or 2 g for patients weighing more than 60 kg) IV is recommended every 3 to 4 hours while the surgical incision is open. Cefuroxime 1.5 g IV is another alternative. Patients at increased risk for MRSA (known or presumed), including those undergoing an operation using prosthetic valvular or vascular material, should have vancomycin 1 to 1.5 g (or 15 mg/kg weight adjusted) added. Patients with known beta-lactam allergy should be dosed with vancomycin as above, and an aminoglycoside such as gentamicin 4 mg/kg should be added for gram-negative coverage. Redosing of vancomycin and the aminoglycoside are not recommended. The guidelines also recommend that the antibiotic should be administered within 1 hour of incision or 2 hours for vancomycin.[101]

Intraoperative Management

This section focuses on management of general cardiac surgery from the time the patient enters the OR until his or her care is safely transitioned to the ICU team. What follows is a sequential description of events that occur during most cases, so that the anesthetist can gain an understanding of important perioperative milestones. The rationale for pharmacologic and hemodynamic management, as well as patient monitoring, was discussed previously. Management of specific cases and specialized equipment follow.

The cardiothoracic OR is a fast-paced, high-intensity environment where up to a dozen practitioners must focus for extended periods. The patient population is high risk because of the prevalence of multiple comorbidities in addition to the primary cardiac pathology. The surgical procedures can be quite complex, and manipulation of the heart and vasculature can profoundly impact hemodynamic function. Thus the anesthetist is required to intently focus on both the surgical procedure and the patient's response to widely varying levels of stimulation. Problems must be anticipated and interventions prompt. Throughout the process, communication between the anesthesia, surgical, nursing, and perfusion teams is critical. Failure to communicate can have devastating consequences. Closed-loop communication, the practice of clearly repeating back information when one team member makes a request of another, is imperative for safety.

Precardiopulmonary Bypass Period. The precardiopulmonary bypass period refers to the period beginning when the patient arrives at the operating suite and ends when the patient is on cardiopulmonary bypass (CPB.) A review of the patient's preoperative vital signs and cardiac function will help the anesthetist determine the "normal" range for that particular individual. The general goal during the period is to maintain hemodynamic stability. Individual hemodynamic perturbations must be considered within the context of the patient's baseline status. For example, a patient with an acceptable heart rate, mean arterial pressure (MAP), oxygen saturation, and arterial pH does not need an inotropic agent if the cardiac index is below the "normal range." In this particular instance, general anesthesia reduces oxygen demand, and the decreased cardiac output is probably adequate to meet demand. Starting an inotrope to increase the cardiac index within the normal range (higher than 2.2 L/min/m^2), might paradoxically lead to ischemia by increasing myocardial oxygen demand.

The prebypass period is marked by periods of variable stimulation. The most intense stimulation occurs at intubation, incision, sternal split and spread, sympathetic nerve dissection, pericardial incision, and aortic cannulation. Hypertension and tachycardia that occur as a result of inadequate analgesia or sympathetic activation can lead to ischemia, dysrhythmias, or heart failure. The anesthetist must anticipate these events and consider a preemptive dose of narcotic and/or an increase in the concentration of the volatile agent. Hyperdynamic individuals may also need the addition of a short-acting beta antagonist, such as esmolol (0.1-0.5 mg/kg) or an intravenous infusion of a titratable vasodilator such as nitroglycerin or sodium nitroprusside to treat the adrenergic response to these events. During the remainder of the prebypass period, including preincision and the harvesting of conduit, there is little stimulation and the blood pressure and heart rate tend to decrease. Hypotension and bradycardia may decrease coronary perfusion pressure and lead to ischemia; oftentimes intermittent boluses of phenylephrine or ephedrine are used to support coronary perfusion.

Preinduction Period. During the preinduction period, the patient is interviewed before entering the OR to confirm proper identification and the information reviewed from the preoperative assessment. The airway is reexamined and the patient is interviewed to ascertain whether there have been any changes in the patient's medical condition, with a particular focus on worsening symptoms and recent infectious illness. Medications taken within the last 24 hours are recorded. The interview also gives the anesthesia provider an opportunity to assess patient anxiety, communicate expectations, and provide emotional support.

Once in the OR, the patient is moved to the OR table and standard monitors are applied (see Table 24-7). Some institutions use external, adhesive defibrillation pads for those patients that may require emergent defibrillation, that is, patients with a history of ventricular tachycardia or those with an automatic implantable cardioverter defibrillator. Pulse oximetry volume should be

loud enough to provide an audible warning to the clinician in case of decreasing oxygen saturation while the clinician's attention is focused on another task. Some centers routinely administer supplemental oxygen during the preinduction phase whereas others use oxygen as needed. A large-bore peripheral intravenous catheter (14 or 16 gauge) is placed using local anesthesia for patient comfort. Patients with normal left ventricular function will often benefit from supplemental sedation, especially if invasive monitors need to be placed. The decision as to the location and timing of invasive monitoring was previously discussed in the monitoring section of the chapter. Once the arterial line is placed, a baseline arterial blood gas (ABG) and activated clotting time (ACT) are measured. Central cannulation is most often deferred until after induction, but regardless of the timing, baseline measurements including the cardiac output are recorded after placement. When the patient and all teams (nursing, perfusion, surgery, and anesthesia) are prepared, induction can commence.

Induction and Intubation. The plan for induction is based on the length and complexity of the proposed procedure as well as multiple patient-specific considerations including cardiac pathology, comorbidities, ventricular function, and the airway examination. No combination of induction medications has proven superior in cardiac anesthesia. Rather the artful skill each practitioner uses to administer preferred drugs to achieve hemodynamic stability and block the stimulating effects of laryngoscopy is most important. Most often a combination of a sedative, hypnotic, opioid, volatile agent, and muscle relaxant with or without lidocaine, and a beta-blocker are used. Achieving hemodynamic stability can be especially challenging when a difficult airway must be secured, or when 100% oxygen has been advocated for cardiac surgery to maximize O_2 tensions, but a lower inspired concentration may prevent absorption atelectasis and reduce the risk of oxygen toxicity. Because inhalation anesthetics have been correlated with improved outcomes in cardiac anesthesia (most likely because of the preconditioning effect), they are usually included in the maintenance plan**.** Patients with severe LV dysfunction may require a primary narcotic technique because all inhalational agents cause some degree of myocardial depression and afterload reduction.

Preincision Period. The preincision period is generally not very stimulating, therefore the anesthetic level often needs to be reduced and occasional boluses of phenylephrine may be required for hemodynamic support. A second PIV is inserted if necessary and central access obtained. Use of a multiple-access large-bore introducer should be considered for redo sternotomy patients and other cases in which large volume shifts are anticipated. The stomach is decompressed with an oral gastric tube before placement of the TEE probe. It is important to ensure the TEE probe is not in the locked position prior to insertion and a generous amount of water-soluble jelly is placed in the oropharynx to facilitate placement. The combination of a tongue and jaw lift together with turning the head slightly to the right usually helps the probe advance smoothly to the 30-cm marking. To prevent damage to the esophagus, never use force in placing the TEE probe. The TEE examination is completed by a credentialed provider. The urinary catheter, which often incorporates a temperature monitor, is inserted and a nasopharyngeal temperature probe (if used) is placed.

Next, the patient is carefully positioned and pressure points are padded. All routine positioning precautions apply, along with some areas of special concern. Brachial plexus injury can occur if the arms are hyperextended or chest wall retraction is excessive. Brachial and radial artery or nerve compression can occur if the upper arm is compressed by the ether screen or the post used to support the chest wall retractor during dissection of the internal thoracic artery (ITA). The heels and sacrum are prone to ischemia, especially during long procedures with hypothermia, so commercial foam dressings can be prophylactically applied. Occipital alopecia is a common problem that develops in the weeks after surgery; the head should be on a well-padded surface and repositioned frequently during the operation.

After final positioning the anesthetist should reconfirm the position of the endotracheal tube. The antibiotic infusion should be completed (vancomycin may take longer) and the antifibrinolytic agent initiated. Proper placement of monitors and lines should be verified, transducers should be balanced, and given the multiple access ports and IV's used in cardiac surgery, stopcocks should be neatly secured for easy access. Hemodynamic parameters, blood gasses, and blood chemistry are all rechecked and any abnormalities treated. Hypokalemia is not typically treated during the pre-CPB period because cardioplegia solution contains significant amounts of potassium. Insulin infusions may be required to lower the serum glucose level, especially in those with diabetes mellitus. The STS guidelines recommend that blood glucose should be treated for levels greater than 180 mg/dL intraoperatively in both diabetic and nondiabetic patients (see Box 24-1).[94] Insulin should be titrated cautiously to avoid dramatic changes in serum glucose.

Incision to Bypass. The incision to bypass period begins with intensely stimulating events: incision, sternotomy, and sternal spread. The anesthetist should prepare for these events by deepening the anesthetic and administering additional muscle relaxant if needed. The highest rate of recall in cardiac surgery has been recorded during this period; therefore an amnestic can be given if not previously administered. The lungs should be deflated during sternotomy to decrease the risk of cardiac or pulmonary laceration.

Repeat, or redo sternotomy requires greater preparation and vigilance. Patients that have had a prior CABG may have an arterial or venous bypass graft lying directly beneath the sternum. Patients that have had prior chest radiation (often for breast cancer or lymphoma) can also have adherent scar tissue that is difficult to dissect. In these situations, the surgical team will examine the patient's lateral radiograph and possibly a magnetic resonance image (MRI) or computed tomography (CT) scan to determine the proximity of the cardiac structures to the sternum. If the heart appears to be adherent to the sternum, there are several management options for sternotomy and dissection. Some surgeons may expose the femoral vessels so they can quickly cannulate and institute CPB if arterial or cardiac trauma occurs at sternotomy, whereas other surgeons will cannulate before sternotomy and institute CPB during dissection (the heart is not arrested and continues beating). An oscillating saw is used for slow, cautious sternotomy. Communication between the surgeon and anesthetist is crucial, because the lungs may need to be deflated several times for short periods. In the rare event that a cardiac structure or great vessel is entered and bleeding becomes uncontrollable, intravenous heparin (300-400 units/kg) should be administered centrally. If the patient is not already cannulated, the surgeon will emergently place the arterial cannula in the femoral artery or aorta and the cardiotomy suckers will be used for venous return in what is sometimes called "sucker bypass." Blood pressure should be kept high enough to maintain adequate coronary perfusion, yet hypertension should be avoided to minimize excess bleeding. Crystalloid or colloid can be administered if necessary, but hemodilution will exacerbate preexisting anemia. Packed red blood cells should always be prepared and ready for rapid transfusion in all redo sternotomies because the potential for inadvertent vascular injury is significantly increased, as previously discussed.

After sternotomy, the conduit will be harvested if the procedure involves a CABG. The anesthetic considerations related to conduit are reviewed later in the chapter during the discussion of CABG. If no conduit is required, the heart and vascular structures are dissected as individual exposure requirements of the surgical procedure dictate. The period of harvesting and dissection is generally less stimulating so anesthetic levels can be reduced. Often dissection requires considerable manipulation of the heart and vasculature that can result in hypotension and dysrhythmias. Vigilance is required on the part of the anesthetist so the surgeon can be alerted when excessive manipulation results in hypotension and/or dysrhythmias. Hypotension usually responds to placing the patient in Trendelenburg position (head down) and administering small doses of phenylephrine. The surgeon may ask for ventilation to be held and the lungs deflated to improve the surgical view. When the lungs are down, it is recommended that the anesthetist either leave the ventilator alarm sounding or keep his or her hand on the anesthesia bag as a reminder to resume ventilation. Inadvertent failure to ventilate is a real hazard in cardiac anesthesia that can have devastating consequences. Both sympathetic nerve dissection and opening of the pericardium are additional stimulating events that may require increased levels of anesthesia. After the anterior pericardium is opened, it may be lifted (especially in the ministernotomy approach) and sutured to improve the surgical view. This surgical maneuver is likely to cause bradycardia and hypotension because the position of the heart in the pericardium is changed, decreasing venous return with activation of the parasympathetic nervous system. Most patients respond to small doses of phenylephrine or ephedrine, but occasionally the anesthetist must ask the surgeon to decrease tension on the pericardial sutures. After the pericardium is opened, surgical preparation for cannulation is begun.

Cannulation. Cannulation is the next major event in the prebypass period. Full heparinization is essential before cannulation. Heparin (300-400 units/kg) should be administered through a central line after aspiration of blood confirms line patency and to ensure intravascular administration. The ACT or heparin concentration assay should be checked 3 to 5 minutes after the heparin is administered. Muscle relaxation is given if needed because movement during cannulation could prove disastrous. The aortic cannula is placed first, followed by the single venous cannula or double venous cannulae (see Figures 24-9 and 24-10). Then the antegrade and retrograde cardioplegia cannulae may be inserted, or the surgeon may wait until after CPB is initiated.

Surgical manipulation of the heart and great vessels during cannulation often leads to hypotension and dysrhythmias; therefore careful attention and clear communication between the anesthetist, surgeon, and perfusionist are critical. Before the aortic cannula is placed, blood pressure should be decreased to a systolic blood pressure (SBP) of 90 to 100 mmHg or a MAP less than 70 mmHg to decrease the risk of aortic dissection. To achieve this goal, the anesthetic level can be deepened or vasodilators can be carefully titrated. The aortic cannula and aortic line from the CPB machine should be connected and inspected, and all air bubbles should be purged. Complications of aortic cannulation include arterial dissection, hemorrhage, plaque or air embolization, and inadvertent placement of the distal tip of the cannula in an aortic arch vessel. Once aortic cannulation is completed, the perfusionist will confirm intraarterial placement of the arterial cannula by verifying pressure variation in the manometer connected to the aortic line (called *checking the swing*) and administer a test transfusion to confirm normal flow into the cannula. The anesthesia provider may then allow the blood pressure to increase by either decreasing the anesthetic or discontinuing vasodilators. The perfusionist can give volume through the aortic line to augment MAP.

BOX 24-2

Preparation for Bypass: Prebypass Checklist

1. Anticoagulation
   a. Heparin administered
   b. Desired level of anticoagulation achieved
2. Arterial cannulation
   a. Absence of bubbles in arterial line
   b. Evidence of dissection or malposition?
3. Venous cannulation
   a. Evidence of superior vena cava obstruction?
   b. Evidence of inferior vena cava obstruction?
4. Pulmonary artery catheter (if used) pulled back
5. Are all monitoring/access catheters functional?
6. Transesophageal echocardiograph (if used)
   a. In "freeze" mode
   b. Scope in neutral/unlocked position
7. Supplemental medications
   a. Neuromuscular blockers
   b. Anesthetics, analgesics, amnestics
8. Inspection of head and neck
   a. Color
   b. Symmetry
   c. Venous drainage
   d. Pupils

From Grocott HP, Stafford-Smith M, Mangano CT. Cardiopulmonary bypass management and organ protection. In: Kaplan JA, et al. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Saunders; 2011.

Next the venous cannulae are placed. Again the anesthetist should watch for hypotension, dysrhythmias, or hemorrhage. Once placement is completed, the perfusionist may initiate the RAP (retrograde autologous priming) process. As described earlier, this process requires an increased blood pressure. Finally, the surgeon may choose to place the retrograde cardioplegia cannula. Because this is done by palpation of the coronary sinus, a posterior structure, it almost inevitably leads to hypotension and dysrhythmias. For this reason, some surgeons place this cannula after bypass has been initiated. The retrograde cannula is sometimes connected to a pressure transducer to watch the mean. The baseline retrograde pressure is generally reflective of venous pressure and should increase about 20 mmHg when retrograde cardioplegia is infused. If the retrograde pressure is low, it could indicate the cannula has fallen into the atria; if it is too high (greater than 40 mmHg), the catheter could be positioned too distally, increasing the risk of coronary sinus rupture. Box 24-2 contains a preparation-for-bypass checklist.

Cardiopulmonary Bypass Period

Initiation. Initiation of cardiopulmonary bypass (CPB) can begin after the ACT is greater than 400 seconds. The venous clamp is first released, allowing blood to fill the venous reservoir; then the arterial clamp is removed, initiating CPB. Adequate venous drainage is necessary for the pump flow to be gradually increased to reach a calculated cardiac index of 2.0 to 2.5 L/min/m^2. Acceptable venous drainage usually correlates with a CVP of less than 5 mmHg (and even negative with vacuum-assisted venous drainage [VAVD].) The heart should appear empty and not distended. Hypotension is common at the initiation of bypass and is most likely related to the instantaneous hemodilution and reduced blood viscosity that occurs, which can then result in a reduction of SVR. Phenylephrine boluses administered by the perfusionist

are routinely necessary to augment the MAP during the initial phase of CPB. The most ominous reason for significant persistent hypotension (MAP less than 30 mmHg) is an aortic dissection. The diagnosis can be confirmed by TEE, and the surgeon may note a hematoma on the wall of the aorta. If a dissection is suspected, CPB must be discontinued until the aorta can be recannulated distal to the dissection. Other causes of persistent hypotension while on CPB include vasoplegia and sepsis.

When the CPB machine reaches full flow, there will no longer be a pulsatile trace visible on the pulmonary artery (PA) or A-line indicating that blood is now bypassing the lungs; mechanical ventilation can be held. Passive insufflation of the lungs with oxygen (200 mL/min) is usually continued. During CPB, the anesthetist must ensure adequate levels of anesthetic and muscle relaxant are maintained. Equipment integrity should be verified throughout the duration of CPB. If a volatile agent is to be used, the vaporizer must be properly seated on the oxygenator gas inlet of the CPB machine and turned on. An improperly seated vaporizer can obstruct gas flow to the oxygenator, resulting in hypoxemia. The infusion of all intravenous fluids and medications is stopped with the exception of aminocaproic acid. Insulin is often necessary because hyperglycemia usually manifests during CPB. The PA catheter, if present, should be pulled back 2 to 3 cm to prevent inadvertent wedging. Sometimes the surgeon will complete the dissection of the heart while it is still beating on CPB before aortic cross-clamp. The vent for the left ventricle is inserted most often through the left superior pulmonary vein.

Next the surgeon will ask the perfusionist to temporarily decrease the CPB flow while the aortic cross-clamp is applied. The clamp time is noted because this represents the beginning of cardiac arrest. After the cross-clamp is applied, full CPB flow will be resumed and cardioplegia infused through a catheter placed in the aorta between the cross-clamp and the heart. As the infusion of the high-potassium solution reaches the myocardium via the coronary arteries, the heart arrests in diastole, and electrical and mechanical asystole should ensue quickly. As explained earlier, achieving diastolic arrest can be difficult in patients with significant aortic regurgitation because some of the cardioplegia leaks into the ventricle rather than perfusing the coronaries. Any heart rhythm besides asystole indicates incomplete myocardial protection and the need for additional cardioplegia. Retrograde cardioplegia through the coronary sinus may also be administered or cardioplegia may be given directly into the coronary ostia if the aorta is opened. To further enhance myocardial and cerebral protection, the surgeon may allow the patient's temperature to "drift" toward the ambient room temperature or begin active cooling centrally through the CPB circuit. Some surgeons cool topically by packing ice around the heart. Box 24-3 contains a checklist of items the anesthetist should check after bypass is initiated.

Maintenance. The flow rate on CPB is maintained at 50 to 60 mL/kg/min to reach a calculated cardiac index of 2.0 to 2.5 L/min/m^2. The ideal systemic pressure on CPB is 50 to 70 mmHg, depending on the patient's age and comorbidities. The mixed venous oxygen saturation should be monitored and maintained at 70%. Hypertension may indicate a light anesthetic level. This can be treated by increasing the vapor or administering a supplemental dose of narcotic or benzodiazepine. If hypertension persists, a vasodilator may be added. Hypotension is usually treated with bolus doses of phenylephrine by the perfusionist, but occasionally an infusion of a vasopressor may be needed. The train-of-four (TOF) should be completely suppressed to prevent movement or shivering during CPB. Shivering may not be obvious, but it greatly increases O_2 consumption, which may be manifested as low O_2 on the venous gas.

BOX 24-3

Anesthesia Checklist at the Initiation of Bypass

Face	Examine for color, temperature, plethora, edema, and symmetry.
Eyes	Examine pupils for size and symmetry and conjunctiva for edema.
CPB lines	Arteriovenous color difference should be visible.
PAC	If present, pull back 3 to 4 cm. Pressure should be less than 15 mmHg mean.
CVP	Less than 5 mmHg, possibly negative with VAVD.
Heart	Avoid distension.
Ventilation	Stop when PA ejection and/or aortic ejection ceases.

CPB, Cardiopulmonary bypass; *CVP*, central venous pressure; *PA*, pulmonary artery; *PAC*, pulmonary artery catheter; *VAVD*, vacuum-assisted venous drainage.

ABGs and ACTs should be monitored every 30 minutes. Acid/base balance should be corrected as needed. Blood may be needed depending on the patient's hematocrit and comorbidities as well as on the complexity of the surgical procedure. Blood glucose usually increases to a level that requires treatment with an insulin infusion. Patients often develop some level of hyperkalemia probably related to the potassium in the cardioplegia solution. The insulin infusion counters this problem by driving K+ into the cell. Urine output should be monitored: 1 mL/kg/hr is considered satisfactory. If urine output is low and the pump volume is adequate, the addition of a diuretic should be considered, especially if the patient was taking a diuretic preoperatively. If the hematocrit is low, hemoconcentration (ultrafiltration) through the cardiopulmonary bypass circuit can be considered as a blood conservation technique.

Preparation for Separation from CPB. Box 24-4 outlines many of the factors that must be considered in preparation for separation from CPB. The need for possible inotropic or vasopressor support should be anticipated and infusions prepared. Rewarming begins as the surgeon is completing the repair. The process should begin early enough to facilitate slow, gradual warming to 36° to 37° C nasopharyngeal or esophageal.[95] During rewarming, the bladder temperature may lag 2° to 4° C behind the nasopharyngeal or esophageal temperatures.[96]

Arterial and venous blood gases should be normalized before termination of CPB. Potassium should be treated if greater than 5.5 mEq/L or less than 4.0 mEq/L to decrease the incidence of dysrhythmias. If the patient is hyperkalemic, calcium also may be given to counteract the potassium and stabilize the membrane to prevent dysrhythmias. The administration of calcium is somewhat controversial. Some clinicians have a low threshold for treating low ionized Ca^{2}+ given its beneficial positive inotropic effects and essential role in the coagulation cascade. Other clinicians avoid calcium because it contributes to coronary vasospasm and may exacerbate reperfusion injury. Magnesium (2-4 g IV) is frequently administered prophylactically to minimize dysrhythmias. In a recent review, CABG patients who received IV magnesium intraoperatively experienced a significant reduction in postoperative atrial fibrillation.[97] Treatment for high glucose levels should continue, but the rate of insulin infusion often can be lowered significantly, especially in a nondiabetic patient after separation from CPB.

BOX 24-4

Preparation for Separation-from-Bypass Checklist

1. Air clearance maneuvers completed
2. Rewarming completed
   a. Nasopharyngeal temperature 36°-37° C
   b. Rectal/bladder temperature ≥ 35° C, but ≤ 37° C
3. Address issue of adequacy of anesthesia and muscle relaxation
4. Obtain stable cardiac rate and rhythm (use pacing if necessary)
5. Pump flow and systemic arterial pressure
   a. Pump flow to maintain mixed venous saturation ≥ 70%
   b. Systemic pressure restored to normothermic levels
6. Metabolic parameters
   a. Arterial pH, P_{O_2}, P_{CO_2} within normal limits
   b. Hct: 20%-25%
   c. K^+: 4.0-5.0 mEq/L
   d. Ionized calcium
7. Are all monitoring/access catheters functional?
   a. Transducers re-zeroed
   b. TEE (if used) out of freeze mode
8. Respiratory management
   a. Atelectasis cleared/lungs re-expanded
   b. Evidence of pneumothorax?
   c. Residual fluid in thoracic cavities drained
   d. Ventilation reinstituted
9. Intravenous fluids restarted
10. Inotropes/vasopressors/vasodilators prepared

From Grocott HP, Stafford-Smith M, Mangano CT. Cardiopulmonary bypass management and organ protection. In: Kaplan JA, et al. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Saunders; 2011.
Hct, Hematocrit; *TEE*, transesophageal echocardiography.

An adequate circulating blood volume is necessary for separation from CPB. The amount needed varies with the patient's weight, prebypass volume status, ventricular function, and comorbidities. As previously indicated, the ideal hematocrit is a matter of debate, but most cardiac surgical patients require a hematocrit of 22% to 25% to ensure adequate tissue perfusion.[47]

As the cardiac chambers are surgically closed, the lungs are inflated to remove air from the heart and pulmonary veins and to assist in filling the heart. Warm reperfusion cardioplegia solution ("*Hot Shot*") is administered, and the perfusionist lowers the pump flow temporarily as the surgeon removes the aortic cross-clamp. The time of clamp removal is noted. It is not uncommon for the heart to fibrillate, especially if there was insufficient myocardial preservation or electrolyte imbalances. Intracardiac air can migrate into the coronary artery, most commonly the right coronary artery, because it is anatomically superior and air will rise. Ischemic changes may manifest on the ECG and echo. The surgeon may shake the heart or insert a needle through the muscle into the ventricle it in an attempt to displace residual air. Echocardiography and the ECG can aid the surgeon in determining when all air pockets have been removed.

If fibrillation occurs, the heart is defibrillated with internal cardiac paddles placed directly on the myocardium using 10 to 20 joules. Antidysrhythmics such as lidocaine or amiodarone also may be administered. The MAP can be increased using phenylephrine boluses if necessary to improve coronary blood flow to ensure optimal ventricular function. In some centers, magnesium (1-2 g) IV and lidocaine (100 mg) IV are administered prophylactically with discontinuation of CPB. The optimal heart rhythm is sinus, and a rate between 80 and 90 bpm represents a balance between adequate cardiac performance and myocardial oxygen demand. Temporary ventricular pacing wires are routinely placed because the intrinsic conduction system of the heart may be temporarily or permanently altered.

Atrioventricular pacing is preferred for bradycardia because the atrial contribution to the cardiac output can be preserved. Unfortunately, atrial tissue is more prone to disruption or damage when the pacing wires are removed in the postoperative period, so they are placed less commonly. Patients with chronic atrial fibrillation are generally unable to conduct with atrial pacing. After separation from CPB when electrocautery is used, the pacemaker may sense discharge from the electrocautery as intrinsic cardiac activity—the pacemaker will not discharge. Therefore an asynchronous pacing mode, VOO (ventricular asynchronous) or DOO (atrial ventricular sequential asynchronous), is frequently employed to prevent electrocautery-induced pacemaker inhibition. However, asynchronous pacing modes place the patient at risk for developing ventricular fibrillation as a result of the R-on-T phenomenon. The pacer should accordingly be converted to a synchronous mode as soon as electrocautery use becomes limited.

Once the heart begins ejecting, the lungs should be gently reinflated manually limiting the positive pressure to 30 cm H_2O and mechanical ventilation resumed. The anesthesia provider should visually inspect the lungs as they reinflate, in order to detect atelectasis and adequacy of reinflation. Positive end-expiratory pressure (PEEP) or manual sighs can be used to treat significant atelectasis. However, overinflation of the lungs must be avoided, especially in CABG patients because an in-situ ITA bypass graft may be stretched, or even disrupted, during hyperinflation of the lungs. Delivery of inhalation or intravenous anesthetic should be continued by the anesthetist. Monitors and transducers should be zeroed to atmospheric pressure and recalibrated. Ventricular function should be assessed using TEE and direct visual inspection of the heart in the surgical field. The surgeon should be notified of any echocardiographic findings that are of concern. Valvular integrity and ventricular wall motion are carefully examined. If ventricular function is marginal, an inotrope, most commonly epinephrine, dopamine, or dobutamine should be initiated. If hypotension persists, a vasoconstrictor such as norepinephrine may be started. Once the volume, hemodynamic function, and ventilation are satisfactory, weaning from CPB can begin.

Separation from CPB. The perfusionist uses a clamp to gradually occlude the venous return to facilitate filling of the right ventricle. The right ventricle moves volume through the pulmonary system and into the left ventricle. As the beating heart continues to fill, ejection resumes and arterial pressure rises. Then the perfusionist gradually decreases CPB flow. Volume (preload) can be added through the arterial pump line until loading conditions are optimized. Once adequate volume is given through the in-situ arterial cannula, the line is clamped and separation time from CPB is recorded. The immediate postbypass period demands close attention because hemodynamic instability and cardiovascular collapse may occur. If a radial arterial line is present, the practitioner must be aware of the potential discrepancy between radial and aortic pressure.[78] If a PAC was pulled back during the procedure and is now in the right ventricle, it can be repositioned into the pulmonary artery.

If pulmonary pressures rise precipitously with concurrently falling arterial pressures, this may indicate severely decreased ventricular function and an inability to separate from CPB. If the patient fails separation despite significant efforts at support, CPB can be

reinstituted, and the situation reevaluated focusing on potentially reversible causes of demise. TEE is an invaluable tool to assist in diagnosis and guide management. Visual inspection of the operative field may reveal a surgically correctable problem, such as a kinked bypass graft. If, however, no obvious anatomic problem is identified, a period of resting perfusion on CPB will help resolve cardiac stunning that commonly occurs after cardiac surgery. Pharmacologic inotropic or vasopressor support is initiated or increased. If pharmacologic support is insufficient for separation from CPB, an intra-aortic baloon pump (IABP) may be placed. As a last resort, extracorporeal membrane oxygenation (ECMO) or a ventricular assist device (VAD) may be used for ventricular support. The indications and use of these devices is discussed in the mechanical circulatory support of heart failure section of the chapter.

Postbypass Period

Decannulation. Blood from the pump is transfused to the patient either at a slow but continuous rate or in 100-mL increments. Caution is taken to prevent overdistention and volume overload of either ventricle. Once major surgical bleeding is controlled and hemodynamic stability is satisfactory, preparation for decannulation can begin. The blood pressure is usually lowered to 90 mmHg systolic or a MAP of 70 mmHg or less to reduce bleeding. The atrial (venous) cannula(e) are removed first, then the aortic cannula is removed and the time is recorded. Blood that remains in the CPB reservoir and pump tubing is sent to the cell saver device so that it can be washed and reinfused.

Protamine Administration. Protamine is used to reverse the anticoagulation caused by heparin. Protamine neutralizes heparin through electrostatic interaction, forming a heparin-protamine complex that renders heparin inactive. A test dose of 10 mg protamine is routinely given to check for anaphylaxis because allergies or intolerance to protamine are relatively common.[98] Protamine reactions can range from mild hypotension to anaphylaxis. Some surgeons prefer to give the test dose of protamine while the aortic cannula is in the aorta in case anaphylaxis develops. Otherwise, the protamine should not be administered until the patient is decannulated because clot formation in the CPB pump will have devastating consequences. Slow drug administration is the most effective strategy to use to avoid hypotension, which is common when protamine is delivered rapidly. Giving protamine over a period of 10 to 15 minutes will decrease the probability of both type I (systemic vasodilation) and type III (pulmonary vasoconstriction) protamine reactions. However, an anaphylactic reaction (type III) can occur at any rate of administration.[98] The normal dose of protamine is one milligram of protamine to reverse every 100 units of heparin that was given. Therefore a normal heparin dose of 30,000 units would require 300 mg of protamine for reversal. An ACT is obtained after the entire protamine dose is given to confirm that the clotting time has returned to baseline. Alternatively, a heparin dose response machine can be used to determine optimal protamine dose and check for residual heparin after protamine administration. Additional protamine doses of 50 to 100 mg are routinely administered to cover residual anticoagulation, and if inadequate, hemostasis is visualized in the surgical field.

Hemodynamic Management. After CPB, most patients fall into one of four groups.[50] The first group includes patients with good LV function preoperatively and few comorbidities; they usually separate from CPB easily and require little support. Patients with good ventricular function usually have a blood pressure, heart rate and rhythm, and cardiac output within the normal range. This group of patients may need some occasional adjustments of their volume or blood pressure, but they are generally stable during the postbypass period.

The second group consists of patients with significant concentric LVH and diastolic dysfunction. This group tends to be volume dependent. The intravascular volume status should be continually reassessed using TEE, because LVEDP may be falsely elevated secondary to decreased ventricular compliance. When volume is optimized, the patients may be hypertensive with an adequate cardiac index. As discussed in the beginning of the chapter, patients with concentric ventricular hypertrophy require a high MAP and adequate diastolic time to fill the noncompliant ventricle (see Table 24-4). If the MAP decreases, they are prone to ischemia; therefore they may benefit from a low-dose vasoconstrictor such as norepinephrine if the blood pressure is low after volume has been optimized. On the other hand, if they become hypertensive, cautious titration with a vasodilator infusion is indicated.

The third group of patients present with persistent hypotension in the post-CPB period. In this group, the cardiac output is usually normal or high. Patients in this group may be septic because of preexisting endocarditis or they develop vasoplegic syndrome. Vasoplegic syndrome is a type of well described vasodilatory shock that occurs after CPB. The reported incidence (9%-44%) varies widely, as do the purported causes.[99-101] Preoperative administration of angiotensin-converting enzyme (ACE) inhibitor and calcium channel blockers, amiodarone, and IV heparin are implicated as potential causative agents. Diabetes and moderate to poor LV dysfunction are also correlated with this syndrome.[100,102] Unfortunately, no particular medical history consistently predicts manifestation of this syndrome; however, hypotension early in the pump run is predictive of its development after CPB.[99,100,102] Patients with the syndrome often require large doses of phenylephrine or even norepinephrine while on CPB. Post-pump, they develop resistance to phenylephrine and respond much better to boluses of norepinephrine (16-32 mcg) or vasopressin (1-2 units.) A norepinephrine and/or vasopressin infusion is often needed to support the blood pressure. Vasopressin has been demonstrated as being more effective in the management of vasoplegic syndrome than norepinephrine.[101-104] Although a patient's cardiac output may fall into the normal or even hyperdynamic range, the heart may still benefit from low to moderate doses of inotropic support to sustain contractility in this state of vasodilatory shock.[103] Maintaining a relatively high hematocrit level augments preload and also improves blood pressure.[50]

The fourth and final group of patients comprises those that develop systolic failure after CPB. This group can be further subdivided into left, right, or biventricular failure.[50] Patients with poor preoperative left or right ventricular function, long CPB runs, complex procedures, and inadequate myocardial protection on CPB are at high risk for failure. The pathophysiology of failure was discussed early in the chapter (see Tables 24-3 and 24-4). LV systolic failure is managed with an inotrope such as epinephrine combined with gentle afterload reduction with a vasodilator such as nitroprusside if the SVR is high. An inodilator such as milrinone will provide inotropic support and reduce afterload and may be used alone or in conjunction with other inotropes and vasopressors. RHF can be initially managed with a combination of epinephrine to support contractility and nitroglycerin titrated to reduce afterload while maintaining blood pressure to support coronary perfusion. If this is ineffective, a bolus and/or infusion of milrinone can be helpful because it is particularly effective in reducing pulmonary vascular resistance, thereby lowering right ventricular afterload. Unfortunately, milrinone may cause an excessive decrease in the SVR that leads to hypotension. A norepinephrine infusion

may be initiated to augment blood pressure to a level sufficient for coronary perfusion. Rarely (due partly to cost) is nitric oxide used to selectively dilate the pulmonary vasculature and decrease right heart afterload. If maximal pharmacologic support fails, then mechanical support of the ventricle is considered, including the use of an IABP, ECMO, or VAD. Because management of these devices is complex and rather specialized, the anesthetic considerations are discussed separately in the section on the treatment of heart failure.

Additional Considerations. After the patient is decannulated, the surgeon may pack the chest to encourage hemostasis. Electrocautery is used routinely. During this period the surgeon may need to lift the heart to inspect for bleeding on the posterior surface. Lifting and manipulation of the heart and vasculature can cause significant dysrhythmias and hypotension. The surgeon should be informed if hypotension is severe or excessive in duration. As previously mentioned, electrocautery-induced suppression of the pacemaker can occur; often the pacemaker is placed in an asynchronous mode. Synchronous pacing should be resumed as soon as possible. Most patients require volume supplementation after the pump and often a combination of crystalloid, colloid, and cell saver blood is used. The combination usually results in a hematocrit of 25% to 30%.

Persistent bleeding after CPB occasionally develops, especially if the surgery was complex and required a long pump run. The causes are multifactorial, but readily treatable problems should be addressed. Adequate reversal of heparin should be confirmed via ACT or heparin concentration assay and additional doses of protamine given if needed. Hypothermia accentuates hemostatic defects, so the patient and room should be warmed to normothermia. Surgical causes of persistent bleeding should be sought because inadequate surgical hemostasis may develop and progress insidiously. If oozing persists, laboratory coagulation studies may reveal a deficiency in the coagulation cascade. Platelets, plasma, cryoprecipitate, and red cell transfusions may be required depending on the underlying deficiency. In severe bleeding situations, desmopressin (DDAVP) and factor VII can be administered.

As discussed in the section on physiologic effects of CPB, a host of other complications can arise including ARDS, renal failure, and neurologic injury. Although these are most evident in the postoperative period, problems with adequately ventilating the patient may occur in the OR as well. Most patients will respond to the addition of PEEP and other recruitment measures. Occasionally acute lung injury is so severe that an ICU ventilator with advanced ventilating modes is required.

Chest Closure. When hemostasis has been achieved and the patient is hemodynamically stable, preparations are made for chest closure and transport to the ICU. The lungs are deflated to facilitate chest closure. Cardiac output and echocardiogram (if available) are reviewed before and after chest closure because the preload decreases and afterload increases with chest closure. If the patient becomes unstable, the wires are released and the situation reevaluated. Patients that have received massive transfusions or require high-dose pharmacologic and/or mechanical support may not be able to tolerate the hemodynamic consequences of chest closure. In this situation, the patient may have the chest left open with surgical dressings and a sterile covering applied. The patient is maintained in the ICU for the next 24 to 48 hours. Later when hemostasis and hemodynamic stability are achieved, the patient will be returned to the OR for chest closure.

Once the chest is closed, preparations for safe transport to the ICU are initiated. Emergency medications and airway equipment are gathered for transport because transfer to the ICU represents a particularly vulnerable time period outside of the OR. Although some stable patients may be extubated at the end of the procedure, most surgeons prefer that fast-tracking occur in the ICU after they ensure minimal chest tube output as evidence of adequate hemostasis. Most patients are sedated with propofol or dexmedetomidine infusions until extubation. The echo probe is removed at the end of the procedure and an oral gastric tube inserted to decompress the stomach.

Transport. With the numerous monitors, invasive lines, chest tubes, pharmacologic infusions, and requisite airway equipment, moving a patient safely to the ICU can be complicated and hazardous; a thorough patient-handoff to ICU personnel is vital. A hand-off checklist helps to ensure that all critical information is communicated to the ICU team.

Postoperative Bleeding and Cardiac Tamponade

Bleeding is not uncommon after cardiac surgery and about 4% to 10% of cases are returned to surgery to have the chest re-explored for persistent bleeding, tamponade, or unexplained hemodynamic instability that is presumed to be tamponade.[9] Cardiac tamponade is reported to occur after cardiac surgery, between 0% and 8.8% depending on the complexity of the surgical procedure and patient comorbidities.[102,103] Cardiac tamponade occurs when fluid trapped in the pericardial sac increases in volume enough to cause myocardial compression. The compression then limits diastolic filling of the heart, thus reducing stroke volume and cardiac output. Severe hypotension, myocardial ischemia, and eventually cardiac arrest can ensue once venous pressures fall below pericardial pressures causing ventricular collapse. Pericardiocentesis, subxiphoid drainage, or mediastinal exploration must occur without delay once decompensated cardiac tamponade occurs to prevent complete cardiac collapse.

Cardiac tamponade can occur from nonloculated pericardial effusions, which can be caused by many medical conditions such as malignancies, viral pericarditis, uremia, and bacterial infections. Coagulopathy, postoperative bleeding, and/or localized compression from blood that is in contact with the heart, because of the open pericardium, may all contribute to tamponade that occurs in the immediate postoperative period after cardiac surgery. Cardiac tamponade should be suspected after cardiac surgery if there is a sudden dramatic decrease in chest tube drainage with concomitant hypotension, tachycardia, increased and equalizing filling pressures, and decreased cardiac indices despite increased inotropic and vasopressor support. Pulsus paradoxus, electrical alternans, and the Beck triad are all considered classic clinical indicators of cardiac tamponade. Pulsus paradoxus is defined as a drop in systolic blood pressure greater than 10 mmHg on inspiration. Venous return to the right ventricle increases on inspiration, causing the ventricular septum to bulge into the LV and decrease cardiac output. With positive pressure ventilation, venous return is greatest on exhalation, so the blood pressure drop occurs then. Electrical alternans is the cyclic alteration in the magnitude of P waves, QRS complexes, and T waves that occurs as a result of the tamponade. The Beck triad is characterized by low blood pressure, jugular venous distension, and distant heart sounds. A chest x-ray will often reveal an enlarged cardiac silhouette, and TEE examination will find diastolic collapse of the right atrium or right ventricle.[73,103]

Crystalloid, colloid, and/or blood should be administered to optimize preload until pericardiocentesis or mediastinal exploration can be undertaken in the ICU or operating suite. If the postoperative cardiac surgical patient is brought to the operative room for re-exploration because of tamponade, sedatives or narcotics

should be carefully titrated to prevent further cardiac depression until the tamponade is relieved. Ketamine, pancuronium, and small doses of epinephrine are often chosen for induction of anesthesia because sympathetic tone and myocardial function are supported. If cardiac arrest seems likely to occur with induction, a temporary improvement in cardiac function can be achieved by performing a pericardiocentesis under local anesthesia before induction to remove enough drainage to provide some relief. Postoperative cardiac surgical patients returning to the OR because of bleeding and tamponade, who no longer have invasive monitoring in place, will require insertion of an A-line and CVP. However, surgical drainage should not be delayed for placement of central access. TEE is useful for monitoring ventricular function and as an aid in guiding the surgeon in removing trapped fluid. The patient is sometimes kept spontaneously breathing to prevent further decreases in ventricular filling caused by positive pressure ventilation. If positive pressure ventilation is used, tidal volumes should be reduced. Once the tamponade is surgically relieved, an immediate improvement in hemodynamics is usually noted. At this time hypertension and tachycardia from endogenous catecholamine release should be anticipated by the anesthetist and treated accordingly.

ANESTHETIC CONSIDERATIONS FOR SPECIFIC CARDIAC DISEASES AND SURGICAL PROCEDURES

Coronary Artery Disease and Myocardial Revascularization

Pathophysiology

On-pump coronary artery bypass graft (CABG) surgery is the most frequently performed cardiac surgical procedure. Anesthetic management for these patients requires an understanding of coronary anatomy and physiology, as discussed in Chapter 23, as well as an understanding of the key physiologic principles covered at the beginning of this chapter. This section focuses on the considerations that pertain to CABG surgery.

Coronary artery disease (CAD) is a complex disease state that involves narrowing of the coronary arteries. The pathogenesis of CAD is not definitively clear, but several theories have been proposed. Scientists believe the endothelium or innermost layer of the artery becomes injured. Over time, cholesterol agents such as low-density lipoproteins and macrophages adhere to the endothelium and form plaques. The plaques continue to build and decrease the vessels' ability to distend. Because coronary oxygen extraction is maximal at rest, the only way to increase oxygen delivery to the tissues is to increase coronary flow. In normal coronaries, flow can increase 3 to 5 times over baseline when demand increases. However, this increase in flow, known as coronary reserve, is limited in patients with CAD. Thus when patients with CAD increase demand by exercise or stress, they develop *demand ischemia*, which can then be symptomatically experienced as predictable stable angina. General anesthetics protect against demand ischemia.

Acute coronary syndromes (ACSs) and perioperative ischemia are usually caused by *supply ischemia*.[104,105] Ischemia occurs when a piece of the plaque ruptures, causing a thrombus to form that significantly or totally occludes a segment of a coronary artery, leading to ischemia, dysrhythmias, and/or myocardial infarction (MI). The problem can be exacerbated by spasm, which can develop even in normal adjacent vessels.[9] Great strides have been made in the nonsurgical treatment of CAD and ACS in the past two decades. The development and evolution of coronary stents has revolutionized care. Most patients presenting for CABG surgery with CAD and/or ACS will have been referred for some type of percutaneous coronary intervention (PCI). Surgeons and anesthesia providers must take this into consideration when planning care. Much research has been done comparing the risk-benefit ratio of surgical intervention to optimal medical management. The ACC/AHA guidelines state that surgical intervention is indicated for patients with stenosis of greater than 50% in the left main trunk (LMT) or triple vessel disease. Additionally, patients who have failed PCI or who have coronary lesions not amenable to PCI will benefit from surgery.[106] In these situations, CABG has been found to have a lower mortality risk of major cardiovascular complications or cerebral events than optimal medical management.[106-109]

Anesthetic Considerations and Surgical Options for On-Pump CABG

The anesthetist should carefully review preoperative cardiac tests to determine the location and extent of the lesions, to assess ventricular function, and to detect the possible presence of concurrent cardiac abnormalities such as aortic stenosis. Table 24-2 reviews significant findings on cardiovascular preoperative testing. Preoperative ventricular function correlates with the risk of developing postoperative low cardiac output syndrome (LCOS). Patients with ACS or NYHA class IV heart failure (see Table 24-5) are at high risk of LCOS. If the patient develops cardiogenic shock, often requiring an IABP to maintain stable hemodynamics, the patient is in the highest risk category. Patients who have had bare metal stents implanted within 3 months of surgery and/or drug-eluting stents within 1 year of surgery will have special considerations because of their antiplatelet therapy. The general management of drugs affecting coagulation has already been discussed. However, in patients with recent coronary stents, the cardiologist and surgeon collaborate to determine the best management for the individual patient. For emergency procedures, both aspirin and glycoprotein IIb/IIIa inhibitors may be continued despite the increased risk of bleeding.[110]

Optimizing myocardial oxygen supply and minimizing demand are clearly key anesthetic considerations in CABG surgery (see Figure 24-1). The patient must be monitored carefully for ischemia throughout the procedure. Using a combination of ECG and TEE findings, together with direct inspection of the heart, is advised.[92] Table 24-1 outlines causes and treatments for myocardial ischemia. Anesthetic considerations are summarized in Table 24-9. It is most important to keep a relatively high MAP to maintain coronary perfusion, while keeping the heart rate and LVEDP low. Patients with left-main and triple-vessel disease should have an arterial line and large-bore IV in place before induction so that hypotension can be treated promptly. Beta-blockers are used to control heart rate, and the preferred vasodilator for CABG is nitroglycerin.[110] Preoperative beta-blockade is a quality metric for both the National Quality Forum and the STS database, which is used for quality report cards in conjunction with Consumer Reports.[111,112] In low doses, nitroglycerin acts immediately to reduce preload by decreasing vascular tone; in higher doses it also decreases coronary artery resistance. Kaplan showed that nitroglycerin is superior to nitroprusside in CABG patients.[113]

Volatile anesthetics should also comprise part of the anesthetic plan because of their preconditioning effect.[95] Nitrous oxide should be avoided because of the possibility of expanding gaseous spaces. Patients considered for fast-track protocols, generally those with EFs above 35%, should receive a limited dose of narcotics. The highest-risk patients may still require a primary narcotic technique to maintain hemodynamic stability.

Conventional on-pump CABG surgery is performed through a median sternotomy with CPB. Different types of conduit can be used to bypass occluded areas of the patient's native coronary arteries to revascularize the myocardium distal to the occlusions

TABLE 24-9 Anesthetic Considerations in the Management of CABG

Factor	Hemodynamic Consideration	Anesthetic Considerations
Preload	Decrease	↓ LVEDP will ↑ MvO_2 supply and ↓ demand Nitroglycerin selectively dilates coronary vessels
Heart rate	Slow normal	Too fast → ischemia; consider β-blockade Too slow → not enough CO for coronary perfusion
Rhythm	Maintain sinus	Maintains atrial contribution to cardiac output
Compliance	Decrease	Concentric ventricular hypertrophy common with history of hypertension
Contractility	Depress if normal LVF	↓ Contractility → ↓ MvO_2 demand If poor LVF, may not tolerate depression
SVR	Maintain	Hypertension better tolerated than hypotension Treat hypotension promptly with phenylephrine
PVR	Maintain	Usually not a problem

↓, Decrease; ↑, increased; →, leads to; β, Beta; *CABG*, coronary artery bypass graft; *CO*, cardiac output; *LVEDP*, left ventricular end-diastolic pressure; *LVF*, left ventricular function; MvO_2, myocardial oxygen demand; *PVR*, pulmonary vascular resistance; *SVR*, systemic vascular resistance.

(Figure 24-11). The surgeon must take into consideration the viability of the myocardium, quality of the target vessel, and the type and length of conduit needed to reach distal to the occlusions. The most commonly used conduits are the internal thoracic arteries (formerly internal mammary arteries) and greater saphenous veins. The free radial artery graft is popular with some surgeons whereas others question its long-term patency.[114] Arterial grafts are generally reserved for high-grade lesions because flow in the native coronary can compete with flow in the arterial bypass graft. If there is not enough flow in the muscular artery, it will spasm and shut down. Topical (papaverine) and intravenous antispasmodic drugs such as calcium channel blockers or low-dose nitroglycerin infused intraoperatively is used to treat spasm.

The left internal thoracic artery (LITA) is usually left in situ at its proximal origin from the left subclavian artery, dissected from the chest wall, and most commonly anastamosed to the left anterior descending (LAD) artery. A LITA graft to the LAD artery has a 10-year patency rate of 85% to 99.1%.[115,116] The right internal thoracic artery (RITA) is usually transected from its proximal origin to become a free graft with its proximal anastomosis off the aorta or another conduit. The surgical table is elevated and turned while the internal thoracic artery (ITA) is dissected. Lung volumes are reduced to improve the surgical view. The patient's arm should be well padded because the axillary artery can be compressed by the chest wall retractor, lowering radial A-line pressures. A noninvasive cuff on the contralateral arm helps confirm the diagnosis. Heparin is usually administered before the LITA pedicle is clamped.

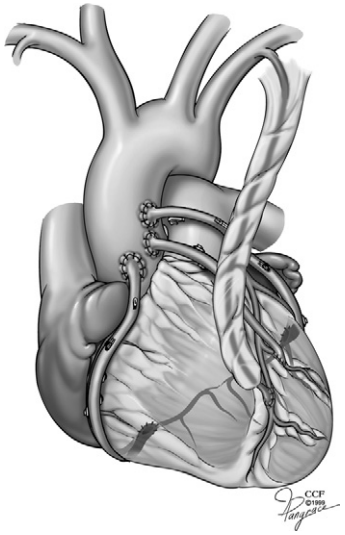

FIGURE 24-11 Coronary artery bypass graft (CABG) surgery. The in-situ left internal thoracic artery (ITA) is most often grafted to the left anterior descending (LAD) native coronary. Free grafts (saphenous vein grafts [SVGs], free radial artery, or right internal thoracic artery) are anastomosed proximally to the aorta (or branched from another bypass—not shown) and distally to a *target* area of the native coronary vessel that is beyond the obstruction. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)

The saphenous vein graft (SVG) and radial artery conduit can be harvested by open surgery or endoscopically. As with any endoscopic procedure, the respiratory rate may have to be increased to compensate for the addition of carbon dioxide. Most vein grafts are now removed endoscopically, but there are concerns that endovascular vein harvest (EVH) might decrease long-term graft patency.[117,118] The surgeon reverses the vein to avoid the valves. The distal anastomosis to the native coronary artery is usually completed first and then the proximal portion is sewn to the aorta or bridged off another graft.

Several surgical and technical complications can result in ischemia. In addition to the previously mentioned concerns about reoperations, patients who have undergone prior CABG surgery may have a patent LITA or other grafts lying directly under the sternum. Sternotomy can lead to marked ischemia if flow in the vessel is accidentally disrupted. The surgeon must take care to make bypass grafts the perfect length. LITA grafts that are too short can be overstretched with vigorous lung inflation and SVGs can be overstretched when the heart is filled. On the other hand, grafts that are too long can kink when the chest is closed. Other causes of ischemia include coronary embolization of air or debris (discussed earlier) and coronary spasm.

Anesthetic Considerations and Surgical Options for Off-Pump CABG

The first off-pump coronary artery bypass (OPCAB) procedures were attempted in the 1950s, but there has been a resurgence in popularity since retractors and epicardial stabilizing devices such as the Octopus (Medtronic) were developed in the 1990s. Off-pump surgery is also called *beating heart bypass surgery*. Although the procedure is typically performed through a full median sternotomy without the aid of CPB, a perfusionist and a primed or dry pump (based on surgical preference) should be in the OR on standby throughout the case. Occasionally a limited anterior

thoracotomy (minimally invasive coronary artery bypass [MIDCAB]) approach is used. The implications of the MIDCAB incision are detailed in the section on minimally invasive surgery. It is estimated that OPCAB accounts for 20% to 30% of all CABG procedures.[110] OPCAB is performed to avoid the risks and complications associated with conventional CABG and CPB, but further research is necessary on its relative safety. Aortic cross-clamping is avoided, theoretically decreasing the risk of debris embolization. Recent studies comparing the techniques showed that patients from both groups had equivalent rises in inflammatory biomarkers[119] and similar neuropsychologic outcomes.[120] Additionally, incomplete revascularization was slightly more common in the OPCAB patients and 1-year patency significantly worse.[120] The STS recommends OPCAB as a blood conservation technique.[47]

Anesthetic implications and monitoring are similar to those of on-pump CABG with a few additional concerns. The procedure is usually limited to patients with relatively good LV function and bleeding is less of a concern, so patients are even more likely to be candidates for a fast-track anesthetic plan. Volume depletion is not uncommon in patients admitted to the OR. In contrast to on-pump cases, in which patients are going to be diluted by priming volume, OPCAB patients require crystalloid and/or colloid solutions to correct fluid deficit and the hemodynamic changes inherent to the procedure. Patient temperature likewise cannot be corrected on-pump; therefore hypothermia becomes a concern. Normothermia is maintained by warming the room and using fluid warmers, warm water mattresses, or forced-air warming devices. Anticoagulation is necessary, but the decision to partially heparinize (100-200 units/kg with an intended ACT of more than 300 seconds) or fully heparinize (300-400 units/kg with an intended ACT of more than 400 or 480 seconds) depends on the surgeon's preference. ACTs should be monitored at least every 30 minutes and heparin administered as needed to maintain adequate anticoagulation. Aminocaproic acid is not routinely used because the blood is not exposed to CPB. Arterial blood gases, electrolytes, and blood glucose should be monitored every half-hour to 1 hour and should be treated.

To perform the bypass on the beating heart, the surgeon employs specialized compressive footplate stabilizers (Figure 24-12) and retractors that use suction to lift and suspend the heart, *verticalizing* the apex (Figure 24-13). These maneuvers compress cardiac chambers and distort valvular apparatuses, resulting in well-documented hemodynamic compromise and acute ischemia.[121,122] Every team member needs to be prepared for the possibility of converting to an on-pump procedure in case of hemodynamic deterioration. Less myocardial manipulation is needed to bypass the LAD or diagonal coronary artery lesions (see Figure 24-12), but as shown in Figure 24-13, near verticalization of the apex is necessary to expose the posterior lateral wall for posterior descending artery (PDA) and circumflex lesions to be grafted. Some surgeons routinely shunt the coronary lesion being grafted, whereas others only shunt the lesion if regional ischemia develops. Close communication between the anesthesia providers and the surgical team is critical. Monitoring must be vigilant and interventions timely. The CPP is maintained by keeping a relatively high MAP (90-100 mmHg) during distal anastomosis. Hypotension is initially treated with volume and vasopressors, by bolus or infusion as needed to maintain the blood pressure. The Trendelenburg position will facilitate surgical exposure and help restore MAP and cardiac output.[123,124] Occasionally patients will also require an inotrope to maintain hemodynamic stability. Dramatic hemodynamic changes can occur when the heart returns to a physiologic position, necessitating the abrupt withdrawal of pharmacologic support. Later, when the surgeon uses a side-clamp to perform the proximal graft-aortic anastomoses, the MAP is routinely lowered to around 60 to 70 mmHg. Surgical drying and closure is often more rapid in off-pump than in on-pump procedures, because bleeding is minimized.

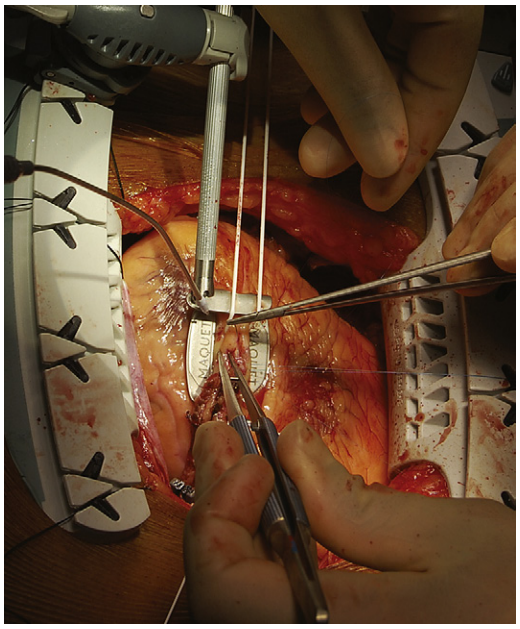

FIGURE **24-12** Left anterior descending (LAD) artery anastomosis during off-pump coronary artery bypass grafting using a left internal mammary artery (LIMA) graft. The view is from the head of the patient. The Maquet mechanical stabilizer (MAQUET, Wayne, NJ) is in place together with vascular snare sutures used to transiently occlude the artery. The LIMA is being anastomosed to the LAD, assisted by use of pressurized and heavily humidified carbon dioxide ("mister blower" metal cannula) to facilitate visualization of the vessel lumen. Valvular Heart Disease and Cardiac Valve Surgery

Although the prevalence of rheumatic heart disease has decreased in industrialized countries, degenerative heart disease, which correlates closely with advanced age, is increasing. It is estimated that 2.5% of the overall U.S. population has valvular heart disease, but prevalence rises dramatically with increasing age, reaching 13.2% after the age of 75.[125] Infective endocarditis is also an important cause of valvular disease, and patients who have this condition can

be unusually challenging for both the surgeon and the anesthetist. The proportion of cardiac surgeries that include valvular procedures has doubled over the past two decades.[126] Currently 20% of cardiac surgeries involve valve repair or replacement, and a significant proportion of these cases will include multiple lesions or concurrent myocardial revascularization. Aortic stenosis is the most common valvular defect requiring surgical intervention, followed by mitral regurgitation, aortic regurgitation, and finally, mitral stenosis. Right-sided valvular disease occurs much less often.[125] Often multiple lesions are present and a valve may exhibit both stenosis and regurgitation. In this condition, usually one problem predominates and management is dictated by the pathology causing the majority of the patient's symptoms.

Valvular heart disease causes abnormalities in the pressure and volume-loading conditions of the heart that result in structural and functional changes. Management requires a clear understanding of the anatomy, pathophysiology, and natural history of each lesion as discussed in Chapter 23. Echocardiography is an invaluable tool in the diagnosis and management of valvular heart disease. Three factors determine valvular flow: valve area, the pressure gradient across the valve, and the duration of flow in systole or diastole. Management of valvular heart disease requires hemodynamic manipulation of heart rate and rhythm, preload, afterload, and contractility to enhance forward flow in stenotic lesions and to minimize backward flow in regurgitant lesions. Although hypertrophic cardiomyopathy (HCM) is not technically a valvular defect, its hemodynamic management is similar to that of aortic stenosis, so it is addressed in this section of the chapter.

Aortic Stenosis

Aortic stenosis (AS) is the most common valvular lesion among patients in industrialized countries. About 1% to 2% of the population has a congenitally bicuspid valve. This valve has a smaller orifice, which subjects the valve apparatus to increased sheer stress and degeneration. Hence the majority of younger patients (30-50 years of age) undergoing valve replacement have bicuspid valves.[127] Risk factors for the development of acquired aortic stenosis are the same as those for atherosclerosis: increased age, male gender, smoking, hypertension, and hyperlipidemia. The prevalence markedly increases with age.[9] About two thirds of aortic valve replacements are combined with CABG.[125] Some patients will be referred for aortic valve replacement (AVR) in preparation for subsequent noncardiac surgery because aortic stenosis is one of the active cardiac conditions for which the AHA and ACC recommend intensive management before noncardiac surgery.[128]

Pathophysiology. The normal aortic valve measures 3 cm^2 ± 1 cm^2. Stenosis is considered severe when the valve area decreases to 1 cm^2 and critical when it is 0.7 cm^2 or less. The stenotic orifice obstructs the LV outflow and the ventricle compensates by becoming thicker (concentric hypertrophy), attempting to generate enough pressure to push the blood forward past the stenosis. This forward motion causes accelerated, turbulent blood flow as it crosses the valve, somewhat like the water flow when a garden hose is partially occluded. Secondary to the Venturi effect, this increased flow results in a pressure drop as it crosses the valve so that pressure in the aorta is significantly less than the pressure in the LV. A jet velocity 4.0 m/sec or more and a mean pressure gradient drop of 40 mmHg or more suggests severe AS. The pressure drop results in a characteristic slow upstroke and high dicrotic notch on the A-line with a classic narrow pulse pressure (systolic − diastolic) associated with AS. The thick, hypertrophied cardiac muscle mass has a high oxygen requirement and increased LVEDP. The high ventricular pressure inhibits coronary perfusion. Because there is a high prevalence (more than 50%) of coexisting CAD, the patient with AS is very prone to ischemia. The fibrosed ventricle is noncompliant; consequently, diastolic filling becomes compromised even though LV systolic function is initially normal. Patients with AS are dependent on atrial augmentation of their cardiac output. Atrial kick can contribute up to 40% of LVEDV. The classic triad of AS symptoms—angina, syncope, and congestion causing dyspnea—correlate closely with 5-, 3-, and 2-year survival, respectively.[9] Ventricular function remains normal until late in the course of the disease, when the LV loses systolic function and dilates.

Anesthetic Considerations and Surgical Options. Valve replacement is indicated in symptomatic patients or in patients who manifest a reduction in LVF.[127,129] Preoperatively, great caution is required in treating angina with nitrates because hypotension can initiate a rapidly developing downward spiral of decreasing coronary perfusion, which can result in cardiac arrest and sudden death. Cardiac compressions can rarely generate enough pressure to provide adequate coronary perfusion to permit resuscitation. In patients with AS, hypotension should therefore be treated aggressively with phenylephrine to prevent this hemodynamic decompensation.[73]

Anesthetic management follows directly from an understanding of cardiovascular pathophysiology. Table 24-10 outlines the anesthetic considerations. The anesthesia provider must be prepared for hemodynamic instability on induction and should choose the medications and speed of their administration accordingly. Patients often present with a significant degree of hypertension preoperatively. The blood pressure may rise or fall abruptly during the case depending on the level of stimulation. Hypertension is better tolerated than hypotension, but keep in mind that hypertension can also be a source of increased myocardial oxygen demand. Patients with severe AS have at least a 40 to 50 mmHg mean pressure gradient between the left ventricle and the aorta. Consequently, a systolic pressure of 180 mmHg in the aorta means that systolic pressure in the left ventricle is at least 220 mmHg.[130] Tachycardia decreases the diastolic time needed for adequate coronary perfusion and ventricular filling while increasing myocardial oxygen demand at the same time. Hypotension or tachycardia must be treated promptly to avoid increased myocardial consumption, which can provoke the cycle of ischemia that can be disastrous. All vasodilators should be titrated cautiously. High-dose inhalation anesthesia can be problematic if it leads to a nodal rhythm with loss of atrial augmentation of cardiac output.

Stenotic aortic valves rarely lend themselves to repair. The choice of valve depends on patient preference, age, and comorbidities, but about 80% are replaced with a bioprosthetic (tissue) valve. Other options include a mechanical valve, aortic homograft (cadaver valve), or a Ross procedure, which uses the native pulmonic valve. Table 24-11 shows various surgical options and key points about each alternative. Mechanical valves can theoretically last a lifetime, but the patient is required to take Coumadin and occasionally prophylaxis against endocarditis.[131] It should be noted that the recommendations for antibiotic prophylaxis in patients with valvular heart disease have undergone important revisions that are clearer and should improve compliance. Although tissue valves do not require Coumadin, they nevertheless degenerate over time. In a 50-year-old patient, there is a 50% chance that the valve will have to be replaced in 15 years. A tissue heart valve tends to last longer as the recipient's age increases. The STS mortality risk benchmark for an isolated aortic valve replacement is

TABLE 24-10 Anesthetic Considerations in the Management of Aortic Stenosis

Factor	Hemodynamic Consideration	Anesthetic Considerations
Preload	Increase	Need volume to stretch noncompliant LV Increased preload reduces the gradient across LVOT LVEDP greater than LVEDV—Use echo to evaluate
Heart rate	Slow Normal	Too fast →, ischemia Too slow →, not enough CO for coronary perfusion
Rhythm	Maintain Sinus	Atrial kick can contribute up to 40% of LVEDV Cardiovert early
Compliance	Reduced	Thick, sclerotic LV prone to diastolic failure ↑ LVEDP reduces coronary perfusion Cautiously treat with NTG maintaining LVEDV and MAP
Contractility	Normal LVF till late in course	Concentric hypertrophy with normal chamber size Normal or ↑ EF initially Late dilation and falling EF
SVR	Elevated and relatively fixed	Hypertension better tolerated than hypotension Treat hypotension promptly with phenylephrine Dilate cautiously for severe hypertension
PVR	Normal till late in course	Diastolic failure can lead to dyspnea

↑, Increased; ↓ leads to; *CO*, cardiac output; *EF*, ejection fraction; *LV*, left ventricle; *LVEDP*, left ventricular end-diastolic pressure; *LVEDV*, left ventricular end-diastolic volume; *LVF*, left ventricular function; *LVOT*, left ventricular outflow tract; *MAP*, mean arterial pressure; *NTG*, nitroglycerin; *PVR*, pulmonary vascular resistance; *SVR*, systemic vascular resistance.

2.4% in an otherwise healthy patient, but can increase to over 15% if the patient has multiple comorbidities and the surgery is combined with other procedures.[69] According to the STS database, in 2010 there were 25,219 isolated aortic valve replacements (AVR) and 18,040 combined AVR and CABG.[132]

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is the preferred contemporary nomenclature for this disease, but it was formerly known as idiopathic hypertrophic subaortic stenosis (IHSS) or hypertrophic obstructive cardiomyopathy (HOCM). HCM is a common familial inherited disease that affects globally about 1 in 500 persons of all ages. It is a heterogeneous disease with diverse clinical presentations ranging from asymptomatic to life-threatening. When complications of HCM develop, they fall into three categories, which are not mutually exclusive: ventricular tachydysrhythmias, which can lead to sudden cardiac death, especially in young athletes; progressive diastolic heart failure, despite normal LV function; and atrial fibrillation, with a predisposition to stroke. It is recommended that diagnosis and treatment of HCM take place in a clinical center that specializes in management of this disease.[127]

Pathophysiology. Concentric LVH is the primary problem in HCM as opposed to AS, in which the LVH is secondary to stenosis. The pathophysiology of HCM is complex and can include left ventricular outflow tract (LVOT) obstruction, mitral regurgitation, diastolic dysfunction, ischemia, and dysrhythmias. HCM can be either obstructive or nonobstructive, based on the degree of outflow tract obstruction and the presence or absence of systolic anterior motion (SAM—discussed later.) Clinical management is guided by this finding. Echocardiography is used to determine the presence of obstruction and to document the gradient across the obstruction. A gradient of more than 30 mmHg is considered significant, and greater than 50 mmHg is the conventional threshold for surgical or percutaneous intervention if symptoms persist despite optimal medical management. About one third of patients manifest nonobstructive HCM, one third manifest obstruction even at rest, and finally, one third have variable obstruction based on loading conditions. About 25% of patients exhibit autonomic dysfunction that causes their blood pressure to decrease or increase only slightly in response to exercise, which increases the degree of obstruction.[133]

Because of LVH, patients can have angina and ischemia even without significant CAD.[9] Some patients will present with dyspnea, angina, and syncope; but in more than half the cases, sudden death or cardiac arrest is the presenting finding. It is imperative that HCM patients be evaluated for the risk of sudden cardiac death (SCD).[73] In the subset of patients in whom septal hypertrophy has become so extensive as that it obstructs the LVOT, ventricular contraction becomes hyperdynamic, forcing the blood to eject at high velocity to pass the obstruction. This rapid blood flow can then lead to a Venturi effect that causes the anterior leaflet of the mitral valve to be pulled into contact with the septal wall during systole, a phenomenon called *systolic anterior motion* (SAM) of the mitral valve. SAM increases LVOT obstruction and causes mitral regurgitation (MR). Any reduction in ventricular volume, directly or reflexively, will increase the degree of SAM–septal wall contact and exacerbate LVOT obstruction. Therefore, increases in heart rate and contractility and/or decreases in preload and afterload must be avoided.[134]

Medical management of HCM includes treatment of comorbidities, β-blockers to prevent sympathetically induced tachycardia and to treat atrial fibrillation, calcium channel blockers to improve diastolic relaxation, and disopyramide or other antidysrhythmics to reduce contractility and treat dysrhythmias. It is also important to maintain sinus rhythm, because as with AS, the atrial contribution to cardiac output can be considerable. Patients with a history of cardiac arrest or symptomatic ventricular dysrhythmias will likely have internal cardiac defibrillators (ICDs). ICDs should have their antitachyarrhythmia function suspended before surgery to prevent electrocautery-induced discharge. Other nonsurgical invasive therapies include septal ethanol ablation and biventricular pacing, in which the goal is slight pre-excitation of the RV apex, resulting in paradoxical septal motion that decreases the ejection velocity and reduces SAM.[135] Biventricular pacing is reserved for patients who are inappropriate candidates for surgical correction or alcohol ablation or who have a biventricular pacer implanted for another reason.[11,127,136]

Anesthetic Considerations and Surgical Options. Patients who remain symptomatic with gradients of 50 mmHg despite optimal medical management are candidates for septal reduction therapy. Surgical septal myotomy via the aortic approach at an experienced surgery center is preferred over alcohol septal ablation.[133] Approximately two thirds of patients will also have structural malformations of the mitral valve. It is not uncommon to find that the mitral valve will need repair or replacement at the time of myectomy.[73] Anesthetic management (Table 24-12) is

TABLE 24-11 Surgical Options for the Aortic Valve

Surgical Option	Surgical Considerations
Repair	
 (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)	Used for aortic regurgitation, usually due to bicuspid valve Technically more difficult than mitral repair Can last a lifetime, but 20%-25% need replaced in 10 years Preserves heart muscle strength and natural heart anatomy Decreased risk of infection Decreased requirement for life long anticoagulation
Replacement with a Mechanical Valve	
 (Courtesy Medtronic Inc., Minneapolis, Minn.)	Designed to last a lifetime Require the use of lifetime anticoagulation so lifestyle, childbearing, and compliance must be considered Some antibiotic prophylaxis Some make a clicking noise
Replacement with a Bioprosthetic (Tissue) Valve	
 (Courtesy Medtronic Inc., Minneapolis, Minn.)	Made of cow (bovine) or pig (porcine) pericardium sewn on a frame Coumadin not required unless patient is in atrial fibrillation At age 40, 50% chance of lasting 15 years, but generally less durable if younger and more durable if older at age of implantation Straightforward, relatively low risk
Replacement with a Homograft (Also Called Allograft)	
 (From Otto CM, Bonow RO. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease.* 3rd ed. Philadelphia: Saunders; 2009.)	Human aortic or pulmonic valve Ideal for endocarditis because they are least prone to infection May be good choice for athletes because of excellent flow characteristics and no need to take Coumadin Technically challenging and limited availability Last only about 15 years; durability varies with age
Ross Procedure (Also Called Switch Procedure)	
 (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)	Patient's own pulmonary valve is removed and used to replace the aortic valve; coronaries are reimplanted Pulmonary valve is replaced with a pulmonary homograft Main advantage is that the valves can grow, so a good choice in teens Lifetime anticoagulation is not required Pulmonary autograft (in aortic position) has about a 50% chance of lasting a lifetime; pulmonary homograft has a 10% chance of needing replacement in 10 years Technically difficult and reoperation is challenging

TABLE 24-12 Anesthetic Considerations in the Management of HOCM

Factor	Hemodynamic Consideration	Anesthetic Considerations
Preload	Increase	Volume is key → optimize preload to: Stretch noncompliant LV Reduces the gradient across LVOT Prevent SAM and MR Volume is first treatment for hypotension LVEDP greater than LVEDV—Evaluate with echo
Heart rate	Low-normal	Too fast → ischemia and not enough time for ventricular filling
Rhythm	Maintain Sinus	Atrial kick contributes LVEDV Cardiovert early
Compliance	Reduced	Due to concentric hypertrophy
Contractility	Usually hyperdynamic	Inhalation agents and/or β-blockers are used to depress
SVR	Avoid reductions	Hypertension better tolerated than hypotension Treat hypotension with volume and phenylephrine
PVR	Maintain	Not usually a problem

↑, Increased; ↓, decreased, leads to; *EF,* ejection fraction; *HOCM,* hypertrophic obstructive cardiomyopathy; *LV,* left ventricle; *LVEDP,* left ventricular end-diastolic pressure; *LVEDV,* left ventricular end-diastolic volume; *LVOT,* left ventricular outflow tract; *MR,* mitral regurgitation; *PVR,* pulmonary vascular resistance; *SAM,* systolic anterior motion of the mitral valve; *SVR,* systemic vascular resistance.

directed at optimizing preload, avoiding increases in septal wall–anterior leaflet contact caused by increases in heart rate or contractility, and preventing sudden reductions in afterload. Excision of the hypertrophied basal septum may result in disruption of the conduction system of the heart with new-onset heart block requiring pacing. After CPB is terminated, the outflow tract and mitral valve are examined using TEE.[9] To determine adequacy of surgical repair, the patient's heart rate and contractility are deliberately increased while the blood pressure is simultaneously decreased with an infusion of isoproterenol, dobutamine, or rapid ventricular pacing (rate of 120 bpm) The medications are used to mimic the physiologic hyperdynamic state, such as exercising. The echocardiographic examination will reveal whether obstruction, SAM, or MR develops with the tachycardia and hypotension. If more muscle needs to be excised or the valve needs repair or replacement to prevent SAM, CPB will resume so the surgeon can make the necessary adjustments.

Aortic Insufficiency or Regurgitation

Aortic insufficiency (AI) or regurgitation occurs because malcoaptation of the aortic valve leaflet or annular dilation allows a portion of the ejected stroke volume to be regurgitated or flow backward during diastole from the aorta into the LV. The regurgitant blood flow causes the left ventricle to be volume overloaded. AI can develop acutely or chronically and can be caused by a primary disease affecting the valve itself or secondary as a result of aortic root dilation. Acute AI results in rapid deterioration and is most frequently caused by trauma, endocarditis, or aortic dissection. Chronic AI can be tolerated for decades and can develop due to long-standing calcific degeneration, a congenitally bicuspid aortic valve, rheumatic fever, inflammatory or connective tissue diseases, idiopathic aortic root or valve dilation, hypertension-induced aortoannular ectasia, syphilis, or Marfan and Ehlers-Danlos syndromes.[137]

Pathophysiology. The increased LVEDV causes increased diastolic wall tension that leads to a pattern of LV enlargement known as *eccentric hypertrophy* whereby the sarcomeres replicate in series. By virtue of the Frank-Starling mechanism, the increased preload results in a large stroke volume that in turn rapidly raises aortic systolic pressure. Diastolic run-off is rapid as well, because blood can progress forward down the aorta or retrograde through an incompetent aortic valve back into the LV. The rapid systolic ejection and diastolic run-off leads to the well-described physical examination finding of widened pulse pressure (systolic − diastolic), a bounding pulse and an arterial waveform with rapid rise in systolic pressure and low dicrotic notch. Sometimes a double systolic peak called *pulsus bisferiens* can be seen on the arterial line. The magnitude of the regurgitant volume is directly proportional to regurgitant orifice size, diastolic time, and SVR. Ventricular compliance is increased and LVEDV can be three to four times greater than normal. The regurgitation is graded as mild (1+ [<40%]) to severe (4+ [>60%]), based on echocardiographic findings. As volume overload progresses, wall tension also increases, resulting in LV pressure overload and some degree of concentric hypertrophy.[103,138] The hypertrophy increases oxygen demand and angina can develop in patients with normal coronaries. However, the oxygen debt incurred for muscle shortening is relatively low so that ischemia is much less of a problem than with AS.[9] The natural history of chronic AI is such that dilation occurs slowly over years so that the ventricle compensates allowing the patient to be asymptomatic until AI is severe, causing permanent LV dysfunction. Surgery is recommended before ventricular function falls below 55%. Even after symptoms develop, life expectancy remains at 9 years as opposed to severe AS, for which the prognosis is more ominous.[138]

Acute AI can cause rapid deterioration because the normal ventricle is unable to compensate for the sudden increase in volume. Ventricular distension leads to increased LVEDV and pressure. As the LVEDP approaches aortic diastolic pressure, coronary perfusion decreases and this in turn causes ischemia and systolic dysfunction. Pulmonary congestion is likely because the forward blood flow from the LA is reduced due to higher LV diastolic volume and pressure. Mitral regurgitation can develop as the LV dilates further.[139] TEE is invaluable in the etiologic diagnosis and treatment of acute AI and can help determine the need for urgent or emergent surgery.

Anesthetic Considerations and Surgical Options. Hemodynamic management of AI (Table 24-13) is focused on enhancing forward flow and minimizing the regurgitant volume. A relatively high heart rate is used to minimize diastolic time. Judicious vasodilation lowers the SVR to enhance forward flow and reduce the regurgitant volume while still maintaining adequate pressure to support coronary perfusion.

During CPB, AI can lead to ventricular distention and pressure overload that directly opposes coronary perfusion and myocardial preservation. When CPB is initiated, a slow heart rate or ventricular fibrillation can lead to distension. After the aortic cross-clamp is applied, cardioplegia that is usually infused into the aortic root intended for antegrade flow down the coronaries can instead run into the LV secondary to the aortic valve's incompetence. Even mild to moderate AI can cause distention;

TABLE 24-13 Anesthetic Considerations in the Management of Aortic Insufficiency

Factor	Hemodynamic Consideration	Anesthetic Considerations
Preload	Increased	Need increased volume to maintain forward flow
Heart rate	High-normal	Decreased diastolic time minimizes regurgitation Avoid bradycardia
Rhythm	Usually sinus	Not usually a concern
Compliance	Increased	Eccentric hypertrophy can lead to a LVEDV 3-4 times normal Return large pump volume judiciously after bypass to prevent failure
Contractility	Normal LVF till late	Surgery indicated when EF less than 55% May need inotropes after pump
SVR	Decrease	Judicious vasodilation enhances forward flow
PVR	Increased with acute AI	Acute failure develops rapidly
CPB	LV distention	Can develop due to slow HR or nonbeating heart Consider LV vent; retrograde or ostial cardioplegia

AI, Aortic insufficiency; *CPB,* cardiopulmonary bypass; *EF,* ejection fraction; *HR,* heart rate; *LV,* left ventricle; *LVEDV,* left ventricular end-diastolic volume; *LVF,* left ventricular function; *PVR,* pulmonary vascular resistance; *SVR,* systemic vascular resistance.

consequently, the presence of AI increases the risk of other cardiac surgical procedures as well. Achieving diastolic standstill in these situations often requires cardioplegia to be delivered directly into the coronary ostia and/or retrograde through the coronary sinus. An LV vent is placed to suction away fluid, thereby alleviating or preventing distension. A positive inotrope is often useful after CPB, especially if there was LV dysfunction prebypass or questionable preservation during bypass.

Valve repair is possible but technically more challenging than mitral repair. Traditional replacement options are the same as for aortic stenosis (see Table 24-11). Percutaneous replacement is discussed later in the chapter, but this procedure is limited to severe inoperable stenotic lesions at this time.

Mitral Stenosis

Mitral stenosis (MS) is the least common left-sided valvular defect because it is caused primarily by rheumatic heart disease (RHD), which is now rare in developed countries. Although RHD affects men and women equally, MS is 2 to 3 times more prevalent in women. Occasionally MS also develops as the result of severe mitral annular calcification caused by the atherosclerotic process. Clinically, significant stenosis takes decades to develop and symptoms does not usually appear until the normal 4 to 5 cm^2 valve area is reduced to 2.5 cm^2.[140]

Pathophysiology. As the valve orifice narrows, diastolic filling of the LV is limited and a pressure gradient develops across the mitral valve. Initially, left atrial pressure increases, which can result in pulmonary hypertension (PHTN). Eventually right ventricular failure can develop if the PHTN is left uncorrected. Stenosis is considered severe when the valve area is less than 1.0 cm^2, the mean gradient exceeds 10 mmHg, and pulmonary artery systolic pressures are greater than 50 mmHg.[136] The presence of PHTN increases the risk of surgery by 4% to 9%.[141] Flow across the valve will decrease in response to an increase in cardiac output or a decrease in diastolic time. Hence, symptoms are usually first experienced during exercise or stress. Conditions such as pregnancy and sepsis may provoke atrial fibrillation (AF) in a previously asymptomatic patient, leading to decompensation. Approximately 40% of patients develop AF. The rapid heart rate is the primary cause of hemodynamic instability, rather than the loss of atrial kick. Patients with MS and AF have an embolic stroke rate of 7% to 15% per year. Long-term anticoagulation and heart rate control are important in the management of MS.[136]

Anesthetic Considerations and Surgical Options. Although avoiding tachycardia and treating AF helps control the symptoms, MS causes mechanical obstruction to ventricular filling. The three procedures used to relieve this obstruction are mitral baloon valvotomy, open commissurotomy of the mitral valve, and replacement with a mechanical or biologic valve. Closed commissurotomy is no longer recommended. Valvotomy or repair is generally preferred to replacement, but a left atrial thrombus, concurrent mitral regurgitation, or annular calcification may make replacement the treatment of choice. If the patient has a history of AF and the valve is approached through a full sternotomy, the surgeon will often elect to add a Maze procedure or pulmonary vein isolation to treat AF. Choice of the traditional cut-and-sew technique, radiofrequency (heat), or cryotherapy (cold) ablation is based primarily on surgical preference. Anesthetic considerations for the Maze procedure and other options for atrial ablation are discussed after the valve section of this chapter.

Anesthetic considerations for MS are outlined in Table 24-14. Keeping the heart rate low-normal is a priority so there is adequate time in diastole time to fill the LV. If atrial fibrillation is present or develops, the ventricular rate must be controlled. Conditions or situations that could exacerbate pulmonary hypertension should be avoided. These include hypercarbia, hypoxemia, nitrous oxide, and the Trendelenburg position. MS is the only valve defect that causes the LV to be chronically underloaded. Volume management can be challenging, because an adequate preload is needed to maintain flow across the stenotic valve, but too much volume can lead to pulmonary congestion. The majority of patients have normal left ventricular function; however, the increase in ventricular volume that occurs after valve replacement can cause the chronically underloaded left ventricle to dilate. If failure occurs, it is generally responsive to inotropic support.[142] Pulmonary hypertension with resultant RV failure can be more problematic. Patients may benefit from mild hypocapnea, judicious vasodilator therapy, and inotropic support with epinephrine or milrinone. In extreme cases, nitric oxide, an inhaled pulmonary vasodilator, may be beneficial in reducing RV afterload. Routine use of nitric oxide is limited by cost.

Mitral Regurgitation or Insufficiency

Mitral regurgitation (MR) or insufficiency occurs during systole when blood is ejected back into the left atrium because of an incompetent mitral valve. The causes of MR are considered organic or structural when the regurgitation is due to a problem with the valve leaflets or chordae; or functional, when insufficiency results from a dilated LV stretching a structurally normal valve. In developed countries, MR is usually caused by degenerative processes, but it can also arise secondary to infective endocarditis, mitral annular calcification, RHD, and connective tissue disorders such as Marfan syndrome. Functional MR is most often caused by ischemic heart disease, but it can also develop in patients who have idiopathic

TABLE 24-14 Anesthetic Considerations in the Management of Mitral Stenosis

Factor	Hemodynamic Consideration	Anesthetic Considerations
Preload	Reduced	LV chronically underloaded Adequate preload needed to maintain flow across valve Avoid hypovolemia
Heart rate	Low-normal	Need adequate diastolic time to fill LV Too fast →; ↑ gradient across valve
Rhythm	Atrial fibrillation in 40%	May decompensate if rapid ventricular response, otherwise reasonably well tolerated
Compliance	Normal	Not a problem
Contractility	LV usually okay but RV can be ↓	LV may need inotropic support after pump Administer volume cautiously after pump, watching for RV dysfunction and volume overload RV may need support with epinephrine or milrinone Judicious RV unloading with NTG or nitric oxide
SVR	Normal	May need vasoconstrictor to offset vasodilation from milrinone, but watch for pulmonary vasoconstriction
PVR	Increased	Pulmonary hypertension can be mild to severe Avoid hypercarbia, hypoxia, acidosis, Trendelenburg position, and nitrous oxide Severe cases may benefit from nitric oxide

↑, Increased; ↓, decreased; →, leads to; *LV*, left ventricle; *NTG*, nitroglycerin; *RV*, right ventricle; *PVR*, pulmonary vascular resistance; *SVR*, systemic vascular resistance.

cardiomyopathy.[142] The presentation of the patient with MR varies depending on the etiology or acuity of the condition.

Pathophysiology. In patients with MR, there is no isovolumetric contraction phase of systole because the LA acts as a low-resistance vent for ventricular ejection. Both the left atrium and ventricle are volume overloaded because the total stroke volume is equivalent to the volume of blood that goes antegrade down the aorta plus the amount of blood that is ejected retrograde into the LA. Consequently, the EF that is calculated by TEE overestimates the actual forward flow. Pressure and volume overload leads to LA dilation. Atrial fibrillation develops in about 50% of the patients who undergo surgery.[73] The amount of regurgitation is dynamic and based on the size of the mitral orifice, the pressure gradient between the LA and LV, the time available for regurgitant flow, and the compliance of the receiving chamber. The LA and LV compensate for the chronic volume overload by eccentrically dilating (parallel replication of sarcomeres), increasing compliance to accommodate the volume loads. Consequently, patients with MR may be asymptomatic for years. Large increases in volume can occur with minimal increases in LA or PAEDP. Increases in heart rate and decreases in preload and/or afterload help minimize the regurgitation and enhance forward flow.[9] Often TEE is used to evaluate the extent of regurgitation while the blood pressure is pharmacologically manipulated at various systolic driving pressures. Eventually volume overload induces pressure overload and LV dysfunction develops. Since cardiac output is an afterload-dependent measurement, it can be normal or only mildly reduced even in the face of significantly compromised ventricular function. An EF of less than 60% in a patient with severe MR represents significant LV dysfunction and is predictive of a poorer outcome.[138] The problem is often first unmasked during the attempt to separate from CPB after valve repair or replacement. Pharmacologic support with epinephrine or dobutamine should be considered if LV dysfunction occurs.[73]

Patients with acute MR often deteriorate rapidly. The LA cannot handle the abrupt increase in volume so the fluid backs up, resulting in acute pulmonary edema and right heart failure. The pulmonary capillary wedge pressure (PCWP) will classically show an enlarged V wave, but the size does not reliably correlate with the degree of MR.[142] Acute MR must often be treated on an urgent or emergent basis with mitral repair or replacement. Oftentimes an intra-aortic baloon pump will be used to increase coronary perfusion, decrease afterload, and support the patient during the perioperative period.[129]

Anesthetic Considerations and Surgical Options. The preload is elevated and must be judiciously maintained or gently reduced to enhance forward flow and minimize regurgitation. Inhalation agents and vasodilators are generally effective in reducing afterload and maintaining heart rate in the high-normal range (Table 24-15). Valve repair or replacement increases afterload and may unmask previously compensated LV dysfunction. An inotrope or inodilator may be needed after bypass. Occasionally SAM develops after repair, especially if the anterior leaflet is long or has redundant tissue. TEE is used to diagnose this problem.[9]

Mitral valve repair is almost always favored over replacement whenever possible, depending on the native valve pathology and on surgical expertise. The advantages of repair include improved postoperative LV function, increased long-term and short-term survival, improved quality of life, lower risk of complications, and less need for long-term anticoagulation.[129,139] Over the past decade, as surgeons have gained experience with valve repair techniques, the volume and approaches to mitral repair have risen dramatically. The mitral valve can be accessed through a traditional sternotomy, partial upper sternotomy, right minithoracotomy, and a robotically assisted endovascular approach. The latest advance in mitral valve repair involves a percutaneously introduced clip. These alternative approaches are discussed later in the chapter. Posterior leaflet problems are often repaired using a triangular or quadrangular resection with a complete or partial annuloplasty ring (Figure 24-14). Involvement of the anterior leaflet increases the complexity of the repair and requires greater surgical expertise because the chords must often be shortened, transferred, or replaced. If the patient has atrial fibrillation, a Maze procedure or ablation may be performed. Severe mitral annular calcification or rheumatic disease may make repair impossible, in which case the valve can be replaced with a tissue or mechanical device.[129]

Surgical Therapy for Atrial Fibrillation

Early in 1990, Cox et al. developed the "Maze" procedure in which several incisions are made in a specified pattern around the atria to create a maze of scar tissue that would block the reentry circuits that cause atrial fibrillation (AF) while still allowing conduction of an impulse from the sinus to the atrioventricular node.[143,144] The original procedure has been improved, so that the Cox-Maze III procedure cures AF 99% of the time. It is indicated for drug intolerance, arrhythmia intolerance, or recurrent embolic

TABLE 24-15 Anesthetic Considerations in the Management of Mitral Regurgitation

Factor	Hemodynamic Consideration	Anesthetic Considerations
Preload	Increased	Cautiously maintain or ↓ to enhance forward flow
Heart rate	High-normal	Decreased diastolic time minimizes regurgitation Avoid bradycardia
Rhythm	Sinus or atrial fibrillation	Not usually a concern as long as rate adequate
Compliance	Increased	Eccentric hypertrophy of LA and LV
Contractility	Normal early Reduced late	Surgery indicated when symptomatic or EF ↓ May have LV dysfunction even with mildly ↓ EF May need inotropes after pump
SVR	Decrease	Cautious vasodilation enhances forward flow
PVR	Avoid further increases	Acute pulmonary edema and/or RV failure can develop with acute MR or longstanding chronic MR May need to treat urgently with MV repair or replacement and/or an IABP
CPB	LV dysfunction	Can be unmasked after surgery

events.[145] The number of surgical and catheter-based techniques used to treat AF has expanded greatly as the understanding of causation has grown. Today many catheter-based ablative procedures are available in the electrophysiology laboratory, but this discussion will be limited to procedures performed in the operating suite.

Surgical procedures used to ablate AF are often carried out in conjunction with, and usually just prior to, other cardiac procedures, but they can also be performed independently. Traditionally, the Maze requires CPB and includes the ligation or stapling of the left atrial appendage because it is considered a major source for emboli. The right atrial appendage is a significant source of atrial natriuretic peptide, so it is not removed. The procedure can be carried out through a traditional sternotomy or through a minimally invasive right anterior thoracotomy with femoral cannulation. Newer technology now allows surgeons to use a variety of alternate energy sources to quickly and simply make lesions that interrupt the reentry pathways.[73] The pulmonary veins have been found to be a site of reentry, so they are now frequently isolated using ablative energy.[146] Options for energy sources include radiofrequency (RF) and microwave energy, ultrasound, cryotherapy (freeze), and laser. The development of epicardial probes has enabled surgeons to now perform ablative procedures on beating hearts through keyhole incisions off-pump.[147,148]

Minimally Invasive Surgical Approaches

Overview

Minimally invasive cardiac surgical techniques have evolved considerably in the past two decades. Much of the technology was first developed for other surgical specialties and then adapted to cardiac surgery. The driving force behind the growth has been twofold—first to reduce the use of CPB and second to make the procedures less invasive. As the population ages, the prevalence of comorbidities and aortic atherosclerosis increases. Avoidance of CPB, aortic manipulation, and cross-clamping ideally would prevent some of the known complications. Indeed, transcatheter aortic valve implantation (TAVI) was recently approved for the population of patients with aortic stenosis that is deemed too high risk for traditional surgery. Additionally, the public assumes that less is more, so they seek out minimally invasive surgeons on the intranet.

What actually constitutes a minimally invasive approach is quite variable. In some cases, only the skin incision is smaller and the sternotomy is full. In other cases, the approach is robotic and/or endoscopic. Figure 24-15 shows some of the common incisions that are used in minimally invasive surgery. The field is rapidly evolving, but this chapter focuses on the most innovative approaches at the time of its writing.

Minimally Invasive Mitral Valve Procedures

Surgical Approaches. Minimally invasive mitral valve surgery involves repair or replacement of the mitral valve by a variety of less invasive surgical incisions and approaches than the traditional full median sternotomy. Minimally invasive mitral valve surgery has evolved extensively over the last 10 to 15 years, that is, since 1996, when Carpentier performed the first video-assisted mitral valve repair through a right minithoracotomy, and 1997, when Mohr performed the first robotic-assisted mitral valve repair.[149,150] Surgical approaches for repair of the mitral valve today may include partial sternotomy, right minithoracotomy, or total endoscopic approach through port chest incisions, with or without the use of video assistance or robotics (see Figures 24-15 and 24-16). The minimally invasive mitral valve approach has shown successful surgical results and positive outcomes in regard

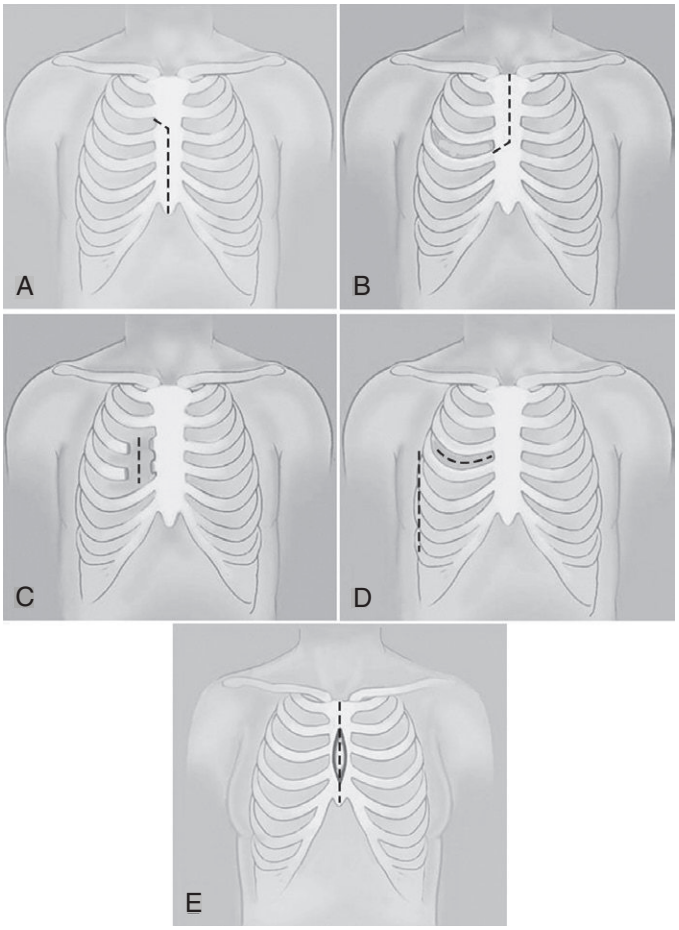

FIGURE **24-15** Minimally invasive incisions. **A,** Lower hemisternotomy. **B,** Upper hemisternotomy. **C,** Parasternal incision. **D,** Anterolateral minithoracotomy. **E,** Full sternotomy with small skin incision. to mortality and morbidity.[149,151-153] Advantages of the minimally invasive approaches to the mitral valve include decreased hospital length of stay, faster patient recovery, decreased blood loss, and improved cosmetics compared to the traditional median sternotomy.[149,153-155] Successful surgical outcomes are dependent on proper patient selection. Contraindications to a minimally invasive approach to mitral valve repair include inability to obtain TEE, severe aortic regurgitation, aortic and/or thoracic disease, Marfan syndrome, and previous aortic and/or thoracic surgery.[156] Atherosclerosis of the descending aorta or femoral vessels preclude surgeries that require retrograde aortic cannulation through the femoral artery.

Anesthetic Considerations. Regardless of the surgical approach adopted, all minimally invasive mitral valve procedures require a general anesthetic. Principles applied to the anesthetic management of patients with mitral valve disease (discussed earlier in the chapter) are also applicable to the patient undergoing a minimally invasive mitral valve procedure, but with some additional considerations. A fast-track approach to the selection of induction and maintenance of medications is usually appropriate. Judicious use of narcotics and muscle relaxants will facilitate achieving the goal of early extubation. It is imperative that the level of muscle relaxation be closely monitored because unwanted patient movement during a robotic procedure could cause significant harm. Measures to maintain normothermia such as fluid warming devices, circuit humidifiers, forced air warming devices, and raising the room temperature must also be considered, especially if early extubation is a goal.

For robotic surgery, patients are positioned supine with a roll placed under the right scapula to elevate the hemithorax 25 to 30 degrees.[152,154] The right arm is carefully positioned (slightly deviated from body to allow port access) and padded along the right side of the patient's body to prevent it from interfering with the robotic device. External defibrillator pads should be placed on all patients because the use of internal defibrillation paddles is not possible with limited incisions.

If a mini-thoracotomy approach is selected, the surgeon makes a 3- to 4-cm right submammary, minithoracotomy incision at the fourth to fifth intercostal space along with separate smaller chest incisions for port access or for robotic instrumentation access.[149,150] If a total endoscopic approach is selected, only several small chest incisions are usually made in the right hemithorax for port access[152] (see Figures 24-16, 24-17, and 24-18). Lung isolation is not necessarily required, but is usually preferred (especially for robotic procedures), to allow more working room in the surgical field. Lung isolation can be accomplished with either a double-lumen endotracheal tube or a bronchial blocker,

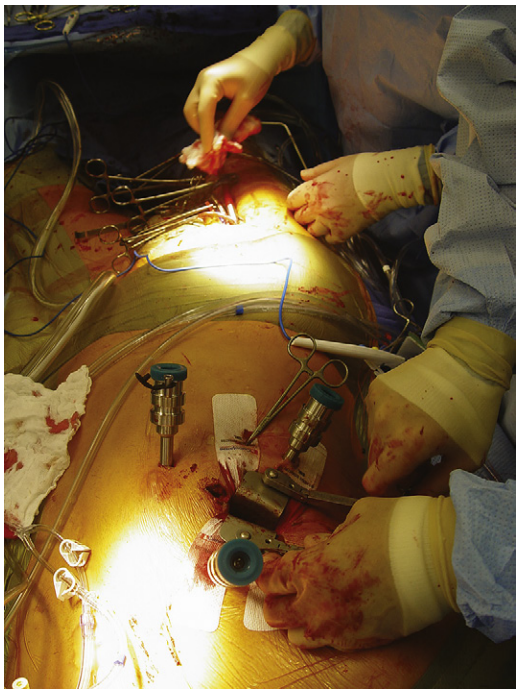

FIGURE **24-17** Intraoperative photograph taken from near the patient's head before robotic-assisted mitral valve repair. Femoral cannulation for cardiopulmonary bypass has been completed (*top*). The primary surgical incision and working ports are also shown (*bottom*). (From Kaplan JA, Reich JA, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia: Saunders; 2011.)

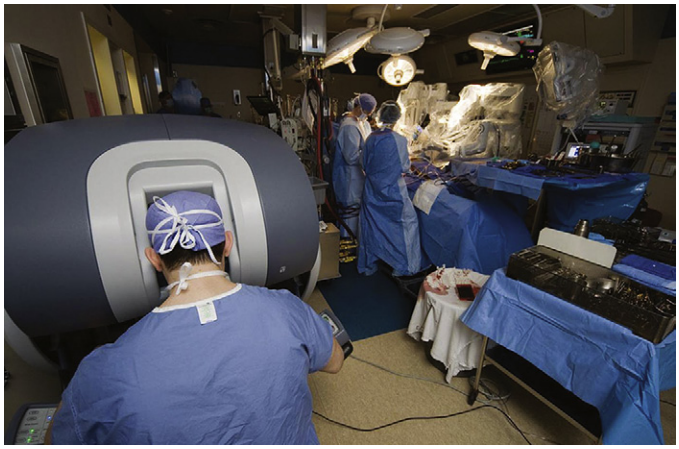

FIGURE **24-18** Robotic-assisted mitral valve repair. The surgeon (*lower left*) controls the robotic arms while seated at a console remote from the patient. (From Kaplan JA, Reich JA, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia: Saunders; 2011.)

keeping in mind that if the patient is not extubated in the OR, the double-lumen endotracheal tube will need to be exchanged for a single-lumen endotracheal tube at the end of the procedure. If the double-lumen endotracheal tube is required, then placement and lung isolation confirmation is necessary after final patient positioning because access to the patient's chest and airway is extremely limited once the robotic arms are placed inside the chest. The anesthetist must not only consider management strategies for one-lung ventilation (if required) but also be prepared to treat and manage the untoward hemodynamic effects of carbon dioxide insufflation that may be used to create a capnothorax.

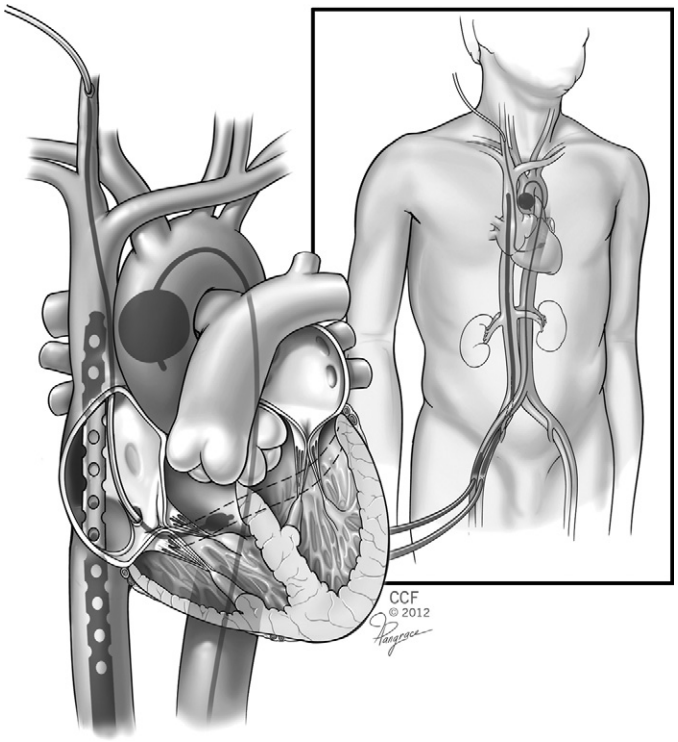

FIGURE **24-19** Overview of cannulation showing femoral venous and arterial cannulas, retrograde coronary sinus catheter, and endoballoon. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)

CPB Cannulation and Cardioplegia. Minimally invasive mitral valve surgery employs the use of CPB. CPB cannulation is usually obtained from the femoral artery and vein under TEE guidance to confirm placement. Complications of femoral CPB cannulation include retrograde aortic dissection, limb ischemia, and chest wall hemorrhage.[156] If additional venous drainage is needed, the surgeon can perform superior vena cava (SVC) cannulation by passing a wire through a 16-gauge right internal jugular catheter using the Seldinger technique. The 16-gauge catheter is often placed by anesthesia after induction and then later prepped into the surgical field. An alternative is cannulating the SVC directly from the surgical field. The anesthetist may also access the right internal jugular vein for placement of a specialized catheter that allows delivery of percutaneous retrograde cardioplegia into the coronary sinus (Figure 24-19). Before placement of the percutaneous coronary sinus catheter, 70 to 100 units/kg of heparin is usually administered to avoid coronary sinus thrombus. Placement of these specialized catheters by the anesthetist is performed under fluoroscopy and/or TEE guidance, or they may be placed directly by the surgeon through the surgical incision. Proper positioning of the retrograde cannula in the coronary sinus can occasionally be quite challenging. If right internal jugular access is obtained for surgical CPB purposes, the left internal jugular vein will have to be accessed by the anesthetist for the administration of central intravenous medication.

Antegrade cardioplegia may be delivered to the aortic root by an aortic cannula inserted into the ascending aorta by the surgeon through a stab or thoracotomy incision.[149] Administration of antegrade cardioplegia also can be delivered by an endoaortic occlusion cannula that is advanced through a second opening (side arm) of a larger arterial femoral cannula (see Figure 24-19). The endoaortic catheter is advanced into the aorta and positioned at

the sinotubular junction using TEE guidance.[154] The baloon on the catheter not only allows for endoaortic occlusion, but also for administration of antegrade cardioplegia via an orifice on the end of the endoaortic baloon. Aortic occlusion also can be achieved by direct transthoracic cross-clamping to avoid potential complications associated with the endoaortic baloon system, such as endoaortic baloon rupture or migration. If the end-clamp system is used for aortic occlusion, correct positioning is confirmed with either TEE or fluoroscopy, and continuous monitoring for endoaortic baloon migration during CPB is necessary. In some centers for percutaneous CPB, the anesthetist places a specialized pulmonary artery catheter (PAC) for venting the PA. Bilateral radial arterial catheters are often placed to detect baloon migration. Migration of the baloon is suspected if a significant discrepancy in pressure readings occurs between bilateral arterial radial catheters.[149,155] Obstruction of the coronary arteries can occur if the baloon migrates toward the aortic valve because of overventing, high systemic flow, or high CPB flow.[149,152,154] Distal migration of the endoaortic baloon can cause neurologic injury due to obstruction of the innominate artery and may result in cerebral hypoperfusion. Distal migration of the endoaortic baloon and obstruction of the innominate artery should be suspected if there is a loss of the right arterial radial pulse.

As mentioned earlier, there are several minimally invasive surgical methods and techniques that are used to repair the mitral valve. Long-shafted instruments and a thorascopic-televised view of the surgical field may be used to repair the mitral valve when the video-assistance approach is selected. If the robotic system is used to repair the mitral valve, the surgeon will sit at a remote console away from the patient and surgical field. From the remote console the surgeon directs the extensors of the robot to perform the desired surgical maneuvers to repair the mitral valve (see Figure 24-18). A surgical assistant is usually present at the surgical field, and he or she guides the robotic arms and moves the robot whenever necessary. Higher cost, increased complexity, and in some reports (due to a learning curve) longer cross-clamp times are reported as disadvantages of robotic use.[149,152,154] Reported advantages of the robotic system over the thorascopic video-assisted approach to mitral valve repair include reduction in surgeon tremor, increased mobility with instrumentation, and three-dimensional vision.[149,150,154]

Minimally Invasive Aortic Valve Replacement

The surgical approach for aortic valve surgery has been traditionally through a full median sternotomy incision extending from the sternal notch to the xiphoid process, allowing complete exposure of the heart and ascending aorta. The alternative surgical approaches to the aortic valve that are in use today were not developed until the mid-1990s. The hemisternotomy (ministernotomy) and right minithoracotomy approaches are the two minimally invasive surgical approaches used today for isolated aortic valve surgery. Minimally invasive aortic valve surgery has demonstrated several advantages over traditional sternotomy. These include not only improved cosmesis but also decreases in length of stay in the ICU and hospital, blood transfusions, and postoperative ventilatory support. The approach is also selected in reoperations to avoid a sternotomy that could potentially disrupt patent bypass grafts. Reported disadvantages include limited surgical exposure, greater difficulty with ventricular de-airing, potential difficulty in placing a coronary sinus catheter for retrograde cardioplegia, and the potential for postoperative femoral wound infections.[157-160]

Both surgical mini-AVR approaches employ CPB. An arterial cannula may be placed directly into the aorta, or arterial access may be obtained from the femoral artery or subclavian artery. Venous cannulation may be accessed directly from the right atrium. If direct venous cannulation limits surgical exposure, then venous access to the right atrium may be obtained from either the internal jugular or femoral vein. If femoral access is obtained for either venous or arterial cannulation, TEE is necessary to guide and confirm placement of the femoral arterial and venous cannulae. TEE is also required to guide and confirm placement of the retrograde cardioplegia catheter into the coronary sinus. Anesthetic management for minimally invasive aortic surgery is comparable to anesthetic management for aortic valve surgery with a traditional sternotomy incision, but with some additional considerations. A fast-track approach may be incorporated into the anesthetic plan, including modalities that maintain normothermia to facilitate early extubation. Internal defibrillation paddles may be difficult to use in a mini-AVR approach; therefore it is necessary to ensure that external defibrillator/pacing pads are placed on the patient before incision. A brief period of hypotension and bradycardia should be anticipated by the anesthetist when the surgeon lifts the pericardium to facilitate maximal surgical exposure prior to cannulation. A preemptive bolus of phenylephrine may be administered prior to lifting the pericardium to maintain vascular tone and successful return to baseline MAP. Direct observation of the myocardium is limited with various mini-AVR surgical incisions. The anesthetist will have to rely on TEE and hemodynamic monitoring to assess adequacy of myocardial contractility and ventricular filling. The anesthetist should always be prepared to convert to a full sternotomy incision if surgical complications arise, such as difficulty in removal of intracardiac air, mediastinal bleeding, and cardiac tamponade.

Minimally Invasive Myocardial Revascularization

The quest to develop less invasive surgical techniques than the traditional median sternotomy for coronary revascularization has been in progress since the first minimally invasive coronary bypass revascularization was reported in 1967. In addition to improved cosmetics, the goals driving development include the desire to lower sternal wound infection rates, brachial plexus injury, cost, and length of stay.[154,161] Several different minimally invasive techniques for single LAD bypass grafting have emerged over the last 40 years. These employ surgical methods already mentioned in this chapter. Total endoscopic coronary artery bypass (TECAB), minimally invasive direct coronary artery bypass (MIDCAB), and port-access coronary artery bypass (PA-CABG) are the most common approaches for minimally invasive coronary revascularization. TECAB is a minimally invasive coronary revascularization approach that uses robotic instrumentation for assistance with anastomosis, and it is performed either on or off pump. The MIDCAB approach is performed through a small left anterolateral thoracotomy incision, usually off pump, and anastomoses are hand sewn (Figure 24-20). A right anterior thoracotomy may be performed for access to the right coronary artery (RCA) or posterior descending artery (PDA). PA-CABG uses video assistance for left internal thoracic artery (LITA) harvesting; CPB is employed, and anastomoses are often hand sewn. Regardless of which minimally invasive technique is selected, the anesthetist should have a detailed discussion with the surgical team beforehand. Topics that should be discussed include the surgical approach, incision, need for one-lung ventilation (OLV), use of CPB, and method of cannulation. Principles governing anesthetic management for CPB and off-pump coronary revascularization (mentioned earlier in the chapter), along with a fast-track approach, are all applicable to the patient selected for minimally invasive coronary revascularization. Additional considerations regarding the

surgical use of robotics or video assistance, OLV, femoral cannulation, and use of the endoaortic catheter system also may need to be incorporated into the anesthetic plan.

Transcatheter Aortic Valve Implantation

Transcatheter aortic valve implantation (TAVI) is an innovative, minimally invasive percutaneous procedure for the correction of severe aortic stenosis. It does not require sternotomy or CPB. A retrograde approach (transfemoral) via the femoral artery or an antegrade (transapical) approach via the left ventricular apex is used to implant a bioprosthetic valve into the native calcified valve. Approximately 30% of patients with critical aortic stenosis are not considered candidates for traditional sternotomy and CPB because advanced age and the presence of comorbidities make the risk prohibitively high.[162-164] On November 2, 2011, the Food and Drug Administration (FDA) announced approval of the SAPIEN Transcatheter Heart Valve for this population.[165] Trials in both Europe and the United States have shown the superiority of this technology over standard medical therapy in reducing the 1-year death rate by 20% as well as improving the quality of life.[166-169] In Europe, where the device has been approved since November 2007, the procedure now represents a significant portion of aortic valve replacement procedures. Now that the United States has approved the valve, the trend is expected to be repeated here.

Surgical Approach. The two types of valves currently in use are the baloon-expandable valve (Cribier-Edwards and Edwards SAPIEN), used for both the transfemoral and transapical approaches, and the self-expanding valve (CoreValveRevalving System), used only with the transfemoral approach. The bioprosthetic valve is delivered over a catheter system into the diseased stenotic valve via a transfemoral or transapical approach. Access is reached by an interventional cardiologist through the right and left femoral arteries and vein for deployment of the device and delivery of rapid ventricular pacing.[162] The femoral arterial and venous access also may be used for rapid CPB cannulation if emergent bypass becomes necessary. To prevent distal movement of the catheter and ensure proper placement of the device, both valvuloplasty and deployment of the valve are performed while ventilation is held (apnea) and a low cardiac output state is induced by rapidly pacing the ventricle at a rate of 200 bpm.[162,170] The lack of ventricular ejection prevents migration of the baloon or stent-valve that the stroke volume from the beating heart may cause during valvuloplasty and actual device deployment.[171] Fluoroscopy and TEE are used throughout the procedure to achieve accurate positioning of the valve and for continuous assessment of cardiac function. The transfemoral approach may be selected if there has been a previous left thoracotomy, chest radiation, or pathology in or near the LV apex.[170,171] The transfemoral approach delivers the bioprosthetic aortic valve in a retrograde fashion through the abdominal and thoracic aorta into the aortic valve (AV) annulus[172] (see Figure 24-20). Contraindications to the transfemoral approach include the presence of an ascending aortic aneurysm and femoral-iliac arteries that have a small diameter, contain great calcification, and are extremely tortuous.[170,173]

In addition to achieving femoral venous and femoral arterial access for the transapical approach, a left anterior minithoracotomy incision is made through the fifth or sixth intercostal space over the LV apex[172] (Figure 24-21). The surgeon opens the pericardium and places purse-string sutures at the LV apex. A puncture at the LV apex is then made to allow the bioprosthetic valve to be delivered (under TEE and fluoroscopy guidance) through the left ventricle into the AV annulus in an antegrade fashion. An antegrade approach is often selected for patients with severe aortic calcification or peripheral vascular disease, or if better surgical control is required over the baloon valvuloplasty and actual device implantation (due to the shorter distance between the LV apex and AV annulus).[162,171,172]

Anesthetic Considerations. Preoperative considerations for the high-risk aortic stenosis (AS) patient who is undergoing a TAVI are similar to those that apply to patients with severe AS, mentioned earlier in the chapter. The anesthetist must be aware of additional considerations that are inherent in a TAVI procedure to facilitate a safe and favorable surgical outcome. They begin with understanding the details of the surgical procedure, the unique set-up of a hybrid operating room, and the hemodynamic challenges that arise during the procedure. Figure 24-22 shows an example of the hybrid OR setup. It must also be recognized that a TAVI procedure is a

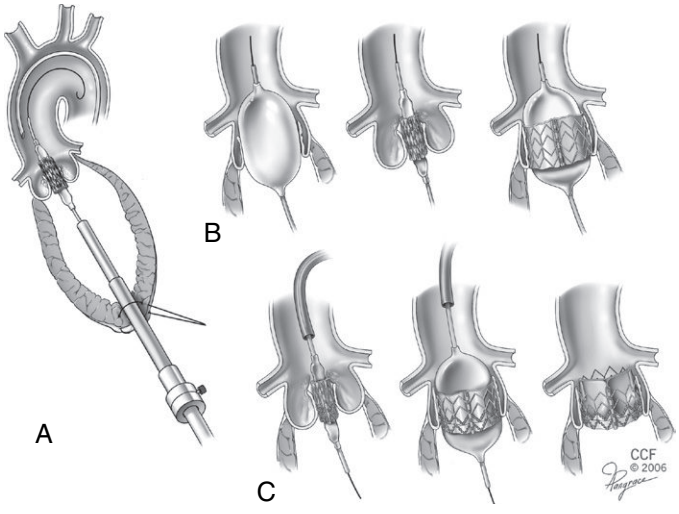

FIGURE **24-20** Transcatheter aortic valve implantation (TAVI). **A** and **B,** Antegrade, transapical approach. A baloon is first used to compress the diseased native valve. Then a compressed tissue heart valve is placed on the baloon catheter, inserted through the ribs into the apex of the left ventricle, and positioned directly inside the diseased aortic valve. Once in position, the baloon is inflated to secure the valve in place. **C,** Retrograde, transfemoral approach. Implantation process is similar, but baloon and catheter are positioned retrograde from the femoral artery. collaborative effort among many disciplines including cardiology, anesthesia, and cardiothoracic surgery and that all team members must clearly communicate with one another. Because fluoroscopy is used throughout a TAVI procedure, protective radiation safety equipment must be worn. Noninvasive and invasive monitoring for TAVI procedures is similar to that of a standard cardiac case, including the use of a radial arterial catheter and pulmonary arterial catheter. All intravenous lines should have the appropriate amount of extension to facilitate safe use of any fluoroscopic device. Patients are positioned supine, with a slight tilt to the right for surgical exposure of the left chest if the transapical approach is selected.

Recent literature has reported the use of local anesthesia with sedation as an anesthetic technique for transfemoral catheter aortic implantation.[162,174] Continuous neurologic assessment, avoidance of complications associated with general anesthesia in high-risk patients who have severe aortic stenosis, and quicker recovery times are reported advantages of using local anesthesia with sedation.[162] To date, however, the majority of procedures are performed using general anesthesia with endotracheal intubation.[162] Advantages of having a protected airway include the ability to use TEE, control ventilation during valve deployment, and urgently institute CPB if needed. A balanced general anesthesia technique is usually selected with the goal of early emergence and extubation. Because the slightest patient movement (even ventilation) can be disastrous during valve deployment, muscle relaxants are used. Minimal doses of narcotics are needed for postoperative pain control. The use of OLV for the transapical approach is based on surgical preference.[171]

Vasoactive medications, such as phenylephrine, norepinephrine, and epinephrine, must be immediately available for administration to promptly treat hemodynamic instability. Although rapid ventricular pacing is usually limited to 10 to 15 seconds for valvuloplasty and stent deployment, preemptive boluses of a vasopressor may be administered to maintain vascular tone, coronary perfusion, and successful return to baseline rhythm and MAP.[162,171,172] Administration of crystalloid or colloid is usually sufficient to meet a patient's intraoperative intravascular fluid requirement during a TAVI procedure. However, typed and cross-matched blood, large-bore peripheral and central access, a fluid warming system, and a CPB team and pump should all be set up and available, in case a major complication develops, such as aortic dissection or pericardial tamponade. Most blood loss is associated with the initial placement and final removal of the deployment device sheath from either the femoral artery and/or LV apex.[171] AV block requiring permanent pacemaker placement has been a repeatedly reported complication after the TAVI procedure.[162,163,170,173,175] The anesthetist must be prepared to treat the sudden onset of any intraoperative dysrhythmias including AV block. The surgical suite should be equipped with a defibrillator and pacemaker. Radiolucent defibrillator pads should be placed on the patient before induction. Significant perivalvular leak, stent malpositioning, coronary obstruction, and stroke caused from atheromatous embolization are all additional perioperative complications that have been reported to occur during transcatheter aortic valve implantation.[163,173,175-177]

The operating table is in the middle of the picture, with a floor-mounted, fixed biplanar C-arm to the left. (From Kaplan JA, Reich DL, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia: Saunders: 2011.)

Percutaneous Mitral Valve Repair

Although still under development, the Alfieri edge-to-edge repair using the MitraClip device is the most common percutaneous mitral valve repair technique today.[150,170,178] Alfieri first performed the procedure in 1991. So far, the majority of percutaneous mitral valve repairs in the United States have been performed in selected institutions under the EVEREST trial and in Europe under the ACCESS trial.[170,178,179] Patient eligibility and selection for repair of the mitral valve using a percutaneous approach is still evolving but has so far been based on severity of mitral regurgitation and specific mitral valve anatomic characteristics.[170,178]

The Alfieri edge-to-edge repair is a transcatheter valve procedure intended to reduce the degree of mitral regurgitation by delivering a clip to help secure and suture the free edge of the anterior mitral leaflet to the free edge of the posterior leaflet at the site of regurgitation. The technique results in the creation of a double-orifice mitral valve from a central suture that connects the opposing leaflets.[170,178] A femoral venous or transseptal approach is used, the procedure is performed under the guidance of TEE, and fluoroscopy A general anesthetic is usually administered for the MitraClip procedure because continuous TEE assessment is required; however, the use of conscious sedation has also been reported.[170,180] Results thus far for the MitraClip procedure have shown a reduction in mitral regurgitation (less than 2+) in the majority of patients, low rates of morbidity and mortality, and reduced hospital length of stay compared with traditional mitral valve surgical repairs.[170,178]

Devices and Procedures Developed to Manage Heart Failure

Mechanical Circulatory Assist Devices

Intra-Aortic Baloon Pump. An intra-aortic baloon pump (IABP) is a mechanical circulatory-assist device that reduces afterload and increases diastolic coronary perfusion to the heart. The IABP was first introduced in 1968. Since then its role as a key component of left ventricular support has grown in both medical and surgical settings. Medical uses include the management of cardiogenic shock, MI, intractable angina, and arrhythmias. In the perioperative setting, it is used to stabilize patients preoperatively and/or to help wean a patient who is having difficulty separating from CPB. The IABP is also used to help support coronary perfusion to high-risk patients during OPCAB procedures. Sepsis, descending aortic disease, severe peripheral vascular disease, and severe aortic regurgitation are contraindications to IABP placement.[181,182]

The IABP consists of a flexible catheter attached at one end to a drive console that contains computerized circuitry to determine

proper timing for inflation and deflation. At the other end of the catheter is an inflatable, cylindrical, polyethylene baloon that comes in various sizes between 25 and 50 mL. The baloon can be filled with helium or carbon dioxide. It is usually placed percutaneous through the femoral artery using the Seldinger technique and positioned 2 cm distal to the origin of the left subclavian artery so that the tip of the baloon is situated at the junction of the aortic arch and descending aorta.[181,183] Proper sizing and positioning are important considerations to prevent complications such as inadvertent vascular damage or vessel occlusion. Fluoroscopy, echocardiography, or chest x-rays are used to confirm IABP placement.

The IABP should be timed with the dicrotic notch of the arterial waveform so that the baloon inflates once the aortic valve closes and diastole begins. The inflated baloon (during diastole) will act as a seal within the proximal descending aorta, increasing pressure and displacing blood flow antegrade toward the coronary arteries. Consequently, coronary artery perfusion is enhanced and ultimately myocardial oxygen delivery improves. Deflation of the baloon is timed immediately before the onset of systole at the beginning of the R wave of the ECG. The deflation creates a vacuum effect that lowers the aortic pressure to reduce afterload, facilitates ventricular ejection, relieves ventricular workload, and reduces myocardial oxygen demand. Proper timing of the IABP is essential to prevent further strain on the myocardium and to achieve a maximal counter-pulsation benefit. Figure 24-23 shows arterial waveforms with correct timing and placement, and Figure 24-24 demonstrates arterial waveforms associated with incorrect IABP timing.

The IABP is synchronized with either the ECG or the arterial pressure waveform. More modern consoles are unaffected by electrical noise caused by electrocautery, and they can also differentiate pacer spikes from the QRS complex when pacing is used. Timing can be difficult with irregular rhythms such as atrial fibrillation and faster heart rates. IABP is usually timed to inflate with each heartbeat (1:1) or every other beat (1:2) until ventricular function improves. Then the counter pulsation ratio can be gradually weaned. To avoid the risk of thrombus, anticoagulation is needed for long-term IABP use; and except during CPB, an IABP is never completely turned off while it remains in the aorta. Vascular injury, infection at the IABP insertion site, and thrombocytopenia are the most common complications of IABP use.[184,185]

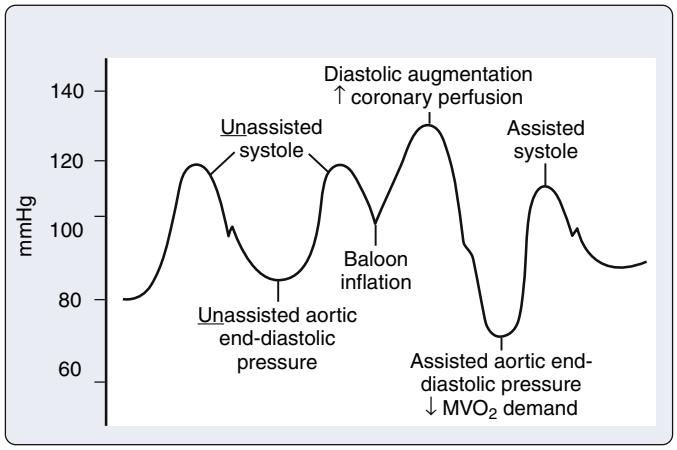

FIGURE **24-23** Arterial waveforms seen during intra-aortic baloon pump (IABP) assist. The first two waveforms are unassisted, and the last is assisted. Notice the decreased end-systolic and end-diastolic pressures and augmented diastolic pressures caused by IABP augmentation and the (correct) point at which baloon inflation occurs. These are waveforms generated by a correctly positioned and timed baloon. (Courtesy Datascope Corporation.)

Extracorporeal Membrane Oxygenation. Extracorporeal membrane oxygenation (ECMO) is a mechanical circulatory-assist device that can provide both pulmonary and systemic arterial perfusion support. It is a temporary (up to 30 days), closed circuit device that allows the heart and/or the lungs to recover from injury or trauma while maintaining oxygenation and perfusion. The primary conditions that call for use of ECMO are cardiogenic shock, failure to wean from CPB, right heart failure, heart failure that cannot be treated with a VAD, and (as a last resort) resuscitation of patients requiring cardiopulmonary resuscitation (CPR).[182,184] ECMO is also used to support patients with severe respiratory failure and ARDS that have failed to respond to standard treatments and advanced modes of mechanical ventilation.

There are two types of ECMO, and their goals and cannulae placement are somewhat different. Venovenous ECMO is the preferred method of treatment for respiratory failure.[184,186] It supports the lungs by improving gas exchange and allowing lung protective ventilation modes. In venovenous ECMO, the femoral and internal jugular veins are often selected as cannulation sites. If left ventricular support is required in addition to pulmonary support, venoarterial ECMO is selected. In contrast to venovenous ECMO, venoarterial ECMO bypasses pulmonary circulation altogether and a higher arterial oxygenation is achieved. The carotid artery and jugular vein or femoral artery and vein are common sites for venoarterial ECMO cannulation. In either case, blood drains through the venous cannula to a centrifugal or roller pump that then circulates the blood at a rate of 3 to 6 L/min through a membrane oxygenator (artificial lung), where carbon dioxide is removed and oxygen is added. Before the blood is returned to the patient, a heat exchanger rewarms the blood that has cooled. The oxygenated blood is then returned either through an arterial or venous cannula, depending on whether venoarterial or venovenous ECMO isused. The process is similar to CPB.

Anticoagulation with heparin administration is necessary with ECMO to prevent clot and thrombus formation. Because heparinization is required, bleeding becomes a major risk factor for patients supported with ECMO. The risk of stroke caused by bleeding or emboli, risk of infection, and hemolysis all contribute to the limited duration of support that ECMO may provide patients who are in cardiac or respiratory failure.

Ventricular Assist Devices

General Considerations. Heart transplantation is the only definitive treatment for end-stage heart failure. It is estimated that close to 40,000 patients would benefit from a transplant; but over the past several years, because of the lack of donors, only about 2000 heart transplants are performed each year. Additionally, the prevalence of heart failure increases with age and patients over 65 years of age are often not eligible transplant candidates.[187,188] Ventricular assist devices (VADs) are bringing new hope to this population.

Today VADs are used to assume the function of the failing ventricle or ventricles as a bridge to recovery, bridge to transplant, or as destination therapy. Heart failure patients considered for long-term VAD support typically have become refractory to standard medical therapy. They are often symptomatic at rest and are receiving intravenous inotropic support.[189] It is not uncommon for these patients to develop end-organ dysfunction caused by decreased perfusion pressure and a low cardiac output. Cardiogenic shock from an acute MI, viral cardiomyopathies, or post CPB can all be indications for short-term VAD support (lasting days or weeks) and bridge to recovery.[190] In this situation, the myocardium is granted time to rest while the VAD maintains circulation and decompression of the ventricle. Studies show that the decreased wall tension and myocardial oxygen demand that occur as a result

of the ventricular unloading allow remodeling and recovery of the ventricle.[191,192] Careful patient selection is key to achieving a successful outcome with VAD placement. Contraindications to VAD insertion include active infection or sepsis, irreversible renal or hepatic dysfunction, severe pulmonary hypertension unrelated to cardiac disease, metastatic cancer, and major coagulation disorders such as hemophilia and von Willebrand disease.[193] Since the first successful VAD implant performed in 1966 by Dr. Michael DeBakey for post-cardiotomy cardiogenic shock, ventricular assist devices and their management have greatly evolved. Several studies have shown that VAD support is effective in stabilizing multiorgan failure in end-stage heart failure patients who are awaiting transplant.[194,195] The REMATCH trial compared long-term left ventricular assist device (LVAD) support to medical management for patients with end-stage heart disease who were not eligible transplant candidates. Patients who received an LVAD showed a 48% reduction in the risk of death, fewer adverse events, shorter hospital stays, lower prescription cost, and improved quality of life.[190,196] Improved outcomes have also been demonstrated in early institution of VAD support with the use of a CentriMag assist device for cardiogenic shock after cardiotomy.[197]

Components, Types, and Heart Mate II. The VAD is a mechanical circulatory assist device that is attached to the heart through cannulae. An LVAD collects oxygenated blood that is returned to the left atrium from an inflow cannula usually placed at the apex of the left ventricle. From the inflow cannula blood enters a pumping chamber. The pumping chamber then ejects blood into the systemic circulation through an outflow cannula that is usually attached to the aorta. A right ventricular assist device (RVAD) is similarly constructed, except that it receives deoxygenated blood from the right atrium and pumps blood into the pulmonary circulation. The RVAD inflow cannula is anastomosed to either the right atria or right ventricle, and the RVAD outflow cannula is anastomosed to the pulmonary artery.

VADS are categorized according to type of blood flow (continuous or pulsatile), length of time the device can be used for support (short, intermediate, long-term), location of device (intra-, extra-, or paracorporeal), and their source of driving power (pneumatic or electric). Two generations of VADS are currently in clinical use and more generations are under development. A complete discussion of VADs is beyond the scope of this chapter, but Tables 24-16 and 24-17[187] list some of the important characteristics of devices

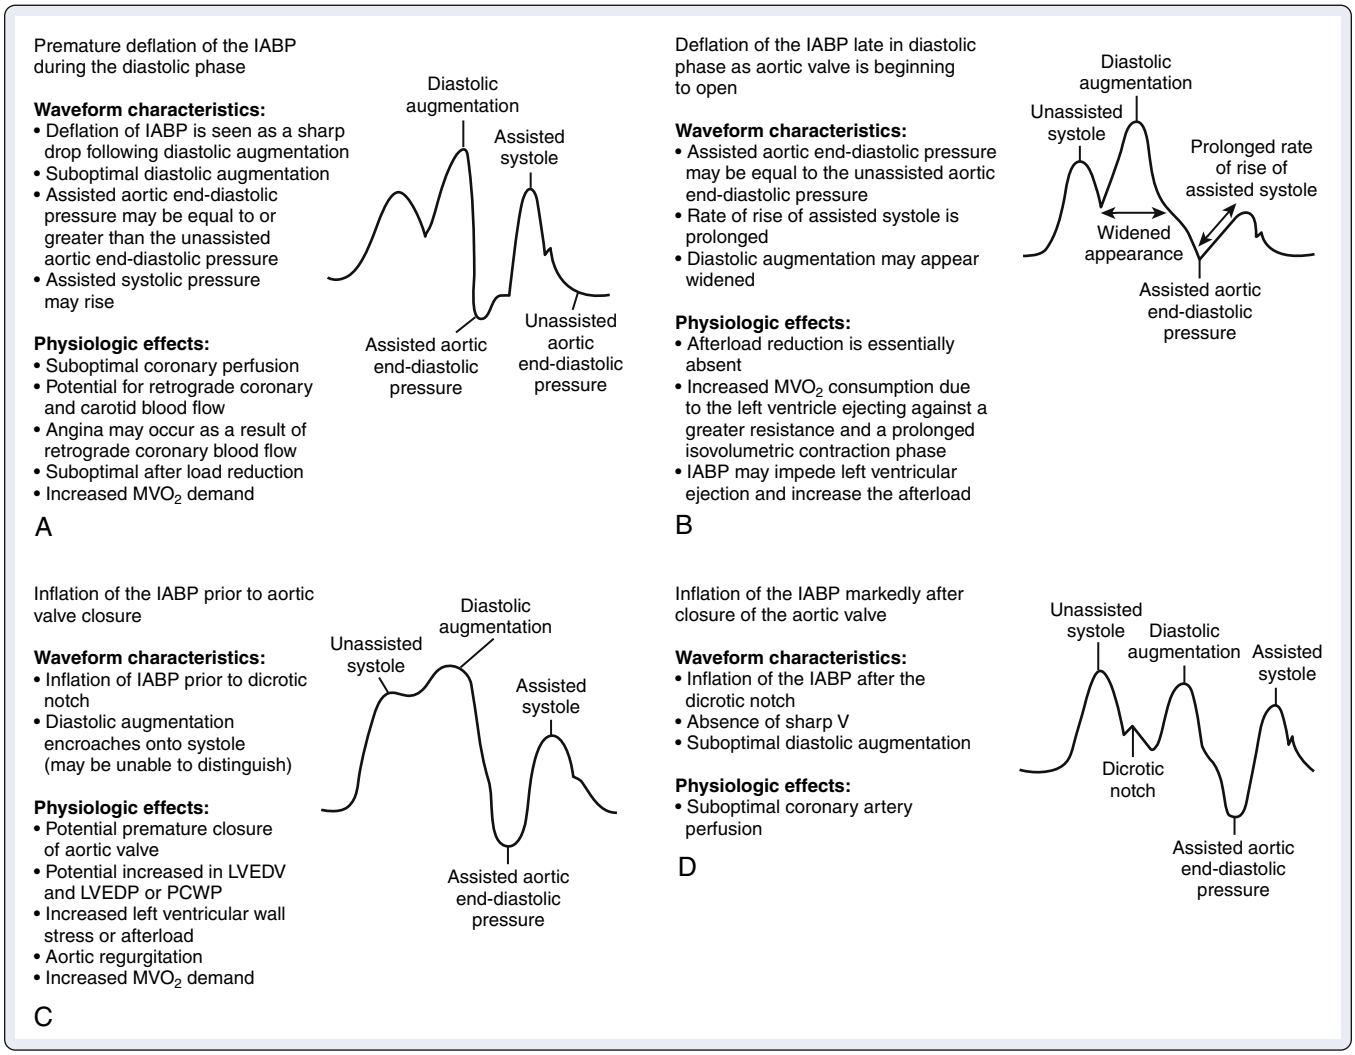

FIGURE **24-24** Alterations in waveform tracings caused by errors in timing of intra-aortic baloon pump (IABP). **A,** The baloon was deflated too early. **B,** The baloon was deflated too late. **C,** The baloon was inflated too early. **D,** The baloon was inflated too late. *LVEDP,* Left ventricular end-diastolic pressure; *LVEDV,* left ventricular end-diastolic volume; MVO_2; mixed venous oxygen saturation; *PCWP,* pulmonary capillary wedge pressure. used for short-term and long-term support. HeartMate II is currently the only second-generation LVAD approved for intermediate- to long-term support or destination therapy (Figure 24-25).

HeartMate II is an intracorporeal and nonpulsatile continuous flow device. An electrically powered axial-flow pump can generate up to 10 liters per minute of continuous blood flow. It can also operate at lower speeds, allowing the ventricle to assist with the workload. The HeartMate II is 60% smaller (weight 400 g) than the HeartMate I and is more durable.[193] Common complications from VAD support such as stroke, postoperative bleeding, RV failure, and percutaneous lead infection have been shown to be far fewer with HeartMate II than with HeartMate I.[142] Anticoagulation is required with the HeartMate II.

Anesthetic Management. Anesthetic management of the LVAD candidate begins with preoperative assessment of the end-stage heart failure patient. Neurologic deficits, hepatic and renal dysfunction, and current cardiac function should be noted. Hepatic congestion from right heart failure, preoperative use of anticoagulation drugs, and exposure of the patient's blood to nonbiologic surfaces of the LVAD device can all contribute to potentially substantial blood loss and coagulopathy that may develop after placement. Blood products (platelets, fresh frozen plasma [FFP]) and red blood cells should be available, and large-bore central and peripheral intravenous access should be secured before incision, in case rapid transfusion becomes necessary. Antifibrinolytic agents such as aminocaproic acid may be administered perioperatively to minimize blood loss. Placement of a radial or brachial arterial catheter and pulmonary arterial catheter in addition to standard ASA monitors prior to induction is recommended to assist the anesthesia provider in achieving hemodynamic stability during induction. Decreases in preload and increases in afterload are poorly tolerated in end-stage heart failure patients. These patients are extremely dependent on heart rate and considered to have a relatively fixed cardiac output, with an inability to increase stroke volume. Rapid deterioration and cardiovascular collapse can occur on induction if the patient becomes bradycardic or loses

TABLE 24-16 Basic Characteristics of the Devices Currently Used for Short-Term Support*

Device	Type of Support	Fill Mechanism	Drive Mechanism	System Control and Output
Abiomed BVS5000	Pulsatile	Gravity drainage	Pneumatic compression of blood chamber	Automatically adjusts rate of pumping to provide up to 5 L/min of outflow (output depends on intravascular volume status and downstream vascular resistances)
Thoratec	Pulsatile	Vacuum assisted	Pneumatic compression of blood chamber	Depending on the mode of operation, user-defined settings determine the output (intravascular volume status is important)
Abiomed AB5000 ventricle	Pulsatile	Vacuum assisted	Pneumatic compression of blood chamber	Automatically adjusts rate of pumping to provide up to 6 L/min of outflow (output depends on intravascular volume status and downstream vascular resistances)
Centrifugal pumps	Nonpulsatile	Gravity drainage assisted by vortex	Centrifugal force drives blood	Output is dependent on user-defined speed of impeller rotation and afterload
CentriMag	Nonpulsatile	Gravity drainage assisted by vortex	Centrifugal force drives blood	Output is dependent on user-defined speed of impeller rotation and afterload

sympathetic tone. Judicious use of etomidate and a neuromuscular blocker, or a high-dose narcotic with a neuromuscular blocker such as pancuronium, may be selected to minimize hemodynamic instability. Because sepsis is the leading cause of mortality in LVAD recipients, attention should be given to the antibiotic regimen and strict sterile technique should be maintained.[185,187,198]

A complete TEE examination assists with placement and detection of anatomic problems that can potentially complicate proper functioning of the device. Aortic insufficiency, intracardiac shunts (PFO), mitral stenosis, tricuspid insufficiency, presence of thrombus, right ventricle function, and adequacy of VAD inflow and outflow function can all be determined from the TEE.[199] Many concerns, such as AI, tricuspid regurgitation, or a patent foramen ovale will require surgical correction before LVAD placement for the device to function properly.[187] TEE also serves as a monitor of right and left ventricular function, thereby helping to guide the anesthetist with fluid and hemodynamic management.

Before separation from CPB, ventilation is reestablished, the device is de-aired, and its function is evaluated to confirm that it will support circulation. The right ventricle is assessed closely because it is needed to fill the left ventricle. Unfortunately, 30% of LVAD recipients do develop right ventricular dysfunction after LVAD implantation, most likely because of a combination of factors, including left ventricular decompression, myocardial stunning from CPB, fixed pulmonary hypertension, and right ventricular overload from LVAD activation.[142] The TEE and filling pressures are closely monitored to avoid overloading the right ventricle. Inotropes, such as epinephrine, or a phosphodiesterase III inhibitor, such as milrinone, help support function and decrease right ventricular afterload. Inhaled nitric oxide may be used to dilate the pulmonary vasculature. If right ventricular dysfunction ensues despite pharmacologic support, biventricular support should be considered.

LVAD flow is very dependent on volume. The anesthetist should be prepared to administer volume (mainly blood and blood products) rapidly if massive bleeding and a coagulopathy develop. Patients who are potential future transplant recipients should receive blood that has been leukocyte-reduced. Vasoplegic syndrome can also develop and is best managed with vasopressin, because it causes less pulmonary vasoconstriction than norepinephrine or phenylephrine and will help prevent increases in right heart afterload. Hypertension should be treated with a vasodilator such as sodium nitroprusside to avoid causing stress and malfunction of the LVAD.[187]

Cardiac Transplantation

General Considerations. The first human heart transplant was performed in South Africa in 1967 by Christiaan Barnard,[200] but it was not until the introduction of cyclosporine in the 1980s that there was significant long-term survival.[188,201-204] Today heart transplantation is the only definitive treatment for end-stage heart failure, and survival rates (adjusted for diagnosis, sex, race/ethnicity, and age) approach 90% at 1 year and 55% at 10 years.[188] The United Network for Organ Sharing (UNOS) is the organization in the United States that is responsible for coordinating organ procurement and allocation. An extensive multidisciplinary evaluation is required to prioritize placement on the donor list, but generally candidates must have New York Heart Association Class IV heart failure, an EF less than 20%, and a diagnosis of end-stage heart disease that is terminal in 1 to 2 years if transplant does not occur. Once on the list, patients are assigned a priority status of 1A, 1B, or 2. Status 1A is the highest priority and usually indicates that the patient is hemodynamically deteriorating, requiring vasopressor and/or mechanical circulatory assist support and mechanical ventilation.[51,205] Ischemic or idiopathic cardiomyopathy is the most common diagnosis of heart transplant candidates, but failure can arise from many other causes.[73] Organ donation comes from a relatively healthy patient who has been declared brain-dead. The donor heart is extensively examined before being deemed suitable. Allocation of the heart is based on the UNOS priority status, ABO blood type compatibility match, and weight ratio (within 20%). The donor and recipient must be close enough geographically to assure that the ischemic time of the heart is not prolonged.

Right ventricular failure is the major cause of short-term morbidity after transplantation. Fixed pulmonary hypertension in the recipient causes acute right heart failure in the donor heart. The pulmonary vasculature is examined closely to determine whether it responds to vasodilator therapy. A larger donor heart, heterotopic heart transplant, or a heart-lung transplant may be considered if the recipient has fixed pulmonary hypertension (transpulmonary gradient greater than 15 mmHg or PVR greater than 5 dynes/second/cm^5).[73,203-205]

Anesthetic Management. The preoperative period has important time constraints. Close communication is imperative among all members of the transplant center's surgical/anesthetic team and the organ procurement team to avoid prolonged donor heart ischemic time (ischemic time should be less than 4 hours).[206] The recipient will have had an extensive evaluation so that all information necessary for a quick assessment is readily available for review. Preoperative evaluation should follow an approach similar to that of any routine urgent preanesthetic evaluation, taking particular note of any recent deterioration. Chronic systemic hypoperfusion, venous congestion, hepatic dysfunction, and abnormal coagulation profiles are common. IABP settings and timing, VAD flow rates and settings, and all inotropic drug infusions should be noted. Patients with ICDs will need them deactivated before use of electrocautery. Because most heart transplantations are usually scheduled on short notice, most recipients will be considered full stomachs, and last oral intake and the need for a rapid sequence or modified rapid sequence induction should be assessed.

Induction of anesthesia for a heart transplant recipient follows many of the same principles for any traditional cardiac surgery on a patient with poor left ventricular function, with some noted

exceptions. All medications must be administered cautiously because severe heart failure patients are extremely sensitive to any alterations in myocardial preload and afterload. Obtaining rapid control of the airway to prevent aspiration during induction is often indicated. It is imperative to maintain the patient's heart rate, intravascular volume, and to avoid decreases in systemic vascular resistance to prevent cardiovascular collapse on induction. This can often be achieved with a short-acting hypnotic agent such as etomidate, which produces minimal myocardial depression; a small- to moderate-dose narcotic such as fentanyl to blunt sympathetic response to laryngoscopy and intubation; and a fast-onset muscle relaxant such as succinylcholine or rocuronium. Longer circulation times due to low ejection fractions in transplant candidates should be anticipated.

Once surgery begins, cross-matched, irradiated blood should be available. A repeat sternotomy may warrant cannulation of the femoral arterial and venous sites or axillary cannulation, to avoid trauma to the great vessels or preexisting coronary artery bypass grafts. Otherwise, the distal ascending aorta is cannulated and the inferior vena cava (IVC) and superior vena cava (SVC) are individually cannulated via the high right atrium.[203] Before venous cannulation, the pulmonary arterial catheter should be withdrawn from the right atrium and left in the sterile protective sheath so that it can be refloated into the pulmonary artery after CPB.

Ninety-eight percent of heart transplantation is orthotopic.[205] The biatrial techniques can be seen in Figures 24-26, *A* and *B*. If the size mismatch between donor and recipient hearts is gross, or if significant irreversible pulmonary hypertension exists, heterotopic heart transplant may be indicated. In heterotopic heart transplantation, the recipient's heart is not excised. Instead the donor's heart is placed in the right anterior thorax and anastomosed to the recipient's native heart, which creates a parallel circulation. Acute right ventricular failure in the donor heart may be avoided with heterotopic placement because the recipient's native right ventricle will provide most of the right-sided ventricular output against elevated pulmonary arterial pressures.

A high dose of glucocorticoid (methylprednisolone) is administered either preoperatively or before release of the aortic cross-clamp to decrease the chance of a hyperacute immune response. Pharmacologic inotropic support such as an isoproterenol and/or an epinephrine (direct acting) infusion may be initiated prior to CPB separation for both inotropy and chronotropy purposes. In addition to pharmacologic agents, temporary epicardial pacing may be needed due to the presence of slow junctional rhythms and loss of sinus node function.[207] Insertion of a permanent cardiac pacemaker is required in 5% to 25% of transplanted patients.[205,208] Proper oxygenation, ventilation, and acid/base balance is necessary to adequately manage right heart failure that may occur during separation from CPB. In addition, inhaled nitric oxide, prostaglandin, and/or a phosphodiesterase inhibitor such as milrinone may be used to promote pulmonary vasodilation. The transplanted heart becomes extremely preload dependent once it is denerved. Due to the loss of normal vagal tone, sympathetic and parasympathetic innervation, the denerved transplanted heart responds to hypovolemia and hypotension by initially increasing stroke volume (Frank-Starling mechanism). The administrations of ephedrine or anticholinergic drugs such as atropine are ineffective in increasing heart rate in the transplanted heart. Only pharmacologic agents such as epinephrine and isoproterenol that have direct-acting effects on catecholamines will be effective in increasing heart rate.

The anesthetist should anticipate potential post-CPB bleeding and coagulopathy, which can develop for many reasons including preoperative chronic anticoagulation, chronic hepatic congestion, extensive surgical suture lines, and CPB-induced platelet dysfunction. Anesthetic management and evaluation of ventricular function and pulmonary hypertension can be further guided by the TEE and hemodynamic measurements from the pulmonary arterial catheter.

Once hemostasis is achieved, the chest is closed in the usual fashion and the transplanted recipient, intubated, is transported to the ICU. Opportunistic infection, acute allograft rejection, and renal, pulmonary, and hepatic dysfunction are all possible postoperative complications of cardiac transplantation.[206,209]

Surgery on the Ascending Aorta and Aortic Arch

General Considerations

The cause of aortic disease is usually congenital (e.g., Marfan syndrome, Ehlers-Danlos syndrome, bicuspid AV) in patients who present at younger ages for surgery but acquired (e.g., hypertension, inflammation) in older ones.[9] A discussion of aortic disease, as well as the classification, etiology, diagnosis, and treatment of thoracic aneurysms (TA), can be found in Chapter 25. This chapter focuses on anesthetic management for surgeries on the ascending aorta and arch. Care of patients having aortic surgery requires close communication between the surgeon, perfusionist, and anesthesia provider. Management will vary markedly, depending on what segment(s) of the aorta are involved and whether the aortic valve can be preserved, repaired, or replaced. The plan for cannulation, invasive monitoring, and cerebral protection should be discussed prior to the case.

Surgery is generally indicated for ascending thoracic aneurysms that are dilated to 5.0 cm for congenital lesions or 5.5 cm for acquired lesions.[210] TAs generally grow slowly over a period of years, and are often found coincidentally after an x-ray in an

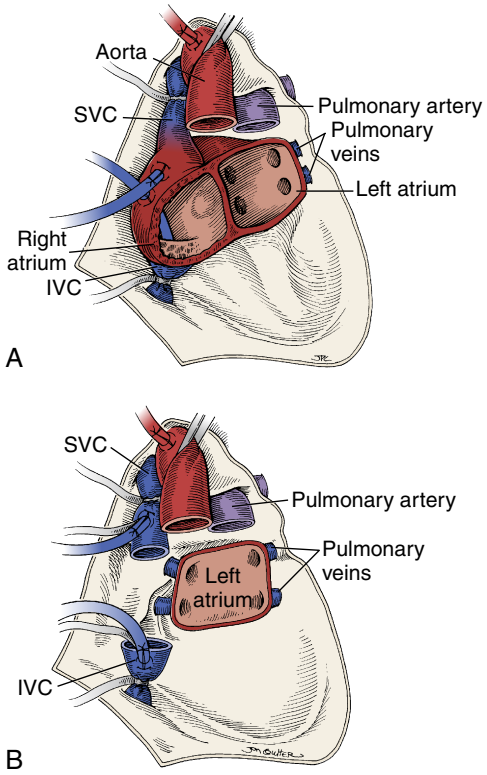

FIGURE **24-26** Mediastinum after excision of the heart but before allograft placement. Venous cannulas are present in the superior (SVC) and inferior vena cava (IVC), and the arterial cannula is present in the ascending aorta. **A,** Classic orthotopic technique. **B,** Bicaval anastomotic technique. (From Kaplan JA, Reich JA, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia: Saunders; 2011.)

asymptomatic patient. Large TAs can cause a mass effect that leads to a variety of symptoms including cough, dysphasia, or hoarseness due to compression on the trachea, esophagus, or recurrent laryngeal nerve.[9] Sometimes, superior vena cava syndrome develops. TAs of the ascending aorta and arch are usually repaired using a median sternotomy. The type of procedure will vary depending on the extent of the aneurysm and the function of the aortic valve. TEE is an invaluable assessment tool for determining whether the valve can be spared or repaired and for measuring the aorta.

Ascending Aortic Aneurysms

When the aortic aneurysm involves only the root and proximal aorta, standard aortic cannulation and CPB can be used because the distal aorta can be cannulated and a clamp placed between the cannula and the aneurysm. The femoral artery may be used as an alternate arterial cannulation site when the aortic cannula cannot be placed without jeopardizing flow to the head vessels. In this case, arterial flow is retrograde from the femoral artery to the great vessels. Newer approaches also include cannulation of the right axillary or carotid artery, allowing antegrade perfusion of the innominate.[211] Usually a single, standard two-stage venous cannula suffices. A simple tube graft can be used to replace the aorta when the aortic root and valve are normal (Figure 24-27). If the aortic annulus or sinuses of Valsalva (where the coronary arteries attach) are involved, the options become more complicated and the selected technique may depend on the surgeon's expertise and preferences. When the sinuses of Valsalva are normal, the coronary arteries do not have to be reimplanted. The valve is repaired or replaced, the sinuses spared, and a tube graft is used to repair the aneurysm. If the aortic root is dilated, a technically difficult valve-sparing operation known as a modified David's reimplantation procedure can be used (Figure 24-28). A special instrument known as the Hegar's dilator is used to sew the native aortic valve (repaired if necessary) inside the graft used to repair the aneurysm. The coronary arteries are then reimplanted into the graft. When the valve cannot be spared, an alternative procedure is the Bentall procedure, in which the surgeon uses a composite valve-graft conduit. That is, a prosthetic AV (or pulmonary homograft) is sewn into one end of the conduit and the resulting composite valve-graft is used to replace both the aortic valve and ascending aorta. Again, the coronaries must be reimplanted or alternatively, an aortocoronary bypass graft can be used (Cabrol technique).[146]

Aortic Arch Aneurysms

Aneurysms that involve the arch are much more complicated. Because the vessels perfusing the brain are involved, the risk of neurologic injury is high from both the threat of global ischemia and embolization of atherosclerotic debris. CPB is used with a technique known as deep hypothermic circulatory arrest (DHCA) employed to protect the brain while the arch is replaced. DHCA is addressed under the discussion of anesthetic management. If only the proximal aortic arch is involved, a hemiarch or partial arch replacement can be done. The origins of the arch vessels are usually dissected *en bloc* so that the three vessels lie on an island of native aortic tissue that can be anastomosed to the synthetic graft. The surgeon completes the distal anastomosis to the descending aorta first and then sews on the island of tissue containing the arch vessels. Next the aortic clamp is moved proximal to the arch vessels so that CPB flow can be reestablished and the cerebral vessels perfused. Finally, the proximal aortic graft anastomosis is completed[211] (Figure 24-29). Aneurysms that involve the entire thoracic aorta are extremely complicated and are often repaired in stages combining both open and endovascular techniques.

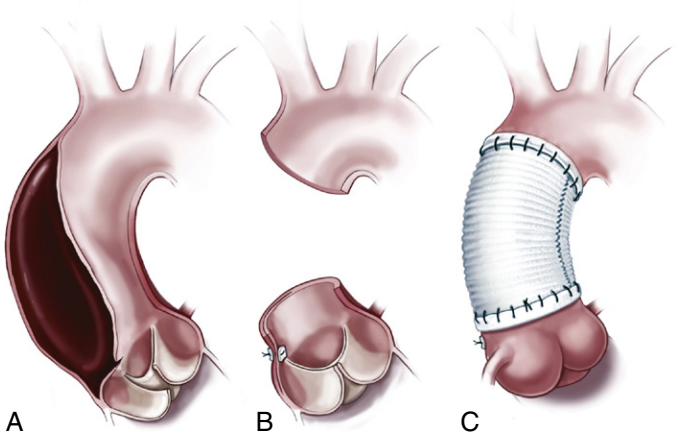

FIGURE **24-27** Ascending aortic disssection repair. **A,** The dissecting hematoma is seen and usually extends all the way to the iliac arteries. **B,** The compromised commissure of the valve is resuspended by a full-thickness pledgeted suture. **C,** The ascending aorta is replaced with a vascular graft, usually using strips of felt to reinforce the delicate adventitial tissues. (From Otto CM, Bonow RO. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*. 3rd ed. Philadelphia: Saunders; 2009.)

Anesthetic Management

Anesthesia implications are similar to those of other cardiac surgeries involving a median sternotomy with CPB, but there are several additional concerns. The anesthetist must prepare for the possibility of a difficult airway if the aneurysm is large and possibly causing a mass effect. Occasionally a reinforced endotracheal tube must be used and advanced beyond the point of compression. Caution is advised if there is resistance to passing the TEE probe or oral gastric tube as the aneurysm may be compressing the esophagus as well. An epi-aortic echocardiographic examination may be necessary. If AI is present, all the anesthetic management principles previously discussed regarding acute and chronic AI apply. In general, maintenance of a relatively high heart rate and low SVR will enhance forward flow. It is important to control the systolic pressure, keeping it less than 120 mmHg to minimize the chance of dissection.[9] Vasodilators are often indicated to control blood pressure and lower the SVR. Pulmonary artery catheters are usually indicated because large shifts in volume can be reasonably anticipated, especially if the arch is involved. Blood loss can be significant, so several units of red cells should be available. Fresh frozen plasma and platelets are transfused as needed based on coagulation studies and nonsurgical bleeding. A large-bore multilumen PAC introducer is helpful. Alternatively, several large-bore PIVs can be used with a standard introducer. The best location for the arterial line is determined by the plan for placement of the aortic cannula and aortic cross-clamp. For ascending aortic aneurysms, there is no consensus in the literature as to the best location for the arterial line; the left brachial artery as well as the left and right radial arteries have all been advocated.[138,146,211] When the arch is involved, two A-lines are placed one in either radial or brachial artery and one in a femoral artery. If the right axillary artery is to be cannulated for CPB, then the left radial or brachial is preferred. Some practitioners place three A-lines, one in each upper extremity as well as the femoral artery. The surgeon can then be alerted to pressure differences between the A-lines that most likely indicate inadequate flow and potential ischemia. Nasal or tympanic temperature is monitored as a reflection of brain temperature. The nasal probe should be placed before heparin is administered, to prevent bleeding in this fragile area.

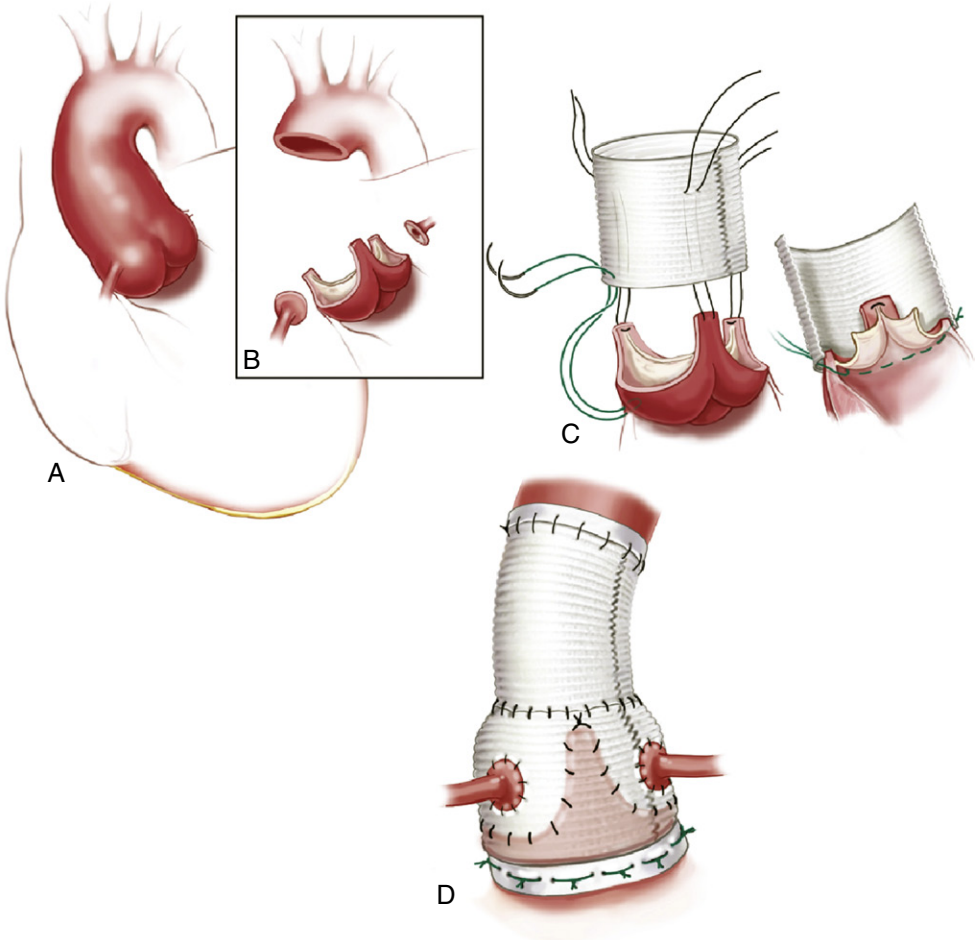

FIGURE **24-28** David procedure. Aneurysmal root (**A**) is resected (**B**) including sinuses of Valsalva with coronary "buttons" mobilized away. **C**, Subannular sutures (six to eight) are placed. Commissural posts are drawn up inside the valve and the annular sutures are passed through the proximal end of the graft. **D**, Annular sutures are tied gently. Then the valve is reimplanted with continuous 5-0 polypropylene suture inside the graft. Aortic continuity is reestablished with another graft of a size appropriate to the desired sinotubular junction and proximal arch. (From Otto CM, Bonow RO. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*. 3rd ed. Philadelphia: Saunders; 2009.)

Usually bladder and PA temperatures are also measured to help in the rewarming process.

Aortic Dissection

Acute ascending or aortic arch dissections are highly lethal, and timely surgical intervention correlates with survival.[9] The dissection begins from an intimal tear that can spread antegrade or retrograde throughout the aorta, possibly encompassing the great vessels and/or the aortic valve. Chapter 25 discusses in detail the pathophysiology of aortic dissection and the management of descending aneurysms. Patients usually present with sudden severe chest pain, but symptoms mimicking a stroke, myocardial infarction, or arterial embolization also can occur. Syncope is an ominous sign that cerebral or cardiac circulation is compromised. Diagnosis can be made with TEE, contrast-enhanced spiral computed tomography (CT) scan, or magnetic resonance imaging (MRI). Acute AI, tamponade, or limb ischemia can develop at any time. Initially, it is important to gain adequate vascular access to monitor and transfuse the patient. The arterial line site should be carefully selected, avoiding ischemic limbs and locations that will be impacted by surgical cannulation. The aim of hemodynamic management is to decrease sheer forces that can cause further dissection or rupture. The heart rate and blood pressure are most often controlled using a beta-blocker first to achieve a heart rate of about 60 bpm followed by cautious vasodilation to achieve a systolic blood pressure lower than 120 mmHg.[146] Coexisting myocardial depression can make medication titration challenging.[9,146,211] Some institutions have the patient prepped and draped prior to induction in case urgent CPB must be initiated because of rupture. All of the previously mentioned anesthetic considerations apply.

Deep Hypothermic Circulatory Arrest

Cerebral perfusion must be temporarily interrupted during repair of aneurysms involving the aortic arch. Deep hypothermia is the most important therapeutic intervention to prevent cerebral ischemia. The patient is cooled using CPB to maximally decrease the cerebral metabolic rate and oxygen consumption, thereby extending the period that the brain can tolerate circulatory arrest. As cooling on CPB is initiated, most institutions cool the brain topically by placing ice bags around the head. Care should be taken to protect the eyes and skin. The optimal temperature, the best site for temperature measurement, and a safe duration for deep hypothermic circulatory arrest (DHCA) remain matters of debate.[212] Generally, a nasopharyngeal temperature is measured and the patient is cooled to 15° to 22° C. Arrest periods of

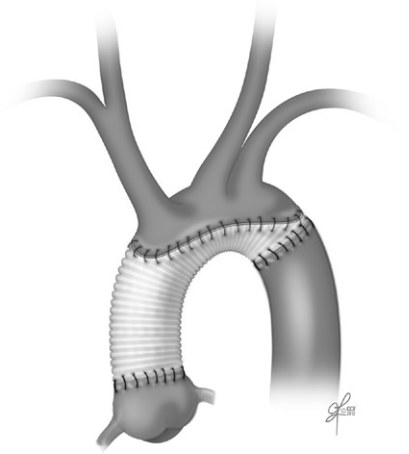

FIGURE **24-29** Repair of the ascending aorta and aortic arch. Note that the great vessels to the head are usually resected as an island of tissue that is anastomosed to the graft. (Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography © 2006-2012. All rights reserved.)

less than 25 minutes are generally considered safe.[211] One study showed that at least 50 minutes of cooling or a nasopharyngeal temperature of 12.1° C was needed to produce electrical silence on the EEG in 95% of patients.[213] The traditional goal is to have a flat EEG, but the bispectral index (BIS) and cerebral oximeters also have been used to try to detect, and thus prevent, cerebral ischemia.[214] Other efforts to improve the safety of DHCA include reducing blood viscosity and hematocrit in an effort to counteract the increased blood viscosity that develops secondary to cooling. Pharmacologic attempts at neuroprotection include the administration of barbiturates or propofol to decrease cerebral oxygen demand. Steroids, lidocaine, and mannitol also have been used. However, because no pharmacologic intervention has proved effective, these are not considered a substitute for achieving adequate hypothermia.[215]

Retrograde Cerebral Perfusion. To further protect the brain during DHCA, the surgeon may choose to use retrograde cerebral perfusion (RCP). A snared cannula is introduced into the right atrium and advanced into the superior vena cava (SVC) for use during the period of arest.[146] When the patient is cooled to the desired temperature and the EEG shows burst suppression or the BIS is 0, the pump is turned off. During the period of arrest, cold oxygenated blood between 8° C and 14° C is infused at a rate of 220 to 600 mL/min through the SVC cannula. Ideally flow reaches the brain in a retrograde fashion through the venous system. The patient is kept in slight Trendelenburg position to prevent air embolism. High-pressure tubing used to measure the CVP pressure port of the PAC is disconnected (the port is capped) and reconnected to the side port introducer to measure SVC pressure. The SVC pressure should be maintained below 25 mmHg during RCP.[146] Alternatively, some surgeons attach the arterial cannula of the CPB circuit to the SVC cannula and direct low flows through the cannula to maintain an SVC pressure of about 20 mmHg.[211] Although there are no randomized controlled trials demonstrating the benefit of RCP, a recent large-scale, single-center study found a decrease in the rates of mortality and stroke.[216]

Antegrade Cerebral Protection. If DHCA is expected to last more than 30 minutes, selective antegrade cerebral protection (ACP) into the axillary, innominate, subclavian, or even internal carotid artery has been attempted.[217] The perfusionist controls antegrade flow with a roller pump. Rates between 400 and 1000 mL/min are typical, the goal being to maintain MAP at about 50 to 80 mmHg. Efficacy of the technique has been demonstrated with ACP times of 75 to 235 minutes.[218]

Rewarming. Once systemic perfusion is reestablished using CPB, a period of hypothermic reperfusion is recommended. When rewarming begins, it should be done gradually, maintaining a temperature gradient no greater than 10° C in the heat exchanger, and cerebral hyperthermia must be avoided.[210] Even slight hyperthermia in patients with cerebral ischemia or infarction may exacerbate any damage.[219] The optimal temperature for coming off bypass is a matter of debate. Some believe that a bladder temperature of 36.5° C should be achieved to decrease bleeding, while others hold that 35° C is cerebral protective and that bleeding is due to the procedure and to other causes.[146,220]

SUMMARY

As the population ages, coronary artery disease, valvular heart disease, and heart failure will continue to be major health burdens. The risk profile of the average cardiac surgical patient and the complexity of the procedures continue to rise. Technology and innovative surgical approaches to managing cardiovascular disease has changed the landscape of cardiac anesthesia. A clear understanding of the core physiologic and pathophysiologic principles that impact coronary blood flow and myocardial function will enable the anesthetist to adapt anesthetic management in this ever-evolving field. Each clinician is encouraged to stay abreast of the evidence-based outcome studies that have so greatly impacted our clinical practice. Enjoy the excitement and challenge of cardiac anesthesia and always remember to "take care of the pipes, the pump and the volume."

Anesthesia for Vascular Surgery

CHAPTER 25

◆ *Sass Elisha*

PERIPHERAL VASCULAR DISEASE

Atherosclerosis is the most common cause of occlusive disease. This degenerative process involves the formation of atheromatous plaques that may obstruct the vessel lumen and thereby cause a reduction in distal blood flow. The pathophysiologic processes that affect the arteries include plaque formation, which obstructs the lumen (stenosis); thrombosis, which can result in acute ischemia; embolism from microthrombi or atheromatous debris, which decreases distal blood flow; and weakening of the arterial wall with aneurysm formation. The most common risk factors associated with atherosclerosis are shown in Box 25-1. Cigarette smoking and diabetes mellitus are major risk factors in the pathogenesis of atherosclerosis in the peripheral vascular system. Typical symptoms of peripheral occlusive disease include claudication, skin ulcerations, gangrene, and impotence.[1] The extent of disability is primarily influenced by the development of collateral blood flow. Initially, collateral blood flow sufficiently meets tissue oxygen demands. As the disease process progresses, supply is unable to meet demand, and limb ischemia becomes symptomatic, requiring therapeutic intervention. The mortality rate associated with patients with vascular disease is two- to sixfold higher than within the general population.[2] There is a relationship between inflammation and the development of atherosclerosis. Platelet interaction with leukocytes and other cells that modulate the immune response play a major role in the development of atherosclerosis.[3,4] Researchers have discovered heritable genetic factors that predispose patients to developing vascular disease.[5]

Treatment for peripheral occlusive disease may range from pharmacologic therapy to surgery. Surgical therapy includes transluminal angioplasty, endarterectomy, thrombectomies, endovascular stenting, and arterial bypass procedures. Some common surgical maneuvers used for bypassing occlusive lesions are aortofemoral, axillofemoral, femorofemoral, and femoropopliteal bypass techniques. Bypass techniques may be classified as *inflow* or *outflow* procedures, depending on the level of the obstruction, with the dividing axis being at the level of the groin. Temporary occlusion of the operative artery is mandatory when bypass procedures are used. The response to aortic cross-clamping in patients with aortoiliac occlusive disease produces less hemodynamic variability as compared to patients with aneurysmal disease. The development of collateral circulation provides alternative vascular blood flow in patients with occlusive disease.[6,7]

Preoperative Evaluation

The atherosclerotic process in occlusive disease is not limited to the peripheral arterial beds and should be expected to be present in the coronary, cerebral, and renal arteries. More than half the mortality associated with peripheral vascular disease results from adverse cardiac events.[8] It has been estimated that 42% of patients presenting for abdominal aortic aneurysm (AAA) repair have significant coronary artery disease (CAD).[9] The identification and management of cardiac pathology, which often occurs in this patient population, must be managed aggressively to optimize cardiac functioning and decrease morbidity and mortality from cardiac causes. For a complete discussion of a preoperative cardiac evaluation, refer to Chapter 19.

The advantages of β-blockade as relates to factors that affect myocardial oxygen supply and demand have been extensively studied in this patient population, and the judicious use of β-blockers is recommended in patients at high risk for myocardial ischemia and infarction.[10] For patients having AAA repairs, there is a 10-fold decrease in cardiac morbidity.[11] β-blockade therapy should be instituted days to weeks before surgery and titrated to a target heart rate between 50 and 60 beats per minute (bpm).[12] Vascular surgery patients with limited heart rate variability after receiving β-blocking medication exhibit less cardiac ischemia and troponin values postoperatively and have a decreased mortality from all causes 2 years postoperatively.[13] It has been suggested that because of their antiinflammatory effects, a statin drug should be instituted 30 days prior to the surgical procedure.[14]

The presence of concurrent pulmonary, renal, neurologic, and endocrine dysfunction should be identified, and measures should be taken to improve organ function before surgery. Preoperatively, the greater number of comorbidities that exist, the greater the risk of morbidity and mortality during the perioperative period.

Monitoring

The extent of perioperative monitoring should be based on the presence of coexisting disease and the type of surgery. Clearly the detection of myocardial ischemia should be a primary objective in patients with vascular disease. Methods for assessing cardiac function include electrocardiographic, pulmonary artery pressure, and transesophageal echocardiography (TEE) monitoring. The effectiveness of pulmonary artery catheters (PACs) in improving patient outcomes has been controversial for years. Many randomized controlled trials have been performed to assess whether they offer any benefit. It was determined that PAC monitoring had no effect on mortality or length of hospital stay. Additionally, there were higher rates of pulmonary embolism, pulmonary infarction, and hemorrhage in the PAC group.[15-17] Practice guidelines provided by the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization states that the routine use of PACs is not warranted.[18]

Because of the global nature of atherosclerotic disease, some degree of systemic cardiovascular disease in patients with peripheral vascular disease should be assumed.[9] Patients with hypertension and/or angiopathology rely on increased mean arterial pressures to perfuse their vital organs. Thus cerebral and coronary autoregulation occurs at higher than normal pressures. Direct intraarterial blood pressure monitoring allows for near–real-time

determination of blood pressure values and is warranted because of dramatic fluctuations that can occur during anesthesia.

Anesthetic Selection

The anesthetic technique chosen for patients having vascular surgery depends on the type of surgical procedure to be performed and the presence of coexisting disease. In certain instances, infiltration of local anesthetic and intravenous sedation may be sufficient, whereas other situations may require the use of general anesthesia. Regional anesthesia for surgery on the lower extremities may decrease the overall morbidity and mortality associated with this patient population. Numerous studies have failed to yield demonstrative advantages for any single anesthetic technique. A comprehensive meta-analysis combining data from 141 studies involving 9559 patients suggested a 30% reduction in mortality for those patients who received a combined general anesthetic and epidural combination. A reduction in the rate of myocardial infarction stroke and respiratory failure was found when epidural anesthesia was used in patients undergoing aortic surgery.[19] Several major studies have been conducted evaluating various end points associated with major vascular surgery.[20] None of the studies have definitively concluded that superior outcomes depend on the anesthetic technique used.[21] The major advantages to using a epidural technique are most noted during the postoperative period. Specific physiologic benefits of an epidural used for major abdominal vascular surgery are summarized in Box 25-2. Some considerations include the findings that inhalation anesthetic agents induce cardioprotection in patients having noncardiac surgery.[22] In addition, many vascular patients are receiving anticoagulant therapy; therefore, neuraxial anesthetic techniques must be used with caution to avoid epidural hematoma formation.[23]

BOX 25-1

Risk Factors Related to the Development of Atherosclerotic Lesions

- Hypercholesterolemia
- Elevated triglycerides
- Cigarette smoking
- Hypertension
- Diabetes mellitus
- Obesity
- Genetic predisposition
- Sedentary lifestyle
- Sex (male at greater risk than female)
- Impaired long-term glucose regulation
- Homocysteine
- C-reactive protein

Postoperative Considerations

Postoperative pain management is an important issue related to peripheral vascular surgery. Most clinicians agree that postoperative administration of narcotics not only provides patient comfort but also contributes to cardiac stability. The use of epidural opioid and local anesthetics in patients recovering from vascular surgery is an important component of postoperative care because pain can greatly enhance sympathetic nervous system stimulation. Despite a decrease in discomfort during the postoperative course, these patients must be monitored in an appropriate surgical unit that is capable of detecting possible adverse events, such as myocardial infarction or respiratory depression, which could be attributed to the administration of epidural opioids and local anesthetics. Presently data are insufficient to confirm that adequate analgesic techniques decrease morbidity and mortality from postoperative complications.[24]

ABDOMINAL AORTIC ANEURYSMS

Incidence

The incidence of abdominal aortic aneurysm (AAA) is estimated to range between 3% and 10% for patients older than 50 years of age who reside in the western world.[25] Improved detection of AAAs is the result of increased screening of asymptomatic aneurysms by noninvasive diagnostic modalities, such as computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography. The occurrence of AAAs has increased because of the increased age of the general population and the vascular changes that occur as a result of aging.[26]

BOX 25-2

Benefits of the Epidural Technique in Vascular Surgery

Endocrine
- Inhibits surgical stress response
- Inhibits epinephrine and cortisol release
- Inhibits hyperglycemia
- Inhibits lymphopenia and granulocytosis
- Causes nitrogen sparing
- Blocks sympathetic tone
- Inhibits inflammatory mediator release

Cardiovascular
- Decreases myocardial oxygen demand and afterload
- Increases endocardial perfusion at ischemic zone
- Increases hemodynamic stability
- Decreased blood loss
- Decreases general anesthetic medication requirements
- Redistributes blood to lower extremities

Pulmonary
- Decreased effect on FVC, FEV_1, and PEFR
- Decreases ventilation perfusion mismatch
- Improves atrioventricular oxygen differentiation
- Decreases pulmonary postoperative complications
- Decreased incidence of thromboembolism

Renal
- Increases blood flow in the renal cortex
- Decreases renovascular constriction

Geriatric
- Inhibits physiologic stress
- Improves postoperative mental status

Miscellaneous
- Allows earlier extubation, ambulation, and discharge
- Improves postoperative pain control

FEV_1, Forced expiratory volume in 1 second; *FVC*, forced vital capacity; *PEFR*, peak expiratory flow rate.

Risk Factors

The incidence of AAAs in a given population depends on the presence of risk factors (Box 25-3). Independent risk factors thought to be causes rather than markers for the development of a AAA include age, gender, and smoking. Smoking is the risk factor that is most highly correlated with AAA. In cigarette smokers, the incidence of AAAs increases fivefold.[25]

Mortality

Elective AAA repair is one of the most frequent vascular surgical procedures, with approximately 40,000 operations performed in the United States annually.[27,28] Mortality rates for elective abdominal aortic aneurysmectomies have decreased since the 1970s. The present mortality rate ranges from 1% to 11%, although it is most commonly estimated at 5%. This is compared with mortality rates of 18% to 30% in the 1950s.[25,29-35] Advanced detection capabilities, earlier surgical intervention, extensive preoperative preparation, refined surgical techniques, better hemodynamic monitoring, improved anesthetic techniques, and aggressive postoperative management have all contributed to this improvement in surgical outcomes. Data suggest that risk of rupture is very low for AAAs less than 4 cm in diameter, but the risk dramatically increases for AAAs with a 5-cm or greater diameter. Surgical intervention is recommended for AAAs 5.5 cm or greater in diameter.[36] Unfortunately, mortality rates for those with undetected or untreated ruptured aortic aneurysms have not followed the trend of those who have surgical intervention. Estimates of mortality resulting from ruptured AAAs vary from 35% to 94%.[28,37-40] Combining prehospital with operative mortality, the overall mortality for AAA rupture is 80% to 90%. The 5-year mortality rate for individuals with untreated AAAs is 81%, and the 10-year mortality rate is 100%.[33] Other criteria for surgical intervention for AAA include ruptured AAA, 4- to 5-cm AAA with greater than 0.5 cm enlargement in less than 6 months, patients who are symptomatic for AAA, and 5.0-cm AAA or greater for elective repair for patients with a reasonable life expectancy. Early detection and elective surgical intervention can be lifesaving because elective surgical mortality is less than 5% in most series.[41]

Diagnosis

Frequently, asymptomatic aneurysms are detected incidentally during routine examination or abdominal radiography. Smaller aneurysms are often undetected on routine physical examination. Diagnostic techniques, such as ultrasonography, CT scan, and MRI, may identify vascular abnormalities in these patients. Such noninvasive techniques not only reveal the presence of aneurysms but also provide information about aneurysm size, vessel wall integrity, and adjacent anatomic definition.[42] Invasive techniques, including contrast-enhanced CT scan, contrast angiography, and digital subtraction angiography, can provide additional information and more detailed representations of arterial anatomy.

BOX 25-3

Conditions and Traits Associated with Development of Abdominal Aortic Aneurysm

- Smoking
- Older age
- Gender, male more often than female
- Family history
- Coronary artery disease
- High cholesterol
- Chronic obstructive pulmonary disease (COPD)
- Height (per 7 cm interval)
- Hypertension
- Peripheral vascular occlusive disease
- Caucasian

ABDOMINAL AORTIC RECONSTRUCTION

Patient Selection

As a result of recent advances in surgical and anesthetic techniques, the mortality associated with elective repair of AAAs is fairly low compared with nonsurgical management. Most patients with abdominal aneurysms, including the elderly, are considered surgical candidates. Although advancing age contributes to an increased incidence of morbidity and mortality, age alone is not a contraindication to elective aneurysmectomy.[43] However, physiologic age is more indicative of increased surgical risk than chronologic age. Contraindications to elective repair include intractable angina pectoris, recent myocardial infarction, severe pulmonary dysfunction, and chronic renal insufficiency.[6] Patients with stable CAD and coronary artery stenosis of greater than 70% who require nonemergent AAA repair do not benefit from revascularization if β-blockade has been established.[44] Table 25-1 lists characteristics that define high-risk patients; however, in most cases the presence of an AAA warrants surgical intervention.[33]

The dimensions of an aneurysm can change over time. Abdominal aortic aneurysms grow approximately 4 mm/yr.[45] Aneurysmal vessel dimensions correspond to the law of Laplace:

$$T = P \times r$$

where T = wall tension, P = transmural pressure, and r = vessel radius.

TABLE 25-1 Criteria for High Risk in Abdominal Aortic Aneurysm Repair

Parameter	Criterion
Age	Older than 70 years
Gender	Female
Cardiac	History of myocardial infarction Angina pectoris Myocardial disease Q waves on electrocardiogram (ECG) ST/T wave changes on ECG Ventricular ectopy Hypertension with left ventricular hypertrophy Congestive heart failure
Endocrine	Diabetes
Neurologic	Stroke
Renal	Chronic or acute renal failure
Pulmonary	Chronic obstructive pulmonary disease Emphysema Dyspnea Previous pulmonary surgery

TABLE 25-2 Range of Potential Rupture Rates for a Given Size of Abdominal Aortic Aneurysm

AAA Diameter (cm)	Rupture Risk (%/yr)
<4	0
4-5	0.5-5
5-6	3-15
6-7	10-20
7-8	20-40
>8	30-50

From Brewster DC, Cronenwett JL, Hallett JW Jr, et al. Guidelines for the treatment of abdominal aortic aneurysms: report of a subcommittee of the Joint Council of the American Association for Vascular Surgery and Society for Vascular Surgery. *J Vasc Surg*. 2003;37:1106-1117.
AAA, Abdominal aortic aneurysm.

As the radius of a vessel increases, the wall tension increases. Therefore the larger the aneurysm, the more likely the risk of spontaneous rupture. As stated, aneurysms measuring more than 4 to 5 cm in diameter generally require surgical intervention,[29] but aneurysms measuring less than 4 to 5 cm should not be considered benign. An aneurysm has the potential to rupture regardless of its size. As the diameter of the aneurysm increases in size, the risk of rupture increases, as shown in Table 25-2.

Patient Preparation

Perioperative myocardial infarction is the most common reason for poor outcomes in noncardiac surgery. Optimization of myocardial oxygen supply and demand and modification of cardiac risk factors is the major goal of preoperative risk reduction. β-blockers, statins, and aspirin are the hallmark pharmacologic treatments for medical management. Prophylactic coronary revascularization is recommended only as per the same indications as the nonoperative setting. Preoperative cardiac testing is recommended only if interpretation of the results will change anesthetic management.[46-48]

Preoperative fluid loading and restoration of intravascular volume are perhaps the most important techniques used to enhance cardiac function during abdominal aortic aneurysmectomies. Reliable venous access must be secured if volume replacement is to be accomplished. Large-bore intravenous lines and central lines can be used to infuse fluids or blood. Massive hemorrhage is an ever-present threat; therefore, the availability of blood and blood products should be ensured. Provisions for rapid transfusion and intraoperative blood salvage should be confirmed.

Routine Monitoring

Standard monitoring methods include electrocardiography (with display of lead II for detection of dysrhythmias and the precordial V_5 lead for analysis of ischemic ST-segment changes), pulse oximetry, and capnography. An esophageal stethoscope allows for continuous auscultation of heart and breath sounds, as well as temperature monitoring. Placement of an indwelling urinary catheter is necessary for continuous measurement of urinary output and renal function. Neuromuscular function is also routinely monitored.

Invasive Monitoring

Maintaining cardiac function is crucial for a successful surgical outcome; cardiac function should be closely monitored during abdominal aortic reconstruction. Invasive blood pressure monitoring permits beat-to-beat analysis of the blood pressure, immediate identification of hemodynamic alterations related to aortic clamping, and access for blood sampling. However, information obtained from pulmonary artery catheters has been shown to have low sensitivity and low specificity in detecting myocardial ischemia when compared with electrocardiographic and transesophageal echocardiography (TEE). As previously discussed, pulmonary artery catheters are not routinely used unless a specific indication is warranted in these procedures.[18,49]

By detecting changes in ventricular wall motion, two-dimensional TEE provides a sensitive method for assessing regional myocardial perfusion. TEE is a primary method of intraoperative cardiac assessment in patients undergoing surgery on the heart and the aorta.[46,50,51] Wall motion abnormalities also occur much sooner than electrocardiographic changes during periods of reduced coronary blood flow.[52] Myocardial ischemia poses the greatest risk of mortality after abdominal aortic reconstruction. Intraoperative monitoring may enable earlier detection and intervention during ischemic cardiac events.

Aortic Cross-Clamping

Abdominal aortic reconstruction may be one of the most challenging situations for the anesthetist. Patients with AAAs tend to be elderly and have varying degrees of coexisting disease. In addition to the risks associated with any major surgical procedure, these patients also experience physiologic changes that are specific to abdominal aortic aneurysmectomies. Perhaps the most dramatic physiologic change occurs with the application of an aortic cross-clamp. Temporary aortic occlusion produces various hemodynamic and metabolic alterations.

Hemodynamic Alterations

The hemodynamic effects of aortic cross-clamping depend on the application site along the aorta, the patient's preoperative cardiac reserve, and the patient's intravascular volume. The most common site for cross-clamping is infrarenal, because most aneurysms appear below the level of the renal arteries. Less common sites of aneurysm development are the juxtarenal and suprarenal areas.

During aortic cross-clamping, *hypertension* occurs *above* the cross-clamp and *hypotension* occurs *below* the cross-clamp. Aortic cross-clamping results in a series of complex metabolic and humoral responses involving the sympathetic and renin-angiotensin-aldosterone systems. There is an absence of blood flow distal to the clamp in the pelvis and lower extremities.[6] Increases in afterload cause myocardial wall tension to increase. Mean arterial pressure (MAP) and systemic vascular resistance (SVR) also increase. Cardiac output may decrease or remain unchanged. Pulmonary artery occlusion pressure (PAOP) may increase or display no change. Table 25-3 summarizes the physiologic changes associated with aortic cross-clamping.

Patients with adequate cardiac reserve commonly adjust to sudden increases in afterload without the occurrence of adverse cardiac events. However, patients with ischemic heart disease or ventricular dysfunction are unable to fully compensate, as a result of the hemodynamic alterations. The increased wall stress attributed to aortic cross-clamp application may contribute to decreased global ventricular function and myocardial ischemia. Clinically, these patients experience increases in PAOP in response to aortic cross-clamping. Aggressive pharmacologic intervention is required for restoration of cardiac function during this time. An algorithm that depicts the systemic hemodynamic responses to aortic cross-clamping is shown in Figure 25-1.

TABLE 25-3 The Physiologic Changes Associated with Aortic Cross-Clamping

Hemodynamic Changes	Metabolic Changes	Intraoperative Interventions
Increased arterial blood pressure above the clamp	Decreased total body oxygen consumption	*Reduce Afterload* Sodium nitroprusside Inhalation anesthetics Milrinone Shunts and aorta to femoral bypass
Decreased arterial blood pressure below the clamp	Decreased total body carbon dioxide production	*Reduce Preload* Nitroglycerin Atrial to femoral bypass
Increased wall motion abnormalities and left ventricular wall tension	Increased mixed venous oxygen saturation	*Renal Protection* Fluid administration Mannitol Furosemide Dopamine N-acetylcysteine Renal cold perfusion
Decreased ejection fraction and cardiac output	Decreased total body oxygen extraction	*Miscellaneous* Hypothermia Decrease minute ventilation Sodium bicarbonate
Decreased renal blood flow	Increased catecholamine release	
Increased pulmonary occlusion pressure	Respiratory alkalosis	
Increased central venous pressure	Metabolic acidosis	
Increased coronary blood flow

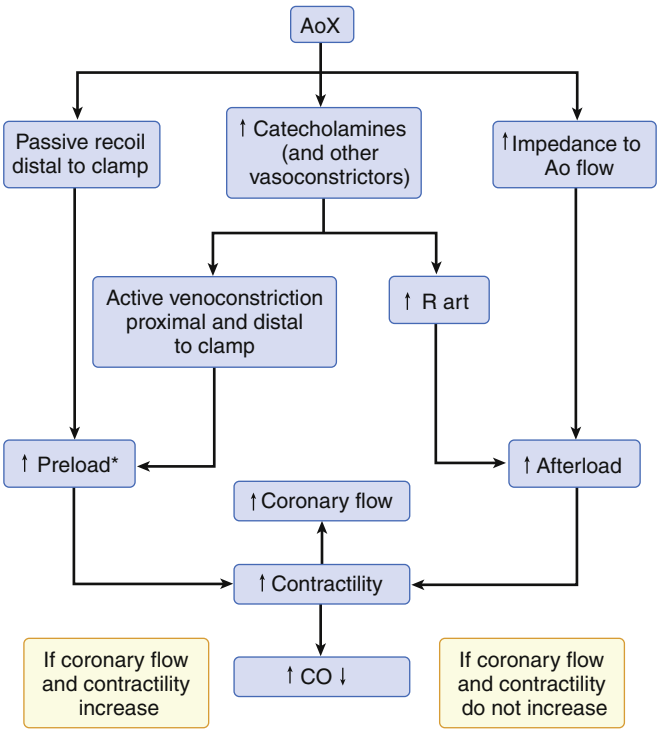

FIGURE 25-1 Systemic hemodynamic response to aortic cross-clamping. Preload *(asterisk)* does not necessarily increase with infrarenal clamping. Depending on splanchnic vascular tone, blood volume can be shifted into the splanchnic circulation, and preload will not increase. *Ao*, Aortic; *AoX*, aortic cross-clamping; *R art*, arterial resistance. (Adapted from Gelman S. The pathophysiology of aortic cross-clamping. *Anesthesiology*. 1995;82:1026-1060.)

Metabolic Alterations

After the application of an aortic cross-clamp, the lack of blood flow to distal structures makes these tissues prone to developing hypoxia. In response to hypoxia, metabolites such as lactate accumulate. Both epinephrine and norepinephrine stimulate myocardial β_1-receptors that can increase heart rate and myocardial oxygen demand.

The release of arachidonic acid derivatives also may contribute to the cardiac instability observed during aortic cross-clamping. Thromboxane A_2 synthesis, which is accelerated by the application of an aortic cross-clamp, may be responsible for the decrease in myocardial contractility and cardiac output that occurs. Numerous studies have attempted to determine whether cyclooxygenase inhibition caused by the administration of aspirin or ibuprofen before elective aneurysmectomies can preserve myocardial function.

Traction on the mesentery is a surgical maneuver used for exposing the aorta. Mesenteric traction syndrome is associated with this procedure. Decreases in blood pressure and SVR, tachycardia, increased cardiac output, and facial flushing are common responses to mesenteric traction. Although the cause of this syndrome is unknown, it has been associated with high concentrations of 6-keto-prostaglandin F_1, the stable metabolite of prostacyclin at the time of mesenteric traction.[53] The 6-ketoprostaglandin F_1 levels and hemodynamic stability return to preclamp values as reperfusion occurs.

The neuroendocrine response to major surgical stress is believed to be mediated by cytokines such as interleukin (IL)-1B, IL-6, and tumor necrosis factor, as well as plasma catecholamines and cortisol.[54] These mediators are thought to be responsible for triggering the inflammatory response that results in increased body temperature, leukocytosis, tachycardia, tachypnea, and fluid sequestration. Patients who have an exaggerated plasma stress mediator release had longer operative and cross-clamp times and required a greater number of blood transfusions.

TABLE 25-4 Hemodynamic Responses to Aortic Declamping and Therapeutic Interventions

Hemodynamic Changes	Metabolic Changes	Intraoperative Interventions
Decreased arterial blood pressure	Increased lactate	Decrease anesthetic depth
Decreased myocardial contractility	Increased total body oxygen consumption	Decrease vasodilators
Decreased systemic vascular resistance	Decreased mixed venous oxygen saturation	Increase fluids
Decreased central venous pressure	Increased prostaglandins	Increase vasoconstrictor drugs
Decreased preload	Increased activated complement	Reapply cross-clamp for severe hypotension
Decreased cardiac output	Increased myocardial depressant factors	Consider administration of mannitol and sodium bicarbonate
Increased pulmonary artery pressure	Decreased temperature	
	Metabolic acidosis	

Adapted from Norris EJ. Anesthesia for vascular surgery. In: Miller RD, et al, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010; Fillinger MF. Abdominal aortic aneurysms: evaluation and decision making. In: Cronenwett JL, Johnston W, eds. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Saunders; 2010.

Effects on Regional Circulation

Structures distal to the aortic clamp are underperfused during aortic cross-clamping. Renal insufficiency and renal failure have been reported to occur after abdominal aortic reconstruction. Suprarenal and juxtarenal cross-clamping may be associated with a higher incidence of altered renal dynamics; however, reductions in renal blood flow occur even when aortic cross-clamping occurs below the renal arteries. Infrarenal aortic cross-clamping is associated with a 40% decrease in renal blood flow.[55] Renal insufficiency more commonly occurs with suprarenal than infrarenal cross-clamping. Suprarenal clamp time longer than 30 minutes increases the risk of postoperative renal failure. These effects may lead to acute renal failure, which is fatal in 50% to 90% of patients who have undergone aneurysmectomies.[56] Neither renal dose dopamine nor mannitol has been definitively proven to preserve or improve renal function postoperatively. Preoperative evaluation of renal function is the best method to assess and anticipate which patients may develop postoperative renal dysfunction. A complete evaluation of renal function is required during the preoperative period.

Spinal cord damage is associated with aortic occlusion. Interruption of blood flow to the greater radicular artery (artery of Adamkiewicz) in the absence of collateral blood flow has been identified as a factor that causes paraplegia in patients having AAA repair. The incidence of neurologic complications increases as the aortic cross-clamp is positioned in a higher or more proximal area. Somatosensory evoked potential (SSEP) monitoring has been advocated as a method of identifying spinal cord ischemia. However, SSEP monitoring reflects dorsal (sensory) spinal cord function and does not provide information regarding the integrity of the anterior (motor) spinal cord.[6] Motor evoked potential (MEP) monitoring is capable of determining anterior cord function. This monitoring modality relies on intact neuromuscular functioning for analysis, which limits its use in abdominal aortic aneurysmectomies because neuromuscular blocking drugs are routinely used. Alternative methods for reliable evaluation of spinal cord ischemia are still under investigation.[57]

Ischemic colon injury is a well-documented complication associated with abdominal aortic resections. Ischemia of the colon is most often attributed to manipulation of the inferior mesenteric artery, which supplies the primary blood supply to the left colon. This vessel is often sacrificed during surgery, and blood flow to the descending and sigmoid colon depends on the presence and adequacy of the collateral vessels. Mucosal ischemia occurs in 10% of patients who undergo AAA repair. In less than 1% of these patients, infarction of the left colon necessitates surgical intervention.[56]

Aortic Cross-Clamp Release

While the aorta is occluded, metabolites that are liberated as a result of anaerobic metabolism, such as serum lactate, accumulate below the aortic cross-clamp and induce vasodilation and vasomotor paralysis. As the cross-clamp is released, SVR decreases, and blood is sequestered into previously dilated veins, which decreases venous return. Reactive hyperemia causes transient vasodilation secondary to the presence of tissue hypoxia, release of adenine nucleotides,[56] and liberation of an unnamed vasodepressor substance, which may act as a myocardial depressant and peripheral vasodilator. This combination of events results in decreased preload and afterload. The hemodynamic instability that may ensue after the release of an aortic cross-clamp is called *declamping shock syndrome*.[58] Evidence demonstrates that venous endothelin (ET)-1 may be partially responsible for the hemodynamic alterations that accompany declamping shock syndrome. Venous ET-1 has a positive inotropic effect on the heart and a vasoconstricting and vasodilating action on blood vessels. Table 25-4 summarizes the most commonly observed hemodynamic responses to aortic declamping and therapeutic interventions.

The magnitude of the response to unclamping the aorta may be manipulated. Although SVR and MAP decrease, intravascular volume may influence the direction and magnitude of change in cardiac output. Restoration of circulating blood volume is paramount in providing circulatory stability before release of the aortic clamp.[7,56,58-60] The site and duration of cross-clamp application, as well as the gradual release of the clamp, influence the magnitude of circulatory instability. For this reason, it is vital that communication between the anesthetist and the surgical team occurs. Partial release of the aortic cross-clamp over time often results in less severe hypotension. An algorithm depicting the systemic hemodynamic response to aortic unclamping is shown in Figure 25-2.

Surgical Approach

The standard approach for elective abdominal aortic reconstruction is the transperitoneal incision. The advantages of this route include exposure of infrarenal and iliac vessels, ability to inspect intraabdominal organs, and rapid closure.[61] Unfavorable consequences associated with this approach include increased fluid losses, prolonged ileus, postoperative incisional pain, and pulmonary complications.

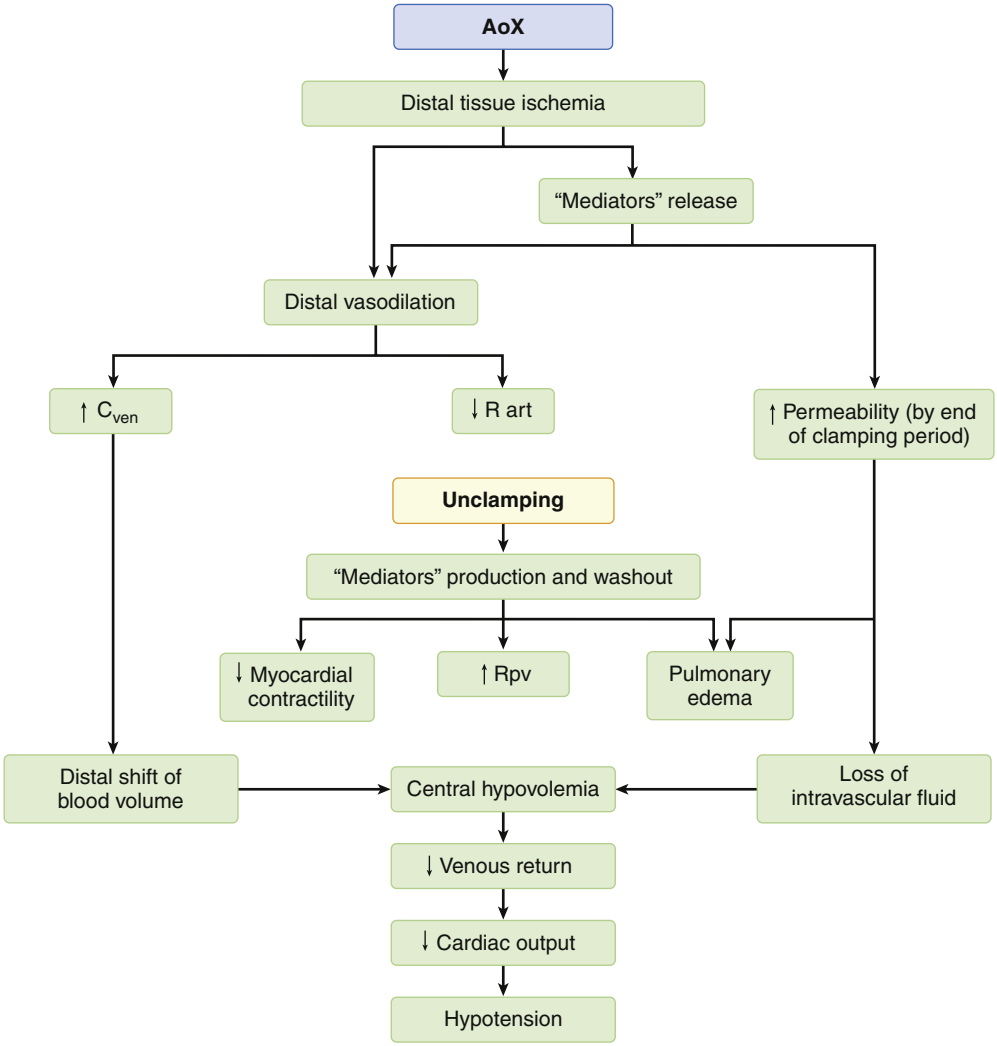

FIGURE **25-2** Systemic hemodynamic response to aortic unclamping. *AoX,* Aortic cross-clamping; C_{ven}, venous capacitance; *R art,* arterial resistance; *Rpv,* pulmonary vascular resistance. (From Gelman S. The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology.* 1995;82:1026-1060.)

The retroperitoneal approach is an alternative to the standard route. Its advantages include excellent exposure (especially for juxtarenal and suprarenal aneurysms and in obese patients), decreased fluid losses, less incisional pain, and fewer postoperative pulmonary and intestinal complications. After implantation with a synthetic graft, the aortic adventitia is closed (Figure 25-3). In addition, the retroperitoneal approach does not elicit mesenteric traction syndrome.[61] The reported limitations of this approach are unfamiliarity of surgeons with this technique, poor right distal renal artery exposure, and inability to inspect the integrity of the abdominal contents. Table 25-5 compares the standard and retroperitoneal surgical approaches.

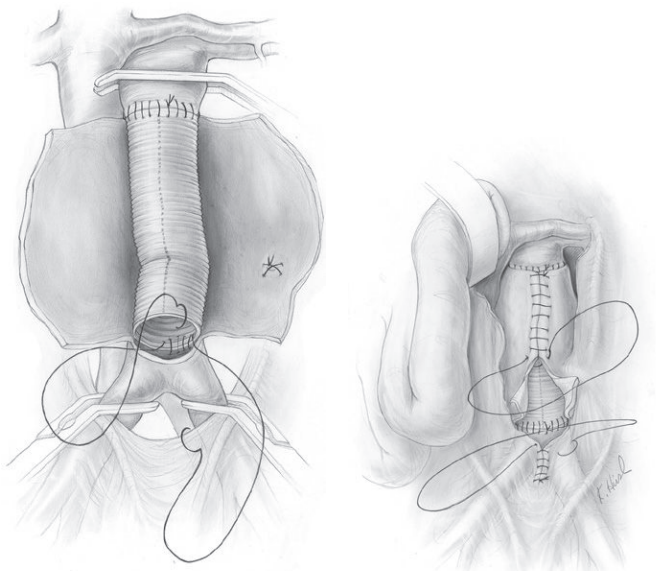

FIGURE **25-3** Dacron graft used to repair aneurysm. (From Zarins CK, Gewertz BL. *Atlas of Vascular Surgery.* 2nd ed. Philadelphia: Churchill Livingstone; 2009.)

Management of Fluid and Blood Loss

Extreme loss of extracellular fluid and blood should be expected with abdominal aortic aneurysmectomies. The degree of surgical and evaporative losses and third spacing will determine the magnitude of the patient's fluid volume deficit. Furthermore, the surgical approach, duration of the surgery, and the experience of the surgeon affects the total blood loss. Most blood loss occurs because of back bleeding from the lumbar and inferior mesenteric arteries after the vessels have been clamped and the aneurysm is opened.[56,62] The use of heparin also contributes to blood loss. Excessive bleeding, however, can occur at any point during

surgery, and blood replacement is commonly administered during abdominal aortic resections.

Owing to the heightened awareness of transfusion-related morbidity, the use of autologous blood via a cell saver system is a standard procedure. Presently, three options are available for administering autologous transfusions: preoperative deposit, intraoperative phlebotomy and hemodilution, and intraoperative blood salvage. Preoperative deposit is becoming more feasible because asymptomatic aneurysms are being detected with greater frequency. Ideally, patients donate their own blood to minimize the intraoperative use of homologous blood products and the subsequent risk of transfusion-related viruses. With anemia and decreased hemoglobin, oxygen transport is decreased, thus making the patient with systemic vascular disease at increased risk for myocardial infarction and stroke. Autotransfusion systems may be used for replacing intraoperative blood loss. In a study at the Mayo Clinic in which intraoperative autologous red-cell salvage was used, 75% less banked blood was transfused. In a prospective study of 100 patients who underwent elective abdominal aortic resections, 80% of the patients received only their own blood.[62]

TABLE 25-5 Comparison of Transperitoneal and Retroperitoneal Approaches

Transperitoneal	Retroperitoneal
Advantages	
Familiarity	Exposure for juxtarenal and suprarenal aneurysms
Access to infrarenal aorta and iliac vessels	Decreased fluid loss
Visualization of intraabdominal viscera	Improved postoperative respiratory function
Rapid opening and closure	Better-tolerated incisional pain avoids formation of intraabdominal adhesions
Versatility	Mesenteric traction syndrome, nonelicited
Disadvantages	
Increased fluid losses	Inaccessibility to distal right renal artery complications
Less postoperative ileus	
More frequent postoperative respiratory complications	
Increased postoperative incisional pain	

Modified from Sicard GA, et al. Retroperitoneal versus transperitoneal approach of repair of abdominal aortic aneurysms. *Surg Clin North Am*. 1989;69:795-806; Rubin BG, Sicard GA. Abdominal aortic aneurysms: open surgical treatment. In: Cronenwett JL, Johnston W, eds. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Saunders; 2010.

Presence of Concurrent Disease

Preoperative Management

The presence of underlying CAD in patients with vascular disease has been well documented. Reports suggest that CAD exists in more than 50% of patients who require abdominal aortic reconstruction and is the single most significant risk factor influencing long-term survivability.[7,8,63-65] Myocardial infarctions are responsible for 40% to 70% of all fatalities that occur after aneurysm reconstruction.[6,7,32,65] Preoperative cardiac evaluation begins with the identification of risk factors that may contribute to adverse cardiac events and subsequent death. When preoperative CAD exists, an increased incidence of postoperative adverse cardiac complications has been demonstrated.[66]

The end-point of any method of preoperative cardiac evaluation for aneurysmectomy is identification of functional cardiac limitations. Depending on the degree of cardiac dysfunction, preoperative optimization of cardiac function may range from simple pharmacologic manipulation to surgical intervention. The American College of Cardiology and the American Hospital Association guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery are generally followed when preparing patients for these procedures. Optimizing patient preoperative pathophysiologic states as described in Box 25-4 minimizes the overall rate of morbidity and mortality.

BOX 25-4

Optimization of Body Systems Prior to Abdominal Aortic Aneurysm Repair

Cardiac Evaluation
- Quantify risk factors and optimize cardiac function
- Institute appropriate β-blocker therapy
- Control hypertension
- Institute appropriate anticoagulation therapy

Pulmonary Evaluation
- Smoking cessation
- Radiologic tests and pulmonary function testing as indicated
- Pharmacologic therapy may include corticosteroids and bronchodilators

Renal Evaluation
- Assess electrolytes, creatinine, and glomerular filtration rate

Adrenal Evaluation
- Steroid supplementation for patients at risk for acute adrenal crises

Deep Vein Thrombosis Prophylaxis
- Pharmacologic prophylaxis
- Graduated compression stockings
- Intermittent pneumatic compression
- Venous foot pumps

Musculoskeletal Evaluation
- Assess neck range of motion prior to airway management
- Assess functional limitations for positioning to avoid postoperative paresthesia

Endocrine Evaluation
- Because of the high incidence of diabetes, short- and long-term glycemic control is mandatory

Miscellaneous Considerations
- Laboratory assessment—complete blood count (CBC), coagulation panel, electrolyte panel, blood urea nitrogen, creatinine, albumin, blood sugar, liver function tests, type and crossmatch 6 units packed red blood cells

Intraoperative Management

Anesthetic Selection

Several anesthetic techniques are available for abdominal aortic resections. Although each technique has its advantages and disadvantages, a superior technique has not been identified. Anesthetic selection should be based on the following objectives: providing optimum analgesia and amnesia, facilitating relaxation, maintaining hemodynamic stability, preserving renal blood flow, and minimizing morbidity and mortality.

General Anesthesia. Circulatory stability is desirable for patients undergoing AAA reconstruction, especially for those with CAD. All inhalation anesthetics may depress the myocardium and cause hemodynamic instability. Therefore, high concentrations of inhalation agents in patients with moderate to severe decreased ejection fraction should not be used. Because the degree of myocardial depression is dose dependent, it is acceptable to administer inhalation agents at lower inhaled concentrations. Beneficial effects attributed to inhalation agents include the ability to alter autonomic responses, reversibility, rapid emergence, potentially earlier extubation, and neurologic- and cardioprotection.[22] Cardiovascular stability provided by opioids has been well documented, and this feature is especially attractive for patients with ischemic heart disease and ventricular dysfunction. Provision of intense analgesia for the initial postoperative period after major abdominal vascular surgery (via the administration of neuraxial opioid) does not alter the combined incidence of major cardiovascular, respiratory, and renal complications.[67] Despite the absence of direct myocardial depression, the sympathetic nervous system inhibition that ensues may decrease systemic vascular resistance and heart rate. Therefore, especially in an individual with a moderate to severely decreased ejection fraction, narcotics should be carefully titrated to the patient's hemodynamic response.

Regional Anesthesia. The use of epidural anesthesia for abdominal aneurysmectomies is commonly considered. The benefits of epidural use include decreased preload and afterload, preserved myocardial oxygenation, reduced stress response, excellent muscle relaxation, decreased incidence of postoperative thromboembolism, increased graft flow to the lower extremities, decreased pulmonary complications, and improved postoperative analgesia. Potential disadvantages include anticoagulation and the possibility of epidural hematoma, and if local anesthesia is employed intraoperatively, severe hypotension during blood loss or declamping.[23,68]

Combination Techniques. Combining anesthetic techniques for major vascular surgery is more popular than using them alone; the advantages of each technique contribute to a smoother anesthetic. Epidural anesthesia combined with light general anesthesia provides the benefits of epidural anesthesia and the ability to provide amnesia and controlled ventilation.

In summary, all the aforementioned anesthetic techniques can be used safely and can demonstrate positive outcomes. Even more important than anesthetic selection is the clinical management of each patient. Observation, accurate interpretation, and immediate intervention during the anesthetic process reduce morbidity and mortality to a much larger extent than does selection of the superior anesthetic technique.

Fluid Management

Maintaining intravascular volume may be an extreme challenge during abdominal aortic resections. Controversy exists regarding whether the administration of crystalloids or colloids affects the overall incidence of morbidity and mortality. Crystalloids may be used for replacing basal and third-space losses at an approximate rate of 10 mL/kg/hr.[60] Blood losses initially can be replaced with crystalloids at a ratio of 3:1. The combination of crystalloid and colloid administration is also acceptable. Regardless of the choice of fluid, volume replacement must be dictated by physiologic parameters. Fluid replacement should be sufficient to maintain normal cardiac filling pressures, cardiac output, and urine output of at least 1 mL/kg/hr.[7] Patients with limited cardiac reserve can develop congestive heart failure if hypervolemia occurs. As mentioned previously, cell saver blood retrieval is commonly used, and two large-bore intravenous lines in addition to a central venous catheter is warranted.

Hemodynamic Alterations

Hemodynamic changes are likely to occur throughout the procedure. Adequate preoperative sedation should be given before placement of invasive monitoring equipment. Momentary fluctuations in heart rate and blood pressure should be anticipated during induction and intubation. Preoperative replacement of fluid deficits prevents exaggerated responses to vasodilating induction agents. For patients with adequate left ventricular function, hemodynamic stability can be preserved with a "slow" induction using opioids and β-adrenergic blocking agents. Etomidate has minimal myocardial depressant effects and may be most suitable for patients with limited cardiac reserve. The response to mesenteric traction (discussed previously) is also associated with momentary hemodynamic changes.

Renal Preservation

Mortality is four to five times greater in patients who develop acute kidney injury postoperatively. Mechanisms for preserving renal function during aortic cross-clamping include maintaining adequate hydration, avoiding severe and prolonged hypotension, and using renal protection agents such as mannitol, dopamine, furosemide, and N-acetylcysteine. With suprarenal clamp placement, the use of renal cold perfusion at 5° C of hypoosmolar crystalloid solution instilled into the kidney may be an effective renal protection strategy. The theorized mechanism is a decrease in renal metabolic rate resulting in a 7% reduction in oxygen consumption for each degree Celsius drop in temperature.[55] However, the best predictor of postoperative renal dysfunction is based on the patient's preoperative renal function.

Postoperative Considerations

Cardiac, respiratory, and renal failure are the most common complications observed postoperatively in patients recovering from abdominal aortic reconstruction. Cardiovascular function must be closely monitored in the intensive care unit (ICU) for at least 24 hours after surgery. Maintaining adequate blood pressure, intravascular fluid volume, and myocardial oxygenation is paramount during this period. Myocardial infarction frequently contributes to postoperative morbidity and mortality; serial cardiac enzyme analysis may be justified. Pharmacologic agents used in the treatment of hypertension must also be available.

Most patients require ventilatory assistance during the postoperative period. Vigilant monitoring of respiratory function is mandatory, especially when epidural catheters are used for postoperative analgesia. To address the significant number of serious postoperative complications, which are noted in Box 25-5, intensive and continuous assessment of the patient condition is vital. Patients are admitted to the ICU for high-acuity care.

Juxtarenal and Suprarenal Aortic Aneurysms

Although most AAAs occur below the level of the renal arteries, 2% extend proximally and involve the renal or visceral arteries.[60,70]

Juxtarenal aneurysms are located at the level of the renal arteries, but they spare the renal artery orifice. More proximal suprarenal aneurysms include at least one of the renal arteries and may involve visceral vessels. The effects of aortic cross-clamping for juxtarenal or suprarenal aneurysms are similar to those for infrarenal aortic occlusions; however, the magnitude of hemodynamic alterations increases as the aorta is clamped more proximally.

Renal failure, although possible during infrarenal aortic cross-clamping, occurs more often because of suprarenal aortic occlusion. Maintaining adequate intravascular volume and administering osmotic and loop diuretics may minimize renal ischemia and dysfunction.

Paraplegia is possible when the blood supply to the spinal cord is interrupted by aortic cross-clamping at or above the level of the diaphragm. Increasing the MAP or decreasing cerebrospinal fluid (CSF) pressure by placing a catheter in the subarachnoid space to drain CSF may be used as a means to increase spinal cord perfusion pressure.[7,69,70] Total body hypothermia and multimodal neurological monitoring including somatosensory and motor evoked potentials can be used to decrease the incidence of paraplegia. Neurologic deficits can become evident weeks after surgery. Box 25-6 summarizes the complications that may result from juxtarenal or suprarenal aortic occlusion.

Ruptured Abdominal Aortic Aneurysm

A high mortality rate of 80% to 90% is associated with a ruptured AAA, whereas postoperative mortality is estimated to range from 40% to 50%.[71] Endovascular aortic repair is being used to treat ruptured AAAs and may decrease the overall mortality. The most common symptoms of ruptured AAAs include a triad of severe abdominal discomfort or back pain, hypotension, and a pulsatile mass.[72] Other common symptoms include syncope, groin or flank pain, hematuria, and groin hernia. Risk factors associated with an increase in mortality in patients with a ruptured AAA are noted in Box 25-7.

Hypotension and a history of cardiac disease are two factors associated with the poorest prognosis.[37,39] Patients with these symptoms should be immediately transferred to the operating room for surgical exploration. When hypotension is absent, more time is available for a comprehensive preoperative assessment and testing.

Once the patient arrives in the operative suite, a brief preoperative evaluation, establishing venous access, and provisions for fluid and blood product administration can be completed. Hemodynamic stability must be the primary objective, and anesthetic induction and maintenance agents must be selected on a case-by-case basis.

Cardiovascular stability is the primary focus until blood loss from the proximal aorta is controlled by surgical intervention. Fluid resuscitation can begin with crystalloids; colloids and blood products can be administered as they become available. Intraoperative blood salvage provisions should be available. Coagulation studies and other laboratory tests including hemoglobin, hematocrit, and ionized calcium values should be obtained. Calcium is a positive inotrope, and it is necessary for normal myocardial excitation contractile coupling. Large amounts of citrate used as a preservative in banked blood bind calcium ions and result in relative hypocalcemia. Decreased myocardial contractility as evidenced by hypotension, increased left ventricular end-diastolic pressure, and increased central venous pressure can be caused by hypocalcemia. If hypocalcemia occurs, calcium chloride can be administered as an intravenous drip to reestablish normocalcemia. Dilutional thrombocytopenia is the most common reason for coagulopathy to develop after massive intravenous fluid and blood administration. The use of fresh frozen plasma has been shown to decrease the total transfusion requirements and the incidence of coagulopathies.[37] The ability to administer platelets also may be necessary.

After initial fluid resuscitation has been performed and hemodynamic stability has been ensured, direct arterial blood pressure monitoring must be instituted. A central venous or pulmonary artery catheter may be inserted. The hemodynamic effects of aortic cross-clamping and release are similar to those for elective surgery; however, responses may be extreme, especially if hypotension exists when the clamp is released. Because most patients

BOX 25-5

Postoperative Considerations for Patients Having Abdominal Aortic Aneurysm Repair

- Continue invasive hemodynamic monitoring
- Treat acute blood pressure extremes, arrhythmias (atrial fibrillation)
- Assess for postoperative myocardial infarction
- Ventilatory management with weaning and extubation
- Assess for abdominal compartment syndrome
- Evaluate hemoglobin, hematocrit, coagulation status, and adequacy of volume replacement
- Assess blood urea nitrogen/creatinine and urine output
- Institute deep vein thrombosis prophylaxis per protocol

BOX 25-6

Potential Complications of Juxtarenal or Suprarenal Aortic Occlusion

- Renal failure
- Hemorrhage
- Distal arterial occlusion
- Infarction
- Pulmonary or cardiac dysfunction
- Impotence
- Paraplegia
- Thrombosis
- Pseudoaneurysm formation
- Aortoenteric fistula

BOX 25-7

Risk Factors Associated with an Increased Risk of Mortality in Patients with Abdominal Aortic Aneurysm Rupture

- Increasing age
- Women
- Nonwhite race
- Insurance status (higher for those who self-pay or are on Medicaid in the United States)
- Comorbid conditions
- Congestive heart failure
- Renal failure
- Valvular heart disease

(From Cronenwett JL, Johnston W. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Saunders; 2010.)

require large amounts of fluid and blood replacement, postoperative mechanical ventilation is recommended.

THORACIC AORTIC ANEURYSMS

The mortality associated with elective thoracic aneurysms is 22%, and if rupture occurs, this figure increases to 54%.[73] Patients with aortic dissections have only a 3-month survival if they do not undergo surgical repair, because the incidence of rupture is high.[74] Aneurysms have been described for hundreds of years, but not until 1951 did the development of the arterial prosthesis lead to successful bypass options.[75] The refinement of synthetic grafts, surgical and perfusion techniques, and intraoperative management has contributed to improved surgical outcomes. Improved outcomes are associated with those medical centers that treat a high volume of patients with thoracic aortic aneurysms.

TABLE 25-6 Classification Schemes of Acute Aortic Dissection

Classification	Site of Origin and Extent of Aortic Involvement
DeBakey	
Type I	Originates in the ascending aorta and extends at least to the aortic arch and often to the descending aorta (and beyond)
Type II	Originates in the ascending aorta; confined to this segment
Type III	Originates in the descending aorta, usually just distal to the left subclavian artery, and extends distally
Stanford	
Type A	Dissections that involve the ascending aorta (with or without extension into the descending aorta)
Type B	Dissections that do not involve the ascending aorta

Braverman AC, et al. Diseases of the aorta. In: Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 9th ed. Vol. 2. Philadelphia, Saunders; 2012:1320.

Classification

Aneurysms of the thoracic aorta may be classified with respect to type, shape, and location. Typically, aneurysms involving all three layers of the arterial wall—tunica adventitia, tunica media, and tunica intima—are considered to be *true aneurysms*. In comparison, aneurysms that solely involve the adventitia are termed *false aneurysms*. The shape of the lesion also can serve as a means of characterizing aneurysms. Fusiform aneurysms have a spindle shape and result in dilation of the aorta. Saccular aneurysms are spherical dilations and are generally limited to only one segment of the vessel wall. Aortic dissection is the result of a spontaneous tear within the intima that permits the flow of blood through a false passage along the longitudinal axis of the aorta. There are two major classification schemes of aortic dissection based on the location. They are the DeBakey and Stanford classifications. (Table 25-6). Thoracoabdominal aortic aneurysms (TAAA) are classified using the Crawford classification as shown in (Figure 25-4).

Etiology

Atherosclerosis is the most common cause of aneurysmal pathology. Atherosclerotic lesions occur most often in the descending and distal thoracic aorta and are most often classified as fusiform. Less common causes include aortic dissection and various mechanical, inflammatory, and infectious processes. The various causes of aortic aneurysms are classified in Box 25-8.

Diagnosis

The symptomatology of thoracic aneurysms is often related to the site of the lesion and its compression on adjacent structures. Pain, stridor, and cough may result from compression of thoracic structures. Symptoms related to aortic insufficiency may be observed in aneurysms of the ascending aorta. An upper mediastinal mass

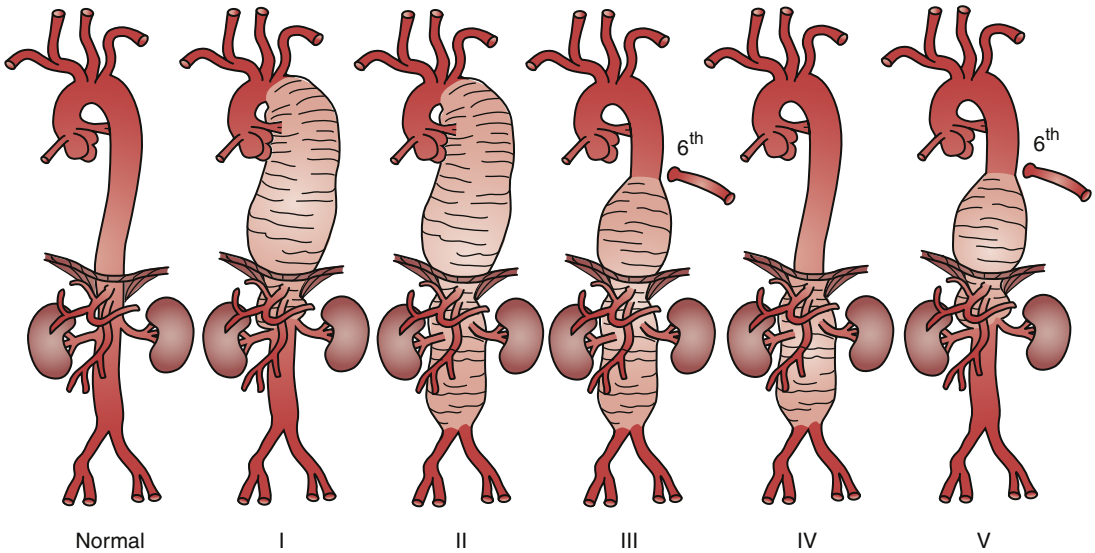

FIGURE 25-4 Crawford classification of thoracoabdominal aortic aneurysms. *Type I*, distal to the left subclavian artery to above the renal arteries. *Type II*, distal to the left subclavian artery to below the renal arteries. *Type III*, from the sixth intercostal space to the renal arteries. *Type IV*, from the 13th intercostal space to the iliac bifurcation (entire abdominal aorta). *Type V*, below the sixth intercostal space to just above the renal arteries. (From Cronenwett JL, Johnston KW. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Saunders; 2010:2021.)

may be an incidental finding on conventional chest radiography in an asymptomatic patient. Further investigation with noninvasive methods such as CT scan and MRI can describe the configuration and location of the aneurysm.

Treatment

As previously described, a high mortality rate is associated with rupture of thoracic aneurysms. Therefore early detection and surgical intervention make a significant contribution to long-term survival. Surgical approach and the method of aneurysm resection vary according to the location of the lesion within the thoracic aorta. Resection of the ascending aorta and graft replacement necessitate the use of cardiopulmonary bypass. The aortic valve also may require replacement. Surgical resection of lesions in the transverse arch compromises cerebral perfusion, although various bypass techniques combined with profound hypothermia and circulatory arrest have been used.[76] Aneurysms of the descending aorta may be resected by application of an aortic cross-clamp. However, perfusion to distal organs can be compromised during this procedure.

AORTIC DISSECTION

Aortic dissection is characterized by a spontaneous tear of the vessel wall intima, permitting the passage of blood along a false lumen. Although the cause of the dissection is unclear, lesions that were thought to be related to cystic necrotic processes may actually be caused by variations in wall integrity. Hypertension is the most common factor that contributes to the progression of the lesion. Manipulation of the ascending aorta during cardiac surgery may be associated with aortic dissection.[77] The symptoms of aortic dissection are the result of interruption of blood supply to vital organs. The most serious complication is aneurysm rupture. Diagnosis can be accomplished by the previously mentioned noninvasive techniques.

Treatment of dissecting aortic lesions depends on their location within the thoracic aorta (Figure 25-5). Type A lesions have the highest incidence of rupture and require immediate surgical intervention. Type B lesions may initially be managed medically, with the administration of arterial dilating and β-adrenergic blocking agents.

In summary, surgical resection of thoracic aortic lesions enhances long-term survival. Refinement of surgical techniques and improvement in perfusion technology have reduced the overall mortality rate. The surgical method used is dependent on the location of the aortic lesion. Anesthesia for aneurysms of the ascending and transverse aorta requires cardiopulmonary bypass.

DESCENDING THORACIC AND THORACOABDOMINAL ANEURYSMS

Preoperative Assessment

Patients who undergo major vascular surgery often are elderly and have varying degrees of concurrent disease. Most patients who develop a descending thoracic aortic aneurysm (DTAA) are asymptomatic. Operative surgical decisions are based on the size, extent, and rate of expansion of the aneurysm. For patients with degenerative aortic disease, surgical repair is advised for aneurysms 6 cm or larger. Independent risk factors for DTAA include pain,

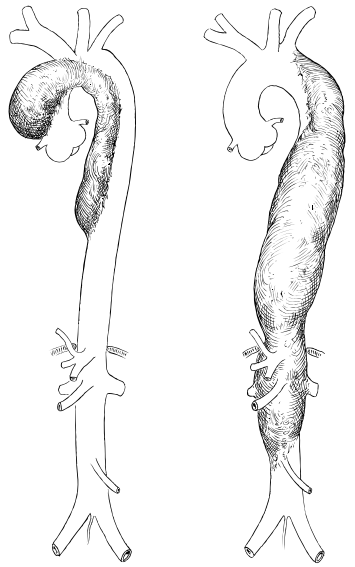

FIGURE **25-5** Types of aortic dissection. *Type A* involves the ascending aorta and may extend into the aortic arch. *Type B* starts at the proximal descending aorta and extends distally.

BOX **25-8**

Etiology of Thoracoabdominal Aortic Aneurysms

Degenerative
- Nonspecific (commonly considered arteriosclerotic), dysplastic (80%)

Mechanical (Hemodynamic)
- Dissections (15%-20%)
- Poststenotic
- Arteriovenous fistula
- Blunt or penetrating trauma

Connective Tissue
- Ehlers-Danlos syndrome
- Marfan syndrome

Inflammatory (Noninfectious)
- Takayasu's disease
- Behçet's syndrome
- Reiter's syndrome
- Kawasaki disease
- Microvascular disorder (e.g., polyarteritis)
- Ankylosing spondylitis
- Rheumatoid aortitis
- Periarterial inflammatory disease (e.g., pancreatitis)

Infectious
- Tuberculosis
- Bacterial
- Fungal
- Spirochetal (syphilis)

Anastomosis
- Postarteriotomy
- Postoperative pseudoaneurysm

increased age, chronic obstructive pulmonary disease (COPD), renal insufficiency, aneurysm size, and aneurysm expansion rate.[78]

The importance of a thorough preoperative evaluation cannot be overemphasized. Special attention should be directed toward cardiac, renal, and neurologic function. Although most fatalities related to thoracic aortic surgery are cardiac in origin, renal and neurologic dysfunction contribute to poor surgical outcomes.[79] Preoperative renal dysfunction is directly related to postoperative renal failure and is thought to be one of the strongest contributors to renal deterioration after surgery.[79,80] Neurologic function should be carefully assessed in the preoperative phase. Because paraplegia is one of the most devastating consequences of thoracic aortic surgery, any alteration in lower-extremity function should be noted. Hoarseness related to compression of the recurrent laryngeal nerve should be assessed and documented. The left recurrent laryngeal nerve is most susceptible to damage because of its close proximity to the aortic arch. Bilateral recurrent laryngeal nerve compression or damage can result in respiratory compromise.

Intraoperative Management

Monitoring

Intraoperative monitoring devices used for thoracoabdominal aneurysm resection are the same as for those used for abdominal aneurysmectomies. Direct intraarterial blood pressure and pulmonary artery pressure monitoring is standard during extracorporeal circulation. If the aneurysm involves the thoracic region or the distal aortic arch, right radial arterial line monitoring is preferred because left subclavian arterial blood flow may be compromised during surgery. Use of TEE is suggested for cardiac monitoring in patients with myocardial dysfunction. An indwelling urinary catheter is used for assessing renal function. To facilitate exposing the descending thoracic aorta, a double-lumen endotracheal tube is inserted to allow for one-lung ventilation. As a result, careful monitoring of oxygenation is mandatory. Routine use of pulse oximetry may be limited if the left subclavian artery is manipulated; therefore, the right hand, the ear, or the nasal passages should be used for monitoring oxygen saturation. Finally, a lumbar intrathecal catheter is inserted to access CSF. Somatosensory evoked potentials or MEPs are often used to monitor and detect neurologic dysfunction.

Spinal Cord Ischemia

Neurologic dysfunction is a serious complication of thoracic aortic reconstruction. Spinal cord injury is categorized into immediate and delayed paraplegia. The incidence of immediate paraplegia with DTAA ranges from 0% to 3% if surgery is performed with adjunctive procedures or clamp times are less than 10 minutes. However, for patients having TAAA, postoperative neurologic injuries vary from 2% to 20% depending on the type of aneurysm, surgical technique, cross-clamp time, and use of spinal cord protection interventions.[81-83] The exact incidence of delayed paraplegia is unknown, but it is believed that 25% of all spinal cord injuries are delayed. The primary preoperative risk factors for delayed paraplegia include type 2 aneurysms, emergency procedures, number of sacrificed segmental segments, and renal failure. The main postoperative factors include hemodynamic instability caused by atrial fibrillation, bleeding, multiorgan failure, and sepsis.[78]

Neurologic deficits are the result of hypoperfusion to the spinal cord during thoracic aortic reconstruction. The artery of Adamkiewicz, also known as the *greater radicular artery*, originates from an intercostal branch between T8 and L2 and provides the majority of blood flow to the anterior spinal artery. The anterior spinal artery perfuses the ventral aspect of the spinal cord, which is responsible for motor control.[80] Although attempts are made to reimplant the intercostal branches that contribute blood flow to the spinal cord, these efforts do not always decrease the incidence of paraplegia.[80,84]

Several techniques have been successful in an effort to decrease the incidence of neurologic dysfunction after thoracic aortic surgery. These include SSEP and MEP monitoring, CSF drainage, hypothermia, reattachment of intercostal arteries, and distal aortic perfusion. Systemic hypothermia and selective cooling of the spinal cord may lengthen ischemic time intervals; however, the clinical benefits of these hypothermia methods are unclear.[85,86] The use of various bypass mechanisms and distal shunts may minimize the length of aortic occlusion time.

Spinal cord perfusion pressure can be estimated by calculating the arterial blood pressure minus the CSF pressure. During aortic clamping, CSF pressure increases while arterial pressure decreases distal to the clamp. The spinal cord perfusion pressure can therefore be manipulated by altering arterial blood pressure and draining CSF through the intrathecal catheter.[86,87] Postoperative CSF drainage for as long as 72 hours is believed to decrease the incidence of late paraplegia. Avoiding prolonged periods of hypotension is vital to avoid spinal cord deficits.

Methods for detecting spinal cord ischemia were previously discussed. The intraoperative use of SSEPs and MEPs can provide early identification of neurologic dysfunction, but these monitoring modalities do not ensure spinal cord integrity. Factors that contribute to the development of neurologic deficit include level of aortic clamp application, ischemic time, embolization or thrombosis of a critical intercostal artery, failure to revascularize intercostal arteries, and urgency of surgical intervention.[86,87] Delayed paraplegia also may be the result of reperfusion injury, although the exact mechanism of injury has not been proven.[78,88-90]

Renal Dysfunction

The incidence of renal dysfunction after thoracoabdominal aortic resection is estimated to be between 10% and 20%.[78,91,92] The major causes of renal insufficiency is type and size of aneurysmal disease, ischemic time, and the degree of preoperative renal dysfunction. Kidney protection during TAAA repair includes distal aortic perfusion, cold crystalloid perfusion, and normothermic blood perfusion. Intraoperative hypotension has been identified as an independent predictor of postoperative renal dysfunction, and a MAP of 60 mmHg is warranted.[78] Maintenance of intravascular volume and stable circulatory status appears to be the most reliable method of minimizing renal dysfunction. Preoperatively, volume status should be corrected with non–glucose-containing crystalloid solutions. Intraoperative volume replacement should be guided by invasive monitoring.

In summary, neurologic and renal dysfunction are devastating consequences of thoracic and thoracoabdominal aortic resections. A complete preoperative evaluation, identification of risk, optimization of organ function, and use of the suggested methods to minimize the consequences of ischemia all contribute to optimal surgical outcomes. Additional complications of thoracoabdominal aortic reconstruction are listed in Box 25-9.

Anesthetic Management

The principles of perioperative management of thoracic or thoracoabdominal aneurysms are similar to those previously discussed for abdominal aortic aneurysmectomies. Anesthetic selection should be based on the presence of concomitant disease processes, with the objective of maintaining cardiovascular stability and minimizing morbidity and mortality. Intraoperative monitoring should

BOX **25-9**

Complications After Thoracoabdominal Aortic Aneurysm Repair

Early Complications
- Respiratory failure (most common complication)
- Hemorrhage
- Myocardial infarction
- Congestive heart failure
- Early paraplegia
- Embolization/thrombosis
- Distal artery occlusion
- Bowel ischemia
- Sexual dysfunction
- Infection
- Renal failure
- Cerebrovascular accident

Late Complications
- Delayed paraplegia
- Graft thrombosis
- Fistula formation
- False aneurysm
- Graft infection

focus on detection of myocardial, neurologic, and renal ischemia. The hemodynamic consequences of aortic cross-clamping should be attenuated by the use of pharmacologic adjuncts. Restoration of circulating blood volume minimizes the hemodynamic alterations caused by the release of the aortic clamp.

Unique to thoracic aortic surgery is the use of one-lung ventilation. To detect potential inadequacies in ventilation and oxygenation with this approach, the highest degree of vigilance must be used. Extreme blood loss should be anticipated. Venous access and blood product availability should be confirmed during the preoperative phase. Methods of minimizing the use of homologous blood products (e.g., perioperative blood salvage) are commonly used. Coagulopathy is a constant threat with the administration of blood products. Close monitoring of coagulation parameters and administration of fresh frozen plasma, platelets, or specific coagulation factors can minimize the incidence and severity of coagulopathies.

Postoperative Considerations

After surgery is completed, if a double-lumen endotracheal tube was used, it should be replaced with a standard endotracheal tube to provide a secure airway since postoperative ventilatory assistance is usually required. Airway anatomy may become edematous during surgery, causing difficulty with ventilation and reintubation. Under these circumstances, the double-lumen endotracheal tube may be left in place. Replacement can proceed in the postoperative period after the airway edema has dissipated.

Close observation of neurologic, circulatory, pulmonary, and renal status is warranted in the postoperative phase. Hemodynamic control is vital to maintaining perfusion to vital organs without creating excessive demands on the heart or the aortic graft. Careful monitoring of respiratory status aided by arterial blood gas analysis is important. Epidural analgesia using local anesthetics, narcotics, or both can be administered for pain relief.

ENDOVASCULAR AORTIC ANEURYSM REPAIR

In 1991, the first endovascular stent was performed to repair an infrarenal aortic aneurysm. The development of this technique has created a less invasive approach to aortic aneurysm repair. Studies suggest that severe cardiac and respiratory pathology make as many as 30% of patients with aortic aneurysms poor surgical candidates.[93] Endovascular aortic aneurysm repair (EVAR) was initially developed to help patients with severe coexisting disease who were not considered to be surgical candidates. The popularity of EVAR has increased as the success of the procedure has improved. It is estimated that 90% of all AAA repairs will be accomplished using the EVAR technique within the next 10 years.[94] Schermerhorn et al.[95] suggested that the patient population who may benefit most from EVAR are high-risk patients.

The largest source of data is EUROSTAR (*EURO*pean collaborators on Stent/graft *T*echniques for aortic *A*neurysm *R*epair), a registry that provides insight on the potential advantages and shortcomings of EVAR. The registry contains data from patients who were treated in over 135 European medical centers. The patient population included patients with infrarenal aortic aneurysms. Results suggest that the larger the diameter of the AAA (greater than 5.5 cm), the greater the 30-day mortality rate. Cumulatively, the 30-day operative mortality was 2.5%. There were no statistically significant differences in the AAA-related death rate at 1 year comparing EVAR with open surgical treatment (98.2% versus 98.6%).[96] Five years after EVAR, the patient survival rate was 76%. There was a low incidence of intraoperative AAA rupture occurring in only 32 patients. The cumulative rate of rupture was estimated to be approximately 1% per year. *Endoleak* (defined as persistent blood flow and pressure ["endotension"] between the endovascular graft and the aortic aneurysm), graft migration, and kinking were determined to be significant risk factors for late open conversion. The overall risk of late failure was approximately 3% per year.[95,97]

The results comparing EVAR with traditional open AAA repair for abdominal aortic aneurysm assessing short-term success are promising. Two large randomized controlled studies have compared the effects of EVAR to open AAA repair—the Endovascular Aneurysm Repair Trial 1 (EVAR 1) and the Dutch Randomized Endovascular Aneurysm Management (DREAM). A national audit of the effectiveness of EVAR by the Canadian Institute for Health Information database provides information that supports the endovascular technique.

The purpose of the EVAR 1 trial was to determine which surgical intervention—endovascular or open aneurysmectomy—was superior in patients who were deemed fit for open AAA repair. Patients were randomized to either the EVAR group (n = 543) or the open AAA repair group (n = 539). The 30-day mortality rate was 1.7% in the EVAR group versus 4.7% in the open AAA repair group. Secondary interventions were more common in the EVAR group (9.8% versus 5.8%).[98] However, there was no significant difference between the groups with respect to 2-year survival.

The DREAM study was a multicenter randomized controlled trial comparing short-term results (30 days) of conventional and endovascular repair of AAAs in 345 patients whose aneurysms were a minimum of 5 cm in diameter. For the open repair group, the operative mortality was 4.6%, and severe complications occurred in 9.8% of patients. In the EVAR group, operative mortality was 1.2%, and severe complications occurred in 4.7% of patients. The conclusion was that EVAR was superior to open repair in this patient population. However, it was also determined that 2-year moderate and severe adverse patient events were nearly identical for both groups. The researchers stated that long-term follow-up studies were needed to determine whether the advantages of EVAR would be sustained.[99]

The Canadian National Audit included results from 1996 patients with nonruptured AAAs. A comparison of EVAR

Data from Townsend CM, et al. *Sabiston Textbook of Surgery*. 19th ed. Philadelphia: Saunders; 2012.

(n = 178) versus open aneurysm repair (n = 1818) was completed. The findings indicated that in-hospital mortality was 0.6% and mean length of stay (LOS) was 5.8 days for EVAR, whereas in-hospital mortality for open procedures was 4.6% and LOS 11.9 days. The conclusion was that EVAR was presently being underused in Canada.[100]

Endovascular aortic aneurysm repair is also being used to treat patients with thoracic aortic aneurysms. The mortality rate for EVAR for elective descending thoracic aneurysm repairs range from 3.5% to 12.5%, as compared with an open approach, where mortality is approximately 10%.[101] Reports also show that EVAR has a low incidence (0% to 6%) of spinal cord ischemia and paraplegia.[102] Potential explanations for the absence of spinal cord complications are (1) no thoracic aortic cross-clamping and (2) no prolonged periods of extreme hypotension. Perioperative hypotension (MAP less than 70 mmHg) was a significant predictor of spinal cord ischemia in patients having EVAR for thoracic aneurysm repair.[103] Endograft therapy has also been used with success and may eventually become the treatment of choice for thoracic aneurysm repair in patients older than 75 years of age.[104]

The mortality rate for patients with a ruptured AAA who are alive when diagnosed in emergency departments is 40% to 70%.[105] Since the 1950s, mortality from ruptured AAAs has only decreased 3.5% per decade.[106] The EVAR approach has been used successfully to repair ruptured AAAs, but the number of patients treated and the quality of randomized controlled data on this subject are limited. However, 30-day mortality rates were 10% to 45%.[107] Medical centers that consider EVAR for ruptured AAA repair must have emergent CT imaging capabilities, trained endovascular teams, adequate endovascular supplies available, and a specially arranged surgical suite.

From the data presented above, it would appear that EVAR has specific advantages as compared with the traditional open AAA repair.[108,109] However, there are questions about the procedure that have yet to be answered, most importantly, Is there a long-term survival benefit to EVAR? As described in EVAR 1, reinterventions due to endoleak were required in three times as many patients who had EVAR. Of these, 7% of endoleaks were discovered within 1 month of implantation and another 13% occurred within 4 years postoperatively.[110] Problems with graft migration and durability are the primary determinants of this complication. However, the majority of this data was collected while physicians were implanting first- and second-generation endografts. Newer-generation endografts and superior surgical techniques may decrease this adverse effect in the future.

FIGURE **25-7** Aortic endovascular graft.

A comparison of outcomes evaluating EVAR and open AAA repair in nearly 23,000 patients was reported.[108] The conclusion was that EVAR was associated with lower short-term morbidity and mortality. Three-year survival rates were similar for both surgical approaches. Further randomized controlled studies must be done on the long-term effects of EVAR. Patients who are prone to aortic aneurysm development commonly have coexisting diseases as listed in Box 25-10.

Procedure

Endovascular aortic aneurysm repair involves deployment of an endovascular stent graft within the aortic lumen. The graft restricts blood flow to the portion of the aorta where the aneurysm exists. This procedure can be performed for patients who have descending thoracic aortic aneurysms or AAAs. Cannulation of both femoral arteries is performed. As seen in Figure 25-6, a guide wire is threaded through the iliac artery to the level of the aneurysm. Next, a sheath is inserted over the guide wire and positioned at the aneurysm location through use of fluoroscopy. The proximal end of the sheath must extend beyond the aneurysm. Once the sheath is deployed, radial force or fixation mechanisms such as hooks or barbs on the stent become embedded into the aortic wall to prevent stent migration (Figure 25-7).

The procedure frequently takes place in an interventional radiology suite. Compared with the conventional surgical method, advantages of the endovascular approach include no aortic cross-clamping, improved hemodynamic stability, decreased incidence of embolic events, decreased blood loss, reduced stress response,

BOX **25-11**

Potential Complications Associated with EVAR

Graft and Deployment Complications
- Failed deployment
- Microembolization
- Migration/occlusion of major branch arteries (i.e., renal, mesenteric)
- Aortic perforation/aneurysm rupture
- Aortic dissection
- Hematoma formation
- Endoleak
- Stenosis/kink/thrombosis
- Graft tear
- Damage to access arteries (femoral → iliac)
- Infection

Radiologic Implications
- Radiation exposure
- Allergy to contrast dye
- Renal insufficiency from contrast dye

Systemic Complications
- Neurologic (CVA, paraplegia)
- Cardiac morbidity/mortality
- Pulmonary insufficiency
- Renal insufficiency
- Postimplant syndrome

EVAR, Endovascular aneurysm repair; *CVA*, cardiovascular accident.

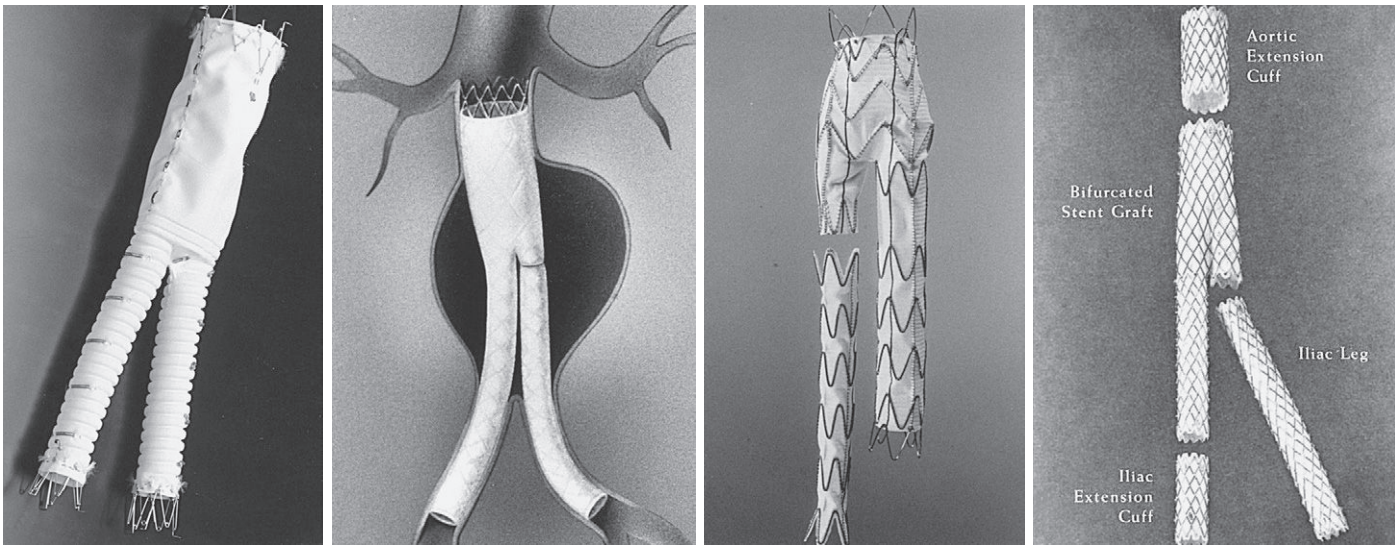

FIGURE **25-8** Various types of endovascular grafts. (Adapted from Cronenwett JL, Johnston KW. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Saunders; 2010:1363-1383.)

decreased incidence of renal dysfunction, and decreased postoperative discomfort.[111,112] Systemic anticoagulation with heparin, 50 to 100 units/kg, is administered prior to catheter manipulation.[113] Antibiotic coverage is recommended at the beginning of surgery. The anesthetic techniques that can be used for EVAR include general anesthesia, neuraxial blockade, or local anesthesia with sedation.[114] There is presently a lack of data suggesting that one anesthetic technique is clearly superior for patients having EVAR. Local anesthesia with sedation, as compared with general anesthesia, is associated with a decrease in nonfatal cardiac morbidity, respiratory complications, renal failure, and overall mortality.[115,116] There is also a decreased pulmonary morbidity as compared with general anesthesia, and local anesthesia with sedation is associated with a shorter length of stay as compared with general and neuraxial anesthesia.[117] The goals for intraoperative management for EVAR include maintaining hemodynamic stability, providing analgesia and anxiolysis, and being prepared to rapidly convert to an open procedure.

With infrarenal or suprarenal EVAR, creatinine clearance values decreased by 10% in the first year.[118] However, proximal endovascular graft migration can occur, causing renal artery occlusion and postoperative renal failure.[119] Further randomized controlled trials are needed to substantiate these results. Plasma catecholamine concentrations and mediators of the systemic immune response were decreased in patients who underwent the endovascular approach as compared with patients who underwent conventional repair.[120,121] Pearson et al.[122] determined that plasma cortisol release was lower in patients having EVAR than in those having traditional open AAA repair. The EVAR group also developed significantly less sepsis and systemic immune response syndrome. Complications that can arise from the EVAR approach include endograft thrombosis, migration or rupture, graft infection, iliac artery rupture, and lower extremity ischemia.[123] Fatal cerebral embolism resulting in sudden respiratory arrest has occurred during EVAR.[124] Box 25-11 lists potential complications associated with EVAR.

Endovascular graft design and durability continue to improve. Graft devices are either unibody (comes in one piece) or modular (comes in multiple pieces). The endograft fabric is either woven polyester (Dacron) or polytetrafluoroethylene. There is no significant difference in biologic response when comparing these two materials.[125] The graft skeleton is constructed of stainless steel, Nitinol, or Elgiloy (Figure 25-8). Nitinol stents are popular because they exhibit minimal shortening after deployment. There is considerable interest and research involving drug-eluting stents.

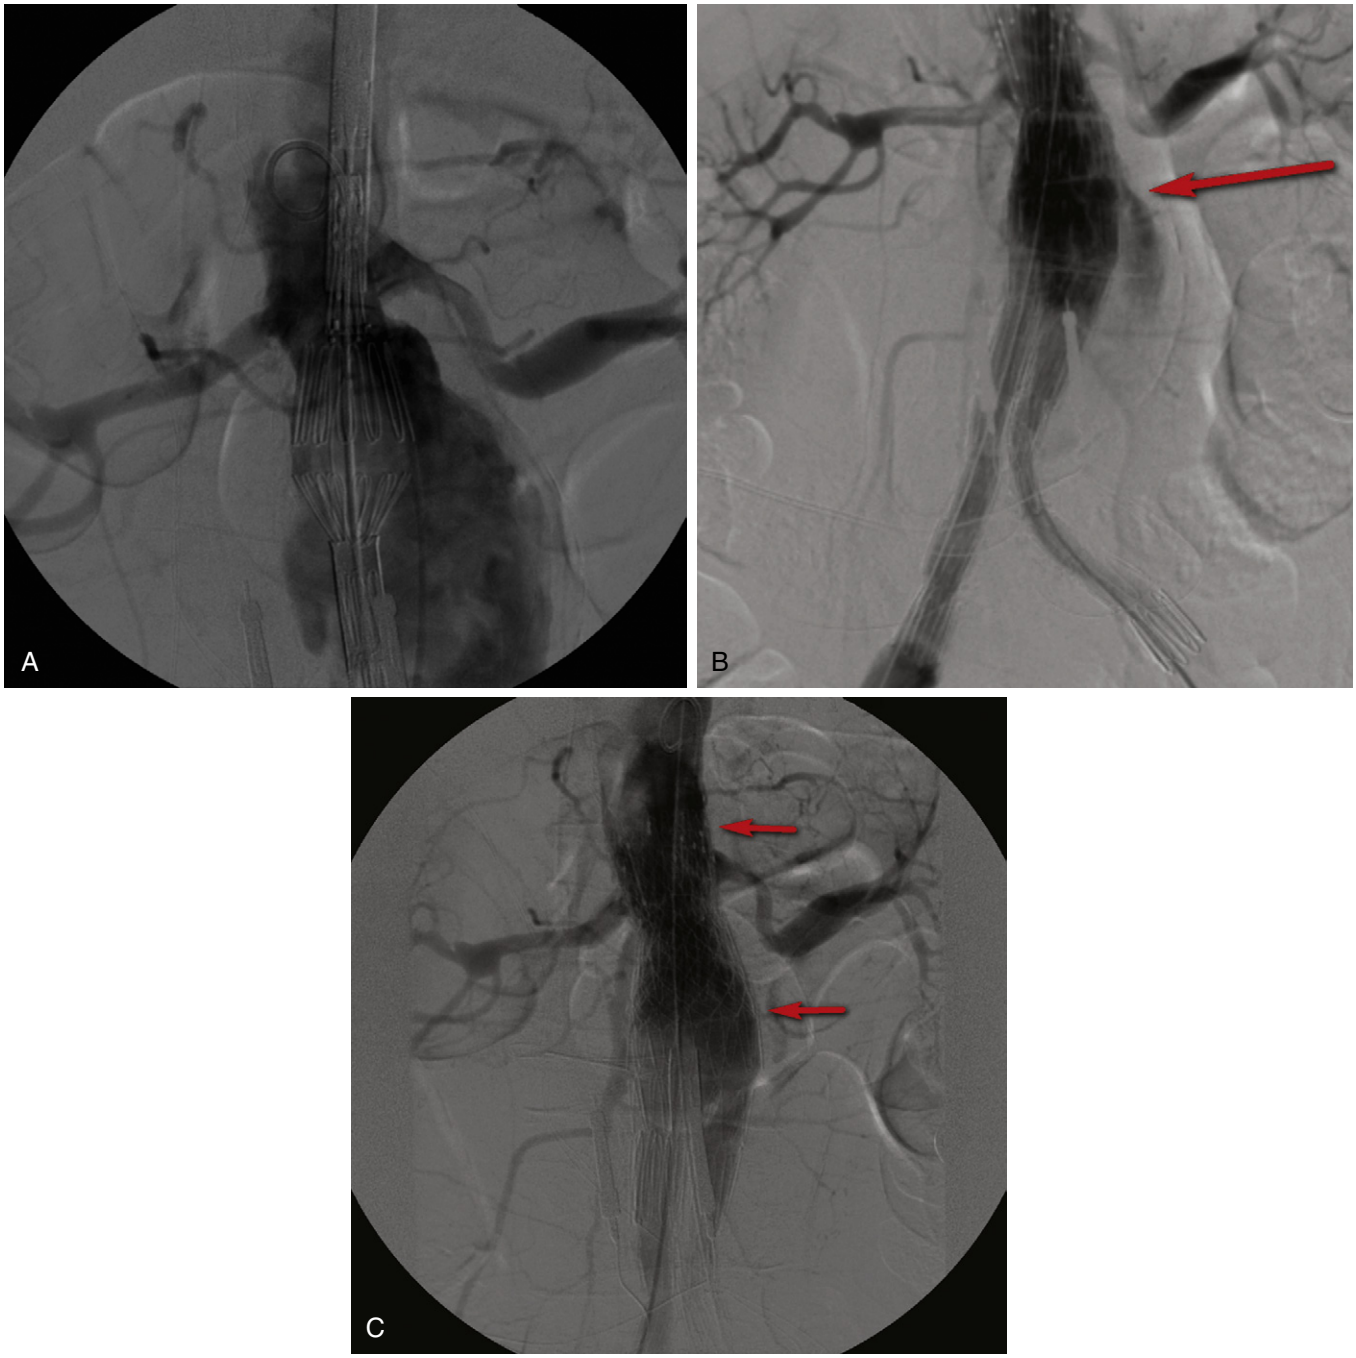

FIGURE **25-9** **A,** Short aortic neck immediately before endovascular aneurysm repair. **B,** Type IA endoleak (arrow) after initial endograft placement and molding balloon angioplasty. **C,** Resolution of the type IA endoleak after placement of a 5010 "giant" Palmaz stent (*arrows* show proximal and distal extent). (From Cronenwett JL, Johnston W. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Saunders; 2010:1306.)

Drugs being tested are immunomodulators, antiinflammatories, and antiproliferative drugs. Researchers have shown in initial clinical trials that restenosis rates are improved with the newer-generation endovascular stents.[126,127]

Endoleak, shown in Figure 25-9 and noted earlier as persistent blood flow and pressure (endotension) between the endovascular graft and the aortic aneurysm, is a serious complication of this procedure. Types of endoleaks are listed in Table 25-7. Endoleak diagnosed by postoperative CT scan has been reported to occur in 15% to 52% of patients.[128] Most are type II, and 70% spontaneously close within the first month after implantation.[129] Type II endoleaks are caused by collateral retrograde perfusion. Type I and type III endoleaks are caused by device-related problems. The most frequent interventions used to correct these complications include implantation of a second endograft or open repair.[130] Long-term results of endovascular aortic aneurysm repair have demonstrated that this procedure yields good results, but the overall durability of conventional surgical techniques is superior.[131]

Postoperative follow-up care for patients who have undergone EVAR is vital because long-term outcomes have not been quantitatively established. Physical examination and contrast-enhanced CT scan are recommended at 1, 6, 12, and 18 months

TABLE 25-7 Classification of Types of Endoleak

Classification	Description	Treatment
Type I endoleak	Attachment site leaks Perigraft channel	Proximal or distal graft extension Secondary endograft Open repair
Type II endoleak	Branch leaks (i.e., lumbar artery, renal artery, internal iliac artery, inferior mesenteric artery)	Conservative Laparoscopic clip application Embolization
Type III endoleak	Graft defect (fabric tear, modular disconnection)	Secondary endograft Open repair
Type IV endoleak	Graft wall fabric porosity/suture holes	Observation Open repair
Endotension	Systemic pressure in aneurysm sac despite no evidence of endoleaks	Secondary endograft Open repair

postoperatively and then annually.[132] Additionally, abdominal x-rays should be obtained on a regular basis. Lifelong radiographic evaluation and surveillance is necessary to monitor aneurysm size, graft migration, and endoleak. Intensive follow-up care, the need for reinterventions, and the cost of the endograft make EVAR more expensive than open repair.[133]

In the future, minimally invasive aortic aneurysm surgery will continue to be used. Improvements in surgical techniques, imaging, and graft devices will allow a greater number of patients to experience the technical and physiologic advantages of EVAR.

CEREBROVASCULAR INSUFFICIENCY AND CAROTID ENDARTERECTOMY

Carotid endarterectomy is the second most common vascular operation performed in the United States per year (the first being coronary revascularization). Cerebrovascular accidents, or strokes, are the third leading cause of death in the United States.[134,135] Most strokes are caused by cerebral ischemia as compared with intracranial hemorrhage. In carotid atherosclerotic disease, subintimal fatty plaques can increase in size over time and incrementally occlude the vascular lumen, which results in decreased cerebral blood flow. The plaque may rupture and release fibrin, calcium, cholesterol, and inflammatory cells. This phenomenon can lead to abrupt occlusion of the lumen from thrombosis due to platelet activation, or an embolus may form and decrease cerebral blood flow distal to the carotid artery. In each scenario, an abrupt decrease in cerebral blood flow (CBF) leads to transient ischemic attacks (TIAs) or strokes. Note the anatomic details of the plaque removal as seen in Figure 25-10.

More than half of all strokes are preceded by a TIA. The Framingham study reported that the risk of a stroke was 30% 2 years after a TIA and approximately 55% 12 years after a TIA had occurred.[136] It is this increased risk of stroke associated with TIA that provides the rationale for use of carotid endarterectomy (CEA), the surgical procedure in which the internal carotid artery is incised and the plaque within the carotid arterial lumen removed to improve cerebral blood flow.

Indications

Since 1954, specific indications for and expected outcomes of CEA have been the subject of heated debate. Ischemic stroke accounts for approximately 80% of first-time strokes and is primarily caused by atheromatous plaques. The initial indication for CEA was symptomatic stenosis but not complete occlusive carotid disease. This presentation occurs in most patients who undergo carotid surgery. Some centers have extended the indications to include evolved ("nondense"), nonhemorrhagic strokes and asymptomatic severe stenosis or lesser stenosis associated with contralateral occlusive disease.[134] The North American Symptomatic CEA Trial concluded that CEA for patients with recent hemispheric TIAs and high-grade stenosis (70% to 99%) had a risk reduction of 65% for the development of an ipsilateral stroke 2 years after surgery, compared with patients whose condition was medically managed.[137] The Executive Committee for Asymptomatic Carotid Atherosclerosis Study demonstrated that asymptomatic patients with carotid artery stenosis of at least 60% who underwent CEA had a 53% lower 5-year risk of ipsilateral stroke than patients who were treated medically.[138] Other widely reported large-scale studies including the Asymptomatic Carotid Atherosclerosis Study (ACAS) and the European Asymptomatic Carotid Surgery Trial (EACST) demonstrated a benefit of CEA with medical therapy (aspirin and atherosclerotic risk factor reduction) over medical therapy alone for patients with carotid stenosis in the 60% to 99% range.[139,140] These trials showed a similar absolute and relative reduction in risk for stroke of approximately 5% and 50%, respectively, at 5 years for CEA over medical therapy. Symptomatic patients are at a higher risk than asymptomatic patients for perioperative adverse events. The benefit, however, of CEA in patients with recent ipsilateral carotid territory symptoms and moderate to severe carotid stenosis is much greater than the benefit of CEA in asymptomatic patients.[141]

Morbidity and Mortality

The surgical outcomes reported for CEA vary because of differences in patient populations and varying degrees of surgical expertise. Other variables that cannot be stratified in studies but may affect patient outcomes include the state of collateral flow through the circle of Willis, the presence of concurrent atherosclerotic disease in the cerebral vasculature, the size and morphology of the

CEA, Carotid endarterectomy.

offending plaque, the specific presenting symptoms, and the presence of concurrent cardiovascular disease.[142] Carotid artery stenosis is the primary cause of approximately 20% of all strokes.[143] The recommended acceptable perioperative stroke rates should be limited to less than 3% in asymptomatic patients, less than 5% in symptomatic patients, and 10% or less in patients with recurrent disease or existing strokes.[144] Morbidity rates related to CEA have been reported to be at or below these recommended limits.[144,145] The perioperative myocardial infarction rate of 2% to 5% illustrates the global nature of atherosclerotic disease and represents the greatest contribution to overall morbidity. The perioperative mortality rate for CEA is approximately 0.5% to 2.5%,[146,147] and the long-term postoperative stroke incidence ranges from 1% to 3% per year.[134,148,149]

Patient Selection

The risks associated with having surgery and the possibility of a stroke must be measured against the risks associated with not having surgery and undergoing medical management. Those patients who have the greatest benefit from CEA are those with stenosis of greater than 70%, and it is of lesser benefit in symptomatic patients with 50% to 69% stenosis.[143] Surgical intervention was most beneficial in men who are older than 75 years of age and within 2 weeks of their last ischemic event.[150] As mentioned previously, the Framingham study identified the incidence of stroke after TIAs and demonstrated an increased risk of stroke in untreated disease. Preoperative neurologic dysfunction was found to be the most significant factor for predicting postoperative stroke incidence (4%). Several conditions that can increase the risk of perioperative complications include severe preoperative hypertension, CEA performed in preparation for coronary artery bypass, angina, internal carotid artery stenosis near the carotid siphon, age older than 75 years, and diabetes mellitis.[151,152] Box 25-12 identifies various factors that contribute to morbidity during CEA.

Diagnosis

The neurologic symptoms associated with cerebral vascular dysfunction such as TIAs and strokes are most often related to decreased CBF. Asymptomatic carotid bruits may be a sign of the possibility of carotid artery disease. Amaurosis fugax, or monocular blindness, occurs in 25% of patients with high-grade carotid artery stenosis. This syndrome is believed to be caused by microthrombi that travel into the internal carotid artery and decrease the blood supply of the optic nerve via the ophthalmic artery. Standard diagnostic imaging techniques used to assess the extent of carotid disease include duplex ultrasonography, digital subtraction angiography, computed tomographic angiography, and magnetic resonance angiography (MRA).[153]

Preoperative Assessment

The presence of concurrent CAD and carotid stenosis is well documented. Although stroke is a devastating consequence of CEA, myocardial infarction contributes more often to poor surgical outcomes than stroke. Although coronary angiography may not be justified in all patients undergoing CEA, a systematic approach for identifying CAD and its subsequent risks should be performed before elective surgery.

Patients with no significant medical history, normal physical examination, and normal electrocardiography should proceed directly to surgery; these patients have low surgical risks. When abnormal cardiac information is obtained, further evaluation should be performed. The presence of significant comorbidities will determine the extent to which further preoperative testing is appropriate. Box 25-13 lists some preoperative risk factors in patients having carotid endarterectomy.

Intraoperative Considerations

Cerebral Physiology

Cerebral blood flow (CBF) can remain relatively constant at different cerebral perfusion pressures as a result of cerebrovascular autoregulation. Cerebral perfusion pressure can be expressed as the difference between MAP and intracranial pressure. During CEA, intracranial pressure is usually not elevated; therefore, MAP plays the predominant role in determining cerebral perfusion pressure. When MAP is maintained between 60 and 160 mmHg, CBF remains constant. However, the adverse effects of chronic systemic hypertension shift the patient's cerebral autoregulatory curve to the right, and therefore a higher than normal MAP may be required to ensure adequate cerebral perfusion. Cerebral blood flow is also influenced by arterial carbon dioxide and oxygen concentrations, as well as by inhalation agents.

Normal CBF is approximately 50 mL/100 g/min. Neuronal function is generally maintained at levels greater than 25 mL/100 g/min. Levels less than this critical value jeopardize cellular function. Decreased perfusion and ischemia can be reflected in changes in consciousness. Cellular death occurs at levels less than 6 mL/100 g/min, as evidenced by flattening seen on an electroencephalogram.

Carotid occlusive disease jeopardizes the cerebral perfusion pressure in the ipsilateral artery. Ischemia leads to the disruption of autoregulation and compensatory vasodilation, and thus blood flow becomes pressure dependent. During CEA the anesthetic goals must focus on improvement and protection of CBF and diligent monitoring of brain function.

Cerebral Monitoring

In addition to standard monitoring, direct intraarterial pressure must be continuously assessed via arterial line placement. During CEA, blood pressure fluctuation commonly occurs. Owing to the high incidence of CAD and neurovascular disease in this patient population, prompt tight control of blood pressure is imperative. Pulmonary artery catheterization is not warranted in most individuals unless the presence of concurrent cardiac disease justifies its use. Carbon dioxide has a potent effect on cerebrovascular tone. Hypocapnia decreases and hypercapnia increases CBF; therefore, maintenance of normocapnia is paramount.

During repair, the carotid artery cross-clamp is applied. Various monitoring techniques have been proposed for assessing the adequacy of CBF during this maneuver. A summary of select cerebral monitoring techniques is presented in Box 25-14. Each of these monitoring modalities has limitations; the most sensitive and specific measure of adequate cerebral blood flow is responsiveness in an awake patient. Electroencephalographic monitoring constitutes the gold standard in identifying neurologic deficits related to carotid artery cross-clamping.[143,154] Electroencephalogram has demonstrated reliability in monitoring cortical electrical function.[155] Loss of β-wave activity, loss of amplitude, and emergence of slow-wave activity all are indicative of neurologic dysfunction.

Carotid stump pressure has been used as a means of assessing collateral flow.[156] After the carotid cross-clamp is placed, distal pressure in the operative internal carotid artery is measured. A carotid stump pressure of less than 40 to 50 mmHg reflects neurologic hypoperfusion and is a criterion for shunt placement. However, there is no correlation between stump pressures and electroencephalographic changes.[145] In a study by Harada et al.,[157] a carotid stump pressure of less than 50 mmHg had a positive predictive value for only 36% of patients who exhibited ischemic electrocardiogram (EEG) changes during carotid artery cross-clamping.

SSEP monitoring can be used to identify inadequate CBF during cross-clamping; however, false-positive results can occur. In addition, SSEPs are a measure of the integrity of the dorsal or sensory portion of the spinal cord. Therefore, a motor deficit can occur despite a normal SSEP waveform. Additionally, there are no values for decreased amplitude and increased latency that correlate with cerebral ischemia.

Transcranial Doppler velocity monitoring has been used as a method of detecting adverse cerebral events during CEA. McDowell et al.[158] used intraoperative transcranial Doppler monitoring during 238 carotid endarterectomies. They concluded that this method was more reliable than EEG for assessing interior integrity of the cerebral hemispheres.

The use of cerebral oximetry using near-infrared spectroscopy to determine the adequacy of cerebral perfusion has been shown to be useful.[159] The reduction of critical oxygen saturation during clamping of greater than 25% or 20% if persistent for longer than 4 minutes indicates the potential for deficits. As compared with stump pressure monitoring, cerebral oximetry more accurately predicts cerebral oxygenation.[160] Box 25-14 outlines the cerebral monitoring modalities during general anesthesia for CEA.

Cerebral Protection

The major objective during carotid artery revascularization is to maintain CBF and decrease cerebral ischemia. Prevention of cerebral ischemia can be accomplished in one of two ways: by increasing collateral flow (placement of intraluminal shunt) or by decreasing cerebral metabolic requirements (pharmacologic adjunct). Multiple interventions are available for cerebral protection including avoiding hyperglycemia, hemodilution, maintenance of normocarbia, and tight control of arterial blood pressure.

BOX 25-14

Cerebral Monitoring Modalities During General Anesthesia for CEA

- *Electroencephalogram (EEG)*: Assesses cortical electrical function

CEA, Carotid endarterectomy.

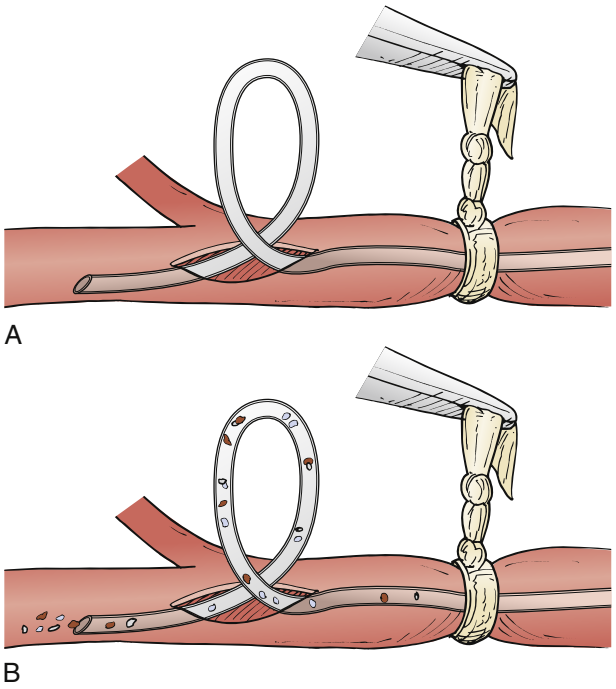

FIGURE **25-11** Pitfalls of carotid shunt placement. **A,** Potential traumatic injury to the distal internal carotid artery intima. **B,** Potential for embolization of atherosclerotic debris or air. (From Cronenwett JL, Johnston W. *Rutherford's Vascular Surgery*. 7th ed. Vol. 2. Philadelphia: Saunders; 2010:1452.)

Anesthetics, except for etomidate, have cerebral protective properties and may be used to minimize the degree of cerebral ischemia. Shunt placement is commonly used during carotid artery clamping to augment cerebral blood flow during intimal plaque dissection. The application of a shunt imposes the risk of embolic complications and intimal dissections. Potential complications of carotid shunt placement are depicted in Figure 25-11.

Cerebral ischemic events are most often the result of embolic complications. The need for shunt placement is based on information obtained using intraoperative monitoring techniques that determine CBF.

Cerebral Metabolism

Propofol decreases cerebral metabolism to 40% below normal values.[86] Dexmedetomidine also decreases cerebral oxygen consumption and cerebral blood flow in animal models.[161]

During transient focal ischemia, propofol decreases the cerebral metabolic rate of oxygen consumption, which results in cerebral protection. The disadvantages of administering propofol during CEA surgery include myocardial depression and delayed emergence. The surgeon may request that one of these cerebral depressants be administered before the carotid artery is cross-clamped. The inhalation agents also decrease cerebral metabolic rate of O_2 consumption ($CMRO_2$) in a dose-dependent fashion. Nitrous oxide should be avoided.[143,150]

Blood Pressure Control

The presence of hypertension in patients with cerebrovascular disease is well known. Therefore, one of the most challenging aspects of care associated with anesthesia for CEA is blood pressure control. Patients with cerebral insufficiency are vulnerable to perioperative blood pressure instability. Hypotension occurs in 10% to 50% of patients who undergo CEA and is believed to be the result of carotid sinus baroreceptor stimulation. Conversely, 10% to 66% of patients experience hypertension, which is attributed to surgical manipulation of the carotid sinus.[162] Preoperative blood pressure control, volume status, and depth of anesthesia also can contribute to intraoperative hemodynamic instability.

Blood pressure control must begin in the preoperative phase. All patients should continue taking their antihypertensive medications until the time of surgery. Patients with systolic blood pressure greater than 180 mmHg may be at increased risk of stroke and death.[150] Additional pharmacologic adjuncts may be required in the preoperative period, especially during the insertion of intravenous and intraarterial catheters, to reduce increases in heart rate and blood pressure. The induction of anesthesia, the initial incision, the dissection, the manipulation of the carotid sinus, and the emergence from anesthesia are all events that precipitate blood pressure fluctuations. The use of pharmacologic adjuncts, such as short-acting β-adrenergic blockers, may stabilize blood pressure during induction and emergence. Continuous intravenous use of nitroglycerin or sodium nitroprusside should be available to treat hypertension. Patients with chronic hypertension are predisposed to dramatic decreases in blood pressure after the induction of general anesthesia. This condition must be treated promptly and can be successfully managed by providing intravenous fluids or administering appropriate vasopressors. Hypotension and bradycardia, which result from carotid sinus baroreceptor manipulation, may be inhibited by stopping surgical stimulation and infiltrating with a local anesthetic.

Anesthetic Management

The anesthetic objectives for vascular surgery are similar to those for any type of elective procedure: to provide analgesia and amnesia, to facilitate surgical intervention, and to minimize operative morbidity and mortality. Goals that are specific to CEA include maintaining cerebral and myocardial perfusion and oxygenation, minimizing the stress response, and facilitating a smooth and rapid emergence. However, it may be difficult to maintain the integrity of one system without adversely affecting the other. For example, raising the arterial blood pressure to augment cerebral perfusion can increase myocardial oxygen demand, which may lead to ischemia. In addition, significantly decreasing blood pressure can lead to cerebral hypoperfusion. Therefore, the anesthetic goal is to optimize perfusion to the brain, minimize myocardial workload, ensure cardiovascular stability, and allow for rapid emergence. An understanding of the physiology of the cerebrovascular system is important for optimal anesthetic management. Figure 25-12 illustrates the anatomy of structures in this region. This knowledge enables the selection of appropriate monitoring and anesthetic techniques that will protect and improve cerebral and myocardial perfusion.

Anesthetic Selection

The long-standing question has been whether there is an advantage of regional versus general anesthesia for CEA. The General Anesthetic versus Local Anesthetic for Carotid Surgery Trial (GALA) as well as a Cochrane meta-analysis indicate no significant difference between the two anesthetic techniques.[163,164] The anesthetic selection is based on the surgeon's preference, the patient's condition, and the preoperative evaluation. Advantages of a regional technique are that an awake patient can respond to commands and allow for continuous assessment of neurologic function. Other potential benefits include high patient satisfaction, lower shunting requirements, less cost, and minimizing potential postoperative cognitive effects associated with general anesthesia.[165-167] Disadvantages include patient agitation and inability to remain still, minimal airway control, seizure or stroke during clamping, and limited ability to give cerebral neuroprotectants. Advantages of general anesthesia include the ability to perform more extensive and difficult surgical procedures, better airway control, ability to administer cerebral protectants, and improved blood pressure control.[143,150]

Regional Anesthesia. A regional anesthetic technique during CEA requires anesthesia of cervical nerves II to IV (CN II-CN IV). [143] This can be accomplished by local infiltration, superficial and deep cervical plexus block, or a combination of these techniques. Superficial cervical blocks do not anesthetize the angle of the mandible, which is innervated by the trigeminal nerve. Local infiltration may be required. As noted above, the greatest advantage of regional anesthesia is the ability to directly assess neurologic function in an awake individual. Assessing level of consciousness is the most effective method of assessing the adequacy of cerebral blood flow and detecting cerebral ischemia. In fact, assessment of consciousness in the awake patient may be more sensitive than conventional EEG in detecting cerebral ischemia. Corson et al.[168] reviewed data from 399 patients who underwent CEA in which general and regional techniques were used. The authors concluded that perioperative strokes occurred less often when a regional anesthetic was provided, especially in high-risk patients. McCarthy et al.[169] compared middle cerebral artery blood flow velocity using transcranial Doppler monitoring in patients undergoing CEA with either local or general anesthesia. It was determined that preservation of cerebral circulation was better maintained in patients who received local anesthesia. In addition, 67% of the general anesthesia group and 15% of the local anesthesia group received shunts.[170-174] However, despite these seemingly physiologic advantages, no differences occurred in outcomes between the local and general anesthesia groups. The use of regional anesthesia has been associated with shorter operative times, less frequent cardiopulmonary complications, and shorter postoperative hospitalization.

One limiting factor for use of a regional technique is patient acceptance. Because the individual is awake, preoperative education is essential, and their cooperation during surgery is vital. Anxiety, fear, and apprehension can initiate sympathetic stimulation, and as a result, extreme hemodynamic responses can occur. Deep sedation, which can be required in an apprehensive patient, may confound the neurologic assessment, negating the advantages of a regional technique. Additionally, hypercarbia can result from hypoventilation, and dysphoria is more likely to occur. Furthermore, converting to a general anesthetic technique once surgery

has begun can be problematic. If adequate cerebral perfusion is compromised, symptoms include dizziness, contralateral weakness, decreased mentation, and loss of consciousness. In the event this scenario occurs, immediate shunt placement is warranted. Emergent airway management may be necessary.

General Anesthesia. Although the use of regional anesthesia has numerous advantages, general anesthesia is also used during CEA. Perhaps the greatest benefit of this technique is that it counters the most cited disadvantage of regional anesthesia: lack of patient cooperation. General anesthesia promotes a motionless field during surgery. In addition, inhalation agents may provide hemodynamic stability and may have beneficial effects on cerebral circulation.[175] By decreasing cerebral and cardiac metabolism, the inhalation agents provide a degree of protection against ischemia, an effect called *anesthetic preconditioning*.[176-178]

Comparison of inhaled agents with narcotic-based techniques yields no scientific evidence to suggest that patient outcome is improved. In studies of inhalation agents, the critical regional CBF (the blood level below which electroencephalographic signs of ischemia occur) during isoflurane anesthesia was less than when other volatile anesthetics were used.[175,179] The effects of sufentanil on cerebral hemodynamics were similar to those of isoflurane.[180] Remifentanil can be used; its rapid metabolism improves neurologic recovery. The inhalation agents may alter the monitoring methods used for detecting cerebral ischemia, such as EEG and SSEP monitoring. In these cases, general anesthetic techniques may require modification, and direct communication is required between the anesthesia and surgical teams. The use of nitrous oxide during CEA can potentially increase the incidence of a clinically significant pneumocephalus. During shunt placement and carotid artery cross-clamp release, microbubbles can be entrained into carotid artery blood flow. When carotid artery cross-clamping without shunting occurs, MAP values should approximate or be slightly above preoperative levels to help ensure adequate cerebral perfusion through the contralateral carotid artery. Most clinicians avoid nitrous oxide. If nitrous oxide is used, it should be discontinued before removal of the carotid artery cross-clamp.[143,150,181]

In summary, there is no scientific consensus supporting the idea that one anesthetic technique is superior in terms of decreasing perioperative morbidity and mortality. An anesthetic plan that allows for a rapid assessment of neurologic function at the completion of surgery should be selected.

Postoperative Considerations

Perhaps the most common problem experienced in the postoperative period is hypertension. Although the specific cause remains unclear, postoperative hypertension is likely related to changes in sensitivity of the carotid baroreceptor reflex. A systolic blood pressure greater than 180 mmHg is associated with an increased incidence of TIA, stroke, or myocardial infarction.[151] Those patients with systolic blood pressures of 145 mmHg or less had fewer postoperative complications.[137] Postoperative hypotension

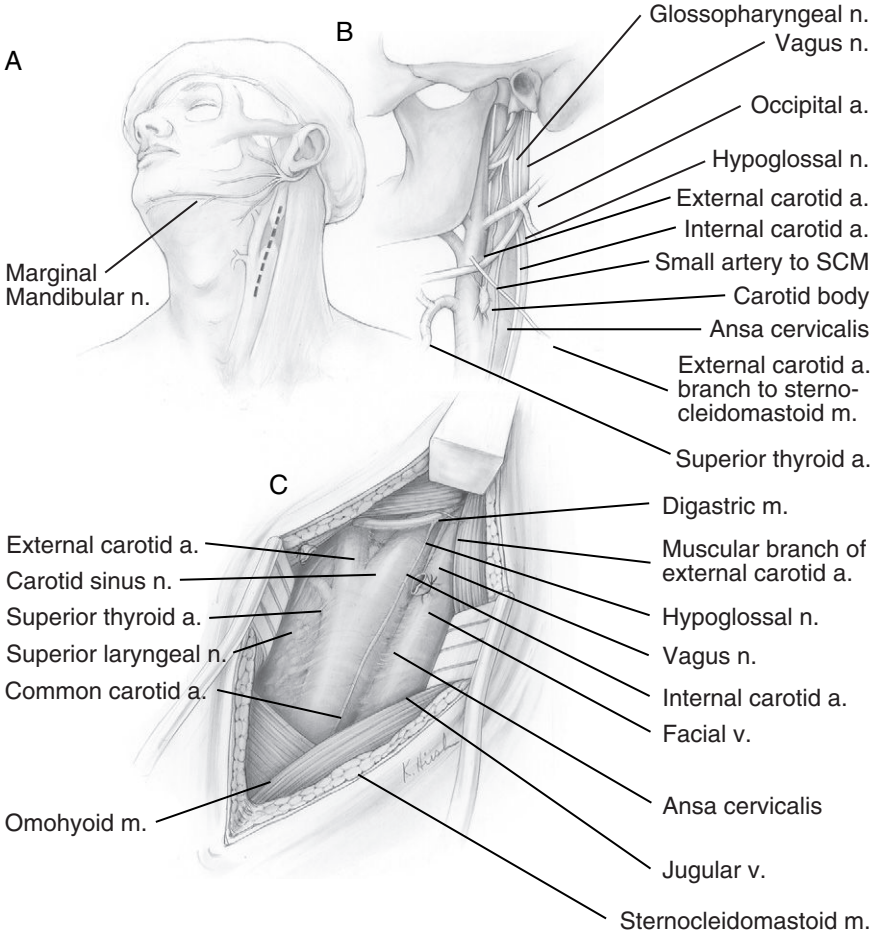

FIGURE **25-12** Carotid endarterectomy. **A,** Incision site. **B** and **C,** Anatomic structures presented at the carotid surgical site. *a.*, Artery; *n.*, nerve; v., vein. (From Zarins CK, Gewertz BL. *Atlas of Vascular Surgery*. 2nd ed. Philadelphia: Churchill Livingstone; 2009.)

is less common but can be a more difficult problem to treat because raising the blood pressure too much may unduly stress the heart. Reestablishing normal pressures can be accomplished by careful titration of fluids and vasopressors.

Although an uncommon complication, carotid artery hemorrhage can occur in the postoperative phase. Hemorrhage is a devastating event that requires immediate surgical intervention. Initial manifestations of hemorrhage may be those of upper airway obstruction, which may make reintubation difficult because of tracheal deviation. Emergency management of a patient with airway compromise as a result of carotid artery hemorrhage includes immediate evacuation of the hematoma. In addition, recurrent laryngeal nerve damage can occur and routinely manifests as inspiratory stridor. Respiratory insufficiency can be problematic for patients who have preexisting respiratory conditions. Tension pneumothorax also can occur, because the apices of the lungs extend above the clavicles toward the surgical site. Treatment includes immediate needle decompression. Damage to the carotid body can lead to a blunting of the chemoreceptor reflex, and therefore supplemental oxygen should be administered. Lastly, cerebral hyperperfusion syndrome (CHS) may result from increased blood flow to the brain as a result of loss of cerebral vascular autoregulation. The mechanism of action causing this phenomenon is unclear; however, it is hypothesized that CHS may occur as a result of chronic cerebral ischemia or altered cerebrovascular autoregulation. Signs and symptoms of CHS include severe headache, visual disturbances, altered level of consciousness, and seizures. CHS may occur more often in patients who have had a contralateral CEA within the last 3 months and undergo a second CEA for occlusion on the ipsilateral side.[182]

The incidence of postoperative stroke after CEA was discussed previously. Unfortunately, even after successful revascularization of the carotid artery, occlusion can recur at a rate of 3% per year.[147] Although symptoms are present in only a small percentage of patients (3% to 5%), the incidence of recurrent carotid stenosis may be much larger than that reported, because asymptomatic cases may be overlooked.[182] As many as 25% of patients experience a neurocognitive decline up to 1 month after surgery. Patients who are predisposed are those with diabetes and advanced age.[183] The exact mechanism responsible for the cognitive dysfunction has not been scientifically identified. Postoperative complications of CEA are listed in Box 25-15.

Owing to the anatomic location and potential neurologic complications after CEA, postemergence neurologic integrity should be assessed. In addition to neurocognitive functioning, clinical assessment of cranial nerve function should be performed (Table 25-8). The anatomic location of the cranial nerves in relation to the internal, external, and common carotid arteries are shown in Figure 25-13.

BOX 25-15

Postoperative Complications After Carotid Endarterectomy

- Hemodynamic instability
- Myocardial ischemia/infarction
- Cerebral hyperperfusion syndrome
- Stroke
- Respiratory insufficiency
- Recurrent/superior laryngeal nerve damage
- Hematoma
- Carotid body dysfunction
- Tension pneumothorax
- Acute carotid occlusion

CAROTID ARTERY ANGIOPLASTY STENTING

A less invasive surgical approach for treatment of carotid artery stenosis is carotid artery angioplasty and stenting (CAS). Controversy exists regarding the degree of success that this procedure affords as an alternative to CEA. The best application of CAS is still evolving and many studies comparing stenting with endarterectomy are ongoing. Best practices regarding proper patient selection, technique, and timing of the procedure are still being explored.[184,185] The current incidence of stroke after CEA is approximately 2%. A recent meta-analysis noted that when comparing CEA with CAS, endarterectomy decreases the risk of stroke at 30 days, increases the risk of myocardial infarction, and does not have an effect on the risk of death.[186]

The first large multicenter randomized controlled trial comparing CEA versus CAS was the Stenting and Angioplasty with Protection Patients at High Risk for Endarterectomy (SAPPHIRE) trial.[187] The rate of event-free survival at 1 year postsurgery was

TABLE 25-8 Cranial Nerve Assessment for the Patient Scheduled for CEA

Cranial Nerve	Function	Abnormal Response
VII (facial)	Muscles of facial expression, saliva secretion	Inability to smile symmetrically; contralateral asymmetry indicates possible stroke; nerve injury on ipsilateral side
IX (glossopharyngeal)	Swallowing, pharyngeal muscle	Difficulty swallowing with ipsilateral Horner syndrome (i.e., ptosis, miosis, exophthalmos, reduced sweating)
X (vagus) → superior and recurrent laryngeal nerves	Laryngeal muscles movement	Minor swallowing problems, fatigued voice; vocal cord paralysis, hoarseness, inadequate gag reflex; may test speech by having the patient say "EEE"
XI spinal accessory	Shoulder muscles	Ipsilateral weakness in neck and shoulder with shrugging
XII (hypoglossal)*	Muscles of tongue	Stick tongue out, move tongue side to side; tongue droops to ipsilateral side, difficulty with speech and chewing, high-pitched sounds, hoarseness

*This nerve traverses the internal carotid artery.
CEA, Carotid endarterectomy.

88% for the CAS group and 79.9% for the CEA group. The stroke rate after 1 year was lower in the CAS group as compared with the CEA group—6.2% versus 7.9%, respectively. As for cardiac morbidity, the rate of myocardial infarction for CAS versus CEA was 1.9% versus 6.6% 30 days postoperatively. Overall cardiac morbidity was 3% for CAS and 6.2% for CEA. The conclusion from the SAPPHIRE trial was that CAS does not yield inferior outcomes as compared with CEA. However, the study methodology was criticized and some experts questioned whether the results could be replicated.[188] A new 3-year follow-up report of the SAPPHIRE study group indicates that in patients with severe carotid artery stenosis and increased surgical risk, no significant difference could be shown in long-term outcomes between patients who underwent carotid artery stenting with an emboli-protection device and those who underwent endarterectomy.[189]

The Endarterectomy versus Angioplasty with Symptomatic Severe Carotid Stenosis (EVA3S) trial was designed to compare the outcomes from CAS versus CEA. The study population included patients with symptomatic carotid stenosis of at least 60%. The study was stopped early because of a high incidence of stroke and death—9.6% compared with 3.9% for CEA 30 days after surgery. The conclusion was that CEA was superior to CAS for this patient population when considering risk of stroke at 30 days and 6 months postoperatively.[190] Another randomized controlled trial, the Stent-Protected Angioplasty versus Carotid Endarterectomy (SPACE), yielded high but similar statistics for 30-day stroke death rates—CAS 6.8% and CEA 6.3%.[191]

The goal of the Carotid Revascularization versus Stenting Trial (CREST), a randomized controlled trial, was to determine which procedure, CAS or CEA, was more effective in preventing stroke and death. Inclusion criteria were patients who were symptomatic and had greater than 50% carotid artery stenosis and those who were asymptomatic with greater than 60% carotid artery stenosis. The preliminary results from the first stage of the trial, which included 1000 patients, are encouraging and compare favorably with CEA. Death or stroke rates from any cause during the 30 days after procedure include 3% for asymptomatic patients younger than 80 years of age and 2.7% for symptomatic patients younger than 80 years of age.[192] Initial indications were that CAS was associated with an increased incidence of stroke in octogenarians. However, it has now been determined the incidence of stroke resulting from CAS is similar to the CEA results for all age groups.[193] The health-related quality of life comparing CAS with CEA using CREST data show that CAS is superior to CEA for as long as 1 year postoperatively.[194]

Case selection guidelines for carotid artery stenting are listed in Table 25-9.

Prior to the CAS procedure, patients receive an aortic arch, carotid, and cerebral angiogram or a high-resolution MRI. This allows evaluation of the individual anatomy and angiopathology of the aortic arch, brachiocephalic artery (for right carotid artery stent), or left common carotid artery. Determination of the type of sheaths, stents, and cerebral embolic protection device can then be planned. Femoral artery access is obtained, then a sheath is threaded through the aortic arch and into the operative carotid artery. The guide wire/embolic protection device is advanced through the sheath and positioned across the stenotic region. An embolic protection device sequesters emboli during angioplasty and stenting to avoid distal occlusion in cerebral arteries (Figure 25-14). A distal embolic protection lowers the risk of intraoperative and postoperative adverse events.[195] This filter-like device is inserted distal to the area of stenosis prior to the angioplasty and stent deployment to catch microthrombi and pieces of plaque that could lodge within the brain. Angioplasty with a 5-mm balloon dilates the carotid artery, then the stent is deployed. The guide wire/device wire is removed after angiographic confirmation that carotid artery dissection or occlusion has not occurred. Figure 25-15 shows carotid artery patency after angioplasty and stent placement.

Anesthetic Considerations

The anesthetic technique used most often for patients having CAS is local anesthesia at the femoral insertion site and minimal sedation, antithrombotic therapy, and observation for hypotension and bradycardia.[196] Anticoagulation is initiated with a heparin bolus, 50 to 100 units/kg, to maintain activated clotting time (ACT) at greater than 250 seconds.[197] Balloon inflation in the internal carotid artery can stimulate the baroreceptor response, resulting in prolonged bradycardia and hypotension. Glycopyrrolate or atropine can be given prior to inflation to offset this vagal response. Fluoroscopy will be used throughout the surgery, so it is important that all operating room personnel are protected with lead shielding.

Complications associated with CAS are listed in Box 25-16. The most common complication associated with this procedure is stroke caused by thromboembolism.[198] Interventions for a patient with an acute stroke include airway and hemodynamic management. Currently, the only treatment approved for acute ischemic stroke is intravenous recombinant tissue plasminogen activator (rt-PA). Mechanical devices such as snares and balloons are being developed so that the surgeon will be able to physically remove a thromboembolic material and restore blood flow.

Patients typically remain in the postanesthesia care unit for 30 minutes after carotid stent placement and then are transferred to a monitored floor. A carotid duplex scan is performed prior to discharge, and then routinely obtained at 6 weeks, 6 months, 1 year, and then yearly. Patients remain on aspirin therapy for anticoagulation for life.[199]

BOX **25-16**

Complications Associated with Carotid Artery Stenting

- Stroke
- Myocardial ischemia/infarction
- Bradycardia
- Hypotension
- Deformation of expandable stent
- Stent thrombosis
- Horner syndrome
- Cerebral hyperperfusion syndrome
- Carotid artery dissection
- Carotid artery rupture
- Hemorrhage resulting from anticoagulation

SUMMARY

Because of the increase in the mean age of people in the United States, treatment of vascular disease is one of the fastest changing areas of medicine. Minimally invasive vascular surgical techniques are being introduced that are revolutionizing the options available for treatment. Many highly invasive surgical techniques are now being performed as interventional radiologic procedures. Anesthetic management for vascular procedures is far different from just a few years ago and requires that we adapt to ever-new treatment strategies. As practice evolves, we will be better able to assess growing evidence that suggests the superiority of these procedures in decreasing patient morbidity, mortality, and convalescence.

26 CHAPTER Respiratory Anatomy, Physiology, Pathophysiology, and Anesthetic Management

◆ *Michael Rieker*

Knowledge of the respiratory system is essential to the practice of anesthesia. Anesthetists are known as the airway experts, but they are also expected to possess an excellent command of the entire respiratory system. This is not surprising considering that they administer oxygen to the majority of patients, administer inhaled anesthetics down a cascade of concentration gradients through the lungs, provide artificial ventilation for many patients under general anesthesia, and monitor and interpret blood gas analysis, capnography, and oximetry. Indeed, the visual hallmark of an anesthetist is frequently a stethoscope earpiece pinned to the scrub top; a device that places each patient breath at the forefront of the anesthetist's consciousness.

Besides the basic functions of the respiratory system, which include extracting oxygen (O_2) from the atmosphere and delivering it to the blood while excreting carbon dioxide (CO_2), the respiratory system functions in the processes of maintaining acid-base balance, phonation, pulmonary defense, and metabolism (synthesis and breakdown of bioactive materials). These functions are all discussed in this chapter.

ANATOMY OF THE RESPIRATORY SYSTEM

Knowledge of airway anatomy is not only necessary for understanding respiratory physiology but also essential for the practice of anesthesia nursing. The airway consists of the nose, mouth, pharynx, larynx, trachea, and lower airways.

The components of the respiratory system are the conducting airways, the lungs and their blood supply, the portions of the central nervous system responsible for control of the muscles of ventilation, the chest wall, and the thoracic muscles responsible for ventilation.

Nose

Inhaled air enters the body through the nose or mouth. Air passing through the nose is filtered, heated to body temperature, and humidified. The external nose is only a small part of the nasal air passageway, the major portion of which lies directly behind the nose and includes three scroll-shaped turbinate bones, also called the *nasal conchae*.

The cartilage around the entrance to the nostrils that can flare during heavy breathing is called the *alar cartilage* or *ala nasae* ("nasal wings"). Each nostril opening (anterior naris) leads directly into the vestibule, which is the forwardly expanded portion of the nasal cavity. The vestibule is lined with cutaneous epithelium. In its lower half, it has sebaceous glands and coarse hairs, which serve to filter incoming air. The floor of the nose is at a level higher than the opening of the nostril; therefore, during nasal intubation, the apex of the nose should be elevated superiorly with gentle pressure while the tube is inserted parallel to the roof of the mouth. The tube should not be directed upward into the turbinates but rather along the floor of the nose formed by the superior aspect of the palatine bone, which forms the hard palate of the mouth directly below the nose. Prolonged nasotracheal intubation is associated with obstruction of the nasal sinuses, sinus infection, and fever. Intranasal infections can produce intracranial infection via vascular connections, as discussed later in this section.

The anterior portion of the external nose, the vestibule, expands above and behind into triangular spaces, or fossae. The fossae are separated from each other by the nasal septum, which also separates the two nostrils. The septum is formed by the ethmoid and vomer bones superiorly and the vomeronasal and nasal septal cartilages inferiorly. The nasal fossae usually communicate freely with the paranasal air sinuses (frontal, ethmoid, maxillary, and sphenoid). They open into the nasopharynx by the posterior nares (also known as *choanae*) and are bordered medially by the nasal septum and laterally by three turbinates arranged one above the other.

Choanal atresia is a birth defect characterized by obstruction of the posterior nasal airway. This obstruction may be life threatening in the obligate nose-breathing newborn.

The conchae are scroll-shaped prominences projecting from the lateral walls and have their free margins directed downward and inward. The conchae overlie the superior, middle, and inferior meatus, which contain the openings to the paranasal sinuses. The superior concha is by far the smallest of the three, and the middle concha extends forward much farther than the superior concha. The inferior concha, which lies along the lower part of the lateral wall of the nasal cavity, is in the pathway of airflow in the nose, and it is the one most commonly injured during nasal intubation. It extends to within approximately 2 cm of the middle of the anterior naris, and its posterior tip lies approximately 1 cm in front of the pharyngeal orifice of the eustachian tube. Eustachian drainage can become obstructed when the inferior concha or adenoid tonsils become inflamed. Such obstruction can lead to middle ear pathology.

The nasal cavities are lined with mucous membranes that are continuous with those of the pharynx. The mucosa can be divided into respiratory and olfactory areas because it not only lines the tracts followed by respired air but also covers the cells that act as the receptors for smell. The olfactory epithelium occupies the apical third of the nasal cavity. This epithelium contains afferent fibers from the olfactory nerves (cranial nerve I) that communicate through the cribriform plate of the ethmoid bone to the adjacent olfactory bulb. Signals then progress to the other parts of the rhinencephalon. The respiratory mucosa lines the lower two thirds of the nose and consists of pseudostratified ciliated columnar epithelium interspersed with goblet cells that produce mucus. Although the morphology of cells changes progressively toward the terminal bronchioles, this general arrangement of stratified ciliated epithelium with goblet cells persists throughout the majority of the air passages of the respiratory system. The direction of motion of the cilia is toward the exterior of the nasal cavity.

The principal arterial supply of the nasal fossae comes from the ophthalmic arteries through the anterior and posterior ethmoid

branches and from the internal maxillary artery through the sphenopalatine arteries. Because of the location of the interior maxillary artery, it is sometimes ligated for the treatment of persistent nosebleed. The veins accompany the arteries; the ethmoid veins open into the superior sagittal sinus, and the nasal veins drain into the ophthalmic veins and then into the cavernous sinuses. Infections in the nose can result in meningitis because of this venous communication between the intracranial and intranasal circulation. The sensory nerves from the upper respiratory tract come from the ophthalmic nerve and the maxillary nerve (both are branches of cranial nerve V). Lymphatic drainage from the cavities of the nose is via the deep cervical lymph nodes adjacent to the internal jugular vein.

Through the functioning of the nasal hairs, the mucus-producing epithelium, and the rich arterial supply, the nose carries out important functions that include filtration, humidification, and heating of inspired air. As long as the incoming air is not extremely cold, the nose can warm the inspired air to nearly body temperature and moisten it to nearly 100% relative humidity. The heating and humidifying functions of the nose are affected by general anesthesia. The inspiration of cold, dry gas often dries the nasal and pharyngeal passageways, causing sore throat even if no instrumentation of the airway takes place.

The hairs at the entrance to the nostrils are of minor importance to filtration because they remove only large particles. Much more important is the removal of particles by turbulent precipitation. Air passing through the nasal passageways hits many obstructions including the septum, the turbinates, and the pharyngeal wall. When the inspired air is forced to change direction, the inhaled particles cannot change course as rapidly, and they become embedded in the mucus-covered surfaces of these processes. The particles trapped in the mucus are moved by the cilia either to the naris or posteriorly to the pharynx to be expectorated or swallowed. This occurrence is important because it denies entry of infectious, carcinogenic, or irritating substances. Nasal filtration is extremely effective for particles above 10 μm and less than 1 nm, but filtration efficiency is inverse to particle size for particles that are between 10 nm and 1 μm.[1]

Pharynx

The pharynx is a wide muscular tube that is a part of both the respiratory tract and the alimentary canal. Its upper border is the base of the skull, and it extends to the level of the C6 vertebra, where it becomes continuous with the esophagus. At this level, ingested foreign bodies, such as coins, are frequently lodged. The pharynx is lined by a musculomembranous coat and divided into three parts: the nasopharynx, which extends from the posterior nares (choanae) to the end of the soft palate; the oropharynx, which is bounded superiorly by the soft palate and anteriorly by the tonsillar pillars and oral cavity and extends inferiorly to the tip of the epiglottis; and the hypopharynx (laryngopharynx), which extends from the tip of the epiglottis to the level of C6, or the beginning of the esophagus.

The pharyngeal region includes the tonsils, which are composed of three aggregations of lymphoid tissue: the palatine tonsils (major tonsils), which lie in the tonsillar fossae at the boundary of the oral cavity and oropharynx; the lingual tonsils, which extend across the tongue from the base of each palatine tonsil; and the pharyngeal tonsils (adenoids), which lie on the lateral walls of the nasopharynx. The lymphoid tissue of the tonsils forms the Waldeyer tonsillar ring, which acts as a first line of defense against bacterial invasion of the nasal and buccal passages. If inflamed, the pharyngeal tonsils may obstruct airflow through the choanae and are sometimes removed by an adenoidectomy. Likewise, chronic tonsillitis may lead to removal of the palatine tonsils by tonsillectomy.

TABLE 26-1 The Nine Cartilages of the Larynx

3	Cricoid	8 and 9	Cuneiforms

Larynx

The adult larynx extends from vertebrae C3 to C6 and is a protective structure that prevents aspiration during swallowing; vocalization evolved secondarily. The larynx consists of one bone, nine cartilages (Table 26-1), ligaments, muscles, and membranes.

The hyoid bone is the chief support for the larynx and is the only bone that does not form a joint with another bone. Its anterior aspect can be easily palpated, and its location is sometimes used as a measure of airway assessment for laryngoscopy. The thyroid cartilage and the cricoid cartilage make up the principal part of the framework of the larynx, whereas the epiglottis guards its entrance.

Laryngeal Cartilages

The epiglottic cartilage lies closest to the root of the tongue and is vertical to the opening of the larynx. It is attached to the body of the thyroid cartilage by the thyroepiglottic ligament just above the vocal cords and to the base of the tongue by the glossoepiglottic folds. The furrow between the glossoepiglottic fold and the base of the tongue is called the *vallecula epiglottica* and serves as the situation point for the tip of a curved laryngoscope blade. The epiglottis serves to protect the larynx from foreign body entry. During swallowing or laryngospasm, elevation of the larynx closes the epiglottis, effectively "sealing off" the trachea.

The thyroid cartilage is the largest cartilage of the larynx, formed by two quadrangular plates or laminae fused near the midline anteriorly. Its strength affords a great deal of protection to the larynx. The thyroid cartilage forms the Adam's apple. Being larger and covered with less subcutaneous fat, the thyroid cartilage is more prominent in adult males.

The cricoid cartilage is palpable just below the thyroid gland, and its level corresponds to the beginning of the trachea and the esophagus. It is the only true ring of cartilage encircling the airway. Anteriorly, the cricoid cartilage lies below the thyroid cartilage, with the cricothyroid membrane intervening. The cricoid is the most inferior of the nine laryngeal cartilages. The arytenoid cartilages articulate on the superior posterior aspect of the cricoid cartilage, which is slanted forward. The paired arytenoid cartilages are attached to the posterior ends of the vocal cords. The paired corniculate (median) and cuneiform (more lateral) cartilages are embedded in the aryepiglottic folds and give support to these structures. These cartilages cause the two bumps seen in the aryepiglottic folds, which are often (but incorrectly) called the "arytenoids" when visualized during laryngoscopy.

In adults, the narrowest portion of the larynx is the cricoid opening between the vocal cords; in children younger than 10 years, the narrowest part is just below the vocal cords at the cricoid cartilage. This anatomic difference is of clinical significance: a tube with adequate clearance through the vocal cords may create

BOX **26-1**

Intrinsic Muscles of the Larynx

Laryngeal Inlet
- Closed by the aryepiglottic and oblique arytenoid muscles
- Opened by the thyroepiglottic muscle

Glottic Opening

- Closed by the transverse arytenoid and the lateral cricoarytenoid muscles

True Vocal Cords
- Lengthened by the cricothyroid muscles
- Shortened by thyroarytenoid muscles

mucosal pressure at the level of the cricoid ring. For this reason, traditionally, uncuffed endotracheal tubes have been used in children less than 8 to 10 years of age. Although an uncuffed tube may offer advantages in terms of positioning,[2] it is becoming more commonplace to use an adjusted-size cuffed tube in pediatric patients for the added assurance of tidal volume delivery and to reduce the necessity to change the tube because of incorrect sizing.[3]

Membranes of the Larynx

The thyrohyoid membrane suspends the larynx from the hyoid bone. The cricothyroid membrane lies between the cricoid and the thyroid cartilages. The easiest and most rapid laryngotomy can be performed through this membrane. Cricothyrotomy is recommended for the emergency establishment of an airway when both endotracheal intubation and mask ventilation are unsuccessful. The *transtracheal block* to deposit local anesthetic inferior to the vocal cords is also performed through the cricothyroid membrane.

Interior of Larynx

The cavity of the larynx is divided into three compartments by the false vocal cords and the true vocal cords. The supraglottic area, also called the *vestibule*, extends from above the false cords to the tip of the epiglottis. On each side of the vestibule is located a pharyngeal sinus (the pyriform sinus). This recess is a potential location for lodging of foreign bodies that enter the pharynx or for noncentered endotracheal tubes. The second compartment of the larynx is the area between the false cords and the true cords known as the *laryngeal ventricles*. The third area is the infraglottic region below the true cords and above the beginning of the trachea. The rima glottidis (cricoid opening) is the space between the true cords.

Movements of the Vocal Cords

The true vocal cords are fibromembranous folds attached anteriorly to the thyroid cartilage and posteriorly to the arytenoids. The focal points of movement are the arytenoid cartilages, which rotate and slide up and down on the sloping cricoid cartilage. The muscles controlling laryngeal movement (Box 26-1) are most conveniently thought of as pairs having opposing actions. The laryngeal inlet is closed by the aryepiglottic muscle and opened by the thyroepiglottic muscle. The cricoid opening is dilated by the posterior cricoarytenoid muscles and closed by the interarytenoid muscles assisted by the lateral cricoarytenoid muscles. The cricothyroid muscles lengthen the true vocal cords, and the thyroarytenoid muscles shorten them. Both sets of muscles can alter the tension on the vocal cords and are important for determining the pitch of the voice.[4]

Nerve Supply to the Larynx

Both the superior and inferior laryngeal nerves are branches of cranial nerve X, the vagus nerve. The superior laryngeal nerve arises from the ganglion nodosum of the vagus and divides into two branches, the internal and external. The external segment gives a branch to the inferior constrictor muscle of the pharynx and also to the cricothyroid muscles. These muscles change the position of the cricoid and thyroid cartilages and in doing so lengthen or increase the tension of the vocal cords. If these muscles are paralyzed, the voice becomes weak, rough, and easily fatigued. Voice hoarseness, particularly of recent onset, should be investigated in the preoperative evaluation as a potential indicator of vocal cord palsy or airway obstruction. The internal branch of the superior laryngeal nerve enters the larynx and then the thyrohyoid membrane and is distributed to the mucous membranes of the larynx and epiglottis. It provides sensation from the inferior side of the epiglottis down to the true cords (the superior side of the epiglottis is innervated by the glossopharyngeal nerve). The internal branch also innervates the interarytenoid muscles, which are important in phonation.

The inferior (or recurrent) laryngeal nerves arise from the two vagus nerves at different levels. The left nerve descends with the vagus and then loops around the arch of the aorta to come back up to the neck. The right nerve travels with the vagus nerve as far as the subclavian artery; it loops around this artery and then comes back up the neck. The recurrent laryngeal nerve supplies sensation to the larynx below the level of the vocal cords and innervates all the muscles of the larynx except the cricothyroid and part of the interarytenoid muscles. Damage to the recurrent laryngeal nerve(s) during surgery on the neck or from airway devices or anesthetic blocks can lead to unilateral or bilateral vocal cord paralysis with hoarseness or dyspnea, respectively.[5,6] Blood supply to the larynx is provided by the superior thyroid artery (a branch of the external carotid artery) and the inferior thyroid artery (a branch of the thyrocervical trunk, which arises from the subclavian artery).

Trachea

The trachea is lined by pseudostratified ciliated columnar epithelium, and it extends from the inferior larynx to the carina, where it bifurcates into the two mainstem bronchi. In adults of normal size, the distances are fairly constant: the distance from the incisors to the larynx is approximately 13 cm, as is that from the larynx to the carina. Therefore, the distance from the incisors to the carina is approximately 26 cm (note the length markings on endotracheal tubes). The blood supply to the trachea is through the inferior thyroid artery, which comes from the thyrocervical branch of the subclavian artery. Some perfusion is also received from the superior thyroid, bronchial, and internal thoracic arteries. Blood is drained by the inferior thyroid veins. Sensory innervation of the trachea is via the vagus nerve for both parasympathetic and nociceptive stimuli.

The trachea has a diameter of approximately 2.5 cm and is supported by incomplete rings of cartilage that open posteriorly and prevent tracheal collapse under the negative pressure generated during spontaneous respiration. The trachea extends down to the level of T4-T5, where the carina is located. This level corresponds anteriorly to the angle of Louis on the sternum, which is the articulation of the second rib. The trachea is not a rigid structure; it expands and contracts to accommodate head and neck movement. In an intubated patient, flexion of the neck elevates the carina. As a result, the endotracheal tube moves downward and endobronchial intubation may result. During extension of the head and

neck, the trachea moves downward, the endotracheal tube moves upward, and extubation can occur. In pediatric patients, the range of this movement was demonstrated to increase with patient age and height.[7] The apparent movement of the endotracheal tube in relation to head flexion may seem paradoxical; the mnemonic "the hose follows the nose" can be used as a memory aid. Neck rotation to the left or right tends to cause tracheal elevation and risk of endobronchial intubation.

Bronchi

At the carina, the trachea divides into the right and left bronchi (Figure 26-1). The cellular structure begins to change at this point from columnar to cuboidal epithelium, and the cartilaginous rings thin into plates once the bronchi penetrate the lungs. From the carina, the bronchi branch off at slightly different angles. The right bronchus takes a less acute angle from the trachea, about 25 degrees, whereas the left bronchus takes off at 45 degrees. Also, the right mainstem bronchus is wider and shorter (2 cm) than the left one (4 cm).[8] Because the right bronchus is more nearly vertical than the left, the tendency is much greater for endotracheal tubes, suction catheters, or aspirated foreign materials to enter the right side after passing the carina. Additionally, the beveled tip of an endotracheal tube makes right-sided intubation more likely. The side hole (Murphy's eye) near the end of the endotracheal tube allows the delivery of gas if the beveled tip of the tube is closely opposed to the similarly angled right main bronchus.

Each mainstem bronchus divides into lobar bronchi (three on the right; two on the left), that lead to the major lung lobes. The right mainstem bronchus ends only 2 to 2.5 cm from the carina before giving rise to the right upper lobe (RUL) bronchus. After the RUL takeoff, the main bronchus then continues for 3 cm as the *bronchus intermedius* before giving rise to the right middle lobe bronchus and the right lower lobe bronchus. The left main bronchus is 4 to 5 cm long and terminates by bifurcating into the left upper lobe bronchus and the left lower lobe bronchus. The left upper lobe bronchus further branches into a superior division and an inferior division (the lingular branch).

Each successive division of the airways is referred to as a *generation*, with the mainstem bronchi representing the first generation, the lobar bronchi representing the second, and so on. The lobar bronchi divide into the third generation of airways, called *segmental bronchi*, which deliver ventilation to the various bronchopulmonary segments of the lung. There are 10 bronchopulmonary segments in each lung, but on the left, the apical and posterior segments and the anterior basal and medial basal segment pairs each arise from a single bronchial branch (Box 26-2). Therefore, only eight third-generation bronchi are found on the left. Segments whose names contain the word *basal* are located adjacent to the diaphragm. The bronchopulmonary segments create distinct anatomic and functional units. The segments are separated by connective tissue, so gas-exchange properties or pathology tend to be isolated to a segment. A bronchopulmonary segment also can be excised as a unit.

Each subsegmental bronchus divides several times, giving rise to many bronchioles. With succeeding generations and multiplication of the number of airways, the total cross-sectional area becomes very large, and the airflow velocity decreases. There are 20 to 25 total generations before the alveoli. By the seventh generation, the diameter of bronchioles is about 2 mm, beyond which they are referred to as *small airways*. When the diameter has decreased to 1 mm they are referred to as *terminal bronchioles*. The terminal bronchioles are the last structures perfused by the bronchial circulation and are the end of the conducting airways (anatomic dead space, as discussed later). In the latter generations, the cross-sectional area of the airway has expanded so much that the velocity of airflow becomes very slow, and gas moves largely by diffusion rather than by bulk flow.

With succeeding generations, the histology of the airways changes, in a progression characterized by thinning of the walls, to transition to the gas-exchanging morphology of the *respiratory*

BOX 26-3

Characteristics of Progressive Airway Divisions

zone (Box 26-3). The terminal bronchioles divide into the respiratory bronchioles that are perfused by the pulmonary circulation and are the first place in the airway at which exchange of gas with the blood occurs. These airways are characterized by occasional outpouching of alveoli, or air sacs. The respiratory bronchioles divide into several alveolar ducts that lead to circular spaces called *atria*. Each atrium opens into two to five alveolar sacs, which are spaces lined by alveoli. The terminal airways are very small, and their walls are no longer tented open by cartilage but rather by connection with the adjacent matrix of pulmonary parenchyma in which they are situated. For this reason, they are prone to closure from compression of the pulmonary tissue during respiration or if emphysema, for example, expands the volume of adjacent air spaces and compresses the airways. The lung volume at which small airways tend to close is called the *closing volume*. In those with obesity and chronic obstructive pulmonary diseae (COPD), the closing volume increases into the range of normal tidal breathing such that some airways close before the intended tidal volume has been expired. Small pores in the alveoli, known as the *pores of Kohn*, serve to allow collateral gas flow between alveoli and provide a mechanism of relief from gas stagnation from airway closure.[9]

Respiratory Zone

The respiratory bronchioles and alveolar ducts, sacs, and alveoli comprise the *respiratory zone*, the area where gas exchange takes place. All parts of the airway prior to this (nose to terminal bronchioles) conduct gas without exchanging gas with the blood and are referred to as the *conducting zone*. Some refer to the respiratory bronchioles and alveolar ducts where limited gas exchange takes place as the *transitional zone* because structures here function both to conduct gas and also to participate in some gas exchange. The alveoli are the air sacs that are tightly packed and closely approximated with pulmonary capillaries. The typical maximum number of approximately 300 million alveoli is reached by age 9 years. The alveoli are characterized by very thin walls composed of squamous epithelium. There are three types of cells that form the alveoli: type I pneumocytes, which are the structural cells; type II pneumocytes, which produce surfactant to reduce alveolar collapse from surface tension; and type III pneumocytes, which are macrophages. The average alveolar diameter is approximately 250 µm; therefore the total surface area available for gas exchange is 60 to 80 m^2.[10]

Pulmonary Hila and Coverings

The nerve supply to the bronchi and lungs arises chiefly from the sympathetic nerves and the vagus nerve (which supplies sensory and parasympathetic innervation). All conduits to the lung pass through the hilum, which is the connection of the mediastinum to the pedicle of each lung. The structures included in each hilum include the mainstem bronchus, pulmonary artery and vein, bronchial arteries and veins (which drain into the azygos system), lymphatics, lymph nodes, pulmonary nerve plexuses, and pulmonary ligament. All of this is surrounded by connective tissue. The serous membrane covering the lung is called the *pleura*. The parietal pleura lines the chest wall, mediastinum, and diaphragm, and at the hilum is then reflected back to cover the lungs as the visceral pleura. Between these two layers is a potential space called the *pleural cavity*. The touching surfaces of the two layers of pleura are kept slippery by a small amount of serous fluid. Certain conditions can result in occupation of the pleural space by liquids or gas (Table 26-2) and may affect ventilation and lung expansion. Infected intrapleural blood can clot and organize to form a fibrothorax, which must be peeled from the surface of the lung (in a procedure called *lung decortication*) so the lung can reexpand.

TABLE 26-2 Conditions That Affect the Pleural Space

Material in Pleural Space	Medical Name
Air	Pneumothorax
Air under pressure	Tension pneumothorax
Blood	Hemothorax
Serous fluid	Pleural effusion
Pus	Empyema or pyothorax
Organized blood clot	Fibrothorax
Lymph	Chylothorax

TABLE 26-3 Divisions of the Mediastinum

Subdivision	Location	Contents
Superior	Above level of the sternal angle, extending superior to the thoracic inlet	Thymus, esophagus, trachea, great vessels
Anterior	Between sternum and pericardium	Thymus
Posterior	Between vertebral column and posterior pericardium	Esophagus, thoracic aorta, thoracic duct
Middle	Between anterior and posterior divisions, bounded laterally by the parietal pleura	Heart, distal trachea, mainstem bronchi, and great vessel trunks

Mediastinum

The mediastinum is the region between the two pleural sacs. It lies roughly in the center of the thoracic cavity but is slightly displaced to the left by the presence of the heart. Therefore the left lung represents 45% of the total lung capacity (TLC), whereas the right lung represents 55%. Perforation of the larynx, trachea, pharynx, or esophagus, which sometimes occurs during esophagoscopy, bronchoscopy, or traumatic intubation, can produce mediastinitis, a life-threatening infection of an area containing the trachea, esophagus, and major blood vessels and heart. The mediastinum is divided into four divisions separated by the pericardium (Table 26-3). Common procedures involving the mediastinum include coronary artery bypass, cardiac valve replacement, aortic aneurysm repair, thymectomy for myasthenia gravis, resection of tumors, and mediastinoscopy for diagnosis and staging of cancer.

Pleura

The pleura is a serous membrane that lines the thoracic wall and lungs. The parietal pleura is attached to the chest wall, diaphragm, and mediastinum but is then reflected back to cover the lungs and afterward referred to as the *visceral pleura*. These two layers are closely opposed, with only a capillary-thin layer of pleural fluid between them in a potential space known as the *pleural space*. The parietal pleura is very sensitive to pain, and conditions that cause accumulation of pleural fluid or friction between the layers can be very uncomfortable. Different areas of the pleura may produce characteristic pain patterns: the costal pleura creates localized pain, the diaphragmatic pleura creates diffuse pain, and areas supplied by the phrenic nerve may radiate pain to the neck or back. Posterior to the mediastinum, the pleura doubles up and descends downward as the "pulmonary ligament."

If communication is created across the pleura, accumulation of air in the pleural space is referred to as *pneumothorax*. In a closed chest (e.g., a pulmonary bleb ruptures, creating a communication to the pleural space) a tension pneumothorax develops as inspired air accumulates in the pleural space and is not expelled. With an opening through both pleura (such as with open chest trauma) the external wound may create a simple pneumothorax, which does not tend to cause high intrathoracic pressures. In either type of pneumothorax, the elastic recoil of the lung tends to favor lung collapse once the negative pressure of the pleural space is disrupted by the breach.

MECHANICS OF BREATHING

Contraction of the muscles of inspiration lowers intrathoracic pressure and causes the volume of the thoracic cavity to increase. Boyle's law explains that the increase in volume creates a reduction in pressure, which causes air to enter from the atmosphere. Spontaneous respiration therefore involves passive movement of gas, as opposed to positive-pressure ventilation, which requires generation of positive pressure in the upper airway to overcome intrathoracic pressure and expand the lungs.

The diaphragm and external intercostal muscles contract during normal breathing (eupnea). While the diaphragm increases the superior-inferior dimension of the chest, the external intercostals increase the anterior-posterior diameter by elevating the ribs and sternum. Each half of the diaphragm is innervated by a branch of the phrenic nerve, which arises from the third, fourth, and fifth cervical spinal nerve roots. This anatomy gives rise to the mnemonic "C-3, 4, and 5 keep the diaphragm alive." The diaphragm is almost solely responsible for quiet respiration, and loss of the function of intercostal muscles (by a thoracic spinal cord injury or high spinal or epidural block) usually does not impair respiration. However, if coupled with paralysis of the phrenic nerve and resulting paralysis of a hemidiaphragm (such as may occur with interscalene blocks), dyspnea may result. Spinal cord injuries above the level of C-5 usually lead to dependence on mechanical ventilation.

Normally, eupneic expiration results from passive recoil of the chest wall and does not require muscular contraction, although the internal intercostal muscles may be used to augment exhalation. During forced exhalation (e.g., with coughing and the clearing of secretions), the abdominal muscles, particularly the rectus abdominis, the transversus abdominis, and the external and internal oblique muscles, are used. For forced inhalation, the intercostal muscles play a more prominent role, and accessory breathing muscles in the neck are also used. The diaphragm descends approximately 1 to 2 cm during eupneic breathing, but this excursion can increase to as much as 10 cm during forceful breathing. For air to move into the alveoli, alveolar pressure must be less than atmospheric pressure. This can be achieved either through an increase in atmospheric pressure (as in positive-pressure ventilation) or a reduction in alveolar pressure, as during spontaneous ventilation (negative-pressure breathing). During forceful inspiration, the sternocleidomastoid and scalene muscles contract in conjunction with the diaphragm and intercostals.

The muscles of ventilation are attached to the cartilaginous and bony components (ribs, sternum, and vertebrae) of the chest. Conditions that impede chest excursion, such as thoracic kyphosis, may require reduction to further increase the chest diameter. The two domes of the diaphragm separate the thoracic and abdominal cavities and function separately, such that injury to a phrenic nerve results in paralysis in the diaphragm only on that side. The central tendon on the underside of the diaphragm provides a site of rigidity, allowing the diaphragm to tense and flatten without pulling against an external insertion point, as do other muscles. The central tendon includes an orifice for passage of the inferior vena cava. There are two other prominent openings through the diaphragm; the esophagus passes through the esophageal hiatus, and the aorta, azygous vein, and thoracic duct pass through the aortic hiatus. When the diaphragm contracts during spontaneous inspiration, it flattens and moves the abdominal contents downward, raising intraabdominal pressure while lowering intrathoracic pressure. Pressure within the alveoli becomes slightly negative with respect to atmospheric pressure, and gas flows inward through the conducting airways to expand the lungs. When the diaphragm is paralyzed, it cannot contract; therefore, it moves upward from its normal position, owing to the effects of intraabdominal pressure and negative intrapleural pressure. When the normal diaphragm contracts (moving downward), the paralyzed diaphragm moves upward, and when the normal diaphragm relaxes (moving upward), the paralyzed diaphragm moves downward, resulting in paradoxical movements.

Lung Compliance

Lung compliance is defined as the change in volume divided by the change in pressure (V/P). For a given change in pressure, a more compliant lung has a greater change in volume than a less compliant one. Figure 26-2 shows pressure-volume relationships for a lung. As with many concepts in respiratory physiology, the reader must make the jump from considering the application to a single alveolus (which aids in understanding) to conceptualizing the overall average state in the pulmonary system, which involves many regions existing along a continuum of conditions. In considering lung compliance, the curve in Figure 26-2 represents the collective contribution of alveoli that are almost collapsed at the beginning of inspiration, alveoli that are distended, and alveoli that exist at various intermediate volumes.

Static effective compliance describes the pressure-volume relationship for a lung when air is not moving; that is, reflecting compliance of the lung and chest wall alone. Static compliance is decreased by conditions that make the lung difficult to inflate, such as fibrosis, obesity, vascular engorgement, edema, acute respiratory distress syndrome (ARDS), and external compression (e.g., that caused by tight dressings or a surgeon leaning on the patient's chest). Static compliance is increased by emphysema, which destroys the elastic tissue of the lung. This makes the emphysematous lung easier to inflate. The problem with emphysema is not inflation but rather deflation, because the loss of elastic tissue results in small airway collapse as the lung deflates, which causes

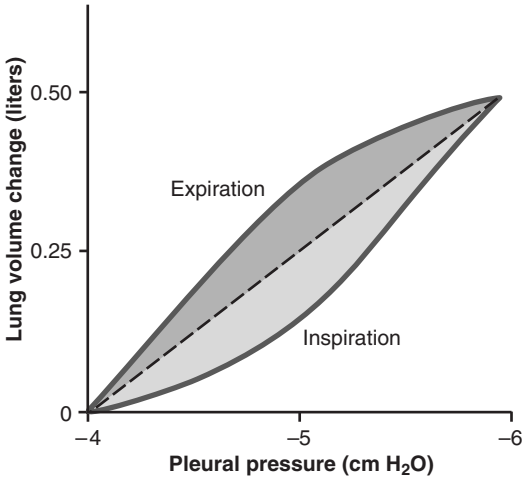

FIGURE **26-2** Compliance curve of the lungs. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology.* 12th ed. Philadelphia: Saunders; 2011:467.)

gas trapping. It is important to note that compliance changes as lung volume changes. In other words, compliance is volume dependent. Figure 26-2 shows that the lung is less compliant both at very low and at very high lung volumes. Alveoli require greater pressure to be inflated when they are almost empty or almost full, respectively. When an alveolus is collapsed, a great increase in pressure is necessary for inflation to begin. Observe in Figure 26-2 that the slope of the inspiratory curve is less at both low volumes and very high volumes. At low volumes, it takes more energy (more negative pressure, i.e., less compliant) to begin to expand the lungs. At high volumes, the alveoli are almost at capacity, and further changes in pressure result in less change in volume (less volume per given pressure = less compliant). As you follow the curve along the expiratory side, notice that an initial increase in pressure (with slower volume change) as the chest wall relaxes is followed by a smooth reduction in volume back to the resting level. Lung compliance results from the interplay of various factors that tend to either expand the lungs or restrict lung expansion. Much of the energy required to expand the lungs, particularly at low volumes, is created by surface tension in the fluid lining of the alveoli, which tends to attract the alveoli toward a smaller volume. Perhaps counterintuitively, a lung filled with fluid (and therefore without an air/fluid interface and the resulting surface tension) has a very high compliance—it requires much less energy to expand. Although not a high-fidelity measurement, static effective compliance can be calculated easily using the following equation:

$$\text{Static effective compliance} = \frac{\text{tidal volume}}{\text{(plateau pressure-PEEP)}}$$

Plateau pressure is the pressure observed if you retard exhalation momentarily when the lungs are at end-inspiration. An inspiratory pause on the ventilator is an easy way to observe the plateau pressure. After subtracting the added pressure of PEEP, the plateau pressure is then divided into the measured tidal volume of that breath, producing a measure of lung compliance. A static compliance of 60 to 100 mL/cm H_2O is considered normal. However, the most useful clinical application of compliance measurement is in monitoring trends to evaluate changing physical status or the effectiveness of positive end-expiratory pressure (PEEP) or other treatment modalities.

Dynamic compliance is the compliance of the lung while the air is moving. Dynamic compliance is influenced by the forces involved in static compliance as well as the effects of airway resistance. Airway obstruction (e.g., that caused by bronchospasm or the presence of foreign bodies in the airway) can greatly decrease dynamic compliance.[11] Dynamic compliance is calculated as the tidal volume divided by peak inspiratory pressure − PEEP. Many modern anesthesia ventilators can calculate and trend compliance through tracing of pressure-volume curves.

Lung Elastic Recoil

The forces that cause elastic recoil of the lung are responsible for emptying the lung during exhalation and have a significant influence on lung compliance. In addition to actual elastic fibers, the surface tension of the liquid film that lines the alveoli contributes to elastic recoil of the lung. Surface tension occurs at a gas/liquid interface and is generated by the cohesive forces among the molecules of the liquid. Surface tension is what causes water to bead and form droplets.

Surface tension at the gas-fluid interface between the alveolar walls and the gas inside them contributes to reducing the size of alveoli, particularly when the alveoli are at low volumes. At end-expiration, surface tension increases the pressure required to inflate the alveoli, contributing to the flat portion of the lung compliance curve. This concept is often attributed to the law of Laplace (P = T/r), which states that if surface tension (T) is constant, pressure (P) would increase as radius (r) decreases. *Pulmonary surfactant* secreted by alveolar type II cells counteracts the influence of surface tension on the lungs. With surfactant present, as alveolar radius decreases, surface tension also decreases, so that pressure remains more constant. Surfactant consists of proteins and phospholipids, primarily, dipalmitoylphosphatidylcholine. The surface active agent serves to lower the surface tension of the fluid lining the alveoli and decrease the work of breathing.

Although the law of Laplace has traditionally been applied to understanding alveolar pressure-tension relationships, there is controversy over whether alveoli should be treated as spherical (and thus subject to the law) or not. Geometricians postulate that closely packed alveoli would not maintain the shape of spheres, but rather of polyhedrons because their sides would be flattened against each other. The classical application of LaPlace described the concept of alveoli as distinct balloon-like structures wherein pressure differentials can cause small alveoli to collapse and expel their gas into larger ones. The fact that alveoli are not individually suspended, but rather part of a connective tissue mesh, argues against this concept. The presence of pores of Kohn also argues against this theory, because the pores allow pressure equalization between adjacent alveoli. Connective tissue and elastic forces probably play the most important role in preventing alveolar closure.[12]

In any case, it is clear that surfactant is crucial for reducing surface tension and preventing collapse of alveoli and, perhaps more importantly, small airways. The cylindrical shape of airways lends to the application of the law of LaPlace to the role of surfactant in these structures. Surfactant probably also helps prevent fluid bridging (connection of fluid lining from opposite sides of an airway at low volumes), which could impair gas flow.[13] In the fetus, surfactant is not produced until approximately 28 to 32 weeks of gestation and does not reach mature levels until approximately 35 weeks' gestation. The lack of surfactant is the prevalent cause of respiratory distress syndrome (RDS) in premature infants. Formation of surfactant can be hastened by the administration of glucocorticoids (particularly a steroid that crosses the placenta,

such as betamethasone) to the parturient mother when premature delivery is threatened or imminent. The direct administration of synthetic surfactant to the airways of premature newborns has also greatly reduced the incidence of RDS. Amniocentesis is sometimes performed to determine whether mature surfactant levels are present in the premature fetus. The ratio of lecithin to sphingomyelin (the L/S ratio) indicates the amount of mature surfactant (dipalmitoyl lecithin) in proportion to the amount of surfactant precursor (sphingomyelin).

Respiratory Pressure

Although the elastic forces of the lung tend to favor lung collapse, the chest wall is constantly under tension to expand. This is why normal inspiration requires very little energy. At the end of eupneic exhalation, the outward recoil of the chest wall is balanced by the inward elastic recoil of the lung. At this resting end-expiratory point, the opposing forces of the lungs and chest wall produce negative pressure in the pleural space.

The difference between intraalveolar pressure and intrapleural pressure is called the *transpulmonary pressure*. Under normal circumstances, the pleural pressure is always slightly negative, owing to the opposing forces of lung tissue contraction and chest wall expansion. The intrapleural pressure becomes slightly more negative during inspiration and slightly less negative during expiration. The transpulmonary pressure fluctuates as the alveolar pressure oscillates between slightly negative during inspiration to slightly positive during expiration, returning to zero whenever airflow is stopped at end-inspiration or end-expiration (Figure 26-3). During normal inspiration, intraalveolar pressure fluctuates only by 1 to 2 mmHg. Therefore very little pressure is applied during eupneic ventilation. During maximal expiration with a closed glottis (such as during coughing), intraalveolar pressure may exceed 100 mmHg, whereas during obstructed inspiration, it may be reduced to as low as −90 mmHg. During the first few breaths of life, a newborn can attain an intraalveolar pressure from −40 to −60 mmHg as the fluid-filled lungs are first aerated. In conditions of low lung compliance, more work is required to expand the lung, and the transpulmonary pressure rises (greater difference between intrapleural and intraalveolar pressure required to increase the lung volume).

Resistance to Breathing

In addition to the static elastic recoil of the lung, frictional resistance of lung tissues and resistance to airflow opposes inflation of the lung. Rheologic characteristics of airflow affect its ability to pass through conducting airways. Laminar flow is an orderly movement, where molecules are moving along a generally straight path. In laminar flow, the gas in the center of the stream moves faster than that closer to the wall because frictional resistance slows molecules near the vessel wall. Laminar flow is characterized by lower pressure than turbulent flow. During turbulent flow, resistance greatly increases because molecules move in various directions. The rheologic calculation of Reynolds number predicts when flow of a fluid (or gas) will be laminar or turbulent. Reynolds number (Re) is calculated as follows:

$$Re = \rho v d/\eta$$

where v = velocity of fluid flow, d = diameter of the vessel, p = density of the fluid, and η = viscosity of the fluid. This version of the formula would apply to flow through a tube (such as the airways). In open systems, *length* is substituted for diameter. When the inertial forces of density, velocity of flow, and diameter increase, Reynolds number increases. Increasing viscosity of the fluid reduces the product. Products up to 2000 predict laminar flow; above 4000 predict turbulent flow, and a transitional area exists when results are between those numbers.

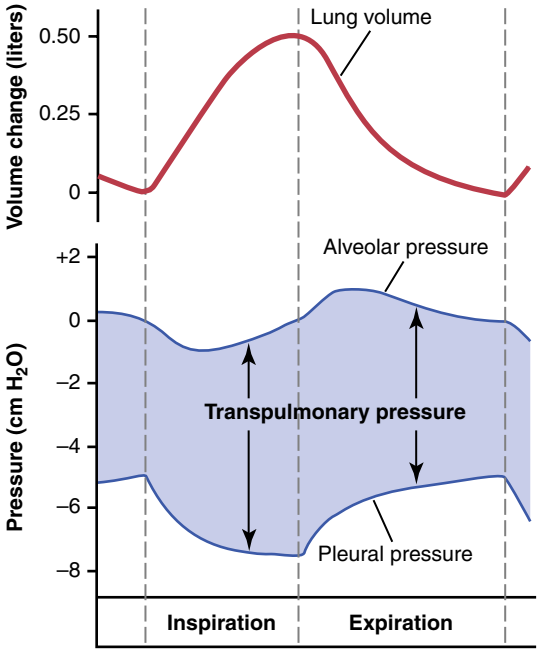

FIGURE **26-3** Alveolar, pleural, and transpulmonary pressures. (From Hall JE. *Guyton and Hall Textbook of Medical Physiology.* 12th ed. Philadelphia: Saunders; 2011:466.)

Throughout the airways, both laminar and turbulent flows occur. True laminar flow occurs in smaller airways, where the diameter is small and linear velocity is very low. Linear velocity is inversely proportional to cross-sectional area for any flow rate. Turbulence is greatest in large airways, and turbulence caused by branching of the airways produces the breath sounds heard on auscultation. Resistance to laminar flow follows Poiseuille's law ($R = 8\eta l/r^4$, where η equals viscosity). Resistance (R) to laminar airflow is directly proportional to the length (l) of the tube and inversely proportional to the fourth power of the radius (r). Therefore doubling the radius of the tube decreases resistance 16 (2^4) times. Normally, about 40% of the total airway resistance resides in the upper airways (nasal cavity, pharynx, and larynx).

Although resistance to airflow is greatest in individual small airways, the net total resistance to airflow of the small airways is very low because they represent a massive number of parallel pathways. Under normal circumstances, the greatest resistance to airflow resides in medium-sized bronchi, whose smooth muscle tone greatly affects airway resistance. During lung inflation, increasing lung volumes exert retractive forces on the airways, resulting in a reduction in airway resistance. During forced expiration, dynamic compression of the airways increases airway resistance and may promote airway collapse (most likely in small airways with no cartilaginous support).

The clinical application of these concepts resides in strategies to reduce airflow resistance. Bronchodilators will reduce resistance to airflow by increasing the radius of the pathway, as predicted by Poiseuille. Selection of an endotracheal tube size may confer greater or lesser resistance, based on the length and (much more significantly) the internal diameter of the tube. Clinical application of Reynolds number suggests that lower velocity (lower inspiratory flow or lower inspiratory:expiratory ratio) and lower density would promote laminar flow and create lower ventilating

TABLE 26-4 Glossary for Static Lung Volumes and Capacities

Measurement	Symbol	Definition	Capacity (mL)
Volumes			
Residual volume	RV	Volume of air remaining in the lungs after maximum expiration	1200
Expiratory reserve volume	ERV	Maximum volume of air expired from the resting end-expiratory level	1100
Tidal volume	V_T	Volume of air inspired or expired with each breath during quiet breathing	500
Inspiratory reserve volume	IRV	Maximum volume of air inspired from the resting end-inspiratory level	3000
Capacities			
Inspiratory capacity	IC = IRV + V_T	Maximum volume of air inspired from the end-expiratory level (the sum of IRV and V_T)	3500
Vital capacity	VC = IRV + V_T + ERV	Maximum volume of air expired from the maximum inspiratory level	4500
Functional residual capacity	FRC = RV + ERV	Volume of air remaining in the lungs at the end-expiratory level (the sum of RV and ERV)	2300
Total lung capacity	TLC = IRV + V_T + ERV + RV	Volume of air in the lungs after maximum inspiration (the sum of all volume compartments)	5800

pressures. The reduction in density is the conceptual basis for combining helium with oxygen ("heliox") to improve pulmonary gas distribution in obstructive lung disease.[14]

Other influences on airflow include the autonomic nervous system and pathologic conditions. The autonomic nervous system affects the tone of the bronchial smooth muscle. The sympathetic nervous system, as well as sympathomimetic drugs (e.g., norepinephrine, epinephrine, and isoproterenol), produce bronchodilation. The parasympathetic nerves and parasympathomimetic drugs (e.g., acetylcholine) cause bronchoconstriction. Parasympatholytic drugs (e.g., atropine and ipratropium) therefore cause bronchodilation (though mildly). Irritation of the airway by foreign bodies or inhaled irritants causes reflex bronchoconstriction.

Lung Volumes

The following discussion of lung volumes uses the parameters of a normal 70-kg male. Table 26-4 gives an overview of related terms and normal values. The amount of gas that enters and leaves the body with each eupneic breath is approximately 350 to 500 mL and represents the *tidal volume* (V_T). The *minute volume* (MV) equals V_T multiplied by the respiratory rate. However, because some ventilation occupies the conducting zone, only a portion of the minute ventilation ($\dot{V}_E$) participates in gas exchange. The amount of *alveolar* ventilation in a minute equals V_T minus anatomic dead space (the volume of the conducting airways, which is approximately 2 mL per kg of body weight) multiplied by the ventilatory rate. The rate of alveolar ventilation will be indirectly proportional to the arterial CO_2 tension. The residual volume (RV) is the volume of gas left in the lung after a maximal exhalation (approximately 1.5 L). The RV cannot be removed from the lungs voluntarily and is important because it is a component of the functional residual capacity, which represents alveolar gas used for oxygenation of the blood between breaths or in periods of apnea. The expiratory reserve volume is the volume of gas expelled from the lungs during a maximal forced exhalation, starting at the end of a normal tidal exhalation. The inspiratory reserve volume is the volume of gas inhaled into the lungs during a maximal forced inhalation, starting at the end of a normal tidal inspiration (2.5 L).

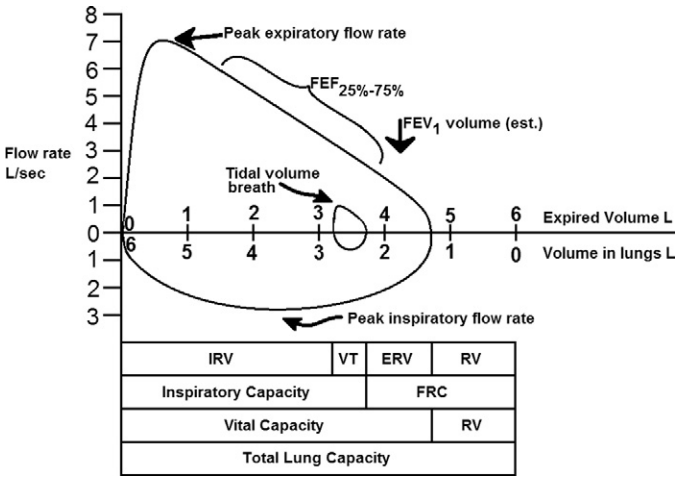

FIGURE **26-4** Pulmonary flow-volume loop indicating key pulmonary function test measurements and static lung volume divisions.

The sum of the four basic lung volumes is the total lung capacity (TLC). Several types of lung capacity measures exist, each of which is the sum of two or more lung volumes. TLC is the volume of air in the lungs after a maximal inspiratory effort (approximately 6 L in a 70-kg adult). The vital capacity is the amount of air that can be forcibly exhaled from the lungs after a maximal inspiratory effort (approximately 4.5 L). The functional residual capacity (FRC) is the volume of gas contained in the lungs after normal quiet expiration. It is the sum of the RV and expiratory reserve volume (approximately 3 L). The inspiratory capacity is the volume of air inhaled into the lungs during a maximal inspiratory effort that begins at FRC (approximately 3 L). Figure 26-4 gives a graphic representation of lung volumes and normal flow measurements.

Closing volume describes the phenomenon during exhalation when small airways collapse, hindering further emptying of lung units distal to them. Closing volume is defined as the volume above residual volume where small airways close, whereas closing capacity describes the absolute volume of gas in the lung

when small airways close (the closing capacity is the sum of the closing volume plus the residual volume). The closing volume increases from approximately 30% of the TLC at age 20 years to approximately 55% at age 70 years. Certain conditions increase the closing volume, such as supine positioning, pregnancy, obesity, COPD, congestive heart failure, and aging.[15] In abnormal conditions, if the closing volume exceeds the FRC, airway closure occurs during tidal breathing, resulting in poorly ventilated or unventilated alveoli and intrapulmonary shunting. The shearing forces of repetitive airway opening and closing also leads to airway injury.[16] Measurement of closing volume analyzing washout characteristics of inert gas is a more sensitive indicator of small airway disease (such as from smoking) than is measurement of spirometry.[15]

GAS EXCHANGE IN THE LUNGS

Dead Space

Dead space refers to ventilation that does not participate in gas exchange. The volume of the conducting airways represents the *anatomic dead space* and normally equals approximately 2 mL/kg of body weight. Alveoli that are ventilated but not perfused comprise the *alveolar dead space* because they do not deliver oxygen nor do they remove CO_2 from the blood. The sum of the anatomic dead space plus the alveolar dead space is the physiologic dead space (V_D). Because perfused ventilation equilibrates with arteriolar CO_2 and nonperfused (dead space) ventilation does not, the proportion of dead space ventilation can be calculated by comparing the ratio of CO_2 in the arterial blood and in the exhaled gas. This is calculated with the Bohr equation:

$$\%\,V_D = (Paco_2 - Peco_2) / Paco_2$$

where $Paco_2$ is the arterial partial pressure of CO_2 as determined from arterial blood gas (ABG) measurement, and $Peco_2$ is the Pco_2 of mixed expired gas as determined with a capnogram. Certain pathologic conditions, such as pulmonary embolus, increase the alveolar dead space and can abruptly decrease the end-tidal CO_2 levels monitored with capnography.

Regional Distribution of Alveolar Ventilation

Gravity and other factors influence ventilation and perfusion such that both are unevenly distributed throughout the lungs. In the normal upright lung, the alveoli at the base are more compliant than those at the apex, meaning that those at the base exhibit a greater change in volume with each breath. This is considered to be a result of the effect of gravity on the interconnected parenchyma of the lung, whereby the greatest "pull" is exerted on the more superior portions of lung. Therefore, the alveoli in those areas are held in a more open state even at rest, whereas alveoli at the base are more compressed. During inspiration then, the alveoli at the bases are able to accept more new gas (Figure 26-5). Alterations to the resting volume or impingements on lung compliance may change this relationship. Pregnancy or obesity may hinder expansion of lower units or may cause compression that results in collapsed dependent areas. In that case, other lung areas become the most compliant. The sigmoidal shape of the compliance curve (see Figure 26-2) reveals that alveoli become less compliant at higher volumes (e.g., in nondependent alveoli at high lung volume) and also at very low volumes (e.g., in dependent alveoli at very low resting lung volumes).

Alveolar Oxygen and Carbon Dioxide Levels

The levels of O_2 and CO_2 in alveolar gas are determined by several factors. These include the amount of alveolar ventilation, the inspired concentrations of O_2 and CO_2, the flow of mixed venous blood to the lungs, and the body's consumption of O_2 and production of CO_2. In a person spontaneously breathing room air, each breath brings approximately 350 mL of fresh air (21% of which is O_2) into the alveoli, which already contain over 2 L of gas (the FRC). Each exhalation removes approximately 350 mL of gas consisting of 5% to 6% CO_2. Every minute, approximately 250 mL of O_2 diffuse from the alveoli into the pulmonary capillary blood, whereas approximately 200 mL of CO_2 diffuse from the pulmonary capillary blood into the alveoli. The ratio of the amount of CO_2 produced to the quantity of O_2 consumed is called the *respiratory quotient* (RQ = 200 mL CO_2 produced divided by 250 mL O_2 consumed = 0.8). The proportion of CO_2 production and O_2 consumption varies with energy source (greater with more carbohydrates and lower with more fat), but 0.8 is the typical result from a mixed diet.

Approximately 21% of dry atmospheric air is O_2; therefore, at the standard barometric pressure of 760 mmHg, Po_2atm equals 0.21 × 760 mmHg, or 160 mmHg. Only 0.04% of atmospheric air is CO_2, so Pco_2atm = 0.3 mm Hg. As the inspired air passes through the upper airways, it is heated to body temperature and humidified to a relative humidity of nearly 100%. The partial

FIGURE **26-5** Concept of gravity effect on regional alveolar compliance. A suspended helical coil demonstrates compression of lower coils and extension of upper coils at rest, such that upon expansion (as in inflation of the lung), lower units undergo greater change in volume.

pressure of water vapor at body temperature is a fairly constant 47 mmHg. The P_{O_2} of inspired air (P_{IO_2}) saturated with water vapor at standard atmospheric pressure = 0.21 × (760 mmHg − 47 mmHg), or 149 mmHg.

The inspired gas mixes with the gas already in the alveoli (FRC) and rapidly equilibrates with the pulmonary capillary blood. The alveolar P_{O_2} (P_{AO_2}) can be calculated with the alveolar air equation:

$$P_{AO_2} = P_{IO_2} - (P_{ACO_2} / RQ)$$

Thus during the breathing of atmospheric air, when P_{ACO_2} is 40 mmHg and the RQ is 0.8, then P_{AO_2} = (0.21 × [760 mmHg − 47 mmHg]) − 40 mmHg/0.8 = 99 mmHg. Therefore, using the alveolar air equation, one can calculate the P_{AO_2} if the atmospheric pressure, inspired O_2 concentration, and P_{ACO_2} (which is approximately equal both to the end-tidal P_{CO_2} and the arterial P_{CO_2} [Pa_{CO_2}]) are known, because water vapor pressure and RQ are fairly constant. If the inspired O_2 concentration differs from that of room air, then that fraction replaces the 0.21. P_{AO_2} is less than P_{IO_2} because the CO_2 is delivered to the alveoli by the pulmonary blood flow at the same time that O_2 is taken up from the alveoli. Therefore P_{ACO_2} divided by the RQ approximates the amount of O_2 that was removed from the alveoli by the pulmonary capillary blood flow.

Effects of Alveolar Ventilation on Carbon Dioxide and Oxygen

Within certain limits P_{ACO_2} is inversely proportional to alveolar ventilation. If alveolar ventilation is doubled, then P_{ACO_2} and Pa_{CO_2} are reduced by half (if CO_2 production remains unchanged).

As alveolar ventilation increases, P_{AO_2} also increases slightly. However, doubling alveolar ventilation does not double P_{AO_2}; according to the alveolar air equation, reduction of the P_{ACO_2} raises the P_{AO_2}, bringing P_{AO_2} closer to the P_{IO_2}.

PULMONARY BLOOD FLOW

The lungs have a dual blood supply: (1) the bronchial arteries (usually one on the right and two on the left), and (2) the pulmonary arteries, which bring unoxygenated blood to the lungs from the right ventricle. The bronchial arteries arise from the descending aorta and carry approximately 2% of the cardiac output to nourish the nonrespiratory tissues: lung parenchyma, bronchi, nerves, pulmonary vessels, and visceral pleura. Bronchial arteries do not participate in fresh gas exchange with the alveoli. The branches of the bronchial arteries accompany the bronchial divisions as far as the respiratory bronchioles. The bronchial veins return deoxygenated blood from the first part of the bronchi and drain into the azygos, hemiazygos, or posterior intercostal veins. The remainder of the deoxygenated blood is returned by the pulmonary veins.

The pulmonary circulation provides blood flow to the structures distal to the terminal bronchioles, including distal nonrespiratory tissues and the respiratory units. The pulmonary artery arises from the right ventricle and branches into the right and left pulmonary arteries, which further branch to accompany the bronchi. Although the pulmonary artery carries the entire cardiac output of the right ventricle, its walls are less muscular and more distensible that those of the aorta, and the pulmonary artery pressure is considerably less than the pressure in the aorta. The pulmonary arteries rapidly subdivide into terminal branches, which have thinner walls, much less smooth muscle, and greater internal diameters than corresponding branches of the systemic arterial tree. Pulmonary vessels are also much shorter than systemic vessels, and according to Poiseuille's law, a decrease in length decreases resistance. Subsequently, pulmonary vascular resistance is very low, being approximately one-eighth of systemic vascular resistance.

Pulmonary vascular resistance is fairly evenly distributed among the arteries, capillaries, and veins, whereas most of the resistance in the systemic circulation is in the muscular arteries. Although pulmonary venous resistance is very low, it can decrease further when blood flow increases. This is because of passive changes in resistance caused by recruitment and distensibility of the pulmonary vessels. *Recruitment* is the opening to perfusion of pulmonary vessels that were previously not perfused. *Distensibility* is an increase in diameter of a pulmonary vessel that is already being perfused, and it results from the vessel's compliance.

The sympathetic nervous system has some influence on pulmonary vascular resistance, as do certain substances circulating in the pulmonary blood. Pulmonary vascular resistance is increased by norepinephrine, serotonin, histamine, hypoxia, endothelin, leukotriene, thromboxane, prostaglandin (e.g., $PGF_2\alpha$), and hypercapnia.[17] It is decreased by prostacyclin analogs (e.g., epoprostenol), endothelin receptor antagonists (e.g., bosentan), phosphodiesterase type 5 inhibitors (e.g., sildenafil),[18] acetylcholine,[19] and isoproterenol (minimal effect).[20] Short-term or limited-use medications to reduce pulmonary vascular resistance include inhaled nitric oxide, calcium channel blockers (e.g., amlodipine), and adenosine.[18]

The respiratory units are the site of gas exchange between alveolar air and the pulmonary capillary blood. After participating in gas exchange in the respiratory zone, blood is returned to the heart by way of the pulmonary veins. The pulmonary vessels also anastomose with the bronchial vessels at the junction of the terminal and respiratory bronchioles. Therefore, the pulmonary veins carry oxygenated blood from the respiratory units and deoxygenated blood from the visceral pleura and distal bronchi. The venous bronchopulmonary anastomoses are significant in their contribution to the normal anatomic shunt (the addition of unoxygenated blood to the left chambers of the heart). Evidence of this crossover is observed during complete cardiopulmonary bypass: blood enters the left atrium, even though all blood is shunted from the right heart by the venous cannula. This is because blood flow continues through the bronchial vessels, which anastomose with the pulmonary veins, which in turn ultimately drain into the left atrium—one reason a ventricular drain may be inserted during the surgery to prevent overdistention of the heart. Five pulmonary veins ultimately return blood to the left heart.

Influences on Pulmonary Blood Flow

Although pulmonary vessels have less muscular content than systemic arteries, the low pressure of the system makes pulmonary blood flow very sensitive to small changes in arterial tone. Unlike the systemic circulation, where hemodynamic influences are more global, pulmonary blood flow is more prevalently regulated locally by changes in oxygen and carbon dioxide tension. In contrast to the systemic circulation, high oxygen tension and hypocapnea vasodilates pulmonary vessels (which helps those vessels pick up more oxygen), whereas hypercarbia and acidosis cause vasoconstriction. Having the strongest influence on pulmonary local regulation, blood flow to hypoxic or atelectatic alveoli is actively diverted at a precapillary site by a process known as *hypoxic pulmonary vasoconstriction*. This decreases blood flow away from focal diseased areas of the lung and improves matching of ventilation and perfusion. See Chapter 27 for a discussion of the significance of hypoxic pulmonary vasoconstriction during pulmonary surgery.

Relationship of Pulmonary Blood Flow and Ventilation

In the normal upright lung, a greater portion of the blood flow is distributed to the dependent regions because of the effects of hydrostatic pressure and greater distention of dependent pulmonary vessels. Likewise, differences in compliance of the ventilating tissue also result in a general increase in the proportion of ventilation from nondependent (least ventilation) to dependent (most ventilation) of the lungs. There are two caveats to these rules. Although they fit the spontaneously breathing patient fairly well, the spatial distribution of these relationships are altered during positive-pressure ventilation. Also, the lung zones are commonly portrayed in textbooks in nicely demarcated lines of latitude, a model appreciated for its simple elegance.

Although there may be a general increase in perfusion from top to bottom of the lung, it should be noted that gravity alone does not determine physiologic perfusion. If it did, then it would be observed that the greatest blood flow in the body would be in the lower extremities, with the least in the head, a cogent point of explanation offered by Levitzki.[21] Gravity interacts with elastic forces to influence ventilation and with vessel recruitment to alter distribution of perfusion. There is evidence that regional perfusion zones may be situated with the greatest blood flow in the lower, core areas of the lungs, with zones 2 and 1 more resembling concentric spheres radiating toward the periphery.[22] Nonetheless, the classic explanation of ventilation-perfusion zones described by West in 1964 serves as a useful model for considering the relationships between ventilation and perfusion,[23] and more specifically, the conditions under which intraalveolar pressure may impede vascular flow.[24] In this model, regions of the lung are considered in zones, according to the relative intravascular and intraalveolar pressure (Figure 26-6).

In the parts of the lung where alveoli exist at a greater resting volume, alveolar pressure can exceed pulmonary artery pressure (PAP), so that perfusion is impeded. This is called *zone 1* and represents alveolar dead space because the region is ventilated but not perfused. Normally, zone 1 exists only in a very small margin of lung area around the apical border during spontaneous ventilation, but the use of PEEP or high airway pressures during mechanical ventilation can create or expand this zone.

The intermediate zone, where there is a variable relationship between vascular and alveolar pressure, is *zone 2*. A point is described in zone 2 along the continuum of decreasing intraalveolar pressure where arterial pressure exceeds alveolar. Below that point, flow is solely dependent upon arterial flow, and unrelated to alveolar or venous pressure. This concept is described as a waterfall zone, as when rising water finally overflows a dam. At that point, the height of the dam does not influence the flow, only the upstream inflow does. The zone 2 relationship is not static, but fluctuation in alveolar pressure related to respiration can variably occlude capillary flow.

The dependent portion of the lung, where both pulmonary arterial and venous pressures exceed alveolar pressure, is known as *zone 3*. This zone represents continuous blood flow, and it is in this zone that the tip of a pulmonary artery catheter should lie, for example, to ensure continuous communication with the left heart. Alveoli in this zone rest at a lower volume than in zone 1, and so they have greater compliance and represent the greatest proportion of ventilation in the lung; however, the perfusion is also greatest here, and so there is no obstruction to blood flow. West later described a fourth zone in the most dependent portions of lung, wherein extravascular pressure from mechanical compression or interstitial fluid compresses the vessels and occludes their flow.[25]

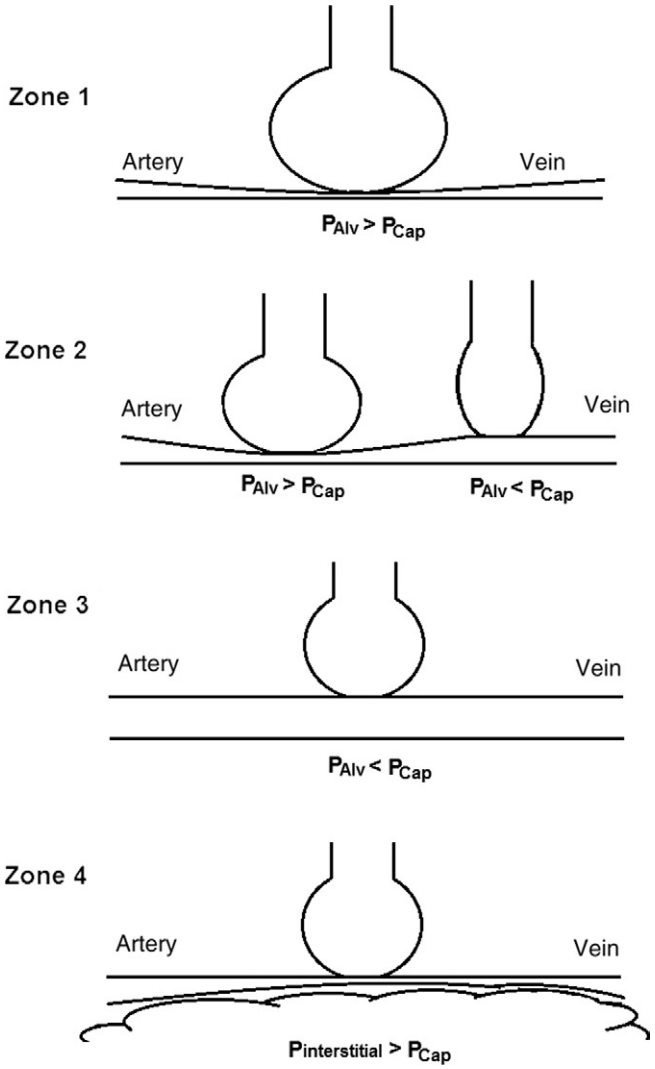

FIGURE **26-6** Ventilation-perfusion relationships described as the "Zones of West." *Zone 1*, Gravity induces low perfusion pressure in capillary and larger resting volume of alveoli, owing to traction from parenchyma below. Alveolar air pressure is greater than capillary pressure, causing high $\dot{V}/\dot{Q}$ dead-space effect. *Zone 2*, Systolic capillary pressure rises higher than alveolar air pressure, but diastolic capillary pressure falls below alveolar air pressure. Blood flow is intermittent, depending on the relationship of both throughout the respiratory cycle. *Zone 3*, Capillary pressure is highest because of hydrostatic gradient. Alveoli are relatively compressed by weight of parenchyma above and therefore have highest compliance. Ventilation and perfusion are both greatest in this zone, although not perfectly matched. *Zone 4*, Interstitial fluid or mechanical compression creates extravascular pressure which creates a high $\dot{V}/\dot{Q}$ area in the most dependent portion of lung. P_{Alv}, Alveolar pressure; *PCap*, pulmonary capillary pressure.

Pulmonary Edema

The normal distance for diffusion from the alveolar air space into the pulmonary capillary blood cells is less than 1 micrometer. The gas must traverse the surfactant layer, the flat alveolar type I cells, the interstitial space, the endothelial cells that make up the wall of the pulmonary capillary, a minute amount of plasma, and then finally the membrane of the red blood cell. The pulmonary system is designed to allow free passage of gases across this series of structures, collectively called the *respiratory membrane*. However, that inherent "leakiness" does predispose this area to unintended movement of fluid.

BOX 26-4

Management of Pulmonary Edema

- Correct underlying cause
- Support oxygenation with supplemental O_2, CPAP, mechanical ventilation, and PEEP, as necessary
- Consider steroids to stabilize capillary membranes
- For cardiogenic pulmonary edema:
  - Administer diuretics
  - Improve hemodynamics—morphine or nitroglycerin to reduce preload; inotropes or vasodilators to promote forward flow

CPAP, Continuous positive airway pressure; *PEEP,* positive end-expiratory pressure.

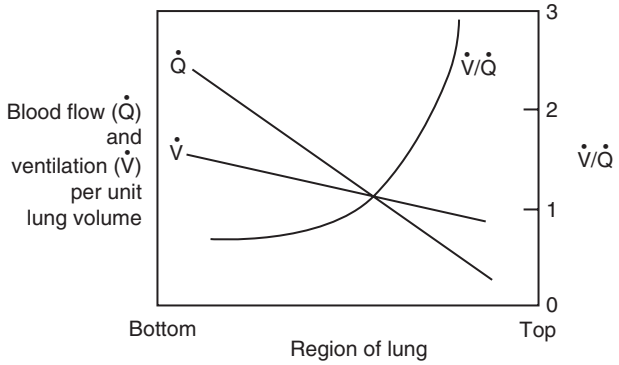

FIGURE **26-7** Ventilation-perfusion relationships throughout the lung.

There is a fine balance between the plasma colloid oncotic pressure, which tends to hold fluid in the pulmonary capillaries, and the capillary hydrostatic pressure, interstitial fluid colloid oncotic pressure, and negative interstitial fluid pressure, which all tend to favor fluid movement into the interstitial space. In normal circumstances, the net of these forces favors movement into the interstitium, helping to divert fluid from the adjacent "leaky" capillaries away from the alveoli and thereby prevent accumulation there.[26] Although the interstitium has a large compliance for removing accumulating transudated fluid, derangements in the factors above can lead to fluid accumulation in the interstitium or alveoli and disrupt gas exchange.

Pulmonary vascular congestion causes increased capillary leakage into the interstitium, which can increase the distance for gas diffusion. If the capillary leak overcomes the compliance of the interstitial space, the fluid may then begin to pass into the alveoli. Pulmonary edema affects oxygenation more than CO_2 excretion because CO_2 is 20 times more diffusible than O_2. Many conditions can result in pulmonary edema. The high capillary pressures associated with heart failure or the excessive administration of intravenous fluids can increase lung water content. The size of the pulmonary capillary pores can be increased by sepsis, smoke inhalation, and other toxic conditions. Brain trauma can produce an intense sympathetic discharge, resulting in neurogenic pulmonary edema.

A condition that occasionally occurs during emergence from anesthesia is postobstructive pulmonary edema, also referred to as *negative-pressure pulmonary edema* (NPPE). After extubation, if the patient experiences laryngospasm and then attempts forceful inhalation against the closed glottis, the drastic decrease in intrathoracic pressure pulls fluid from the pulmonary capillaries. The onset of pulmonary edema is rapid and relatively easy to treat. The symptoms resolve rapidly; in most cases, patients are discharged within 24 hours. Treatment includes removing the precipitating condition (relieving airway obstruction) and general supportive measures: oxygen, maintenance of a patent airway, noninvasive continuous positive airway pressure (CPAP), and intubation with PEEP if required to maintain oxygenation. Unlike pulmonary edema related to fluid overload, NPPE does not call for diuretic therapy. However, many reported cases do include the use of controversial treatments of diuretics and corticosteroids.[27] The three mainstays of treatment remain treatment of the precipitating condition, normalization of ventilation and oxygenation, and reduction of lung congestion and fluid. Treatment summary is in Box 26-4.

Ventilation-Perfusion Relationships in the Lung

Normally, ventilation ($\dot{V}$) is approximately 4 L/min, whereas pulmonary blood flow ($\dot{Q}$) is approximately 5 L/min. Therefore, the ventilation-perfusion ratio ($\dot{V}/\dot{Q}$) for the whole lung is 0.8. However, $\dot{V}$ and $\dot{Q}$ must be matched at the alveolar-capillary level for gas exchange to occur in the lung.

Dependent portions of the lung receive relatively more blood flow than nondependent portions because of the effects of gravity and vessel recruitment and distensibility. Additionally, ventilation goes to the more compliant portions of the lung. Normally at FRC, the dependent regions of the lung are more compliant, and the alveoli of the nondependent portions are more inflated ("tented open") and less compliant. Therefore, relatively more ventilation and perfusion go to the dependent portions, and this results in optimal gas exchange.

Although distribution of ventilation normally decreases moving from dependent to nondependent regions of the lung, the accompanying decrease in perfusion is even greater; therefore the ratio, $\dot{V}/\dot{Q}$, increases as measured progressively from dependent to nondependent lung areas (Figure 26-7). Also, $\dot{V}/\dot{Q}$ varies: in alveoli that are ventilated but not perfused, $\dot{Q}$ equals 0, so $\dot{V}/\dot{Q}$ equals infinity (i.e., dead space); in alveoli that are perfused but not ventilated, $\dot{V}$ equals 0, so $\dot{V}/\dot{Q}$ equals 0 (i.e., a shunt). Similarly, alveoli that are ventilated but poorly perfused are described as "deadspace-like," whereas alveoli that are perfused but poorly ventilated are termed *shuntlike*; the latter contribute to the $\dot{V}/\dot{Q}$ mismatch of the lung. Shuntlike alveoli (low $\dot{V}/\dot{Q}$) have relatively low P_{O_2} and high P_{CO_2} when compared with deadspace-like alveoli (high $\dot{V}/\dot{Q}$), which have relatively high P_{O_2} and low P_{CO_2}.

$\dot{V}/\dot{Q}$ mismatch can result from a number of causes. A pulmonary embolus of thrombus, air, or other material that passes through the pulmonary artery to obstruct blood flow through the pulmonary capillaries creates alveolar dead space. Likewise, very high airway pressure from aggressive ventilation or PEEP can produce alveoli that are ventilated but not perfused. Similarly, very low cardiac output (CO) results in low pulmonary blood flow and therefore increases the $\dot{V}/\dot{Q}$ ratio. This is reflected by a low end-tidal CO_2 on capnography and a wide gradient between the end-tidal and the arterial P_{CO_2}.

Total pulmonary venous admixture (unoxygenated blood delivered to the left side of the heart) is the sum of the shunt and shuntlike states. It can be calculated with the shunt equation, which is discussed later. Bronchopulmonary anastomoses are a cause of normal anatomic shunt, along with thebesian veins, which drain into the left side of the heart and usually account for less than 2% of the CO. Airway obstruction, alveolar collapse (atelectasis), and alveolar filling processes, such as pneumonia, also produce shunt.

Some diagnostic studies can definitively identify ventilation-perfusion abnormalities. A lung scan after a single breath of xenon 133 (^{133}Xe) gas or aerosolized technetium-99m can be used to

determine the location of poorly ventilated areas in the lung, whereas IV injection of dissolved radioisotope reveals areas of the lung that are poorly perfused. Together, these comprise a ventilation-perfusion scan. Pulmonary angiography (radiography with injection of IV contrast dye) of the pulmonary vasculature can be used to demonstrate whether any pulmonary blood vessels are obstructed, such as in pulmonary embolism.

Effects of General Anesthesia on Respiratory Physiology

General anesthesia affects the matching of ventilation and perfusion in several ways. Changing position from upright to supine and induction of general anesthesia produce a significant decrease in the FRC (see Chapter 27). With positive-pressure ventilation, the distribution of ventilation becomes more uniform throughout the lung, so both the dependent and nondependent alveoli receive about the same amount of ventilation. This leads to a wider scatter of ventilation and perfusion because there is relatively more ventilation of underperfused alveoli. General anesthesia usually also causes a significant decrease in the CO, which is exacerbated by positive-pressure ventilation, especially if it is accompanied by PEEP. This may promote an extension of zone 1 areas, although this theoretic effect is probably overstated. Atelectasis is a common finding with general anesthesia and is the main cause of the 10% shunt commonly observed in patients under anesthesia.[26]

Although hypoxic pulmonary vasoconstriction is partially effective in diverting blood flow away from poorly ventilated lung regions, most inhaled anesthetics (as well as potent vasodilators, such as nitroprusside and nitroglycerin) decrease the effectiveness of hypoxic pulmonary vasoconstriction, whereas most intravenous anesthetics do not. The inhibition of hypoxic pulmonary vasoconstriction contributes to the decrease in Pa_{O_2} and the increase in the alveolar-arterial P_{O_2} difference usually seen when volatile inhaled anesthetic agents are used in significant concentrations.

Although general anesthesia, particularly when administered in combination with muscle relaxants, tends to increase chest-wall compliance, the decrease in FRC actually produces a large decrease in the compliance of the respiratory system. Laryngoscopy and endotracheal intubation can increase airway resistance by stimulating airway irritant receptors, thereby decreasing dynamic compliance. However, most inhaled anesthetics (except for nitrous oxide [N_2O]) act as bronchodilators. Also, general anesthesia depresses the ventilatory response to CO_2, metabolic acidosis, and hypoxia (as discussed later in this chapter).[28]

Oxygen and Carbon Dioxide Exchange

As blood flows through the lungs, the mean pulmonary transit time is approximately 4 to 5 seconds, with the blood spending approximately 0.75 second in the pulmonary capillaries. However in the normal lung, it takes only one third of this, or 0.25 second, for equilibration to occur between the alveolar air and the pulmonary capillary blood. During exercise, CO may be so greatly increased that the time a blood cell spends in a pulmonary capillary can be reduced to 0.25 second. This decreased time available for diffusion has a much greater effect on exchange of O_2 than on that of CO_2 because CO_2 diffuses approximately 20-fold times more rapidly than O_2 does. *Diffusivity* is defined as the solubility divided by the square root of the molecular weight. CO_2 is a slightly heavier molecule than O_2, but it is 24-fold as soluble in body fluids as O_2.[4]

Oxygen Transport

The blood carries O_2 in two ways: (1) physically dissolved in the plasma, and (2) bound to hemoglobin (Hgb) in the red blood cells.

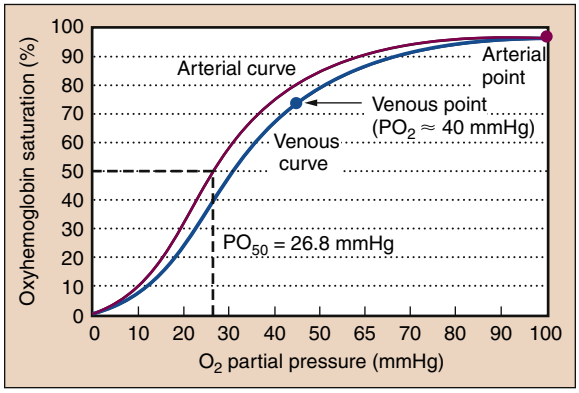

FIGURE **26-8** Oxyhemoglobin dissociation curve. *Dotted line* indicates P_{50}, the measure used to quantify any shift in the curve. (From Miller RD, Pardo Jr MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Saunders; 2011:56.)

Normally 99.7% of the O_2 carried is bound to hemoglobin. Without adequate hemoglobin, the cardiovascular system could not transport sufficient O_2 to meet the metabolic demands of the tissues.

The solubility coefficient of oxygen in plasma is 0.003, so there is 0.003 mL of O_2 per every 1 mmHg partial pressure of P_{O_2} dissolved in 100 mL of whole blood. Therefore, with a Pa_{O_2} of 100 mmHg, only 0.3 mL of O_2 is transported dissolved per deciliter of plasma. Each gram of hemoglobin can combine with 1.39 mL of oxygen; however, because of factors that contaminate this process (such as the presence of methemoglobin), a factor of 1.36 is applied in clinical calculations. Therefore, if the level of hemoglobin is 10 g/100 mL, then at 100% saturation, 1.36 mL of O_2 is bound to hemoglobin per 100 mL of blood. Note that a hemoglobin level of 10 g/100 mL of blood corresponds to a hematocrit of 30%—the hematocrit is normally approximately equal to the hemoglobin level multiplied by 3.

The normal hematocrit for a male is approximately 45% (Hgb 15 g/dL) and for a female is approximately 39% (Hgb 13 g/dL). Centrifugation of the blood in a capillary tube separates the cells from the plasma. A thin layer called the *buffy coat* separates the plasma and the red blood cells (erythrocytes). This thin layer (approximately 1% of the volume of the blood) consists of white blood cells and platelets.[4]

Oxyhemoglobin Dissociation Curve

The affinity of hemoglobin for oxygen fluctuates with various conditions in the physiologic milieu. This unique characteristic means that hemoglobin can more efficiently carry oxygen, because in the lung it can bind much more oxygen than simple diffusion would allow, and it can readily unload that oxygen for delivery in the tissues. The affinity is described by the relationship between the saturation of hemoglobin at a given P_{O_2} in the plasma and is represented by the oxyhemoglobin ($HgbO_2$) dissociation curve (Figure 26-8). This relationship between P_{O_2} and $HgbO_2$ is described by a sigmoidal curve that is steep at lower P_{O_2} values and nearly flat when the P_{O_2} is greater than 70 mmHg. As the P_{O_2} of the plasma increases, the amount of O_2 bound to the hemoglobin also increases, but not in a linear manner. This is because each of the four hemoglobin subunits combines with O_2, and each combination facilitates the next. Similarly, when the O_2 is being unloaded at the peripheral tissues, each dissociation facilitates the next. Therefore, this S-shaped curve is extremely important physiologically. Interaction between O_2 and hemoglobin is also influenced by pH, P_{CO_2}, temperature, and 2,3-diphosphoglycerate (a metabolite of glucose hydrolysis) levels.

The changing affinity of hemoglobin for O_2 facilitates loading at the pulmonary capillaries and unloading of the O_2 at the peripheral tissues. The S-shaped $HgbO_2$ dissociation curve is displaced to the left of the normal curve by hypocapnea, a decrease in temperature, alkalosis, and a decrease in 2,3-diphosphoglycerate levels, resulting in an increased affinity of the hemoglobin for O_2 (a higher saturation for a given P_{O_2}). When exposed to increased temperature, hypercapnia, acidosis, and elevated 2,3-diphosphoglycerate levels, the affinity of hemoglobin for O_2 decreases. This results in a shift of the $HgbO_2$ dissociation curve to the right, and therefore the O_2 is given up to the tissues. Note that the conditions that favor the release of O_2 from the hemoglobin to the tissues are likely to be associated with increased tissue metabolism, which would increase the O_2 demand of the tissues. The influence of pH and P_{CO_2} on the $HgbO_2$ dissociation curve is referred as the *Bohr effect*. The position of the oxyhemoglobin curve can be quantified by the P_{50}. The P_{50} is the Pa_{O_2} at which 50% of the hemoglobin is saturated. Under normal conditions, adult human blood has a P_{50} of 26 to 27 mmHg. If the $HgbO_2$ dissociation curve shifts to the right, the P_{50} increases; if it shifts to the left, the P_{50} decreases.

Other factors that affect O_2 transport include carbon monoxide poisoning and methemoglobinemia. Carbon monoxide binds to hemoglobin (forming carboxyhemoglobin) with 210 times the affinity of O_2.[29] The carbon monoxide binds with hemoglobin at the site that O_2 would occupy, making the carboxyhemoglobin unable to transport O_2. Without a multiple-channel oximeter, carboxyhemoglobin provides a misleadingly high reading because it interprets the hemoglobin as being "saturated," without distinguishing the inability of the hemogloibn to unload its cargo.

Methemoglobin is hemoglobin with its iron in the ferric state (Fe^{3+}) instead of the normal ferrous state (Fe^{2+}). In the ferric state, the hemoglobin iron atoms do not combine with O_2. Methemoglobinemia can be caused by nitrate poisoning (nitroglycerin overdose) or toxic reactions to oxidant drugs, such as the local anesthetic prilocaine. Methemoglobinemia is treated with O_2 therapy and methylene blue at a dose of 1 to 2 mg/kg intravenously over 5 minutes.[30]

Oxygen Content Calculations

Hemoglobin saturation is continuously monitored in anesthetized patients, but the saturation provides only a relative value; 100% saturation of a hemoglobin level that is one half of normal represents the same amount of oxygen as a 50% saturation of the normal amount of hemoglobin. Absolute values for the amount of O_2 in arterial blood are yielded by the O_2 content equation:

$$Ca_{O_2} = (1.36 \times Hgb \times \%\ \text{arterial Hgb saturation}) + (Pa_{O_2} \times 0.003)$$

where Ca_{O_2} is the arterial O_2 content, and Pa_{O_2} and percent of Hgb saturation are obtained from ABG analysis. Ca_{O_2} is normally approximately 20 mL of O_2 per 100 mL of arterial blood (when hemoglobin is 15 g/dL and Pa_{O_2} greater than 90 mmHg).

The amount of O_2 in mixed venous blood is calculated with the following equation:

$$C\bar{v}o_2 = (1.36 \times Hgb \times \%\ \text{mixed venous Hgb saturation}) + (P\bar{v}o_2 \times 0.003)$$

where $C\bar{v}_{O_2}$ is the mixed venous O_2 content, and $P\bar{v}_{O_2}$ and percent of hemoglobin saturation are obtained from mixed venous blood gas analysis of blood drawn from the distal lumen of a pulmonary artery catheter (the only site in the body with truly mixed venous blood). $C\bar{v}_{O_2}$ is normally about 15 mL of O_2 per 100 mL of mixed venous blood when hemoglobin is 15 g/dL and $P\bar{v}_{O_2}$ is 40 mmHg.

Subtraction of $C\bar{v}_{O_2}$ from Ca_{O_2} yields the arteriovenous O_2 content difference. This difference is useful in determining the relationship between O_2 delivery to the body's tissues and the O_2 demand of the tissues. Normally the difference is approximately 5 mL/dL of blood. A difference greater than 5 mL/dL of blood can be associated with low CO because the blood takes longer to traverse the capillaries in the tissues; therefore, more O_2 is extracted. A difference of less than 5 mL/dL of blood can be associated with systemic arteriovenous shunts, which allow blood to bypass the tissue capillaries; such shunts occur during hyperdynamic sepsis.

The amount of O_2 in pulmonary capillary blood is calculated with the following equation:

$$Cpco_2 = (1.36 \times Hgb \times \%\ \text{pulmonary capillary Hgb saturation}) + (Ppco_2 \times 0.003)$$

where $Cpco_2$ is the pulmonary capillary O_2 content. $Ppco_2$ (partial pressure of oxygen in the pulmonary capillary) is derived from the alveolar air equation described earlier in this chapter; the assumption is made that pulmonary capillary blood equilibrates completely with the partial pressure of oxygen in the alveolar air. The pulmonary capillary oxygen saturation cannot be measured, but is estimated by plotting the $Ppco_2$ on the oxyhemoglobin dissociation curve and determining the corresponding hemoglobin saturation. $Cpco_2$ is normally approximately 21 mL of O_2 per 100 mL of pulmonary capillary blood (when Hgb is 15 g/dL and $Ppco_2$ is 99 mmHg).

The Ca_{O_2}, $C\dot{V}_{O_2}$, and $Cpco_2$ are used in the shunt equation:

$$\dot{Q}S / \dot{Q}T = (Cpco_2 - Ca_{O_2}) / (Cpco_2 - C\bar{v}o_2)$$

In this equation, $\dot{Q}S$ is the shunt blood flow, $\dot{Q}T$ is the total blood flow (CO), $Cpco_2$ is the pulmonary capillary O_2 content, Ca_{O_2} is the arterial O_2 content, and $C\bar{v}_{O_2}$ is the mixed venous O_2 content.[28] The shunt equation estimates the fraction of cardiac output that perfuses alveoli that are absolutely nonventilated. In actuality, the shunt calculation represents the sum effects of countless lung units of varying ($\dot{V}/\dot{Q}$) relationships throughout the lung; however, the calculation is useful to monitor trends in oxygenation, help diagnose the cause of observed hypoxemia, and guide alveolar recruitment maneuvers, such as PEEP. The proof of this equation is illustrated in Figure 26-9 and lies in the assumption that if there were no shunt (Figure 26-9, *A*), all arterial blood would have been fully oxygenated in the alveolar capillaries. Therefore, ($Cpco_2 = Ca_{O_2}$), and the numerator of the equation would be zero, thus so would its quotient. On the other hand, with a theoretic 100% shunt (Figure 26-9, *B*), no blood would become oxygenated and thus ($C\bar{v}_{O_2} = Ca_{O_2}$); the difference of each from $Cpco_2$ would be the same, and the number divided by itself would equal 1.0, denoting 100% shunt. Figure 26-9, *C*, illustrates a theoretic 50% shunt, where the Ca_{O_2} equilibrates between the $Cpco_2$ and the $C\bar{v}_{O_2}$, so its difference from the $Cpco_2$ is twice that from the $C\bar{v}_{O_2}$, denoting a 0.5 shunt fraction.

One characteristic of the existence of a significant shunt proportion is hypoxemia unresponsive to supplemental oxygen administration. When blood is passing through the lungs unoxygenated, no increase in Fi_{O_2} delivered to other regions can overcome the hypoxemia (Figure 26-10). This is because under normal circumstances, those normal lung regions are already achieving 100% saturation of the hemoglobin. Therefore they cannot overcompensate for the venous admixture contributed by the shunt areas. In assessing hypoxemia, once hypoventilation and low inspired oxygen are ruled out, improvement in PaO_2 in response to supplemental oxygen favors $\dot{V}/\dot{Q}$ mismatch, as opposed to true shunt or possibly a diffusion disorder (the latter of which can be identified through a test of diffusing capacity of carbon monoxide in the lung [DLCO]).

Transport of Carbon Dioxide

The blood carries CO_2 in three forms: (1) in physical solution, (2) chemically combined with the amino acids of blood proteins, and (3) as bicarbonate ions. Approximately 5% to 10% of the total CO_2 transported in the blood is carried in physical solution. Chemical combination of CO_2 with the terminal amine groups of blood proteins forms carbamino compounds. The reaction occurs rapidly and does not require enzymes. Carbamino compounds constitute another 5% to 10% of the blood's total CO_2 content. The remaining 80% to 90% of the CO_2 in the blood is carried as bicarbonate. In the presence of carbonic anhydrase, CO_2 combines with water to form carbonic acid. The carbonic acid can dissociate into a bicarbonate ion and hydrogen (H^+) according to the following chemical reaction:

$$CO_2 + H_2O \xrightarrow{\text{carbonic anhydrase}} H_2CO_3 \rightarrow H^+ + HCO_3^-$$

When HCO_3^- leaves the blood cells, chloride ions enter to maintain electrical neutrality (the so-called "chloride shift" or "hamburger shift").[31]

Carbon Dioxide Dissociation Curve

As expected, decreases in the P_{aCO_2} correspond to a decrease in the total CO_2 content of the blood. This is because of corresponding decreases in the levels of bicarbonate and carbamino compounds. When the P_{aCO_2} falls, the amount of the total CO_2 decrease is affected by the presence of O_2 in the blood. When blood contains mainly oxygenated hemoglobin, the CO_2 dissociation curve shifts to the right, reducing the blood's capacity to hold CO_2. When the blood contains mostly deoxyhemoglobin, the curve shifts to the left, increasing the capacity to carry CO_2. This effect is known as the *Haldane effect*, and it allows the blood to load more CO_2 at the tissue level, where more deoxyhemoglobin is present, and to unload CO_2 at the lung, where more $HgbO_2$ is present (Figure 26-11).

The fact that deoxyhemoglobin is a weaker acid than $HgbO_2$ accounts for the Bohr and Haldane effects. Deoxyhemoglobin more readily accepts the H^+ produced by the dissociation of carbonic acid. This permits more CO_2 to be carried in the form of bicarbonate ions (Haldane effect). Conversely, the association of H^+ with the amino acids of hemoglobin lowers the affinity of hemoglobin for O_2, shifting the $HgbO_2$ dissociation curve to the right at low pH or high P_{CO_2} (Bohr effect).[28]

ACID-BASE BALANCE

The respiratory system plays an important role in maintaining a normal pH balance in the body. It works along with the kidneys and the buffer systems to balance the acids and bases of the blood and other body tissues, allowing them to function normally. Hydrogen ions interact with negatively charged regions of other molecules, such as proteins, altering their structural conformation and in doing so altering their behavior. Besides affecting the $HgbO_2$ dissociation curve, blood pH alters the activity of various

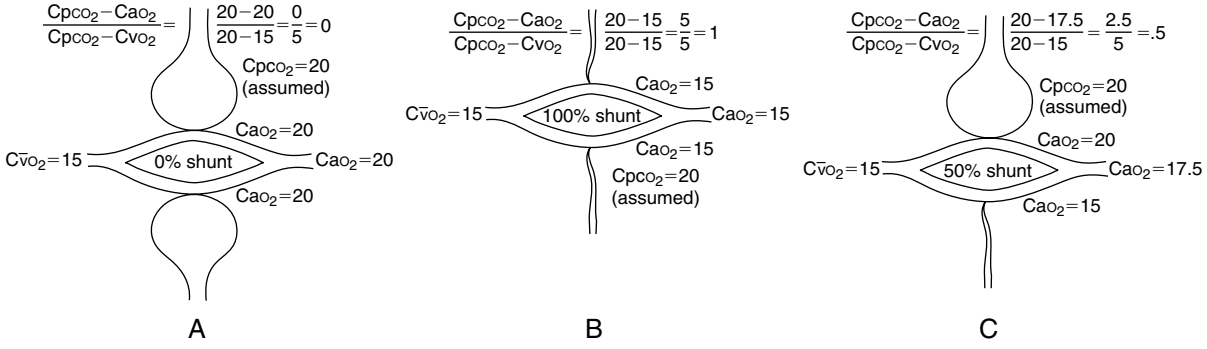

FIGURE **26-9** Calculation of the shunt fraction for various theoretic conditions. **A,** No shunt; **B,** complete shunt; **C,** 50% shunt.

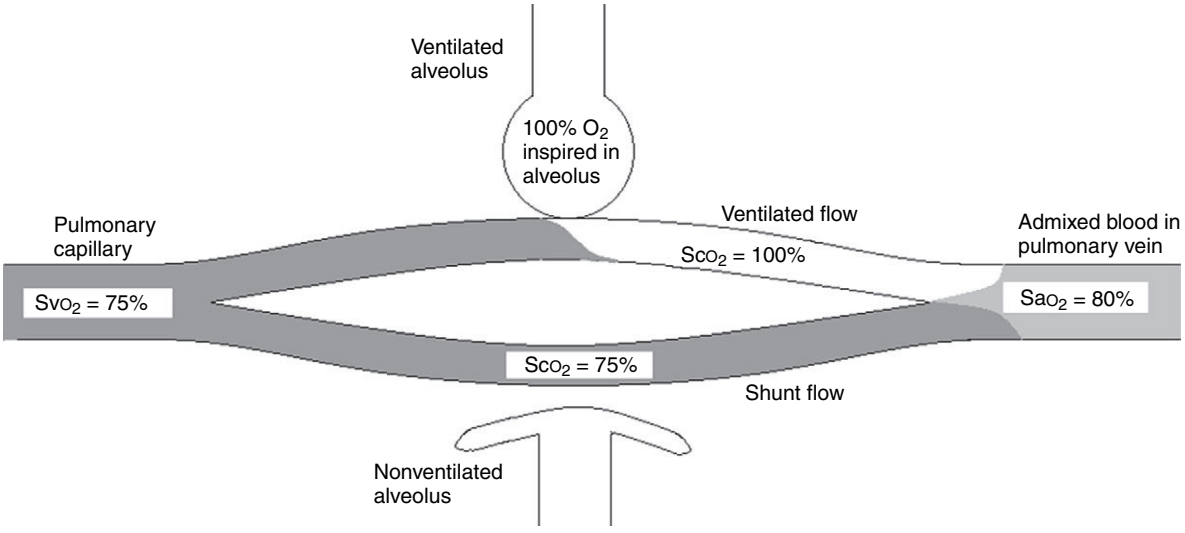

FIGURE **26-10** True shunt; unresponsiveness to supplemental oxygen. Sa_{O_2}, arterial oxygen saturation; Sc_{O_2}, capillary oxygen saturation; Sv_{O_2}, venous oxygen saturation.

enzymes, thereby changing metabolic functions in all body tissues. Severe metabolic acidosis that results from prolonged cardiopulmonary arrest must be treated with sodium bicarbonate because protein-receptor sensitivity and other enzymatic functions must be restored before epinephrine can be effective in resuscitation.

Metabolism of substances ingested as food produces mainly acidic metabolic waste products. Under normal conditions, a tremendous amount of the acid produced daily can be removed from the body by the respiratory system as exhaled CO_2. The acidic products are known as *volatile acids* because they can be converted from carbonic acid into CO_2 gas that is exhaled. Through exhalation of CO_2, the lung eliminates over 10,000 mEq/day of carbonic acid. A much smaller amount of nonvolatile or fixed acids also is produced during normal metabolic breakdown of food at the rate of approximately 100 mEq/day; these acids are primarily removed by the kidneys.[28]

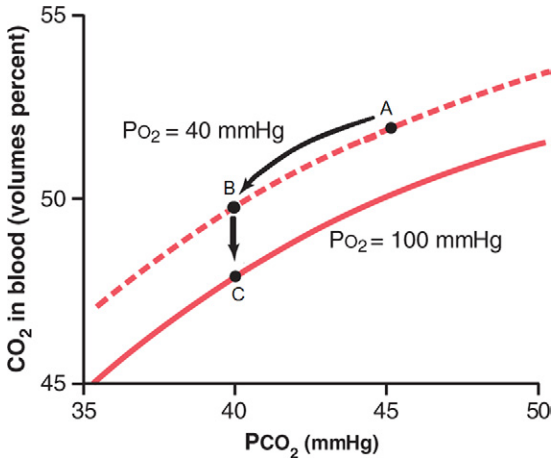

FIGURE **26-11** Carbon dioxide dissociation curve demonstrating the Haldane effect. At a P_{aCO_2} of 45 mmHg in the tissues (Point A), 52 vol% of carbon dioxide are carried in blood (including all forms). Upon entering the lungs, the drop in P_{aCO_2} would be from 52 to 50 vol% (*A-B*). However, in the presence of high oxygen concentration, CO_2 dissociation from hemoglobin is enhanced by the Haldane effect, doubling the drop in P_{CO_2} (Point *B* to Point C) to 48 vol%. (Modified from Hall JE. *Guyton and Hall Textbook of Medical Physiology.* 12th ed. Philadelphia: Saunders; 2011, p. 504.)

In addition to the efforts of the respiratory system and kidneys to regulate pH levels, buffers in the human body maintain pH in the physiologic range. The buffers consist mainly of bicarbonate, phosphate, and proteins. A buffer is a mixture of substances that usually consists of a weak acid and its conjugate base. When a strong acid or base is added to a buffer system, the changes in H^+ concentration are much smaller than those that would occur if the same amount of acid or base were added to pure water or another nonbuffered solution.

Interpretation of Arterial Blood Gases

Analysis of ABGs can provide useful information concerning the relationship of acid production and acid removal by the lungs and kidneys. Acid-base disturbances can be categorized into four major groups: respiratory acidosis, metabolic acidosis, respiratory alkalosis, and metabolic alkalosis.

Although it may seem that a great number of acid-base states are possible, actually only 11 conditions exist (Table 26-5). Blood gases in a normal individual have a pH in the range of 7.35 to 7.45, P_{aCO_2} ranges from 35 to 45 mmHg, and bicarbonate concentration is normally 22 to 26 mEq/L.

Acidosis

Any process that leads to an elevation in P_{aCO_2} tends to lower the arterial pH, resulting in respiratory acidosis. An acute change in P_{aCO_2} of 10 mmHg is associated with a change in pH of 0.08 units. An increase in P_{aCO_2} with a normal bicarbonate level is termed *uncompensated respiratory acidosis*.

TABLE 26-5 Acid-Base States

Physiologic State	pH	P_{aco_2} (mmHg)	HCO_3^- (mEq/L)	Examples
Normal	7.40 ± 0.05	40 ± 5	25 ± 4	
Uncompensated respiratory acidosis	↓↓	↑↑	↔	Acute hypoventilation (opioid overdose)
Uncompensated respiratory alkalosis	↑↑	↓↓	↔	Acute hyperventilation (neurogenic, or pain)
Uncompensated metabolic acidosis	↓↓	↔	↓↓	Metabolic acidosis with controlled mechanical ventilation (respiratory compensations not possible)
Uncompensated metabolic alkalosis	↑↑	↔	↑↑	Metabolic alkalosis with controlled mechanical ventilation
Compensated respiratory acidosis	↓	↑↑	↑↑	Chronic hypoventilation (as in chronic obstructive pulmonary disease)
Compensated respiratory alkalosis	↑	↓↓	↓↓	Chronic hyperventilation (as in chronic increased intracranial pressure)
Compensated metabolic acidosis	↓	↓↓	↓↓	Renal failure or diabetic ketoacidosis
Compensated metabolic alkalosis	↑	↑↑	↑↑	Long-term hypokalemia or bicarbonate ingestion
Mixed respiratory and metabolic acidosis	↓↓↓	↑↑	↓↓	Respiratory and circulatory arrest
Mixed respiratory and metabolic alkalosis	↑↑↑	↓↓	↑↑	"Over-resuscitation" (hyperventilation and excess bicarbonate administration)

Metabolic acidosis should more properly be referred to as *nonrespiratory acidosis* because it does not always involve alterations in metabolism. Causes of this condition include ingestion (poisoning), infusion, production of a fixed acid (lactic acidosis), and decreased excretion of acid by the kidneys. A base change of 10 mEq/L is associated with a pH change of 0.15 unit (in the absence of a change in Pa_{CO_2}). Therefore, if the bicarbonate level increases by 10 mEq/L, then the pH also increases by 0.15 unit. A decrease in bicarbonate level when the P_{CO_2} remains at approximately 40 mmHg is termed *uncompensated metabolic acidosis*. The combination of respiratory acidosis and metabolic acidosis is termed *mixed acidosis* and can produce a drastically decreased arterial pH.

Alkalosis

When alveolar ventilation exceeds that necessary to keep up with CO_2 production in the body, both P_{ACO_2} and Pa_{CO_2} decrease to below 35 mmHg. As the pH rises, this hyperventilation results in respiratory alkalosis. Elevated pH accompanied by a decrease in Pa_{CO_2} in the presence of a normal bicarbonate level is termed *uncompensated respiratory alkalosis*. The relationship between alveolar ventilation and CO_2 production that results in hyperventilation can occur because of an increase in alveolar ventilation or a decrease in CO_2 production, as occurs with hypothyroidism or hypothermia, if alveolar ventilation is maintained at normal levels.

Metabolic alkalosis occurs when fixed acid loss is increased or when the intake of bases is abnormally high. Elevated pH accompanied by above-normal increases in the bicarbonate level when the P_{CO_2} is maintained at approximately 40 mmHg is termed *uncompensated metabolic alkalosis*. The combination of respiratory alkalosis and metabolic alkalosis produces mixed alkalosis, in which the arterial pH is markedly elevated.

Compensatory Mechanisms

The respiratory system can rapidly compensate for metabolic acidosis or alkalosis by altering alveolar ventilation. It normally occurs because changes in blood H^+ concentrations affect the chemoreceptors, which in turn increases or decreases alveolar ventilation, altering Pa_{CO_2} within minutes. The kidneys can compensate for respiratory acidosis and metabolic acidosis of nonrenal origin by excreting fixed acid and retaining bicarbonate. Conversely, the kidneys compensate for respiratory alkalosis or metabolic alkalosis of nonrenal origin by decreasing H^+ excretion and decreasing retention of bicarbonate. Renal compensatory mechanisms act more slowly than do respiratory mechanisms and may take several days. When evaluating blood gas analyses, *compensated acidosis* involves finding abnormalities of both the CO_2 and the HCO_3^- in the same direction, with the pH below 7.4 but above 7.35. Conversely, *compensated alkalosis* involves finding abnormalities of both the CO_2 and the HCO_3^- in the same direction, with a pH above 7.4 but less than 7.45. Ascribing the abnormality to respiratory or metabolic is then based upon which abnormality (CO_2 or HCO_3^-) in their present level would be responsible for the directional change in pH (toward acidosis or alkalosis). In spite of observing a compensatory change in CO_2 or bicarbonate, an acid-base disorder is considered *uncompensated* if that mechanism has not been able to bring the pH back into a normal range. Compensation will not "overshoot" and create a pH disorder in the other direction, because the drive for compensatory mechanisms is diminished as the pH approaches normal. Acid-base disorders wherein the CO_2 and HCO_3^- are both abnormal in different directions (one high, the other low) are termed *mixed acidosis* or *alkalosis*.

Treatment of Blood Gas Abnormalities

For the patient being mechanically ventilated, respiratory acidosis and respiratory alkalosis can be treated with a simple increase or decrease in the amount of alveolar ventilation. Respiratory acidosis should not be treated with sodium bicarbonate, because through the reversible reaction in the equation on p. 607, the bicarbonate dissociates into more CO_2, worsening the acidosis. To restore a stable spontaneous circulation, mild to moderate metabolic acidosis can be treated with hyperventilation and correction of shock. Certain types of severe metabolic acidosis (pH less than 7.20) may be treated with sodium bicarbonate. The total body bicarbonate deficit equals the base deficit (in mEq/L) that is obtained from the blood gas values: the patient's bicarbonate level is subtracted from the normal bicarbonate level; the difference is multiplied by the patient's weight (in kilograms) and then by 0.3 (which is equal to the extracellular fluid compartment and the volume of distribution for bicarbonate). Complete correction of the base deficit is not indicated; only half of the calculated dose of bicarbonate is recommended as an initial dose. Severe lactic acidosis is treated with bicarbonate, but the acidosis associated with renal failure is better treated with dialysis. The hyperosmolarity and high sodium content of bicarbonate are usually contraindicated for patients with renal failure.

CONTROL OF BREATHING

The respiratory centers in the brainstem control breathing by automatically generating a cycle of inspiration and expiration (Figure 26-12). This spontaneously generated cycle can be modified by reflexes or by higher centers in the brain. The respiratory centers affect the nerves of the spinal cord, which innervate the muscles of respiration (the cervical branches of the spinal nerves C3, C4, and C5 form the phrenic nerves, which innervate the diaphragm). The spontaneous respiratory rhythm is generated by the medullary respiratory center, which is found in the reticular formation of the medulla under the floor of the fourth ventricle. The dorsal respiratory group and ventral respiratory group are dense aggregations of respiratory neurons located in the *tractus solitarius*. This area contains projections of cranial nerves IX and X and processes signals related to chemoreceptors, lung stretch receptors, gag and cough reflexes, and others. The dorsal respiratory group is considered the

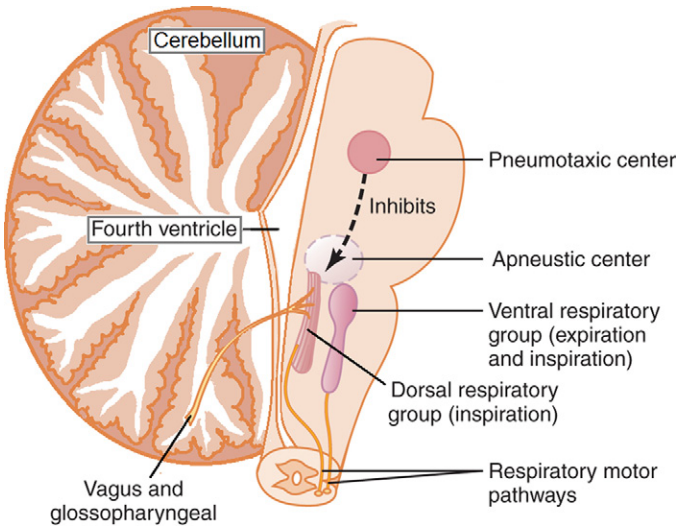

FIGURE **26-12** Organization of the respiratory center. (Adapted from Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 12th ed. Philadelphia: Saunders; 2011:506.)

pacemaker of normal breathing—the area that drives respiration. The ventral respiratory group contains neurons controlling inspiration and expiration, but is quiescent during normal respiration. The pons contains the apneustic center (in the lower pons) and the pneumotaxic center (in the upper pons), both of which modify the output of the medullary respiratory center. The normal function of the apneustic center is unknown, but if it is severed, the result is "apneustic breathing"—prolonged inspiration with occasional expiration. The pneumotaxic center is thought to be the inspiratory "cut-off" switch, which functions to smooth the respiratory pattern.

The activity of the brainstem's breathing centers is modulated by information received from afferent spinal nerves and higher brain centers, as occurs in voluntary control of breathing. Additionally, a great number of sensors in the lungs, cardiovascular system, muscles, tendons, skin, and viscera can affect the control of breathing by eliciting reflex changes. Stimulation of stretch receptors in the lungs can elicit three respiratory reflexes: the Hering-Breuer inflation reflex, the Hering-Breuer deflation reflex, and the paradoxical reflex of Head. The Hering-Breuer inflation reflex may help prevent overdistention of the alveoli at high lung volumes by inhibiting large V_Ts and may decrease the frequency of the inspiratory efforts by causing a transient apnea. The Hering-Breuer deflation reflex may be responsible for the increased ventilation elicited when the lungs are deflated abnormally, such as in pneumothorax, or it may have a role in the periodic spontaneous deep breaths (sighs) that help to prevent atelectasis. The paradoxical reflex of Head results during partial block of the vagus nerves, such that lung inflation results in further deep inspiration instead of the apnea expected when the vagus nerve is fully functional. This reflex may be involved in generating the first breath of the newborn baby.[32]

Chemical or mechanical irritation of the airways may elicit a reflex cough or sneeze, hyperpnea, bronchoconstriction, and increased blood pressure. The vagus nerve provides afferent pathways for all of the airway's irritant receptors, except for the nasal mucosa receptors, which send information centrally by means of the trigeminal and olfactory tracts. Pulmonary embolism (PE) typically causes rapid, shallow breathing, whereas pulmonary vascular congestion causes hyperpnea. The vascular receptors that initiate these responses are named *J receptors* (for "juxtapulmonary capillary"). Stimulation of receptors in the muscles, tendons, and joints can also increase ventilation during exercise. Elevated blood pressure stimulates the arterial (carotid and aortic) baroreceptors, resulting in apnea and bronchodilation. Somatic pain tends to cause hyperpnea, whereas visceral pain usually causes apnea or decreased ventilation. Stimulation of the arterial chemoreceptors by decreased Pa_{O_2}, increased Pa_{CO_2}, or low pH tends to increase lung inflation and cause hyperpnea, bronchoconstriction, and an increase in blood pressure. Table 26-6 summarizes the respiratory control reflexes.

Chemical Control of Breathing

The arterial and cerebrospinal fluid partial pressures of CO_2 are probably the most important inputs to the brainstem centers for establishing the ventilatory rate and V_T. Hypoxemia potentiates the ventilatory response to CO_2. Its effect is that for any particular Pa_{CO_2}, ventilatory response becomes greater as the Pa_{O_2} decreases. Opioids and hypnotic drugs (Figure 26-13) may profoundly depress

TABLE 26-6 Reflex Mechanism of Respiratory Control

Stimulus	Reflex	Receptor	Afferent Pathway	Effects
Lung inflation	Hering-Breuer inflation reflex	Stretch receptors within smooth muscles of large and small airways	Vagus	Respiratory—cessation of inspiratory effort, apnea, or decreased breathing frequency; bronchodilation; Cardiovascular—increased heart rate; slight vasoconstriction
Lung deflation	Hering-Breuer deflation reflex	Possibly J receptors, irritant receptors in lungs, or stretch receptors in airway	Vagus	Respiratory—hyperpnea
Lung inflation	Paradoxical reflex of head	Stretch receptors in lungs	Vagus	Respiratory—inspiration
Negative pressure in upper airway	Pharyngeal dilator reflex	Receptors in nose, mouth, upper airways		Respiratory—contraction of pharyngeal dilator muscles
Mechanical or chemical irritation of airways	Cough	Receptors in upper airways, tracheobronchial tree	Vagus	Respiratory—cough; bronchoconstriction
	Sneeze	Receptors in nasal mucosa	Trigeminal, olfactory	Respiratory—sneeze; bronchoconstriction; Cardiovascular—increased blood pressure
Face immersion	Diving reflex	Receptors in nasal mucosa and face	Trigeminal	Respiratory—apnea; Cardiovascular—decreased heart rate; vasoconstriction
Pulmonary embolism		J receptors in pulmonary vessels	Vagus	Respiratory—apnea or tachypnea
Pulmonary vascular congestion		J receptors in pulmonary vessels	Vagus	Respiratory—tachypnea, possible sensation of dyspnea
Specific chemicals in the pulmonary circulation	Pulmonary chemoreflex	J receptors in pulmonary vessels	Vagus	Respiratory—apnea or tachypnea; bronchoconstriction
Low Pa_{O_2}, high Pa_{CO_2}; low pH	Arterial chemoreceptor reflex	Carotid bodies, aortic bodies	Glossopharyngeal, vagus	Respiratory—hyperpnea; bronchoconstriction, dilation of upper airway; Cardiovascular—decreased heart rate, vasodilation, etc.

TABLE 26-6 Reflex Mechanism of Respiratory Control—cont'd

Stimulus	Reflex	Receptor	Afferent Pathway	Effects
Increased systemic arterial blood pressure	Arterial baroreceptor reflex	Carotid and aortic arch stretch receptors	Glossopharyngeal, vagus	Respiratory—apnea, bronchodilation; Cardiovascular—decreased heart rate, vasodilation
Increased systemic arterial blood pressure		Muscle spindles, tendon, organs, proprioceptors	Various spinal pathways	Respiratory—provide respiratory controller with feedback about work of breathing; stimulation of proprioceptors in joints causes hyperpnea
Somatic pain		Pain receptors	Various spinal pathways	Respiratory—hyperpnea Cardiovascular—increased heart rate, vasoconstriction

the ventilatory response to CO_2. Chronic obstructive pulmonary disease (COPD) also depresses the ventilatory response to hypercapnia, so the hypoxic drive may be more prominently responsible for maintaining spontaneous breathing in these patients, and administering high FiO_2 may reduce their spontaneous ventilatory drive. Metabolic acidosis shifts the CO_2 curve to the left, so that for any particular PCO_2, ventilation is increased during metabolic acidosis.

A depressed or abnormal response to CO_2 during sleep may be involved in central sleep apnea (characterized by pauses of at least 10 seconds' duration between breaths, with cessation of respiratory effort).[33] Central sleep apnea, which possibly is caused by a defect in the chemoreceptors or brainstem respiratory control center, may be an important contributor to sudden infant death syndrome.

Increased $PaCO_2$ and decreased PaO_2 and arterial pH stimulate the arterial (peripheral) chemoreceptors, with the carotid bodies apparently exerting a much greater influence on the medullary respiratory centers than the aortic bodies. The afferent nerve from the carotid body is Hering's nerve, a branch of the glossopharyngeal nerve. The afferent pathway from the aortic body is the vagus nerve. The central chemoreceptors are in contact with cerebrospinal fluid but are not directly exposed to arterial blood (because of the blood-brain barrier). CO_2 is rapidly diffusible through the blood-brain barrier; therefore, changes in $PaCO_2$ are rapidly transmitted to the cerebrospinal fluid, taking less than 2 minutes. Hydrogen ions and bicarbonate ions are slowly diffusible through the blood-brain barrier, so changes in arterial pH that do not result from changes in PCO_2 take considerably longer to affect the cerebrospinal fluid. The central chemoreceptors are located just beneath the surface of the medulla. They are not stimulated by hypoxia; their activity may even be suppressed by it. The central chemoreceptors are majorly responsible for determining the resting ventilatory level and long-term maintenance of blood CO_2 levels. The central chemoreceptors contribute about two thirds of the ventilatory response, whereas the peripheral chemoreceptors contribute the remaining one third and may be more important in short-term responses to CO_2.[34]

RESPIRATORY SYSTEM PATHOLOGY

OBSTRUCTIVE SLEEP APNEA

Definition

Obstructive sleep apnea (OSA) is a mechanical obstruction to breathing that occurs during sleep, when pharyngeal musculature relaxes. It is characterized by episodes of breathing cessation that last 10 or more seconds. Obesity hypoventilation syndrome (OHS) is a distinct entity from OSA. It is defined as the triad of obesity, daytime hypoventilation, and sleep-disordered breathing without an alternative neuromuscular, mechanical, or metabolic cause.

Incidence and Outcome

OSA occurs in 2% to 4% of the population[35] and affects more than twice as many men as women.[36] Obesity is the most significant precipitating factor, with OSA being noted in 70% of patients presenting for bariatric surgery.[36] OSA is becoming increasingly prevalent in children and bears many of the same characteristics as observed in adults.[37] Between 7% and 10% of children are habitual snorers, and OSA is estimated to exist in 1% to 3% of preschool-aged children.[38] OSA is associated with increased postoperative complications and is an independent risk factor for increased morbidity and mortality.[36]

Etiology and Pathophysiology

The primary causative factor for OSA is obesity, although it can exist in nonobese individuals. Factors in the pharyngeal musculature cause collapse during sleep under negative inspiratory pressure. Chronic hypoxemia and hypercarbia lead to an inflammatory state and a variety of secondary pathologies. OSA has been linked as a causative factor in atherosclerosis, hypertension, stroke, insulin resistance, diabetes, dyslipidemia, and other disorders (Table 26-7).[39,40]

Clinical Features and Diagnosis

Patients with sleep apnea often present with multiple comorbidities related to their obesity or to chronic hypoxemia from the apneic disorder. Common comorbidities include systemic and pulmonary hypertension, ischemic heart disease, and congestive heart failure. A hallmark of OSA is habitual snoring and fragmented sleep, which can lead to daytime somnolence.

Polysomnography (see below) provides an objective measure of sleep apnea, but it is expensive and impractical to apply to every patient with risk factors who presents for surgery. A number of questionnaires such as the Berlin questionnaire have been developed as screening tools for OSA. These provide a low-cost, simple approach to identifying OSA. The components of the STOP questionnaire are as follows: S, snore loudly; T, daytime tiredness; O, observed to stop breathing during sleep; P, high blood pressure. The STOP questionnaire is often paired with four additional variables of the Bang questionnaire: B, body mass greater than 35 kg/m^2; A, age older than 50 years; N, neck circumference greater than 40 cm; G, male gender). Used together, the STOP-Bang questionnaire demonstrates sensitivity of nearly 100% and specificity of approximately 40%.[36] See Chapter 43, Box 43-2.

Polysomnography is used to establish the diagnosis of OSA, which is based upon is the number of abnormal respiratory events per hour of sleep (the apnea plus hypopnea index—AHI). Diagnostic criteria vary among institutions, but an index of greater than 5 if associated with sleep-related symptoms, or an index of greater than 15 alone are diagnostic for the condition.[35] The AHI also describes severity, with AHI greater than 15 being moderate, and AHI greater than 30 being severe.[35]

Treatment

Weight loss is an important goal for the obese patient with OSA. Some surgical procedures are used to relieve the physical obstruction, such as uvulopalatopharyngoplasty in adults and adenotonsillectomy in pediatric patients.[37,41] The use of continuous positive airway pressure (CPAP) devices has become common in the management of OSA. CPAP devices use a facemask held tightly to the face during sleep with a hose attached to the machine that provides positive airway pressure by means of an electrically powered air pump. This pressure tents the airway open, relieves the obstruction, and promotes more continuous breathing and sleep. Adjunctive therapy includes analeptic drugs such as modafinil and armodafinil, methylxanthines, doxapram, serotonin modulators, tricyclic antidepressants, and others. Drug therapy is intended to reduce daytime sleepiness, reduce cardiovascular complications,[42] strengthen pharyngeal musculature, and reduce REM (rapid eye movement) sleep, among other effects.[43]

TABLE 26-7 Comorbidities Associated with OSA

Category	Condition	Prevalence (%)
Cardiac	Treatment-resistant hypertension	63-83
	Congestive heart failure	76
	Ischemic heart disease	38
	Atrial fibrillation	49
	Dysrhythmias	58
Respiratory	Asthma	18
	Pulmonary hypertension	77
Neurologic	First-ever stroke	71-90
Metabolic	Type 2 diabetes mellitus	36
	Metabolic syndrome	50
	Hypothyroidism	45
	Morbid obesity	50-90
Surgical	Bariatric surgery	71
	Intracranial tumor surgery	64
	Epilepsy surgery	33
Others	Gastroesophageal reflux disease	60
	Nocturia	48
	Alcoholism	17
	Primary open-angle glaucoma	20
	Head and neck cancer	76

OSA, Obstructive sleep apnea.

Anesthetic Management

Careful airway evaluation is the first step in management. Redundant tissue in the neck region is common in OSA (even more so than in general obesity) and may impede effective head positioning, mask ventilation, or laryngoscopy. The anesthetist should anticipate airway difficulty and rapid desaturation from reduced FRC. Preoperatively, sedative medications should be used cautiously. As a result of central nervous system sensitization, patients may be hypersensitive to effects of benzodiazepines and opioids. Effective doses may be extremely small. The same concerns apply postoperatively. Extubation must be undertaken carefully, when indications are that the patient will maintain a patent airway. In the recovery area, vigilance must be afforded to the potential for airway obstruction from residual anesthetic effects, which heighten the preexisting sensitivity to respiratory depressant drugs. Airway obstruction occurs in 25% of pediatric patients with OSA after tonsillectomy, in contrast to 1% of those without OSA.[38] Analgesics and general somnolence may lead to airway obstruction in the recovery area. Multimodal analgesia and regional techniques may help limit the need for systemic opioids.

Patients with moderate to severe OSA should be provided with additional monitoring postoperatively. This may include longer postanesthesia care unit (PACU) time, admission to a monitored bed, prolonged Spo_2 (pulse oximetry) monitoring, and disqualification from same-day discharge, depending on the patient condition.[36] CPAP is helpful in the PACU, and patients who use this treatment at home should be encouraged to bring their device for use in the postanesthetic period.

PULMONARY FUNCTION TESTING

An understanding of pulmonary function evaluation will be helpful before discussing pathologies that involve airflow limitations. A number of examinations may be performed to evaluate lung volumes and the inspiratory and expiratory flow of gas. Many of these are derived by having the patient breathe through a closed circuit with measurement of gas flow and composition. Measurement of pulmonary volume over time is called *spirometry*. A glossary of static lung volumes and capacities is presented in Table 26-4. A standard flow-volume loop is drawn in a clockwise direction, with inspiratory flow below the x-axis, and expiratory flow above it. Flow rates (in liters per second) are represented on the y-axis (see Figure 26-4). The zero point on the x-axis represents full inspiration, because the lungs cannot be totally emptied due to the residual volume. In Figure 26-4, the scale below the x-axis provides corresponding approximate absolute values of lung volume. The most important portion of the loop in most cases is the expiratory flow and volume that begins at this point and ends when the loop reaches the x-axis again as it transitions to inspiratory flow.

Values for an individual's flow and volume pattern are measured in absolute terms, and are also compared to "predicted" values based upon performance of healthy subjects with similar anthropometric characteristics (age, gender, and height, and sometimes other factors such as weight and race).

Spirometry is based on a forced air capacity (FVC) maneuver, which requires concerted patient effort; a lack of effort may produce erroneous results.[44] The FVC is divided into several time intervals, of which the FEV_1 (forced expired volume in 1 second) is the most reproducible. The volume of air that is exhaled in 1 second from a maximal inspiration is measured as the FEV_1. Patients with increased airway resistance exhibit decreased FEV_1 and FEV_1/FVC ratios. Normal FEV_1 varies with age, declining as age increases.[45] Normally, the FEV_1 volume is at least 80% of the vital capacity, an important point that is used to differentiate low FEV_1 due to obstruction from low FEV_1 due to restrictive disease (in which later case the vital capacity is also reduced, and the ratio of FEV_1/FVC is preserved).

Respiratory activity represented by the midportion of the expiratory curve is the most effort-independent and the most sensitive indicator of small airway disease. The parameter measured is the $FEF_{25\%-75\%}$ or the forced expiratory flow rate between 25% and 75% of the exhaled breath. The normal $FEF_{25\%-75\%}$ of 4 to 5 L/sec may decrease markedly in those with pulmonary disease, with early changes evident sooner in patients with obstructive disease than in those with restrictive disease. Reduction in the $FEF_{25\%-75\%}$ wherein the curve begins to take a concave shape, usually appears before significant change occurs in the FEV_1.[44] It is not as reproducible as the FEV_1, but it is more sensitive to airway obstruction.[46]

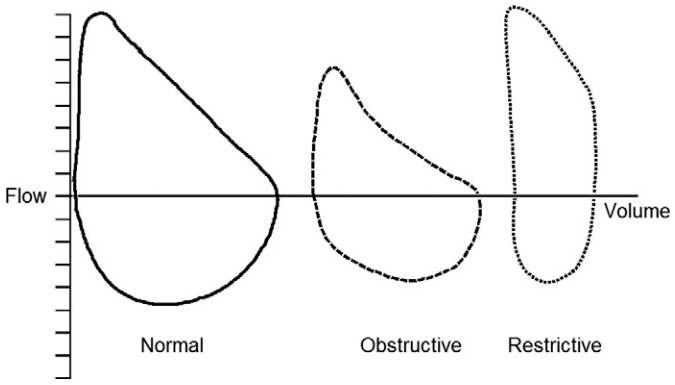

FIGURE **26-14** Flow-volume loops in disease. Characteristic deformities of pulmonary flow-volume loops related to obstructive and restrictive disease.

Flow-volume loops also provide information about disease processes through characteristic shapes (Figure 26-14). Obstructive disease is characterized by a reduced peak flow rate and a sloping of the expiratory limb. This occurs as small airways close during expiration, noticeably reducing the flow rate during expiration. Restrictive disease is characterized by normal or heightened peak expiratory flows, but a very narrow loop, reflecting the reduced vital capacity. Obstructions to airflow also may be variable, as in tracheomalacia, such that changes in pressure may both augment and reverse the obstruction in the course of each respiratory cycle. In this case, the location of the lesion (being intrathoracic or extrathoracic) determines whether the obstruction will be opened or compressed by inspiration or expiration (Figure 26-15). Airway obstructions lead to characteristic patterns on a flow-volume tracing, as well (Figure 26-16).

The diffusion capacity (DL) is another form of pulmonary function testing that assesses the ability of gas to traverse the alveolar-capillary membrane. Factors related to Fick's law of diffusion correlate the diffusion capacity to clinical conditions; that is, thickness of the membrane (fibrosis) and surface area for diffusion (emphysema). The diffusion capacity is also influenced by ventilation-perfusion matching. The DL test is commonly performed by having the patient inhale a single breath containing a small amount of carbon monoxide. Carbon monoxide is highly diffusible and binds avidly with hemoglobin, so that any reduction in transfer to the blood is indicative of loss of surface area of the alveolar-capillary membrane.[46] The diffusion capacity for carbon monoxide (DLCO) is reported as the uptake of CO in mL/min/mmHg or as a percentage of predicted value.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The American Thoracic Society and European Respiratory Society define chronic obstructive pulmonary disease (COPD) as a "preventable and treatable disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases…"[47] COPD should be considered in any patient with ongoing cough, sputum production, or dyspnea with history of exposure to risk factors. Diagnosis is made by spirometric demonstration of airflow obstruction that is not fully reversible (post-bronchodilator FEV_1/FVC ratio less than 0.7).[48]

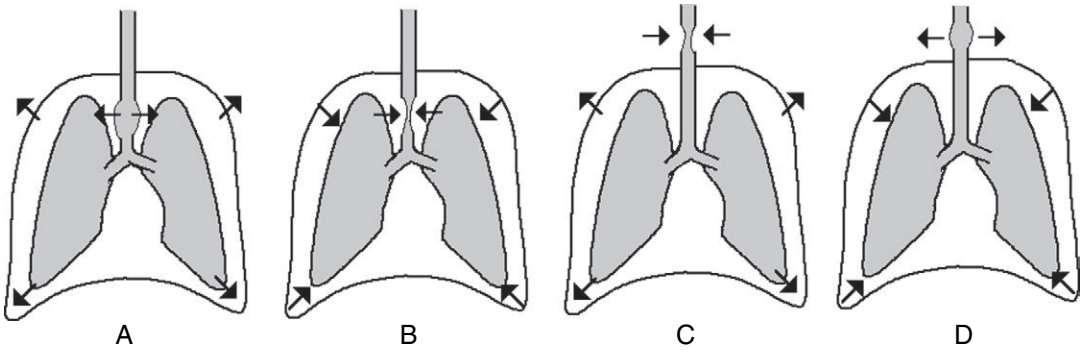

FIGURE **26-15** Variable airway obstructions during spontaneous respiration. A variable intrathoracic obstruction will be subjected to negative pressure during inspiration and will be tented open (**A**); however, as intrathoracic pressure rises during expiration, an intrathoracic obstruction will be compressed (**B**). A variable extrathoracic obstruction will be subjected to negative intratracheal pressure during inspiration and will be compressed (**C**); however, as intratracheal pressure rises during expiration, the extrathoracic obstruction will be pushed open (**D**).

The terms *chronic obstructive pulmonary disease* and *chronic obstructive lung disease* are widely used as synonyms for pathology involving airflow obstruction that does not change over months to years. COPD is caused by a mixture of small airways disease and parenchymal destruction in various combinations and proportions from one individual to the next. Two specific disorders, emphysema and chronic bronchitis, provide the prototypes of pathologic changes in COPD. Emphysema is characterized by the destruction of parenchyma that leads to loss of surface area, elastic recoil, and structural support to maintain airway patency. Bronchitis is characterized by narrowing of small airways by inflammation and mucous production. There are also numerous chronic conditions referred to collectively as *peripheral airways disease* or *small airways disease*. These entities are not mutually exclusive; peripheral airway disease often precedes onset of emphysema, and chronic bronchitis and emphysematous changes often coexist to define COPD. As a rule, COPD is observed most often in individuals with an extensive history of smoking, and the disease process takes 30 years or longer to manifest. Other chronic diseases such as cystic fibrosis, tuberculosis, and bronchiectasis are not included in the definition of COPD,[47] nor are restrictive diseases of scoliosis, other forms of pulmonary fibrosis, or obesity. Differential diagnosis of COPD compared with other common lung disorders is noted in Table 26-8.

Definition

Peripheral airways disease involves inflammation of the terminal and respiratory bronchioles, fibrosis and narrowing of the airway walls, and goblet cell metaplasia.[49] A small sampling of conditions that are characterized as small airways disease includes sarcoidosis, Wegener granulomatosis, mineral dust–associated airways disease, disease from exposure to fumes and toxins, and bronchocentric granulomatosis.[50] Chronic bronchitis refers to chronic or recurrent excess mucous secretion occurring on most days for at least 3 months of the year for at least 2 successive years.[49] A critical element is the presence of airway obstruction of expiratory airflow. Emphysema is defined as "a condition of the lung characterized by abnormal permanent enlargement of the air spaces distal to the terminal bronchiole, accompanied by destruction of their walls and without obvious fibrosis."[49] Destroyed alveolar tissue is largely incapable of regeneration, and therefore the changes that occur in emphysema are irreversible. Emphysema is subclassified as centrilobular, or panlobular. In centrilobular emphysema, dilation predominantly affects the respiratory bronchioles in the upper lung lobes. In panlobular emphysema, tissue destruction is widespread, affecting all areas of the acinus (the cells that define the "berry-bunch" shape of the alveoli) and distributed throughout the lung.[44] Destruction of tissue in emphysema leads to four primary alterations in pulmonary function: (1) increases in size of acini causes compression of adjacent small airways and increases airflow resistance; (2) consolidation of alveoli leads to loss of alveolar surface area and impairs gas diffusion; (3) heterogeneity of disease in different parts of the lungs leads to mismatch of ventilation and perfusion; and (4) loss of alveolar walls also decreases the amount of pulmonary capillaries, resulting in greater work on the right ventricle.[4]

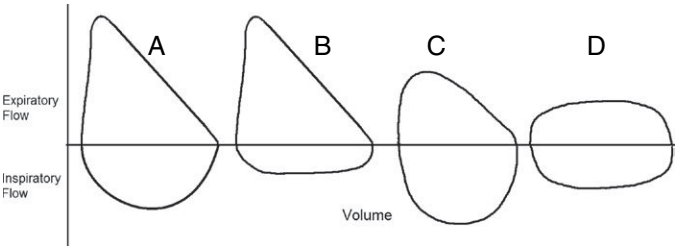

FIGURE **26-16** Flow-volume loops with airway obstructions. The dynamic effects of variable airway obstructions will be reflected in flow-volume loops in comparison to a normal tracing (**A**). An intrathoracic obstruction will be compressed during expiration, thus the expiratory curve will be affected (**B**). An extrathoracic obstruction will be collapsed during inspiration, thus the inspiratory portion of the curve will be affected (**C**). With a fixed obstruction (as in a foreign body in the airway), airflow will be reduced during both phases of breathing, and peak flow rates of inspiration and expiration will be reduced (**D**).

Incidence and Outcome

Chronic obstructive pulmonary disease affects more than 5% of adult Americans and is the third leading cause of death.[48] Chronic bronchitis and emphysema are the most common causes of COPD. The social and economic impacts of COPD are enormous. Patients in advanced stages of obstructive lung diseases are unable to work and frequently cannot participate in activities of daily living. Even in milder cases, activities often are restricted. The economic cost of COPD is estimated to be over $50 billion in the United

TABLE **26-8** Differential Diagnosis of COPD

Diagnosis	Suggestive Features*
COPD	Onset in midlife; symptoms slowly progressive; long-term smoking history; dyspnea during exercise; largely irreversible airflow limitation
Asthma	Onset early in life (often childhood); symptoms vary from day to day; symptoms occur at night or in early morning; allergy, rhinitis, or eczema also present; family history of asthma; largely reversible airflow limitation
Congestive heart failure	Fine basilar crackles on auscultation; chest radiograph shows dilated heart, pulmonary edema; pulmonary function tests indicate volume restriction, not airflow limitation
Bronchiectasis	Large volumes of purulent sputum; commonly associated with bacterial infection; coarse crackles or clubbing on auscultation; chest radiograph or CT scan shows bronchial dilation, bronchial wall thickening
Tuberculosis	Onset at all ages; chest radiograph shows lung infiltrate or nodular lesions; microbiologic confirmation; high local prevalence of tuberculosis, or known exposure
Obliterative bronchiolitis	Onset at younger age, in nonsmokers; may have history of rheumatoid arthritis or fume exposure; CT scan taken on expiration shows hypodense areas
Diffuse panbronchiolitis	Most patients are male and nonsmokers; almost all have chronic sinusitis; chest radiograph and HRCT scan show diffuse small centrilobular nodular opacities and hyperinflation

From Rable KF, et al. Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. *Am J Respir Crit Care Med.* 2007;176:532-555.
*These features tend to be characteristic of the respective diseases but do not occur in every case. For example, a person who has never smoked can develop COPD (especially in developing countries, where other risk factors may be more important than cigarette smoking); asthma can develop in adult and even elderly patients.
COPD, Chronic obstructive pulmonary disease; *CT*, computed tomography; *HRCT*, high-resolution computed tomography.

States.[48] Death related to COPD is not only from respiratory failure, but also associated with related comorbidities such as lung cancer and heart disease.[51]

Etiology and Pathophysiology

In general, COPD appears to be an exaggerated inflammatory reaction in the lungs. The principal factor that predisposes a patient to the development of COPD is cigarette smoking.[51] Environmental pollution appears to have some role, but its effects are minor compared with those of cigarette smoking, particularly as the disease occurs in the United States. COPD may develop in some patients because of an imbalance between protease and antiprotease activities in the lungs; α_1-antitrypsin deficiency is the primary genetically related cause. In people with this deficiency, smoking causes release of neutrophil elastase that is inadequately inhibited because of the deficient levels of α_1-antitrypsin. This results in degradation of pulmonary connective tissue and in the early development of COPD.[52] Unfortunately, α_1-antitrypsin administration is expensive and has not demonstrated good results as a treatment.[52,53]

The dominant feature of the natural history of COPD is progressive airflow obstruction, as reflected by a decrease in FEV_1. Three causes of decreases in FEV_1 are as follows: (1) a decrease in the intrinsic size of bronchial lumina; (2) an increase in the collapsibility of bronchial walls (this cause is the most difficult to quantify); and (3) a decrease in elastic recoil of the lungs.[44] Distinct morphologic changes can be found in the airways of patients exposed to ongoing inflammatory challenges. In chronic bronchitis, a proliferation of the compound tracheobronchial mucous glands occurs in the subepithelial layers of the airway wall. Excessive airway mucus and thickened airway walls cause a narrowing of the functional airflow channel. Airway narrowing in COPD is primarily related to a thickening of the airway walls, and not an increase in smooth muscle tone, as is more prominently observed in asthma. Destruction of parenchyma results in a loss of elastic support, which also contributes to airway narrowing.[54] Although COPD is defined as being irreversible, contemporary science is focusing on the limited amount of reversibility that can improve patients' quality of life and slow progression of the disease. Between 25% and 50% of patients with COPD also have enhanced airway reactivity.[55] While bearing similarities to asthmatic bronchial reactivity, it appears that in COPD, airway hyperresponsiveness affects small airways more so than larger ones.[56]

The defense system of a patient with COPD is disrupted by the excessive production of mucus and by paralysis of the mucociliary transport system, which leads to microbial colonization. The presence of microbial organisms in the airway secretions of patients with chronic bronchitis is common and does not necessarily imply the presence of an acute infection. Instead, chronic colonization of the airway plays a cyclic role in the ongoing pathogenesis of COPD, whereby bacteria increase mucous production, reduce ciliary motility, cause influx of neutrophils that lead to fibrosis, alter the host response to cigarette smoke, induce a chronic inflammatory response, and enhance airway reactivity.[57] General changes in lung functioning from COPD include the following:

1. Destruction of lung connective tissue that normally provides elastic pull on the outsides of bronchi and bronchioles reduces the tethering of airways of the pulmonary interstitium, leads to premature collapse of the airways from external pressure, and increases the unevenness of distribution of inspired air to different regions of the lungs. Consequently, the exchange of CO_2 and O_2 between the blood and alveolar air is impeded. Compensation for lower diffusion of gases is partly achieved via collateral ventilation by diffusion across alveolar walls.[58]
2. Injury and inflammation of the bronchial tubes and alveoli increase the resistance to airflow during both inspiration and expiration. More forceful breaths or quicker breaths are needed for maintaining even normal levels of ventilation.[59]
3. Lung compliance increases with the tissue damage, and the airways' narrowing and greater collapsibility impede the ability of the ventilatory muscles to empty the lung completely. Hyperinflation results, raising the resting end-expiratory position of the lungs. Because the lung is more expanded, the inspiratory muscles operate from a shorter initial length and produce less force when shortened.
4. The more horizontally placed diaphragm is less able to lift the rib cage. The diaphragm may contract ineffectively, such that the abdomen moves inward rather than outward with each inspiration.[60]
5. Because of the increased demands for work output placed on the respiratory muscles, the energy requirement of these muscles escalates. A greater proportion of the cardiac output goes to these muscles. If hypoxemia is present and increased ventilation is required (e.g., as in exercise), the energy supply of the muscles may become inadequate, and respiratory muscle fatigue ultimately is produced.[61]
6. The expansion of the lung and thorax also misaligns the intercostal muscles and accessory respiratory muscles. To compensate, patients may assume special postures, such as leaning forward.[62]
7. Inflammation allows noxious agents in the air to reach the more deeply located tissues in the lung and gain access to blood vessels, macrophages, mast cells, and nerves in the lung. Airway irritation increases; as a result, asthmatic episodes occur because the introduction of noxious agents causes the release of spasmogenic agents from tissue cells and nerve endings.[62]

General Gas Exchange Characteristics

The ability of compensatory mechanisms to preserve ventilation and ABG tensions varies. Ventilation usually is very well protected, even more than is gas exchange. CO_2 is 20 times more soluble than O_2 and therefore is more diffusible.[63] Also, if hypercapnia should occur, pulmonary ventilation is stimulated. Minute ventilation ($\dot{V}_E$) in COPD generally is normal to above normal. Usually, P_{aCO_2} does not increase beyond normal levels in COPD until FEV_1 is less than 1 L. In comparison, P_{aO_2} is not appreciably restored by an increase in depth of breathing, and even slight variations in $\dot{V}/\dot{Q}$ ratios in the lung adversely affect oxygenation.[49] O_2 delivery (DO_2) to the tissues is preserved as much as possible by an increase in CO, a greater extraction of O_2 from the blood, polycythemia, or some combination of these three factors. Consequently, respiratory muscle work is greater than normal, and O_2 use by the muscles is increased.

Associated Conditions

Cigarette Smoking

Cigarette smoking has been firmly established as the primary environmental risk factor associated with emphysema and bronchitis.[47] Its pathogenic mechanism is not known. The unchecked protease hypothesis holds that emphysema is caused by damage to elastic fibers because of an imbalance between elastase and antielastase in the lung.[64] Also, evidence that oxidants have a role in lung damage is increasing. The lungs of cigarette smokers are subject to an enhanced oxidant burden. Oxidants are highly reactive electron acceptors capable of removing electrons from a variety of molecules. The process of oxidation may reversibly or irreversibly damage compounds of all chemical classes, including nucleic acids,

proteins and free amino acids, lipids and lipoproteins, and carbohydrates. In this regard, oxidants can damage cells and extracellular matrix components critical for normal lung function. Cigarette smoke and activated lung phagocytes generate an increase in the level of oxidants.[65,66] Additionally, excess sputum production and hyperplasia of the mucous glands of the trachea and large bronchi are linked to cigarette smoking.[65] The risk of COPD is not limited to cigarette smoking; smoking other types of tobacco or marijuana, exposure to secondhand smoke, and even fetal exposure to smoke during pregnancy may predispose to COPD.[67]

Chronic lung hyperinflation results in diaphragmatic flattening, and a reduction in contractile force results, attributable to the Frank-Starling mechanism. Besides this gross effect, oxidative stress leads to loss of contractile proteins (i.e., myosin) and results in a reduction in contractile force.[68]

Peripheral Circulation in Chronic Obstructive Pulmonary Disease

COPD can change the determinants of systemic venous return by altering the mechanical characteristics of either the heart or lungs. When a patient adapts a forced expiratory breathing pattern (e.g., during exercise), positive intrathoracic pressure is generated during expiration. The positive swings in pressure cyclically decrease systemic venous return, leading to an exaggeration of respiratory variation in arterial blood pressure or to pulsus paradoxus.[69] Pulsus paradoxus is present in two thirds of patients with severe COPD, and its severity correlates with the degree of airflow obstruction.[70] Increases in lung volume may directly impede systemic venous return through compression of the vena cava or heart. Normally, inspiration augments systemic venous return because of a decrease in right atrial pressure.[71]

Patients with COPD often have an increase in CO mediated by an increase in catecholamine levels and by a redistribution of blood flow and volume from the high-capacitance splanchnic regions to the lower-capacitance cardiac, cerebral, and muscle regions.[71]

A characteristic enhanced heart rate response also has been identified. Four parameters of airway obstruction (forced vital capacity [FVC], the ratio of FEV_1 to FVC [% FEV_1], the ratio of RV to TLC [RV/TLC], and % RV) have been correlated with the heart rate response to hypoxia. This increased response appears to be the result of an unknown mechanism of diseased lung tissue.[72]

Fluid Retention in Chronic Obstructive Pulmonary Disease. It appears that patients with hypoxic and hypercapnic respiratory failure from emphysema or chronic bronchitis, or from both, have impaired renal function, with reduced renal plasma flow and decreases in glomerular filtration.[73]

Note that cardiac responses to chronic and acute pressure increases are not the same. Chronic pressure overload causes right ventricular hypertrophy, whereas acute pressure changes cause right ventricular dilation.

Other Air Space Abnormalities

Bullae, a manifestation of some forms of emphysema, are air-containing spaces greater than 1 cm in diameter that result from the destruction and dilation of air spaces distal to terminal bronchioles. Bullae have an outer wall consisting of the visceral pleura and an inner wall consisting of tissue derived from confluent alveoli. Bullae can grow to sizes occupying a significant proportion of the hemithorax, in which case they are referred to as "giant."[74] A bulla or bullae that become symptomatic may warrant surgical resection. Similar to bullae, blebs are collections of air within the layers of the visceral pleura. They occur when air migrates from the lung parenchyma, and they usually form near the apices. Because blebs do not involve the acinus, they are not a form of emphysema; however, they do pose the risk of causing pneumothorax.

TABLE 26-9 Clinical Hallmarks of COPD

Assessment	Typical Finding
General appearance	Range from overweight and dusky, to thin, emaciated; pursed-lip breathing; anxious; prominent use of accessory muscles; barrel chest; jugular vein distention; rapid weight loss carries poor prognosis
Cough	Chronic, productive throughout the day (most characteristic with prominent bronchitis)
Dyspnea	Chronic, progressive increase (dyspnea precipitated by decreasing levels of activity)
Breath sounds	Rhonchi, wheezing
Heart sounds	Split S2, pulmonary/tricuspid insufficiency
Radiographic features	Flat diaphragm; areas of increased radiolucency; rapid tapering of vascular markings
Spirometry	Elevated TLC, RV, FRC, RV/TLC ratio; reduced FEV_1, FEV_1/FVC ratio
Echocardiography	Increased pulmonary artery pressure, decreased RV contractility
Blood gas exchange	Reduced DLCO; Hypoxemia (most characteristic of prominent emphysema)

Clinical Features and Diagnosis

The clinical presentation of COPD varies markedly, and crippling changes for one person may be a minor incapacity for another. Chronic productive cough and progressive exercise limitation are the hallmarks of COPD. Other common symptoms are dyspnea and wheezing, but COPD may progress to respiratory failure or cor pulmonale. Key findings in COPD are listed in Table 26-9.

Diagnostic Testing

Pulmonary Function Tests. Spirometry is not recommended as a screening tool, and it has limited benefit in anesthetic risk assessment, in contrast to the cost of performing the procedure.[75] Although the FEV_1 indicates the degree of airflow obstruction, it correlates poorly with symptoms and therefore may not solely indicate the severity of pulmonary disease.[44] Furthermore, severe pulmonary disease will manifest in functional limitations and characteristic physical facies, which will be evident to the anesthetist even in the absence of airflow measurement. Spirometry is most useful to primary care providers in evaluating patients with unexplained dyspnea and in those in whom COPD is suspected. Current evidence-based guidelines note that a smoking history of greater than 40 pack-years is the single best variable for predicting airflow obstruction, and the combination of greater than

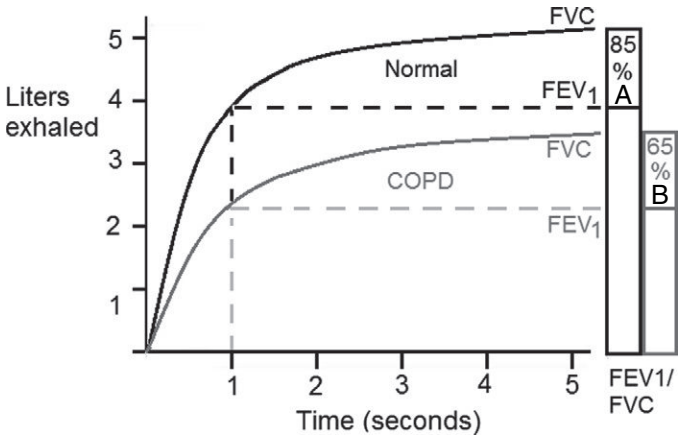

FIGURE **26-17** Schematic diagram of the forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC). The total volume of air exhaled in the first second should be equivalent to at least 80% of the FVC *(A)*. In the presence of obstructive airway disease, the FEV_1 is less than 80% of the FVC *(B)*. (Modified from Miller RD, Pardo Jr MC. *Basics of Anesthesia*. 6th ed. Philadelphia: Saunders; 2011.)

55–pack-year history, wheezing on auscultation, and patient self-reported wheezing almost assures that obstruction (FEV_1/FVC ratio less than 0.7) is present.[48]

Reduction in the FEV_1 is a hallmark of obstructive disease; however, it may also characterize restrictive disease. In severe obstructive lung disease, expiratory flow rates are greatly decreased and the FEV_1/FVC ratio is reduced. The ratio is evaluated in addition to the FEV_1 alone, because in restrictive disease, the FEV_1 is reduced secondary to a reduction in the vital capacity, so the reduction in FEV_1 alone does not indicate expiratory airflow obstruction. A low FEV_1 combined with a normal FEV_1/FVC is indicative of restrictive disease (Figure 26-17). Measurement of lung volumes in obstructive disease demonstrates an increased RV and often an increased FRC. Slowing of expiratory flow and gas trapping behind prematurely closed airways is responsible for the increase in RV. When spirometry is used to grade the severity of COPD (FEV_1/FVC less than 0.7), the post-bronchodilator FEV_1 compared to predicted levels is the primary determinant: FEV_1 ≥ 80% = mild, 50% to 79% = moderate, 30% to 49% = severe, and less than 30% = very severe.[67] The number of exacerbations and hospitalizations per year is also directly correlated with 3-year mortality and can be considered in the evaluation of severity of COPD.[67]

Arterial Blood Gas Analysis. ABG analysis is helpful in determining the severity of gas exchange abnormality and guiding management of patients with COPD. COPD may manifest with retained oxygenation (PaO_2 greater than 60 mmHg, $PaCO_2$ normal) or impaired exchange of oxygen and CO_2 (PaO_2 less than 60 mmHg, $PaCO_2$ greater than 45 mmHg, and presence of cor pulmonale), generally based upon the severity of the disease and the relative contributions of emphysema and chronic bronchitis, respectively. When emphysema predominates, compensatory hyperventilation can maintain oxygenation until the disease is very advanced. Although patients maintain adequate ABG values, they do so at the cost of significantly increased work of breathing, and general muscle wasting occurs. In chronic bronchitis, the alveolar capillary membrane is intact, but excess mucous in the airways impedes gas flow. Chronic hypoxia in the lung causes pulmonary vascular resistance to rise and to increase work on the right ventricle. The patients become polycythemic and hypoxemic. Cyanosis is more common in chronic bronchitis.

Chest Radiography and Computed Tomography. Radiographic abnormalities may be minimal, even in the presence of advanced COPD. Hyperlucency of the lungs (caused by arterial vascular deficiency in the lung periphery) and hyperinflation (flattening of the diaphragm with loss of the silhouette) suggest the diagnosis of emphysema.[4] If bullae also are present, the diagnosis of emphysema is virtually certain; however, only a small percentage of patients who have emphysema have bullae. Computed tomography (CT) can delineate the pulmonary parenchyma much better than standard chest radiography. CT also may be used to quantify the amount of air trapping. Although conventional radiography has 60% to 80% sensitivity to diagnose COPD, CT scanning improves sensitivity to 90%.[46]

Treatment

Treatment of COPD is focused on relieving symptoms and reducing the incidence of exacerbations. There is no treatment to reverse the course of COPD, but smoking cessation can slow the forward progression of the disease. Medical management is aimed at promoting bronchodilation using inhaled β_2-agonists, corticosteroids, or anticholinergics. Although a low baseline level of cholinergic tone normally influences bronchial caliber, cholinergic influence is found to be elevated in COPD, with fluctuations in airway diameter attributable to changes in cholinergic tone.[76] Ideally, anticholinergics that block the M_1 and M_3 receptors would be ideal, because the M_2 acts in negative feedback to reduce acetylcholine release. However, the M_2 receptor also reduces adenylate cyclase, so blockade of the M_2 receptors also confers the advantage of enhancing the response to beta agonists.[54] Tiotropium is a long-acting anticholinergic that is more selective for the M_3 receptor than ipratropium and atropine, and it dissociates more rapidly from the M_2 receptor. Given a 24-hour duration of action, tiotropium is gaining popularity as the ideal anticholinergic for reducing cholinergic tone in COPD.[77,78] The choice of agents in general is largely based on individual patient response and tolerance of different agents. A joint position statement by the American College of Physicians, American College of Chest Physicians, American Thoracic Society, and the European Respiratory Society recommends the following approach to medical management of symptomatic patients[48]:

1. Bronchodilators *may* be used for mild COPD (FEV_1 60%-80%)
2. Bronchodilators are *recommended* for FEV_1 less than 60%. The specific drug prescribed is based upon patient tolerance, side effects, and cost and may consist of a long-acting β_2-agonist, anticholinergic, or corticosteroid. Combination therapy may be used, although combination therapy does not show a consistent advantage over monotherapy.
3. Pulmonary rehabilitation may be used for patients with FEV_1 greater than 50% and is recommended for those with FEV_1 less than 50%.
4. Oxygen therapy is used to maintain PaO_2 greater than 60 mmHg (SpO_2 greater than 88%) for patients who have resting hypoxemia below this level.

At all stages of COPD progression, removal of offending and exacerbating factors is recommended (particularly cessation of smoking and administration of the influenza vaccine). Surgical treatments that are used to reduce symptoms in COPD include lung volume reduction surgery (LVRS), bullectomy, and lung transplantation. LVRS removes severely diseased portions of lung, leaving behind a greater proportion of better-functioning tissue. The result is improvement in elastic recoil, diaphragmatic function, and reduction in exacerbations. LVRS is most effective for predominantly upper lobe emphysema.[67]

TABLE 26-10 BODE Scale: Point Values for Relevant Variables of Obstructive Disease

	POINTS ON THE BODE INDEX			
Variable	**0**	**1**	**2**	**3**
FEV_1 (% of predicted)	≥ 65	50-64	36-49	≤ 35

Preoperative Evaluation

The surgical site and the preoperative status of the patient are critical factors in predicting the incidence of postoperative complications. The risk of respiratory complications is generally proportional to the proximity of the surgical site to the diaphragm.[47] Multiple factors are predictive of postoperative respiratory difficulties, but no preoperative pulmonary function test establishes absolute contraindications to surgery. The preoperative evaluation of patients with COPD should determine the severity of the disease and identify treatments for reducing inflammation, improving secretion clearance, treating underlying infection, and increasing airway caliber to ensure the best surgical outcome. Although the FEV_1 has previously been used as the primary indicator of disease severity, other factors such as body mass index, functional dyspnea, and exercise tolerance along with the FEV_1 provide useful assessment of prognosis in patients with COPD.[51,79] The multidimensional BODE index (*B*ody mass index, airflow *O*bstruction, *D*yspnea, and *E*xercise capacity) provides better insight into the severity of disease than does spirometry alone[80] (Table 26-10).

The causes of acute exacerbations of COPD are multiple and may be explained only partially by airway infection or inflammation. Multiple contributing factors, including bronchitis, underlying airway hyperresponsiveness, inhalation of noxious agents, mucous plugging, pneumonitis, cardiovascular disease, congestive heart failure (CHF), and generalized systemic inflammation, must be considered. Signs of COPD may be subtle. The clinician must assess for increased respiratory effort, altered breathing patterns, abnormal breath sounds, and a productive cough. A consensus statement by the American Thoracic Society defines dyspnea as "a subjective experience of breathing discomfort that is comprised of qualitatively distinct sensations that vary in intensity. The experience derives from interactions among multiple physiologic, psychologic, social, and environmental factors and may induce secondary physiologic and behavioral responses."[81] Because dyspnea, like pain, is a very subjective sensation, it can be difficult to quantify a patient's level of dyspnea or to evaluate the degree of response to therapy. In evaluating dyspnea, visual analog scales, verbal ordinal scales, or combined scales are commonly used[82] (Figure 26-18).

A history of or the presence of atopy (predisposition to allergies), childhood respiratory impairment, high serum immunoglobulin E (IgE) levels, and eosinophilia is suggestive of asthmatic bronchitis, which is generally more responsive to treatment than is smoking-induced COPD. The value of preoperative pulmonary function

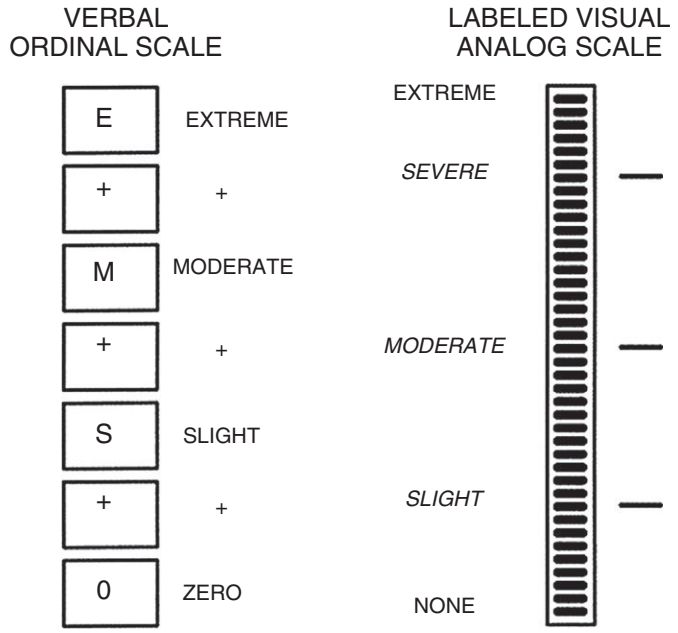

FIGURE **26-18** A verbal ordinal scale and visual analog scale used to evaluate the degree of dyspnea. (From Lansing RW, et al. Measurement of dyspnea: word labeled visual analog scale vs. verbal ordinal scale. *Respir Physiol Neurobiol*. 2003;134[2]:77-83.)

tests is questionable for nonpulmonary surgery.[47] Data from resting Spo_2, dyspnea-related functional limitation, exercise capacity, and body mass index will lead to useful assessment of the patient's pulmonary reserve. If pulmonary function tests (PFTs) are available, spirometry should be assessed before and after bronchodilator or steroid treatment (or both) so that airway disease reversibility can be evaluated. The patient's response to bronchodilators provides important information about the manageability of the COPD, with an improvement in FEV_1 of 12% to 15% from baseline indicating a significant response.[44] Other changes considered significant are improvement in FVC of at least 10% and improvement in $FEF_{25\%-75\%}$ of at least 20%, but a lack of significant improvement does not preclude use of bronchodilators during anesthesia.[46]

Numerous conditions predispose a patient with COPD to infectious complications, including dehydration, decreased ability to cough, immobility, and decreased mucociliary clearance. Optimal control of airway inflammation may require antimicrobial therapy preoperatively. Increasing cough, dyspnea, chest pain, fatigue, worsening blood gas values, and other signs may indicate an acute exacerbation of COPD. The patient may report a change in sputum volume, color, or consistency. Viruses are the most frequent causative organisms in acute exacerbations of chronic bronchitis.[83] Acute infection is associated with epithelial desquamation and correlates with airway hyperreactivity that may persist for 3 to 6 weeks after the resolution of symptoms.[84] Measures to improve respiratory skeletal muscle strength include good nutrition and balanced fluid and electrolyte intake. Bronchodilators should be used if the patient exhibits some degree of airway obstruction (coughing may temporarily increase in frequency as greater quantities of sputum are removed). Some commonly used bronchodilators are listed in Table 26-11. If pulmonary function tests are performed, the degree of reversibility (Figure 26-19) will suggest the potential for and the means of improving ventilation in the perioperative period.

An increased plasma concentration of bicarbonate in the presence of a low or normal $Paco_2$ suggests that acute hyperventilation

TABLE 26-11 Medications Used for COPD

Drug	Formulation	Delivery	Usual Frequency
Short-Acting β_2-Agonists			
Albuterol	90 mcg/inhalation	MDI/Neb	q4-6hr prn

is masking chronic CO_2 retention. If the Pa_{CO_2} has been chronically elevated, it is important that the hypercarbia not be corrected too quickly. Sudden decreases in Pa_{CO_2} can result in alkalemia because the kidneys cannot instantly excrete the excess bicarbonate.

Anesthetic Management

There is no standard recipe of anesthetic management of the patient with COPD, but some general principles should guide anesthetic planning. It is crucial to realize that COPD patients are susceptible to the development of acute respiratory failure during the postoperative period. Therefore, continued intubation of the trachea and mechanical ventilation of the lungs may be necessary, particularly after thoracic and upper abdominal surgery. Postoperative ventilation is more likely to be needed in those patients with low Pa_{O_2} and dyspnea at rest. Assessment of respiratory function can be performed effectively and inexpensively by considering relevant factors, such as the BODE score (see Table 26-10). In initial

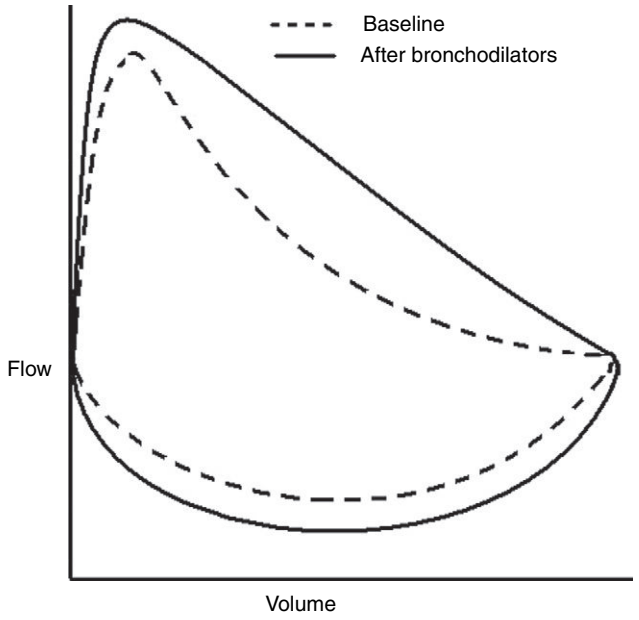

FIGURE **26-19** Flow-volume loop, demonstrating expected improvement after bronchodilator therapy.

study, the BODE score was lower among survivors than among those who died from any cause up to 52 months postoperatively (3.7 ± 2.2 vs. 5.9 ± 2.6, P <0.005).[80] When categorized into four quartiles (BODE indices of 0 to 2, 3 to 4, 5 to 6, and 7 to 10, respectively), there was significant correlation in the mortality rates among patients in higher-scored quartiles.[85]

Regional Anesthesia

Regional anesthesia is useful if sedation is not needed, and it may be less challenging than general anesthesia, to avoid manipulation of the airway and ventilation. However, anesthetists must nonetheless maintain a high level of vigilant monitoring if regional rather than general anesthesia is used. Complications such as pneumothorax and impaired respiratory muscle function (from phrenic nerve block or high spinal block) can lead to respiratory embarrassment quickly in the compromised patient. Neuraxial anesthetic techniques that produce sensory anesthesia above T6 are not recommended. The potential for decreasing expiratory reserve volume, impairing cough effort, and creating anxiety-provoking weakness is too great.[86]

General Anesthesia

General anesthesia often is provided with a volatile anesthetic (to facilitate bronchodilation) and humidification (to prevent drying of secretions). Maintaining adequate anesthesia in patients with significant lung disease presents a challenge. General anesthesia is often associated with an increase in the alveolar-arterial difference in P_{O_2} ($P_{AO_2} - Pa_{O_2}$). Causes include a fairly consistent 20% decrease in FRC when neuromuscular relaxants are used, as well as small airway closure and atelectasis. Atelectasis normally occurs after induction of general anesthesia and has been found to worsen with muscle paralysis and prolonged surgical duration.[87] It is interesting to note that patients with chronic hyperinflation appear to be less likely to develop atelectasis than subjects with healthy lungs, possibly because of airway closure before alveolar collapse or because of resistance to early alveolar collapse from long-standing lung hyperinflation, which prevents prompt formation of atelectasis.[88]

There is some evidence that volatile anesthetics reduce the function of cilia in the respiratory tract.[89] Opioids pose less threat to disrupting ventilation-perfusion matching, and may be an appealing option. However, the residual respiratory depressant effects of opioids must be managed, particularly in the COPD population, which is generally of advanced age. An opioid-heavy technique also requires attention to amnestic coverage. If nitrous oxide (N_2O) is used for this purpose, bullae may enlarge and rupture; therefore, presence of bullous emphysema is a contraindication to use of N_2O. A well-balanced anesthetic, therefore, will minimize many of these concerns.

Ventilation Management

Ventilation strategy should focus on maintaining adequate oxygenation, eliminating CO_2, avoiding barotrauma from excessive inspiratory pressures, avoiding tissue injury from repetitive airway closure and reopening, and avoiding volutrauma from either excessive tidal volumes or from auto-PEEP. Oxygenation is managed first with Fi_{O_2}, but care must be taken to reduce absorptive atelectasis or damaging oxidative effects from overzealous oxygen administration. If concerns about N_2O exist, then oxygen and air provide a useful combination of carrier gases. Attention should be given to adequate hydration to prevent excessive drying of respiratory secretions. In managing CO_2 elimination, providers should avoid correction of a chronic hypercapnia during mechanical ventilation. In the face of long-term renal compensation, doing so may result in an unintended alkalemia and may make ventilator weaning difficult.

Patients with COPD present challenges to both getting gas into the respiratory zone, as well as getting it out again. Airway secretions and bronchial reactivity provide impedance to inspiration. Intermittent vital capacity maneuvers to recruit atelectatic alveoli will help improve oxygenation during surgery,[88] and PEEP will help maintain small airway patency. If the airways are noncompliant, such as with bronchitis, then slower inspiration, perhaps with an inspiratory pause, is helpful to allow time for gas to redistribute from higher compliance areas to less-ventilated areas of lung. Obstructive disease, however, may conflict with those strategies at maximizing oxygenation. With obstructive disease, longer expiratory times are useful (lower inspiration/expiration [I:E] ratio) to allow more time for expiration. The lower I:E ratio is used at the sacrifice of peak pressures, which will rise as higher inspiratory flow is used to deliver the tidal volume in a shorter inspiratory cycle. Leatherman demonstrated that there is no benefit to prolonging expiratory time beyond 4 seconds.[90] With COPD, on expiration, small airway closure and emphysematous loss of elasticity impede full emptying of the tidal breath. As a result, inspiration begins at volumes at which the respiratory system exhibits positive recoil pressure. In other words, pressure builds due to incomplete emptying at the time that the next inspiration begins. This is known as auto-PEEP or intrinsic PEEP (PEEPi).[91,92] In the past, external PEEP (PEEPe) was generally not used in patients with COPD because hypoxemia often is improved with increases in the fraction of inspired O_2 (Fi_{O_2}) and because the risk of barotrauma resulting from further hyperinflation was deemed too great. The risk of PEEP exacerbating incomplete emptying is greater in patients with COPD.[93] However, cyclic closure and reopening of small airways with each breathing cycle is also detrimental, and judicious use of PEEP may avoid this low-volume tissue injury.[93] Research suggests that a PEEPe that is less than the PEEPi in the presence of expiratory flow limitation may assist patients in overcoming the inspiratory mechanical load of PEEPi, ultimately decreasing the work of breathing and eliminating or decreasing atelectatic areas and airway closure.[93-95] Patients whose peak cycling pressures remain

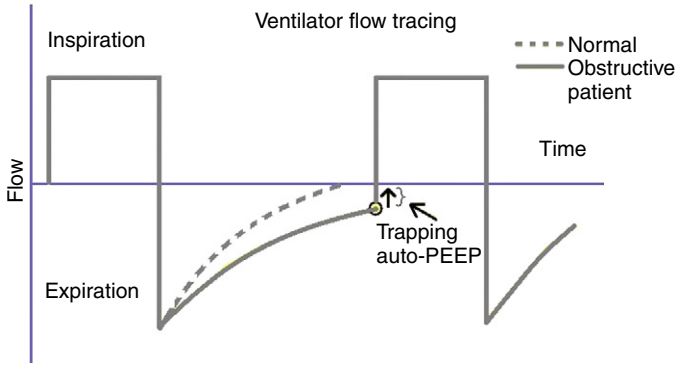

FIGURE **26-20** Development of intrinsic positive end-expiratory pressure (PEEPi) is suspected when the expiratory flow tracing does not reach the zero line before the subsequent inspiration begins. (From García Vicente E, et al. Ventilación mecánica invasiva en EPOC y asma. *Med Intensiva*. 2011; 35[4]:288-298.)

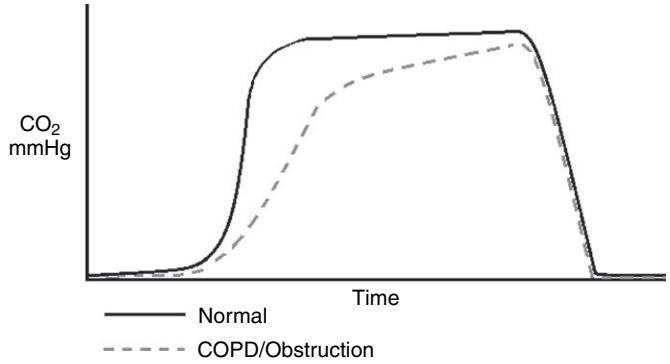

FIGURE **26-21** Capnograph of a patient with expiratory airway obstruction.

essentially unaffected by PEEPe experience the greatest improvement and the least hazard.[96] In the operating room, the clinician can best diagnose PEEPi by assessing whether exhalation is still taking place when the next inhalation starts.[97] This is becoming easier with newer-generation anesthesia machines, which provide dynamic flow and volume tracings of the respiratory cycle (Figure 26-20). Monitoring flow-volume tracings or the capnograph for expiratory airflow obstruction (Figure 26-21) also may help guide decision making about whether incomplete emptying threatens the development of PEEPi. When PEEPe is added, it should be titrated in 2.5- to 5-cm H_2O increments while peak cycling pressures are closely monitored. Because PEEP is intended to avoid closure of small airways and alveoli that would exist at the lower (flat) portion of the compliance curve, the pressure-volume tracing can be used to determine the appropriate amount of PEEP to administer. Research demonstrates that PEEP set just above the lower inflection point of the compliance curve provides optimal oxygenation[98-100] (Figure 26-22). Although it can be difficult to determine this point clinically,[101] the concept is important, because it connects understanding of the physiologic concept of the compliance curve with the clinical intervention of PEEP.

Postoperative Care

Postoperative care of patients with COPD is directed at minimizing the incidence and severity of pulmonary complications, because such patients are at increased risk for the development of acute respiratory failure.[102] Postoperative pulmonary complications are most often characterized by atelectasis followed by

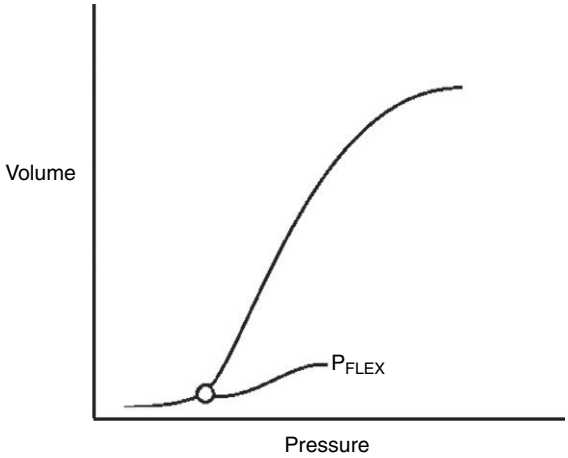

FIGURE **26-22** The lower inflection point (P_{FLEX}) of the pressure-volume curve of the airway suggests an optimal pressure for setting positive end-expiratory pressure (PEEP).

pneumonia and decreases in Pa_{O_2}.[97] These patients require close monitoring; worsening $\dot{V}/\dot{Q}$ mismatch after extubation may not be detected by ABG analysis, possibly because of changes in breathing pattern and cardiovascular function. In fact, minute ventilation may not change, but often respiratory rate increases, and V_T decreases after the termination of mechanical ventilation.[96] The choice of drugs or techniques for producing anesthesia does not seem to predictably alter the incidence of postoperative pulmonary infections. Whether a relationship exists between the duration of anesthesia and the incidence of postoperative pulmonary complications is not clear.

ASTHMA

Definition

The National Asthma Education and Prevention Program Expert Panel Report 3 (EPR-3) defines asthma as "a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: in particular, mast cells, eosinophils, neutrophils (especially in sudden onset, fatal exacerbations, occupational asthma, and patients who smoke), T lymphocytes, macrophages, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of coughing (particularly at night or in the early morning), wheezing, breathlessness, and chest tightness. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment."[103] Although asthma involves chronic inflammation of the respiratory tract, it is propagated by different mediators of inflammation than in COPD, which is what primarily differentiates the pathogenesis of the two diseases.[67]

Various theories underlie the cause of asthma. The three overarching theories suggest that asthma may result from the following:

1. *Deficiency of acquired immunity*. Lack of exposure to immunologic challenges in early life allows predominance of the Th2-type cytokine response and a general atopy.
2. *Genetics*.
3. *Exposure to respiratory system irritants*. These include airborne allergens (house-dust mite), irritants (tobacco smoke), and viral respiratory infections (respiratory syncytial virus).

A general approach to classification discriminates between extrinsic or intrinsic asthma. Although this system is conceptually helpful, its two groups are not mutually exclusive. Extrinsic asthma (or allergic asthma) most commonly affects children

and young adults and involves exacerbation by infectious, environmental, psychological, or physical factors, whereas intrinsic asthma (or idiosyncratic asthma) usually develops in middle age without specifically identifiable attack-provoking stimuli. It is of significance that the clinical features of idiosyncratic asthma are essentially indistinguishable from the immune-mediated response.

Incidence and Outcome

Up to 22 million persons in the United States have asthma. It is the most common chronic disease of childhood, affecting an estimated 6 million children. The burden of asthma affects the patients, their families, and society in terms of lost work and school, lessened quality of life, and avoidable emergency department (ED) visits, hospitalizations, and deaths.[103]

Pathogenesis and Pathophysiology

Our contemporary understanding of asthma is that it is not a single entity, but rather a heterogeneous clinical syndrome characterized by episodes in which airways are hyperresponsive at times interspersed with symptom-free periods.[104] Bronchoconstriction is a factor long associated with the asthmatic symptom complex, but asthma is much more than bronchoconstriction. Airway inflammation and a nonspecific hyperirritability of the tracheobronchial tree are now recognized as being central to the pathogenesis of even mild cases of asthma. Permanent changes in airway anatomy, referred to as *airway remodeling*, magnify the inflammatory response.[104,105] Some manifestations of airway remodeling include fibrosis, mucus hypersecretion, smooth muscle hypertrophy, and angiogenesis.[103]

Allergic (atopic) asthma is triggered by antigens that provoke a T-lymphocyte–generated, IgE-mediated immune response.[106] It is often associated with a personal or familial history of allergic disease. In susceptible patients, exposure to even minute amounts of an offending agent can cause activation of lymphocytes and cytokine release, setting into motion an immune-mediated inflammatory response. Endobronchial biopsy specimens, even from asymptomatic patients, frequently show an active inflammatory process. Eosinophils, mast cells, neutrophils, and macrophages are prominent features in asthmatic airways, and their activation and degranulation fuel the proinflammatory cascade.

Potent biochemical mediators released from proinflammatory and airway epithelial cells promote vasoconstriction, increased smooth muscle tone, enhanced mucus secretion, submucosal edema, increased vascular permeability, and inflammatory cell chemotaxis. Leukotrienes have been identified as especially potent spasmogenic and proinflammatory substances. Released molecules that are toxic to the airway epithelium cause patchy desquamation, exposing cholinergic nerve endings and compounding the bronchoconstrictive and hyperresponsive response. The asthmatic diathesis creates airways that are inflamed, edematous, and hypersensitive to irritant stimuli, and the degree of airway hyperresponsiveness and bronchoconstriction appears to parallel the extent of inflammation.[107,108] When airway reactivity is high, asthmatic symptoms are generally more severe and unrelenting, and the amount of therapy required to control the episode is greater.[104]

The mechanisms underlying nonimmunologic asthma are less clearly defined. Nonimmunologic asthma occurs in patients with no history of allergy and normal serum IgE. These patients typically develop asthmatic symptoms in response to some provocative or noxious stimulus such as cold air, airway instrumentation or irritation, climate changes, or an upper respiratory illness. Recent upper respiratory infection may precipitate bronchospasm in any patient, but the risk is higher in patients with a history of asthma. The increased bronchomotor tone associated with viral respiratory infections may persist for as long as 5 weeks.[84] Nonasthmatic children with an upper respiratory infection are two to seven times more likely to experience an adverse event perioperatively and are more prone to postoperative desaturation.[109] Asthma itself, however, appears not to be a risk factor for postoperative complications, if it is controlled.[110] Poorly controlled asthma (defined by rescue inhaler use or emergency department visits within 30 days) is associated with an increase in respiratory complications.[111]

Immune mechanisms appear to be causally related or contributory to the development of asthma in more than 50% of cases, but many patients with asthma have disease mechanisms from both categories. Asthma that has its onset in childhood tends to have a strong allergic component, whereas asthma that arises in adults tends to be nonallergic or to have a mixed cause.[104] As a general rule, nonallergic mechanisms of exacerbation are more prevalent in the perioperative period.[112]

IgE-mediated asthma occurs after initial antigen exposure has resulted in IgE antibody formation. On repeat exposure, in the presence of IgE, mast cells release multiple mediators. These mediators directly constrict small and large airways, increase capillary permeability, stimulate vasoconstriction, and increase mucous gland secretion, which contributes to mucus plugging (Figure 26-23).

The mechanism of exercise-induced bronchospasm (EIB) is unknown. One popular theory suggests that a high minute ventilation ($\dot{V}E$) and the low temperature or low H_2O content of inspired gas (which requires greater heat and water transfer from the mucosal surface to the inspired gas) generates a bronchoconstrictive response. Another theory proposes that the evaporation of water from respiratory mucosa and the resultant increase in the osmolarity of the surface-lining fluid induces the degranulation of mast cells. A third theory suggests that reactive hyperemia of the bronchial mucosa occurs with rewarming, resulting in airway narrowing.[113] Regardless of the mechanism, most symptoms last less than 1 hour and are usually very responsive to administration of β_2-adrenergic receptor agonists.[114]

Occupational asthma develops when irritants directly stimulate vagal nerve endings in the airway epithelium. Infection-induced asthma with acute inflammation of the bronchi may be caused by viral, bacterial, or mycoplasmal infections. Aspirin-induced asthma occurs when, in some predisposed persons, cyclooxygenase inhibition drives arachidonic acid metabolism toward the lipooxygenase pathway, resulting in production of leukotrienes, thereby triggering the asthma attack.[115] This peculiar response also can occur with the use of other nonsteroidal antiinflammatory agents. The aspirin-induced asthma variant is not IgE mediated or allergic in nature. It is clinically associated with the presence of nasal polyps.

Clinical Features and Diagnosis

Airflow limitation is caused by a variety of changes in the airway, all influenced by airway inflammation[103]:

- *Bronchoconstriction*—bronchial smooth muscle contraction that quickly narrows the airways in response to exposure to a variety of stimuli, including allergens or irritants
- *Airway hyperresponsiveness*—an exaggerated bronchoconstrictor response to stimuli
- *Airway edema*—As the disease becomes more persistent and inflammation becomes more progressive, edema, mucus hypersecretion, and formation of inspissated mucus plugs further limit airflow

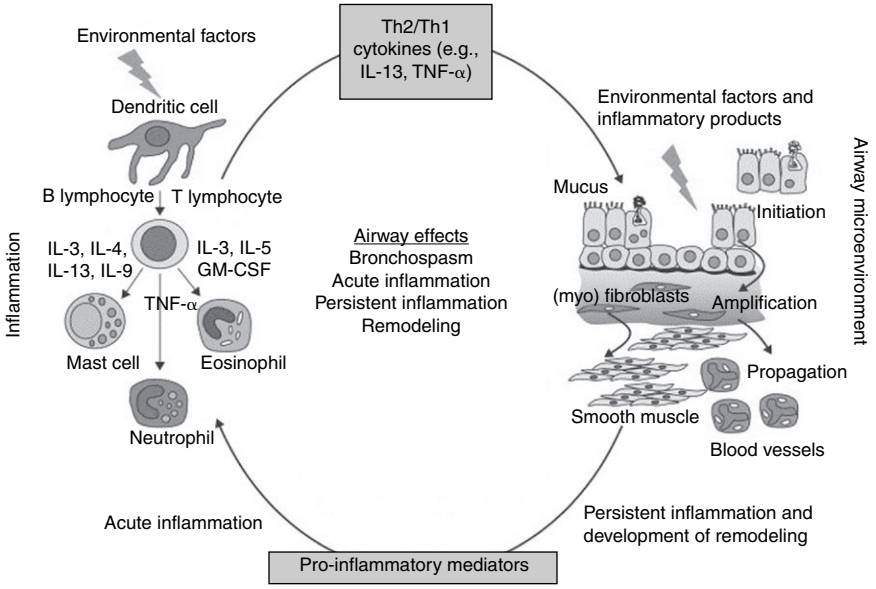

FIGURE **26-23** Factors limiting air flow in acute and persistent asthma. *GM-CSF*, Granulocyte-macrophage colony-stimulating factor; *IgE*, immunoglobulin *E*; *IL-3*, interleukin 3 (and similar); *TNF-α*, tumor necrosis factor-alpha. (Modified and reprinted from Holgate ST, Polosa R. The mechanisms, diagnosis, and management of severe asthma in adults. *Lancet*. 2006;368:780-793.)

Key hallmarks of asthma include[103,107]:

- Recurrent wheezing
- Dyspnea (may parallel the severity of expiratory airflow obstruction)
- Cough (productive or nonproductive; frequently at night or early morning)
- Recurrent labored respirations with accessory muscle use
- Tachypnea (a respiratory rate greater than 30 breaths per minute and a heart rate of 120 suggests severe bronchospasm)
- Recurrent chest tightness
- Prolonged expiratory phase of respiration
- Fatigue
- Symptoms occur or worsen with exercise, viral infection, environmental allergens or irritants, changes in weather, stress, or menstrual cycles

Clinical classification of asthma is noted in Table 26-12, and corresponding treatment protocols are shown in Figure 26-24. Typical attacks are short-lived, lasting minutes to hours. Between attacks the asthmatic patient may be entirely symptom free; however, underlying airway remodeling is still evident.[105,106] Severe obstruction that is refractory to bronchodilator therapy is known as *status asthmaticus*. This variant occurs in persons with a genetic predisposition[116] and requires an escalating approach to therapy for symptoms that may persist over a number of days. Status asthmaticus also can represent an emergency situation. At times, anesthetists are called upon to administer ketamine or volatile anesthetics as part of the treatment for status asthmaticus.[117-119] Use of accessory muscles of respiration and the increased work of breathing associated with a protracted asthmatic episode can result in respiratory muscle fatigue and respiratory failure.

During exacerbations, pulmonary function tests may reflect acute expiratory airflow obstruction (↓ forced expiratory flow [$FEF_{25\%-75\%}$]; ↓ FEV_1/FVC). Viscid mucus secretion may compound the airway narrowing and produce airway collapse.[114] The asthmatic episode produces not only airflow obstruction but also gas exchange abnormalities. The resulting low $\dot{V}/\dot{Q}$ state produces arterial O_2 desaturation.[120] Hypoxemia is common, but in most

TABLE 26-12 Clinical Asthma Classification

Steps	Clinical Characteristics Before Therapy
Step 1—Intermittent asthma	Signs and symptoms occur 0-2 days/week Nighttime symptoms 0-2 days/month SABA use 0-2 days/week No activity limitation Exacerbations 0-1 times/year FEV_1 ≥80% of predicted value; FEV_1/FVC normal
Step 2—Mild persistent asthma	Signs and symptoms 2-6 days per week, but not > 2 times/day Nighttime symptoms 3-4 times/month SABA use 3-6 days/week, but not more than once daily Minor activity limitation Exacerbations ≥ 2 times/year FEV_1 ≥80% of predicted value; FEV_1/FVC normal
Step 3—Moderate persistent asthma	Daily symptoms Nighttime symptoms occur more than once per week but not nightly Daily use of SABA Some activity limitation Exacerbations > 2 times/year FEV_1 60%-80% of predicted value; FEV_1/FVC reduced 5%
Step 4—Severe persistent asthma	Continuous signs and symptoms Often nightly symptoms SABA use several times/day Extremely limited physical activity FEV_1 ≤60% of predicted value; FEV_1/FVC reduced >5%

Modified from National Heart Lung and Blood Institute. *National Asthma Education and Prevention Program, Expert Panel Report 3. Guidelines for the Diagnosis and Management of Asthma*. Bethesda, Md: US Department of Health and Human Services; 2007.
FEV_1, Forced expiratory volume in 1 second; *FEV_1/FVC*, forced expiratory volume in 1 second/forced vital capacity; *SABA*, short-acting β_2-agonist.

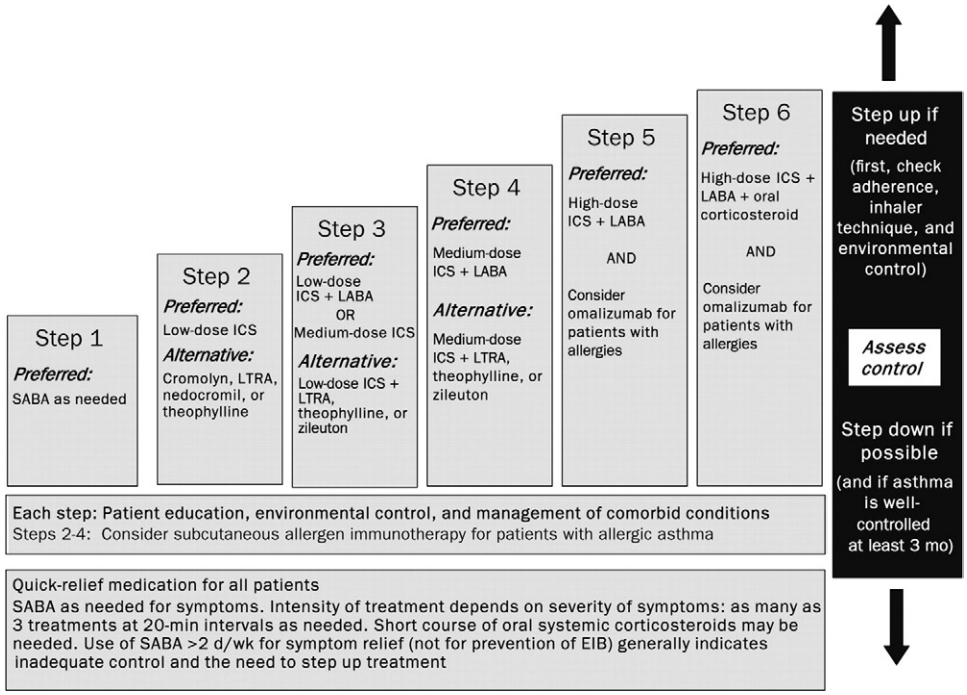

FIGURE **26-24** Stepwise approach to treating asthma in adults. *EIB*, Exercise-induced bronchospasm; *ICS*, inhaled corticosteroid; *LABA*, long-acting β-agonist; *LTRA*, leukotriene receptor antagonist; *SABA*, short-acting β-agonist. NOTES: Zileuton is a less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels. In *step 6*, before oral corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials. *Steps 1, 2*, and *3* preferred therapies are based on Evidence A; *step 3* alternative therapy is based on Evidence A for LTRA, Evidence B for theophylline, and Evidence D for zileuton. *Step 4* preferred therapy is based on Evidence B, and alternative therapy is based on Evidence B for LTRA and theophylline and Evidence D for zileuton. *Step 5* preferred therapy is based on Evidence B. *Step 6* preferred therapy is based on EPR-2 (1997) and Evidence B for omalizumab. Immunotherapy for steps 2 to 4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults. Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur. (From National Heart Lung and Blood Institute. *National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma*. Bethesda, Md US Department of Health and Human Services; 2007.)

patients with acute bronchospasm, CO_2 elimination is relatively well preserved until $\dot{V}/\dot{Q}$ abnormalities are severe. An increased arterial CO_2 tension may indicate impending respiratory failure in the acutely ill asthmatic patient. Chronic asthma may eventually lead to irreversible lung destruction, loss of lung elasticity, pulmonary hypertension (PH), and lung hyperinflation.

Diagnostic Testing

Pulmonary Function Tests. Lung function testing offers limited value to anesthetic risk assessment and should not be performed routinely based solely on the presence of asthma. Although spirometry is used to determine candidacy for lung resection surgery, it has limited value before extrathoracic surgery, even in patients with asthma or other lung disease. Even when spirometry is used to document the degree of airflow limitation, there is not a known threshold that precludes surgery.[110]

When pulmonary function tests are performed, they provide information related to the degree of impairment and the reversibility of airway limitation. RV, FRC, and TLC all increase because of an increase in volume of the gas trapped beyond closed airways, and lung deflation is less because of airway obstruction. Comparison of current and prior pulmonary function test results is useful. Tolerance of activities is used for classifying the degree of dyspnea.[121] The patient in remission may have negative results on all parameters of pulmonary function and may be tested with a cholinergic agonist such as methacholine for bronchial provocation and clarification of the diagnosis of asthma.[122] The hallmark of an incipient exacerbation of asthma is a reduction in the peak expiratory flow rate.[103]

Arterial Blood Gas Analysis. Increased diffusibility of CO_2 (compared with that of O_2) in combination with an often increased respiratory rate generally produces ABG analysis results that reflect the presence of respiratory alkalosis. Even slight hypercapnia may indicate severe air trapping and potential impending respiratory failure.

Chest Radiography. Because nearly 75% of asthma patients have a normal chest radiograph, chest radiography is not helpful in diagnosing or determining the severity of asthma. Hyperinflation with flattening of the diaphragm may be evident. Chest radiography is more helpful in detection of complications.

Electrocardiography. Changes evident on electrocardiography, such as ST-segment changes, right ventricular strain, and right axis deviation, usually manifest only in severe attacks and generally are of little significance with regard to the asthmatic condition.

Sputum Analysis. Eosinophilia, which is common in asthmatic patients, may be manifested as the production of grossly purulent sputum. Microscopic evaluation may reveal Curschmann spirals and Charcot-Leyden crystals, rather than polymorphic neutrophils associated with infection.

Serum Values. Eosinophilia (defined as more than 275 eosinophils per cubic millimeter of blood) is common in asthmatic patients with active IgE-mediated bronchial asthma, but its presence does not serve to differentiate extrinsic from intrinsic asthma. Asymptomatic patients with asthma generally have a total blood eosinophil count that is less than 50/mm^3, with an increasing count often signaling the acceleration of bronchial asthma even before such patients experience symptoms. Determination of an increased eosinophil value in the absence of signs and symptoms of asthma requires that a differential analysis be undertaken. Tests for detection of IgE antibodies are performed only if an identifiable and avoidable substance is suspected. In this instance, consultation with a physician skilled in testing for allergic disease may be indicated.

Anesthetic Management

Several important anesthetic considerations and risk-reduction strategies have been reported. The EPR-3 recommends the following to reduce the risk of complications during surgery[103]:

- Before surgery, review the level of asthma control, medication use (especially oral systemic corticosteroids within the past 6 months), and pulmonary function.
- Provide medications before surgery to improve lung function if lung function is not well controlled. A short course of oral systemic corticosteroids may be necessary.
- For patients receiving oral systemic corticosteroids during the 6 months before surgery, and for selected patients on long-term high-dose inhaled corticosteroids (ICS), give 100 mg hydrocortisone every 8 hours intravenously during the surgical period, and reduce the dose rapidly within 24 hours after surgery.

Preoperative Evaluation

A careful preoperative history and physical examination are essential to discerning the current disease status and medication profile. Frequent nocturnal awakenings due to respiratory difficulty, recent increases in medication use, and signs of viral infection may signal an increased likelihood of intraoperative difficulties.[123] Elective procedures in patients who are exhibiting significant respiratory symptoms should be postponed, and the condition of such patients should be normalized as much as possible.[124]

The predictive value of routine pulmonary function testing does not warrant screening use of this modality, rather, it should be used only when patient condition and surgical procedure cause concern for the patient's pulmonary recovery.[48] FEV and peak expiratory flow rate, which can be measured with inexpensive handheld devices, may be helpful in assessing current respiratory status. Values that fall 30% to 50% below expected baseline values indicate a moderate episode of bronchoconstriction. Values below 50% of normal indicate a severe episode.[123]

Medication management of asthma is similar to that of COPD, with anticholinergics more commonly used in COPD, whereas corticosteroids are slightly better supported for asthma.[125] Pretreatment with systemic corticosteroids has been advocated in asthma patients undergoing surgical procedures. Kabalin et al.[126] studied the administration of corticosteroids in asthmatic surgical patients. Of the 89 subjects in the study, 86 had no postoperative wheezing when given either prednisone or hydrocortisone preoperatively. Complications of steroid therapy such as delayed wound healing, infection, or adrenocortical insufficiency were not noted. Ensuring that a patient who is currently receiving inhaled or systemic steroids receives them immediately before surgery is a prudent course.

Routine preoperative medications should be given to allay anxiety. The anticholinergics atropine and glycopyrrolate exhibit mild bronchodilating effects. As noted earlier, asthmatics experience an increased parasympathetic tone, and these agents are most effective as prophylactic drugs given 20 to 30 minutes preoperatively, rather than for acute therapy.[127] Caution must be exercised when administering narcotics to patients whose respiratory difficulties are evident or when using narcotics associated with histamine release, such as morphine. Fentanyl and the other phenylpiperidine analogs commonly used in anesthesia have been widely used and are safe.[127-129] The use of histamine-2 (H_2)–receptor blocking agents such as cimetidine and ranitidine to reduce gastric volume and acidity should be avoided.[109,129] Bronchospasm after their use has been reported, possibly resulting from loss of inhibitory feedback control via presynaptic H_2-receptor blockade, resulting in increased histamine release. Usual drug therapy for asthma is listed in Table 26-13.

Intraoperative Management

Despite a lack of definitive controlled clinical studies, regional anesthetic techniques are generally considered to be safer than general anesthesia.[130] Spinal or epidural levels to the midthoracic area or higher, however, decrease FRC, expiratory reserve volume, and the ability to cough and should be avoided.

All of the common induction drugs—propofol, etomidate, and ketamine—have been used successfully in asthmatic patients, but some differences exist. Ketamine is the only induction drug with bronchodilating properties, which makes it the agent of choice in patients with active asthmatic symptoms who require emergency surgery. Pizov et al.[131] compared thiopental, thiamylal, methohexital, and propofol in a double-blind randomized study in patients with and without asthma. None of the asthmatic patients who received propofol exhibited wheezing 2 and 5 minutes after intubation. Wheezing after intubation occurred in 26% to 45% of the patients who received one of the three barbiturates. The authors suggested that propofol is advantageous for routine induction in asthmatic patients.

The potent inhalation agents produce bronchial relaxation and have all been successfully used in asthmatic patients after administration of an intravenous induction drug. Isoflurane and desflurane, however, are both mild respiratory irritants, which may be a consideration during emergence. It is common practice to blunt this effect with the administration of opiates. Sevoflurane has been shown to be effective for inhalation induction in children.[132,133] Other anesthesia-related medications that should be avoided in asthmatic patients include atracurium and morphine because of histamine release, and β-receptor blockers, which may produce bronchoconstriction. If a β-blocker is desired, esmolol is a good choice, because of its relative β-1 selectivity and very short half-life. Prostaglandins, such as the F2α subtype that is used to stop obstetric bleeding, should be avoided in asthmatic patients, as should ergonovine and related ergot derivatives because of the risk of bronchospasm. Many practitioners avoid long-acting muscle relaxants and the associated possibility of residual muscle weakness in patients with asthma. Ketorolac and other nonsteroidal

TABLE 26-13 Drug Therapy for Asthma

Medication	Adult Use	Adverse Effects	Comments
Corticosteroids			
Methylprednisolone Prednisolone Prednisone	7.5-60 mg daily in a single dose	*Short-term use*: Reversible Abnormalities in glucose metabolism, hypertension, peptic ulcer, and rarely aseptic necrosis *Long-term use*: Adrenal axis Suppression, hypertension, diabetes, Cushing syndrome, muscle weakness	
Inhaled Long-Acting β_2-Agonists (LABAs)			
Salmeterol DPI 50 mcg/blister Formoterol DPI 12 mcg/single-use capsule	1 dose every 12 hours	Tachycardia, skeletal muscle tremor, hypokalemia, prolongation of QTc interval in overdose	Should not be used for acute symptom relief or exacerbations Use only with ICSs Capsules should be used only with the inhaler and should not be taken orally
Combined Medications			
Fluticasone/salmeterol DPI HFA 45 mcg/21 mcg 115 mcg/21 mcg 230 mcg/21 mcg	1 inhalation bid; dose depends on level of severity or control		
Budesonide/formoterol HFA MDI 80 mcg/4.5 mcg 160 mcg/4.5 mcg	2 puffs bid, dose depends on level of severity or control		
Cromolyn/Nedocromil			
Cromolyn MDI 0.8 mg/puff Nebulizer 20 mg/ampule	2 puffs qid (or 1 ampule of nebulizer) qid	Cough and irritation 15%-20% of patients complain of an unpleasant taste from nedocromil	One dose of cromolyn before potential precipitating event provides effective prophylaxis for 1-2 hours Not as effective as inhaled $beta_2$-agonists for EIB as SABA
Nedocromil MDI 1.75 mg/puff			
Immunomodulators			
Omalizumab (Anti IgE) Subcutaneous injection	150-375 mg subcut every 2-4 weeks, depending on body weight and serum IgE level	Pain and bruising of injection sites in 5%-20% of patients Anaphylaxis has been reported in 0.2% of treated patients Malignant neoplasms were reported in 0.5% of patients compared with 0.2% receiving placebo; relationship to drug is unclear	Monitor patients after injections Be prepared and equipped to identify and treat anaphylaxis that may occur
Leukotriene Modifiers			
Leukotriene receptor antagonists (LTRAs) Montelukast	10 mg nightly	No specific adverse effects have been identified	Long-term, may attenuate exercise-induced bronchospasm in some patients, but less effective than ICS
Zafirlukast	40 mg daily	Infrequent cases of reversible hepatitis and, rarely, irreversible hepatic failure resulting in death and liver transplantation	Zarfirlukast is a microsomal P450 enzyme inhibitor that can inhibit the metabolism of warfarin; doses of these drugs should be monitored accordingly
5-Lipoxygenase inhibitor Zileuton 600-mg tablet	2400 mg daily (give tablets qid)	Elevation of liver enzymes has been reported; limited case reports of reversible hepatitis and hyperbilirubinemia; monitor hepatic enzymes (ALT)	Zileuton inhibits P450 enzymes and can inhibit the metabolism of warfarin and theophylline Doses of these drugs should be monitored accordingly

TABLE 26-13 Drug Therapy for Asthma—cont'd

Medication	Adult Use	Adverse Effects	Comments
Methylxanthines			
Theophylline Liquids, sustained-release tablets, and capsules	Starting dose: 10 mg/kg/day up to 300 mg maximum; usual maximum 800 mg/day	Dose-related acute toxicities include tachycardia, nausea and vomiting, tachyarrhythmias (SVT), central nervous system stimulation, headache, seizures, hematemesis, hyperglycemia, and hypokalemia Adverse effects at usual therapeutic doses include insomnia, gastric upset, aggravation of ulcer or reflux, increase in hyperactivity in some children, difficulty in urination in elderly males who have prostatism	Adjust dosage to achieve serum concentration of 5-15 mcg/mL at steady state (at least 48 hours on same dosage) Due to wide interpatient variability in theophylline metabolic clearance, routine serum theophylline level monitoring is essential Various factors (diet, food, febrile illness, age, smoking, and other medications) can affect serum concentrations.

DPI, Dry powder inhaler; *EIB*, exercise-induced bronchospasm; *HFA*, hydrofluoroalkane; *ICS*, inhaled corticosteroids; IgE, immunoglobulin E; *MDI*, metered-dose inhaler; *NA*, not available (either not approved, no data available, or safety and efficacy not established for this age group); *SABA*, short-acting β_2-agonist.

inflammatory agents should be avoided in patients with aspirin-intolerant asthma.[134]

A strategy for mechanical ventilation that avoids lung hyperinflation and barotrauma while allowing for longer expiratory times should be chosen. A reduction in $\dot{V}_E$, by limiting inspiratory times and prolonging expiratory times, and moderate permissive hypercapnia have been suggested.[135-137]

Intraoperative Bronchospasm

The onset of an asthmatic episode may occur abruptly in surgical patients. Airway manipulation, acute exposure to allergens, or the stress of surgery can provoke wheezing in a patient who was previously asymptomatic. The lability of the disease makes assiduous observation crucial. Wheezing often suggests potentially reversible bronchoconstriction, but the extent or degree of wheezing is a notoriously poor indicator of the degree of airway obstruction.[121] In addition, care must be taken to differentiate wheezing of asthmatic origin from other causes of wheezing, such as pneumothorax, endotracheal tube obstruction, endobronchial intubation, anaphylaxis, pulmonary edema, and pulmonary aspiration.[138]

In anesthetized patients, prominent manifestations of the asthmatic episode are wheezing, mucus hypersecretion, high inspiratory pressures, a blunted expiratory CO_2 waveform, and hypoxemia. Mechanical ventilation and positive airway pressure are associated with a higher incidence of air trapping and lung hyperinflation, and the associated inflammation can result in a pneumothorax.[120] Additionally, alveolar overdistention may lead to decreased venous return and diminution of cardiac output. The combination of impaired ventilation and hypoxemia can precipitate increased pulmonary vascular resistance, enhanced right ventricular afterload, and finally hemodynamic collapse.

If an episode of bronchospasm occurs during anesthesia, the following steps are recommended:

1. Deepen the level of anesthesia with a volatile agent, ketamine, propofol, lidocaine, or a combination that rapidly increases anesthetic depth.
2. Administer 100% O_2.
3. Administer a short-acting β_2-agonist (SABA).
4. In severe cases, administer epinephrine intravenously or subcutaneously (in doses of 10 mcg/kg).
5. Administer intravenous corticosteroids—hydrocortisone 2 to 4 mg/kg.
6. Consider intravenous aminophylline if long-term postoperative mechanical ventilation is planned.

Theophylline has little efficacy for the treatment of acute bronchoconstrictive episodes.[139] Episodes of severe airway obstruction may not respond to bronchodilator treatment, and cessation of wheezing may occur with the worsening of obstruction (i.e., the "ominously silent chest").

In treating bronchospasm, SABAs may be administered by metered-dose inhaler or nebulizer, without a clear outcome advantage of either. Multiple doses may be necessary, but it should be noted that these drugs do exhibit a plateau in efficacy. Therefore extremely high does or intravenous β-agonist do not confer additional advantage. Anticholinergic agents such as ipratropium bromide (0.25-0.5 mg nebulizer every 20 minutes × 3) should be used in moderate to severe cases as a second-line therapy to SABA. Because inflammation is central to asthma exacerbation, corticosteroids are becoming more acceptable for acute usage, to prevent the need for longer-term therapy.[140,141] In cases refractory to other bronchodilators, magnesium sulfate (2 gm IV over 20 minutes) has been demonstrated to be safe and effective. Magnesium is effective both as a direct smooth muscle relaxant, and also as an antiinflammatory.[142] Research attention is turning to traditionally chronic-acute medications such as montelukast for their contribution to acute therapy.[140] In severe cases, use of helium-oxygen and noninvasive ventilation may promote gas flow and prevent intubation in cases of impending respiratory failure.[103]

Emergence

The primary issue during emergence is when to extubate. Some authors suggest deep extubation to avoid the mechanical stimulation from the endotracheal tube on awakening. Others fear that the loss of a secure airway before patient awakening may present a greater difficulty than the presence of the endotracheal tube. Either way, a judgment must be made as to when to extubate the patient, with the understanding that the earliest possible time is advantageous for prevention of mechanical bronchial stimulation. Administration of lidocaine and opiates may help diminish airway sensitivity.

The use of anticholinesterase reversal agents also has been an area of concern. The anticholinesterase should be administered in the minimum adequate dose. To ensure a more complete anticholinergic effect, a small increase in the coadministered dose of atropine or glycopyrrolate is suggested.

Asthma and the Pregnant Surgical Patient

Maintaining asthma control during pregnancy is important for the health and well-being of both mother and baby and for ensuring adequate oxygen supply to the fetus. Uncontrolled asthma increases the risk of perinatal mortality, preeclampsia, preterm birth, and low-birth-weight infants. It is safer for pregnant women to be treated with asthma medications than to have asthma symptoms and exacerbations. The EPR-3 report recommends the following general strategies when caring for the pregnant patient[103]:

- The course of asthma improves in one third of women and worsens for one third of women during pregnancy.
- Albuterol is the preferred short-acting β-agonist, (SABA). The most data related to safety during human pregnancy are available for albuterol.
- Inhaled corticosteroids are the preferred long-term control medication. Budesonide is the preferred ICS, because more data are available on using budesonide in pregnant women than are available on other ICSs, and the data are reassuring. However, no data indicate that the other ICS preparations are unsafe during pregnancy.
- Around the time of delivery, note that β-agonists, which promote bronchodilation, also relax the uterus and may impede the progress of labor or encourage postpartum bleeding. Conversely, prostaglandin preparations and ergot alkaloids, which reduce uterine bleeding, can lead to bronchoconstriction.

PULMONARY HYPERTENSION

Definition

Pulmonary hypertension (PH) is defined by a mean pulmonary artery pressure at least 25 mmHg with a pulmonary capillary occlusion pressure of no more than 15 mmHg.[143] Pulmonary arterial hypertension (PAH) is a subgroup of pulmonary hypertension characterized by vascular cell proliferation and cellular changes in low-resistance pulmonary arteries that increase the pulmonary vascular resistance.[144] PAH represents an advanced stage of a large number of cardiovascular diseases.[145]

Although patients with severe PAH would not be considered candidates for nonessential surgical procedures, an anesthetist may encounter patients with PAH presenting for lung transplant or balloon atrial septostomy as treatment.[146,147]

Incidence and Outcome

PAH is a rare disorder, and its true incidence is unknown; however, it is estimated to affect approximately 15 million people.[145] PAH is characterized by a rapidly progressive course with a 79% mortality rate within 5 years of clinical diagnosis.[148] The degree of increase in pressure in the pulmonary circulation has an important influence on the patient's life expectancy,[149] and prognosis is largely determined by right ventricular integrity.[150] Factors that predict perioperative complications include emergency surgery, major surgery, long operative time, use of general anesthesia, and worse New York Heart Association functional class.[144] Pulmonary hypertension carries an increased risk of respiratory failure (approximately 25%), heart failure, and death following noncardiac surgery.[151,152] The perioperative mortality rate associated with PAH is high, even in mild to moderate disease.[145] Recent reviews of outcomes among patients with PAH demonstrated perioperative death rates of 7%,[144] and 18%.[153] The mortality rate among obstetric patients with PAH undergoing surgery is 25%.[154]

Etiology

PAH may be caused by many associated conditions including drug effects, connective tissue disorders, COPD, sarcoidosis, and idiopathic/genetic causes. Five main categories describe the type of pulmonary hypertension: pulmonary arterial hypertension (PAH); pulmonary hypertension due to left heart disease; pulmonary hypertension due to lung diseases and/or hypoxia; chronic thromboembolic pulmonary hypertension; and causes with unclear mechanisms.[154]

Pathophysiology

The normal pulmonary circulation is mostly passive, of low resistance, and highly distensible.[155] PAH is characterized by an increase in vascular tone and the growth and proliferation of pulmonary vascular smooth muscle. Initial reversible vasoconstriction may progress to muscle hypertrophy and irreversible degeneration.[156] Overload of the right ventricle can lead to cor pulmonale and inhibition of coronary perfusion.

Clinical Features and Diagnosis

PAH may be either acute or chronic. In almost all patients with PAH, dyspnea and exercise intolerance usually are the first complaints.[150,157] Patients also may have angina. Right atrial hypertrophy or right ventricular hypertrophy (or both) may be evident on electrocardiogram (ECG). Chest radiography may demonstrate an enlarged pulmonary artery.[158] Cardiac catheterization combined with pulmonary angiography is most informative in assessment of PAH, cardiac reserve, and the effects of pulmonary vasodilator therapy.[156] Vasodilator therapy is attempted when a vasoconstrictor component is identified. Vasodilator challenge may be performed with cardiac catheterization using a rapid and effective pulmonary vasodilator such as nitroglycerin, isoproterenol, nifedipine, prostaglandin E_1, prostacyclin, prostaglandin E_2, hydralazine, nitroprusside, or adenosine for evaluation of the reversibility of PAH.[159] Frequently, open-lung biopsy is performed for assessment of the histopathologic composition of small pulmonary arteries.[160] Noninvasive evaluation includes Doppler echocardiography for measurement of the velocity of tricuspid regurgitation (which correlates well with invasive PAP measurements) and pulmonic peak flow velocity.[161,162]

Attempts to alleviate pulmonary hypertensive disease states have had varied success. Vasodilator agents are used most commonly and may be helpful in patients with reversible vasoconstriction (Table 26-14). Alpha- and beta-adrenergic antagonists have shown the least benefit, whereas prostacyclin has shown the best, and new drugs such as rho-kinase inhibitors show good promise.[146] Possible beneficial effects of pulmonary arterial dilation are preservation of lung function, prevention of right ventricle deterioration, and improved survival.

Anesthetic Management

The principal objectives during anesthesia in patients with PAH are preventing increases in PAH and avoiding major hemodynamic changes.[157] Preoperative evaluation should include ECG, echocardiogram, chest x-ray, and arterial blood gas. Underlying medical conditions (such as COPD) should be optimized. Chronic therapy for PAH should not be discontinued for fear of its hypotensive effect. Instead, intraoperative hypotension should be treated with vasopressors.[145]

TABLE 26-14 Medication Treatment Options for Patients with Pulmonary Hypertension

Drug or Drug Class	Rationale	Potentially Responsive Types of Pulmonary Hypertension	Limitations
Anticoagulants	Reduce risk of pulmonary thromboembolism	Primary PAH and PAH secondary to acute pulmonary thromboembolism, chronic pulmonary thromboembolism, and anorectic drugs	For primary hypertension, concomitant vasodilator treatment also required
Vasodilators			
Calcium channel blockers	Inhibit influx of calcium into smooth muscle cells with elevated vasomotor tone; preferentially act on pulmonary vasculature	Primary PAH and PAH secondary to connective tissue vascular disease and COPD	Initial treatment in specialized centers recommended to avoid severe adverse outcomes such as negative inotropic effects
Epoprostenol (Flolan)—prostacyclin	May replace deficiencies in endogenous prostacyclin; also inhibits smooth muscle proliferation and platelet aggregation	Primary, persistent PAH of the neonate and PAH secondary to ARDS, crises after heart surgery in infants, and connective tissue disease in adults	Peripheral adverse effects occur when administered by continuous IV infusion
Nitric oxide	Interferes with endogenous vasoconstrictor mechanisms	Primary, persistent PAH of the neonate and PAH secondary to corrective cardiac surgery in children, lung or lung-heart transplant surgery in adults, and COPD	Potential adverse effects include increased bleeding times, negative inotropic effects, and formation of potentially toxic products (e.g., nitrogen dioxide, methemoglobin)
Alprostadil (prostaglandin E_1)	Interferes with endogenous vasoconstrictor mechanisms	Secondary to ARDS	Impaired pulmonary metabolism may result in systemic hypotension
Bosentan (Tracleer)	Oral endothelin receptor antagonist	Severe PAH	Hepatotoxicity
Treprostinil (Remodulin) Ambrisentan (Letairis) Sildenafil (Revatio) Tadalafil Iloprost (Ventavis)	Prostacyclin analog Selective endothelin type A (ET_A) receptor antagonist Inhibits phosphodiesterase type 5 Synthetic analog of prostacyclin PGI2	Primary PAH; classes II-IV Treatment of symptomatic patients (WHO class II or III) with pulmonary arterial hypertension (PAH) Treatment for PAH along with anticoagulant and a diuretic Treatment of PAH in patients with NYHA class III or IV symptoms	Given by continuous infusion via wearable infusion pump; peripheral edema, nasal congestion, and serious birth defects may occur Headaches, dyspepsia, and transient color vision Requires inhalation administration 6-9 times a day
Inhibitors of Vasoconstriction			
α-Adrenergic receptor antagonists	Direct vasodilation; inhibit vasopressin release from pituitary	Persistent PAH of the neonate (especially preterm infants) and PAH secondary to COPD	Can cause severe systemic adverse effects
ACE inhibitors	Inhibit formation of the vasoconstrictor angiotensin II	Secondary to connective tissue disease, effects of high altitude, and congestive heart failure	Prolonged treatment required to obtain an effect

The anesthetic plan should be based upon maintaining cardiovascular homeostasis, particularly related to the pulmonary vasculature. General or regional anesthesia may be used, but a slight tendency toward more frequent complications has been observed in patients receiving general versus regional anesthesia.[144] In that same review, invasive monitoring with pulmonary artery catheter or transesophageal echocardiography did not reduce complications, but that may have been due to those procedures being used in more complicated patients. Neuraxial anesthesia should be considered because it is appropriate for aortic stenosis—striving for slow, gentle onset and avoiding rapid or extensive changes in SVR. For induction of general anesthesia, etomidate is a likely choice, whereas ketamine, which causes an increase in PVR, should be avoided. A balanced technique will avoid unnecessary vasodilation from volatile agents, and an opioid-heavy technique should rely upon volatile agents for amnesia instead of high concentrations of nitrous oxide. Sympathetic stimulation from desflurane should be avoided. Conditions that increase the PVR (hypoxemia, hypercarbia, acidosis, pain, hypothermia) also should be avoided.[144]

Hypotension during surgery should be treated aggressively, and for this reason, invasive arterial pressure monitoring should be used with few exceptions. Hypotension can begin a downward spiral from which it is difficult to recover, but the anesthetist must also discriminate between a drop in SVR or right ventricular failure as the cause of hypotension. In the former case, vasopressors are indicated, whereas in the latter, inhaled nitric oxide or iloprost would be used.[163,164]

COR PULMONALE

Definition

The term *cor pulmonale* refers to right heart failure secondary to pulmonary pathology. Typically this results from pulmonary hypertension that leads to progressive right ventricular hypertrophy,

BOX 26-5

Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension (PAH)
   - Idiopathic PAH
   - Familial PAH
   - PAH related to:
     - Connective tissue disease
     - Human immunodeficiency virus infection
     - Portal hypertension
     - Drug/toxins
     - Congenital heart disease
     - Persistent pulmonary hypertension of the newborn
   - PAH with venular/capillary involvement (pulmonary venoocclusive disease, pulmonary capillary hemangiomatosis)
2. Pulmonary hypertension with left heart disease
   - Arterial or ventricular
   - Valvular
3. Pulmonary hypertension with lung disease/hypoxemia
   - Chronic obstructive pulmonary disease
   - Interstitial lung disease
   - Sleep-disordered breathing
   - Developmental abnormalities
4. Pulmonary hypertension due to chronic thrombotic and/or embolic disease
   - Thromboembolic obstruction of proximal pulmonary arteries
   - Thromboembolic obstruction of distal pulmonary arteries
   - Nonthrombotic pulmonary emboli
5. Miscellaneous

From Murray JF, Nadel JA. *Textbook of Respiratory Medicine*. 5th ed. Philadelphia: Saunders; 2010.

dilation, and eventual cardiac decompensation. This situation arises from a variety of disorders that affect the structure and function of the lungs (Box 26-5). COPD is the leading cause of cor pulmonale.[165]

Incidence and Outcome

In individuals older than 50 years of age, cor pulmonale is the third most common cardiac disorder (after ischemic heart disease and hypertensive cardiac disease). The male-to-female ratio of incidence of the disease is 5:1, and 10% to 30% of patients admitted to the hospital with coronary heart failure exhibit cor pulmonale.[166] The incidence of pulmonary hypertension among patients with advanced COPD is estimated to be 50%.[167]

Prognosis is determined by the pulmonary disease responsible for the increased PVR. In patients with COPD in whom P_{AO_2} can be maintained at near-normal levels, the prognosis is favorable. However, cor pulmonale associated with hypoxic lung disease is associated with a 70% rate of mortality within 5 years after onset of associated peripheral edema.[168] Prognosis is poor for those patients in whom cor pulmonale is the result of gradual obstruction of pulmonary vessels by intrinsic pulmonary vascular disease or pulmonary fibrosis. These anatomic changes cause irreversible alterations in the pulmonary vasculature, resulting in fixed elevations of PVR.

Etiology

COPD is associated with the functional loss of pulmonary capillaries and subsequent arterial hypoxemia; these events initiate pulmonary vasoconstriction, which is the leading cause of chronic cor pulmonale. The World Health Organization has proposed a classification of conditions associated with cor pulmonale. Diseases associated with hypoxic pulmonary vasoconstriction include the following:

- COPD
- Bronchiectasis
- Chronic mountain sickness
- Cystic fibrosis
- Idiopathic alveolar hypoventilation
- Obesity-related hypoventilation syndrome
- Neuromuscular disease
- Kyphoscoliosis
- Pleuropulmonary fibrosis
- Upper airway obstruction

Diseases that produce obstruction or obliteration of the pulmonary vasculature include the following:

- Pulmonary embolism (PE)
- Pulmonary fibrosis
- Pulmonary lymphangitic carcinomatosis
- Idiopathic PAH
- Progressive systemic sclerosis
- Sarcoidosis
- Intravenous drug abuse
- Pulmonary vasculitis
- Pulmonary venoocclusive disease

Pathophysiology

Pulmonary hypertension is always an underlying pathology of cor pulmonale. In COPD, polycythemia, hypoxic pulmonary vasoconstriction, hyperinflation, and the reduction in size of the pulmonary vascular bed lead to pulmonary hypertension.[169] Sustained pulmonary hypertension produces hypertrophy of the smooth muscle in the tunica media, and remodeling of the vascular smooth muscle leads to irreversible increases in PVR. Also contributory is an imbalance in nitric oxide and endothelin, with the balance tipped toward the vasoconstrictive effects of endothelin.[169] The rate at which right ventricular dysfunction develops depends on the magnitude of pressure increase in the pulmonary circulation and on the rapidity with which this increase occurs. For example, pulmonary embolism may lead to right ventricular failure in the presence of a mean PAP as low as 30 mmHg. By contrast, when PAH occurs gradually, as it does in COPD, right ventricular compensation occurs; congestive heart failure (CHF) rarely occurs before mean PAP exceeds 50 mmHg.

The normal pulmonary circulation can accommodate a maximal right ventricular output with minimal increase in pulmonary pressure via distention of existing vessels or recruitment of unused vessels. The compensatory mechanism for pressure overload on the right ventricle involves enhancement of contractility and an increase in preload, which result in an increase in right ventricular end-diastolic volume.[170] In response to chronic pressure overload imposed by the PAH, right ventricular hypertrophy occurs (chronic leads to hypertrophy). Brain natriuretic peptide shows a positive correlation to ventricular stretch, which occurs in cor pulmonale.[169] Cor pulmonale can be precipitated acutely. For example, patients with COPD have larger than normal increases in PAP when executing maneuvers that increase pulmonary blood flow (e.g., exercise, even if resting hemodynamic status is normal).[171] Cor pulmonale can be produced acutely by sudden increases in PVR, such as from exercise, pulmonary embolism, or ARDS.[172]

Clinical Features and Diagnosis

Clinical manifestations of cor pulmonale often are nonspecific and obscured by coexisting COPD. Echocardiography may be useful,[172] but right-sided heart catheterization usually is required

for diagnosis. Cardiac catheterization combined with pulmonary angiography provides the most definitive information on the degree of PAH, cardiac reserve, and the effects of pulmonary vasodilator treatment.[156]

Symptoms of cor pulmonale are retrosternal pain, cough, dyspnea on exertion, weakness, fatigue, early exhaustion, and hemoptysis.[156] Occasionally hoarseness secondary to left recurrent laryngeal nerve compression by the enlarged pulmonary artery is present.[166] Syncope on effort may occur, reflecting the inability of the right ventricular stroke volume to increase in the presence of a fixed elevation of PVR.

Physical signs of cor pulmonale include the following:

- Elevation of jugular venous pressure
- Cardiac heave or thrust along the left sternal border and S_3 gallop
- Presence of an S_4 heart sound secondary to significant right ventricular hypertrophy
- A widely split S_2 heart sound
- Possible murmur of pulmonic and tricuspid insufficiency
- Hepatomegaly, ascites, and lower-extremity edema (late signs)

Diagnostic Testing

Electrocardiography. Right atrial displacement, right ventricular hypertrophy, right atrial hypertrophy, and right atrial enlargement may be observed. *P pulmonale* (tall, peaked p-waves) are a characteristic sign. Patients may develop concomitant supraventricular tachycardic arrhythmias (i.e., tachycardic atrial fibrillation, sinus tachycardia, and paroxysmal atrial tachycardia).

Imaging Studies. On chest radiography, enlargement of the pulmonary arteries is observed, followed by right ventricular hypertrophy. Meeting criteria for pulmonary artery dilation has 98% sensitivity for diagnosing pulmonary hypertension.[169] Echocardiography may be helpful to demonstrate enlargement, dilation, or thickening of the right ventricle, with or without tricuspid valve regurgitation, and elevated pulmonary artery systolic pressure. All of these findings suggest that at least acute or possibly chronic PAH is present. Shifting of the intraventricular septum as a result of increased right ventricular end-diastolic volume is another characteristic finding.[169] Although more expensive, magnetic resonance imaging provides better evaluation of the ventricular wall thickness than does echocardiography.

Treatment

The three major drug classes for treatment of PAH are prostanoids, endothelin receptor antagonists, and phosphodiesterase inhibitors. The goals of treatment are decreasing the workload of the right ventricle, reducing PVR, preventing increases in PAP, and avoiding major hemodynamic changes. Diuretics may be used to reduce cardiac workload, but caution must be employed to avoid causing inadequate preload.[169] Improvement of gas exchange is the primary focus of treatment in COPD patients with cor pulmonale.[156,173] Treatment includes supplemental administration of O_2 to maintain a Pa_{O_2} of greater than 60 mmHg or an arterial O_2 saturation of greater than 90%. O_2 is the only vasodilator with a selective effect on pulmonary vessels that is not associated with a risk of worsening hypoxemia.[174] Ventilation under anesthesia should focus on maintaining low airway pressures and avoiding PEEPi.[172]

Heart-Lung Transplantation

A heart-lung transplantation may ultimately be needed when cor pulmonale progresses despite the provision of maximal medical therapy.

In general, preoperative preparation of the patient with cor pulmonale includes the following:

- Elimination and control of acute or chronic pulmonary infections
- Reversal of bronchospasm
- Improvement in clearance of secretions
- Expansion of collapsed or poorly ventilated alveoli
- Hydration
- Correction of any electrolyte imbalance

Anesthetic Management

Regional anesthesia technique may be appropriate as long as a high sensory level of anesthesia is not required, because any decrease in systemic vascular resistance in the presence of a fixed PVR may produce undesirable degrees of systemic hypotension.[175]

General Anesthesia

Volatile agents decrease PVR. Studies have demonstrated that PAP is decreased by isoflurane. N_2O has been shown to increase PVR in patients with PPH. Intravenous agents, with the exception of ketamine, appear to have little effect on PVR. During all stages of anesthesia, manipulations that increase PAP must be avoided. Five key principles should be followed[156]:

- Maintain good oxygenation.
- Avoid acidosis.
- Avoid the use of exogenous and endogenous vasoconstrictors.
- Avoid presenting stimuli that increase sympathetic tone.
- Avoid hypothermia.

PULMONARY EMBOLISM

Definition

Pulmonary embolism (PE) is the impaction of a dislodged thrombus into the pulmonary vascular bed. A significant thrombus obstructs blood flow and causes forward ischemia and rearward cardiac overload.

Incidence and Outcome

Being a major source of morbidity and mortality, PE affects between 300,000 and 600,000 people in the United States annually. One-third of them develop post-thrombotic syndrome (long-term complications such as swelling, pain, and discoloration in the affected limb), one-third of people with PE die within 1 month of diagnosis, and one-fourth of them present with sudden death as the first symptom.[176] Pulmonary emboli originate from deep vein thrombosis (DVT) of the iliofemoral vessels in approximately 90% of patients, although other sites of thrombus formation include the pelvic veins, the renal and hepatic veins, the axillary veins in the upper extremities, and the right atrium.[177] PE occurs in approximately 1% of surgical patients overall,[178] but the incidence is as high as 30% among high-risk orthopedic procedures.[179] Mortality from perioperative PE is approximately 10%.[178,180]

Etiology

PE is considered by some to be a clinical manifestation of DVT rather than a separate entity, because almost all incidents of PE result from an embolized vein thrombosis. The incidence of symptoms from DVT is greater with more proximal sites of thrombosis. Three major factors promote the formation of venous thrombi: stasis of blood flow, venous injury, and hypercoagulable states. These three components are described as the Virchow triad and underlie the risk factors for venous thrombosis (Box 26-6). Smoking and obesity have been shown to be independent risk factors for PE in women,[181] and malignancies are a particularly high risk for

BOX **26-6**

Risk Factors for Venous Thrombosis, Based Upon Virchow's Triad

Stasis
- Congestive heart failure or cor pulmonale
- General anesthesia
- Immobility
- Obesity
- Prior venous thrombosis
- Varicose veins

Hypercoagulability
- Disseminated intravascular coagulation
- Estrogen therapy/oral contraceptive use
- Infection
- Malignancy
- Nephrotic syndrome
- Pregnancy
- Thrombophilias:
  - Anticardiolipin antibody
  - Factor V Leiden mutation
  - Protein C and S deficiencies
  - Antithrombin III deficiency

Vascular injury
- Trauma
- Surgery

Modified from Ozsu S, et al. The role of risk factors in delayed diagnosis of pulmonary embolism. *Am J Emerg Med*. 2011;29(1):26-32; Epley D. Pulmonary emboli risk reduction. *J Vasc Nurs*. 2000; 18(2):61-8;69-70; Dijk FN, et al. Pulmonary embolism in children. *Paediatr Respir Rev*. 2012;13[2]:112-122.

PE. Cancer patients are found to have over twice the incidence of venous thromboembolism as that in the general population, and this risk is heightened further when indwelling central venous catheters are in place.[182] Other, less common causes of PE include air, tumor, bone, fat, catheter fragments, and amniotic fluid. Fillers used in illicit drug preparations by intravenous drug abusers also may cause PE. Of particular concern to anesthesia providers are air emboli caused by the opening of venous structures during surgery or by disconnected intravenous lines.

Most pulmonary emboli resolve within 8 to 21 days of the initial presentation; 10% to 20% are estimated to develop into unresolved emboli, and 0.5% to 4% lead to the development of chronic PAH. Chronically unresolved emboli that lodge in major pulmonary arteries may become incorporated into the vascular walls and obstruct blood flow. Patients with such emboli are surgical candidates, representing approximately 1000 cases in the United States each year.[183]

Pathophysiology

Once a thrombus has formed, it rarely remains static. It can be dissolved through fibrinolysis, become "organized" into a vessel wall, or be released into the circulation. Because thrombi are most friable early in their development, it is then that the greatest risk for embolization exists.

If the fragment is released from its site of formation, it can be rapidly swept into one of the pulmonary arteries. It may pass through the vasculature completely, disintegrate, and block several smaller pulmonary vessels; or if the thrombus is sufficiently large, it may impact against one or both pulmonary arteries and cause pulmonary collapse, massive infarction, and ultimately cardiac arrest.[184]

Within the pulmonary capillaries, hemorrhage is frequently seen distal to the site of the embolism. The alveolar structures in this area can remain viable for a period of time.[184] However, if the clot does not dissolve or if it is not quickly squeezed through the vasculature, the alveolar structure will be permanently damaged. Bronchial circulation limits this consequence of pulmonary infarction, and substantial damage is unusual unless an embolus completely blocks a large artery or preexisting lung disease is present.[185] In fact, less than 10% of emboli actually cause any type of infarction.[186]

Mechanism

When a pulmonary artery is occluded, ventilation distal to the obstruction is decreased. This is a result of the direct effect of alveolar P_{CO_2} (P_{ACO_2}) on the smooth muscle of the local small airways, which is bronchoconstriction. The reduction of airflow to the unperfused lung reduces the amount of wasted ventilation. This mechanism is very short lived, with distribution of ventilation returning to normal within several hours.[184,186] The elastic properties of the embolized region may change some hours after the event; localized atelectasis is believed to result from a loss of pulmonary surfactant, the rapid turnover of which requires adequate blood flow.[186]

Pulmonary Function

Pulmonary Circulation. Normally the pulmonary circulation has a very large reserve capacity. However, when PAPs increase, previously unfilled capillaries are recruited, and distention occurs. This allows for obstruction of at least half of the pulmonary circulation before a substantial increase in PAP becomes manifest.[184] Obstruction of perfusion begins a damaging cycle, as blood flow is further reduced by serotonin and platelet-activating factor from platelets of the embolus, vasoactive peptides from plasma, and histamine from mast cells.[187] Occlusion of approximately 70% of the pulmonary vascular bed results in PAH with subsequent right ventricular failure, increased end-diastolic pressures, and development of arrhythmias and possibly of tricuspid valve incompetence.[185] Pulmonary edema may follow, because blood flow is diverted to alternate areas of lung.[184,188] Acute pulmonary edema develops when hyperperfusion from intact circulation to the perfused lung results in extravasation of fluid into the alveoli. If the clot breaks up and passes quickly or if the affected area is minimal, the PAPs gradually decrease with embolus resolution by fibrinolysis or transformation onto the vessel wall as a scar.[185]

The right ventricle will initially increase stroke volume through adrenergic activation. Eventually, though, the increased ventricular volume shifts the intraventricular septum and reduces left heart output. The reduction in left ventricular output can compromise coronary filling, and lead to ischemia, which further degrades contractility.[187]

Gas Exchange. An embolus can have a significant effect on gas exchange. Moderate hypoxemia without CO_2 retention is often seen after PE as both physiologic shunt and dead space increase. In spontaneously breathing patients, P_{aCO_2} is maintained at the normal level after PE by increasing the respiratory rate. The resultant increase in ventilation may be substantial because of the large physiologic dead space. Because the anesthetized patient who is not spontaneously breathing cannot increase his or her ventilation, the P_{aCO_2} rises and O_2 saturation decreases more quickly.[186,189]

BOX 26-7

Differential Diagnosis of Acute Intraoperative Pulmonary Embolism

- Anaphylactic reaction
- Aortic dissection
- Aortic stenosis
- Brainstem stroke
- Bronchospasm
- Heart failure
- Hypertrophic cardiomyopathy
- Myocardial infarction
- Pulmonary hypertension
- Tension pneumothorax

The difference between Pa_{CO_2} and end-tidal P_{CO_2} ($P_{ET}CO_2$) is a very useful indicator in PE, with high sensitivity and specificity.[186] The mixed $P_{ET}CO_2$ tends to be low because of the high $\dot{V}/\dot{Q}$ ratio in the embolized region. Particularly if underlying ventilation and perfusion prior to embolization were well matched, the $P_{ET}CO_2$ is an accurate and immediate indicator of the status of pulmonary gas exchange. In anesthetized patients, the Pa_{CO_2} continues to increase more quickly because of this increase in dead space without ventilatory compensation. If the embolus does not completely occlude the vessel, the discrepancy between $P_{ET}CO_2$ and Pa_{CO_2} may not be as great.[184]

Clinical Features and Diagnosis

The patient's clinical presentation depends largely on the size of the embolus. Signs and symptoms of PE vary and are common to a number of disorders. Therefore, the differential diagnosis may be difficult (Box 26-7). Dyspnea of sudden onset appears to be the only common historic complaint. Sudden hypotension and tachycardia, wheezing, tachypnea, and signs of right ventricular overload are common. Hypoxemia is a constant feature of PE, possibly owing to intrapulmonary shunting. Because PE often occurs without premonitory signs and the symptoms are not highly specific, in the acute setting, diagnosis is often presumptive and by exclusion. Table 26-15 outlines common clinical findings (history and symptoms) in patients who developed pulmonary embolism.

Small emboli often go unrecognized; however, multiple small emboli can produce extensive obstruction of the pulmonary capillary bed, possibly causing PAH and cardiac failure. Generally, however, small thromboemboli are incorporated into the arterial wall and have little effect on either parenchyma or the circulation. Patients may complain of dyspnea on exertion that may lead to syncope; sometimes, a right ventricular "heave" or a split-second heart sound can be detected on examination. Patients with medium-sized emboli may present with pleuritic pain accompanied by dyspnea, a slight fever, and a productive cough that yields blood-streaked sputum. These patients usually are tachycardic. A small pleural effusion can develop and mimic the appearance of pneumonia.

Massive emboli can produce sudden cardiac collapse. Preceding symptoms range from pallor, shock, and central chest pain to sudden loss of consciousness. In patients with cardiac collapse, the pulse becomes rapid and weak, blood pressure decreases, neck veins become engorged, and cardiogenic shock may be present or impending. Also, a decrease in $P_{ET}CO_2$ and an increase in Pa_{CO_2} occur, with the difference between the values increasing as conditions worsen. If a pulmonary artery catheter is in place, pulmonary artery pressures (PAPs) are observed to increase rapidly. The ECG may begin to show right ventricular strain. The prognosis for these patients is very poor.[184]

TABLE 26-15 Associated Factors in Patients with Pulmonary Embolism*

Finding	Incidence
Dyspnea	96%
Tachycardia	71%
Acute onset of symptoms (<48 hr)	70%
Syncope	35%
Arterial hypotension (SBP <90 mmHg)	34%
Congestive heart failure	32%
History of venous thrombosis	29%
Recent major operation (within 10 days)	27%
Cancer	12%
Major trauma or fracture within 10 days	11%
Chronic pulmonary disease	11%
Stroke	2%

*Data from 1001 patients with pulmonary embolism.
SBP, Systolic blood pressure.

Diagnostic Testing

Few of the common preoperative tests indicate the presence of PE. A number of imaging and laboratory tests are available for diagnosis (Table 26-16). The most common electrocardiographic signs are noted in Box 26-8. In addition, echocardiography may demonstrate right ventricular dilation or dyskinesis, septal shift, tricuspid regurgitation, or dilation of the pulmonary artery. In the patient with PE, ABG analysis generally reveals hypoxemia and increased differences between Pa_{CO_2} and $P_{ET}CO_2$, which result from ventilation of unperfused alveoli.[189] Massive PE is associated with severe hypoxemia and hypocapnia. An initial difference between Pa_{CO_2} and $P_{ET}CO_2$ is common early during the embolic event.[186] Some common conditions associated with an increased risk for deep vein thrombosis are given in Box 26-9.

There are limited laboratory analyses useful to support the diagnosis of PE. The d-dimer assay cannot rule in PE, but a normal result makes diagnosis of PE very unlikely. Troponin I and troponin T levels are elevated in less than one half of cases of significant PE. Therefore, their presence is not useful for diagnosis, but elevation of troponins is associated with adverse outcomes including death and the need for aggressive resuscitation.[190]

Prevention

Aggressive efforts at prevention have been successful in reducing the incidence of DVT in surgical patients. Use of compression stockings, intermittent pneumatic compression devices, administration of various anticoagulants and thrombolytics, and ambulation are typical measures for preventing embolus formation. Because surgery is a risk factor for venous thromboembolism, care should be taken to reduce risk for every surgical patient. Anesthesia for patients at risk for PE is aimed at avoiding venous stasis, hypercoagulability, and vessel injury. This involves ensuring administration of lower extremity circulatory aids or anticoagulants before anesthetic induction. Anesthetic planning also may contribute to

TABLE 26-16 Diagnostic Tests for Suspected Pulmonary Embolism

Test	Comments
Oxygen saturation	Nonspecific, but suspect PE if there is a sudden otherwise unexplained decrement
Electrocardiogram	May be normal, especially in younger, previously healthy individuals; may provide alternative diagnosis, such as myocardial infarction or pericarditis
Echocardiography	Best used as a prognostic test in patients with established PE, rather than as a diagnostic test; many patients with larger PE will have normal echocardiograms
Lung scanning	Usually provides ambiguous results, used in lieu of chest CT for patients with anaphylaxis to contrast agent, renal insufficiency, or pregnancy
Chest CT	Most accurate diagnostic imaging test for PE; beware if CT result and clinical likelihood are discordant
Pulmonary angiography	Invasive, costly, uncomfortable; used primarily when local catheter intervention is planned
D-dimer	An excellent "rule out" test if normal, especially if accompanied by non-high clinical suspicion
Venous ultrasonography	Excellent for diagnosing acute symptomatic proximal DVT, but a negative test does not rule out PE, because a recent leg DVT may have embolized completely; calf vein imaging is operator dependent
Magnetic resonance imaging	Reliable only for imaging proximal segmental pulmonary arteries; requires gadolinium but does not require iodinated contrast agents

BOX 26-8

Electrocardiographic Signs Associated with Pulmonary Embolism

- Negative T wave in leads V1-V5
- Right axis deviation greater than 90 degrees
- Negative T wave in leads II, III, aVF
- Pulmonary P wave
- R greater than S or Q in aVR
- Complete or incomplete right bundle branch block (RBBB)

From Lewczuk J, et al. Electrocardiographic signs of right ventricular overload in patients who underwent pulmonary embolism event(s). Are they useful in diagnosis of chronic thromboembolic pulmonary hypertension? *J Electrocardiol.* 2004;37(3):219-25.

risk reduction. For example, the use of neuraxial anesthesia, which causes vasodilation in the lower extremities, reduces the incidence of DVT by 50% in comparison to general anesthesia.[191,192]

Medical and Surgical Treatment

Guidelines for treatment of PE are summarized in Box 26-10. Anticoagulation is the most common intervention, aimed at preventing further insult. Clot removal is most often accomplished with thrombolytic agents. Surgical intervention is indicated for patients who are unresponsive to other measures; however, this represents only around 1% of patients.[193] Currently the most common surgical procedure for patients with PE is placement of an umbrella filter, which traps thromboemboli. Vena cava filters are usually indicated for patients with bleeding disorders who are not able to tolerate standard anticoagulant therapy, or for those who are refractory to anticoagulant therapy. The filter is placed in the inferior vena cava under fluoroscopic guidance, usually below the renal veins at the level of the L2 to L3. Suprarenal placement is required when a thrombus directly involves the renal veins or has propagated above the level of the renal veins. The presence of an infrarenal filter in a pregnant woman may place her and her fetus at risk because of the possibility that the filter will come in to contact with the gravid uterus. Suprarenal placement prevents this risk.

Thromboendarterectomy is the treatment of choice for chronic large vessel thromboembolic PAH.[194] Desired results include decreased pulmonary vascular resistance (PVR), improved CO, restoration of exercise tolerance, and resolution of hypoxemia. Improvements in RV function and hemodynamics may be prompt, whereas improvements in gas exchange occur over weeks to months. Although the role of pulmonary embolectomy remains controversial, in the few patients who do not benefit from optimal medical therapy, it remains an acceptable procedure.[195]

Anesthetic Management

Anesthetic management of a patient presenting with a pulmonary embolus is primarily aimed at preventing further embolism and providing respiratory and cardiovascular support.[196] Table 26-17 outlines preventative prophylactic medications for patients at risk of PE. The use of a high F_iO_2 supports pulmonary vasodilation. If PAP is monitored, the anesthesia provider will have additional information to optimize right-sided heart function and assess the effects of anesthetic management on PVR.[188] However, the risk-benefit ratio of a pulmonary artery catheter should consider the possibility that these catheters may dislodge clots in the right side of the heart. Induction is often performed with etomidate. Ketamine may appear to be a compelling choice in the face of cardiovascular compromise, but ketamine may increase PVR.[186] The use of N_2O is generally believed to be acceptable. However, the use of N_2O may be limited by the desire to administer high F_iO_2 and concerns for increasing the PVR. The use of N_2O is contraindicated in patients with venous air embolism, because of the potential for N_2O to rapidly expand the volume of the embolism.[185] Patients with moderate to severe PE often are experiencing acute right-sided heart failure. Cardiac function can be optimized by the use of minimally depressing cardiac agents such as opioids.

Persistent, severe hypotension, such as that accompanying a massive PE, may necessitate the use of a cardiotonic agent or partial or full cardiopulmonary bypass. The goal is preservation of perfusion to the brain and heart until cardiopulmonary bypass is started and surgical removal of the clot attempted.[188] Patients with PE are extremely sensitive to any anesthetic agent. It is critical to have heparin ready to support initiation of bypass if necessary. Although separation from bypass is beyond the scope of this chapter, the anesthetist should anticipate that difficulties may be encountered. Reports of operative mortality during pulmonary embolectomy range from 11% to 55%, with much higher rates among patients experiencing cardiac arrest.[197]

BOX **26-9**

Conditions Associated with Increased Risk for Deep Vein Thrombosis

- Advancing age
- Obesity
- Previous venous thromboembolism
- Surgery
- Trauma
- Active cancer
- Acute medical illnesses—e.g., acute myocardial infarction, heart failure, respiratory failure, infection
- Inflammatory bowel disease
- Antiphospholipid syndrome
- Dyslipoproteinemia
- Nephrotic syndrome
- Paroxysmal nocturnal hemoglobinuria
- Myeloproliferative diseases
- Behçet's syndrome
- Varicose veins
- Superficial vein thrombosis
- Congenital venous malformation
- Long-distance travel
- Prolonged bed rest
- Immobilization
- Limb paresis
- Chronic care facility stay

- Oral contraceptives
- Hormone replacement therapy
- Heparin-induced thrombocytopenia
- Other drugs
- Chemotherapy
- Tamoxifen
- Thalidomide
- Antipsychotics
- Central venous catheter
- Vena cava filter
- Intravenous drug abuse

BOX **26-10**

Guidelines for the Treatment of Pulmonary Embolism

1. Treat DVT or PE with therapeutic levels of unfractionated intravenous heparin, adjusted subcutaneous heparin, or low-molecular-weight heparin for at least 5 days and overlap with oral anticoagulation for at least 4 to 5 days. Consider a longer course of heparin (approximately 10 days) for massive PE or severe iliofemoral DVT. Enoxaparin, tinzaparin, or fondaparinux also may be used depending on renal function and indications.
2. For most patients, heparin and oral anticoagulation can be started together and heparin discontinued on day 5 or 6 if the INR has been therapeutic for 2 consecutive days.
3. Patients with reversible or time-limited risk factors can be treated for at least 3 months. Patients with a first episode of idiopathic DVT should be treated indefinitely. Approved regimen is warfarin, target INR of 2.0 to 3.0 for 6 months, followed by low-intensity warfarin, target INR of 1.5 to 2.0.
4. The use of thrombolytic agents continues to be highly individualized, and clinicians should have some latitude in using these agents. Patients with hemodynamically unstable PE or massive iliofemoral thrombosis are the best candidates.
5. Inferior vena caval filter placement is recommended when there is a contraindication to or failure of anticoagulation, for chronic recurrent embolism with pulmonary hypertension, and with concurrent performance of surgical pulmonary embolectomy or pulmonary endarterectomy.

Detection of Pulmonary Embolism During Anesthesia

In the intubated patient under general anesthesia, clinical presentation is limited to objective signs. A decreasing PET_{CO_2} and tachycardia usually are the first signs of PE.[188,189] These can be followed by a decrease in Sa_{O_2} and the generation of ABG values that indicate unexplained arterial hypoxemia. In the case of massive PE, abrupt, unexplained hypotension and tachycardia are the classic (albeit, nonspecific) signs. Increased PAP and central venous pressure (CVP) are observed in combination with a decrease in systolic and diastolic blood pressures.[189] Bronchospasm may occur.[183] Finally, ECG changes that indicate right axis deviation, incomplete or complete right bundle branch block, or peaked T waves may be observed in the presence or absence of an accompanying systolic ejection murmur.[184,189]

Intraoperative Management of Acute PE

In the case of suspected PE in the anesthetized patient, treatment requires rapid intervention because cardiovascular decompensation can occur quickly. First and most importantly, an airway must be established by intubation if the patient is not already intubated. Second, delivery of the anesthetic agent must be discontinued, and administration of a 100% Fi_{O_2} initiated.[188] Next, the circulatory system should be supported with the infusion of intravenous fluids or blood (or both) as needed, and sympathomimetics initiated if necessary. Norepinephrine may be the vasopressor of choice, because of its ability to support contractility as well as improve brain perfusion through vasoconstriction.[187] Epinephrine, dopamine, or dobutamine + norepinephrine may also be helpful. Ventricular dysrhythmias should be treated with

TABLE 26-17 Prevention of Venous Thromboembolism

Condition	Strategy
Total hip or knee replacement; hip or pelvis fracture	Warfarin (Coumadin) (target INR 2.5) × 4-6 weeks LMWH/subcut (e.g., fondaparinux 2.5 mg subcut [except for total knee replacement]) or rivaroxaban 10 mg daily or dalteparin 2500-5000 units daily subcut where available IPC ± warfarin
Gynecologic cancer surgery	LMWH consider 1 month of prophylaxis
Thoracic surgery	IPC *or* GCS *plus* unfractionated heparin, 5000 units bid or tid
High-risk general surgery (e.g., prior VTE, current cancer, or obesity)	IPC *or* GCS *plus* unfractionated heparin, 5000 units bid tid or LMWH
General, gynecologic, or urologic surgery (without prior VTE) for noncancerous conditions	GCS *plus* unfractionated heparin 5000 units bid or tid Dalteparin 2500 units subcut once daily Enoxaparin 40 mg subcut once daily
Neurosurgery, eye surgery, or other surgery when prophylactic anticoagulation is contraindicated	GCS ± IPC
Neurosurgery	Unfractionated heparin 5000 units bid or tid Enoxaparin 40 mg subcut once daily GPC *or* IPC Consider surveillance of lower extremity by ultrasonography
Orthopedic surgery	Enoxaparin 30 mg twice daily Enoxaparin 40 mg once daily* Dalteparin 5000 units once daily* Fondaparinux 2.5 mg subcut daily Warfarin (target INR = 2-3) GCS *plus* IPC
General surgery	Unfractionated heparin 5000 units bid or tid Enoxaparin 40 mg daily Dalteparin 2500 or 5000 units once daily GCS *plus* IPC
Pregnancy	Enoxaparin 40 mg daily Dalteparin 5000 units daily
Medical patients	Unfractionated heparin 5000 units bid or tid Enoxaparin 40 mg daily Dalteparin 5000 units once daily Fondaparinux 2.5 mg subcut daily in patient who cannot tolerate heparin Consider surveillance of lower extremity by ultrasonography GCS *plus* IPC
Long distance air travel	LMWH for high-risk patients

intravenous administration of lidocaine or amiodarone, and the patient should receive PEEP for optimization of oxygenation.[185] If symptoms are refractory to treatment, thrombolysis or pulmonary embolectomy may be necessary. Severe hemodynamic difficulty should be anticipated and resuscitative efforts continued. In severe cases, cardiopulmonary bypass may be necessary until the obstruction can be relieved.

Patients with PE present particular management challenges in their postoperative course, including reperfusion edema, persistent hypoxemia, pericardial effusion, psychiatric disorders, and pulmonary blood flow steal. The areas of the lung to which pulmonary artery flow has been restored are subject to development of reperfusion pulmonary edema, presumably as a manifestation of oxidant- and protease-mediated acute lung injury. Other possible causes are extracorporeal circulation, anticoagulation, and an increase in perfusion pressure in a previously obstructed pulmonary artery. Complications include immediate pulmonary hemorrhage and respiratory disturbance, and death may occur.[197] This syndrome may develop 3 to 5 days after surgery.[198] Olman et al.[199] have observed that after pulmonary thromboendarterectomy for relief of chronic thromboembolic PAH, perfusion lung scans often reveal new perfusion defects in segments served by undissected pulmonary arteries. This phenomenon has been labeled *pulmonary blood flow steal* and is believed to be caused by

TABLE 26-18 Common Causes of Restrictive Lung Disease

Cause	Example

postoperative redistribution of regional PVR due to the altered (widened) architecture of the dissected vessels that received arterectomy. No evidence of embolism was found in the previously normal areas.

RESTRICTIVE PULMONARY DISEASES

Definition

Restrictive pulmonary disease is defined as any condition that interferes with normal lung expansion during inspiration, and it is characterized by a TLC below the 5th percentile.[44] Typically, it includes disorders that increase the inward elastic recoil of the lungs or chest wall (Table 26-18). Consequently, the alteration in pulmonary dynamics results in decreases in lung volumes and capacities and in lung or chest-wall compliance. Some restrictive diseases produce ventilation abnormalities and $\dot{V}/\dot{Q}$ mismatching, whereas others lead to impairment of diffusion. FEV_1 and FVC are both decreased, owing to a reduction in TLC or a decrease in chest-wall compliance or muscle strength However, the FEV_1/FVC ratio is normal or elevated.

Impairment-producing restrictive pulmonary diseases can be classified as: (1) acute intrinsic, (2) chronic intrinsic, or (3) chronic extrinsic. Acute intrinsic disorders are primarily caused by the abnormal movement of intravascular fluid into the interstitium of the lung and alveoli secondary to the increase in pulmonary vascular pressures occurring with left ventricular failure, fluid overload, or an increase in pulmonary capillary permeability. Examples of acute intrinsic disorders include pulmonary edema, aspiration pneumonia, and acute respiratory distress syndrome (ARDS). Chronic intrinsic diseases are characterized by pulmonary fibrosis. Conditions that produce fibrosis of the lung include idiopathic pulmonary fibrosis (IPF), radiation injury, cytotoxic and noncytotoxic drug exposure, O_2 toxicity, autoimmune diseases, and sarcoidosis. Chronic extrinsic diseases can be defined as disorders that inhibit the normal lung excursion. They include flail chest, pneumothorax, and pleural effusions. They also include conditions that interfere with chest-wall expansion, such as ascites, obesity, pregnancy, and skeletal and neuromuscular disorders.

The pulmonary system and its functions are directly manipulated by the administration of anesthesia. The effect of intraoperative pulmonary insult or preexisting pulmonary disease on respiratory function during anesthesia and the postoperative period is predictable: greater degrees of pulmonary impairment lead to marked alterations in intraoperative respiratory status and higher rates of occurrence of postoperative pulmonary complications. This section illustrates the pathophysiologic changes involved in these clinical disorders and discusses their clinical presentation, diagnosis, treatment, and anesthetic implications.

Pulmonary Edema

Pulmonary edema is not itself an independent disease entity, but rather the result of a variety of disease processes. Simply stated, pulmonary edema is the accumulation of excess fluid in the interstitial and air-filled spaces of the lung. The mechanisms responsible for its development include an increase in hydrostatic pressure within the pulmonary capillary system, an increase in the permeability of the alveolocapillary membrane, and a decrease in intravascular colloid oncotic pressure.[200]

To understand the etiology and pathophysiology of pulmonary edema, Starling's law of transcapillary fluid exchange must be clearly understood. The pulmonary capillary endothelium is semipermeable. Pulmonary interstitial fluid pressures, both hydrostatic (peak inspiratory flow [Pif]) and osmotic (πif), along with the hydrostatic pressure in the pulmonary capillaries (Pc) and the osmotic pressure of the plasma (πp), are the primary determinants that balance fluid exchange across this semipermeable barrier.[201] These factors, which ultimately determine the amount of fluid that actually leaves the pulmonary vascular space, are incorporated into what is known as the *Starling equation*. A simplified version of this equation is as follows:

$$\dot{Q} = k[(Pc - Pif) - (\pi p - \pi if)]$$

where $\dot{Q}$ is the total amount of fluid that traverses the endothelial membrane and *k* is the fluid filtration coefficient, which describes quantitatively the permeability of the membrane.[200,201]

The Pc, the force favoring fluid movement out of the vessel wall, is in direct opposition to the Pif. The Pif, when positive, tends to force fluid inward through the capillary membrane; when it is negative, it tends to force fluid outward.[4] The πp and Pif also oppose each other, with the πif keeping fluid within the capillary and the Pif pulling it outward into the interstitium. Overall, the balance of forces shown in the Starling equation favors fluid filtration into the interstitial space. Fluid filtered out into the alveolar interstitial space does not enter the alveoli, because under normal conditions, the alveolar epithelium is composed of very tight junctions that prevent fluid and protein from entering the alveolar air spaces. The fluid moves to the extravascular interstitial space, where the lymphatic vessels remove all of the filtered fluid and return it to the systemic circulation.[202]

Pulmonary edema can occur if any variable in the Starling equation is altered in the direction favoring increased fluid filtration. High pressure (Pc) and increased permeability (k) are the two most important components of the Starling equation that are altered in states of pulmonary edema. Because of this, pulmonary edema is classified as being either cardiogenic (high pressure, hydrostatic) or noncardiogenic (permeability is increased).

Cardiogenic pulmonary edema occurs whenever the Pc is increased. Increased Pc is the most common form of pulmonary edema. Cardiogenic pulmonary edema is initiated by some type of left-sided heart incompetence or failure. The term *left ventricular failure* implies that a decrease has occurred in left ventricular contractility, which ultimately leads to a reduction in both stroke volume and CO. Incomplete left ventricular emptying elevates left ventricular end-diastolic volume, which in turn elevates left ventricular end-diastolic pressure. Increased left ventricular end-diastolic pressure is "reflected back," causing elevation of the

left atrial, pulmonary venous, and pulmonary capillary pressures. When pulmonary capillary pressure reaches levels of 20 to 25 mmHg (normal range, 10 to 16 mmHg), the rate of fluid transudation often exceeds lymphatic drainage capacity, and alveolar flooding occurs.

Coronary artery disease, hypertension, cardiomyopathies, mitral regurgitation, and mitral stenosis are a few of the cardiac conditions that may increase pulmonary intravascular hydrostatic pressure (Pc) and predispose a patient to the development of pulmonary edema. Although an elevated left ventricular end-diastolic pressure is the major cause of an increase in Pc, and therefore pulmonary edema, it is important to realize that several noncardiac problems also may increase Pc. These include pulmonary venoocclusive disease, fibrosing mediastinitis, head trauma, cerebrovascular accident, exposure to high altitudes, and overhydration.

Noncardiogenic pulmonary edema is associated with an increase in endothelial permeability caused by an insult that disrupts the barrier function of the blood-tissue interface. Unlike cardiogenic pulmonary edema, in which the capillary endothelium remains intact and no leakage of protein is noted, noncardiogenic pulmonary edema is associated with leakage of both fluid and protein from the vascular space.[201] Because this respiratory membrane disruption cannot be easily or directly measured, noncardiogenic pulmonary edema is said to exist when suspicious chest radiographic evidence coexists with insufficient hemodynamic basis. The presence of a pulmonary wedge pressure less than 12 mmHg and the absence of a significant history of cardiac disease generally suffice for exclusion of a hemodynamic mechanism.

Although a multitude of disorders are associated with noncardiogenic pulmonary edema, the most commonly encountered cause is systemic sepsis that leads to ARDS. Other clinical conditions associated with noncardiogenic pulmonary edema include the aspiration syndromes, inhalation of toxic fumes and gases, and the embolization phenomena (Box 26-11).

Pulmonary edema is nearly always associated with some type of preexisting disease state or insult. If a patient with pulmonary edema has a history of CHF, hypertension, or ischemic heart disease, the presence of cardiogenic pulmonary edema can be assumed. In addition to systemic sepsis, anaphylaxis, pancreatitis, disseminated intravascular coagulation, trauma, multiple transfusions, and near-drowning can all result in noncardiogenic pulmonary edema.

Neurogenic Pulmonary Edema

Neurogenic pulmonary edema begins with a massive outpouring of sympathetic nervous system stimulation triggered by central nervous system insult. This centrally mediated central nervous system overactivity typically occurs in the hypothalamic area.[201] Excessive sympathetic activation induces remarkable hemodynamic alterations—primarily systemic and pulmonary vasoconstriction. The left ventricle fails because of the inordinate pressure work imposed by the systemic hypertension, and pulmonary blood volume increases because of the functional imbalance between the failing left ventricle and the normal right ventricle.[201] Although this sequence seems to parallel that of hemodynamic pulmonary edema, a permeability component exists, as evidenced by the high protein concentration found in the pulmonary secretions of affected patients.

Uremic Pulmonary Edema

Uremic pulmonary edema is seen in those patients with renal insufficiency or failure. Overhydration and expansion of the circulating blood volume lead to increases in pulmonary capillary pressures. Again, a "leaky" component exists because of the metabolic abnormalities associated with uremia. Reducing the circulating blood volume of these patients via hemodialysis promotes resolution of this type of pulmonary edema.[201]

BOX 26-11

Clinical Disorders Associated with Acute Respiratory Distress Syndrome

Sepsis Trauma
- Fat emboli
- Lung contusion
- Nonthoracic trauma

Liquid Aspiration
- Gastric contents
- Fresh and salt water (drowning)
- Hydrocarbon fluids

Drug Associated
- Heroin
- Methadone
- Barbiturates
- Colchicine
- Aspirin
- Hydrochlorothiazide

Inhaled Toxins
- Smoke
- Oxygen (high concentration)
- Corrosive chemicals (NO_2, Cl_2, NH_3, phosgene)

Shock from Any Cause
- Hematologic disorders
- Massive blood transfusion
- Disseminated intravascular coagulation

Metabolic
- Acute pancreatitis
- Uremia

Miscellaneous
- Lymphangiography
- Reexpansion pulmonary edema
- Increased intracranial pressure
- After cardiopulmonary bypass
- Eclampsia
- Air emboli
- Amniotic fluid embolism
- Ascent to high altitude

Primary Pneumonias
- Viral
- Bacterial
- Mycobacteria
- Tuberculosis
- Fungal

High-Altitude–Related Pulmonary Edema

High-altitude–related pulmonary edema can occur in the absence of left ventricular failure whenever an individual overexerts before acclimating to a high altitude. The pathogenesis of this form of pulmonary edema is unclear, but it may be the result of intense hypoxic pulmonary arterial vasoconstriction or massive sympathetic discharge triggered by cerebral hypoxia.[202]

Pulmonary Edema Due to Upper Airway Obstruction

Pulmonary edema caused by upper airway obstruction results from prolonged, forced inspiratory effort against an obstructed upper airway. The most common cause of this type of pulmonary edema in adults is laryngospasm after extubation and general anesthesia. In children, pulmonary edema after obstruction caused by croup, epiglottitis, and laryngospasm also is well documented. Vigorous inspiration against obstruction creates high negative intrathoracic, transpleural, and alveolar pressures, enlarging the pulmonary vascular volume and subsequently the interstitial fluid volume. The capacity of the lymphatics becomes overwhelmed, and interstitial fluid transudes into the pulmonary alveoli. Hypoxia causes a

massive sympathetic discharge that results in systemic vasoconstriction and a translocation of fluid from the systemic circulation to the already expanding pulmonary vascular and interstitial spaces. Hypoxia also increases pulmonary capillary pressures. Because hypoxia alters myocardial activity, left atrial function and left ventricular function are reduced.

During obstruction, vigorous inspiratory efforts are unsuccessful because of the airway obstruction. Unsuccessful expiration produces an increase in intrathoracic and alveolar pressures. Intrinsic PEEP also is produced during this stage. Relief of the obstruction results in cessation of intrinsic PEEP.

The consequence of these events is the sudden massive transudation of fluid from the pulmonary interstitium into the alveoli, which results in pulmonary edema. The malignity of pulmonary edema is determined by the extent of prior alveolar and capillary damage and the immensity of hemodynamic and cardiovascular alterations.

Not all of those who experience an acute airway obstruction develop pulmonary edema, and no specific risk factors for its occurrence have been identified. Factors that may predispose to its formation after obstruction include youth, male gender, long periods of obstruction, overzealous perioperative fluid administration, and the presence of preexisting cardiac and pulmonary disease.

Treatment includes prompt recognition of the condition, securing a patent airway, supportive therapy with oxygenation, and administering diuretics. Although the onset of pulmonary edema after laryngospasm usually is immediate, cases have been reported of the occurrence of pulmonary edema several hours after laryngospasm. Therefore, it is recommended that patients who develop laryngospasm be observed postoperatively longer than the typical 60 to 90 minutes. The diagnosis of pulmonary edema and its differentiation into cardiogenic and noncardiac categories necessitates taking a detailed medical history and performing a physical examination, chest radiography, and ABG analysis.

Physical examination reveals increased respiratory effort. As water accumulates, the lungs become heavy and noncompliant, and a decrease in FRC occurs. This increase in the volume of extravascular lung fluid provides a potent stimulus for surrounding interstitial stretch receptors (J-receptors), the activation of which results in tachypnea. Tachypnea is not relieved by the administration of O_2 and the return of Pa_{O_2} to normal. Intercostal retractions and use of accessory muscles are apparent on physical examination. Signs of sympathetic stress stimulation, such as hypertension, diaphoresis, and tachycardia, often are noted. The expectoration of pink, frothy sputum signals that alveoli have been flooded.[201]

The detection of basilar crackles on auscultation is the traditional hallmark of early pulmonary edema. In reality, by the time these crackles become audible, excess water has already flooded the alveoli and overflowed into the terminal bronchioles.[199] It is in the bronchioles, not in the alveoli, that the crackles of pulmonary edema are generated. The earliest and most often disregarded clinical sign is rapid, shallow breathing.

In cardiogenic pulmonary edema, heart size may be increased. High CVPs, an S_3 or S_4 gallop, and jugular venous distention often are observed.[200] Chest radiography is still the most reliable and expedient tool for early detection of pulmonary edema. In cardiogenic pulmonary edema, the cardiac silhouette may appear abnormal or enlarged; in noncardiogenic pulmonary edema, it can be enlarged or remain normal. Interstitial edema can be observed before the alveoli flood and the onset of clinical signs occurs. Pleural effusions are common, and a "whited-out" or "butterfly" appearance may be noted.[201]

ABG analysis reveals hypoxemia secondary to $\dot{V}/\dot{Q}$ abnormalities. When right-to-left shunting is great, the Pa_{O_2} can be affected by any change in the central venous O_2 content. Increases in O_2 consumption or decreases in CO further reduce the Pa_{O_2}. The Pa_{CO_2} may be low, normal, or elevated. The initial hypocarbia is related to tachypnea and high minute volumes (MVs); at later stages, hypercarbia is frequently secondary to muscle fatigue and exhaustion. Changes in pH usually reflect changes in Pa_{CO_2}, but metabolic or lactic acidosis or both may occur from tissue O_2 deficiency, low CO, or sepsis.

Anesthetic Management

Pulmonary edema is considered a medical emergency, and immediate intervention is required for treatment of the underlying disease, support of other failing organ systems, and optimization of O_2 delivery.[200] O_2 should be administered either by nasal cannula, facemask, or endotracheal tube. If oxygenation does not improve with the administration of high Fi_{O_2}, positive-pressure ventilation with either PEEP or CPAP must be initiated. Institution of positive-pressure mechanical ventilation in patients with acute pulmonary edema usually results in a prompt increase in oxygenation and, in some cases, in CO. Improvement occurs because of superior inflation and $\dot{V}/\dot{Q}$ matching. Improvement in left ventricular function (CO) may occur secondary to four possible mechanisms: (1) improvement in arterial oxygenation and therefore improvement of myocardial O_2 supply; (2) reduction in the extreme pleural pressure swings present with spontaneous ventilation and hence reduction in afterload on the left ventricle; (3) decrease in the workload of the failing heart because of a reduction in work of breathing (and therefore a reduction in O_2 requirement) effected by a mechanical ventilator; and (4) decrease in preload (and a subsequent reduction in venous return) occurring secondary to the use of positive-pressure ventilation.

Pharmacologic therapy includes the use of vasodilators, inotropes, steroids, and diuretics. For more than 50 years, morphine sulfate has been used in the treatment of cardiogenic pulmonary edema because of its venodilatory and preload-reducing properties.[201] Nitroprusside is a very effective preload and afterload reducer. By reducing systemic blood pressure, nitroprusside decreases the afterload on the left ventricle; this may result in better cardiac function, with a subsequent lowering of left atrial pressures. Inotropic agents such as dopamine or dobutamine improve myocardial contractility and lower cardiac filling pressures. In patients with chronic CHF and pulmonary congestion, digitalis augments contractility and promotes decreases in left atrial and ventricular filling pressures. (The use of steroids is discussed later in this chapter in the section on ARDS.)

Fluid balance is managed with both fluid restriction and diuresis. This therapy helps achieve a "negative" fluid balance in hydrostatic pulmonary edema, in which Pc is high. Even in permeability pulmonary edema, in which Pc is thought to be low, any decrease in the hydrostatic pressure further reduces the net movement of pulmonary microvascular fluid outward.[200] Potent diuretics such as furosemide not only lower left atrial filling pressure by decreasing systemic venous tone but also induce diuresis of the expanded extravascular volume.

The type of fluid, whether crystalloid or colloid, that should be used in the presence of pulmonary edema remains controversial. Regardless of type used, it is generally agreed that administration should proceed slowly.

ASPIRATION PNEUMONITIS

Definition

Aspiration is a rare yet serious complication of general anesthesia. Much effort is expended to prevent this untoward occurrence and minimize sequelae if it does occur. It can occur at any time during

the course of anesthesia administration, and if it is severe, a multitude of serious complications may follow. Pneumonitis adds an average of 15 hospital days' stay and over $20,000 to the course of care of a patient who suffers this complication.[203]

Pneumonitis from perioperative aspiration ("Mendelson's syndrome") was described by Curtis Mendelson in 1946 after he observed a number of deaths among obstetric patients.[204] Mendelson's laboratory investigations led him to the conclusion that two entirely separate clinical aspiration disorders existed. One followed the aspiration of solid food and produced a picture of laryngeal or bronchial obstruction, whereas the other resulted from direct acid injury to the lung and produced the "asthma-like" syndrome that now carries his name.[205] Aspiration pneumonitis in anesthetic patients results from the intersection of three components: First, gastric contents escape from the stomach into the pharynx; second, those contents enter the lungs; and third, they are of a caustic nature, which results in tissue injury. This results from preexisting disease, airway manipulation, and the inevitable compromise in protective reflexes that accompany the anesthetized state. Aspirates may be categorized as contaminated, acidic, alkaline, particulate, and nonparticulate. Pneumonitis is a chemical injury and is not synonymous with pneumonia. Less than half of all aspirations lead to pneumonia, which occurs most often in patients who aspirate infected material or who are immunocompromised. Ingestion of highly acidic or particulate aspirate may cause severe respiratory damage without an infectious component. Patients who initially show no signs of infection, however, may develop pneumonia over time because of the severity of the lung injury and prolonged respiratory support.[206]

Incidence and Outcome

Although the incidence of regurgitation is estimated to be frequent (as high as 15%, according to some authors), pulmonary aspiration complicates only about 1 out of 3000 anesthetics.[207] This incidence is roughly doubled for cesarean section surgery[208] and emergency surgery.[209] Fortunately, the majority of aspiration incidents require little or no treatment. Warner et al.[210] reviewed 215,488 general anesthetics and studied the outcomes of pulmonary aspiration. They noted that approximately 60% of episodes were asymptomatic, 20% were symptomatic but required only conservative treatment or short-term ventilation, 15% required mechanical ventilation for more than 6 hours, and 5% of episodes led to death (Figure 26-25). The overall mortality was 1 in 71,829 anesthetic procedures. Several of their findings were interesting. Complications developed in equal percentages among those who received and those who did not receive pharmacologic acid aspiration prophylaxis. Patients who aspirated but did not develop symptoms within 2 hours could be discharged. If signs or symptoms did not emerge in that timeframe, they would not occur subsequently. Not surprisingly, the largest number of aspirations occur during induction and intubation or on emergence within 5 minutes of extubation. They found no serious morbidity from pulmonary aspiration in nearly 120,000 elective procedures in ASA class I or II.

In a later study, the same group reported on the incidence of aspiration in infants and children.[211] Although pediatric patients are often reported as having a higher incidence of aspiration than adults,[209] the researchers found no increase in the incidence among young patients. They noted 24 aspirations in a series of 63,180 general anesthetic procedures. Fifteen of the 24 children did not develop symptoms within 2 hours, and no treatment was required. Five children required respiratory support, three for more than 48 hours. No deaths occurred. Common risk factors for aspiration are given in Box 26-12.

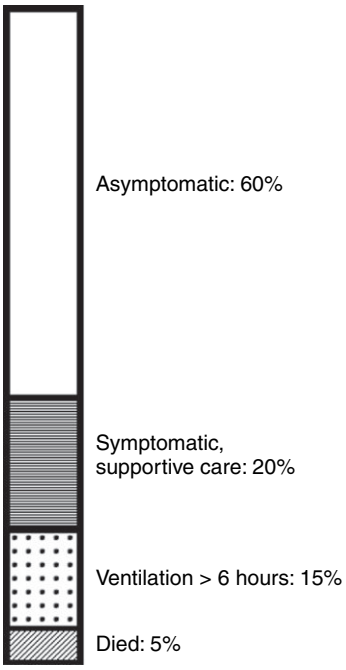

FIGURE **26-25** Outcomes of patients with perioperative aspiration. (Percentages approximate.) (Data from Warner MA, et al. Clinical significance of pulmonary aspiration during the perioperative period. *Anesthesiology.* 1993;78[1]:56-62.)

The Anesthetic Incidence Monitoring Study database in New Zealand noted 133 cases of aspiration out of 5000 reported anesthesia incidents.[212] Five deaths occurred. Aspiration was confirmed by clinical signs or radiography. Predisposing factors included abdominal pathology, obesity, diabetes, neurologic deficit, lithotomy position, difficult intubation, reflux disease, hiatal hernia, and inadequate anesthesia leading to straining and bucking.

In an interesting study, researchers examined general anesthesia by mask in obstetric patients who required surgery immediately after vaginal delivery.[213] Procedures included placental extraction; repair of vaginal, cervical, and perineal tears; and uterine manipulation. This database in Israel involved 1705 anesthetic procedures with only one case of mild pneumonitis.

Etiology

Although vomiting and gastroesophageal reflux are common clinical events, aspiration usually occurs only when normal protective reflexes (swallowing, coughing, gagging) fail.[210] Reflex responses to aspiration are automatically blunted with depression of consciousness. The most common setting for depression of reflex protection occurs during anesthesia induction and emergence.[210]

Three aspiration syndromes have been identified: (1) chemical pneumonitis (Mendelson's syndrome); (2) mechanical obstruction; and (3) bacterial infection. Because acute chemical pneumonitis poses the greatest difficulty to anesthesia providers, the pathophysiology, presentation, and anesthetic implications of Mendelson's syndrome are discussed.

The etiology of aspiration pneumonia often is characterized according to the pH, volume, and type of gastric material aspirated. It has long been considered that gastric fluid volume (GFV) greater than 0.4 mL/kg (25 mL/70 kg) and a pH less than 2.5

BOX **26-12**

Risk Factors for Aspiration

- Emergency surgery
- Full stomach
- Obstetrics
- Gastrointestinal obstruction
- Ascites
- Diabetic gastroparesis
- Gastroesophageal reflux
- Hiatal hernia
- Peptic ulcer disease
- Difficult airway management
- High gastric pressure or reduced lower esophageal sphincter tone
- Impaired airway reflexes
- Head injury
- Depressed level of consciousness
- Seizures
- Obesity
- Scleroderma, CREST, or other connective tissue disorders affecting the esophagus
- Trauma or stress
- Nausea and vomiting
- Opioid administration
- Cricoid pressure
- Residual neuromuscular relaxation
- Cardiac arrest, severe hypotension

CREST, Calcinosis, Raynaud phenomenon, Esophageal dysmotility, Sclerodactyly, and Telangiectasia.

are significant indicators of risk for aspiration sequelae. In 1974, Roberts and Shirley[214] published a classic article advocating these arbitrarily defined surrogate end-points in patients undergoing cesarean section. These markers became widely accepted in clinical practice, and efforts to reach these levels preoperatively in many patient groups included insertion of nasogastric tubes, as well as multidrug pharmacologic intervention. Unfortunately, the experiment by Roberts and Shirley by far lacked adequate scientific design to derive recommendations on assessing risk or administering prophylaxis to patients to reduce aspiration. Questions have therefore been raised as to the validity of the data behind these recommendations, with the suggestion that a reappraisal is in order.[215]

GFVs greater than 0.4 mL/kg are more common, even in fasting individuals, than the overall incidence of aspiration would suggest, if this were a major risk factor for aspiration. In a recent report comparing gastric content differences in healthy obese versus lean patients, GFV greater than 25 mL and pH less than 2.5 were noted in 26.6% of obese and 42% of lean patients.[216] These data suggest that healthy obese patients do not exhibit delayed gastric emptying and that many patients routinely fall into the arbitrary range of GFV greater than 25 mL and pH less than 2.5 without experiencing aspiration. Although the volume *aspirated* correlates with the severity of pulmonary damage, there is less correlation between the volume in the stomach and the risk of pneumonitis. A review of the value of routine nasogastric tube use after abdominal surgery demonstrated a slight *increase* in pulmonary complications among patients nonselectively treated with a nasogastric tube.[217] The applicability of this to short-term use under anesthesia is unknown, but it should be noted that gastric tubes not only provide evacuation but also may provide a conduit for regurgitation. Their value in patients not at risk for aspiration is not clear.[217]

Acidity plays a role in aspiration-induced lung damage; however, preoperative pharmacologic manipulation of gastric pH has not been proven to be clinically effective.[210,211,218] It is time to shift the focus away from GFV and pH and toward patient characteristics, patient condition, and anesthetic practices that place the patient at risk for pulmonary aspiration. Attention to the presence of factors listed in Box 26-12 and in particular to the presence of *multiple* factors from that list will prove more fruitful to the anesthetist's ability to predict aspiration risk than will over-attention to the questionable and nonspecific factors of gastric fluid volume and gastric pH.

Pathophysiology

The pathophysiology of aspiration pneumonitis is typically characterized by four stages: (1) The aspirated substance causes immediate damage to the lung parenchyma, resulting in tissue damage. (2) Atelectasis results within minutes, owing to a parasympathetic response that leads to airway closure and a decrease in lung compliance. (3) One to two hours after the injury, an intense inflammatory reaction occurs, characterized by pulmonary edema and hemorrhage. Inflammatory cytokines, including interleukin-8 and tumor necrosis factor-alpha released by alveolar macrophages, play a central role. The attracted neutrophils also play a key role in this phase by releasing oxygen radicals and proteases. (4) By 24 hours after the insult, secondary injuries result from fibrin deposits and necrosis of alveolar cells.

When aspiration is severe, damage to the entire alveolar-capillary barrier, including the basement membranes and capillary endothelial cells, may occur. It is important to note that physical damage is done to the lung endothelium instantly on contact with caustic aspirate. Therefore, there is no benefit in performing bronchoscopy or deep tracheal suctioning with the intent of halting the damage. Unless the patient has aspirated a particulate substance that can be retrieved, deep suctioning after aspiration will probably cause more irritation than any benefit from reversing the process. Suctioning the mouth and pharynx to prevent further aspiration is helpful.

Hypoxemia occurs secondary to a shunting effect due to atelectasis. Initially, Pa_{CO_2} tends to be low because of hyperventilation from hypoxic drive and because of the mechanical and irritative stimuli to the large airways and parenchyma. Hypercarbia associated with hypoventilation is a negative prognostic sign. Because atelectasis is common, PEEP is commonly a useful treatment modality for patients who require mechanical ventilation. Damage to the lung parenchyma causes an increase in the permeability of the pulmonary blood vessels followed by a profound capillary leak syndrome. This capillary leak produces flooding of the interstitium and alveolar spaces with a protein-rich fluid (permeability pulmonary edema). Mucus rapidly buffers the acidic fluid entering the lungs. Despite this, initial contact with highly acidic material has still been shown

to increase the vascular permeability in a very predictable fashion. In addition to the inactivation of surfactant by the gastric aspirate itself, the loss of protein through the impaired capillary wall can cause changes in surfactant production and, in turn, can contribute to a loss of lung compliance. Hemodynamic changes may include hypotension and reduction in CO from hypoxemia-induced myocardial ischemia, pulmonary hypertension, and acidosis.

In the inflammatory stage, there is a release of various phagocyte-derived substances such as reactive oxygen metabolites, nitric oxide, and proteases. This stage is characterized by neutrophil infiltration, which has been found to be an important negative factor in the eventual outcome after aspiration. Recent research has demonstrated that inhibition of alveolar macrophages will decrease the levels of inflammatory mediators and neutrophil recruitment to the area of injury.[219] Direct inhibition of neutrophils with neutrophil aggregation inhibitors, such as pentoxifylline and lidocaine, are gaining research interest for their potential to improve outcomes of pneumonitis. Lidocaine has been demonstrated to inhibit neutrophil chemotaxis,[209] suppress superoxide production,[220] reduce reperfusion injury,[221] and improve outcomes following acid aspiration.[222]

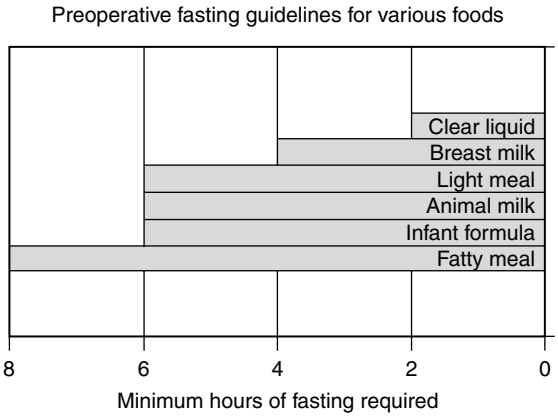

FIGURE **26-26** Preoperative fasting guidelines. (Data from American Society of Anesthesiologists Committee on Standards and Practice Parameters. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective surgery. *Anesthesiology.* 2011;114:495-511.)

Clinical Features and Diagnosis

Arterial hypoxemia, the hallmark sign of aspiration pneumonitis, is frequently the first sign of aspiration. Because the majority of aspiration incidents are asymptomatic or mildly symptomatic, unexplained hypoxemia occurring in otherwise healthy patients postoperatively often may be a vague sign of silent aspiration. Other signs to alert the anesthetist to the possibility of aspiration include tachypnea, dyspnea, tachycardia, hypertension, and cyanosis.

Diagnosis may be difficult to establish unless the aspiration is witnessed or gastric contents are visualized directly in the airway or suctioned from an endotracheal tube. ABG analysis and chest radiography are needed for evaluation. Infiltrates in perihilar and dependent regions along with pulmonary edema are the most common findings on radiography.

Anesthetic Management

Preoperative Management

When dealing with aspiration, "an ounce of prevention is worth a pound of cure." Recognizing risk factors and employing risk mitigation (including avoidance of general anesthesia) are important steps in preventing aspiration. When the use of general anesthesia is unavoidable in at-risk patients, taking the following steps may help minimize the risk of aspiration, or at least limit its consequences.

Nil per os (NPO) policy has been a mainstay of prophylaxis against aspiration, by aiming to reduce patients' intragastric volume by the time they undergo anesthesia. The suggestion by Roberts and Shirley that a gastric fluid volume greater than 0.4 mL/kg would predispose to aspiration gave credence to this approach. Following this concept, practitioners have instructed patients to refrain from oral intake for 8, 12, and sometimes as much as 16 hours (e.g., afternoon-scheduled surgeries, for which the patient is told to remain "NPO after midnight"). However, these long NPO periods are unnecessarily long to ensure stomach emptying of most low-fat foods, and the prolonged NPO periods contribute more to patient discomfort, dehydration, and insulin resistance than to ensuring an empty stomach.[223] It has become evident that clear liquids leave the stomach within 2 hours of ingestion, but gastric acid secretion continues, even in the absence of food intake. Therefore, in the absence of prokinetic stimulation by oral intake, a fasting patient may have a higher gastric volume and acidity than one who was allowed clear fluids closer to the time of surgery. The effects of gastrin and cholecystokinin on stimulating gastric emptying in response to clear liquid ingestion are greater than the effect of the migrating motor complex in emptying the stomach in the absence of food or liquid intake. As a result, patients who are allowed liberal intake (without upper limit of volume) of clear fluids up to 2 hours before a procedure have higher gastric pH and lower volume than those who fasted for more than 4 hours.[224,225] Contemporary understanding of this concept has led to revision of blanket NPO guidelines in favor of food-specific guidelines, particularly a much more liberal approach to clear liquid ingestion preoperatively (Figure 26-26).

Pharmacologic prophylaxis for aspiration may be considered to reduce risk factors for pneumonitis. Agents such as gastrokinetics, histamine blockers, anticholinergics, antacids, proton pump inhibitors, and antiemetics are all used alone or in various combinations to raise gastric pH, lower gastric volume, and reduce the incidence of emesis (Table 26-19). Although research evidence does not support routine use of prophylactic agents, practitioners may administer them when indicated for patients at risk. While previously used to inhibit gastrointestinal activity, anticholinergic agents are no longer supported for prophylactic use, and they may even antagonize other useful agents. For example, metoclopramide raises barrier pressure (which opposes gastric regurgitation) by increasing the tone of the lower esophageal sphincter; however, anticholinergics inhibit this effect. Metoclopramide stimulates gastric emptying and acts as an antiemetic.

Clear, nonparticulate antacids such as sodium citrate or sodium citrate with citric acid ("bicitra") have been shown to be clinically effective in increasing the pH of gastric contents. Desired onset of action occurs within 15 minutes, and duration of action is 1 to 3 hours. Although citrate preparations may last up to 6 to 7 hours, some patients will also experience a rebound increase in gastric acid production, so if surgery is delayed more than 1 hour after citrate administration, it may be prudent to repeat the dose.[226]

Intravenous administration of the H_2-receptor blockers cimetidine, ranitidine, or famotidine 45 to 60 minutes before surgery can raise gastric pH. Of the H_2 blockers, famotidine provides the best profile of duration of action and low incidence of side effects.[227] Although the H_2 blockers reduce gastrin-induced acid production, they are less effective against vagal or muscarinic influence. In contrast, proton pump inhibitors irreversibly bind to H^+/K^+ ATPase, blocking the final pathway for acid production. They are therefore more effective in reducing acid production, but for maximal effectiveness, they must be administered as a dose the night before surgery and then repeated preoperatively. In emergency cases or where the prior-night dose was not performed, H_2-receptor blockers may provide a better option for single-dose therapy.

Although cricoid pressure has long been considered a foundation of management of aspiration risk, the effectiveness of this technique has recently been called into question.[228-231] Confounding findings include that in a significant number of patients, the esophagus is not aligned directly posteriorly to the trachea,[232,233] so there are numerous reports of aspiration despite application of cricoid pressure.[234] Other suggestions are that cricoid pressure is inconsistently applied, or cricoid pressure itself will reduce lower esophageal sphincter pressure (LESP), thereby increasing the gradient for gastric regurgitation.[235,236] This LESP reduction appears to be a reflex mechanism in response to cricoid pressure and can be blunted by remifentanil.[237] Other nonpharmacologic mechanisms such as elevating the patient's head may offer limited benefit. In a small study of non-obese, awake, non-fasted patients, Jeske et al.[238] found no difference in gastric regurgitation, regardless of 20-degree head elevation or depression. Proponents of cricoid pressure posit that while the procedure may not exactly compress the esophagus as Sellick envisioned, it may nonetheless provide a barrier against regurgitation.[239,240] Although the overall benefit of cricoid pressure is questionable, it is still widely considered a standard of care.[241]

TABLE 26-19 Drug Prophylaxis for Aspiration Risk*

Medication Type	Common Examples
Gastrointestinal stimulants	Metoclopramide
Histamine-2 antagonists	Cimetidine Famotidine
Proton pump inhibitors	Omeprazole Lansoprazole
Antacids	Sodium citrate Sodium bicarbonate Magnesium trisilicate
Antiemetics	Droperidol Ondansetron
Anticholinergics†	Atropine Scopolamine Glycopyrrolate

Data from American Society of Anesthesiologists Committee on Standards and Practice Parameters. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective surgery. *Anesthesiology.* 2011;114:495-511.
*The routine preoperative use of these medications to decrease aspiration risk in patients with no apparent increased risk is not recommended.
†The use of anticholinergics to decrease aspiration risk is not recommended.

Intraoperative Management

If intubation is not expected to be difficult, a rapid-sequence induction (rather than awake endotracheal intubation) is acceptable in the patient with aspiration risk. There is little evidence that "modified" rapid sequence technique (which allows for gentle mask ventilation) worsens aspiration incidence, and this approach may be preferable in patients at risk for rapid oxygen desaturation.[242] Because difficult intubation itself is a risk factor for aspiration, there should be a low threshold for performing awake intubation in a patient with aspiration risk who may also pose airway challenges. Endotracheal intubation is considered the optimal approach for airway isolation, but regurgitated material can seep around the endotracheal tube (ETT) cuff, particularly if it is not lubricated.[243,244] Preventive measures in the anesthetic plan include ensuring that the patient is fully awake before extubation and manifesting protective reflexes, residual neuromuscular blockade is minimized to the extent possible, the degree of narcosis does not impair the level of consciousness postoperatively, and that the stomach has been evacuated.

If vomiting or aspiration occurs during induction, immediate treatment includes tilting of the patient's head downward or to the side, rapid suctioning of the mouth and pharynx, and intubation. There is little benefit in performing tracheal or bronchial suctioning in most cases, and bronchoscopy should be reserved for those patients suspected of having aspirated solid material. If aspiration is severe, surgery may be postponed. ABG analysis should be performed for determination of the extent of hypoxemia. Early application of PEEP is recommended for improving pulmonary function and combating atelectasis.[215]

Oxygenation should be supported with supplemental oxygen only to the minimum extent necessary. The damage to pulmonary parenchyma from caustic aspiration predisposes the tissue to oxygen toxicity. Indiscriminate administration of oxygen may worsen tissue damage.[245] For pharmacologic treatment of aspiration pneumonitis, the use of steroids is controversial. Long considered a mainstay of treatment, steroid therapy is associated with more rapid resolution of radiologic evidence of pneumonitis but also with longer intensive care unit (ICU) stays for some patients. Lidocaine 1.5 mg/kg is probably not harmful, but may be helpful as a neutrophil aggregation for improving long-term outcome after aspiration.[222] Although most aspirations are of sterile material (such as typical gastric acid), leukocytosis, fever, and infiltrate on x-ray are common findings in aspiration pneumonitis. The clinical findings resemble but do not indicate bacterial colonization (i.e., pneumonia). For this reason, the routine use of antibiotics is not recommended. Antibiotics are indicated only if the fever does not resolve within 48 hours, or there is risk for bacterial colonization (e.g., a patient on high-pH gastric tube feedings) or protected-sample bronchial or blood cultures indicate infection. Box 26-13 gives standard treatment protocol for aspiration pneumonitis.

The common time course of symptoms after aspiration has been characterized. Warner et al.[210] noted that the condition of the patient at 2 hours after the aspiration was prognostic of the patient's eventual course. Patients could be discharged if they did not manifest significant symptoms within 2 hours of the incident. Their criteria were as follows: (1) patients did not develop symptoms that included a new cough or a wheeze; (2) no decrease in Spo_2 of greater than or equal to 10% of preoperative levels occurred while the patient was breathing room air; (3) patients did not exhibit an A-a gradient of greater than or equal to 300 mmHg; and (4) no radiographic evidence of pulmonary aspiration was present.

ACUTE RESPIRATORY DISTRESS SYNDROME

Definition

The term *acute respiratory failure* is often used synonymously with *acute* (formerly *adult*) *respiratory distress syndrome* (ARDS). Although ARDS may be caused by or associated with a variety of clinical conditions, most patients with this disease demonstrate similar clinical and pathologic features, regardless of the cause of lung injury. Common features include a history of a preceding noxious event that served as a trigger for the subsequent development of ARDS and insult to the alveolar–capillary membrane that results in increased permeability and subsequent interstitial and alveolar edema.[246] Clinical presentation is characterized by dyspnea, severe hypoxemia, diffuse bilateral pulmonary infiltration, and stiffening and noncompliance of the lungs.[247] The consensus definition is given in Table 26-20.

Incidence and Outcome

Risk factors for the development of ARDS appear to be additive. Taylor[248] reported the incidence of occurrence to be 25% with the presence of one risk factor, 42% with the presence of two, and 85% with the presence of three. The mortality rate for ARDS remains high, around 50%.[249] However, the mortality rate often exceeds 90% when gram-negative septic shock precedes ARDS development.[250]

Etiology

The most common events and risk factors associated with the development of ARDS include: (1) sepsis; (2) bacterial pneumonia; (3) trauma; and (4) aspiration pneumonitis.[251] Other causes include diseases of the central nervous system, metabolic events (e.g., pancreatitis and uremia), disease states that result in the release of inflammatory mediators (e.g., extrapulmonary infections, disseminated intravascular coagulation, anaphylaxis, coronary bypass grafting, and transfusion reactions), and other forms of shock (cardiogenic, or hypovolemic) (see Box 26-11).[247]

BOX 26-13

Treatment of Aspiration Pneumonitis

- Suction mouth and pharynx
- Deeper suctioning only for particulate material
- Administer oxygen; only to extent needed
- Lidocaine to inhibit neutrophil response
- Steroids of questionable benefit
- Intubate as needed to support oxygenation
- Bronchodilator, PEEP to support ventilation
- Antibiotics only if indicated or for fever or ↑ WBC count >48 hours

PEEP, Positive end-expiratory pressure; *WBC*, white blood cell count.

Pathophysiology

The pathophysiology of ARDS is centered on severe damage and inflammation to the alveolar-capillary membrane. Research has focused on the release of cytokines and membrane-bound phospholipids from the capillary endothelium and the activation of leukocytes and macrophages (via the complement system) within the lungs.[252] As in pneumonitis, neutrophils play a role in the pathology of ARDS, and IL-8 (interleukin-8) has been identified as the main chemotactic factor for neutrophils.[253]

Phospholipids are converted into prostaglandins and leukotrienes by the enzymes cyclooxygenase and lipoxygenase, respectively. It is believed that prostaglandin metabolites mediate pulmonary vasoconstriction, alter vascular reactivity (i.e., decrease hypoxic pulmonary vasoconstriction), and cause airway constriction.

In addition, microembolus formation is a common manifestation of ARDS. Complement system activation and the release of thromboplastin from soft-tissue injury can trigger the coagulation system. Damage to the alveolar-capillary membrane impairs oxygenation, and loss of lung compliance leads to challenges in effectively ventilating patients. The effect of microemboli, prolonged alveolar hypoxia and hypercapnia, and injury to the alveolar tissue leads to increases in pulmonary vascular resistance. High alveolar pressures from aggressive positive pressure ventilation further contribute to high afterload on the right ventricle. This afterload leads to cor pulmonale in 25% of cases,[254] and shunting across a patent foramen ovale occurs in 20%.[255] Associated right ventricular dysfunction increases the associated mortality from ARDS,[256] particularly when plateau pressures are high.[257]

Clinical Features and Diagnosis

The clinical presentation of ARDS resembles that of pulmonary edema and aspiration pneumonitis. Patients are dyspneic, hypoxemic, and hypovolemic and often require intubation and mechanical ventilation. Noncardiogenic pulmonary edema is a hallmark finding. Findings on histologic examination are similar to those of aspiration pneumonitis, with the exception that fibrosis of lung is more pronounced. Recovery of lung function is unpredictable. Milder cases resolve quickly, whereas others progress to fibrosis and death.

Treatment

Treatment is supportive and includes correction of hypoxemia, afterload reduction, and inotropic support as indicated. Maintaining tissue oxygenation and reducing further lung damage are the main goals of therapy. Preserving end-organ perfusion is of utmost importance. There is no definitive treatment for ARDS, but some approaches to reducing the inflammatory reaction and improving

TABLE 26-20 American-European Consensus Conference on ARDS: Recommended Criteria for Acute Lung Injury and Acute Respiratory Distress Syndrome

Criteria	Timing	Oxygenation	Chest Radiography	Pulmonary Capillary Wedge Pressure
Acute lung injury	Acute onset	Pa_{O_2}/Fi_{O_2} ≤ 300 mmHg (regardless of PEEP level)	Bilateral infiltrates	<18 mmHg or no clinical evidence of left atrial hypertension
Acute respiratory distress syndrome	Acute onset	Pa_{O_2}/Fi_{O_2} ≤ 200 mmHg (regardless of PEEP level)	Bilateral infiltrates	<18 mmHg or no clinical evidence of left atrial hypertension

From Bernard GR, et al. The American-European Consensus Conference on ARDS: definitions, mechanisms, relevant outcomes, and clinical trial coordination. *Am J Respir Crit Care Med.* 1994;149:818-824.

Fi_{O_2}, Fraction of inspired oxygen; Pa_{O_2}, partial pressure of oxygen in arterial blood; *PEEP*, positive end-expiratory pressure.

oxygenation include corticosteroids, inhaled nitric oxide, exogenous surfactant, and extracorporeal gas exchange.[258,259]

Anesthetic Management

Anesthetic preparation includes evaluation of the patient's respiratory, cardiac, and renal status. The anesthetist should carefully manage vascular volume to avoid transudation of water into the lungs and give meticulous attention to avoiding air in vascular lines, due to the potential for right-to-left shunting. Useful monitoring will likely include cardiac filling pressures, cardiac output, invasive blood pressure, and a urinary catheter.

Ventilator settings should be noted and special attention devoted to peak inspiratory pressures and PEEP levels. Considering the prominence of cor pulmonale, the ventilation strategy must balance the need for alveolar recruitment with the potential for overloading the right ventricle. As PEEP is added, alveoli are recruited, improving oxygenation and reducing afterload on the right ventricle. However, at a point, alveolar overdistention will tip the balance beyond benefit and into detrimental effects, as the intrapulmonary pressure provides impedance to cardiac output.[260] The concept of "permissive hypercapnia" offers license to limit aggressiveness of ventilation in the interest of minimizing mean airway pressures; however, the effects of hypercapnia on increasing the PVR are varied. Some report a significant reduction (20%) in right ventricular ejection,[261] whereas others have found the hemodynamic effects temporary and nondetrimental.[262] In any case, right ventricular function should be monitored along with blood gas results as outcome goals for any ventilation strategy used in ARDS. Rising central venous pressures as well as chamber dilation, reduced ejection fraction, and septal deviation or paradoxical motion by echocardiography are means of identifying RV dysfunction.[263]

A protective ventilation strategy is often used, aimed at minimizing airway pressures and avoiding barotrauma and volutrauma in the face of severely reduced compliance. Some approaches are referred to as "open lung" strategies, inferring a primary goal of preventing atelectasis and airway closure. Open lung approaches have tended toward use of high levels of PEEP, but there is growing evidence that more modest levels may be equally effective.[260,264] Protective ventilation strategies vary in their details. In some cases, very unconventional ventilation approaches such as high-frequency oscillation must be used. Oscillation has been demonstrated to reduce mortality and improve gas exchange over conventional ventilation.[265,266] Strategies focused on supporting right ventricular performance may include prone positioning.[263] Prone positioning improves airway pressures, gas exchange, and reduces the indicators of cor pulmonale.[267-269] Some common modes of ventilation are shown in Table 26-21; however, Table 26-22 provides a sampling of some protective ventilation protocols that have been used in ARDS research or as guidelines.

TABLE 26-21 Common Modes of Positive Pressure Ventilation

	Trigger (signals the beginning of inspiration)	Control Variable (what is guaranteed in each breath)	Notes
Controlled Mandatory Ventilation (CMV)			
Traditional mode of anesthesia ventilators without patient responsiveness. Most suitable for unconscious, apneic patients.			
Machine-initiated breath	Time (set *f*)	V_T (6-8 mL/kg)	Spontaneous breaths not augmented; variable, based on underlying flow present in circuit
Assist Control (AC)			
Machine-initiated breath	Time (set *f*)	V_T (6-8 mL/kg)	High peak pressures may result if lung compliance is low; pressure limit should be set
Patient-initiated breath	Pressure drop or initiation of inspiratory flow	V_T (6-8 mL/kg)	Spontaneous breaths receive full tidal volume; can lead to hyperventilation if tachypneic
Intermittent Mandatory Ventilation (IMV)			
Traditional weaning mode			
Machine-initiated breath	Time (set *f*)	V_T (6-8 mL/kg)	
Patient-initiated breath	No trigger; spontaneous breaths without augmentation	No limit; flow and volume are patient-driven	
Synchronized Intermittent Mandatory Ventilation (SIMV)			
Promotes better patient-ventilator synchrony than IMV.			
Machine-initiated breath	Time (set *f*), but slight variability built in, to correspond with patient effort	V_T (6-8 mL/kg)	
Patient-initiated breath	Pressure drop or initiation of inspiratory flow initiates some breaths	Flow and volume are patient-driven, except for machine-synchronized breaths	Some spontaneous breath efforts will be augmented by regular machine breath
Pressure Control Ventilation (PCV)			
Prevents excessive peak pressure in low compliance, but V_T varies with changes in compliance.			
Machine-initiated breath	Time (set *f*)	Pressure (≈20 cm H_2O; adjusted to obtain V_T 6-8 mL/kg)	

Continued

TABLE 26-21 Common Modes of Positive Pressure Ventilation—cont'd

	Trigger (signals the beginning of inspiration)	Control Variable (what is guaranteed in each breath)	Notes
Patient-initiated breath	Pressure drop or initiation of inspiratory flow	Pressure (≈20 cm H_2O; adjusted to obtain V_T 6-8 mL/kg)	
Pressure Support Ventilation (PSV)			
Useful with SIMV during weaning or for spontaneous breathing under anesthesia (as when using a LMA).			
Machine-initiated breath	N/A, except for devices that incorporate an apneic backup and provide an "escape" rate in the absence of patient effort		
Patient-initiated breath	Pressure drop or initiation of inspiratory flow	Pressure (usually set at 5-20 cm H_2O to achieve desired V_T)	Each spontaneous breath is augmented by generation of the set amount of pressure
Continuous Positive Airway Pressure (CPAP)			
Useful for spontaneously breathing patients.			
Patient-initiated breath	N/A	Pressure (usually set at 5-10 cm H_2O)	A continuous amount of pressure in the breathing circuit both augments inspiration and prevents airway collapse on expiration
Biphasic Positive Airway Pressure (BiPAP)			
Resembles a combination of PS and CPAP.			
Patient-initiated breath	Pressure drop or initiation of inspiratory flow	Two levels of pressure (10-15 cm H_2O, 0-5 cm H_2O): inspiratory and expiratory	Two levels of pressure set, provide (higher) inspiratory augmentation like PS, and continuous (lower) pressure during expiration, like CPAP or PEEP; useful as noninvasive ventilation, such as to avoid intubation in COPD
Airway Pressure Release Ventilation (APRV)			
Like BiPAP, but held at high pressure level most of time, with brief drops to lower level.			
Patient-initiated breath	Time; inspiratory time (high pressure) set ≈5 seconds, expiratory time (low pressure) set ≈0.5 seconds	Two levels of pressure (high level 20-30 cm H_2O; low level 0-5 cm H_2O); pressures should ideally correspond to high and low inflection points on pressure-volume (lung compliance) curve	Patient breathes spontaneously at high level of pressure, which augments inspiration and retards full expiration; low pressure phases help turnover lung volume to promote CO_2 removal; similar to pressure-control, inverse-ratio ventilation

COPD, Chronic obstructive pulmonary disease; *f*, frequency (respiratory rate); *PEEP*, positive end-expiratory pressure; *PS*, pulmonary stenosis; *VT*, tidal volume; *LMA*, laryngeal mask airway.

NOTE: Inspiratory cycles can be determined by pressure, volume, flow, or time for most modes, with wide variability between devices. Intermittent modes determine end-of-inspiration signaling time by the set respiratory rate and I:E ratio. The prototype settings for each mode are presented here. PEEP can be added to most modes.

TRANSFUSION-RELATED PULMONARY DISEASE

With increasing awareness of a host of complications related to blood transfusion, the connection to pulmonary complications has become a significant area of concern. The primary transfusion-related pulmonary complication is transfusion-related acute lung injury (TRALI).

Definition

TRALI is a form of acute lung injury that is associated with blood transfusion and that is characterized by pulmonary infiltrates and hypoxemia. TRALI is defined as acute onset hypoxemia, bilateral lung infiltrations on the chest radiograph, and no evidence of circulatory overload, which occurs during or within 6 hours of blood transfusion in a patient with no other risk factor for acute lung injury (ALI).[270] TRALI resembles ARDS in clinical presentation, but unlike ARDS, it has a lower mortality and is self-limiting with spontaneous resolution usually occurring within 96 hours.[270]

Incidence and Outcome

TRALI was the leading cause of transfusion-related fatalities in years 2005 to 2009, and it is the most common cause of major morbidity and death after transfusion;[271-274] 5% to 10% of cases are fatal.[275,276] Although the incidence is often stated as being one in 5000 blood transfusions, there is a prevailing sense that TRALI is underdiagnosed, and so the incidence may be much higher than that stated figure.[270,274]

Etiology

TRALI is thought to occur because of an interaction between transfused blood products and the recipient's white blood cells.

TABLE 26-22 Ventilation Strategies for ARDS

Name	Description	Notes
ARDSnet ventilator protocol (a)	Any ventilator mode. V_T initially 8 mL/kg PBW; reduce V_T by 1 mL/kg at intervals until V_T = 6 mL/kg PBW; I:E: 1:1 or lower; set initial rate to approximate baseline minute ventilation and adjust to maintain pH > 7.30 or $Paco_2$ < 25 (but not > 35 bpm); adjust V_T and RR to maintain pH > 7.3, Pplat ≤ 30 cmH_2O; use a minimum PEEP of 5 cmH_2O; set Fio_2/PEEP to maintain Pao_2 55-80 mmHg or Spo_2 88%-95%	Acute Respiratory Distress Syndrome Network (ARDSnet) is a clinical network formed by the National Heart, Lung, and Blood Institute, National Institutes of Health to carry out multicenter clinical trials of ARDS treatments
Open lung strategy with staircase recruitment (b)	PCV. Fio_2 adjusted until SpO_2 = 90%-92%; Pplat < 30 cmH_2O, V_T 6 mL/kg IBW; *staircase recruitment maneuver:* pressure set to 15 cmH_2O above the PEEP, and then increased in a stepwise manner to 20, then 30, and then 40 cmH_2O every 2 min, and then reduced incrementally to an absolute minimum of 15 cmH_2O every 3 min until a decrease in Sao_2 ≥ 1% from maximum Sao_2 is observed (derecruitment point); PEEP is then increased to 40 cmH_2O for 1 min and returned to a level 2.5 cmH_2O above the derecruitment point	Greater reduction in some systemic cytokines (IL-8 and TNF-α), improved oxygenation and lung compliance over 7 days in comparison to ARDSnet protocol
Open lung approach (c)	VCV. Fio_2 0.7, RR: 20-40 to achieve pH >7.30 V_T: 6 mL/kg, I:E: 1:1, PEEP set at 20 cmH_2O and a recruitment maneuver with a continuous airway pressure of 50 cmH_2O for 30 sec is performed; after that, PEEP is reduced in decrements of 2 cmH_2O and set at P_{FLEX} (mean PEEP was 15 cmH_2O)	Improved oxygenation and redistributed pulmonary perfusion when compared with the ARDSnet protocol, without differences in lung inflammatory response
Decremental open lung positive end-expiratory pressure titration (d)	PCV. V_T 5-8 mL/kg IBW, I:E: 1:1, RR set to keep arterial pH > 7.20; PEEP is set at 20 cmH_2O and the lungs are recruited by stepwise increases of the driving pressure up to 30 cmH_2O; PEEP is reduced in steps of 2 cmH_2O while measuring the dynamic compliance; PEEP is set 2 cmH_2O over the level that yielded the highest dynamic compliance measurement	Increased oxygenation and improved respiratory system compliance over standard ventilation; evidence of right ventricular stress and strain during recruitment maneuver; otherwise, right ventricular function was significantly improved

Attention first focused on an immune mechanism, particularly surrounding the human leukocyte antigens (HLAs) and human neutrophil alloantigens (HNAs) in the recipient. The finding that some victims did not demonstrate elevated antibody titers, and that TRALI could be induced in excised lungs indicated that there is at least one other mechanism. In cases of nonimmune TRALI, reactive lipid products released from the donor blood cells may act as the trigger. In either form of TRALI, neutrophils play an important role. Theories often entertain a "two hit" hypothesis, assuming that a preexisting factor is present in victims and leads to the abnormal reaction to the allograft blood.[277,278] This hypothesis helps explain why TRALI occurs only in some individuals.

Predisposing factors for TRALI seem to surround events that may "prime" the immune system—recent surgery, malignancy, and sepsis, as well as alcoholism and liver disease. Increased levels of HLA and previous ALI as a risk factor point to immunologic predisposition as another factor.[279] Donor risk factors also play an important role in development of TRALI. For example, pregnancy causes an elevation in HLA in many women and a high proportion of TRALI cases arise in individuals who receive blood products donated by women with leukocyte antibodies. For this reason, the United Kingdom halted use of plasma from female donors in 2003, and a significant reduction in the incidence of TRALI ensued. The U.S. Food and Drug Administration is considering methods to implement a similar policy.[274] Although TRALI has occurred in association with a wide variety of blood products, the greatest incidence follows platelet transfusion.[270]

Pathophysiology

Upon activation, neutrophils become trapped within the pulmonary microvasculature, causing congestion and leading to noncardiogenic pulmonary edema. Complement activation and release of oxygen free radicals and proteases then cause damage to the capillary endothelium, which also promotes fluid leak into the alveoli. Platelets also play an important role in TRALI, because they are activated and then sequestered in the lungs through some interaction with neutrophils.[280]

Clinical Features and Diagnosis

TRALI, by definition, is associated with blood transfusion, so symptoms begin during or up to 6 hours after transfusion of any blood product. Acute onset and hypoxemia are key findings, with Pao_2/Fio_2 ratio less than 300. Bilateral infiltrates are found on chest radiography. Clinical symptoms include fever, chills, and dyspnea. Hypertension and hypotension occur with equal frequency.

It is important to distinguish TRALI from other causes of lung dysfunction; therefore diagnosis must exclude any other precipitating factor for acute lung injury. Cardiogenic causes and acute

hypersensitivity reactions or ABO incompatibility reactions must also be excluded. TRALI appears with similar symptomatology as transfusion-related circulatory overload (TACO). TACO usually presents with tachycardia, dyspnea, and pulmonary edema. The key differentiating factor is that signs of circulatory overload or predisposition to circulatory overload (e.g., CHF) exist in TACO but not in TRALI. For patients with coronary artery disease, congestive heart failure, or who are status post lung resection (particularly with peripheral edema, jugular vein distension, S3 heart sound), circulatory overload should be ruled out before presuming a diagnosis of TRALI. Patients who develop TACO often show signs of circulatory overload prior to the blood infusion.

Treatment

Treatment is largely supportive, as is the treatment for ARDS. A lung-protective ventilation strategy is used for patients requiring mechanical ventilation.

Anesthetic Management

Management of the patient who develops TRALI requires immediate cessation of the transfusion. IV fluids are used to support blood pressure if the patient is hypotensive, and diuretics are not indicated, because the respiratory distress is due to microvascular injury rather than fluid overload; 70% of cases require mechanical ventilation, but resolution occurs more quickly than does ARDS.

Appropriate attribution of cause is important to guide the correct treatment. Finding of anti-HLA or HNA antibodies in plasma support the diagnosis of TRALI, whereas signs of fluid overload (clinical signs or elevated brain natriuretic peptide) support the diagnosis of TACO.[281,282]

DRUG-INDUCED PULMONARY DISEASE

Currently, more than 100 pharmacologic agents are known to produce adverse effects on the lung parenchyma, the pleura, and the airway. Drug-induced pulmonary injury occurs in several hundred thousand people each year in the United States. Knowledge of doses and the potential adverse effects of the prescribed medications may prevent or minimize drug-induced damage. The rapid development of nanotechnology also lends concern for new forms of pulmonary toxicity. Nanoparticles, because of their extremely small size, can gain access to physiologic areas that traditional molecules cannot. In particular, in the respiratory tract, carbon nanotubes cause damage to alveolar cells, form granulomas, and led to fibrosis. This damage leads to release of proinflammatory cytokines and generation of oxygen free radicals.[283-285] With the growing use of nanotubes in medications, cosmetics, disease treatment, and other applications, it is likely that new forms of pulmonary toxicity will grow in incidence.

Mechanism

The mechanism of drug-induced pulmonary injury is not well defined. It has been shown that cytotoxic drugs used in the treatment of cancer cause pulmonary insult by a combination of the direct toxic effects of a drug or its metabolite and of their indirect effects—that is, the enhancement of inflammation or immune processes. The clinical features produced by different cytotoxic agents are similar, but chronic pneumonitis and fibrosis are the most commonly associated clinical syndromes. Box 26-14 lists various chemotherapeutic agents that may produce pulmonary toxicity. The pathogenesis of pulmonary toxicity is uncertain but has been found to include disruption of the endothelial cells and changes in calcium homeostasis that lead to toxic injury. The mechanisms of drug-induced pulmonary injury associated with noncytotoxic drugs are less well defined but may involve changes in pulmonary homeostasis. Noncytotoxic agents can induce the development of numerous clinical syndromes. Several commonly implicated agents are discussed in the following sections.

BOX 26-14

Classification of Drug-Induced and Related Pulmonary Diseases by Type of Medication

Chemotherapeutic

Cytotoxic
- Azathioprine inhibitors
- Bleomycin*
- Busulfan
- Chlorambucil
- Cyclophosphamide
- Etoposide
- Interleukin-2
- Melphalan
- Mitomycin C*
- Nitrosamines
- Procarbazine
- Tumor necrosis factor
- Vinblastine
- Zinostatin

Noncytotoxic
- Bleomycin*
- Cytosine arabinoside*
- Gemcitabine
- Methotrexate*
- Procarbazine*

Antibiotic
- Amphotericin B*
- Nitrofurantoin
  - Acute*
  - Chronic
- Sulfasalazine

Antiinflammatory
- Acetylsalicylic acid*
- Gold
- Interferons
- Leukotriene antagonists
- Methotrexate
- Nonsteroidal antiinflammatory agents
- Penicillamine

Analgesic
- Heroin*
- Methadone*
- Naloxone*
- Placidyl*
- Propoxyphene*
- Salicylates*

Cardiovascular
- Amiodarone*
- Angiotensin-converting enzyme
- Anticoagulants
- β-Blockers*
- Dipyridamole
- Flecainide
- Protamine*
- Tocainide

Inhalant
- Aspirated oil
- Oxygen

Intravenous
- Blood*
- Ethanolamide maolate (sodium morrhuate)*
- Ethiodized oil (lymphangiogram)
- Talc

Miscellaneous
- Appetite suppressants
- Bromocriptine
- Dantrolene
- Complement-mediated leukostasis*
- Hydrochlorothiazide*
- Methysergide
- Radiation
- Systemic lupus erythematosus (drug induced)
- Tocolytic agents*
- Tricyclics*
- l-Tryptophan

From Murray JF, Nadel JA. *Textbook of Respiratory Medicine*. 5th ed. Philadelphia: Saunders; 2010.
*Typically manifests as acute or subacute respiratory insufficiency.

Noncytotoxic Drug-Induced Pulmonary Disease

Amiodarone

Amiodarone is one of the most frequently prescribed medications for ventricular dysrhythmias. Pulmonary disease from amiodarone occurs with 5% to 15% prevalence and takes the form of chronic interstitial pneumonitis, organizing pneumonia, ARDS, or a solitary mass of fibrosis.[286] Toxicity may be related to direct toxicity,

immunologic mechanisms, or related to activation of the renin-angiotensin system.[287]

Clinical diagnosis of amiodarone-induced pulmonary toxicity is based on the presence of two or more of the following signs and symptoms[288]:

1. New onset of pulmonary symptoms such as dyspnea, cough, or pleuritic chest pain
2. Detection of new chest radiographic abnormalities such as an interstitial or alveolar infiltrate
3. A decrease in DLCO of 20% from the pretreatment value; if no pretreatment values are available, then a value equal to less than 80% of the predicted value
4. Abnormal gallium-67 uptake by the lungs
5. Characteristic histologic changes of lung tissue obtained by bronchoscopic or open-lung biopsy

Amiodarone-induced pulmonary toxicity is commonly characterized by an insidious onset with nonproductive cough, hypoxemia, progressive dyspnea, weight loss, pleuretic chest pain, pleural effusion, and occasional fever.[286,289] Some patients present with a rapidly progressive dyspnea, high fever, and hypoxemia. Chest radiographs demonstrate parenchymal infiltrates with a predominant diffuse alveolar, interstitial, or mixed pattern that may progress to fibrosis.[290] Pleural thickening and effusions also have been reported. Pulmonary function tests performed at the onset of pulmonary toxicity reveal abnormalities typical of restrictive lung disease. Onset usually occurs after 2 months and is dose-related, occurring most commonly if doses greater than 400 mg/day are used.[286] Toxicity is rare when given acutely. Therapeutic options are limited. In cases where drug withdrawal is not desirable, corticosteroids are helpful at ameliorating the disease.[291] When the drug is discontinued, resolution of toxic signs is gradual due to the drug's half-life of approximately 40 to 70 days. Fibrosis, when it occurs, is not reversible.[286]

Cytotoxic Drug-Induced Pulmonary Disease

Three clinical syndromes are associated with cytotoxic drug-induced pulmonary injury: (1) chronic pneumonitis and fibrosis, (2) acute hypersensitivity lung disease, and (3) noncardiogenic pulmonary edema.[292] These syndromes may coexist.

Chronic Pneumonitis and Fibrosis

Interstitial pneumonitis and fibrosis is the most frequently encountered pattern in drug-induced pulmonary injury. The mechanism of injury is a direct cytotoxic effect of a drug or its metabolites on the endothelial, interstitial, or alveolar epithelial cells. On lung parenchyma, the cytotoxic effect elicits an inflammatory response characterized by the proliferation of macrophages, lymphocytes, and other inflammatory cells. This inflammatory response leads to the deposition of fibrin within the alveoli, which produces interstitial inflammation and fibrosis.

Interstitial pneumonitis can be classified as acute, subacute, or chronic; the chronic form is the most frequently encountered. Common manifestations of these subgroups include dyspnea, dry cough, low-grade fever, fatigue, and malaise that develop over several weeks to months. Chest radiography demonstrates diffuse interstitial infiltrates. Bleomycin is the causative agent most often implicated in interstitial pneumonitis. Treatment includes discontinuation of the offending agent with or without institution of corticosteroid therapy; prognosis is variable. Other antineoplastics implicated in pneumonitis and fibrosis are trastuzumab, gemcitabine, temsirolimus, everolimus, paclitaxel, docetaxel, irinotecan, gefitinib, oxaliplatin, tubotecan, and imatinib.[293]

Syndrome of Hypersensitivity Lung Disease

Hypersensitivity lung disease has been associated with the cytotoxic agents bleomycin, methotrexate, L-asparaginase, procarbazine, etoposide, teniposide, and mitoxantrone.[293] Common pulmonary manifestations include a nonproductive cough, dyspnea, and chest pain. The systemic allergic response is manifested as fever, urticaria, arthralgias, hypotension, and eosinophilia. Chest radiography may reveal pneumonitis, pleuritis, and pleural effusion. Corticosteroid use may or may not be indicated, and prognosis is generally favorable.

Drug-Induced Pulmonary Edema

The development of noncardiogenic pulmonary edema is an acute but rare phenomenon that occurs after the administration of some antineoplastic agents. Cytotoxic drugs that contribute to its development include methotrexate, cytosine arabinoside (cytarabine), gemcitabine, imatinib, and cyclophosphamide.

Numerous pharmacologic agents used in the treatment of cancer have been implicated in the development of toxic pulmonary side effects. The agents most commonly implicated in pulmonary insult include bleomycin, busulfan, carmustine, and methotrexate. Pulmonary toxicity in the use of antineoplastic agents is defined as the development of clinical signs and symptoms of pulmonary distress that were not present during the pretreatment studies. The prevalence of diffuse pulmonary infiltration occurring as a result of drug toxicity is reported to be as high as 20%.

Prototype Agents Implicated in Pulmonary Insult

Bleomycin. Bleomycin, an antitumor antibiotic, is the most common chemotherapeutically induced potentiator of pulmonary injury. Despite the benefits of bleomycin therapy, the development of pulmonary toxicity is the limiting factor of its use.[294] The most common adverse effect of bleomycin is the development of interstitial fibrosis. The incidence of pulmonary fibrosis is approximately 20%, with a 1% mortality rate. Anesthesia-related problems occur postoperatively and are associated with exposure to high O_2 concentrations. Symptoms of toxicity initially include a dry hacking cough and dyspnea on exertion. Progression of lung disease is associated with dyspnea at rest, tachypnea, fever, and cyanosis. Changes on chest radiography usually occur later and manifest as bibasilar reticular infiltrates that may progress to frank consolidation.

Several investigators have suggested that patients undergoing general anesthesia who have a concurrent history of bleomycin therapy should receive the lowest possible O_2 concentrations that allow maintenance of adequate Pa_{O_2}.[295,296] The use of steroids has been effective in some patients.

Anesthetic Management of Bleomycin-Treated Patients. Although universally accepted guidelines for the management of a bleomycin-treated patient undergoing general anesthesia are lacking, the following suggestions have been made:

- O_2 saturation should be monitored continuously and ABG analysis performed intermittently.
- Immediately before anesthesia, 100% O_2 should be administered for 1 to 4 minutes.
- After induction, a target Pa_{O_2} should be chosen and the Fi_{O_2} maintained at the lowest level that allows adequate oxygenation.
- The use of PEEP should be considered.
- Crystalloid solutions should be administered carefully and the use of colloid solutions considered if large fluid volumes are required.

- The patient should be informed of the possible need for postoperative ventilation.
- Postoperatively the Fi_{O_2} should be kept at the lowest possible setting that maintains the target Pa_{O_2}.

The choice of anesthetic technique varies, but as with all surgical procedures, careful evaluation and management are essential. There are no reports suggesting the superiority of regional anesthesia in patients treated with bleomycin.

Methotrexate. Methotrexate is an analog of folic acid that inhibits cellular reproduction by causing an acute intracellular deficiency of folate coenzymes. Methotrexate is used in the treatment of malignant and benign conditions, including leukemia, osteogenic sarcoma, choriocarcinoma, polymyositis, psoriasis, and connective tissue disorders (particularly rheumatoid arthritis). Regardless of the route of administration, pulmonary toxicity has been reported to occur with all forms of delivery, with an incidence of 7.6%. Clinically, the onset of pulmonary dysfunction may be chronic, but more commonly it is acute. The syndrome often develops over 7 to 14 days and is characterized by fever, dry cough, dyspnea, hypoxemia, and bilateral pulmonary infiltrates. Improvement may begin 10 to 14 days after onset.

PULMONARY OXYGEN TOXICITY

Etiology

As with all prescribed drugs, the risks of the adverse effects of O_2 administration must be considered, despite its beneficial effects. The prolonged use of high concentrations of O_2 (greater than 50% for longer than 24 hours) is potentially toxic and may result in irreversible lung damage.[295] The rate of development of O_2 toxicity is directly related to the exposure: partial pressure of inspired O_2[297] and duration of administration. Deleterious effects have been reported with more brief administrations.[297]

Normobaric hyperoxia can result in four clinical syndromes: (1) acute tracheobronchitis, (2) absorption atelectasis, (3) acute alveolar lung injury (ARDS), and (4) bronchopulmonary dysplasia. When nitrogen is replaced with O_2, absorption atelectasis occurs in the alveoli that are poorly ventilated. The loss of the so-called "nitrogen splint" promotes alveolar collapse.

Pathophysiology

The pathogenesis of pulmonary O_2 toxicity is linked to the excessive production of free O_2 radicals.[298] Free radicals are molecules that contain one or more unpaired electrons. Free radicals are highly reactive metabolites of O_2 (e.g., superoxide anion, hydrogen peroxide, and hydroxyl radical) that overwhelm antioxidant systems, including cellular enzymatic defenses (superoxide dismutase, catalase, glutathione peroxidase) and nonenzymatic scavengers (α-tocopherol acetate). Free radicals exert their toxic effect on cell and organelle membranes; they interfere with vital cellular functions, causing inactivation of enzymes and transport proteins, membrane lipid peroxidation, and inhibition of cell growth and division. Factors predisposing to oxygen toxicity are increased exposure (concentration × duration), advanced age, and radiation therapy to the thorax and use of chemotherapeutic agents that alter antioxidant defense mechanisms or generate oxidants.

Clinical Features and Diagnosis

The earliest manifestations are related to the effects on the tracheobronchial mucosa. Symptoms may occur after 6 hours of O_2 exposure and include substernal chest pain that is prominent with inspiration, tachypnea, and a nonproductive cough. By 24 hours, paresthesia, anorexia, nausea, and headache occur. Physiologic changes include a decrease in tracheal mucous velocity, vital capacity (VC), pulmonary compliance, and diffusing capacity and increased $P_{AO_2} - Pa_{O_2}$. Some individuals develop signs of mild airway obstruction. Chest radiography demonstrates an alveolar and interstitial pattern.

Management

Both hyperoxia and hypoxemia have undesirable effects. Therefore, deciding the must judicious administration of O_2 requires astute clinical judgment. The goal is to deliver the lowest level of Fi_{O_2} needed for maintaining adequate arterial O_2 saturation (generally, a Pa_{O_2} of greater than 90 mmHg). Measures such as PEEP should be used for decreasing the need for high Fi_{O_2}. In cases of frank oxygen toxicity, corticosteroid therapy reduces antioxidant enzyme activity and may be useful.

AUTOIMMUNE DISORDERS

Autoimmune diseases, *connective tissue diseases*, *collagenosis*, and *rheumatologic diseases* are terms used interchangeably in clinical medicine. These entities are often characterized by multiple-organ involvement and inflammation. On the whole, these disorders have unknown causes; however, the inflammatory process is immunologically mediated, as evidenced by the presence of autoantibodies, rheumatoid factor, and immune complexes, as well as by elevation of the sedimentation rate and the observation of certain clinical characteristics. Pulmonary manifestations are common and often assume a major role in the disease process. Characteristic restrictive lung changes may result if pulmonary impairment is sufficiently severe. Box 26-15 lists pulmonary manifestations of various collagen vascular diseases.

Sarcoidosis

Sarcoidosis is a multisystemic disorder characterized by the presence of epithelioid-cell granulomata. It is described as an intense interaction of activated lymphocytes and macrophages that results in tissue injury. The disease most often involves the lungs, reticuloendothelial system, skin, eyes, and myocardium. The prevalence of disease globally is 16.5/100,000 men and 19/100,000 women. The disease predominantly occurs in those aged 20 to 40 years.[299] A preponderance of the disease among African Americans and varying phenotypes among other ethnic groups points to a strong genetic influence.[300] The cause of sarcoidosis is unclear; no organic or inorganic causative agent has been consistently found. The route of transmission also is uncertain and may be related to human lymphocyte antigen polymorphisms, which lead to granuloma formation after various interactions of antigens, HLA molecules, and T-cell receptors.[301] Interferon-gamma and cytokines such as tumor necrosis factor-alpha (TNF-α), IL-12, and IL-18 play a critical role in the formation of granulomatous lesions.[302]

Most sarcoid granulomata resolve spontaneously, leaving no scar. Others persist for a longer duration, with little or no fibrosis, and still others become hyalinized, fibrotic areas that cause tissue damage. Pulmonary involvement is primarily in regions rich in lymphatic vessels, such as the subpleural, perivascular, and peribronchial areas. Often, adjacent nonspecific inflammatory changes as well as alveolitis with cellular infiltrates are noted.[303]

Parenchymal infiltration and fibrosis result in a decrease in lung compliance, impairment of diffusing capacity, and a reduction in lung volumes. A restrictive pattern of ventilation is usually observed, but many patients exhibit a reduced FEV_1/FVC and increased airway resistance. $\dot{V}/\dot{Q}$ imbalance and an increase in Pa_{O_2} occur in response to a nonuniform decrease in lung compliance. An obstructive pattern resulting from endobronchial disease or peribronchial fibrosis may occur simultaneously. Pulmonary

BOX **26-15**

Pulmonary Manifestations of Some Collagen Vascular Diseases

Rheumatoid Arthritis
- Pleural disease (effusions)
- Diffuse interstitial pneumonitis
- Necrobiotic nodules
- Caplan syndrome
- Pulmonary hypertension (arteritis)
- Apical fibrobullous disease
- Bronchiolitis obliterans with and without organizing pneumonia
- Cricoarytenoid arthritis

Systemic Lupus Erythematosus
- Pleural disease (pleuritis, effusions)
- Atelectasis
- Acute lupus pneumonitis
- Diffuse interstitial lung disease
- Pulmonary hemorrhage
- Respiratory muscle dysfunction

Progressive Systemic Sclerosis
- Diffuse interstitial fibrosis
- Pulmonary vascular disease
- Aspiration pneumonia
- Chest-wall restrictions secondary to thoracic skin sclerosis
- Pleural disease

Polymyositis—Dermatomyositis
- Interstitial pneumonitis
- Aspiration pneumonia
- Respiratory myositis
- Pulmonary hypertension
- Bronchiolitis obliterans organizing pneumonia

Mixed Connective Tissue Disease
- Diffuse interstitial lung disease
- Pulmonary hypertension (vasculitis)
- Pleural disease
- Diaphragmatic muscle dysfunction

Sjögren Syndrome
- Respiratory mucosal dryness
- Pleurisy
- Chronic airway disease
- Lymphocytic interstitial pneumonia
- Pseudolymphoma
- Lymphoma
- Amyloid
- Pulmonary hypertension (vasculitis)

hypertension occurs in varying percentages, but is reportedly as high as 50% to 70% in some groups (particularly lung transplant patients).[304] Cor pulmonale may develop in the presence of severe pulmonary fibrosis. Inhaled prostacyclin and sildenafil may be used to reduce pulmonary hypertension.

Clinical presentation is varied and may be categorized as asymptomatic (occurring in 20% of individuals investigated and based on the detection of abnormality of chest radiography) or symptomatic (characterized by nonspecific features ranging from fever, fatigue, anorexia, weight loss, chills, and night sweats to dyspnea and blindness). The lung is the most commonly affected organ, with pulmonary involvement occurring in more than 90% of individuals with sarcoidosis.[301] Respiratory symptoms are those typical of interstitial involvement and include dyspnea, dry cough, and retrosternal chest pain (35% to 50% of patients). Less common symptoms include wheezing, hemoptysis, pleural effusion, and clubbing of the fingers. Sarcoidosis is one of the few chest diseases that concurrently involve lymph nodes in the lung (hilar region) and the mediastinum. On radiography, intrathoracic involvement has been classified into three categories. Stage I is characterized by bilateral, symmetric, hilar, and mediastinal adenopathy; stage II by hilar adenopathy and diffuse pulmonary infiltrates; stage III by diffuse pulmonary infiltrates without adenopathy; stage IV by pulmonary fibrosis.[301] Stage I is associated with the most favorable prognosis, and stage IV with the worst.

The diagnosis of sarcoidosis requires evidence of multisystem disease (i.e., multiorgan presence of granulomas). Extrathoracic involvement typically involves lymphatics, skin, liver, eye, spleen, and bone. Salivary glands, heart, nervous system, and larynx involvement occur in small percentages. Although not a common site, laryngeal involvement should cause concern about possible difficulty with airway instrumentation. Laryngeal involvement is signaled by hoarseness, dyspnea, dysphagia, dysphonia, cough, or stridor.[299] When laryngeal involvement exists, it affects the supraglottic area in 80% and the subglottic area in 20%.[299] Tracheotomy, transoral resection, corticosteroids, and laser resection may be used to treat laryngeal granulomas.

The overall prognosis in sarcoidosis is good. The acute onset usually is followed by a self-limiting course of approximately 2 years' duration with spontaneous resolution in approximately 20%.[301] Treatment with corticosteroids (topical, inhaled, enteral, or parenteral) is frequently used and produces relief of symptoms, clinical remissions, and suppression of inflammation and granuloma formation. Conversely, because spontaneous and permanent remissions occur in 50% of patients, the use of corticosteroids in these individuals is controversial. Other therapies include methotrexate, azathioprine, leflunomide, and mycophenolate.[301] Considering a prominent role of tumor necrosis factor, infliximab, a monoclonal antibody to TNF, has been found effective in treating sarcoidosis.[305,306]

The mortality rate for patients with sarcoidosis after 5 years is approximately 4% to 10% and is attributed to respiratory failure, azotemia from renal injury caused by chronic hypercalciuria, cardiac arrest resulting from myocardial involvement, and massive hemoptysis due to colonization of bullae by *Aspergillus fumigatus*.

FLAIL CHEST

Flail chest, a condition that results from chest trauma and multiple rib fractures, is reported to occur in 5% of patients who sustain thoracic injury (Figure 26-27).[307] The hallmark of flail chest is paradoxical movement of the chest wall at the site of the fracture. During inspiration, the chest wall is drawn inward, owing to the negative intrathoracic pressure; and outward during expiration, when the intrathoracic pressure increases above atmospheric pressure (Figure 26-28). Inefficient lung inflation caused by rib fracture and paradoxical breathing limits alveolar ventilation and may progress to hypoventilation, hypercapnia, and progressive alveolar collapse.[308] Treatment includes pain control with measures such as intercostal nerve block with a local anesthetic or insertion of an epidural catheter with a local anesthetic or opioid, and in severe

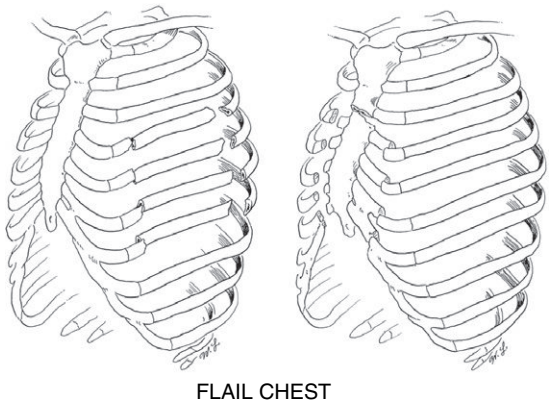

FIGURE **26-27** Fracture of several adjacent ribs in two places with lateral flail or central flail segments. (From Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Mosby; 2010:389.)

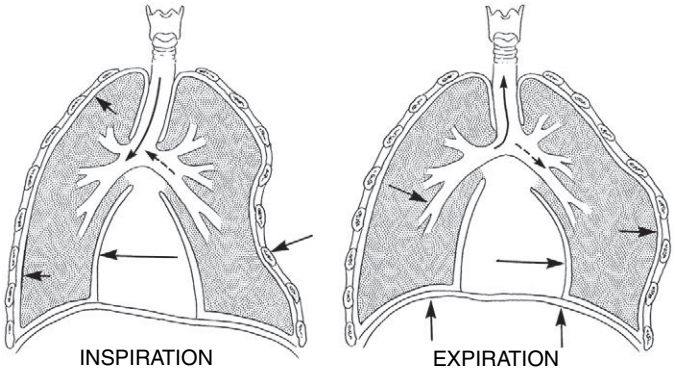

FIGURE **26-28** Flail chest: Paradoxical respiration. On inspiration, flail section sinks in as chest expands, impairing ability to produce negative intrapleural pressure to draw in air. Mediastinum shifts to uninjured side. On expiration, flail segment bulges outward, impairing ability to exhale. Mediastinum shifts to injured side. Air may shift uselessly from side to side in severe flail chest *(broken arrows)*. (Redrawn from Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Mosby; 2010:394.)

BOX **26-16**

Indications for Treatment of Flail Chest with Mechanical Ventilation

Respiratory Failure Manifested by One or More of the Following Criteria

- Clinical signs of respiratory fatigue
- Respiratory rate >35/min or <8 min
- P_{AO_2} <60 mmHg at Fi_{O_2} ≥0.5
- Pa_{CO_2} <55 mmHg at Fi_{O_2} ≥0.5
- Alveolar-arterial oxygen gradient >450
- Clinical evidence of severe shock
- Associated severe head injury with lack of airway control or need to ventilate
- Severe associated injury necessitating surgery

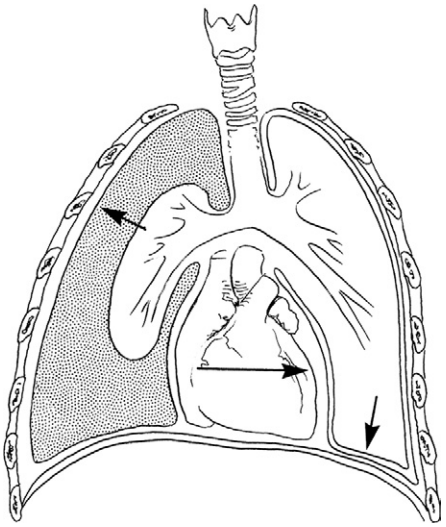

FIGURE **26-29** Closed pneumothorax. Simple pneumothorax is present in the right lung, with air in the pleural cavity and collapse of right lung. (From Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Mosby; 2010:393.)

cases, tracheal intubation with mechanical ventilation and PEEP (Box 26-16). Ventilator settings are adjusted so that wide swings in pleural pressure are decreased or avoided. Surgical fixation of the rib cage may be indicated in some patients for persistent pain, severe chest wall instability, or a progressive decline in pulmonary function testing in a patient with flail chest.[309] The mortality rate is directly related to the underlying and associated injuries and is reported to be between 8% and 35%.[308]

PNEUMOTHORAX

Pneumothorax can be subdivided into three categories, depending on whether air has direct access to the pleural cavity.

Simple Pneumothorax

In simple pneumothorax, no communication exists with the atmosphere (Figure 26-29). Additionally, no shift of the mediastinum or hemidiaphragm results from the accumulation of air in the intrapleural space. The severity of pneumothorax is graded on the basis of the degree of collapse: collapse of 15% or less is small; collapse of 15% to 60% is moderate; and collapse of greater than 60% is large. Treatment of a simple pneumothorax is determined by the size and cause of injury and may include catheter aspiration or tube thoracostomy; close observation of the patient with simple pneumothorax is essential.

Communicating Pneumothorax

In communicating pneumothorax, air in the pleural cavity exchanges with atmospheric air through a defect in the chest wall (Figure 26-30). Communicating pneumothorax represents a severe ventilatory disturbance because the affected lung collapses on inspiration and expands slightly on expiration. The exchange of air in and out of the wound results in a large functional dead space and a decrease in the efficacy of ventilation.

The wound should be covered with an occlusive dressing immediately. The dressing should prevent influx of air, but should allow egress of air from inside the thorax to avoid development of tension pneumothorax (see next section). Treatment measures include administration of supplemental O_2, tube thoracostomy, and intubation; mechanical ventilation may be indicated.

Tension Pneumothorax

Tension pneumothorax develops when air progressively accumulates under pressure within the pleural cavity (Figure 26-31). If the

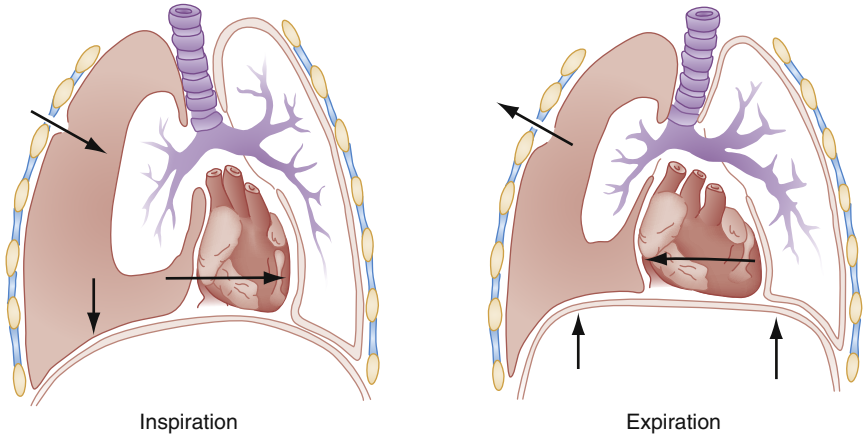

FIGURE **26-30** Communicating pneumothorax. The right lung has collapsed, and air is present in the pleural cavity, with communication to the outside through the defect in the chest wall. In sucking chest wounds, lung volume is greater with expiration. (From Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Mosby; 2010:394.)

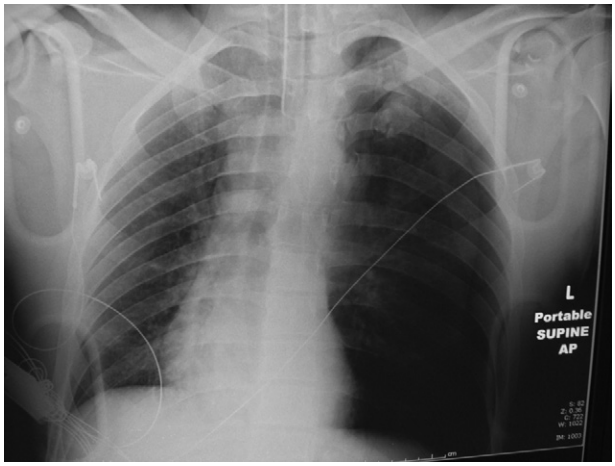

FIGURE **26-31** Tension pneumothorax. Hyperlucency is noted, mostly toward the left lung base, because the x-ray is a supine exposure. Shift of the mediastinum toward the right is noted. (From Marx JA, et al, eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. Philadelphia: Mosby; 2010:394.)

pressure becomes too great, the mediastinum shifts to the opposite hemithorax, and this causes compression of the contralateral lung and great vessels. Subsequently, venous return is decreased, and air enters the pleural space but cannot exit. Respiratory and cardiac disturbances ensue, exhibited by a decrease in CO, a decrease in blood pressure, an increase in CVP, and a shunting of blood to nonventilated areas. The hallmark signs of tension pneumothorax are hypotension, hypoxemia, tachycardia, increased CVP, and increased airway pressure. Other findings include absence of breath sounds on the affected side, asymmetric chest wall movement, tracheal shift, displacement of the cardiac impulse, and hyperresonance to percussion in the affected hemithorax. The patient may exhibit extreme anxiety or a feeling of impending doom.

Tension pneumothorax is potentially lethal; therefore, immediate treatment is essential. Decompression of the chest can be performed with the insertion of a 14-gauge angiocatheter into the second or interspace anteriorly or the fourth or fifth interspace laterally. A rush of air is heard when decompression occurs. The angiocatheter converts the tension pneumothorax to a simple pneumothorax.

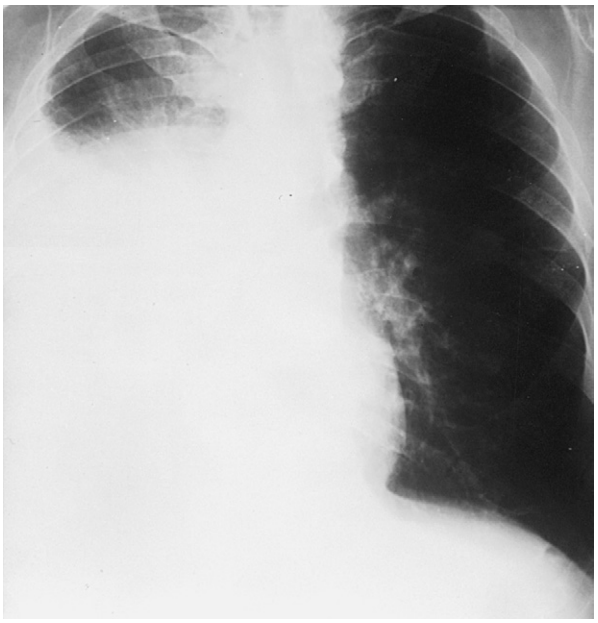

FIGURE **26-32** Dense opacity on the right side with meniscus, indicating hemothorax. (From Townsend CM, et al. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: Saunders; 2007:499.)

Hemothorax

A hemothorax is the accumulation of blood in the pleural cavity. It usually is a result of trauma (Figure 26-32), but other causes include the rupture of small blood vessels in the presence of inflammation, pneumonia, tuberculosis, or erosion by tumors.

The treatment of hemothorax consists of airway management as necessary, restoration of circulating blood volume, and evacuation of the accumulated blood. Thoracostomy may be indicated if the initial bleeding rate is greater than 20 mL/kg/hr. If bleeding subsides but its rate remains greater than 7 mL/kg/hr, if chest radiograph worsens, or if hypotension persists after initial blood replacement and decompression, thoracostomy is indicated.

Pathogenesis

Different presentations may be distinguished, according to the mechanism of injury.

Spontaneous. Pneumothorax usually is caused by rupture of alveoli near the pleural surface of the lung after a forceful sneeze or cough. This mechanism is most common in individuals with a long narrow chest and in those with emphysema.

Traumatic. Hemothorax, pneumothorax, and flail chest may occur after blunt chest trauma; however, they most often occur after rib fracture. Hemopneumothorax also may occur with penetrating injury.

Iatrogenic. Hemothorax and pneumothorax may occur after any of the following:

- Subclavian central line insertion (incidence 2% to 16%)
- Supraclavicular brachial plexus block (interscalene and intercostal block are possible, but less prevalent causes)
- Barotrauma (resulting from overdistention of the alveoli by PEEP or high peak pressure; abrupt deterioration of Pa_{O_2} and cardiovascular function during mechanical ventilation should arouse suspicion of pulmonary barotrauma, especially pneumothorax)
- Other surgical procedures (e.g., mediastinoscopy, radical neck dissection, mastectomy, axillary lymph node dissection, or nephrectomy)

Nitrous Oxide and Pneumothorax

The blood-gas partition coefficient of N_2O (0.47) is 34 times greater than that of nitrogen (0.014). This differential solubility means than N_2O can leave the blood to enter an air-filled cavity 34 times more rapidly than nitrogen can leave the cavity and enter the blood. As a result, the volume or pressure of the air-filled cavity surrounded by a compliant wall increases. An often-cited study determined that 75% N_2O doubles the volume of a pneumothorax in 10 minutes.[310] If in the presence of pneumothorax the chest tube is patent and functioning, N_2O is theoretically acceptable, because little pleural air should be present, and any accumulation should be evacuated by the chest tube. A closed pneumothorax is a contraindication to the administration of N_2O. Decreased pulmonary compliance (increased pulmonary inspiratory pressure) during administration of anesthesia to patients with a history of chest trauma may reflect the expansion of an unrecognized pneumothorax.

ATELECTASIS

Definition

Atelectasis is an abnormal condition characterized by a collapse of pulmonary tissue that prevents the respiratory exchange of CO_2 and O_2. Atelectasis can involve a small localized area or an entire lung. Atelectasis is common with all general anesthetics. It commonly develops within the first few minutes of induction of anesthesia, regardless of the mode of ventilation used, and persists for hours to days after anesthesia, depending on the extent and location of surgery.[311] Atelectasis commonly forms adjacent to the diaphragm in dependent lung regions. Compression of lung tissue, absence of diaphragmatic-induced negative pressure, impaired surfactant, and absorption of oxygen from nitrogen-free alveoli are common causes of atelectasis. Affecting 90% of patients under general anesthesia, atelectasis and airway closure are responsible for the vast majority of gas exchange impairment observed under anesthesia.[312]

Etiology and Pathophysiology

Atelectasis results from a blockage or obstruction of many small bronchi or of a major bronchus. The loss of diaphragmatic tone and function during general anesthesia is a major contributing factor to atelectasis, which characteristically develops within minutes after anesthesia induction. As small airways close due to maldistribution of ventilation under positive-pressure breathing, or due to the cephalad migration of abdominal contents, the gas within the affected alveoli is absorbed, and there is no further ventilation to reopen those alveoli. Reduction in the Fi_{O_2} can help reduce the degree of atelectasis (as measured by the shunt fraction).[313]

Incidence and Outcome

Atelectasis occurs almost universally under general anesthesia and is the most common cause of postoperative respiratory dysfunction. Postoperatively, it occurs most often after thoracic and upper abdominal procedures, with rates of incidence reaching 80%. In lower-risk surgeries, postoperative atelectasis most often is subclinical and resolves spontaneously within 24 to 48 hours. No recent data support that atelectasis predisposes one to the development of pneumonia.

Treatment

Historically, practitioners used large tidal volumes (10 to 15 mL/kg) to combat atelectasis intraoperatively. Although the concept of injury related to high-pressure barotraumas has been long understood, the understanding of ventilator-associated lung injury (VALI) being related to high ventilating volumes, even in the presence of moderate-peak inspiratory pressures (volutrauma) has changed the approach to establishing ventilator tidal volumes.[273,314] To reduce the deleterious effect of high volumes, smaller tidal volumes of 6 to 10 mL/kg are more beneficial for mechanical ventilation, particularly in cases of respiratory distress syndrome. There is evidence that this reduction in tidal volume does not worsen the degree of atelectasis.[315] Instead, PEEP and various maneuvers to reopen ("recruit") and maintain alveoli have been proposed to reduce atelectasis.[316] Most common of these are vital capacity maneuvers, where the lungs are intermittently expanded to vital capacity or 30 cm H_2O and held in that state for around 10 seconds.[313,317] Such recruitment maneuvers are most effective when combined with other strategies such as reduction in Fi_{O_2} or "open-lung" ventilation approaches.

Open-lung ventilation describes myriad approaches to providing mechanical ventilation with the goal of preventing atelectasis. Pressure-control inverse ratio ventilation (PC-IRV) and, more recently, airway pressure release ventilation (APRV) are approaches designed to maintain a higher mean lung volume and thereby reduce airway closure and atelectasis. Airway pressure release ventilation is analogous to CPAP, with intermittent release phases that allow the lung volume to drop briefly. APRV has an advantage over more "controlled" ventilation modes (such as PC-IRV) in that it is useful in spontaneously breathing patients to reduce neuromuscular blockade, preserve respiratory effort and protective reflexes, and cause less patient-ventilator dyssynchrony.[318]

Standard postoperative measures for improving pulmonary function include incentive spirometry, deep breathing, intermittent positive-pressure breathing, and administration of CPAP, with the last of these offering the greatest superiority in increasing FRC.

PLEURAL EFFUSION

Pleural effusion is the abnormal accumulation of fluid in the pleural space. It usually is an indication of disorders or disease complications in the surrounding structures. Possible causes of effusion are: (1) blockage of lymphatic drainage from the pleural cavity; (2) cardiac failure, which causes an increase in pulmonary capillary pressures and eventual movement of fluid into the pleural cavity; (3) reductions in plasma colloid osmotic pressure; and

(4) infection or any other inflammatory process of the pleural membranes that alters capillary membrane permeability.

Treatment modalities include tube thoracostomy, thoracentesis, and pleurodesis. Pleurodesis is a procedure used to prevent the reaccumulation of pleural fluid. Inflammation is produced with injection of a sclerosing agent, usually tetracycline, into the chest tube; adhesion formation and fusion of the pleural membranes result.

SKELETAL DISORDERS

The primary pathophysiology of skeletal disorders is an alteration in the structure of the thorax that diminishes chest-wall excursion. Disorders commonly producing this restriction of breathing include sternal deformities, kyphoscoliosis, and ankylosing spondylitis (AS).

Pectus Deformities

Pectus Excavatum

Pectus excavatum, also referred to as *funnel chest*, is the most common chest wall deformity, occurring in 1 in 400 children.[319] It is a congenital anomaly characterized by depression of the sternum (usually above the xiphoid-sternal junction) and symmetric or asymmetric prominence of the ribs on either side. Pectus excavatum has a genetic linkage, which is shared with that of adolescent scoliosis.[320] If uncorrected, the disease usually worsens at adolescence. A widely used surgical procedure, the Nuss procedure, inserts a metal rod behind the sternum to reverse the concavity.[321]

Clinically the majority of patients are asymptomatic unless pectus excavatum is extreme. Patients with pectus excavatum have reduced chest cavities and TLC compared with normal subjects; however, pulmonary function often is normal except in severe cases, in which VC, TLC, and maximum breathing capacity may be diminished. The indications for repair of pectus excavatum are the subject of controversy. Conflicting data have been presented regarding whether the repair of pectus excavatum is performed only for cosmetic purposes or whether it actually improves cardiorespiratory function and exercise tolerance.[321] Patients with Marfan syndrome have a high incidence of chest-wall deformities. They usually are seen in their most severe form and often are accompanied by scoliosis. Other musculoskeletal diseases may be present in patients with pectus excavatum. Congenital heart disease, mitral valve prolapse, and asthma also occur more frequently in patients with pectus excavatum. Electrocardiographic abnormalities are common and attributable to the abnormal chest-wall configuration and to the displacement and rotation of the heart into the left thoracic cavity. A systolic ejection murmur of grades II to III or IV often is identified.

Pectus Carinatum

Pectus carinatum is characterized by a longitudinal protrusion of the sternum. It is the second most common chest deformity, occurring in 1 or 2 persons per 1000. A familial tendency exists, and the disorder is more frequent in males than in females (4:1). The pathogenesis is unclear, and the disorder may be congenital or acquired. The development of pectus carinatum is thought to result from the overgrowth of the costal cartilages, which results in displacement of the sternum. The development of pectus carinatum also has been associated with severe childhood asthma and rickets.[322] The physiologic effects are probably related to the restriction of thoracic excursion. Patients with pectus carinatum have an increased incidence of congenital heart disease, including ventricular septal defect, patent ductus arteriosus, atrial-septal defects, and mitral valve abnormalities.[323] Surgery is the only effective treatment for pectus carinatum and is performed to alleviate possible cardiopulmonary dysfunction and to prevent progressive postural deformities, as well as for cosmetic reasons.

Kyphoscoliosis

Definition

Kyphosis is a deformity marked by an accentuated posterior curvature of the spine. Scoliosis is a lateral curvature. Kyphoscoliosis results when kyphosis and scoliosis occur concomitantly, causing a lateral bending and rotation of the vertebral column. Scoliosis alone, despite its severity, does not cause sensory or motor impairment. In contrast, kyphosis and kyphoscoliosis may induce cord damage because of the sharp angulation of the spine. Respiratory dysfunction is associated with scoliosis, significant kyphosis, and severe kyphoscoliosis.

Incidence and Outcome

Scoliosis is the most common spinal deformity, with an incidence of 4 persons per 1000.[324] The etiologic classification of scoliosis falls into five categories: idiopathic, congenital, neuropathic (e.g., poliomyelitis, cerebral palsy, syringomyelia, and Friedreich's ataxia), myopathic (e.g., muscular dystrophy and amyotonia congenita), and traumatic. Idiopathic scoliosis is the most common deformity, accounting for 80% of all cases. The presence of cervical scoliosis should alert anesthesia personnel to potential difficulties in airway management. Any significant curvature involving the thoracic spine may alter lung function. Unless deformity is severe, patients with kyphosis are able to maintain normal pulmonary function. In contrast, even mild forms of scoliosis can result in impaired ventilatory function.

Although not totally consistent, VC and FEV_1 less than 50% of that predicted during initial testing suggest an increased risk of pulmonary complications postoperatively.[325-327] The Cobb angle (being greater than 100-110 degrees) is also moderately predictive of complications.[325,326]

Severe thoracic deformity may result in respiratory alterations during sleep. Several types of breathing abnormalities have been documented, including obstructive apnea and hypopnea. The lowest $HgbO_2$ saturations occurred during REM sleep.[328,329] Because of chronic effects on the pulmonary system, surgical correction results in immediate and short-term deterioration of respiratory mechanics in anesthetized patients.[330]

Clinical Features and Diagnosis

Diminution of pulmonary function occurs with curvatures of greater than 60 degrees, and pulmonary symptoms develop with curvatures greater than 70 degrees (as measured by the Cobb technique; Figure 26-33). Curvatures greater than 100 degrees may be associated with significant gas exchange impairment.[331] In general, the greater the curvature, the greater the loss of pulmonary function. Because of this, mechanical ventilation becomes inefficient; this inefficiency is the major factor causing respiratory embarrassment.[329] At the time of diagnosis, it is often possible to document a reduction in lung capacity. The characteristic deformity seen in scoliosis causes one hemithorax to become relatively smaller than the other.

Skeletal chest wall deformity in kyphoscoliosis leads to a reduction in lung volumes and the pulmonary vascular bed.[332] Ventilatory failure associated with severe kyphoscoliosis produces a lung size that is 30% to 65% of normal. As the patient ages, the chest wall becomes less compliant; this increases the work of breathing and leads to hypoventilation and respiratory muscle weakness.

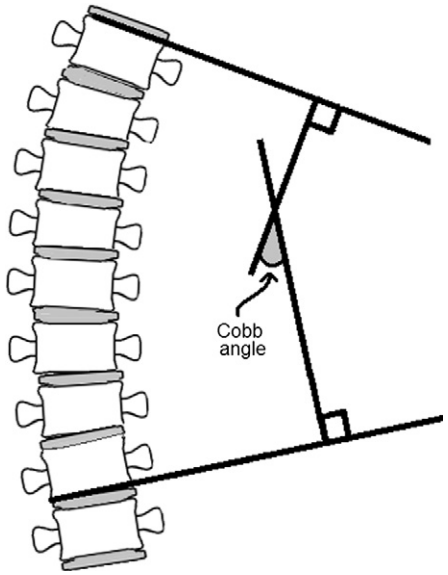

FIGURE **26-33** Cobb method of measuring scoliosis curves. The most tilted vertebrae above and below the curve are identified. Horizontal lines are drawn parallel with the plane of each vertebra. Perpendicular lines intersecting those horizontal lines intersect at the angle of curvature.

The main features of lung mechanics in the patient with early-stage scoliosis are reduced lung volumes (VC, TLC, FRC, and RV) and reduced chest wall compliance; in the late stages of disease, $\dot{V}/\dot{Q}$ mismatching with hypoxemia (attributed to alveolar hypoventilation because of a decrease in V_T), increased PAP, hypercapnia, abnormal response to CO_2 stimulation, increased work of breathing, and cor pulmonale occur and eventually lead to cardiorespiratory failure.[332] Reduction in VC to 60% to 80% of the predicted value is a typical finding.[331] FEV_1/FVC is normal unless other pulmonary diseases are present. Although normocarbia prevails for most of the clinical course, an elevated $Paco_2$ signifies the onset of respiratory failure. The severity of hypercapnia most closely correlates with the patient's age and inspiratory muscle strength.

Associated Conditions

Scoliosis may be associated with several cardiovascular abnormalities, of which mitral valve prolapse is the most common. If mitral regurgitation is present, antibiotic prophylaxis is indicated before surgical manipulation. Other common changes include an increase in PVR and ensuing PAH, which leads to the development of right ventricular hypertrophy. Several contributing factors are thought to be responsible for the development of increased PVR. First, arterial hypoxemia results in pulmonary vasoconstriction. Second, changes in the pulmonary arterioles as a consequence of the increased pulmonic pressure may cause narrowing and result in irreversible PAH. Third, a compressed chest wall may increase vascular resistance in affected areas. Fourth, development of scoliosis at an early age inhibits growth of the pulmonary vascular bed.

Treatment

The management of scoliosis may include: (1) observation of the problem without active medical treatment, (2) treatment by nonoperative methods that include the use of braces or electronic stimulators, and (3) operative methods such as anterior or posterior spinal fusion and instrumentation, such as Harrington rod insertion.[333] Discussion continues regarding the long-term effectiveness of various treatment modalities vis-à-vis short- and long-term complications that can also arise after surgery.[334]

Anesthetic Management

Preoperative Evaluation. Preoperatively a thorough review of systems is essential. The severity of scoliosis and any underlying conditions must be noted. Any reversible pulmonary involvement such as pneumonia should be corrected before elective surgery. ABG analysis may be indicated if there is suspicion of significant pulmonary impairment. Because these procedures can potentially involve large blood losses, young, healthy, asymptomatic patients may donate autologous blood. Blood typing and cross match also are required.

When sedatives are used in the preoperative area, care must be taken to ensure that respiratory status is not depressed. The need for intraoperative monitoring is dictated by the type of surgery and the physical status of the patient. No specific anesthetic techniques have been shown to be superior in patients with scoliosis, but N_2O may increase PVR by direct vasoconstrictive effects on the pulmonary vasculature. It has been suggested that scoliosis is associated with an increased incidence of malignant hyperthermia.[335]

With significant manual distraction of the spine during the procedure, assessment of neural integrity may be required. Although increasingly less common, a "wake-up" test may be requested after placement of surgical instrumentation. This should be communicated between surgeon and anesthetist before the procedure. At the designated time, the anesthetic is lightened and the patient is observed to follow commands and demonstrate motor function. The anesthetic must be planned to allow the patient to become able to hear and follow commands, while still tolerating the endotracheal tube in the prone position. After successful demonstration, anesthesia is quickly reinstituted to facilitate the conclusion of the procedure. The use of somatosensory evoked potentials and motor evoked potential monitoring has reduced the requirement for the wake-up test. Neural monitoring, however, also necessitates customization of the anesthetic plan to reduce interference with the signals. High-dose volatiles or any wide swings in anesthetic level can influence sensory evoked potential monitoring, and muscle relaxants can interfere with motor response monitoring. All anesthetic agents depress somatosensory evoked potentials to a varying degree. Administration of volatile anesthetics should not exceed a minimum alveolar concentration of 1. A technique using primarily N_2O or propofol for hypnosis and continuous infusion of opioid is a common approach. Communication between the monitoring technician and anesthetist is essential.

Intraoperative Management. Considerable fluid and blood loss may occur during surgery. The surgeon may request the institution of deliberate hypotension. Deliberate hypotension can be produced with the use of one or more of the following: potent inhalation anesthetics; vasodilators (e.g., sodium nitroprusside, or nitroglycerin) or β-adrenergic blocking agents (e.g., propranolol or esmolol). The risks and potential benefits should be weighed against the effects of deliberate hypotension. Traditional wisdom was that the mean arterial blood pressure can be safely maintained at a lower level of 60 mmHg. However, the lower limit of cerebral autoregulation is not dependably at this level, and discrepancies between blood pressure measurement devices and the actual perfusion pressure of the brain may be significant. The incidence of both blindness from retinal hypoperfusion in the prone position and cerebral injury from deliberate hypotension call for extreme caution in driving the blood pressure down during this procedure.[336-338] Interventions for prevention of hypothermia, such as use of a hot-air warming blanket, should be used. Careful positioning is essential.

Postoperative Care. The decision of whether to use mechanical ventilation postoperatively is based on the severity of scoliosis

and intraoperative events. Most patients with mild to moderate pulmonary dysfunction are able to undergo safe extubation in the operating room. Those with severe deformity should be weaned slowly.

Ankylosing Spondylitis

Definition

Ankylosing spondylitis (AS), also known as *rheumatoid spondylitis* and *Marie-Strumpell disease*, is a chronic inflammatory disorder that primarily affects the spine and sacroiliac joints and produces fusion of the spinal vertebrae and the costovertebral joints.

Etiology and Incidence

The cause of AS remains unclear. However, it is strongly associated with the histocompatibility antigen HLA-B27, the presence of which is detected in more than 90% of Caucasians with the disease.[339] It is a disease of adults younger than 40 years, and it demonstrates a predilection for males (male-to-female ratio, 9:1). The disease is rare in non-Caucasians.

Clinical Features and Diagnosis

AS is diagnosed on the basis of clinical criteria that include: (1) chronic low back pain with limitation of spinal motion (less than 4 cm as measured by the Schober test), (2) radiographic evidence of bilateral sacroiliitis, and (3) limitation of chest wall expansion (less than 2.5 cm increase in chest circumference measured at the fourth intercostal space). Extraskeletal manifestations of this disease include iritis, cardiovascular involvement (cardiac conduction defects, aortitis, and aortic insufficiency in 20% of individuals), peripheral arthritis, fever, anemia, fatigue, weight loss, and fibrocavitary (fibrobullous) disease of the apexes of the lungs. The most limiting factors associated with the disease are pain, stiffness, and fatigue.

Complications

Pulmonary complications are reported to occur in 2% to 70% of patients with AS. Apical fibrosis is the most commonly occurring abnormality, followed by interstitial lung disease, respiratory impairment due to chest wall restriction, sleep apnea, and spontaneous pneumothorax.[340] In apical fibrosis, the pulmonary lesion begins with apical pleural thickening and patchy consolidation of one or both apexes and often progresses to dense bilateral fibrosis and air space enlargement. Patients with apical fibrosis usually have advanced AS. Cardiac complications associated with AS include aortic valve diseases, conduction disturbances, cardiomyopathy, and ischemic heart disease.[340]

The most common thoracic complication is fixation of the thoracic cage as a result of costovertebral ankylosis, which can lead to pulmonary dysfunction.[341] In patients with this complication, motion of the thoracic cage is restricted due to fusion of the costovertebral joints; this restriction leads to a decrease in thoracic excursion. Respiratory function typically demonstrates a restrictive pattern with mild diminution of TLC, VC, and DLCO and normal or slightly increased RV and FRC. Pulmonary compliance, diffusion capacity, and ABG values usually are normal.[341] Despite having abnormal pulmonary function, the majority of patients with AS are able to perform normal physical activities without pulmonary symptoms.

Bone ankylosis may occur in the numerous joints around the thorax (i.e., the thoracic vertebrae and the costovertebral, costotransverse, sternoclavicular, and sternomanubrial joints), resulting in limitation of chest-wall movement. Patients with AS rarely complain of respiratory symptoms or functional impairment unless they have coexisting cardiovascular or respiratory disease. Progressive kyphosis is equivalent to progressive rigidity of the thorax. Increased diaphragmatic function compensates for decreased thoracic motion, allowing lung function to be well preserved. Regional lung ventilation in patients with AS is normal unless they have preexisting apical fibrosis.

Cervical spondylosis affects levels C5 to C6 and C6 to C7 most often, and less frequently, C4 to C5, C7 to T1, and C3 to C4. The degenerative changes may result in nerve root entrapment by foraminal encroachment. The phrenic nerve, which innervates the diaphragm, is supplied primarily by the C4 nerve root, and to a lesser extent, by the C3 and C5 nerve roots. A case of hemidiaphragmatic paralysis secondary to C4 nerve root compression has been reported.

Cricoarytenoid involvement may exist and can lead to respiratory dysfunction and upper airway obstruction. Cricoarytenoid dysfunction can manifest as a hoarse, weak voice. Respiratory failure from cricoarytenoid ankylosis has necessitated therapeutic tracheostomy. In all reported cases, laryngeal symptoms were present before cricoarytenoid arthritis caused airway compromise. A case of acute respiratory failure and cor pulmonale resulting from cricoarytenoid arthritis also has been reported in a patient with AS.

Treatment

Medical therapy for adult patients with AS is supportive and preventive. Most patients with AS are asymptomatic. Depending on the severity of disease involvement, management may consist of the use of corticosteroids and nonsteroidal antiinflammatory agents. Patients should refrain from smoking tobacco.

Anesthetic Management

Patients with AS have specific anesthetic requirements.[342] Management of the upper airway is the priority because of the potential for obstruction. Cervical spine involvement may result in limitation of movement. The ankylosed neck is more susceptible to hyperextension injury, and cervical fracture may occur. Intubation awake with or without the use of a fiberoptic bronchoscope is indicated. In rare situations, tracheostomy must be performed with the patient under local anesthesia before anesthesia can be induced. A regional anesthetic technique may not be feasible because of skeletal involvement that precludes access or because of neurologic complications such as spinal cord compression, cauda equina syndrome, focal epilepsy, vertebrobasilar insufficiency, and peripheral nerve lesions. Patients with cardiovascular system involvement may require antibiotic coverage, treatment of heart failure, or insertion of a temporary pacemaker before surgery. Restriction of chest expansion and rarely pulmonary fibrosis necessitate performance of a thorough preoperative assessment and immediate postoperative mechanical ventilation. Careful attention to positioning is essential.

SUMMARY

To conduct an accurate patient assessment and manage relevant pathophysiology, knowledge of the anatomy and physiology of the respiratory system is imperative for the anesthetist. Anatomic idiosyncrasies (such as the shorter, straighter, right mainstem bronchus), physiologic derangements from anesthesia (such as the atelectasis and ventilation-perfusion mismatch that occur), perianesthetic complications (such as aspiration pneumonitis), preexisting illness (such as COPD), and iatrogenic illness (such as pulmonary toxicity from chemotherapeutic agents) are all concerns for the anesthetist in caring for the pulmonary system.
