## Table of contents

Preface	xix
Conference organization	xxi
<i>Structural engineering</i>	
Self-vibration characteristics and influence factors analysis on the monopile foundation support structure of offshore wind turbine <i>X. Wang, Z. Y. Li &amp; C. Chen</i>	3
Cyclic loading test and single plastic hinge analytical analyses of Precast Segmental Bridge Columns with a circular section <i>J. Guo, Z.-Y. Bu &amp; W.-Y. Wu</i>	9
Establishment and seismic performance analysis of AFRP-reinforced concrete frame structure finite element model <i>G. Zhao &amp; X.S. Xu</i>	15
Micro damage in the structural deformation verification under expected rare earthquake <i>X.M. Chen, J. Duan, H. Qi &amp; Y.G. Li</i>	21
Experimental study on the axial bearing capacity and ductility of concrete column confined with double stirrups <i>Y. Y. Li, Y. Y. Zhang, L. Z. Sun &amp; L. Sun</i>	27
The model design of fatigue test of steel-concrete composite segment of railway hybrid girder cable-stayed bridge <i>Y. Zhou, Q. Pu, Z. Shi &amp; Z. Liu</i>	31
Mechanical properties of RC pile strengthened by effective CFRP composites <i>N. Zhuang, Y.J. Zhou, H.D. Sun &amp; S. Ge</i>	35
Applied research of acoustic transmission method on the detection of pile foundation <i>J. Zhang, B. Wang, M. Jing, Z. Sun &amp; Y. Lin</i>	41
A brief discussion on the causes and treatment measures of bridge pile foundation defects <i>J. Li, W. Ren, J. Wang, Z. Zhang, X. He &amp; B. Wang</i>	45
Analysis on load-carrying capacity of a ribbed stiffener shallow spherical shell roof <i>D. Y. Jia, T. Wang &amp; J. Yang</i>	47
Analysis on wind-induced effects of simply supported beam roof structure with metal roof panels <i>L. Huang, W. Wang &amp; H. Deng</i>	51
Shaking table test study on a retrofit method of bottom-business multi-story building <i>Y. Liang, X. Guo, Y. Zhou, J. Jiang &amp; Y. Li</i>	59
Force analysis on continuously pouring outer wrapped concrete based on a SRC arch bridge <i>G. Wei &amp; Z. Gu</i>	63
The analysis of the influence of material strength on the shear capacity of steel tube-reinforced concrete composite column <i>B. Wang, X. Liu &amp; T. Xu</i>	69

Research on the strength of structural Steel Tubes and Coupler Scaffolds <i>Z. Lu, Y. Wen, L. Zhao, T. Liu, C. Li, C. Guo &amp; W. Wang</i>	73
Theoretical analysis on the bearing capacity of structural Steel Tube and Coupler Scaffolds <i>Z. Lu, Y. Wen, L. Zhao, C. Huang, S. Cao, C. Guo &amp; W. Wang</i>	79
Vibrations and buckling analysis of Mindlin plates with stepped variable thickness <i>S.F. Yang, H. Chen &amp; J.P. Wei</i>	85
Analysis of a new Tensairity bridge section <i>D.C. Yuan &amp; M.S. Jiang</i>	93
Experimental research on the stability bearing capacity of Q420 high-strength steel tubular members <i>B. Li, P. Cao, D. Zhang &amp; T. Xu</i>	97
Analysis of the slope pre-stressed anchoring effect on Xiaowan Hydropower Station <i>Y.H. Jiang, G.L. Long, Z. Fan &amp; Z.C. Lu</i>	103
Study on mode II fracture initiation using the strain energy density criterion <i>W. Gao, S.N. Wang &amp; Y. Su</i>	109
Discussion on methods of strengthening concrete structures <i>L. Dou &amp; T. Chen</i>	117
Freeze-thaw damage model for polypropylene fiber concrete <i>S.-p. Chen &amp; F. Ten</i>	121
Design and application of real-time deformation monitoring system for factory building <i>X.D. Pan, Z.B. Yao &amp; L. Zhao</i>	127
Analysis for seismic performance of sheer wall-steel truss structure system <i>W. Sun, X. Niu &amp; H. Chen</i>	131
Seismic performance and retrofit for a historic concrete building in Shanghai <i>H.N. Wang &amp; H.B. Liu</i>	137
Strength model of FRP confined concrete cylinders <i>J.-S. Wang &amp; D.-S. Gu</i>	141
Joints transferring forces outside box columns with different beams' height and columns' deviation of verticality—finite element method simulation <i>Z.G. Xu, R. Yang, Z.B. Zhang &amp; C.G. Deng</i>	145
Reliability of non-resonant quasi-integrable Hamiltonian systems under wide-band random excitations <i>J. Lan, H. Y. Wang &amp; Y.J. Wu</i>	149
Research progress on diaphragm-through joint of Concrete-Filled Square Steel Tube and steel beam <i>M. Li, M. Zhao, Y. Wang, W. Tao, S. Li &amp; R. Shan</i>	155
Analysis of influencing factors on stiffness degradation of Parallel Double Coupling Beams with different width <i>M. Li, C. Wang, Y. Wang, W. Tao, B. Wan &amp; R. Shan</i>	159
Study on parameter optimization of static performance for long-span elliptic suspended dome structure <i>K.R. Shi &amp; Z.R. Jiang</i>	165
A review of analyzing influences of excavation of foundation pits on the surrounding environment <i>S.M. Zhang &amp; F.W. Jing</i>	173
A detailed analysis of the steel strand corrosion effect on serviceability state of PC continuous rigid frame bridges <i>P. Wang, F. Wang, L. Zhang &amp; Z. Zhang</i>	177

Research of the composite wallboard mould connection with multiple assembly mould pouring <i>C. Xu, Y. Zhao, F. Chen &amp; C. Xu</i>	183
Effects of height and span of structures on the vibration period of steel moment resistant frames <i>M. Shadab Far, N. Hassani &amp; A. Dalvand</i>	187
Installation study of transverse brace of stacked tied arch bridges for safety of out-plane buckling <i>Y. Niu &amp; P. Lin</i>	195
Experimental study on mechanical properties of stabilized clay soils used in hydraulic engineering <i>J. Chen, J. Leng, Y. Mao, Y. Yang &amp; Y. Pan</i>	199
Experimental study on the interior joints of the unsymmetrical hybrid connection <i>P.X. Liang, H. Zhang &amp; M.G. Sun</i>	203
Application and numerical simulation of polyurethane insulation board in concrete lining canal <i>Y. Yin &amp; D. Zhang</i>	207
<i>Geotechnical engineering</i>	
Test on the mechanical properties of cement treatment soil under triaxial compression <i>T.W. Zhang, Y.Y. Zhao, X.L. Zhang &amp; X.C. Zhang</i>	213
Influence factors analysis of settlement characteristic of CFG pile-net composite foundation during embankment construction <i>H. Zhang, J.-j. Wu, X.-m. Huang, L.-p. Zhang &amp; X.-m. Yang</i>	219
Construction analysis of cellular sheet piles in thick clay condition <i>Y.Z. Bai</i>	223
The soil dynamic structural parameters based on the view of equivalent elastomer <i>X. Chen, H. Guo &amp; Y.X. Yan</i>	227
Comparison of the mechanical properties of clay rock in Tamusu region and abroad <i>H. Liang, Y. Liu, Q. Lu, S. Chen &amp; W. Bian</i>	233
Study on the simulation test for Osterberg cell test of large pile foundation <i>L. Xu</i>	237
Numerical analysis of settlement of the soft clay foundation <i>X. Jiang &amp; Y. Li</i>	243
Numerical analysis of bearing capacity of single pile under axial loading <i>X. Zhang &amp; Y. Li</i>	247
Analysis of dynamic responses of loess slope by compaction loads <i>Z. Sun, J. Zhao &amp; L. Dong</i>	251
Consolidation analysis of concrete-cored sand-gravel columns improved composite foundation <i>G.B. Ye, Q.W. Zhang &amp; Z. Zhang</i>	255
Application of the correlation method on the analysis of the influence factor of heading blast vibration <i>L. Yan</i>	263
Study on the dynamic deformation characteristics of loess landslide <i>X.M. Cui &amp; X.H. Sun</i>	269
The deformation characteristics of Xi'an aquifer sand under high-stress condition <i>X.H. Sun &amp; X.M. Cui</i>	275

Experiment research on the creep model of aquifer sand in Xi'an <i>X.H. Sun &amp; X.M. Cui</i>	281
Fractal study of debris flow provenance granularity in Qinling temple valley <i>X.C. Xue, D. Han, L. Y. Zhang, P.B. Yang, L.J. Shi, S. Y. Huang &amp; Y.C. Zhang</i>	287
Research on the effect of bank slope on rising and drawdown of water level <i>C. Wang, Y. He &amp; M. Zhang</i>	291
Efficient simulation for subsidence induced by dewatering of pit <i>J.H. Wang, L.J. Tao, X. Han &amp; H.L. Zhou</i>	295
Statistical study on bond strength of rock anchor <i>M. Tang, H. Hu &amp; C. Zhang</i>	301
Particle breakage characteristics of calcareous sand under P-wave <i>X.-Y. Xu, X.-F. Chen, G.-H. Chen, S.-J. Di &amp; W.-Q. Cheng</i>	305
Parameter sensitivity analysis of marine steel pipe pile in sandy soil foundation based on <i>p-y</i> curve method <i>S.-j. Di, X.-y. Xu, X.-f. Chen, X. Wang &amp; L.-f. Bu</i>	309
Kinematic analysis of slope failure modes based on stereographic projection <i>S. Xiao, Y.T. Gao, S.C. Wu, B. Liu &amp; Q.M. Tian</i>	313
Numerical analysis of continuous loading oedometer test <i>Y.-S. Zhang, Y.-T. Gao, Z. Wang &amp; T. Zhang</i>	319
A calculating model for acid load settlement based on mass transfer process of AMD corrosion <i>L. C. Jiang, W.W. Li &amp; J.J. Zeng</i>	325
Investigations into creeping characteristics and constitutive models of soft-rock in deep cretaceous strata <i>H. Li &amp; L.-s. Cui</i>	331
Analysis of characteristics of saline soil in Yanqing new town <i>H.D. Wang, Y.H. Sun, X. Huang, Q.X. Lu &amp; J. He</i>	339
The influences of soil characteristics on the Negative Skin Friction on a single pile <i>T. Huang &amp; S. Y. Fu</i>	343
Numerical analysis of pile uplift bearing capacity with enlarged head <i>F.F. Li, H.F. Qian, H.R. Qin &amp; T.Q. Zhou</i>	347
The load deformation behaviour and the bulging patterns of reinforced gabion retaining walls <i>Y. Jiang, H. Shen, J. Xia &amp; B. Chen</i>	351
The influence of geometric parameters on the deformation behaviour of reinforced gabion retaining walls <i>Y. Jiang, H. Shen &amp; J. Xia</i>	355
Study on crack-generated characteristics of expansive soil <i>L. Cao, M.M. Xin, Z.X. Zhai, Q. Zhou &amp; Z. Y. Ye</i>	359
Finite element analysis of reinforced soil retaining wall <i>Q. Wang, F.F. Li, H.F. Qian, H.R. Qin &amp; T.Q. Zhou</i>	365
The research progress of water-salt mechanism and migration model <i>G.-l. Zhu, L. Zhu &amp; C. Yu</i>	369
Application of strain softening model to numerical analysis of deep tunnel <i>X.H. Diao, S.X. Yang &amp; K. Wang</i>	373
Study on the relation between rock size effect and uniaxial compressive strength <i>Q. Zhang, M. Huang &amp; H. Chen</i>	379
Displacement response of buildings under debris flow impact load <i>J.X. Cao, F.L. Zhang &amp; M.H. Zhou</i>	383

### *Tunnel, subway and underground facilities*

- Displacement analytic solution of a deep elliptical tunnel in a transversely isotropic rock mass considering the shear stress effect 393  
*Z. Zhang & X. Li*
- The effect analysis of subway tunnel construction accidents on adjacent buildings 397  
*X.W. Peng & D.C. Yuan*
- Experimental study on properties of zeolite powder concrete under the hot and humid environment 403  
*Z.T. Chen*
- Study on influence of foundation pit excavation on existing tunnels 407  
*Y. Cui, S.M. Zhang, T. Feng, X.Q. Wang & M.M. Sun*
- Study on numerical simulation of influence of excavation on existing tunnels 411  
*S.M. Zhang, Y. Cui, Y.S. Huang & M.M. Sun*
- Study on deformation control of the existing tunnels under foundation pit excavation 415  
*H.F. Xu, W.G. Liu, G.M. Zhao, Y. Cui & S.M. Zhang*
- The study on safety evaluation method of metro construction based on SHEL—BP neural network 419  
*J.X. Zhao, K. Fan, J.H. Sun & M. Liu*
- Influence of box culvert construction on running metro shield tunnel 425  
*T. Liu, G. An & H. Liang*
- Seismic engineering*
- Quasi-static cyclic loading test and simulation of precast segmental bridge columns with a circular section 433  
*Z.-Y. Bu, W.-Y. Wu & J. Guo*
- A hysteretic model for Precast Segmental Bridge Columns with unbonded posttensioned tendons 437  
*Z.-Y. Bu, W.-Y. Wu & J. Guo*
- The effect of convex friction distribution on the seismic performance of friction systems 441  
*B. Wei, T.H. Yang, X.D. Yu, P. Wang & L.Z. Jiang*
- Seismic performance of the convex-friction and damper systems 447  
*B. Wei, T.H. Yang, X.D. Yu, P. Wang & L.Z. Jiang*
- Quasi-static finite element analysis of a precast concrete frame shear wall structure 453  
*Y.g. Zhang, Q. Zhong, L.g. Jia & W.j. Zhao*
- Discussion on the relation between  $V_{S30}$  and  $V_{SZ}$  461  
*Z.R. Tao, B.H. Zhu & X.X. Tao*
- Structural dynamic anti-seismic performance analysis on the main machine hall in conventional island of Tianwan nuclear power station unit 5, 6 465  
*Y.-h. Jin, J. Zhao & G.-x. Wang*
- Behavior of steel double-channel built-up chords of special staggered truss steel frames structure under reversed cyclic bending 471  
*H.D. Ran & W.L. Liang*
- Seismic influences on high-speed elevators in Super-High-Rise buildings 477  
*I. Torguet & W. Lu*
- Comparison of deep soil deposit seismic response with three basement models 489  
*X.B. Peng & W.L. Yang*

### *Coastal engineering*

- An electrochemical impedance spectroscopy method for identifying the Threshold Chloride Level for rebar in simulated concrete pore solutions 495  
*J.Z. Hu, X.Q. Cheng, X.G. Li, P.C. Deng & G. Wang*
- The corrosion of the pipeline steel in thermocline of the tropical oceans 501  
*P.C. Deng, G. Wang, J.Z. Hu, X.G. Li & X.Q. Cheng*
- Numerical study of typhoon waves with the typhoon hindcasted model 505  
*J. Dong, J.-F. Zhai, Z.-X. Zhu & P.-H. Dong*
- Model study on the sediment dynamics in the Bohai Sea 511  
*H. Liu, H.X. Kang, B.S. Yin & D.Z. Yang*
- Three-dimensional numerical simulation of the tidal flat and channel during flood tide 515  
*Z. Jiao, X. Zhang, X. Dou, Y. Pan & L. Ding*
- Numerical modeling of regional hydrodynamic and seabed morphological effects from the construction of artificial islands in Danzhou, Hainan 519  
*S.H. Zuo, B. Li & Z. Zhang*
- 3D numerical simulation of local scour around regulating structures in tidal reaches 525  
*X. Zhang, X. Dou & Z. Jiao*
- Numerical simulation study of sedimentation downstream tide gates influenced by the length of the irrigation channel 531  
*X. Zhang, Z. Jiao & J. Zhang*
- Application of ecological revetment in Lianshen waterway regulation project 535  
*J. Chen, J. Zhang, Y.-p. Zhou & L.-Y. Xu*
- ### *Road and bridge engineering*
- Numerical simulation analysis of the pressure-dispersed anchor cantilever retaining wall's effect mechanism 541  
*C. Wang, C. Li, X.G. Song, H.B. Zhang & Q.Y. Meng*
- Simulations of transit priority under multi-flow conditions 547  
*J. Ding, Y.Y. Ma, M. Yang & W. Wang*
- Diseases of long span steel bridge pavement and their solutions 551  
*S. Ji, Y. Yang & G. Gong*
- The research on the internal force effect of different vertical curves on a curved box girder bridge 555  
*Y.-x. Liao & J.-h. Gao*
- A study on the stretch tensor of the beam end in a curved girder bridge caused by environmental temperature change 559  
*J.-s. Liu & J.-h. Gao*
- Shear-lag effect in a prestressed continuous rigid frame bridge 565  
*X. Wu, H. Li & X. Yuan*
- Analysis of influencing factors on central load and temperature coupling effect of tram monolithic roadbed 569  
*C. Huang, Y. Xie, Y. Wei & K. Wang*
- Shear failure mechanism of highway subgrade in seasonal frozen area during spring-thawing period 577  
*L. Zhou, E. Su, Y. Wei, C. Huang & Y. Xie*
- The study progress of performance reliability of rolling bearings for urban rail 583  
*X.T. Xia, S.J. Dong, W.H. Zhu & Y.Y. Meng*
- Aircraft taxiing trajectories partly update approach for A-SMGCS 587  
*X. Zhu, Z. Tang & Z. Xia*

Performance analysis of prestressed concrete T-beam structure after fire <i>Q.-f. Wang</i>	593
Cross tensioned and Reinforced Concrete composite pavements application in heavy traffic <i>C. Guo, M.-j. Zhang &amp; Z.-r. Lu</i>	597
Study on reinforcement effect of modified epoxy resins by repeated loading <i>L. Zhao &amp; D. Wei</i>	601
Safety evaluation of long and steep slope based on BP neural network <i>J. Zhang, J. Chen &amp; X. Li</i>	605
Safety audit of continuous downhill in Ma-Chao expressway <i>S.H. Chen, J.H. Liao &amp; X. Wang</i>	609
Reynolds-number effects on static force coefficients of $\Pi$ -shape bridge deck section with wind fairing <i>Q. Zhan, Z. Zhou &amp; Y. Ge</i>	613
Study on performance of cold recycling mixture with emulsified asphalt or foamed asphalt <i>M. Hao</i>	619
Analysis of safety criterion on track irregularities of heavy haul railway under 30t axle load <i>H.F. Zhang &amp; S.L. Lian</i>	623
Analysis of rail thermal effect due to wheel-rail rolling contact in heavy-haul railway <i>S.J. Gu, X.W. Yang &amp; S.L. Lian</i>	627
Research of computation methods on self-anchored cable-stayed suspension bridge <i>J.-l. Chai &amp; J. Shi</i>	633
<i>Hydraulic engineering</i>	
Analysis of the influence of Poyang Lake on convective systems and lightning transited <i>Y.H. Cao, X.F. Ye &amp; X.M. Liu</i>	639
Simulation and cause analysis of the piezometer tube abnormality in a dam <i>D. Li, T. Sheng &amp; D. Zhang</i>	643
Restoration of karst water system in Jinan, China <i>J. Zhou, L. Xing, S. Wang, H. Zhuang, T. Dou &amp; Z. Yang</i>	647
Stability analysis of the cracks of the concrete gravity dam due to the explosion damage <i>C.D. Liu, Z.J. Wang &amp; Y. Xiang</i>	653
Optimization of irrigation mode with brackish water for winter wheat in shallow groundwater areas based on the FEFLOW model <i>G.B. Pang, Z.H. Xu &amp; S. Zhang</i>	659
Seepage analysis of human earth-rock dam during a flood <i>C.D. Liu, J.Z. He &amp; Z.J. Wang</i>	665
Review and prospect of urban storm water simulation technology <i>Z.P. Chen, Y.F. Chen, S.H. Chen &amp; M.J. Chen</i>	671
Analysis on the right abutment stability of Gomal Zam Dam against sliding <i>X.E. Xu &amp; H. Y. Fang</i>	675
Study on optimum band combination of multi spectral vegetation information extraction in Taihu Basin <i>T.T. Cui, Y.Q. Long, Y.T. Wang, Q.F. Hu &amp; Y. Liu</i>	681
Agricultural water-saving zoning and suitable water-saving measures in the Yellow River Delta <i>G.B. Pang &amp; S. Zhang</i>	685
Study on the influence of the miter gate thrust on the lock head structure <i>W.C. Xu, Q.C. Ning, C. Li &amp; Y.Q. Shi</i>	691

Study on the prediction of flood disaster in Nanning City based on the gray neural network <i>R. Y. Ma, M. Lu &amp; S. Y. Wang</i>	697
Study on the hydraulic model test of diversion-type hydropower station <i>C. Qiu &amp; C. Liu</i>	701
Discussion on the development of remediation technology in Chinese metropolitan large mountainous river bank protection <i>W. Guo, J. Dai, Y. Zhou &amp; Y. Zeng</i>	707
In-situ measurement study on stress of frozen inclined shaft lining crossing water-rich sand stratum <i>J. Ren &amp; J. Sun</i>	713
Numerical study on effect of opening ratio for flow field of artificial reefs based on VOF model <i>R.J. Zhang, M. Tao, J.M. Zhou, X.Z. Huang &amp; P. Lian</i>	717
Quantities calculation of truncated cone-shaped metal structural steel funnel <i>N.-m. Mo &amp; L.-y. Wang</i>	721
Numerical research on the effect of the water level on the urban drainage network in Huinan, Pudong district <i>J. Huang, S.Z. Wang, S.Z. Deng &amp; X.B. Yang</i>	727
On inverse problems for a beam with added spring <i>X. Tian &amp; C.-x. Li</i>	731
Hydraulic characteristics of nature-friendly groynes in NanSi river <i>B. Qin, L.Q. Yang &amp; J. Ma</i>	735
Research on flood model of Nansi Lake <i>L.Q. Yang, B. Qin &amp; J. Ma</i>	739
Study on the comprehensive response to drought in China <i>B.S. Weng, D.H. Yan &amp; S.J. Bao</i>	743
Distributed hydrological and silty model in Chabagou basin of Yellow River based on DEM <i>H.J. Zhao, Y.D. Jin &amp; F.X. Chai</i>	747
Numerical simulation on the impact of oil spills on a fishing port <i>R.J. Zhang, J.M. Zhou &amp; X.Z. Huang</i>	753
Status review and prospect of the research into physical model of the impact force of ice on Yellow River-related buildings <i>G. Y. Wu, Y.F. Li &amp; C.P. Wu</i>	757
Characterization of urban rainwater quality for the reuse purpose <i>Z. Li, W. Chen, J. Li &amp; S. Yue</i>	761
Converse intruding by density current, case study in the Xiao Lang Di Reservoir <i>T. Li, J. Zhang, H. Ma &amp; Z. Ren</i>	765
Study on the drainage system of the tailing pond by numeric simulation and model test <i>Q.L. Qi, Q. Li, S.X. Zhang &amp; Z.L. Wang</i>	771
Analysis on optimizing preloading water head of water distribution ring pipe in hydropower station <i>B. Liu &amp; J.T. Lai</i>	777
Based on the grey GM (1,1) model to predict the total water consumption of Liaoning Province <i>J. Chen</i>	781
Analysis of research status of the effect of pollutant adsorption on the motion characteristics of sediment <i>Y. Ren, C. Zhu &amp; L. Zhao</i>	785
Discussion of the quality and safeguard measures of secondary water delivery <i>W. Zhang, Y. Deng &amp; A. Wang</i>	791
Model and application of pressure-dependent leakage detection in water distribution network <i>J.J. Wang, Z.Z. Tang, Y.W. Gui, W.Y. Wu &amp; M. Zhao</i>	795

Analysis on the status and measures of development and utilization of water resources in Lanling <i>X. Zhang, J.W. Huang, H.W. Chen, B. Li &amp; Z.H. Zhang</i>	803
Stochastic optimal operation and improved multi-objective particle swarm algorithm for water supply and environment <i>J. He, S.P. Gu &amp; W.X. Tan</i>	809
Influence of moisture gradient to concrete strength based on Weibull statistical model <i>D. Zheng, Q. Chen &amp; S.W. Chen</i>	813
<i>Disaster prevention and mitigation</i>	
The positioning performance comparison of BeiDou-2 second stage and GPS in some typical regions at home and abroad <i>H.-p. Li, H.-p. Cheng &amp; G.-l. Feng</i>	821
Analysis of roof water inrush risk and forecast of the outflow rate of 3229 working face in Tianzhu Coal Mine <i>H. Wang</i>	825
Prediction research on the hazardous extent of volcano secondary debris flow in Changbai Mountains based on simulation of FLOW3D <i>X. Tong, P. Xu, G. Li, M. Zhang, P. Li &amp; Z. Chen</i>	833
Research trend on the prediction of coal and gas outburst <i>X. Wu</i>	837
The research significance of the steel reinforced recycled aggregate concrete's fire resistance <i>B. Wang, X. Liu &amp; L. Gao</i>	841
Constitutive model derivation and numerical simulation of iron based Shape Memory Alloy pipe joint <i>W. Wang, B. Wang, J.Y. Liu &amp; H. Hai</i>	845
Evaluation on thermal stress distribution of a cable-stayed footbridge under temperature loading <i>X.F. Fan, B. Chen, Y.J. Jiang &amp; Y.Q. Xu</i>	849
Investigation on dynamic properties of a steel-concrete composite cable-stayed footbridge <i>X. Fei</i>	855
Wind-induced dynamic responses of a transmission tower with legs at different height <i>Y.J. Wu, B. Chen, X.X. Song &amp; X.F. Gong</i>	861
The interference effect on aerostatic coefficients of beam in parallel bridge <i>J. Wang &amp; J.X. Liu</i>	867
<i>Computer simulation and CAD/CAE</i>	
Study on the effect of batch piling of coal on silo wall <i>T.J. Tao, M.S. Zhao &amp; Q. Kang</i>	875
An algorithm for random cave geometry generation in Karst landform <i>X.-j. Cui &amp; C. Shi</i>	879
Research on the wind-induced vibration response of adhesive integral-lift scaffold <i>W. Pan, N. Kong, X. Ye &amp; G. Li</i>	887
Finite element analysis for a composite rib floor slab of steel fiber foam concrete <i>Y. Wang, G. Dou, C. Xi, L. Qian &amp; H. Liu</i>	893
Finite element analysis of steel reinforced recycled aggregate concrete axial compression short column <i>B. Wang, X. Liu &amp; L. Gao</i>	899
Research and development of visual monitoring system for prestressed steel structure <i>Z. Li</i>	903

Ballast particle model and initial packing numerical simulation <i>W.J. Shao &amp; S.L. Lian</i>	907
The comparison of integration methods in cellular material model <i>L. Hou &amp; Y.Q. Feng</i>	911
<i>Computational mechanics and construction technology</i>	
Radial temperature field simulation of overhead conductor <i>K. Xiao, P.Y. Li, L. Y. Mo, Z.W. Chen &amp; Q. Gu</i>	917
Analysis and optimization of the slab transition story support system <i>S. Y. Xu, S.H. Deng &amp; S.R. Zhu</i>	923
Research of roof waterproof technology of steel structure factory building <i>H. Chen, C.H. Wei &amp; H.L. Li</i>	927
Investigation of the effectiveness of vertical load on bending responses for a pile subjected to combined lateral and vertical loads <i>F. Mei &amp; G. Li</i>	931
Study of integral lifting spots of steel structure for steel truss structures <i>M. Chen &amp; Y.D. Chen</i>	937
Free vibration analysis on paraboloidal shells of revolution using the Wittrick-Williams algorithm with the consideration of shear deformation and rotary inertia <i>X.D. Chen</i>	943
R-Function Theory method for free vibration of slip clamped trapezoidal shallow spherical shell <i>S. Li &amp; H. Yuan</i>	947
Reducing blasting vibration technique of the hole-bottom air space charging <i>M.S. Zhao, Q. Kang &amp; T.J. Tao</i>	951

## Preface

This proceeding contains the accepted papers from The 2015 4th International Conference on Civil, Architectural and Hydraulic Engineering (ICCAHE2015). The first of this conference was held in Zhangjiajie, China on 10–12 August 2012, the second conference was held in Zhuhai, China on 27–28 July, 2013, and the third conference was held in Hangzhou, China on 30–31 July, 2014. Following the success of the previous conferences, The fourth of this conference series (ICCAHE 2015) was held in Guangzhou, China, on June 20–21 2015. This conference series is a forum for enhancing mutual understanding between scientists, engineers, policymakers and experts in the civil, architectural and hydraulic engineering field. This proceeding is enriched by contributions from many experts representing many industry and academic establishments worldwide. Authors from more than 20 different countries have pooled their rich multi-disciplinary up-to-date knowledge, in order to share their invaluable experience with the community. All papers published in this volume have been peer reviewed through processes administered by the proceedings editors. Reviews were conducted by expert referees to the professional and scientific standards.

We would like to express our deep gratitude to all the keynote speakers, authors, referees, exhibitors, technical co-sponsoring organizations, committee members, and many others on whom the success of this prestigious event depends.

The Organizing Committee of ICCAHE2015

# Self-vibration characteristics and influence factors analysis on the monopile foundation support structure of offshore wind turbine

X. Wang, Z.Y. Li & C. Chen

*State Key Laboratory of Hydrology-Water Resources and Hydraulic Engineering, Nanjing Hydraulic Research Institute, Nanjing, China*

**ABSTRACT:** Self-vibration characteristic and influence factors analysis on the monopile foundation support structure of offshore wind turbine was conducted for the structural dynamic design. The results indicated that the fundamental frequency of the towering support structure was 0.437 Hz. The fluid-solid coupling effect was very weak; that is, the self-vibration frequency decreased within 5% when the flow action was considered. The fundamental frequency was affected obviously with the turbine unit mass and the elastic modulus of the soil foundation, and it could be raised through reducing the unit mass. The actual elastic modulus should be employed for vibration analysis. A nonlinear positive relation was shown between the thickness of the support structure wall and the vibration fundamental frequency. The fundamental frequency increased quickly when the surface wall was relatively thin, whereas the increase speed became slow when the wall became thick. It was reasonable that the wall thickness was designed by 1% of the diameter of the monopile.

**Keywords:** offshore wind turbine; monopile; self-vibration characteristics; influence factor

## 1 INTRODUCTION

Due to environment pollution and energy crisis, the wind power as a kind of clean energy has developed swiftly in recent years. Wind energy on the sea was abundant and stable; therefore, offshore wind power has become the investment focus at home and abroad. Europe is leading in the world, and China is still in its beginning stage. The “12th Five-year Plan” of China shows that the offshore wind power capacity would be up to 5 million kilowatt, which indicated that the offshore wind power in China is going to a rapid development period. At present, the planning and development of wind power at sea in China is mainly centered around offshore. The typical monopile foundation widely used at abroad is suitable for the offshore wind power of China, which has adopted in the offshore wind power design, for example the Xiangshui intertidal area wind farm in Jiangsu Province and the Wailuo offshore wind farm in Guangdong Province. The monopile foundation would become a popular type in the offshore wind power in China.

However, the towering structure formed by wind turbine, pylon and foundation pile suffered the impact of the wave and tide flow that did not exist for onshore wind. Meanwhile, there was a complicated coupling effect between the

wave flow and the supporting structure. With the increase in the single unit capacity and weight, the vibration safety of the supporting system has become more outstanding. It is known from the structure dynamic mechanics that the dynamic emphasize coefficient would be up to the maximum value when the self-vibration frequency of the structure is close to the main frequency of the load. So, the self-vibration frequency should be kept away from the main frequency of the load and the deviation should be more than 20%. As the inner reason of vibration, the structure self-vibration characteristics determined the vibration response, and still provided reference for resonance check and structural dynamic design optimization. Therefore, self-vibration characteristics and influence factors analysis such as fluid-solid coupling, unit weight, soil foundation elastic modulus, and structure dimension on the monopile foundation support structure of offshore wind turbine were conducted.

## 2 STUDY METHOD

When the hydraulic structure vibrates, the adjacent fluid inertial force, damping force and elastic force corresponding with the vibration acceleration, velocity and displacement would apply on

the structure, which would change the mass, damping and stiffness of the vibration system and then the vibration characteristic of the structure would be changed. It is shown that the self-vibration frequency of the hydraulic structure would usually decrease by about 20%~30% when the fluid-structure coupling effect is considered. For the steel gate with thin walls, the basic frequency would decrease up to 50%. Therefore, the influence of the fluid on the structure's self-vibration characteristics could not be neglected.

At present, the additional mass method was used to describe the interaction between the fluid and the solid. The most common additional mass method was based on the Laplace equation that is met by the dynamic water pressure. The additional mass matrix was derived for the dynamic equation of the finite element method. That is, the form of the dynamic equation did not vary but added an additional mass matrix based on the mass matrix. Then, the FEM dynamic equation considering the additional mass would become as follows:

$$[K]\{\delta\} + [C]\{\dot{\delta}\} + ([M] + [M_p])\{\ddot{\delta}\} = \{R_0\} \quad (1)$$

where  $[M_p]$  is the additional mass matrix and  $\{R_0\}$  is the load vector. Damping had a little effect on the self-vibration frequency and vibration modes. As a result, the damping of the structure was ignored in the analysis.

### 3 FEM MODEL

Monopile support structure used for offshore wind power was taken for example. A three-dimensional FEM model was built, which consisted of the monopile, the foundation and the flow. The monopile was dispersed by the Shell element with six degrees of freedom and four nodes, the foundation and water were dispersed by the Hexahedral element. The whole model was divided into 17164 nodes and 14460 elements, as shown in [Figure 1](#).

Materials included the support structure, foundation and water, in which the structure and the foundation were regarded as the linear elastic material, and the water was considered as the potential flow to calculate the additional mass. These material parameters are listed in [Table 1](#).

In order to avoid the effect on the modes from the limited range foundation, the stiffness of the foundation without mass was only considered. The wind turbine was not built in the whole model and the unit mass would add to the top of the tower tube. To study the effect factor on the modes of the support structure, some conditions are listed in [Table 2](#), among which, the first was the basic condition.

Figure 1. The FEM grid.

Table 1. Material parameters.

Material	Density ( $\text{kg} \cdot \text{m}^{-3}$ )	Elastic modulus (Pa)	Poisson ratio
Support structure	7850	2.00E+11	0.3
Foundation	0	2.00E+08	0.2
Water	1000	2.56E+09	

Table 2. Calculation conditions.

Condition number	Foundation	Water	Unit mass	Support structure
1	√	√	√	√
2	√		√	√
3	√			√
4	Different elastic modulus		√	√
5	√		√	Different wall thickness

### 4 SELF-VIBRATION CHARACTERISTICS

The first five phases of self-vibration characteristics parameters of the support structure under the basic condition are listed in [Table 3](#), and the first three phases of vibration types are shown in [Figure 2](#). It could be found that the fundamental frequency of the foundation-water-support structure system was 0.437 Hz, which is relatively low due to its towering characteristics. The mode indicated the first phase bend vibration. The second-phase frequency was 2.243 Hz and showed the second-phase bend vibration. The third-phase frequency was 5.482 Hz and showed the third bend vibration. The high-phase modes expressed the local weak component

Table 3. Self-vibration characteristics of the parameters.

Phase number	Frequency/Hz	Mode participation parameters		
		X	Y	Z
1	0.437	-5.89E-03	-6.43E+02	2.91E-11
2	2.243	8.50E-05	4.97E+02	5.21E-10
3	5.482	1.91E-04	3.84E+02	7.53E-09
4	8.911	-4.55E-08	1.46E-07	9.65E+02
5	9.050	1.43E-08	1.92E-08	4.80E-02

Figure 2. The first three-phase vibration modes.

vibration, which would provide little contribution to the support structure vibration.

## 5 INFLUENCE FACTORS ANALYSIS

### 5.1 FSI influence

For the second condition, the water elements were removed from the whole model; that is, the water additional mass was not considered. Table 4 presents the comparison of the self-vibration frequency of the two conditions. It could be found that the self-vibration frequency altered little, and the first five modes were consistent whether the water additional mass was considered. The self-vibration frequency decreased only about 5%, considering the FSI influence. This was mainly because the water force range was relatively little compared with the whole towering support structure, and the force position was still near the bottom of the monopile.

### 5.2 Unit mass influence

With the increase in the unit power of the offshore wind turbine, the blade dimension and the unit mass greatly increased. For the towering, long and thin support structures, the huge mass on the top would affect the self-vibration characteristics and dynamic responses.

The unit was simplified as a concentrate mass on the top of the tower. The first five self-vibration

Table 4. Self-vibration frequency comparison whether the water was considered.

Phase number	Frequency/Hz		Decrease/%
	Without water	With water	
1	0.441	0.437	0.90
2	2.295	2.243	2.24
3	5.754	5.482	4.73
4	9.231	8.911	3.47
5	9.280	9.050	2.48

Table 5. Self-vibration frequency comparison whether the unit mass was considered.

Phase number	Frequency/Hz		Decrease/%
	Without unit mass	With unit mass	
1	0.666	0.441	33.8
2	2.859	2.295	19.7
3	6.804	5.754	15.4
4	10.689	9.231	13.6
5	11.020	9.280	15.8

frequencies of the support structure whether the unit mass was considered are listed in Table 5. It could be found that the fundamental frequency decreased by 33.8% when the unit mass was taken into account, but the first five modes were still consistent. Therefore, the unit mass should not be neglected in the dynamic characteristic analysis. It still indicated that the fundamental frequency could be raised by reducing the unit mass pursue to the technology progress.

### 5.3 Foundation elastic modulus influence

As the monopile connected with the soil foundation, the foundation elastic modulus would influence the whole stiffness of the support structure and then affect the structure's self-vibration characteristics. In order to study the influence of the foundation elastic modulus, several different foundation elastic moduli were adopted to analyze the self-vibration frequency of the support structure. Figure 3 shows the nonlinear relation between the fundamental frequency and the elastic modulus. It could be found that the frequency decreased with the decreasing elastic modulus. When the foundation elastic modulus was low, the self-vibration frequency altered obviously, while with the increase in the modulus, the self-vibration frequency increase became slow. For example, the fundamental

Figure 3. The influence of the foundation elastic modulus.

frequency increased by 14.3% when the elastic modulus increased from  $1e7$  Pa to  $1e8$  Pa, while that increased by 2.4% when the elastic modulus increased from  $1e8$  Pa to  $2e8$  Pa. Therefore, due to the low fundamental frequency of the support structure and the great influence of the foundation elastic modulus, the actual foundation parameter obtained from geological data should be adopted to calculate the self-vibration characteristics of the support structure to ensure the dependability of the result.

#### 5.4 Influence of the monopile wall thickness

The towering structure with a thin wall was mainly comprised of monopile and tower tube, and the wall thickness was designed by about 1% of the monopile diameter at present. With the increase in the unit capacity and mass, blade dimension and mass, the monopile diameter also increased. The support structure was simple and the wall thickness maybe was one of the important influencing factors when the shape dimension was determined. In this paper, the actual project Wailuo offshore wind farm in China was taken as an example. The outer diameter of the monopile was 5.5 m, and the wall thickness was 0.064 m. Several other wall thicknesses were selected to study the influence on the self-vibration frequency and the first three mode frequencies are listed in Table 6. It could be found that the frequency increased with the increase in the wall thickness, but the whole change was very little. Figure 4 shows the nonlinear relationship between the fundamental frequency and the wall thickness. The fundamental frequency increased slowly when the wall thickness increased, simply because the mass of the structure was still increasing. Therefore, for the support structural dynamic design, some structure optimization, such as changing the wall thickness or strength of the wall surface, could change the structure's self-vibration characteristics to avoid resonance.

Table 6. Relationship between the wall thickness and the self-vibration frequency.

Wall thickness/m	Frequency/Hz		
	First phase	Second phase	Third phase
0.03	0.346	2.185	4.574
0.04	0.382	2.208	5.341
0.05	0.408	2.225	5.432
0.064	0.437	2.243	5.482
0.10	0.482	2.274	5.533
0.15	0.514	2.295	5.554

Figure 4. Wall thickness influence on the fundamental frequency.

From the relationship curve, it was reasonable that the wall thickness of the monopile was designed by about 1% of the pile diameter.

## 6 CONCLUSIONS

Self-vibration characteristics and influencing factors of the monopile support structure of offshore wind power were studied to guide the structural dynamic design. Based on the above results, some conclusions were obtained:

1. The fundamental frequency of the towering support structure of the wind turbine was 0.437 Hz. The FSI influence was weak and the self-vibration frequency decreased below 5% when the water additional mass was considered.
2. The frequency was affected obviously by the unit mass and the foundation elastic modulus. The fundamental frequency could be raised by reducing the unit mass, and the actual foundation parameter should be adopted for analysis to ensure the dependability of the result.
3. With the increase in the monopile wall thickness, the fundamental frequency was increased

with a nonlinear relationship. It was reasonable that the wall thickness of the monopile was designed by about 1% of the pile diameter.

**ABSTRACT:** Cyclic loading tests of two precast segmental columns and one monolithic bridge column with a circular section were conducted. Then, a single plastic hinge analytical pushover method for precast segmental bridge columns was presented based on the moment-curvature analyses of critical joints. Energy Dissipation (ED) bar unbonded length and elongation of unbonded prestressing tendon were considered in the method. The P-delta effect was included through iteration after the moment-curvature analyses. The analytical pushover method was validated through comparison with static cyclic loading test results. Parametric analyses were conducted afterwards. The influence of the variation of aspect ratio, axial load of gravity and prestressing, and ED bar ratio on the responses of lateral force-drift, joint opening and tendon stress was investigated.

**Keywords:** segmental column; energy dissipation; pushover analyses; parametric analyses; joint opening

## 1 INTRODUCTION

The Cast-in-Place (CIP) construction of bridge engineering is matured technology nowadays. However, the construction usually causes severe destruction of the natural environment due to the massive labors and equipment needed (Ou et al. 2010). CIP construction also leads to traffic jam and detour to local transportation systems. Accelerated Bridge Construction (ABC) is a strategy plan to address these issues by segmented bridge superstructure and substructure construction technologies developed in recent years (ABC-AC 2008). Among these technologies, the precast columns design was given more attention for its important roles in the seismic-resistant design of bridges.

Previous researchers have conducted analytical pushover analyses with the assumption that the column has a certain plastic hinge length at critical joints (Hewes & Priestley 2002, Chou & Chen 2006, Palermo et al. 2007). This method was also called the beam analogy method. Ou et al. based on this method raised a joint bar-slip rotation method to consider the concentration of inelastic rotation effects (Ou et al. 2010). However, in this method, the axial load was assumed to be constant, which has a conflict with the actual condition.

Bu and Ou suggested a revised analytical pushover method based on the beam analogy method (Bu & Ou 2013).

In this paper, first, the method of literature (Bu & Ou 2013) was introduced and used to analyze the cyclic reversal static test of two Precast Segmental Bridge Columns (PSBC) with a circular section to validate the method. Then, parametric analyses were carried out to study the performance of PSBC with various design parameters of aspect ratio, axial load (tendon ratio and dead load ratio), and Energy Dissipation (ED) bar ratio.

## 2 SINGLE PLASTIC HINGE ANALYTICAL ANALYSES

Through the observations of cyclic loading test results, if the reinforcements are the same for all segment joints, normally one plastic hinge will be formed at the column base. Moment-curvature analyses were conducted first to derive the relation between the exerted lateral force and deformation at the critical section. As the tendons are unbonded with sectional concrete, the consistency conditions between the reinforcement and the concrete no longer exist. An iteration procedure was

required to get a force-balanced state. Then, the lateral force-displacement relation was deduced considering the P-delta effects.

### 2.1 Material models

Concrete was modeled with the Kent-Scott-Park model (Scott et al. 1982), which was composed of the parabolic ascending part, the linear descending part and the horizontal part. ED bars were modeled with an ideal elastic-plastic model with both the post-yielding plateau part and the ascending part. Prestressing tendons were modeled with an ideal elastic-plastic model with the post-yielding ascending part only.

### 2.2 Moment curvature analyses

The moment curvature analyses procedure at critical joints can be summarized in six steps:

1. Increase the curvature from zero to a large value with appropriate intervals.  $\phi_t = \phi_e + \phi_p$ , where  $\phi_t$  is the total curvature;  $\phi_e$  is the elastic curvature; and  $\phi_p$  is the inelastic curvature.
2. Assume the compressive depth  $c$  and calculate the concrete compressive strain at an extreme fiber  $\epsilon_c = \phi_p \cdot c$ .
3. Calculate the joint inelastic rotation  $\theta_p = l_p \cdot \phi_p$ , where  $l_p$  is the plastic hinge length.
4. Calculate the elongation or shortening of the ED bar and tendon, and then calculate the corresponding strain (stress) and the force of the ED bar and tendon.
5. Calculate the resultant force of compressive concrete with the strip method and the integration of stress, check the sectional force equilibrium, if not fulfill then to go to step (2), and change the compressive depth  $c$ .
6. Calculate the sectional moment resistant capacity.

### 2.3 Lateral force-displacement response

The moment in preceding section step (6) equals the sum of the lateral force multiplying the column height and the axial force multiplying the lateral displacement. In stage one, the joint is not decompressed. The column has only elastic deformation. In stage two, joint opens, and the column has both elastic deformation and inelastic deformation. Elastic deformation (curvature and lateral displacement) is in proportion to the applied lateral force. The inelastic deformation can be calculated by multiplying the inelastic curvature by the plastic hinge length  $l_p$  and the column height  $H$ . The lateral force can be updated with the axial force and the lateral displacement to account for the P-delta effect.

### 2.4 Failure criteria

The column is considered to be damaged if the concrete crushes, or the ED bar and/or tendon fractures, or the lateral strength capacity decreases to 80% of the peak value.

## 3 VALIDATION OF THE TEST RESULTS

Three specimens were designed and tested under cyclic reversal static loading. The first specimen MRC was the monolithic column. This specimen was designed as the reference CIP column.

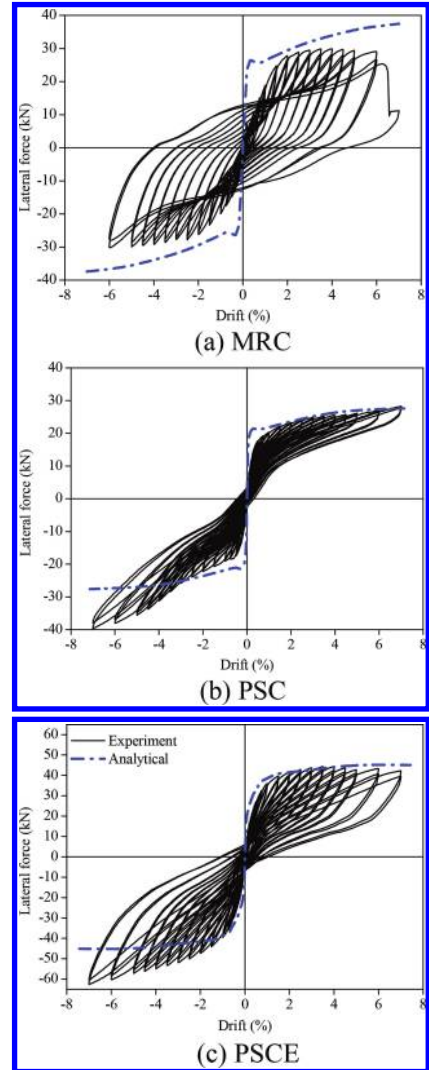

Figure 1. Comparison of lateral force-displacement responses of the specimens.

The second specimen PSC and the third specimen PSCE were segmental columns with four 400 mm-depth segments. The column height measured from the column base to the center of the loading block was 1850 mm for all the three specimens. The section of all the specimens had a diameter of 350 mm. The longitudinal reinforcement of MRC was 10 D12 mm mild steel bars. The longitudinal reinforcement of PSC was 3 D12.7 mm tendon. The specimen PSCE used 3 D12.7 mm tendons plus 6 D12 mild steel bars as ED bars. The latter two specimens had an effective tendon stress of 780 MPa.

Figure 1 shows the lateral force-displacement responses of specimen test results and analytical pushover results. The test results were not symmetric in positive and negative loading directions because of the tendon eccentric at top of the column relative to the base section center.

The analytical result was in good accordance with the tested data. So, the analytical model can be used to study the response of PSBC under the lateral force loading.

#### 4 PARAMETRIC ANALYSES

Three main parameter variations were considered in parametric analyses, i.e. the ED bar ratio, the aspect ratio, and the axial force ratio. The axial force was composed of the superstructure dead load and the tendon force. The ED bar ratio had five cases, with a diameter of 0 mm, 8 mm, 12 mm, 16 mm, and 20 mm, thus taking the value of 0.00%, 0.31%, 0.70%, 1.25%, and 1.96%, respectively. The column height took the value of 875 mm, 1850 mm, and 2625 mm, and the corresponding aspect ratio (A) was  $A = 2.5$ ,  $A = 5.29$ , and  $A = 7.5$ , respectively.

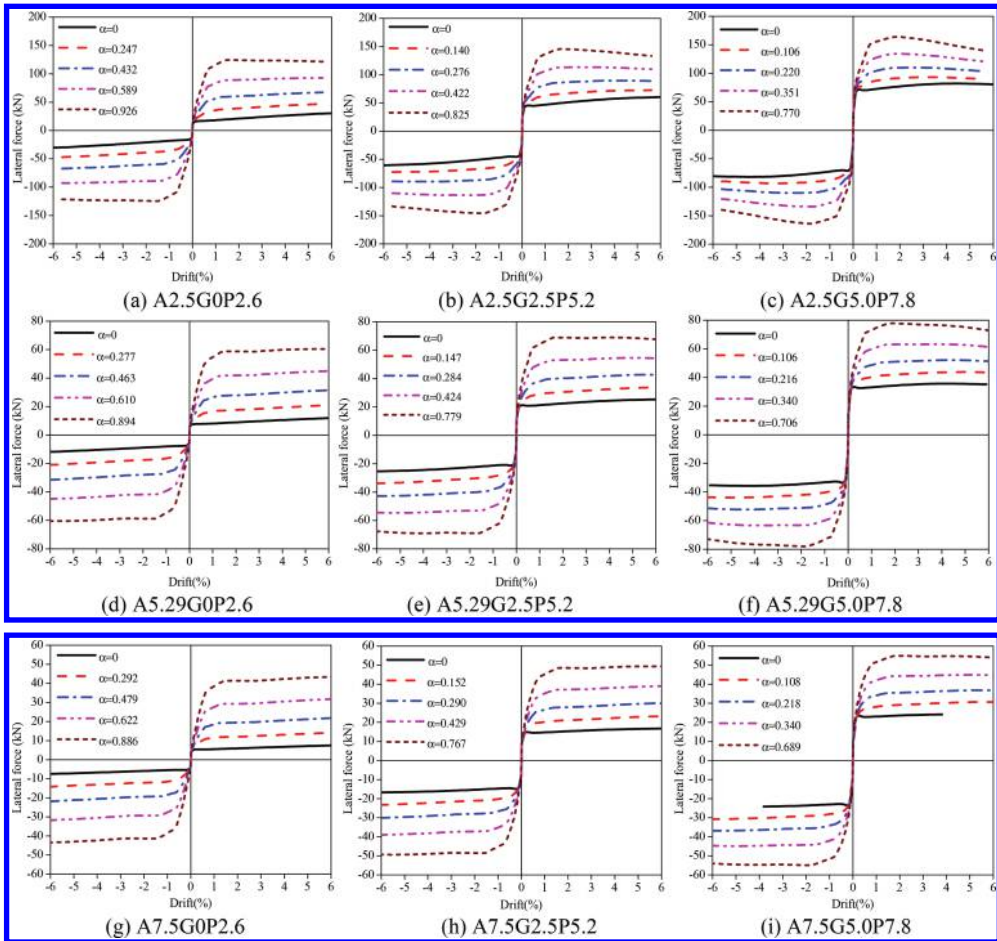

Figure 2. Pushover analyses of 45 column cases.

The axial load had three cases: 77 kN (tendon force only,  $G = 0$ ,  $P = 2.6$ ), 228.1 kN (74.1 kN dead load and 154.0 kN tendon force,  $G = 2.5$ ,  $P = 5.2$ ), and 379.3 kN (148.3 kN dead load and 231.0 kN tendon force,  $G = 5.0$ ,  $P = 7.8$ ), where  $G$  is the ratio of gravity axial load to sectional concrete compressive capacity and  $P$  is the ratio of prestressing axial load to sectional concrete compressive capacity. A total of forty-five cases of columns were calculated in parametric analyses. A parameter represents the ED bar moment contribution defines as  $\alpha = M_s/M_t$ , where  $M_s$  is the moment contribution of the ED bar in tension to the center of the compressive ED bar, and  $M_t$  is the total moment to the center of the compressive ED bar.

Figure 2 shows the parametric analysis results of lateral force-drift responses. The moment contributions of the ED bar corresponding to the ED bar ratios of 0.00%, 0.31%, 0.70%, 1.25%, and 1.96% are also shown in Figure 2. The following points can be derived from the parametric analyses: (1) with the increasing ED bar ratio, the column lateral strength increases; (2) with the increasing axial load, the column lateral strength increases;

(3) with the increasing aspect ratio, the column lateral strength decreases; (4) with the increasing aspect ratio, the moment contribution of the ED bar normally increases, except the G5.0P7.8 cases and the ED bar ratio 1.96% of the G2.5P5.2 cases; and (5) with the increasing axial load, the moment contribution of the ED bar decreases.

Figure 3 shows the base joint opening at a 3% drift in the 45 cases considered in the parametric analyses: (1) with the increasing ED bar ratio, the joint opening decreases; (2) with the increasing axial load, the joint opening decreases; and (3) with the increasing aspect ratio, the joint opening increases.

Figure 4 shows the tendon stress variation with drift for different design parameters of the column: (1) with the increasing ED bar ratio, the tendon stress decreases; (2) with the increasing aspect ratio, the tendon stress decreases and (3) with the increasing axial load, the tendon stress decreases.

## 5 CONCLUSIONS

A simplified pushover analytical method for precast segmental bridge columns was introduced. The analytical model was based on the moment-curvature analysis of the critical joint. The unbonded length and unbonded tendon stress variations of the ED bar were included in the procedure. The method was first validated through comparison with three tested column results. Then, the proposed method was used for parametric analyses. In the parametric analyses, the variation of the aspect ratio, axial load (superstructure gravity load and prestressing tendon force), and ED bar ratio was considered. The following conclusions can be reached on the basis of the investigations undertaken in this paper:

1. The proposed analytical pushover method was capable of predicting the PSBC lateral force-drift response with an acceptable precision.

Figure 3. Base joint opening at the 3% drift.

Figure 4. Tendon stress.

2. The column lateral strength increases with the increasing ED bar ratio and/or axial load, and the column lateral strength decreases with the increasing aspect ratio. The moment contribution of the ED bar decreases with the increasing axial load.
3. The joint opening decreases with the increasing ED bar ratio and/or axial load, and increases with the increasing aspect ratio.
4. The tendon stress decreases with the increasing ED bar ratio, the increasing aspect ratio, and/or the increasing axial load.

# Establishment and seismic performance analysis of AFRP-reinforced concrete frame structure finite element model

G. Zhao & X.S. Xu

*University of Jinan, Jinan, Shandong, China*

**ABSTRACT:** On the basis of the structure test model, AFRP-reinforced concrete frame structural nonlinear finite element model was established. Under repeated load of AFRP-reinforced concrete frame, the simulation analysis of mechanical performance has been carried out, which compared with the test skeleton curve showed that the fitting effect is good; the stress distribution of the AFRP bar is consistent with the experiment. On the basis of these results, and the analysis of hysteretic curve and skeleton curve, ductility, rigidity degeneration, and energy dissipation capacity performance such as seismic performance characteristics of the model, a comprehensive understanding on the seismic performance of the AFRP-reinforced concrete frame is built, providing reference for the design of a FRP-reinforced concrete structure.

**Keywords:** AFRP-reinforced concrete frame; finite element analysis; ABAQUS; seismic performance

## 1 INTRODUCTION

FRP bar is a brittle material, with no yielding phenomenon. Before reaching ultimate strength, the stress-strain relationship is a linear relationship, and tensile strength is significantly higher than ordinary steel, but the compressive strength and modulus of elasticity is relatively small. These characteristics of the FRP bar determine the FRP-reinforced concrete structure in elastic-plastic deformation characteristics, which are also much different compared with the ordinary reinforced concrete structure, which does not conform to the modern seismic design based on the requirement of ductility performance; thus, we should strengthen the test and theoretical research of this aspect.

In recent years, although the research on the FRP bar concrete structure at home and abroad has been the focus in engineering practice, the United States, Japan, Canada and other developed countries successively formulated a series of design standards, construction procedures and application guidelines, but research results are mainly concentrated on bearing performance, durability, and fire prevention performance, such as the basic performance of FRP-reinforced concrete member. The study of the overall seismic performance of FRP-reinforced concrete structure is poor, restricting the development of the FRP-reinforced concrete structure. Therefore, according to the characteristics of FRP bar learning performance, on the basis of bearing performance of FRP-reinforced con-

crete member, we perform further research on the seismic performance of framework, with an overview of the elastic-plastic deformation characteristics of framework, for the FRP-reinforced concrete structure in the promotion and application in the field of civil engineering in China, which has an important scientific significance.

In this paper, with reference to Fukuyama and other researchers who designed a three-layer AFRP-reinforced concrete frame structure specimen (Fukuyama, 1995), using the finite element software ABAQUS, a nonlinear finite element model of AFRP-reinforced concrete frame is established, under repeated load of AFRP-reinforced concrete frame of the simulation analysis of mechanical performance, through the comparative analysis with the test results, verifying the effectiveness of the model. Then, through the analysis of hysteretic curve and skeleton curve, ductility, rigidity degeneration, energy dissipation capacity performance such as seismic performance indicators of the model, a comprehensive understanding of the seismic performance of the AFRP-reinforced concrete frame is built.

## 2 AFRP-REINFORCED CONCRETE FRAME FINITE ELEMENT MODEL

### 2.1 *Source of the model*

Bond performance of the FRP bar and concrete is similar to that of concrete and steel, which is good

and the material performance is certain, and the ordinary design method can be used for designing. In this paper, the analysis model is derived from the AFRP-reinforced concrete frame structure test model of Fukuyama et al. The test model is a three layer of pure frame structure buildings. The building height is 3.6 m. There are two spans across the X axis, with the span of 7 m, and the Y axis direction has three spans, with the span of 5.5 m. AFRP bar is used to bear steel bar and stirrup in beam, plate, column, such as the concrete members, for the C30 strength grade concrete design. The finite element model is a reference to try to design buildings of one framework for the model design of the X direction.

## 2.2 Constitutive relation of the material

### 2.2.1 Constitutive relation model of the AFRP bar

Reference to FRP bar mechanics performance test was made by previous researchers (Xu, 2008). From the beginning loading to the fracture failure of the entire process, the FRP bar is linear elastic, almost producing no plastic deformation, and no obvious yield point and yield stage, so the AFRP bar stress-strain relationship is given in Equation (1):

$$\sigma_f = E_f \varepsilon_f \quad (0 \leq \varepsilon_f \leq \varepsilon_u) \quad (1)$$

where  $\sigma_f$ ,  $\varepsilon_f$ ,  $E_f$  and  $\varepsilon_u$  represent the stress, strain, elastic modulus and ultimate tensile strain of AFRP, respectively.

FRP bar has no yield point and yield stage such as reinforced concrete (Jin, 2006), bonding strength and ductility. FRP bar in the name of the yield point is as follows:

$$\sigma_{f\lambda} = \lambda_f \sigma_{fu} \quad (2)$$

where  $\sigma_{f\lambda}$  is the yield stress in the name of FRP bar;  $\lambda_f$  is the strength reduction factor of the FRP bar, which generally takes the value of 0.75; and  $\sigma_{fu}$  is the ultimate tensile strength of the FRP bar.

### 2.2.2 Constitutive relation model of concrete

In order to easily simulate the mechanical properties of concrete material, ABAQUS comes with diffuse crack, damage in the plastic and brittle fracture of three different concrete constitutive relation models (Nie, 2013; Zhang, 2011). In this paper, the concrete damage in the plastic model is used to simulate the mechanical performance of concrete.

## 2.3 The choice of the finite element model

For the analysis of reinforced concrete structure with finite element analysis software, usually three

Figure 1. Loading system.

kinds of model are used: separate, modular, and integrated (Jiang, 1994). The numerical simulation is used to study, respectively, the stress state in the FRP bar and concrete materials, so the simulation should adopt a separate modeling method to establish the model.

## 2.4 The boundary conditions and load

### 2.4.1 The boundary conditions

FRP-reinforced concrete frame specimen and base were poured integrally; therefore, a layer of the bottom of the column location can be considered as consolidation, and so need to be fixed constraints imposed on the bottom section of the column, with all displacements of the column root cross-section being limited.

### 2.4.2 The load

To better simulate the force bearing status of FRP-reinforced concrete frame under low reversed cyclic loading, we get more complete hysteresis curves, on the basis of the original test loading system, and increase the load series and cycles. A new loading system is shown in Figure 1.

## 3 THE RESULTS OF NUMERICAL SIMULATION

### 3.1 Load-displacement hysteretic curve

According to the simulation results of statistics, we draw the simulated load-displacement curves of specimens, as shown in Figure 2a. When comparing the curves with the hysteretic curve of the test of AFRP-reinforced concrete frame structure, the simulation results show a knead gathering effect, which is not obvious, and plastic deformation is larger. The main reason is that the FRP bar is embedded into concrete when establishing the finite element model. Therefore, the software could not take bond slip into consideration between them while calculating, which led to the part deformation that cannot be recovered.

Figure 2a. Results of the simulation.

Figure 2b. Results of the test.

### 3.2 Skeleton curve

According to the numerical simulation of the load-displacement hysteretic curve, we draw a skeleton load-displacement curve and compare with the load-displacement skeleton curves gained by the analysis of the test results, as shown in Figure 3.

Figure 4 shows that two skeleton curves fit better and have the same tendency. Ultimate bearing capacity of the specimen reaches up to 340.4 KN when the FRP bar is cracked, and the load value of the model is 373.97 KN when the FRP bar approaches the ultimate stress, with a difference of 9.8%. As a whole, for each load peak, the simulated load value is greater than the test load value, with the difference being within 20%. The main reason for the simulation results being greater than the test results is that the numerical simulation belongs to the ideal load, so the model does not have the initial defects, and in software simulation, the concrete is assumed to be an isotropic homogeneous material while it is not the case in the actual situation.

### 3.3 The stress

Figure 4 shows the stress distribution of the FRP bar under a certain load and displacement. From

Figure 3. Comparison chart of the skeleton curve.

Figure 4. Stress diagram of the FRP bar.

the figure, we can see that the stress of the FRP bar has a linear distribution along the direction of the beam body, which is consistent with the results obtained in the experiment. In addition, because of the low compressive strength of the FRP bar, when modeling, the compression of the FRP bar is not considered. So, the stress of the compression the FRP bar is free.

## 4 SEISMIC PERFORMANCE ANALYSIS OF AFRP-REINFORCED CONCRETE FRAME STRUCTURE

### 4.1 Skeleton curve analysis

Through the analysis of the skeleton curve, the elastic-plastic dynamic characteristics of the structure can be studied. The load-displacement skeleton curve of the AFRP-reinforced concrete frame structure does not have a standard antisymmetric shape, as shown in Figure 4, where the reverse loading point load value is greater than the positive load point load values. In addition, the limit displacement of the skeleton curve of the model is larger. Because the lateral displacement size has a great influence on the normal use of the structure, in the design of the FRP-reinforced concrete frame structure, controlling

the structure's lateral displacement or displacement between layers appear to be more important.

#### 4.2 Ductility performance analysis

Ductility is used to measure the deformation of structure, which is an important parameter. In seismic fortification for structural design, some necessary calculation method and design principles are usually considered, to guarantee the ductility of the structure and the component, and the structure design to be more economic and reasonable.

Usually, the ductility of the frame structure can be evaluated by the ductility coefficient: the greater the ductility coefficient, the more better the structure ductility; conversely, structural ductility is worse. Ductility coefficient basically has the displacement ductility coefficient and the curvature ductility coefficient. This paper uses the displacement ductility coefficient  $\mu$  to evaluate the ductility performance of the FRP-reinforced concrete frame structure model, where  $\mu$  can be calculated by using Equation (3):

$$\mu = \frac{\Delta_u}{\Delta_y} \quad (3)$$

where  $\Delta_u$  is the limit displacement and  $\Delta_y$  is the yield displacement.

According to Formula (3), the ductility coefficient of the AFRP-reinforced concrete frame structural model is 5.03, which is relatively small and indicates the poor ductility of the structure.

#### 4.3 Stiffness degradation analysis

Stiffness refers to the structure's ability to resist deformation. Stiffness degradation refers to the structure under the repeated load. The phenomenon of stiffness gradually reduces due to concrete crack and crack development. Stiffness degradation is a major factor of structure seismic performance degradation, so study stiffness degradation situation of the structural analyzes the stiffness degradation rule, which is very necessary.

The stiffness degradation curves of the AFRP-reinforced concrete frame model, as shown in Figure 5, indicate that the load of the displacement is small, the stiffness is larger, stiffness degradation with the increase in load, and the early stage of the stiffness degradation is rapid, and the latter due to the concrete damage tends to be stable and stiffness degradation of the model is slow.

#### 4.4 Energy dissipation analysis

The stand or fall of dissipating energy performance is an important basis of the seismic performance

Figure 5. Stiffness degradation curve of the AFRP-reinforcement concrete frame model.

evaluation of the structure. Viscous damping coefficient can be used to estimate the energy dissipation capacity of the structure, with the equivalent viscous damping coefficient of the AFRP reinforced concrete frame model being 0.369, which explains that the energy dissipation capacity of the AFRP-reinforced concrete frame structure is poor.

## 5 CONCLUSIONS

Through the above analysis, the skeleton curve simulated by the software and test curve fitting effect is shown to be good, and the FRP bar stress distribution is consistent with the experimental measurement results. So, in this paper, we can assume that the mathematical model of the AFRP-reinforced concrete frame is effective and feasible, and the finite element model can be used for seismic performance analysis. By analyzing the hysteretic curve and skeleton curve, ductility, rigidity degeneration, energy dissipation capacity performance such as seismic performance characteristics of the model, we find that the seismic performance of the AFRP-reinforced concrete frame structure has a large difference compared with the reinforced concrete frame structure, so measures must be taken to improve the ductility performance of the AFRP-reinforced concrete frame structure, to enhance AFRP-reinforced concrete structure seismic performance, to expand the FRP-reinforced concrete structure in practical engineering application.

## Micro damage in the structural deformation verification under expected rare earthquake

X.M. Chen, J. Duan, H. Qi & Y.G. Li

*China State Construction Technical Center, Beijing, China*

**ABSTRACT:** In the structural deformation verification under expected rare earthquake, the macro results such as displacement angle and base shear force usually are taken as the criterion for collapse, but sometimes, these horizontal responses cannot embody the probability of vertical collapse exactly. The relative reasons have been researched by numerical method in this paper including the improper constitutive model of material and discrete model of element. For these reasons, the micro damage of member sections must be used together with the macro results as displacement angle to verify the structural property under expected rare earthquake.

**Keywords:** displacement angle; damage; elastic-plastic; time-history analysis

### 1 INTRODUCTION

The design for high buildings may contain two main steps, the first step is the section design for small earthquake or fortification intensity, and the second step is the deformation verification for expected rare earthquake. For the first step, elastic methods such as spectrum analysis are widely used for the structural maximum response, and then probabilistic limit state design method will be used for the section verification and reinforcement. For the second step, usually only the deformation verification has to be done to ensure the structural performance under the expected rare earthquake through the performance point formulated via static PUSH or the envelope of displacement angle via nonlinear dynamic time-history analysis. Compared with the static analysis PUSH, the dynamic time-history method can be used widely for more complex structures without the limitation of first-order mode being dominant.

To ensure the structures without crash under expected rare earthquakes, the limitations of displacement angle are regulated by many national codes, for example, in the ‘Chinese Code for Seismic Design of Buildings’ (2010a), the maximum displacement angle is 1/100 for both shear wall structures and frame-core-tube structures, and the maximum displacement angle is 1/50 for frameworks. Except the displacement angle, several other results are usually taken as the auxiliary tools for assessment or optimization of the structural scheme but not being taken as the main basis for structural crash, such as shear forces at the base,

shear force ratios and turn-over moment ratios carried by frames and shear walls respectively of each floor, damage of those most important members, and so on. This principle doesn’t mean that the structural crash has no direct relationship with the damage of members, in fact, serious damage of some crucial members may lead to instantaneous unloading, and then induce an impact load on the other members which may make the whole structure collapse.

Although the national code (2010b) has concerned the analysis of progressive collapse, but different with the deformation verification of expected rare earthquake by nonlinear time-history method, the analysis of progressive collapse induced by earthquake or other occasionally loads usually is regarded as a different mechanical problem. That is because much more complex nonlinear problem should be considered in the progressive collapse analysis, such as impact and contact. Therefore, this classification is based on the complexity, and there are no essential mechanical differences between them. Actually, in the analysis of deformation verification, the collapse possibility induced by the serious damage of some members mustn’t be neglected, even though the displacement angle may within the limitation.

In this paper, the section damage of frameworks is researched by numerical examples through ABAQUS for deformation verification under expected rare earthquake. The relationship of material damage and envelope of displacement angle is analyzed for the principle of no collapsing with strong earthquakes. Based on these numerical

results, the rationality of the constitute model and elemental discrete mode of frameworks, which is used widely, is also discussed.

The results show that the concrete in the RC columns may be damaged seriously even though the displacement angles are within the limitation, this kind of damage will then reduce the compression area of sections and make the stirrups unworkable and the longitudinal bars buckling, and at last, unreliable displacement angle will be solved out because the degradation of bearing capacity hasn't been estimated accurately.

## 2 MODEL OF MATERIALS AND ELEMENTS

In the analysis of nonlinear time-history under expected rare earthquake, elastic-plastic model with kinematic hardening is used for steel, plastic damage model is used for concrete proposed by Chinese code (2010c), and as the affection of stirrups to concrete is very important as proved

Figure 1. Discrete of RC column.

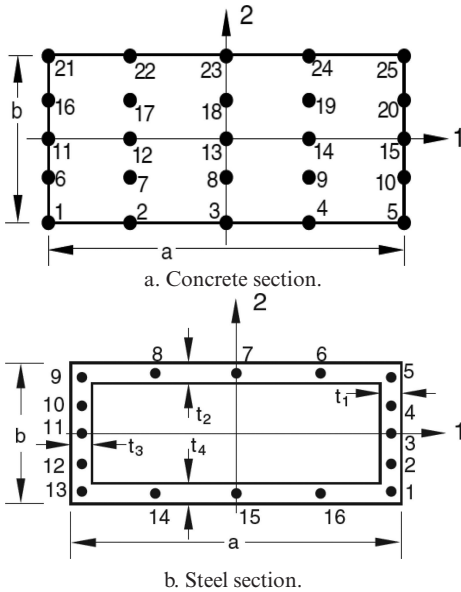

Figure 2. Integral points of sections.

by J.B. Mander [1988a,b], it is also researched by H. Qi (2011).

For the elements in ABAQUS (2006), rebar can be embedded in the shell element for walls and plates, but the same function is not available for beam elements in explicit method, so equivalent discrete models are usually used, in which the concrete section

a. Structural model.

b. Standard floor.

c. Seismic wave.

Figure 3. Structural model and seismic wave.

and the longitudinal bars would be formulated with fiber beam element respectively (Fig. 1). The integral points of each section are shown in Figure 2.

### 3 NUMERICAL EXAMPLE

The frame work, its first floor and the seismic wave are all shown in Figure 3.

According to Chinese codes, the structure would be regarded as no collapse if the displacement angle is less than 1/50 under the maximum acceleration 310 gal. For comparison, the results of the wave with peak acceleration equal to 220 gal is also presented.

The envelopes of displacement angle are shown in Figure 4. It can be seen that the maximum displacement angle is 3/200, and it is less than the limitation of 1/50. If taking the displacement angle as the unique criterion, this structure will not collapse under both two levels of acceleration.

Displacement angle is the direct reflection of structural lateral stiffness. The degradation of lateral stiffness can be induced by the degradation of shear stiffness, but in most situations, it is

induced by the degradation of bending stiffness which is the result of vertical stiffness reduction. Although the degradation of vertical stiffness may lead to collapse directly, but the horizontal stiffness of plates is so enormous that this factor may be underestimated in the calculation of displacement angle. Thus for accurate result about collapse, the vertical stiffness degradation of those most important members should be analyzed in detail.

For both columns A and B noted in Figure 3, the damages of 25 integral points in the concrete section are shown in Figure 5 with the peak acceleration equal to 220 gal, and equivalent strain of the longitudinal bars are shown in Figure 6. It can be seen that both concrete and steel are damaged slightly, and there are only slight fluctuation in the time-history of axial forces in Figure 7.

Amplify the peak acceleration from 220 gal to 310 gal, the concrete is damaged seriously for both columns as shown in Figure 8. For column A, both the left and right sides of concrete section are damaged seriously, and for column B, the whole

Figure 4. Envelope of displacement angle.

Figure 5. Compression damage of concrete section in column A and B under 220 gal.

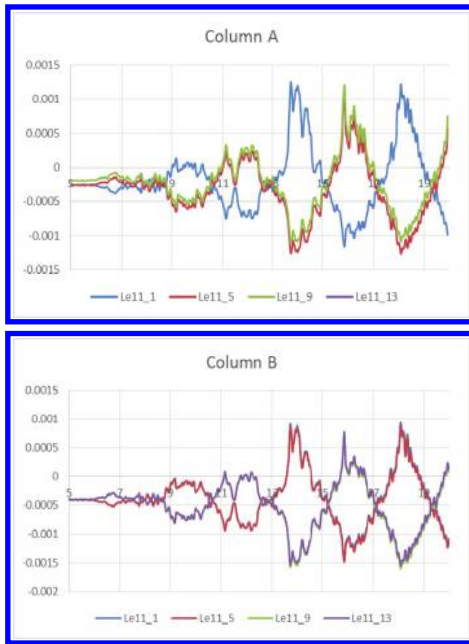

Figure 6. Equivalent strain Le11 of steel in column A and B under 220 gal.

Figure 7. Time histories of SF1 in column A and B under 220 gal.

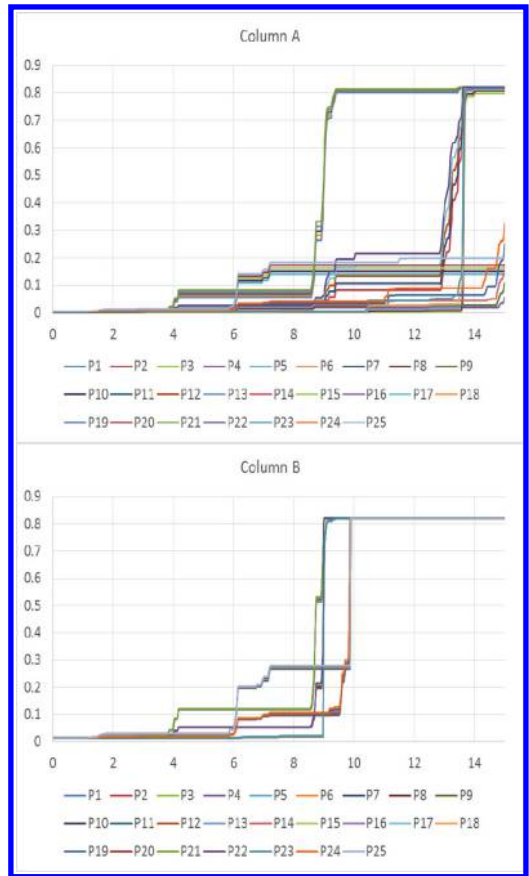

Figure 8. Compression damage of concrete section in column A and B under 310 gal.

concrete section is damaged seriously. Besides this, tremendous plastic deformation occurred in the steel sections (Fig. 9).

For both columns, the axial forces fluctuated significantly because of the compression damage of concrete. As shown in Figure 10, the axial force of column A increased about 1000 KN, but the axial force of concrete section in column B decreased even to zero with the axial force of steel section increased from 500 KN to 3500 KN. It is obvious that this phenomenon is not reasonable. By the result of concrete compression damage, the column B is crushed and the column A only keep a concrete core, both with the stirrups disabled and the longitudinal bars buckled.

Thus it can be seen, the first floor of this structure has lost at least eight columns, and the structure will collapse though the displacement angle is less than the limitation.

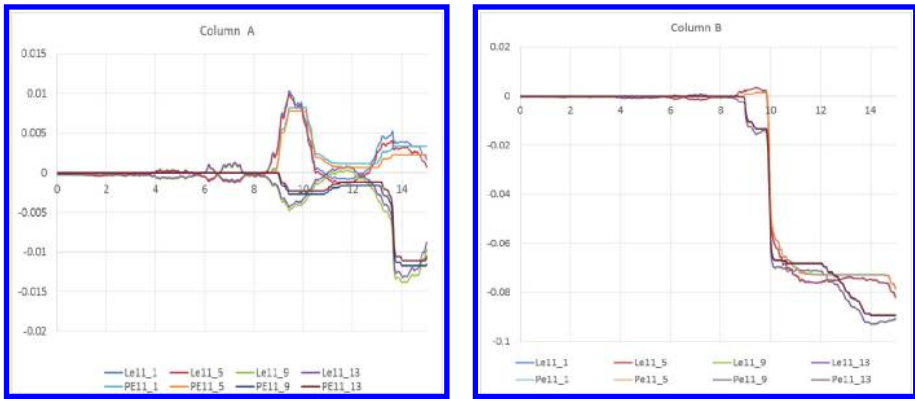

Figure 9. Equivalent strain Le11 and plastic strain PE11 of steel in column A and B under 310 gal.

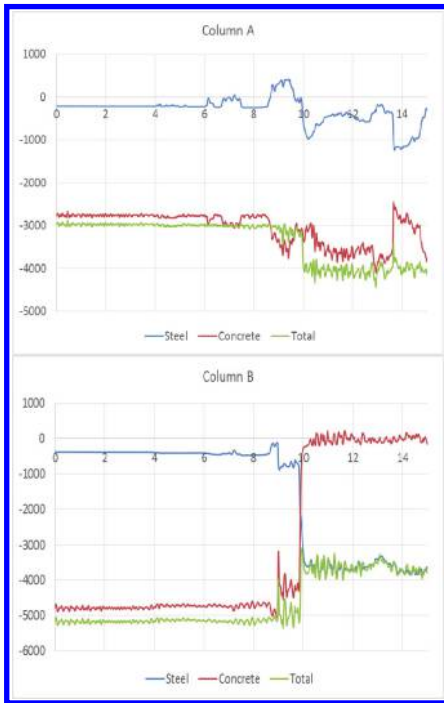

Figure 10. Time histories of SF1 in column A and B under 310 gal.

#### 4 CONCLUSION

Under the action of seismic waves, the envelope of displacement angle is usually taken as the main criterion for collapse. Limited by the material constitutive model and elemental discrete model,

the concrete compression damage in those key members would not be reflected accurately in the displacement angle, and this may lead to unreliable results. Therefore, the displacement angle cannot embody the vertical bearing capacity sufficiently, the degradation of vertical bearing capacity of those key members can lead to collapse with allowable displacement angle. Thus in the deformation verification under expected rare earthquake, the damage of members is as important as the displacement angle.

# Experimental study on the axial bearing capacity and ductility of concrete column confined with double stirrups

Y.Y. Li & Y.Y. Zhang

*Hebei University, Baoding, China*

L.Z. Sun & L. Sun

*Wenzhou University, Wenzhou, China*

**ABSTRACT:** In order to reduce the cross-section size of the reinforced concrete columns in the premise of improving its bearing capacity and ductility, 5 columns confined with double stirrups were designed as the study object. Concentric compression tests were conducted with the columns by using an electro-hydraulic servo loading machine using the displacement controlled loading scheme. The load-deformation behavior of the columns was analyzed. The test results show that the displacement ductility ratio varies between 4.04 and 6.17. By comparing the effects of different factors, it can be found that a better ductility was achieved for columns with a small stirrup spacing and a large stirrup diameter.

**Keywords:** double stirrups; confined concrete; displacement ductility ratio

## 1 INTRODUCTION

In recent years, the most disastrous earthquake has occurred many times in China and abroad, such as the Wenchuan earthquake, Yushu earthquake, Haiti, and Chile earthquake. Many buildings collapsed or destroyed badly in the earthquake, which caused a large number of casualties and huge economic losses. Column is an important bearing component of the structure, its insufficient function or degradation will have a great influence on the whole building, even leading to the collapse of the whole building. An important reason causing the damage of the reinforced concrete column is the lack of ductility. The essays point out that the axial compression ratio and stirrup characteristic value are the two main factors influencing the ductility of concrete columns.

According to Guan Ping and others, the stirrup characteristic value is much more important than other factors in influencing the column ductility. Guo Zhenhai and others in Tsinghua University, who have studied the stirrups concrete stress-strain curve under the action of repeated loading, suggested that enlarging the stirrup ratio can increase the peak strain of the concrete apparently, especially during the drop period, which can change the ductility of concrete substantially. After studying the axial bearing capacity of a single-layer high-strength stirrup and compound high-strength stirrup restraint concrete separately, Yang Kun and others put forward that a high-strength stirrup can

greatly improve the concrete ductility and provide a certain amount of axial bearing capacity. The restriction for core concrete of compound stirrups is stronger than single-layer stirrups and evenly distributed.

At present, lots of research have been done on ordinary strength stirrup concrete and FRP confined concrete by researchers at home and abroad, but the study of double stirrup concrete is much more less. Kent and Park put forward that in the rectangular stirrup-confined concrete, stirrups do not work before the pressure reaches the concrete compressive strength; while gradually achieving the compressive strength, stirrups begin to have a force and deform, which will develop a constraint force in the concrete specimen. Stirrup-confined concrete belongs to active constraint, and its constraint force changes with different stages of the test.

This experiment tries to decrease the size of the column section and improve the ductility of the column through configuring double stirrup, which may increase the stirrup reinforcement ratio.

## 2 TEST GENERAL SITUATION

### 2.1 *Template specimen preparation*

According to the proportion of test, the admixture, water, sand, gravel, cement, fly ash and silica fume are placed in the blender after weighing. There are two steps for pouring. First, casting the column base, after the concrete strength is increased to

70% for the chiseling process, and then casting the scape. Because the spacing of double hoop stirrup reinforced concrete column is small, this test adopts the hierarchical pouring. In order to avoid the phenomenon of honeycomb and empty, the vibrator is used to vibrate the concrete close-grained after casting 300 mm. Natural curing lasts for 60 days after the completion of the casting, ensuring that concrete strength meets the design standards. The specimen size is 25 \* 25 \* 140 cm, a total of five pillars, as shown in Figure 1. Reinforcement parameters are listed in Table 1.

### 2.2 The test procedure

In order to prevent the end effect, a 20 cm FRP carbon fiber cloth is packed at the top of pillars to reinforce the end of pillars before the test. This experiment is conducted on a WAW-10000F type electro-hydraulic servo multi-function experimental machine. First, the component is placed under the pressure plate, and the central axis is drawn around the pillar. Then, the position of the column is calibrated with the laser level. In the compression process, to ensure the specimen under uniform compression, high-strength gypsum is daubed on the top of pillars and pressed flat. A rod displacement meter is installed, whose

SC-4	43.15	HRB335	8 $\phi$ 10/8 $\phi$ 12	1209.5/1321.9	$\phi$ 6@75/ $\phi$ 8@75	180/230
SC-5	43.15	HRB335	8 $\phi$ 10/8 $\phi$ 12	1321.9/1321.9	$\phi$ 8@35/ $\phi$ 8@35	180/230

specification is ZS1100-DT100 on both sides of the pillar. Acquisition instrument is used to collect data. Preloading is carried out on the specimen prior to the commencement of the experiment. The purpose is to eliminate the adverse impact of the internal defects. After completion of preloading, two devices begin to collect at the same time and record the starting time. Loading regimes of the experimental machine are taken as 240 kN/min load to 2000 kN, and then are changed to 0.5 mm/min until the specimen is broken. The test set-up is shown in Figure 2.

## 3 TEST RESULTS

### 3.1 The experimental phenomena

With the gradual increase of the vertical axial force, destructive forms of columns are virtually the same. In the stage of force control, the test specimen has no obvious cracks, and then turns to the stage of displacement control. When the axial force of the concrete column reaches 80% of the ultimate bearing capacity, some small vertical cracks appear on the surface of the test specimen with small noise. When the bearing capacity gets the peak load, a number of cracks explode and develop swiftly. Finally, these cracks become oblique failure surface, which penetrate the concrete column. In this process, there is no obvious sound. When continuing loading on the concrete column, it shows that the bearing capacity of double stirrups concrete column declines slowly, protective layer gradually cracks and then falls off.

After observing the destruction, the longitudinal reinforcement in the test specimens is forced to bend outward. All inner and outer stirrups in the test specimen are not broken, as shown in Figure 3. Because of the form of double stirrups, which have high strength, the stirrup characteristic value improves much. With the load increasing, longitudinal cracks develop rapidly in the inner concrete column, while transverse cracks are effectively blocked. Cracks develop

in the weak layer that is the weld between longitudinal reinforcement and stirrups. The angles between the plane of rupture and the horizontal plane are roughly 60°–80°, which show that the specimens are compression and shear failure.

Figure 2. Test set-up.

Figure 3. Typical failure mode.

Damage characteristics of different concrete columns are given in Table 2.

### 3.2 Analysis of test results

1. The area representing the test specimen with double high-strength stirrups (round inside but square outside) constrained concrete is shown in Figure 4. The four corners of the square stirrups confined core concrete from the figure and sanction decreased slowly from angle to the middle part. The spiral stirrups, which are in the confined area of the outer stirrups work with outer stirrups together and can effectively control transversal strain of concrete, improve the capability of stirrups constraints. The displacement ductility ratios of SC-1~SC-5 are more than 4.04, as given in Table 2. This shows that double stirrups play an important role in the lateral restraint of concrete and can improve effectively the disadvantage that brittle failure in concrete column.
2. As shown in Table 2, displacement ductility ratios of pillars are around 4~6, which show that this test specimen has a good ductility. Specimens SC-1 SC-3 have the same concrete strength and diameter of the stirrup, but SC-3 has a greater inner and outer layer spacing of stirrup than SC-1. Compared with SC-5, SC-1 has the same concrete strength, spacing of stirrup and smaller diameter of the stirrup. Figure 5 indicates that the ductility of SC-5 is better than SC-1 and the ductility of SC-3 is the worst. Because the larger stirrup spacing ( $s$ ) and the smaller diameter ( $d$ ), the test specimens have a lower stirrup parameter so that there is not enough sanction to prevent lateral deformation of specimen, which lead to a bad ductility. These results are consistent with the those reported by Qian, J.R.

Table 2. Failure characteristics of specimens.

Serial number	Inner stirrup characteristic value	Outer stirrup characteristic value	Displacement ductility ratio $\mu_{\Delta} = \Delta_u / \Delta_y$	Failure characteristics	Longitudinal reinforcement yielding conditions	Ultimate load/kN
SC-1	0.552	0.430	5.21	Compression and shear failure	Yield	3578
SC-2	0.562	0.445	4.04	Compression and shear failure	Yield	3342.5
SC-3	0.399	0.311	4.66	Compression and shear failure	Yield	3277
SC-4	0.285	0.431	4.9	Compression and shear failure	Yield	3278.5
SC-5	1.181	0.929	6.17	Compression and shear failure	Yield	3594

\*( $\Delta_u$  represents the ultimate displacement of specimens. The displacement occurs when the bearing capacity is decreased to 50% ultimate load capacity.  $\Delta_y$  is the yield displacement, which is the average value of displacement, when inner and outer longitudinal reinforcement are tensile and subdued).

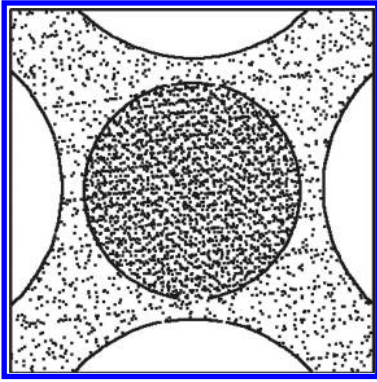

Figure 4. Effective confinement area for double-stirrup column.

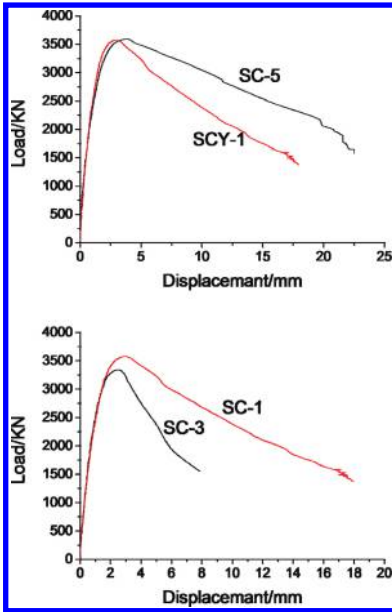

Figure 5. Comparison of load-displacement curves.

#### 4 CONCLUSIONS

1. According to the test results in the present study, using double stirrup can improve the stirrup characteristic value of RC columns and the bearing capacity of high strength concrete columns, as well as prevent the brittle failure effectively. The displacement ductility ratio of the columns tested in this study varies between 4.04 and 6.17.
2. All specimens show good ductility during the process of gradual failure. The axial bearing capacity of the designed specimens was enhanced to a great extent while guaranteeing the ductility. The design can reduce the section

- size of the column, and as a result the cost will reduce, which has a very high economic benefit.
3. Under the same strength grade of concrete, reinforcement characteristic value has a great influence on the ductility of the concrete columns. In addition, the inner and the outer stirrup characteristic values have a disproportionate level of influence on the ductility of the double stirrup reinforcement concrete column. However, the specific influence coefficient needs further study.

# The model design of fatigue test of steel-concrete composite segment of railway hybrid girder cable-stayed bridge

Yang Zhou, Qianhui Pu & Zhou Shi

*School of Civil Engineering, Southwest Jiaotong University, Chengdu, Sichuan, China*

Zhenbiao Liu

*China Railway Siyuan Survey and Design Group Co. Ltd., Wuhan, China*

**ABSTRACT:** The fatigue properties of the steel-concrete composite segment were investigated based on the Yong-Jiang Bridge, the first railway hybrid girder cable-stayed bridge in China. In this paper, the design process of the fatigue model test for steel-concrete composite segment of Yong-Jiang Hybrid Girder Bridge was introduced. In order to investigate the stress condition of the structure, a finite element model of the whole bridge was established by the software MIDAS/CIVIL. Then, the stress state of steel-concrete composite segment was calculated under various working conditions. The stress amplitude plays an important role in fatigue performance of the structure. The steel cells of composite segment located on the bottom plate, which suffered the largest stress amplitude, were selected as the test object. Lastly, considering the effects of the initial defects and laboratory equipment, a full-scale partial model with one steel cell was proposed based on the equivalent stress principle.

**Keywords:** hybrid girder cable-stayed bridge; steel-concrete composite segment; model design; fatigue test

## 1 INTRODUCTION

The first hybrid girder cable-stayed bridge, which combined the advantage of the steel and concrete, was built in Germany in 1972. Later on, this kind of bridge was introduced to China in 1990s and developed very fast in long-span bridges, especially in the field of highway bridges. In recent years, a series of hybrid girder cable-stayed bridges have appeared in China, such as Xupu Bridge, Shantou Queshi Bridge, Wuhan Baishazhou Bridge and Erqi Yangtze River Bridge. Because of the large span development of railway bridges, the hybrid girder cable-stayed bridge was applied to railway engineering. Yong-Jiang Bridge is the first railway hybrid girder cable-stayed bridge in China.

As a critical component of the hybrid girder bridge, the steel-concrete composite segment plays a crucial role in transferring force and transformation of bridge. According to statistics of existing hybrid girder cable-stayed bridges, steel-concrete composite segments can be subdivided into 4 types, in terms of bearing-plate and steel cells. These include a rear bearing-plate without cells, a rear bearing-plate with steel cells, a front bearing-plate with steel cells and both front and rear bearing-plates with steel cells. Meanwhile, shear connectors installed in bearing plate and steel cell are responsible for

connecting the steel and concrete girders and transferring shear force. In China, a majority of hybrid girder cable-stayed bridges adopted a rear bearing-plate with steel cells. In the existing literature, a majority of investigations have been focused on the static mechanical properties of the composite segment. Few researchers have paid attention to the fatigue characteristics of the steel-concrete composite segment because of the huge costs and long time consumption of the fatigue test.

In this paper, the process of designing the test specimen of the steel-concrete composite segment was introduced based on the stress equivalent principle. First, to obtain the internal force and the stress state of the composite segment, a FEM of the Yong-Jiang Bridge was proposed by the software MIDAS/CIVIL. Then, a partial full-scale model was designed by the maximum stress amplitude and test equipment. Lastly, loading force of the test specimen was determined by the stress equivalent principle of several key sections of the composite segment.

## 2 FEM OF THE YONG-JIANG BRIDGE

In this study, the applied load of the test specimen is based on the stress state of the original bridge.

So, a FEM of Yong-Jiang Bridge is established by the software MIDAS/CIVIL, as illustrated in Figure 1. Unlike static structure design, fatigue design is always based on the frequently loading instead of CR-live loading for railway bridges.

A trip of (1DF4 + 14C64) vehicle, whose axle load is ( $6 \times 230 \text{ kN} + 14 \times 4 \times 230 \text{ kN}$ ), has been adopted in this research. The wheelbase is shown in Figure 2. Table 1 (a, b) and Table 2 (a, b) present the internal force and the stress state of the key sections under the dead load and live load, respectively.

### 3 TEST SPECIMEN

#### 3.1 Location selection of steel cells

The fatigue performance of the composite segment is associated with fatigue stress amplitude. The structure would be more prone to fatigue problem if suffering great stress amplitude. The stress state at the top and bottom steel cells are listed in Table 3 and Table 4, respectively. From Table 3 and Table 4, it can be noted that the bottom steel cells are suffering the greater stress amplitude than the top cells. The bottom cells are chosen to be the object of the study.

### 3.2 Selection of bottom steel cells

The test specimen is designed by the stress equivalent principle. The stress of the composite segment is given in Table 1(b) and Table 2(b). Based on the equivalent calculation, the applied loads of the specimen of two steel cells and one steel cell are

given in Table 5 and Table 6. These two kinds specimen are shown in Figure 3 and Figure 4. The maximum applied stress load of the specimen with two steel cells is -3756.16 kN. The test equipment MTS with the maximum loading tonnage of  $\pm 2500$  kN is considered, which does not achieve the applied

load of two steel cells model. So, the specimen with one steel cell is chosen as the final test model.

#### 4 CONCLUSION

In this paper, the design process of the fatigue model test for steel-concrete composite segment of the Yong-Jiang Hybrid Girder Bridge was introduced.

1. First, a finite element model of the whole bridge was established by the software MIDAS/CIVIL to investigate the stress condition of the structure. Then, the stress state of steel-concrete composite segment was calculated under various working conditions.
2. The range of stress amplitude was the main factors influencing the structure fatigue characteristics. The steel cells of composite segment located on the bottom plate, which suffered the largest stress amplitude, were chosen as the test object.
3. Lastly, considering the effects of the initial defects and laboratory equipment, a full-scale partial model with one steel cell was proposed based on the equivalent stress principle.

# Mechanical properties of RC pile strengthened by effective CFRP composites

N. Zhuang, Y.J. Zhou, H.D. Sun & S. Ge

*College of Harbor, Coastal and Offshore Engineering, Hohai University, Nanjing, China*

**ABSTRACT:** Carbon Fiber-reinforced Polymer Fabric (CFRP) as a kind of high quality and efficient new composite material was widely used in various kinds of reinforcement of structure components. CFRP sheet bonding in the concrete face would offer effective lateral confinement and make core concrete under three-dimensional compression, which improved the compressive strength and deformation capacity of column. In this paper, the load features of six Reinforced Concrete (RC) piles, which were strengthened by different widths and strip spacings, were numerically simulated by finite element software. The load was added along the axial direction of the column to research the failure process. By comparing the bearing capacity and displacement of piles, the effect of spacing and width on mechanical property was investigated. The results indicated that the strength of piles was all increased after repair, and the extent of property improving depending on different repairing schemes.

**Keywords:** Carbon Fiber Reinforced Polymer Fabric (CFRP); pile foundation; mechanical properties; numerical simulation; bearing capacity

## 1 INTRODUCTION

### 1.1 Piles of wharf strengthened by composites

Strengthening reinforced concrete members, such as beams, walls, columns, and slabs (Sang-Wook Bae and Abdeldjelil Belarbi, 2009; Issa et al. 2009; Eid et al. 2009; Ilki et al. 2008; Soudki, K.S. 2007; Wang et al. 2006; Adhikary and Mutsuyoshi 2005; Imran A. 2013), with external bonding CFRP is a new strengthening technique with advantages of easy application, lower cost, and high strength to weight ratio. High-piled wharf is normally composed of pile foundation, reinforced concrete beams and slabs. The pile foundation is the most important load-bearing structure that transfers the upper load from the beam and slab to the bottom soil. The pile directly contacts the sea water that causes it under a poor marine environment. So the pile suffers the most severe corrosion among the structure members of high piled wharf. The harsh marine environment makes the pile inevitably to produce corrosion damage in less than a decade. The structure strengthened by CFRP could resist the corrosion caused by acid alkali for CFRP's good corrosion resistance, which is most suitable for the strengthening of the pile in the marine environment.

In this paper, the model of piles strengthened by different widths and spacings of external bonding CFRP strips was built. Then, the mechanical character of the pile before and after reinforcement was investigated.

## 2 NUMERICAL SIMULATION OF PILE STRENGTHENED BY CFRP SHEET

### 2.1 Numerical model of piles

Ordinarily micro cracks usually increased gradually from the pile's surface to its inside as the pile was applied top load. When these micro cracks extended and connected each other into larger cracks, the pile would be divided into some smaller columns and lose the bearing capacity.

The mechanism of CFRP strengthening technique used in pile was that CFRP strips would form an effective circumambient restraint around the pile, and thus, the pile's concrete core was in a three-dimensional state, which resulted in a significant improvement of bearing capacity, ductility, and anti-seismic property of the pile.

In this paper, a three-dimensional finite element model of piles would be simulated and analyzed by finite element software of ANSYS, as shown in [Figure 1](#). The concrete was simulated by the unit of solid 65; the steel bar was simulated by the unit of link 8; and carbon fiber sheet was simulated by the unit of shell 41. The numerical model has 1136 units and 2819 nodes. The numerical pile model took the vertical direction as the Z-axis and the horizontal radial direction of wharf structure as the X-axis; the Y-axis was then determined by the right hand rule. The physical and mechanical parameters of the beam are given in [Table 1](#).

Figure 1. Numerical model of the pile and CFRP.

Table 1. Physical and mechanical parameters of the beam.

Parameter	Concrete	Steel bar	CFRP
Poisson's ratio	0.2	0.3	0.2

Compressive strength/MPa	30		
Tensile strength/MPa			4223
Mass per unit area/ $\text{gm}^{-3}$			200
Thickness/mm			0.167

Figure 2. Different reinforcing methods of CFRP strips.

### 2.2 Simulation of piles strengthened by CFRP

In order to avoid local premature failure caused by stress concentration, the bottom and top sides of the pile were bonded by two layers of CFRP strips. The undersurface displacement of the model was fixed, and the horizontal displacement of the upper surface was free. Axial load was added to piles by the equal-added load method. In the numerical experimentation, the bearing capacity and deformation of each pile reinforced by different CFRP strip widths and spacings was studied, as shown in Figure 2. The column DBZ0 was not strengthened

by CFRP sheet as the control column. Column JGZ6 had zero sheet space and was fully wrapped by CFRP sheet. Columns JGZ2, JGZ4 and JGZ5 that had the same sheet space were applied to study the influence of sheet width. And columns JGZ1-JGZ13 having the same sheet width were used to investigate the influence of sheet space.

## 3 NUMERICAL EXPERIMENTAL RESULTS

### 3.1 Analysis of pile bearing capacity

When concrete subjected to axial load the concrete would generate lateral deformation due to Poisson's effect. When the load was small, the lateral deformation was in proportion to the longitudinal deformation. At critical stress, the lateral deformation grew rapidly, which caused internal cracks in concrete because lateral strain grew faster than the longitudinal strain, as shown in Figure 3. These internal cracks would become big cracks and parallel to the load direction, which caused the failure of concrete at last. The RC pile was reinforced by CFRP reinforcing concrete by restraining concrete lateral deformation through high tension strength of CFRP. And the stress of CFRP increased with concrete deformation. When the lateral deformation was larger, the tension strength would be brought into full play. Then, the bearing capacity would be improved.

The amount and area of CFRP strips were different because the width  $B$  and spacing  $S$  of CFRP were different, which caused different bearing capacities of piles. The maximum bearing capacity of each pile is listed in Table 2. The pile bearing capacity was increased after being repaired, but the

Figure 3. Axial stress to CFRP strain for pile fully wrapped by CFRP.

Table 2. Numerical simulation of column specimens.

Specimens	Sheet width (B/mm)	Space of sheet (S/mm)	Relative sheet width (H)	Ultimate capacity (/kN)	Capacity increasing (%)
DBZ0	0	0	0	1008	0
JGZ1	50	50	0.50	1200	19
JGZ2	50	100	0.33	1090	8
JGZ3	50	150	0.25	1065	6
JGZ4	100	100	0.50	1186	18
JGZ5	150	100	0.60	1160	15
JGZ6	1000	0	1	1650	64

Note:  $H = B/(B + S)$  represented the relative sheet width; the magnitude of the bearing capacity increase was calculated by comparing with the control column of DBZ0.

growth extent was different. Column JGZ6 fully wrapped by CFRP sheet had the biggest increasing level because the full wrap could constrain deformation to the greatest extent and avoid stress concentration in concrete.

It could be concluded that the bearing capacity would increase with relative width H of CFRP strip, as shown in Figure 4. When the relative sheet width was 0.25, 0.33, 0.50, 0.60 and 1, the ultimate bearing capacity of columns increased by 6%, 8%, 18%, 15% and 64% compared with the control pile. Columns JGZ1 and JGZ4 had the same relative sheet width of 0.5, while their width and space of CFRP sheet was 50 mm and 100 mm, respectively. So their increasing degree of ultimate bearing capacity was different, the strengthening effect of JGZ1 was higher than that of JGZ4.

The different spacings of CFRP strip changing with the ultimate bearing capacity are shown in Figure 5. When the width of CFRP strip was constant, the ultimate bearing capacity would decrease with the spacing the CFRP strip increasing. And when the CFRP width was smaller, the growth extent of ultimate bearing capacity would increase obviously.

The effects of different stripe widths on ultimate bearing capacity of the pile are shown in Figure 6 when the spacing of CFRP was constant. The ultimate bearing capacity of pile increased with the CFRP strip width increasing. When the width reached a certain value, the ultimate bearing capacity would not increase because the ends of the pile were not constrained well and result in premature destruction due to a very large increase in the width in the middle of the pile.

The relationship between the axial stress and the height of the pile that was not reinforced by CFRP, as shown in Figure 7. The value of “0” on the horizontal axis represented the bottom elevation of the pile; and the value of “1000” represented the top elevation of the pile.

Figure 4. Relation between ultimate bearing capacity and relative width of CFRP strips.

Figure 5. Various spacings of CFRP strips to ultimate bearing capacity.

And the stress in the middle of pile was relatively uniform and smaller than that of at two ends. As the pile was fully wrapped by CFRP strip, the stress in the concrete was uniform, which could avoid stress concentration and prevent premature failure.

Figure 6. Various widths of CFRP strips to ultimate bearing capacity.

Figure 8. Load-displacement of piles.

Figure 7. Curve of stress-height in control pile named DBZ0.

Figure 9. The second stage of the load-displacement curve.

### 3.2 Analysis of pile load-displacement

The change in load to deformation for pile before and after reinforcement is shown in Figure 8 and Figure 9. The bearing capacity and deformation were both improved when the pile was reinforced by CFRP strips. The load-deformation could be divided into two stages. In the first stage, the restriction of CFRP to the pile was small; and two curves before and after reinforcing were similar. In the second stage, as the pile was subjected to axial stress, the RC pile generated lateral expansion, which caused circumferential deformation of CFRP strips and generated lateral restriction for the concrete of the pile. So after strengthening the bearing capacity, the ductility of the pile was improved obviously. Under the same load, the pile deformation would decrease with the relative CFRP width increasing because the CFRP strips generated more lateral confinement.

## 4 NUMERICAL EXPERIMENTAL RESULTS

This paper presented the results of a numerical experimental program investigating the mechanical properties of CFRP-strengthened reinforced concrete pile. Based on the numerical test results, the following conclusion can be drawn:

Bonding CFRP strips on the surface of RC pile could significantly enhance the performance of RC pile. The ultimate bearing capacity of RC pile reduced along with the increasing spacing of CFRP strips when the CFRP strip was constant.

When the relative width of CFRP strip was over 0.5, the increase extent of bearing capacity would become smaller compared with the relative width of CFRP strip below 0.5. Stress concentration occurred at the both ends of the RC pile, which caused premature local failure when the relative

width of CFRP strips was over 0.5. So, the effect of CFRP reinforcing was not obvious when the relative width of CFRP strip was over 0.5.

The pile fully wrapped by CFRP strips had the highest increasing level because full wrap could constrain deformation to the greatest extent and avoid stress concentration in concrete, which improved the mechanical property and increased the ultimate bearing capacity of the pile.

# Applied research of acoustic transmission method on the detection of pile foundation

Jianning Zhang, Baohui Wang, Mingcheng Jing, Zhaoyu Sun & Yansheng Lin  
Gansu ZhiTong Technology Engineering Detection Consulting Co. Ltd., Lanzhou, China

**ABSTRACT:** The principle, test method and test procedure of the ultrasonic transmission method are elaborated, and the ways to analyze test datum and judge the integrity of pile body are analyzed in detail through practical engineering cases, which is instructive for practical engineering application.

**Keywords:** ultrasonic transmission method; detection of pile foundation; integrity

## 1 INTRODUCTION

In recent years, along with the increasing investment of infrastructure construction project from the country, pile foundation has been widely used as the important component and main foundation form of various engineering structures [1]. According to relevant documents, the amount of the concrete cast in-place piles used in the country exceeds 1 million every year, including the ones of overlength and large diameter, and the cost of pile foundation often accounts for more than a quarter of the whole of the engineering project [2].

The concrete cast in-place piles belong to concealment engineering, and generally the quality of piles cannot judge from the exterior. Because of the influence of factors like construction site environment or construction management and so on, multiple harmful defects like necking, mud-clamping and holes may exist in the shaped pile bodies [4].

## 2 THE PRINCIPLE AND METHOD OF ULTRASONIC DETECTION

### 2.1 The principle of ultrasonic detection

The ultrasonic is a type of mechanical wave, so mechanical vibration and fluctuation are the physics basis of ultrasonic detection. It is also one of the elastic wave test method, with the theoretical basis of the propagation theory of elastic wave in solid medium. The data-processing system realize the judgment of the property, size and position of various defects inside the pile foundation and provide the assessment criteria of concrete overall homogeneity and strength grade according to the synthetical judgment and analysis of various parameters of signals received by the software.

### 2.2 The burying of sonic-testing tubes and testing preparation

#### 2.2.1 The burying of sonic-testing tubes

When the pile diameter is less than 1500 mm, 3 pipes are buried; when the pile diameter is greater than 1500 mm, 4 pipes are buried (see Fig. 1).

The sonic-testing tubes are metal, and the connections of pipes use screw joint, which makes the pipes water-tight. The reliability of the detection results and the success of the detection tests are directly influenced by the burying quality of sonic-testing tubes.

#### 2.2.2 Preparations before detecting

1. The concrete age of the detected piles should be greater than 14 d.
2. The sonic-testing tubes should be filled with water and keep free.
3. Investigate and collect relevant technical documentations and construction records of the projects to be detected.
4. Check the clear condition of sonic-testing tubes before placing the transducers.

Figure 1. The arrangement diagram of testing tubes. (Note: the shaded area in the figure is the effective detecting range of sonic wave).

- Measure the clearance distance between the outside walls of each sonic-testing tube at pile top surface with steel tape, and check the distance measurement between each measured point of the profile section.

### 3 ENGINEERING PROJECTS

#### 3.1 Engineering project 1

The punched grouting pile foundation is used in a project, the design pile diameter of which is  $\phi 1500$  mm and the concrete design strength grade is C25; the construction length of the defective pile is 39.40 m.

Test result (see Fig. 2): within 0.00–2.00 m of the pile body concrete of the tested pile, both of the acoustic velocity and the amplitude are lower than the critical value; the PSD curve is distorted; the departure of wave speed and amplitude between the measured and the average reach around 200 m/s and 10 dB respectively. The phase of the defective position is opposite to that of the normal concrete, inferred that the thickness of concrete cover in that position is low and tendons leak partially.

#### 3.2 Engineering Project 2

The punched grouting pile foundation is used in a project, the design pile diameter of which is  $\phi 1300$  mm and the concrete design strength grade is C25; the construction length of the defective pile is 18.00 m.

Test result (see Fig. 4): the concrete of the tested pile body lies 1.6 m from the pile top, both of the acoustic velocity and the amplitude are lower than the critical value; the PSD curve is seriously distorted; the wave speed of the defective position is 3000 m/s, 1500 m/s deviated from the average value

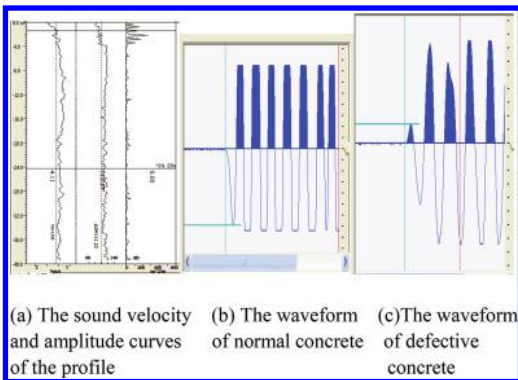

Figure 2. Test results of project 1.

Figure 3. Leakage tendon of the defective position.

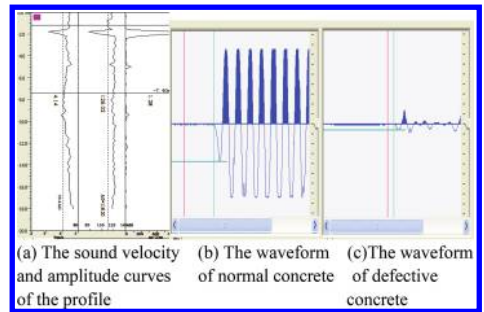

Figure 4. Test results of project 2.

Figure 5. Mud-clamping of defective position.

(the wave speed of norm concrete in nearby area is 4500 m/s), and the departure of the amplitude between the measured and the average is around 30 dB, inferring that the concrete is clamped with mud in this position.

## 4 CONCLUSIONS

Combining the acoustic crosshole transmission method used in the pile foundation detection in the engineering practice, it can be found that: (1) the acoustic crosshole transmission method is an effective way to test the quality of inner concrete, and it can find out the variation conditions of the quality of pile body inner concrete in detail with higher accuracy and resolution and obvious detection effect; (2) the acoustic crosshole transmission method can detect the quality of any section along the length of pile body especially for the piles with large diameter and super length, which is more micromesh and accurate than dynamic measurement method. (3) the application of concrete quality ultrasonic detection provides reliable basis for the quality treatment of concrete.

# A brief discussion on the causes and treatment measures of bridge pile foundation defects

Juan Li, Wenhong Ren, Jihong Wang, Zhao Zhang, Xiaohui He & Baohui Wang  
*Gansu ZhiTong Technology Engineering Detection Consulting Co. Ltd., Lanzhou, China*

**ABSTRACT:** In this paper, several defects and causes of bridge pile foundation commonly observed under construction are analyzed based on the survey of current pile foundation construction status of multiple bridges, and corresponding treatment measures are proposed.

**Keywords:** bridge; pile foundation; defect

## 1 INTRODUCTION

During the construction of bridge pile foundation, some small faults often lead to quality defects of pile foundation, which generally can be prevented. However, it could cause greater economic loss and delay construction schedule if the chosen methods dealing with the defects are inappropriate. In this paper, combining with the analysis of pile foundation construction status, the causes and precautions of bridge pile foundation defects are summarized, and several simple and economical treatment measures are proposed.

## 2 ANALYSIS OF DEFECT CAUSES

### 2.1 *Manually excavated pile*

The construction difficulty is small for the excavated piles, but it has more defects than the bored pile, because it is easily neglected under construction for its small construction difficulty and the causes leading to defects are minor faults mostly, which hardly attracts attention. At present, the schedules of most projects are compressed, and in order to catch the time limit, the majority of excavated piles are altered designed from the bored piles while the groundwater level is high and the capacity of water inrush is large, leading to severe segregation of pile bottom concrete during the construction process.

1. The quality of protective wall is low, and hole collapse occurs when pouring concrete;
2. Concrete disintegrates, segregation layer occurs on the pile body;
3. Pile bottom dreg is too thick.

### 2.2 *bored pile*

The main quality defects of bored pile are pile silted and excessively thick pile bottom sediment layers, and the reasons for the above factors are as follows:

1. Pile silted.
2. Pile bottom sediment layer is too thick.
3. Hole-wall collapses.

## 3 SEVERAL COMMON TREATMENT MEASURES OF DEFECTS

### 3.1 *Rebuild*

Those defects that are discovered in time and detected by ultrasonic during construction can be completely handled by rebuilding a new pile at the origin place after thorough cleaning. This method has a good effect but great difficulty, long operation period and high cost. It can be adopted based on the factors such as importance of project, geological conditions, and number of defects.

### 3.2 *Pile extension*

First, we determine the location of concrete by acoustic detecting on the pile; second, we determine the well-points dewatering based on the geological data offered by the design and excavate the plain concrete to encase the wall.

### 3.3 *Pile core well-shaft method*

This method is easier to be said than done, that is to use a pneumatic pick to chisel a well with a diameter of 80 cm at the center of the defective pile while dewatering at the same time, and the depth

should surpass the defective position at least, and then clean sediments in a sealed manner, place reinforcement cage and cast expansive concrete using the excavating-hole concrete construction method. The daily advance of this method is 0.6 m, but it will involve much more difficulties if individual piles cannot dewater well, leading to massive loss on project quality, schedule and money.

#### 4 TREATMENT MEASURES OF DEFECTIVE PILES

##### 4.1 *For piles of diameter-shrinking and mud-clamping*

This technique attempts to adopt the mudjacking reinforcement method that is commonly used in reinforcing. The conclusion is that the mudjacking reinforcement method is unsuitable for mud-clamping piles.

##### 4.2 *High pressure jet grouting and compaction grouting method*

Strengthening schemes as high pressure water rotary jet grouting cut, eliminating dregs with air, high pressure jet grouting and compaction grouting can be adopted and used on defective piles to achieve the strengthening goal.

##### 4.3 *Static pressure grouting construction*

In order to reduce the possible settlement shrinkage when the jet grouting body consolidates, the size is made to fully penetrate into the bottom of the pile and pile-side gap, and then increase the strength of grouting consolidation body and the friction resistance of pile bottom and hole side effectively, orifice static pressure grouting is proceeded before the final set of cement grout after the processes above are finished, and eliminate the retraction of grout until the orifice is full of grout.

##### 4.4 *Preventive measures of pile breaking*

The key to preventing pile breaking accident is precaution. Each operation aspect and post should be checked and effective preventive measures made seriously before perfusing. The operating instruction should be strictly followed during perfusing, ensuring the continuity, compactness and orderliness of perfusing operation; observe the surface of concrete repeatedly and carefully and calculate the height of concrete surface by theoretical method,

and take the lower one as the standard of disassembling the conductor pipe after comparing; raise the pipe constantly, smoothly and slowly; control the perfusing time in a suitable range. The proper functioning of the facilities should be guaranteed and standby ones prepared; inform the power distribution sector before perfusing to ensure the supply of electricity during perfusing; pay attention to the weather forecast and arrange the perfusing time rationally.

#### 5 CONCLUSIONS

The quality control of pile foundation should be taken seriously in bridge construction, reducing the formation of pile foundation defects as far as possible through studying and knowing various causes of the defects. The existing defects should be treated by the most efficient, economical and quick method, combining the factors as types of defect, severity degree, position and design parameters of pile foundation and synthetically considering the costs, construction schedule and governance effect. Nowadays, the study of defect treatment measures of pile foundation is still inadequate domestically, and there are no proven technical measures to rely on the treatment of defective piles, merely depending on experience and often failing of achieving the best effectiveness in the treatment. It is expected that the relevant administrative and quality supervision departments develop the integral technical measures and reinspection code for the field of treatment measures of pile foundation, and increase the quality control power of the retreatment of defective pile foundation, guaranteeing the quality of bridge pile foundation.

# Analysis on load-carrying capacity of a ribbed stiffener shallow spherical shell roof

D.Y. Jia, T. Wang & J. Yang

School of Civil Engineering and Architecture, Anhui University of Technology, Maanshan, China

**ABSTRACT:** According to the construction data of the roof structure for a 100,000 m<sup>3</sup> gas tank, the FEM model of the ribbed stiffener shallow spherical shell is established. The static analysis is taken to check the strength. The eigenvalue buckling analysis is taken to get the first order buckling mode. Then the arc length method is used on the nonlinear stability analysis, and the critical buckling load and allowable overall stability capacity of the roof structure is obtained. By analyzing the checking results of the strength and the stability, the instability is the decisive factor that causes the roof structure to lose the load carrying capacity.

**Keywords:** roof structure; ribbed stiffener shallow spherical shell; load-carrying capacity; overall stability

## 1 INTRODUCTION

In recent years, according to the reasonable utilization of iron and steel plant by-product energy, reduce air pollution, energy saving and environmental protection requirements, the large capacity storage tanks emerge. However, in practical application, be lacking of theoretical research and design code, structural instability occurs in large scale storage tanks which have been built [1]-[5]. Ribbed stiffener shallow spherical shell is a form of spatial structure which is used for the roof of storage tanks. The load carrying capacity of the roof structure is the important design content.

The roof structure of a 100,000 m<sup>3</sup> gas tank in east China consists of center ring beam, edge ring beam, longitudinal ribs, circumferential ribs, longitudinal secondary ribs and cover plate. The section of ribs is channel C18a, the section of secondary ribs is angle L75x6, the thickness of cover plate is 4 mm. The configuration of the roof structure is shown in Figure 1.

FEM analysis model is established by ABAQUS. For steel materials, density is 7850 kg/m<sup>3</sup>, elastic modulus is 206 GPa, Poisson's ratio is 0.3, yield strength is 235 N/m<sup>2</sup>. The element type for all components is S4R. Tie constraints are set between the components, as well as between the component and the cover plate. Since the edge ring beam is stiffer than ribs and cover plate, the boundary condition is assumed as fixed connection.

Figure 1. Configuration of the roof structure.

## 2 STRENGTH CHECKING

### 2.1 The displacement and stress of cover plate

According to the actual situation of roof structure, the characteristic value of uniform loads are taken as: dead load 0.6 kN/m<sup>2</sup>, live load 0.5 kN/m<sup>2</sup>, dust

load  $0.75 \text{ kN/m}^2$ , snow load  $0.75 \text{ kN/m}^2$ . Because the live load and snow load is not considered at the same time, the combined characteristic load value is taken as:  $0.6 + 0.75 + 0.75 = 2.1 \text{ kN/m}^2$ . The uniform surface load is applied on the FEM model, the static elastic analysis is taken to get the Mises stress and displacement results. Figures 2 and 3 show the distribution of displacement and Mises stress on the cover plate. The maximum displacement value is  $6.003 \text{ mm}$ , appears at central cover plate between secondary ribs in the fourth band; the maximum Mises stress is  $26.43 \text{ N/mm}^2$ , appears at the joint of cover plate and the ring beam in third band.

### 2.2 The displacement and stress of longitudinal rib

The displacement and Mises stress along the longitudinal rib are shown in Figures 4 and 5. The maximum displacement value is  $5.094 \text{ mm}$ , appears at the middle of rib in the sixth band; the maximum Mises stress is  $57.38 \text{ N/mm}^2$ , appears at the joint of longitudinal rib and the edge beam in the first band.

### 2.3 The displacement and stress of circumferential rib

Figures 6 and 7 show the displacement and Mises stress along the circumferential rib at the

Figure 4. Displacement of longitudinal rib.

Figure 5. Mises stress of longitudinal rib.

Figure 2. Displacement of cover plate.

Figure 3. Mises stress of cover plate.

Figure 6. Displacement of circumferential rib.

third band. The maximum displacement value is  $4.712 \text{ mm}$ , appears at the middle of rib; the maximum Mises stress is  $40.52 \text{ N/mm}^2$ , appears at the joint of longitudinal secondary rib and the circumferential rib.

Figure 7. Mises stress of circumferential rib.

Figure 8. Displacement of longitudinal secondary rib.

Figure 9. Mises stress of longitudinal secondary rib.

#### 2.4 The displacement and stress of longitudinal secondary rib

Figures 8 and 9 show the displacement and Mises stress along the longitudinal secondary rib at the first band. The maximum displacement value is 3.518 mm, appears at the middle of rib; the maximum Mises stress is 48.04 N/mm<sup>2</sup>, appears at the

joint of longitudinal secondary rib and the circumferential rib.

### 3 STABILITY CHECKING

#### 3.1 Eigenvalue buckling

Considering the material as ideal elastic type, the first order buckling mode is obtained by the eigenvalue buckling analysis. It can be seen from the Figure 10, the maximum buckling deformation occurs at the middle of cover plate in the fifth and sixth bands.

#### 3.2 Overall instability

Taking the first order buckling mode as the initial structure, the initial imperfection value is taken as 200 mm, which is the value of 1/300 span referring to the rules in “Technical Specification for Space Frame Structures”<sup>[6]</sup>. Considering the material as ideal elastoplastic type, the initial defects of structure as the consistent imperfection modal method<sup>[7]</sup>, the arc length method for nonlinear buckling analysis is taken to obtain the overall instability deformation which is shown in Figure 11. In the figure, a wide range collapse occurs in the sixth and seventh bands.

The node at which the maximum vertical displacement occurs on longitudinal ribs is selected. The load-displacement diagram of the node is shown in Figure 8, which express the whole process of tracking analysis of the instability of the structure. Upon loading, the roof structure initially exhibits a linear relationship between the load and the displacement. The structure displacement is very small, that means the structure is in the elastic state with the larger stiffness; Upon continuing the loading, before the maximum load (the critical buckling load) point is reached, the increment ratio of displacement is larger than the load increment, which shows that the structure is in the elastic-plastic state with the stiffness degradation, but still in a stable equilibrium state. At the first upper extreme point,

Figure 10. Eigenvalue buckling deformation of roof structure.

Figure 11. Overall instability of roof structure.

Figure 12. Load-displacement diagram.

the displacement is 0.087 m, the corresponding load value is 10.97 kN/m<sup>2</sup>. After that, the curve is very steep decline, structure deformation speed up, when the load is reduced to 4 kN/m<sup>2</sup>, the displacement is about 0.64 m. Then the first lower extreme point of the curve is reached, that means the structure achieves the reverse balance position. After that, the curve slowly rises, when the load upon to 3.5 kN/m<sup>2</sup>, the displacement is about 1.05 m, the second upper extreme point is reached, and then the second lower extreme point.

Based on Figure 11 and 12, the whole process of instability of tracking analysis of the roof structure can be obtained. Upon loading, the local buckling occurs at the cover plate with initial imperfections near the sixth band, and then the range of buckling deformation increases as well as the values, the work of structure turns into the elastic-plastic state. After the load reaches the first upper extreme point on the curve, the sharp declination shows that the stiffness degradation and brittle failure characteristics of roof structure. As the deformation continues to increase, although the curve rises slightly at the first lower extreme point, the structural deformation has exceeded the allowable value; the structure is in an unstable equilibrium state. Finally, a larger range of collapse occurs, the roof structure is in the state of overall instability.

According to the work performance of roof structure, the first upper extreme load value, which corresponds to the critical buckling load of the structure, can be regarded as the ultimate overall stability capacity of the structure. Referring “Technical specification for latticed shells” provisions, the stability safety factor of the FEM calculation result is 5<sup>[6]</sup>. The critical buckling load value is 10.97 kN/m<sup>2</sup>, that is, the allowable overall stability capacity of the roof structure is 2.19 kN/m<sup>2</sup>.

#### 4 CONCLUSION

According to an actual gas tank construction, the roof structure is a ribbed stiffener shallow spherical shell. The finite element model is established. Based on the FEM analysis results of strength checking and stability checking, the following conclusions can be obtained:

1. In normal operating conditions, under the characteristic combination of external uniform load 2.10 kN/m<sup>2</sup>, the maximum Mises stress is 57.38 N/mm<sup>2</sup>, which is less than the yield strength; the maximum displacement is 6.003 mm, which are far less than the allowable value (1/300 of span).
2. The external load 2.10 kN/m<sup>2</sup> is slightly less than the allowable overall stability capacity 2.19 kN/m<sup>2</sup>. Therefore, as for the roof structure in the form of ribbed stiffener shallow spherical shell, the instability is one of the decisive factors which leads to the failure of structure.
3. The simplified formula for checking the load-carrying capacity of the ribbed stiffener shallow spherical shell shall be deducted.

# Analysis on wind-induced effects of simply supported beam roof structure with metal roof panels

Li Huang

*Department of Real Estate and Engineering Management, Zhejiang University of Finance and Economics, Hangzhou, China*

Wei Wang & Hua Deng

*Space Structures Research Center, Zhejiang University, Hangzhou, China*

**ABSTRACT:** A simply supported beam roof structure is employed as an example. The mid-span moment time history of the main beam is investigated to study the finite stiffness of the roof panel and the damping properties of the sandwich core effect on simply supported beam wind-induced vibration effects. The numerical results reveal that the finite stiffness of the roof panel and the damping properties of the sandwich core can reduce the amplifying magnitude of the moment and affect the high-frequency segment response mainly, and the extent is limited. For this flexible simply supported beam roof structure, the finite stiffness of the roof panel effect on the wind-induced vibration response of roof structure is prominent.

**Keywords:** metallic roof panel; simply supported beam; roof structure; fluctuating wind; wind-induced vibration

## 1 INTRODUCTION

The impact of the roof panel is usually ignored in the wind-resistant design and analysis of the large span roof structure, during which the wind load is directly applied as a kind of nodal load on the nodes of the main structure generally. Nowadays, the roof panel used in the large span roof structure is the metal composite roof panel, which is made into a kind of sandwich plate in some process. Its top and bottom surfaces are made from thin pressed metal plates, while the middle layer is filed with the damping materials such as polyurethane foaming plastic, the mineral wool or the fiberglass cotton. The sandwich plate is of finite stiffness, so it is not realistic to assume the sandwich plate as the rigid plate in the process of wind load transformation. The roof panel is taken as a thin single plate to consider the effect of its self-vibration, with which the wind vibration coefficient of the large span structure becomes bigger<sup>[1]</sup>. For the polyurethane metal roof panel, a study has shown that its finite stiffness and the damping of its sandwich layer can affect the pulse property of the wind load<sup>[2]</sup>. Beside the effect of the roof panel self-vibration on the amplitude and frequency of the fluctuating wind pressure, the roof panel will work together with the main structure, which affects the stiffness and damping as well as the wind vibration of the whole structure further,

while it is seldom studied in the field of the wind vibration of a large span roof structure.

Research in this paper is focused on the polyurethane metal roof panel. The simply supported beam roof is taken as the numerical example based on the former established composite sandwich shell element for the polyurethane metal roof panel<sup>[3]</sup>, during which the polyurethane metal roof panel is incorporated into the FEM analysis of the roof structure wind vibration. By the analysis of the roof structure wind vibration response incorporating with the influence of the metal roof panel, a preliminary discussion on how much influence the polyurethane metal roof panel will make on the roof structure wind vibration response is presented in this article.

## 2 CALCULATION MODEL

### 2.1 Structure mode

The simply supported beam model is composed of 3 simply supported beams that span 24 m. The distance between the primary beam spacing is 2.4 m, and these beams are connected by the secondary beams (purlins) of 2.4 m spacing. The connections between the primary beams and the secondary beams are rigid, as shown in [Figure 1](#). Section applied for the primary and secondary

Figure 1. Model of a simply supported beam roof structure.

Figure 2. Time history of artificial wind load.

beams is H350 × 175 × 6 × 10 Q235 steel section. The top and bottom surfaces of the roof panel are set by steel with a density of 7850 kg/m<sup>3</sup>, Young's modulus of 206 GPa and Poisson's ratio of 0.3. The density of the hard polyurethane foam sandwich layer is set by 42.87 kg/m<sup>3</sup>, as well as the basic mechanical parameters are set as those described in reference<sup>[4]</sup>. Regardless of the mass of the roof panel, the fundamental frequency of the structure is  $f = 0.95$  Hz, which is almost equal to the fundamental frequency of the large span roof structure with a big span. It shows that the stiffness of the structure is flexible.

Modeling and analysis are processed in the ANSYS software. In order to analyze the influence of the roof panel on the response of the structure wind vibration, comparative analysis is taken by these two kinds of models.

Model 1: beam 4 element is applied as the beams, while the wind load is directly applied on the structure nodes as nodal load, as shown in Figure 1(a).

Model 2: roof panels fully laid on the steel beams are simulated by eight-node sandwich shell elements. The roof panel and the beam connect on the 4 corresponding nodes, which couples 6 freedoms. Wind load is vertically applied on the roof panels as the surface load. This model is shown in Figure 1(b).

## 2.2 Wind load history

Wind pressure is taken as 0.5 kN/m<sup>2</sup>, irrespective of the spatial correlation between the nodes. Wind pressure history on the roof surface is artificially simulated by the AR method, as shown in Figure 2.

## 3 MODEL ANALYSIS

By examining the mid-span moment response of the beam in the middle frame, analysis of the effects of the roof panel stiffness and sandwich damping on the roof structure wind vibration response is carried out.

### 3.1 The influence of the roof panel stiffness

Different material and thickness selection for the top and bottom roof panel surfaces will lead to largely different roof panel stiffnesses. It is so complicated to adjust the parameters described above that in this paper, roof panel stiffness is changed by adjusting the thickness of the sandwich layer, namely, variation of the roof panel stiffness caused by kinds of parameters is unified by adjusting the thickness of the sandwich layer. The sandwich layer thickness is set to 0 mm, 60 mm, 80 mm and 100 mm, which is referred to as model 2-1, model 2-2, model 2-3 and model 2-4, respectively. The structure's damping ratio is set to 0.02 according to the steel structure.

Mid-span moment history curves of these models are shown in Figure 3. As we can see, the structure response amplitude with consideration of roof panels decreases. In Figure 3(f), amplitudes in model 2-2 and model 2-3 are small, while those in model 2-1 and model 2-4 are big, which indicates that from model 2-1 to model 2-3, as the stiffness (thickness) of the roof panel increases, the structure response amplitude decreases, and as the stiffness (thickness) of the roof panel increases further, the structure response amplitude increases again.

The beam mid-span moment Power Spectral Density (PSD) distribution is shown in Figure 4. As we can see, the low-frequency stage in the PSD is very close, but the high-frequency stage diverges significantly. By comparison, the high-frequency PSD amplitude of model 2-4 is the smallest, and the high-frequency PSD amplitude of model 2-1

Figure 3. The time history of mid-span bending moment of the main beam.

is the largest, while the corresponding amplitudes of model 2-2 and model 2-3 are between the two values. The law presented here is that the more rigid the roof panel stiffness is, the smaller the amplitude of the high-frequency moment response PSD will get.

### 3.2 The influence of the sandwich layer damping

Modal strain energy method<sup>[6,7]</sup> is applied to calculate the structure's damping ratio of each order. For model 2, 3 cases are taken to make comparative analysis, which are as follows:

1. Damping ratio is set to 0.02 for all orders, namely, the structure is taken as a regular steel structure, which is called model 2-i-a;
2. The material loss factor of the roof panel sandwich layer is set according to the test in literature<sup>[1]</sup>, and the material loss factor of the steel is taken to be 10<sup>-4</sup>, which is called model 2-i-b;
3. The material loss factor of the roof panel sandwich layer is taken to be 0.5, regardless of its variation with frequency<sup>[8]</sup>, which is called model 2-i-c, where i is the model number in 2.1.

Figure 3. (Continued)

Figure 4. Power spectrum of bending moment time history.

Figure 5. Mid-span bending moment time history of main beam in model 2-1.

Figure 6. Mid-span bending moment time history of main beam in model 2-2.

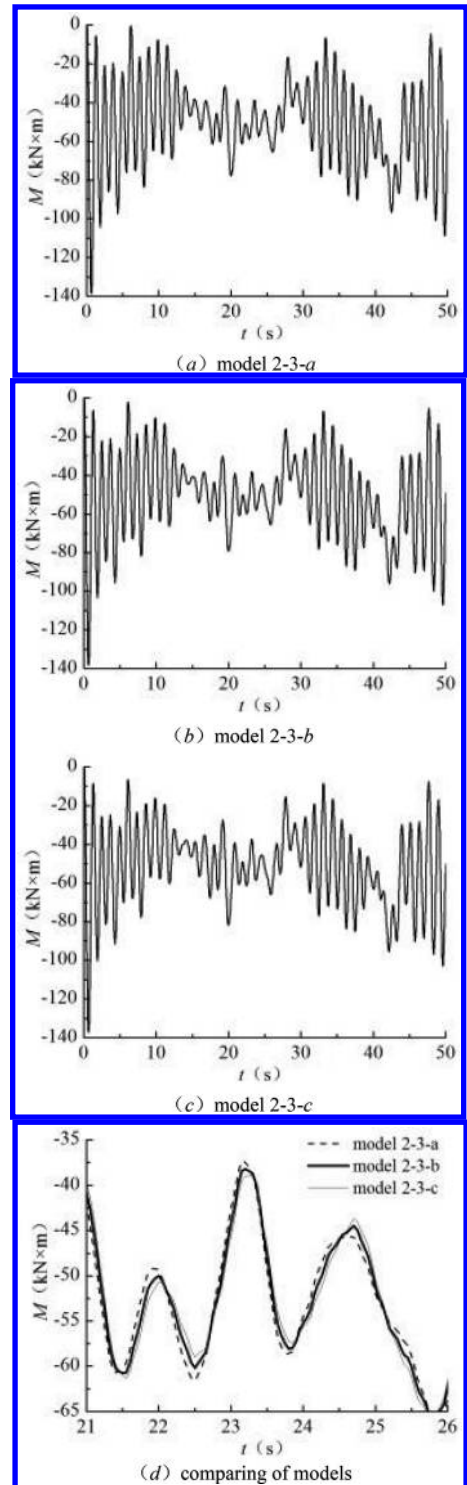

Figure 7. Mid-span bending moment time history of main beam in model 2-3.

### 3.2.1 Model 2-1

The mid-span moment time history curve of the model 2-1 is shown in Figure 5. Curves appear to be similar, while in Figure 5(d) we can see that the amplitudes of the curves show little difference. The amplitude of the model 2-1-c is the smallest, the amplitude of the model 2-1-a is the largest and the amplitude of the model 2-1-b is between the two values. The PSD distributions of the 3 models are similar. Above all, improving the damping ratio of the sandwich layer makes little difference for the whole structure.

### 3.2.2 Model 2-2

The mid-span moment history of model 2-2 is shown in Figure 6, which has the same rule of model 2-1.

### 3.2.3 Model 2-3

The mid-span moment history of model 2-3 is shown in Figure 7, in which it shows the same law as those shown for model 2-1 and model 2-2. Three curves take similar shapes as well as different strain amplitudes.

The moment PSD analysis (Fig. 8) indicates that, during the high-frequency stage, the PSD

Figure 8. Mid-span bending moment time history of main beam in model 2-3.

Figure 9. Mid-span bending moment time history of main beam in model 2-3.

Figure 10. Mid-span bending moment time history of main beam in model 2-4.

amplitude of model 2-3-c is bigger than that of model 2-1-a, which shows the same regular pattern as the one indicated in reference<sup>[1]</sup>, in which the dynamic properties of the roof panel are studied alone. The damping ratio of the sandwich layer changes the spectral character of the structure's dynamic response.

### 3.2.4 Model 2-4

The mid-span moment history curve and moment response PSD attribution are shown in Figure 9 and Figure 10, respectively. Taken together, the results of model 2-4 show the same rule as those for the above 3 models, but the dynamic response amplitude differs more significantly, and the spectral characteristics of the dynamic response change more obviously.

## 4 CONCLUSIONS

1. For the simply supported beam roof structure with relatively soft stiffness, the mid-span

moment response amplitude decreases obviously when the roof panel is taken into account. But the reduced amplitude does not change linearly with the variation of the roof panel stiffness. In general, the roof panel affects the response amplitude of the high-frequency stage;

2. After consideration of the material damping of the roof panel, moment response amplitude becomes lower, though it is of limitation generally and mainly affects the response amplitude of the high-frequency stage;
3. The numerical results show that the stiffness of the roof panel affects the wind-vibration response of the simply supported beam roof structure more significantly.

# Shaking table test study on a retrofit method of bottom-business multi-story building

Yongduo Liang

Earthquake Administration of Liaoning Province, Liaoning, Shenyang, China

Xun Guo & Yang Zhou

Institute of Disaster Prevention, Hebei, Sanhe, China

Jinzheng Jiang & Ying Li

Earthquake Administration of Liaoning Province, Liaoning, Shenyang, China

**ABSTRACT:** Through a comparative experiment between the earthquake simulation shaking table test of three double-deck models, the differences in the aspects of structure frequency, acceleration, displacement and strain state between the common bottom-business multi-story masonry structure, and the bottom-business multi-story masonry structure reinforced through rectangular steel pipe and steel channel are analyzed. Based on the test results, the destroy mode of each longitudinal wall and the invalidate order are obtained, and the feasibility and practicality of the retrofit method through rectangle steel pipe is proved. Finally, the retrofit method of balancing stiffness and increasing ductility is put forward, which may provide reference for retrofitting design of the existing houses.

**Keywords:** bottom-business multi-story masonry structure; earthquake simulation shaking table test; retrofit; seismic resistant capacity; story stiffness

## 1 INTRODUCTION

In Wenchuan earthquake, 80% of the bottom-business multi-story masonry buildings were ruined, while this kind of structure is very popular in the small and middle towns in the south of China and do not disappear in short time. So, it is urgent to study the earthquake-resistant mechanism of this building form and the methods to retrofit the existing buildings in order to reduce the damages caused by earthquakes.

## 2 SHAKING TABLE TESTS

### 2.1 Test preparation

According to the test aim and content, two double-deck models were designed, with the first floor plan of models, as shown in Figure 1, and the front view of model 2, as shown as Figure 2.

There are 16 acceleration sensors, 4 displacement sensors and 26 strain gauges (model 1), 21 strain gauges (model 2) were set at a proper position. During the tests, Wolong wave was used and the tests were carried out in 5 steps (model 1) and 4 steps (model 2).

Figure 1. The first floor plan of the models.

Figure 2. The front view of model 2.

Figure 3. The cracks distribution of model 1 after PGA = 0.82 g.

## 2.2 Test phenomenon

As model 1, after PGA = 0.10 g and 0.35 g, there were no appearance of cracks. From PGA = 0.45 g, near windows of the second floor, there were some fine cracks occurring. With the growing of PGA, the quantity and width of cracks were increasing. After 0.82 g, the damage state could be observed, as shown in Figure 3.

From Figure 3, it could also indicate that the damage order and degree is mid longitudinal wall, back longitudinal wall and front longitudinal wall.

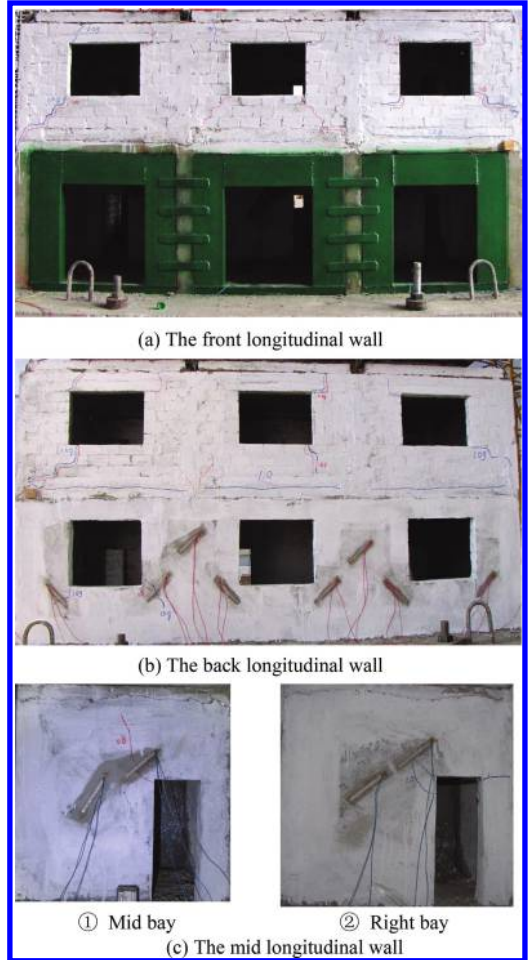

Figure 4. The cracks distribution of model 2 after GA = 0.88 g.

As model 2, the time of cracks appearing is later than model 1, the first fine crack occurs at PGA = 0.84. The details of the damage are shown in Figure 4.

## 3 COMPARISON OF REINFORCEMENT

### 3.1 Modal comparative analysis

The pulsation method is used in testing the modal of the two models before and after loading.

The results include the natural frequency and the torsional frequency, and the details as given in Table 1 and Table 2.

From the two tables, with the increasing load, the frequency of models decreasing trend occurs. The first-order frequency of model 1 reduces by 36%,

Table 1. The modal results of model 1.

Modal	Before load	After PGA = 0.35 g	After PGA = 0.45 g	After PGA = 0.82 g
First-order frequency/Hz	15.0	9.6	9.0	5.6
Second-order frequency/Hz	26.0	13.4	13.4	12.9
Torsional frequency/Hz	24.8	19.6	N/A	19.2

Table 2. The modal results of model 2.

Modal	Before load	After PGA = 0.84 g	After PGA = 0.88 g
First-order frequency/Hz	14.4	5.6	5.4
Second-order frequency/Hz	22.4	13.5	14.1
Torsional frequency/Hz	20.3	15.9	11.3

Figure 5. Acceleration amplification.

Figure 6. Relative displacement.

40% and 63% after PGA = 0.35 g, 0.45 g and 0.82 g, respectively, and the second-order frequency is 36%, 40% and 63%. And torsional frequency reduces by 21% and 23% after PGA = 0.35 g and 0.82 g, respectively. The same law appeared in model 2.

Because of the positive correlation between the frequency and failure degree, it can be proved that the failure degree of model 2 is lighter than that of model 1 at the same level of earthquake.

### 3.2 Acceleration response comparative analysis

The dynamic amplification effect can be attained through the acceleration earthquake response of the model during the earthquake simulation shaking table test. The data curve of the acceleration amplification contrast of the two models is shown in Figure 5.

From the curve, it can be seen that the data of model 1 is larger than that of model 2 at the second floor except at a special point. This indicated that the failure degree of model 1 is more serious than that of model 2 at the same level of earthquake.

### 3.3 Relative displacement comparative analysis

The curve of relative displacement is shown in Figure 6. From the curve, it can be seen that the data are less than 1 mm at the first and second loads, indicating that the structures are in the elastic state. The data of model 2 is larger than that of model 1 obviously, and from the test phenomenon, it is known that the failure level of model 1 is more serious than that of model 2. Thus, the seismic performance of the retrofit model is significantly improved.

### 3.4 Strain comparative analysis

The strain values of the representative corresponding position of the three longitudinal walls of the two models are shown in Figure 7.

From Figure 7, it can be seen that all values are compressive strain and increasing as the

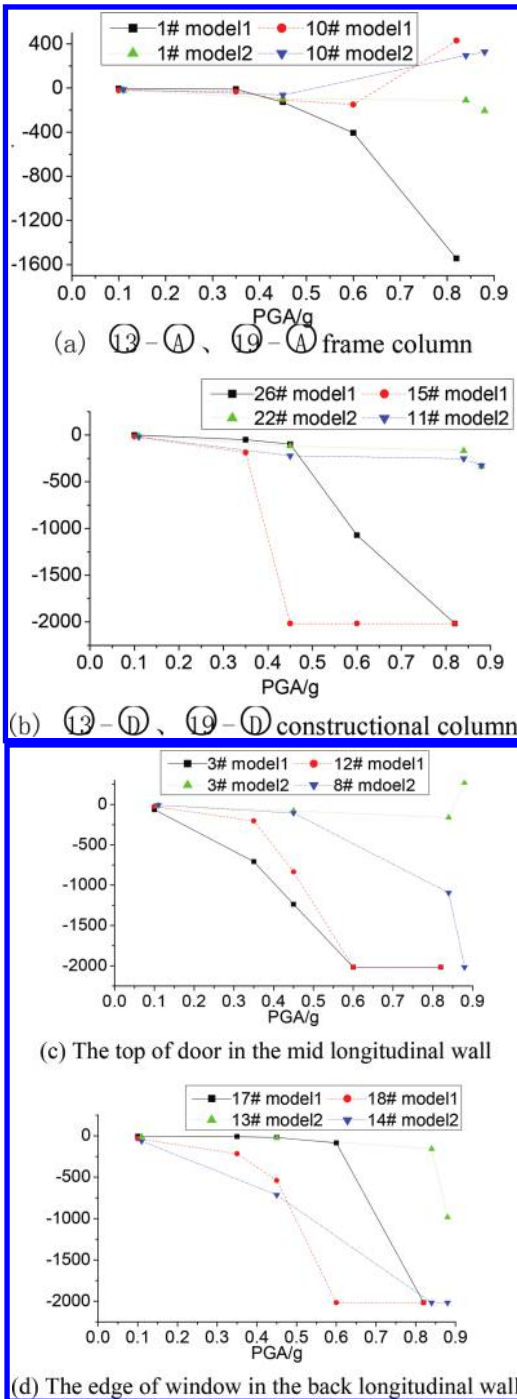

Figure 7. Strain contrast of the corresponding position of the two models.

acceleration of ground motion increases. Collectively, the values of the two models show a consistent rule, that is, the value of mid longitudinal wall is the largest, then the back longitudinal wall and the mid constructional column of transverse wall, the smallest is the front longitudinal wall (frame column and constructional column); and most of the values show the value of model 1 to be larger than that of model 2.

#### 4 SUMMARY

1. The damage degree of model 2 (retrofit) is obviously lighter than that of model 1 (ordinary).
2. The failure sequence of the three longitudinal elements is the mid longitudinal wall, the back longitudinal wall and the front wall (or frame columns).
3. The stiffness of the front longitudinal wall may be strengthened because of rectangle steel pipes and steel channels were added on both sides of the frame columns, and this can balance the distribution of earthquake inertial forces among walls. It is proved that this method may be an effective measure for retrofitting existing normal bottom-business multi-story masonry buildings. The idea may be concluded as “balancing stiffness and increasing ductility”.

# Force analysis on continuously pouring outer wrapped concrete based on a SRC arch bridge

G. Wei & Z. Gu

Guangxi University, Nanning, Guangxi, China

**ABSTRACT:** This paper takes a long-span concrete-filled steel tubular arch bridge as the research object. The model of the main arch rib plate unit, which includes the beam element and the space finite element, is established by Midas Civil 2012. This paper conducts the computational analysis of the construction process of the main arch ring when it adopts inclined cable-stayed buckle to pour outer wrapped concrete continuously. Besides, it also explores the effect of the main arch ring stress and deformation under the control of non-cable-inclined and four inclined cables. The results show that, under the control of four inclined cables, the nominal pressure and tensile stress of the structure are admissible, the structure shows less deformation repetition, and the arch ring has no upper vault deflection. Thus, the results indicate that the control of the cable-inclined method can achieve a good effect.

**Keywords:** Steel Reinforced Concrete arch bridge (SRC); cable-inclined; continuously concreting; outer wrapped concrete; computational analysis

## 1 INTRODUCTION

The concrete-filled steel tubular arch bridge is mainly used in the long-span concrete arch bridge. After more than 20 years development, the construction technology of the SRC has developed rapidly. In recent years, it has gradually become a main type of bridges of the large span bridges, because it has a great spanning capacity, strong bearing, good stability, and convenience of construction. The outer wrapped concrete of the long-span concrete-filled steel tubular is heavy and massive, and the largest stress and deformation emerge in this construction stage, so it is necessary to conduct force analysis in the stage of casting outer wrapped concrete.

## 2 THE THEORY OF THE CABLE-INCLINED CONTINUOUSLY CONCRETING

The stiffness and strength of rigid skeleton gradually form during the outer wrapped concrete construction progress. As this bridge type possesses complicated structural system transformation and much construction difficulties, the construction method of outer wrapped concrete on the main arch ring is crucially significant. The outer wrapped concrete continual pouring refers to dividing rings firstly, concreting the first ring continuously and

symmetrically from the arch foot to the vault, concreting the next ring after the strength formation, until all the concrete is finished. This construction method is convenient, rapid and has good concrete quality. But, if measures are not taken, the stress and deformation will be out of range. Setting several stayed-buckle cables to regulate the nearby peak of the bending moment influences lines of the controlling section, and applying a changing tension above the oblique arch axis can effectively control the vault deflection and the foot arch hogging moment during the continuous concreting of outer wrapped concrete. Thus, the stress and deformation of steel reinforced concrete arch bridge can be kept within the designed range.

## 3 THE GENERAL SITUATION OF ENGINEERING

### 3.1 Engineering background

The bridge is 852 meters in length, and the single span of main bridge reaches 416 m, which is deck concrete-filled steel tubular railway arch bridge. The rise of arch is 99 m, the rise of the span ratio is 1/4.2, the arch axis shape is catenary, and the arch-axis coefficient is 1.8.

The section of the main arch ring is a single box, including three rooms, whose width is changed but height is invariable. The height of the arch rib is 8.5 meters. In the range of 65 m

Figure 4. Arch rib segment division.

from the arch foot to the vault, the width of the arch rib changes from 28 m to 18 m linearly. In the range of 286 m in horizontal length, the length is 18 m and the middle room is 9.8 m in width. The stiff skeleton is mainly composed of steel and

steel tube concrete, the upper and lower chords adopt the steel tube of  $\Phi 750 \times 22$  mm. The chord is connected by angle steel, and transverse cross brace is set in the right position to strengthen the horizontal connection, which forms a steel and concrete-filled steel tubular truss frame. There are 38 lateral braces to connect the arch rib, and the link of each chord is welded. Concrete is poured after the arch rib is finished, the concrete

adopts C80 weakly expansive concrete, and the outer wrapped concrete is C60 high-strength concrete.

### 3.2 The scheme stage of construction

For rational utilization of the original cable, the position of cable-inclined is the same as the lift of steel skeleton. After construction of the steel skeleton, and reaching the designed strength, parts of inclined cables are removed, except 2#, 3#, 5#, and 7# cables. The way of pouring arch ridge concrete is split-ring continuous pouring. The half span arch ridge is divided into 19 parts longitudinally and 6 rings vertically. The Concrete is poured continuously and symmetrically from the arch foot to the vault, the order of concreting is the first side room, then the middle room; first base plate, then the web plate, and finally the roof. The scheme stage of construction is given in Table 1.

## 4 FINITE ELEMENT MODEL

The model includes 3001 nodes and 10852 elements, including 8324 concrete-filled steel tube beam elements and 2528 outer wrapped concrete plate elements. The beam element and the plate element adopt co-node to realize the combination of two structures together into a whole load. The arch-springing is all fixed. The model keeps the longitudinal direction as the X-axis, the transverse direction as the Y-axis, and the vertical as the Z-axis.

Figure 8. The MIDAS/Civil model of the main arch.

A few notes about the model:

1. Regard the concrete-filled steel tube rigid skeleton as the initial state, do not consider the effect of the pre-camber and the steel tube primary stress.
2. The stiffness and strength of the concrete-filled steel tubular member will be reduced if the steel tube and the concrete are void, this article adopts C80 weakly expansive concrete and introduces the lift-up method to place concrete uninterruptedly, so it does not consider the effect of the void.
3. Adopt the material conversion method to calculate the material and geometric characteristics.
4. Do not take into account the effect of the strength of former concrete when pouring on one ring, but regard the weight of concrete as the concentrated force to act on the right element.
5. Consider the combined action of the concrete-filled steel tubular rigid skeleton and the outer wrapped concrete after the strength form.

## 5 THE RESULTS OF FORCE ANALYSIS

This paper takes the bottom concrete, for example, to calculate by using the stress superposition method, the vault deflection, the steel stress, the concrete-filled steel tube stress and the outer wrapped concrete stress as control targets, chooses the foot arch, the L/8, L/4, 3 L/8, the vault and the abrupt change in section as control sections. The finite element analysis on non-cable-inclined and four inclined cables continuous of outer wrapped concrete is carried out to study the stress and deformation of the structure.

According to The Code for Design on Steel Structure of Railway Bridge (TB10002.2-2005), the maximum allowable stress is as follows:

The maximum allowable stress of the Q370 steel is 263 MPa;

The C80 steel tube concrete:

$$f_{cd} = 34.6 \text{ MPa}, f_{td} = 2.14 \text{ MPa} \quad (1)$$

The C60 outer wrapped concrete:

$$[\sigma_b] = 20.0 \text{ MPa}, [\sigma_{tp-1}] = 3.15 \text{ MPa} \quad (2)$$

### 5.1 The vault deflection

Taking the concrete-filled steel tube rigid skeleton for reference, the added displacement of the vault deflection can be taken from the MIDAS model. Thus, the difference between the added displacement of the initial state and each construction step is the current deflection.

Figure 9 shows that the repeated deformation is great and the largest vault deflection reaches 31 cm when continuously concreting the first ring. The reason is attributed to the fact that the stiffness of rigid skeleton is lesser and the deformation is greater when it stands all the weight of concrete. Under the control of four inclined cables, although the arch ring has repeated deformation,

Figure 9. Comparison of vault deflection.

the amplitude is smaller. Besides, the arch ring has no upper vault deflection, whose changing curve is smooth. And the maximum lower vault deflection is 21.0 cm after the first ring is formed, and it meets the requirement of regulation which is  $L/800 = 52.0$  cm, and the effect of regulating the main arch ring deformation by four inclined cables is good.

### 5.2 The stress of the upper and lower chords

Figures 10 and 11 show that the largest pressure stress is 422 MPa of the foot arch, which is exceeded greatly, and the stress of the others control sections is nearly 225 MPa with a lower safety which need to regulate and control. The reason is that the rigid skeleton stands all the concrete weight without stayed-buckle cable before the strength of former concrete formed, which leads to the higher stress of the steel tube.

Figures 12 and 13 show that the largest pressure stress of the upper chord is 194 MPa in the vault section, and the largest pressure stress of the lower chord is 210 MPa in the foot arch. Besides, the range of stress of others chords is 100 MPa to 150 MPa. This means the stress is low and the structure has

Figure 10. Correlation line of pipe stress in control sections of the lateral upper chord member.

Figure 11. Correlation line of pipe stress in control sections of the lateral lower chord member.

Figure 12. Correlation line of pipe stress in control sections of the lateral upper chord member.

Figure 14. Correlation line of concrete stress in control sections of the upper chord member.

Figure 13. Correlation line of pipe stress in control sections of the lateral lower chord member.

Figure 15. Correlation line of concrete stress in control sections of the lower chord member.

a high safety space. Taking the allowable stress of the Q370 steel to check, compared with the non-inclined cable, the steel stress of the control sections is within a permissible range, which means a higher safety. The stress level of the steel tube has improved obviously, and the problem of the over proof lower stress of the foot arch is solved.

### 5.3 The stress of concrete in the steel tube

Figures 14 and 15 show that the maximum nominal tensile stress of concrete in the tube reaches 11.2 MPa in the upper chord of the foot arch, and the maximum pressure stress reaches 47.0 MPa in the lower chord of the foot arch. The nominal and pressure stress of concrete in the steel tube far exceeds its permissible range, which needs to adjust and control. Comparison between the stress of the steel tube and concrete in the steel tube can be made, and it is easy to draw a conclusion that under the corresponding construction step and at the corresponding place, there is a nominal tensile stress in the concrete in the steel tube, but the stress of the steel tube is always under the dimensional compression, because it has original steel stress to counteract partly a smaller nominal stress.

Figures 16 and 17 show that the stress of concrete of the upper and lower chord is pressure in

Figure 16. Correlation line of pipe stress in control sections of the upper chord member.

Figure 17. Correlation line of pipe stress in control sections of the lower chord member.

Figure 18. Outer wrapped concrete stress of ring 1 after construction.

Figure 19. Outer wrapped concrete stress of ring 1 after construction.

the mass, the maximum pressure stress of concrete in the tube reaches 18.2 MPa in the lower chord of the arch foot; parts of the construction steps have a smaller tensile stress and the maximum reaches to 1.04 MPa in the variable section, and the nominal pressure and tensile stress of the control section are within the permissible range.

#### 5.4 The stress of outer wrapped concrete

Figures 18 and 19 show that the outer wrapped concrete stress of the first ring after construction is pressure in the mass, and the maximum pressure and tensile stress reaches to 11.5 MPa and 0.77 MPa. Under the control of four inclined cables, the maximum pressure and tensile stress reaches to 2.45 MPa, nearly 3 L/8 section, and to 1.58 MPa, nearly L/4 section, which are within the permissible range.

On the whole, the stress and deformation of the main arch ring has a great improvement under the control of four inclined cables, which shows that the construction method is feasible.

## 6 CONCLUSION

The computational analysis on the continuous concreting of outer wrapped concrete of a

long-span concrete-filled steel tubular arch bridge is conducted, and comparison between the regulating effects of non-inclined-cable and four inclined cables is made, on the basis of which the following conclusions are drawn:

1. Without cable-inclined concreting, the arch ring produces a greater deformation and has an upper vault deflection. Besides, the stress of the structure far exceeds its permissible range. So, it is necessary to take measure to control.
2. The inclined cables can effectively regulate the stress and deformation of the main arch ring, and keep the vault deflection, the nominal pressure and tensile stress of the structure within the permissible range. The method achieved the continuous concreting of floor outer wrapped concrete successfully, which theoretically proved that the method of cable-stayed buckle to continuous concreting of the main arch ring outer wrapped concrete is feasible.

# The analysis of the influence of material strength on the shear capacity of steel tube-reinforced concrete composite column

Bing Wang, Xiao Liu & Tiancheng Xu

School of Architectural and Civil Engineering, Shenyang University, Shenyang, China

**ABSTRACT:** In this paper, the reasonable selection of component parameters and the property of shear components of the steel tube-reinforced concrete under the effect of lateral horizontal displacement are analyzed using the ABAQUS finite element model. Weak and strong axis loading, concrete strength, and steel yield strength factors are selected as the parameter variation of components. It is concluded that the major axis is higher than the shear bearing capacity of the weak axis, increase of concrete strength against the influence of shear bearing capacity is not obvious, and improving the steel yield strength can effectively improve the bearing capacity of the component.

**Keywords:** steel tube-reinforced concrete; material strength; shear capacity

## 1 INTRODUCTION

In order to overcome the weakness of heavy concrete structure, the poor bending performance and the poor steel fire resistance, concrete and steel are combined, which can play their respective advantageous roles. Besides, a layer of steel tube is wrapped on the component. The structure is in a state of very unsafe because of the sharp decrease in the bearing capacity of the external steel tube under the fire. Inserting i-steel inside the component can continue to play a strong load-bearing role after the outside steel pipe losing bearing capacity. The existence of core concrete delays the internal steel bone expiry time, which gives people plenty of time to escape the rescue, thereby reducing property and life loss [1–4].

Researchers have focused on concrete column, mainly studying the performance of the concrete column under different stress states. Three of which are bending shear, tense bending shear, and tense bending shear twist, which relate to the shear performance of stress. Curved scissors refers to the concrete member only under the effect of transverse shear. Bending shear is influenced by transverse shear force and axial pressure or eccentric. Bending torsional shear refers to the concrete column under transverse shear, axial pressure and torque under the action of stress. Bending shear and bending shear is the basis of the study compound stress; therefore, studying the basic shear performance has an important significance. In this article, the material strength is studied by using finite element analysis software ABAQUS, and the analysis of the strength parameters is carried out to determine their effects on the bearing capacity.

Figure 1. The applied shear load.

## 2 SHEAR LOADING OF THE FINITE ELEMENT MODEL

This article adopts the steel tube concrete column filled with steel bone, which is fixed on the one end and loaded the horizontal transverse load on the other end, as shown in Figure 1.

## 3 PARAMETER SETTING AND ANALYSIS OF STEEL TUBE-REINFORCED CONCRETE COMPOSITE COLUMN

Steel pipe-reinforced concrete composite column is made up of steel pipes, beams and a combination of core concrete composite component. The intensity of each part has different effects on shear bearing capacity. Different force states also lead to different shear bearing capacities. Loading direction will affect the shear bearing capacity as well. This article selects three parameters namely concrete strength, loading direction, and steel strength. We, respectively, study their effect on the

Table 1. Shear component parameters of steel tube filled with steel tube-reinforced concrete composite column.

Serial number	Component size (D × t × l)/mm	Displacement direction	$f_{ck}$ /MPa	$f_{sk}$ /MPa	$f_{tk}$ /MPa	$\theta$	$\lambda$	$n$

E-2	160 × 5 × 500	Strong axis	C70	390	235	0.28	3.125	0

Note:  $\theta$  is the effect of the restraint coefficient;  $\lambda$  is the shear span ratio; and  $n$  is the axial compression ratio.

Figure 2. Strong and weak axial loading diagram.

shear bearing capacity of the steel tube concrete column-filled steel bone.

### 3.1 Component parameter

Component parameter selection is the key step of calculation and analysis. Reasonable parameter selection will take to get twice the result with half the effort effect. On the basis of many times simulation, we select the parameters, as listed in Table 1.

### 3.2 Parameter analysis

#### 3.2.1 The strong and weak axis displacement influences

Due to the geometric characteristics of i-steel, steel pipe-reinforced composite column is not an axisymmetric graphic. There is a difference between the strong axial load and the weak axis load, as shown in Figure 2, and the shear bearing capacity is also different.

This article, respectively, forces the strength and weak axis load to three sets of specimen, namely A-1, A-2, B-1, B-2, C-1, C-2. Using the ABAQUS finite element simulation, the shear capacity curves are shown in Figure 3.

We can find out the following factors from the above chart:

Figure 3. Shear bearing capacity of strength and weak axial loading direction.

1. The elastic stage: elastic modulus of the strong axis load is bigger than the weak axis load. This is because that the built-in i-steel flange is far away from the centroid, and the action of shear function of the flange area is larger in the horizontal strong axis load. The weak axis loading function of the flange area is lesser.
2. The ultimate bearing capacity: strong axial shear ability is superior to the weak axis, because of the strong axial load. The bone involved in the area of tensile steel is bigger than the weak axis load.

### 3.2.2 Concrete strength

The strength of the concrete commonly used ranges from C10 to C90. In order to better use the compressive strength of concrete, in the compression state of steel-reinforced concrete filled steel tube column, high strength concrete is adopted. This paper continues to use high-strength concrete. Using three grades of high-strength concrete, namely C50, C70, C90, in components B-1, D-1, D-2 for simulation analysis, the result is shown in Figure 4.

We can find out the following factors from the P-U curve:

1. With the increase of concrete strength, the shear capacity of steel-reinforced concrete filled steel tube column increases gradually, but the increase is not obvious.
2. The slope of the elastic stage with the increase of concrete strength also has no obvious change, this is because with the strength of the concrete improving, the elastic modulus of concrete also gradually improves. Compared with the steel elastic modulus, concrete elastic modulus nearly equals to 10 percent, which makes little contribution on the whole for the components of the elastic modulus.
3. Regardless of the kind of concrete strength, after the yield point, the shear bearing capacity

Figure 4. P-U curve.

of steel-reinforced concrete filled steel tube did not immediately decrease. On the contrary, there will be a little rising trend, which illustrates that the steel-reinforced concrete filled steel tube column has a very good ductility.

### 3.2.3 Steel strength

There are four kinds of commonly used steel. Their yield strength is Q235, Q345, Q390, and Q420. This article uses only three kinds of steel components, namely Q235, Q345, and Q390, in components B-1, E-1, E-2 and B-1, F-1, F-2 for simulation analysis. The P-U curve are shown in Figures 5 and 6.

We can find out the following factors from the above chart:

1. Shear bearing capacity of whatever strength of steel bone or steel tube, in the elastic stage, the overall elastic modulus is constant, that is because, while it improves the strength of the steel, the elastic modulus of steel has not changed, thus the whole component of the elastic modulus has not changed.

Figure 5. The P-U curve different steel-reinforced intensity.

Figure 6. The P-U curve different steel tube intensity.

2. To be loaded into yield strength of the components, the strength of the steel bone and steel tube is gradually shown. With the improvement of strength of steel pipe and steel bone, yield strength of the components also increased dramatically. While steel yield strength improves to Q390, improving the capacity effect of the components is not obvious. But increasing the yield strength of steel tube to Q390, the promotion effect of component bearing capacity is more apparent.
3. To improve the strength of the steel tube has a more obvious effect on the shear bearing capacity of components than the steel bone.

As can be seen from the above analysis, the loading direction, concrete strength, steel strength, the three parameters selected in this paper has a certain influence on the shear capacity of steel tube-reinforced concrete composite column. In engineering practice, we should strictly control these three factors.

#### 4 CONCLUSION

The ABAQUS finite element model established, the reasonable structure parameters selected in this paper, shear components under the effect of lateral horizontal displacement in the steel tube-reinforced concrete composite column is calculated and analyzed the shear capability. Using the P-U curve of the computational analysis, we analyze the three main parameters, namely loading direction, concrete strength, steel strength, which have the effects on the P-U curve of steel tube-reinforced concrete composite column shear component. We draw the conclusion that the bearing capacity of the strong axis is higher than that of the weak axis, the effect of the increase of concrete strength

against the influence of shear bearing capacity is not obvious, and improving the steel yield strength can effectively improve the bearing capacity of the component.

**ABSTRACT:** How to calculate the bearing capacity of structural steel tubes and coupler scaffolds (henceforth referred to as STCS) was currently an urgent problem to be solved. Based on the previous experimental studies, advanced non-linear FEM of thirteen STCS specimens were established considering the semi-rigid character of the couplers to evaluate the critical loads and failure modes under idealized conditions in ANSYS and to compare with the experimental results. Furthermore, new simplified three-column calculation model and corresponding calculation formulas were established for the STCS under uniform load, which were verified by the experimental and analytical results and turned out to be of valuable reference in predicting the strength.

**Keywords:** structural steel tubes and coupler scaffolds; strength; semi-rigid; full-scale specimen test; three-column model for sway frame

## 1 INTRODUCTION

For many years, structural steel tubes and coupler scaffolds (hereinafter referred to as STCS) were commonly used as a temporary structure to support workers, materials and structural members during construction due to the ease of fabrication, installation and dissemination. However, structural failure of these scaffolds often occurred from time to time due to poor installation, inadequate design and knowledge of relationship between construction factor and bearing capacity.

Currently, most researchers have focused on the door-type modular steel scaffolds, high clearance scaffolds, as well as single-wall and two-wall steel tubular scaffold, but very few have focused on the STCS.

## 2 ANALYTICAL INVESTIGATION AND DISCUSSION

Full-scale static tests were conducted on thirteen STCS specimens in order to obtain the bearing capacity and failure modes of STCS and the corresponding details of all components were described in [1] and [2]. Based on the above experimental studies, advanced non-linear finite element models of thirteen STCS test specimens were established to evaluate the critical loads and failure modes under

idealized conditions in ANSYS. The geometric properties of the specimens, the test results  $P_{\text{test}}$  and the critical buckling load  $P_{\text{FEA}}$  obtained from the eigenvalue buckling analysis are listed in Table 1.

In Table 1,  $L_h$  is the lift height;  $S_1$  and  $S_2$  are the horizontal spacing of posts in transverse and longitudinal direction, respectively;  $H_1$  is the whole height of the tested STCS;  $Br$  is the sweeping staff height;  $Cl_u$  is the U-head height. The loading area was expressed by the arithmetic product of the number of spans in the transverse direction and the number of spans in the longitudinal direction.  $B_{ri}$  is the bridgings setting;  $V$  is the vertical bridgings; and  $H$  is the horizontal bridgings.

From Table 1, it can be revealed that the strength  $P_{\text{FEA}}$  was generally consistent with the full-scale test results, and the effect tendency of all geometric parameters on bearing capacity of STCS was consistent:

1. The bearing capacity of a STCS would increase to some extent if the U-head height reduced, proven by test specimen 11 ( $P_{\text{test}} = 16.64$  kN;  $P_{\text{FEA}} = 15.30$  kN) versus specimen 12 ( $P_{\text{test}} = 19.14$  kN;  $P_{\text{FEA}} = 17.86$  kN).
2. The bearing capacity of a STCS would increase to some extent if the storey height reduced, proven by test specimen 1 ( $P_{\text{test}} = 23.57$  kN;  $P_{\text{FEA}} = 19.54$  kN) versus specimen 13 ( $P_{\text{test}} = 33.90$  kN;  $P_{\text{FEA}} = 33.93$  kN);

Table 1. Comparison of FEM analysis with full-scale test results.

13	1.5	0.9×0.9	5.20	N	0.2	0.50	5×5	33.90	33.93

- The bearing capacity of a STCS would increase to some extent if the lift height and post spacing reduced together, proven by test specimen 7 ( $P_{test} = 21.74$  kN;  $P_{FEA} = 21.13$  kN) versus specimen 9 ( $P_{test} = 21.87$  kN;  $P_{FEA} = 21.58$  kN).
- The bearing capacity of a STCS would increase to some extent (increase 20%–40% approximately) if setting vertical bridgings, proven by test specimen 1 ( $P_{test} = 23.57$  kN;  $P_{FEA} = 19.54$  kN) versus specimen 2 ( $P_{test} = 28.38$  kN;  $P_{FEA} = 30.53$  kN), and that would increase to a higher extent if setting vertical and horizontal bridgings together, proven by test specimen 1 ( $P_{test} = 23.57$  kN;  $P_{FEA} = 19.54$  kN) versus specimen 3 ( $P_{test} = 36.26$  kN;  $P_{FEA} = 38.55$  kN). The degree of improvement not only changed with the geometric parameters but also the bridgings setting. This conclusion provided a useful reference for the adjustment of the calculation result of STCS without bridgings.

### 3 SIMPLIFIED ANALYSIS MODEL FOR STCS

#### 3.1 Formulation

Based on the previous research<sup>[3,4]</sup>, considering the semi-rigid characteristics of the right angle coupler, the STCS system without bridgings could be simplified into a three-dimensional multi-storey semi-rigid frame, and furthermore be simplified into a two-dimensional multi-storey frame model, with semi-rigid rotational restraints at each storey provided by the horizontal tubes and couplers. Considering that the typical failure mode of STCS without bridgings was global buckling about the weak axis, and the three-column model developed by [5], shown in Figure 1, was used to calculate the bearing capacity of STCS here. Thus, the above two-dimensional multi-storey semi-rigid

Figure 1. Three-column model for sway frame.

frame may be further simplified into a single post model.

The strength of the STCS system under a uniform load can then be calculated as a summation of the strength of each single post, which is defined by Equation (1) as follows:

$$P_{cr} = \frac{\pi^2 EI}{(\mu L_c)^2} \quad (1)$$

where  $P_{cr}$  is the strength of each single post;  $EI$  is the flexural resistance;  $\mu$  is the effective length factor of single post;  $L_c$  is the length of single post, which is equal to Lh (lift height). On this basis, considering the effect of bridgings as a safety margin received from test and FEA results, the strength of the STCS system with bridgings could thus be obtained.

### 3.2 Horizontal tube element

The horizontal tube element with semi-rigid restraints at each end is shown in Figure 2. In Figure 2,  $L_b$  is the length of the horizontal tube  $\theta_1$ ,  $\theta_2$  are the end nodal rotations at nodes 1 and 2, and  $R_{k1}$ ,  $R_{k2}$  are the rotational stiffness of springs at nodes 1 and 2, respectively. The relationship between the nodal rotations at nodes 1 and 2 under end moments  $M_1$ ,  $M_2$  are given by Equation (2) as follows:

$$\begin{aligned} M_1 &= \frac{i_b}{R^*} \left[ \left( 4 + \frac{12i_b}{R_{k2}} \right) \theta_1 + 2\theta_2 \right], \\ M_2 &= \frac{i_b}{R^*} \left[ 2\theta_1 + \left( 4 + \frac{12i_b}{R_{k1}} \right) \theta_2 \right] \end{aligned} \quad (2)$$

where

$$R^* = \left( 1 + \frac{4i_b}{R_{k1}} \right) \left( 1 + \frac{4i_b}{R_{k2}} \right) - \frac{4i_b^2}{R_{k1}R_{k2}} \quad (3)$$

$i_b = EI_b / L_b$  is the linear stiffness of the horizontal tube.

In the sway frame, assuming that the horizontal tube was bent in a double curvature, the end nodal rotations  $\theta_1$  and  $\theta_2$  were assumed to be equal at buckling. In addition, the rotational stiffness of springs at nodes 1 and 2 was a constant ( $R_{k1} = R_{k2}$ ); thus, the relationship between the nodal rotations at nodes 1 and 2 under end moments  $M_1$ ,  $M_2$  is given by Equation (4) as follows:

$$M_1 = M_2 = 6i_b \alpha_u \theta_1 \quad (4)$$

where  $\alpha_u = \left( 1 + \frac{2i_b}{R_{k1}} \right) / R^*$ .

### 3.3 Vertical post element

The vertical post element with semi-rigid restraints at each end is shown in Figure 3. The relationship between the nodal rotations at nodes A and B under end moments  $M_A$ ,  $M_B$  is given by Equation (5) as follows:

Figure 2. Horizontal tube element restrained by semi-rigid connections.

Figure 3. Vertical post element.

$$\begin{aligned} M_A &= \frac{EI_c}{L_c} \left[ S_{ii}\theta_A + S_{ij}\theta_B - (S_{ii} + S_{ij}) \frac{\Delta}{L_c} \right], \\ M_B &= \frac{EI_c}{L_c} \left[ S_{ji}\theta_A + S_{jj}\theta_B - (S_{ji} + S_{jj}) \frac{\Delta}{L_c} \right] \end{aligned} \quad (5)$$

where  $\Delta$  is the relative lateral displacement of nodes A and B;  $L_c$  is the length of the vertical post;  $\theta_A$  and  $\theta_B$  are nodal rotations at nodes. The stability function  $S_{ii} = S_{jj}$ ,  $S_{ij} = S_{ji}$  could be expressed as follows:

$$S_{ii} = S_{jj} = \frac{\frac{\pi}{\mu} \sin \frac{\pi}{\mu} - \left( \frac{\pi}{\mu} \right)^2 \cos \frac{\pi}{\mu}}{2 - 2 \cos \frac{\pi}{\mu} - \frac{\pi}{\mu} \sin \frac{\pi}{\mu}} \quad (6)$$

$$S_{ij} = S_{ji} = \frac{\left( \frac{\pi}{\mu} \right)^2 - \frac{\pi}{\mu} \sin \frac{\pi}{\mu}}{2 - 2 \cos \frac{\pi}{\mu} - \frac{\pi}{\mu} \sin \frac{\pi}{\mu}}$$

where  $\mu = \frac{\pi}{kL_c}$  and  $k = \sqrt{\frac{P}{EI_c}}$ .

### 3.4 Effective length factor $\mu$

For the three-column model shown in Figure 1, considering the boundary conditions at the distal end of vertical posts c1, c3 as the roller condition, the moments in vertical posts c1, c2, c3 at nodes A and B are given by Equations (7)–(10) as follows:

$$(M_A)_{c1} = \frac{EI_{c1}}{L_{c1}} \left( S_{ii} - \frac{S_{ij}^2}{S_{ii}} \right) \left( \theta_A - \frac{\Delta}{L_{c1}} \right) \quad (7)$$

$$(M_A)_{c2} = \frac{EI_{c2}}{L_{c2}} \left[ S_{ii}\theta_A + S_{ij}\theta_B - (S_{ii} + S_{ij}) \frac{\Delta}{L_{c2}} \right] \quad (8)$$

$$(M_B)_{c2} = \frac{EI_{c2}}{L_{c2}} \left[ S_{ji}\theta_A + S_{ii}\theta_B - (S_{ii} + S_{ij}) \frac{\Delta}{L_{c2}} \right] \quad (9)$$

$$(M_B)_{c3} = \frac{EI_{c3}}{L_{c3}} \left( S_{ii} - \frac{S_{ij}^2}{S_{ii}} \right) \left( \theta_B - \frac{\Delta}{L_{c3}} \right) \quad (10)$$

The moments in horizontal tubes b1, b2, b3, b4 at nodes A and B are given by Equation (11) as follows:

$$\begin{aligned} (M_A)_{b1} &= 6i_{b1}\alpha_u\theta_A, (M_A)_{b2} = 6i_{b2}\alpha_u\theta_A \\ (M_B)_{b3} &= 6i_{b3}\alpha_u\theta_B, (M_B)_{b4} = 6i_{b4}\alpha_u\theta_B \end{aligned} \quad (11)$$

Considering the equilibrium of vertical post c1, the equilibrium conditions at nodes A and B, and the same flexural resistance of all tubes in STCS, the following calculation equation of effective length factor  $\mu$  can be obtained:

$$\begin{aligned} &\pi \left[ (6\mu^2 - 36\mu^2K - 2\pi^2) \cos^2 \left( \frac{\pi}{\mu} \right) + (\pi^2 - 12\mu^2 \right. \\ &\quad \left. + 24\mu^2K) \cos \left( \frac{\pi}{\mu} \right) + (6\mu^2 + \pi^2 + 12\mu^2K) \right] \sin \left( \frac{\pi}{\mu} \right) \\ &\quad + \mu \left[ (12\pi^2K - 24\mu^2K - 7\pi^2) \cos^2 \left( \frac{\pi}{\mu} \right) + (9\pi^2 \right. \\ &\quad \left. + 24\mu^2K) \cos \left( \frac{\pi}{\mu} \right) + (24\mu^2K + 32\pi^2 \right. \\ &\quad \left. - 12\pi^2K) \right] \cos \left( \frac{\pi}{\mu} \right) - \mu(5\pi^2 + 24\mu^2M) = 0 \end{aligned} \quad (12)$$

where  $K = \frac{\sum_A \alpha_u EI_b / L_b}{\sum_A EI_c / h} = \frac{\sum_B \alpha_u EI_b / L_b}{\sum_B EI_c / h}$  is the end restraint coefficient of the vertical post in the sway frame model, and the length of the vertical post  $L_c$  was equal to the lift height  $h$ . The effective length factor  $\mu$  could be solved numerically. Furthermore, the strength of STCS could be received through substituting  $\mu$  into Equation (1).

#### 4 COMPARISON OF RESULTS FROM TEST, FEA AND ANALYSIS MODEL

The strength of models with various geometric parameters without bridgings  $P_{sim}$  based on the analysis model above is given in Table 2.

In Table 2, Error 1 =  $\frac{P_{sim} - P_{FEA}}{P_{FEA}} \times 100$ . From Table 2, it could be found that the effect of geometric parameters on STCS strength obtained from the analysis model is generally consistent with that obtained from FEA. The bearing capacity of a STCS increased to some extent if the lift

Table 2. Comparison between the results obtained from FEA and the simplified model.

No.	Lh (m)	$S_1 \times S_2$ (m × m)	$P_{FEA}$ (kN)	$P_{sim}$ (kN)	Error 1 (%)
1	1.5	0.9 × 0.9	19.54	11.59	-40.69
2	1.2	0.9 × 0.9	20.39	13.65	-33.06
3	0.9	0.6 × 0.6	21.13	16.47	-22.05
4	0.6	0.4 × 0.4	21.58	20.36	-5.65

height and post spacing reduced, which proved the feasibility and validity of using the three-column model to calculate the STCS strength. It could also be found that the strength  $P_{sim}$  of specimen 3 and 4 were generally consistent with the FEA results, with a maximum difference of -22.05%. Reasons attributing to the discrepancies might include the variance in the rotational stiffness of couplers, the variance in the mechanical properties of steel tubes, and initial imperfections of the steel tubes. The strength  $P_{sim}$  of specimens 1 and 2 was not consistent with the FEA results. The reasons attributing to these discrepancies not only include the above factors, but also include that the effect of additional spans was considered in these two specimens in the FEA but not considered in the simplified model, and the presence of additional spans could increase the system's strength significantly.

#### 5 CONCLUSIONS

1. From the full-scale tests and FEM analyses, it was clear that the bearing capacity of STCS was affected by a series of erection parameters such as lift height, spacing of vertical post, erection height, bridgings setting, and U-head height, and the existence of bridgings and additional spans could increase the strength of STCS significantly.
2. A simplified three-column model was developed for the STCS post, and design formulas were established for calculating the strength of a single post. Both the simplified model and the formulas were verified by the full-scale test and analytical results. In practical projects, the effect of bridgings could be seemed as a safety margin based on these findings.

**ABSTRACT:** Structural Steel Tube and Coupler Scaffolds (STCS) have collapsed quite often at many sites, with a considerable number of reported casualties. However, their behavior has not been studied to the same extent as that of many other permanent structures. Using advanced nonlinear finite element analysis on different STCS models, the strength and failure modes of the STCS's were evaluated in this paper. Furthermore, a simplified model using the theory of single multi-story post with four semi-rigid restraints and corresponding calculation formulae were established for the bearing capacity of STCS. The above presented simplified structural model and formulas are verified by the analytical results, and it has been turned out to be accurate enough for predicting the strength of STCS's.

**Keywords:** structural Steel Tube and Coupler Scaffold; bearing capacity; semi-rigid; finite element analysis; simple formula

## 1 INTRODUCTION

Structural Steel Tube and Coupler Scaffolds (STCS) have been widely used as temporary structures in concrete casting construction, which involves the handling of large loads, in countries such as China and the United Kingdom because of their ease of fabrication, installation, and dissemination. However, STCS failures often occur on construction sites, which cause not only project delays but also serious injuries and casualties among construction workers.

To enhance the safety of scaffolds during construction, experimental and analytical studies had been conducted in the past on the structural behavior of high-clearance scaffolds [1,2], multi-story door-type modular steel scaffolds, single-pole and double-pole steel tubular scaffolds [3]. However, almost no research had been conducted on STCS, which are widely used in China and the UK in the construction of large-span spatial structures such as gymnasiums, train stations, and bridges. So, it is extremely important to understand the structural behavior of STCS's through both experimental and analytical studies and propose rational design recommendations.

On the basis of right angle coupler torsion stiffness tests and thirteen prototype tests on STCS that described in [4] and [5] respectively, the critical

loads and failure modes of many STCS with and without bridging were evaluated using non-linear FEM in ANSYS, and the effect of a series of erection parameters on bearing capacity of STCS was studied quantitatively. Furthermore, a simplified model and formula were put forward for the strength of STCS which consider the semi-rigid character of right-angle couplers and the effect of adjacent horizontal tubes.

## 2 ANALYTICAL INVESTIGATION

Commercial Finite Element Analysis (FEA) software ANSYS was used to study the behavior of STCS models that are commonly used in actual projects. To simulate the semi-rigid behavior of the couplers, a spring-damper element (COMBIN14) was added to simulate the in-plane rotational restraints provided by the couplers. The spring constant was set to 19.0 kN·m/rad, which was the mean initial rotational stiffness obtained from previous coupler tests. The geometric properties of the models and the FEM analysis results are summarized in Table 1. In Table 1,  $\text{Diff} = (P_{b\text{FEA}} - P_{\text{FEA}}) / P_{\text{FEA}} \times 100$ .

From Table 1, it could be concluded that the STCS strength increased to some extent because of

Figure 1. Failure modes identified from nonlinear FEA.

the existence of bridging, but the degree of improvement changed with the geometric parameters and bridging setting. All the above nonlinear analysis results indicated that the typical failure mode of STCS's without bridging was global lateral buckling about the longitudinal weak axis. However, the typical failure mode of STCS's with bridging was local buckling with a large wavelength ranging from two to four times the lift height, which depended on the bridging setting pattern. Typical failure modes identified from the FEA are shown in Figure 1.

### 3 SIMPLIFIED MODEL FOR STCS'S

Considering the semi-rigid characteristics of the right-angle coupler, the STCS system without bridging could be simplified into a three-dimensional multi-story semi-rigid frame. Based on previous research, the STCS system could be simplified into a two-dimensional model and further simplified into a one-dimensional multi-story post, with semi-rigid rotational restraints provided by the horizontal tubes and couplers at each story. The rotational restraint at each story could be expressed by a rotational spring with a rotational stiffness  $C$ . The rotational stiffness  $C$  could be deduced using the slope-deflection method.

Furthermore, the strength of the STCS without bridging under a uniform load could then be calculated as a summation of the strength of each multi-story post, which is defined as

$$P = \frac{\pi^2 EI}{(\mu h)^2} \quad (1)$$

where  $P$  is the strength of a single multi-story post,  $EI$  is the flexural resistance of the steel tube,  $\mu$  is the effective length factor for a single multi-story post with semi-rigid restraints at each story, and  $h$  is the lift height.

From the above FEA results, it was clear that the strength of an STCS increased significantly when the bridging was present; therefore, the bridging is generally required in actual engineering projects. The effective length factor  $\mu$  for a single multi-story post with semi-rigid restraints at each story could be calculated by analyzing the limit state during buckling of the STCS at different bridging settings, and furthermore, the strength of the STCS system without bridging could be determined while considering the effect of bridging as a safety margin. Thus, the strength of the STCS system with bridging could be determined. A simplified model with a buckling wavelength of approximately 3 times the lift height is shown in Figure 2.

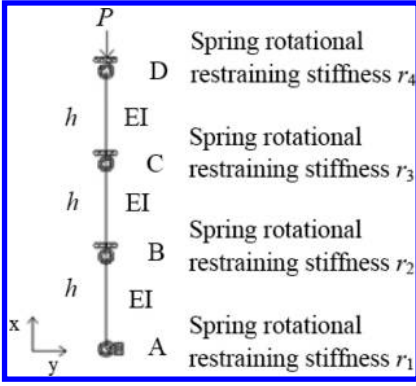

Figure 2. Model for a single multi-story post with four semi-rigid restraints at each story.

In this model, the rotational restraining stiffnesses of the four springs were assumed to be  $r_1$ ,  $r_2$ ,  $r_3$ , and  $r_4$ , considering the variance in the rotational stiffness of couplers and the mechanical properties of steel tubes. The rotational angles of springs at points A, B, C, and D were  $\theta_1$ ,  $\theta_2$ ,  $\theta_3$ , and  $\theta_4$ , respectively, and the vertical post AD underwent buckling. In Figure 2,  $x$  represents the coordinate along the span and  $y$  represents the transverse nodal displacement. The equilibrium of the post under the critical buckling condition is described by the following differential equations.

For  $0 < x < h$ , the equilibrium equation is:

$$-EIy_1'' + r_1\theta_1 = Py_1 \quad (2)$$

Assuming  $k^2 = P/EI$ , the following formula is obtained:

$$y_1'' + k^2y_1 - \frac{r_1\theta_1}{EI} = 0 \quad (3)$$

The general solution of differential equation (3) is given by

$$y_1(x) = \sin(kx) \times C_1 + \cos(kx) \times C_2 + \frac{r_1\theta_1}{k^2EI} \quad (4)$$

The boundary conditions are as follows:

1. At  $x = 0$ , the horizontal displacement is 0:

$$y_1(0) = 0 \quad (5)$$

2. At  $x = 0$ , the shear force is 0:

$$-(EIy_1'''(0) + Py_1'(0)) = 0 \quad (6)$$

Substituting Eqs. (5) and (6) into Eq. (4), the following equation is obtained:

$$y_1 = \frac{\sin(kx)\theta_1}{k} - \frac{\cos(kx)r_1\theta_1}{k^2EI} + \frac{r_1\theta_1}{k^2EI} \quad (7)$$

For  $h < x < 2h$ , the equilibrium equation is

$$-EIy_2''' + r_1\theta_1 + r_2\theta_2 = Py_2 \quad (8)$$

The general solution of differential equation (8) is

$$y_2(x) = \sin(kx) \times C_3 + \cos(kx) \times C_4 + \frac{r_1\theta_1 + r_2\theta_2}{k^2EI} \quad (9)$$

The boundary conditions are as follows:

1. At  $x = h$ , the shear force is 0:

$$-(EIy_2'''(h) + P\theta_2) = 0 \quad (10)$$

2. At  $x = 2h$ , the shear force is 0:

$$-(EIy_2'''(2h) + P\theta_3) = 0 \quad (11)$$

Substituting Eqs. (10) and (11) into Eq. (9), the following equation is obtained:

$$y_2 = -\frac{1}{\sin(kh)k^2EI} \times (-kEI\theta_3\cos(kx - kh) + kEI\theta_2\cos(kx - 2kh) + \sin(kh)r_1\theta_1 + \sin(kh)r_2\theta_2) \quad (12)$$

For  $2h < x < 3h$ , the equilibrium equation is

$$-EIy_3''' + r_1\theta_1 + r_2\theta_2 + r_3\theta_3 = Py_3 \quad (13)$$

The general solution of differential equation (13) is

$$y_3(x) = \sin(kx) \times C_5 + \cos(kx) \times C_6 + \frac{r_1\theta_1 + r_2\theta_2 + r_3\theta_3}{k^2EI} \quad (14)$$

The boundary conditions are as follows:

1. At  $x = 3h$ , the shear force is 0:

$$-(EIy_3'''(3h) + P\theta_4) = 0 \quad (15)$$

2. At  $x = 2h$ , the shear force is 0:

$$-(EIy_3'''(2h) + P\theta_3) = 0 \quad (16)$$

Substituting Eqs. (15) and (16) into Eq. (14), the following equation is obtained:

$$y_3(x) = \frac{1}{k^2 \sin(kh)EI} \times (-kEI \theta_4 \cos(kx - 2kh) + kEI \theta_3 \cos(kx - 3kh) + \sin(kh)r_1 \theta_1 + \sin(kh)r_2 \theta_2 + \sin(kh)r_3 \theta_3) \quad (17)$$

The compatibility conditions among the three tubes are as follows:

1. At  $x = 2h$ , the tubes had the same displacement:

$$y_2(2h) = y_3(2h) \quad (18)$$

2. At  $x = h$ , the tubes had the same displacement:

$$y_1(h) = y_2(h) \quad (19)$$

3. At  $x = h$ , the tubes had the same rotation angle:

$$y_1'(h) = y_2'(h) \quad (20)$$

The following formula is obtained based on the boundary condition at  $x = 3h$ :

$$M_{(3h)} = r_4 \theta_4 \quad (21)$$

If all the four spring rotational restraining stiffnesses were the same, it could be assumed that  $r_1 = r_2 = r_3 = r_4 = C$ . The linear rigidity of the vertical post was assumed to be  $C_c = EI/3h$ ,  $kh = \pi/\mu$ , and the final governing equation for determining the effective length factor  $\mu$  is obtained by simplifying the above simultaneous equations Eqs. (18) to (21):

$$\begin{aligned} & \left[ (324\pi^3 \mu C C_c^3 - 18\pi \mu^3 C^3 C_c) \cos^3\left(\frac{\pi}{\mu}\right) + (18\pi \mu^3 C^3 C_c \right. \\ & \left. - 216\pi^3 \mu C C_c^3) \cos\left(\frac{\pi}{\mu}\right) \right] \sin\left(\frac{\pi}{\mu}\right) + (324\pi^4 C_c^4 + \mu^4 C^4 \\ & - 117\pi^2 \mu^2 C^2 C_c^2) \cos^4\left(\frac{\pi}{\mu}\right) + (-2\mu^4 C^4 - 405\pi^4 C_c^4 \\ & + 144\pi^2 \mu^2 C^2 C_c^2) \cos^2\left(\frac{\pi}{\mu}\right) \\ & + (\mu^4 C^4 - 27\pi^2 \mu^2 C^2 C_c^2 + 81\pi^4 C_c^4) = 0 \end{aligned} \quad (22)$$

#### 4 COMPARISON BETWEEN THE SIMPLIFIED MODEL CALCULATION RESULTS AND FEA RESULTS

The strengths of the models with various geometric parameters without bridging  $P_{sim}$  were calculated

Table 2. Comparison between strengths determined from FEA and the simplified model.

No.	h (m)	$S_1 \times S_2$ (m $\times$ m)	$P_{FEA}$ (kN)	$P_{sim}$ (kN)	Error (%)
1	1.5	0.9 $\times$ 0.9	22.43	20.73	-7.58
2	0.9	1.2 $\times$ 1.2	21.46	22.32	4.01
3	0.9	1.0 $\times$ 1.0	22.08	22.77	3.13
4	0.9	0.9 $\times$ 0.9	24.67	23.01	-6.73

using Eq. (22), as listed in Table 2. In the table, the error represents the difference between  $P_{sim}$  and  $P_{FEA}$ . Accordingly,  $P_{sim}$  could be modified by considering the effect of the safety margin of bridging according to different bridging settings, and the degree of improvement could reference the results that listed in the fifth column in Table 1 approximately. in Table 2  $P_{sim}$  = strength determined from a simplified model calculation. Error =  $(P_{sim} - P_{FEA})/P_{FEA} \times 100$ .

#### 5 CONCLUSIONS

1. From the FEM analyses, it was clear that the main failure mode of the STCS without bridging was global flexural buckling about the longitudinal weak axis and that of the STCS with bridging was local buckling.
2. From FEM analysis results list in Table 1, it was clear that the strength of the STCS was affected by a number of erection parameters such as the lift height, spacing between vertical posts, erection height, U-head height, and it could increase significantly because of the existence of bridging.
3. A simplified model was developed for the STCS post and design formulae were established for calculating the strength of a multi-story post with semi-rigid rotational restraints at each story. The strength of the STCS system without bridging under a uniform load was then calculated as the summation of the strength of each single multi-story post. Accordingly, considering the effect of the bridging setting as a safety margin, the strength of the STCS system with bridging was determined by adjusting the result of the STCS system without bridging.

## Vibrations and buckling analysis of Mindlin plates with stepped variable thickness

S.F. Yang, H. Chen & J.P. Wei

*Chongqing Creation Vocational College, Chongqing, China*

**ABSTRACT:** A new semi-analytical solution has been developed based on the domain superposition method and the differential cubature method as well as the Levy's general solution, for buckling and free vibration analysis of moderately thick plates having stepped thickness. Through Fourier series expansion, the governing equations and boundary conditions of the plate are transformed to one-dimensional differential equations. Then these equations are discretized into several linear algebraic equations by the general differential cubature element method. The basic idea of the differential cubature element method is to divide the entire variable domain into several sub-domains (elements) and to apply the differential cubature method for each element. Compatibility conditions are developed for the conjunction nodes on the interface points of elements in order to connect the elements. When the plate boundary conditions are introduced, a set of algebraic homogeneous equations about the displacements of grid points can be derived. This is a standard eigenvalue problem, from which the buckling parameters and natural frequencies of the plate can be calculated numerically. The convergent characteristics and comparison studies are carried out carefully in order to verify the present method. Also, some new results are tabulated for engineers and investigators to use as benchmarks in future studies.

**Keywords:** stepped thick plates; buckling; free vibration; differential cubature method; domain superposition

### 1 INTRODUCTION

Plates with stepped variable thickness have very wide applications in modern structural engineering. As it can save materials, reduce weight, increase stiffness and improve fundamental frequency, its excellent performance arouses people's interest to research stability and free vibration of this structure, etc. in recent decades. For such problems, many scholars proposed various theories and adopted a variety of methods for extensive study. Chopra<sup>[2]</sup> divided stepped plate into several homogeneous regions, assumed continuous and boundary conditions at the mutation thickness and obtained eigenvalue equation of the problem. However, it has error in dealing with bending moment and shearing force consecutive conditions at the section, as what Yuan and Dickinson<sup>[19]</sup> pointed out. Cortinez and Laura<sup>[6]</sup> adopted Kantorovich continuation method to analyze natural vibration frequency of stepped plate. The formula contains an index optimization parameter. Bambill, etc.<sup>[1]</sup> combined Rayleigh-Ritz solution and Fourier series expansion technique, obtained base and of simply supported rectangular stepped plate. However, continuous assumption of displacement function at the cross-section

is the flaw. Harik, etc.<sup>[9]</sup> made modification when dealing with continuity conditions, used the modified analytical spline to satisfy mutation condition in one direction. Yuan and Dickinson<sup>[19]</sup> used method proposed by Chopra<sup>[2]</sup>, modified continuous condition of bending moment and shearing force, and obtained the exact vibration frequency of stepped plate under simply supported boundary condition. Recently, Cheung introduced a set of interpolation functions that meet C1 continuous condition to solve buckling issue<sup>[5]</sup> of stepped variable section plate. These interpolation functions are composed of beam modal function and piecewise cubic polynomial. The author pointed out: These displacement functions are with advantages of fast convergence, appropriate continuous order and high accuracy of harmonic function. Yingshi Zhang and Chiping Jiang used singular function to establish continuous differential equation of stepped thin plate and provided analytical solution<sup>[22]</sup> of free vibration and forced vibration of stepped plate under various boundary conditions with operator operation.

It is worth noting that, there are two important directions in stepped research: one is committed to seeking the plate analytical solution to

verify calculation accuracy of various numerical solution; the other focuses on establishment of theoretical models of various plates to adapt to a variety of different applications. In this paper, on the basis of Mindlin plate model, semi-analytical method to solve stepped plate with two opposite edges simply supported will be given. First, it uses Levy's solving technique, assumes that displacement function is harmonic function that meets boundary condition in the direction of simply supported edge, substitutes it into governing equation to transform the problem into a one-dimensional one, then uses differential quadrature numerical method for solution.

Differential quadrature method first proposed by Civan<sup>[3-4]</sup> aims to simply and efficiently solve multi-dimensional high-order differential equation, a numerical method for direct holistic dissociation of governing differential equation based on polynomial. Its biggest features are simple formula, easiness to prepare computer program, and overall good convergence. Recently, Liew and Liu, mechanical workers, introduced the method into engineering applications to solve the bending problem<sup>[13-15]</sup> of thin plate and thick plate of arbitrary shape, and achieved very good numerical results. On this basis, Lanhe Wu applied this method to project eigen value problem for the first time to solve free vibration<sup>[20]</sup> of rounded rectangular plate, and also received good results. However, this method can only be used to solve the problem of uniform continuous geometry, unable to be directly applied to solve problems such as stepped plate. To this end, Lanhe Wu combined regional superposition method and differential volumetric method, proposed differential cubature element method<sup>[21]</sup>, and solved vibration problem of plate with mutation geometry characteristic. However, although this method can solve two-dimensional problem in principle, in fact, it is simpler and more effective for one-dimensional problem. Based on the previous study, the paper first uses Fourier series expansion, transforms two-dimensional problem into one-dimensional one, and then reuses one-way differential cubature method to disperse, which gives full play to the advantages of analytical method and differential cubature method and thus is a good method.

## 2 BASIC FORMULA

Considering the rectangular plate shown in Figure 1, we can assume that the plate is only stepped in the direction of  $x$ . Based on the actual thickness mutation, it can be divided into several units in the direction of  $x$ . Each unit has a uniform thickness, uniform boundary condition and

continuous geometry, wherein thickness, rotational inertia of unit  $l$  are  $h_l, J_l$  respectively, elastic modulus, shear modulus, Poisson's ratio and density of the material are  $E, G, \nu, \rho$  respectively. According to Mindlin plate theory, the governing differential equation is

$$\begin{aligned} \frac{D_l}{2} \left[ (1-\nu) \nabla^2 \psi_x + (1+\nu) \frac{\partial \phi}{\partial x} \right] - kGh_l \left( \psi_x + \frac{\partial w}{\partial x} \right) + \rho J_l \omega^2 \psi_x &= 0 \\ \frac{D_l}{2} \left[ (1-\nu) \nabla^2 \psi_y + (1+\nu) \frac{\partial \phi}{\partial y} \right] - kGh_l \left( \psi_y + \frac{\partial w}{\partial y} \right) + \rho J_l \omega^2 \psi_y &= 0 \\ kGh_l (\nabla^2 w + \phi) + \rho h_l \omega^2 w - N \left( \beta \frac{\partial^2 w}{\partial x^2} + \gamma \frac{\partial^2 w}{\partial y^2} \right) &= 0 \end{aligned} \quad (1)$$

where in

$$\phi = \frac{\partial \psi_x}{\partial x} + \frac{\partial \psi_y}{\partial y} \quad (2)$$

In the formula,  $w$  is lateral deflection of plate;  $\psi_x$  and  $\psi_y$  are average angles of the middle surface normal around  $x$  and  $y$  axis respectively;  $k$  is shear correction factor, taken as  $5/6$ ;  $J_l = h_l^3/12$  is rotational inertia of plate;  $D_l = Eh_l^3/[12(1-\nu^2)]$  is bending stiffness of plate;  $\omega$  is system angular frequency;  $N$  is load factor;  $\beta$  and  $\gamma$  are load combination factors;  $\nabla^2$  is two-dimensional Laplace operator.

According to the relationship between internal force and displacement, plate bending moment,

Figure 1. Geometry graph and coordinate of stepped rectangular plate.

torque and shearing force can be expressed with plate deflection and rotation as

$$\begin{aligned} M_x &= D_l \left( \frac{\partial \psi_x}{\partial x} + \nu \frac{\partial \psi_y}{\partial y} \right), \\ M_y &= D_l \left( \nu \frac{\partial \psi_x}{\partial x} + \frac{\partial \psi_y}{\partial y} \right), \\ M_{xy} &= \frac{1-\nu}{2} D_l \left( \frac{\partial \psi_x}{\partial y} + \frac{\partial \psi_y}{\partial x} \right) \\ Q_x &= kGh_l \left( \psi_x + \frac{\partial w}{\partial x} \right), \quad Q_y = kGh_l \left( \psi_y + \frac{\partial w}{\partial y} \right) \end{aligned} \quad (3)$$

If the plate is simply supported at both sides ( $y=0, L$ ) parallel to the  $x$  axis, then the corresponding boundary condition is

$$w = 0; \quad M_y = 0; \quad \psi_x = 0 \quad (4)$$

Assume

$$\psi_x = \Psi_x \sin \frac{n\pi y}{L}, \quad \psi_y = \Psi_y \cos \frac{n\pi y}{L}, \quad w = W \sin \frac{n\pi y}{L} \quad (5)$$

Apparently, it meet simply supported boundary condition in formula (4). Substitute (5) into (1) and obtain

$$\begin{aligned} D_l \left[ \frac{\partial^2}{\partial x^2} - \frac{1-\nu}{2} \left( \frac{n\pi}{L} \right)^2 - kGh_l \right] \Psi_x \\ - \frac{1+\nu}{2} D_l \left( \frac{n\pi}{L} \right) \frac{\partial \Psi_y}{\partial x} - kGh_l \frac{\partial W}{\partial x} + \rho J_l \omega^2 \Psi_x = 0 \\ \frac{1+\nu}{2} D_l \left( \frac{n\pi}{L} \right) \frac{\partial \Psi_x}{\partial x} + D_l \left[ \frac{1-\nu}{2} \frac{\partial^2}{\partial x^2} - \left( \frac{n\pi}{L} \right)^2 - kGh_l \right] \Psi_y \\ - kGh_l \left( \frac{n\pi}{L} \right) W + \rho J_l \omega^2 \Psi_y = 0 \\ kGh_l \frac{\partial \Psi_x}{\partial x} - kGh_l \left( \frac{n\pi}{L} \right) \Psi_y + kGh_l \left[ \frac{\partial^2}{\partial x^2} - \left( \frac{n\pi}{L} \right)^2 \right] W \\ - N \left[ \beta \frac{\partial^2}{\partial x^2} - \gamma \left( \frac{n\pi}{L} \right)^2 \right] W + \rho h_l \omega^2 W = 0 \end{aligned} \quad (6)$$

So the two-dimensional problem is transformed into a one-dimensional one. Now, use differential cubature method to disperse equation (6). As shown in Figure 2. In the entire structure, arbitrarily set  $e$  collocation points along the direction of  $x$ . Assume the starting end collocation point mark

Figure 2. Structure collocation point setting along the direction of  $x$ .

of unit  $l$  is  $m$ , tail end collocation point mark is  $k$ , coordinate of each collocation point is  $x_i (i = m, m+1, \dots, k)$ . To disperse the equation, first define linear differential operator as follows

$$\hat{\lambda}_1 = \frac{d}{dx}, \quad \hat{\lambda}_2 = \frac{d^2}{dx^2} \quad (7)$$

With step of differential cubature method, governing equation (6) in collocation point  $i$  in unit  $l$  can be dispersed into [3-4]

$$\begin{aligned} D_l \left[ \sum_{j=m}^k C_{ij}^{(2)} \Psi_{xj} - \frac{1-\nu^2}{2} \left( \frac{n\pi}{L} \right)^2 \Psi_{xi} - kGh_l \Psi_{xi} \right] \\ - \frac{1+\nu}{2} \left( \frac{n\pi}{L} \right) D_l \sum_{j=m}^k C_{ij}^{(1)} \Psi_{yj} - kGh_l \sum_{j=m}^k C_{ij}^{(1)} W_j \\ + \rho J_l \omega^2 \Psi_{xi} = 0 \\ \frac{1+\nu}{2} \left( \frac{n\pi}{L} \right) D_l \sum_{j=m}^k C_{ij}^{(1)} \Psi_{xj} \\ + D_l \left[ \frac{1-\nu}{2} \sum_{j=m}^k C_{ij}^{(2)} \Psi_{yj} - \left( \frac{n\pi}{L} \right)^2 \Psi_{yi} - kGh_l \Psi_{yi} \right] \\ - kGh_l \left( \frac{n\pi}{L} \right) W_i + \rho J_l \omega^2 \Psi_{yi} = 0 \\ kGh_l \sum_{j=m}^k C_{ij}^{(1)} \Psi_{xj} - kGh_l \left( \frac{n\pi}{L} \right) \Psi_{yi} \\ + kGh_l \left[ \sum_{j=m}^k C_{ij}^{(2)} w_j - \left( \frac{n\pi}{L} \right)^2 w_i \right] \\ - N \left[ \beta \sum_{j=m}^k C_{ij}^{(2)} w_j - \gamma \left( \frac{n\pi}{L} \right)^2 w_i \right] + \rho h_l \omega^2 w_i = 0 \\ (i = m, m+1, \dots, k) \end{aligned} \quad (8)$$

$C_{ij}^{(a)}$  in all the above formula corresponds to quadrature coefficient of differential cubature method of operator  $\hat{\lambda}_a (a=1,2)$ , which can be solved by means of a set of linearly independent monomials, i.e.

$$\begin{aligned} \sum_{j=m}^k C_{ij}^{(\alpha)} (x_j^p) = \hat{\lambda}_\alpha (x_i^p); \quad i = m, 2 \dots, k; \\ p = 0, 1, 2, \dots, k-m \end{aligned} \quad (9)$$

At this point, governing equation has been dispersed into a system of linear algebraic equations concerning collocation point displacement within the unit  $l$ . The connection point of unit  $l-1$  and unit  $l$  should meet the following continuity condition and equilibrium condition

$$\begin{aligned} \Psi_{xm}^{(l-1)} &= \Psi_{xm}^{(l)}; \Psi_{ym}^{(l-1)} = \Psi_{ym}^{(l)}; W_m^{(l-1)} = W_m^{(l)}; \\ M_{xm}^{(l-1)} &= M_{xm}^{(l)}; M_{xym}^{(l-1)} = M_{xym}^{(l)}; \\ Q_{xm}^{(l-1)} - \beta N \frac{\partial W^{(l-1)}}{\partial x} \Big|_{x=x_m} &= Q_{xm}^{(l)} - \beta N \frac{\partial W^{(l)}}{\partial x} \Big|_{x=x_m} \end{aligned} \quad (10)$$

If nodes in various units are consecutively numbered in unification, displacement continuity condition in connection conditions will certainly be met, and then there is only need to consider the later three equations in formula (10). With differential cubature method, values of plate internal force at various points can be represented as weighted combination of all collocation point displacement within the unit

$$\begin{aligned} M_{xi}^{(l)} &= D_l \left[ \sum_{j=m}^k c_{ij}^{(l)} \Psi_{xj} - \nu \left( \frac{n\pi}{L} \right) \Psi_{yi} \right] \sin \frac{n\pi y}{L} \\ M_{xyi}^{(l)} &= \frac{1-\nu}{2} D_l \left[ \sum_{j=m}^k c_{ij}^{(l)} \Psi_{yj} + \left( \frac{n\pi}{L} \right) \Psi_{xi} \right] \cos \frac{n\pi y}{L} \\ Q_{xi}^{(l)} &= kGh_l \left( \sum_{j=m}^k c_{ij}^{(l)} W_j + \Psi_{xi} \right) \sin \frac{n\pi y}{L} \end{aligned} \quad (11)$$

Equilibrium condition of plate at connection point  $m$  can be expressed as

$$\begin{aligned} D_{l-1} \left[ \sum_{j=1}^m c_{ij}^{(l)} \Psi_{xj} - \nu \left( \frac{n\pi}{L} \right) \Psi_{ym} \right] &= D_l \left[ \sum_{j=m}^k c_{ij}^{(l)} \Psi_{xj} - \nu \left( \frac{n\pi}{L} \right) \Psi_{ym} \right] \\ D_{l-1} \left[ \sum_{j=1}^m c_{ij}^{(l)} \Psi_{yj} + \left( \frac{n\pi}{L} \right) \Psi_{xm} \right] &= D_l \left[ \sum_{j=m}^k c_{ij}^{(l)} \Psi_{yj} + \left( \frac{n\pi}{L} \right) \Psi_{xm} \right] \\ kGh_{l-1} \left( \sum_{j=1}^m c_{ij}^{(l)} W_j + \Psi_{xm} \right) - \beta N \sum_{j=1}^m c_{ij}^{(l)} W_j &= kGh_l \left( \sum_{j=m}^k c_{ij}^{(l)} W_j + \Psi_{xm} \right) - \beta N \sum_{j=m}^k c_{ij}^{(l)} W_j \end{aligned} \quad (12)$$

Apply boundary condition at both left and right ends ( $x = x_1, x_e$ ) of plate

$$\text{Simply supported edge (S): } W = 0; M_x = 0; \Psi_y = 0 \quad (13)$$

$$\text{Fixed edge (C): } W = 0; \Psi_x = 0; \Psi_y = 0 \quad (14)$$

$$\text{Free edge (F): } Q_x = \beta N \frac{\partial W}{\partial x}; M_x = 0; M_{xy} = 0 \quad (15)$$

These equations can also be dispersed with differential cubature method. Now, with point 1 as example, write the boundary condition after dissociation

Simply supported edge (S):

$$D_1 \left[ \sum_{j=1}^t c_{ij}^{(l)} \Psi_{xj} - \nu \left( \frac{n\pi}{L} \right) \Psi_{y1} \right] = 0; \Psi_{y1} = 0; W_1 = 0 \quad (16)$$

$$\text{Fixed edge (C): } W_1 = 0; \Psi_{x1} = 0; \Psi_{y1} = 0 \quad (17)$$

Free edge (F):

$$\begin{aligned} D_1 \left[ \sum_{j=1}^t c_{ij}^{(l)} \Psi_{xj} - \nu \left( \frac{n\pi}{L} \right) \Psi_{y1} \right] &= 0; \\ \frac{1-\nu}{2} D_1 \left[ \left( \frac{n\pi}{L} \right) \Psi_{x1} + \sum_{j=1}^t c_{ij}^{(l)} \Psi_{yj} \right] &= 0; \\ kGh_l \Psi_{x1} + kGh_l \sum_{j=1}^t c_{ij}^{(l)} W_j &= \beta N \sum_{j=1}^t c_{ij}^{(l)} W_j \end{aligned} \quad (18)$$

To solve the critical load and inherent frequency of the entire plate, frequency equation of the entire system needs to be established. To this end, all collocation points within the plate zone need to be numbered in unification (overall coding). Then collect the governing equation sets at various nodes together and write in matrix form as follows

$$([K] - \omega^2 [M] - N[\bar{K}])\{d\} = 0 \quad (19)$$

In the formula,  $K$ ,  $M$  and  $\bar{K}$  are structural stiffness matrix, mass matrix and geometric stiffness matrix;  $\{d\}$  is displacement array of the entire structure at various collocation points.

It should be noted that, at connection points of adjacent units, equilibrium condition of connection points between the various units should be used to substitute their respective equations, while applying corresponding boundary condition at both end points.

### 3 CALCULATION EXAMPLES AND DISCUSSION

To facilitate expression, define dimensionless critical load factor and frequency factor as follows

$$\lambda = N_{cr}L^2/(\pi^2 D_1), \quad \Omega = (\omega L^2/\pi^2)\sqrt{\rho h_1/D_1} \quad (20)$$

wherein,  $h_1$  and  $D_1$  are thickness and bending stiffness of first-order plate.

First, with second-order plate of equal length as example, study convergence of the research method. Assume  $h_2/h_1 = 1.1$ ,  $h_1/L = 0.1$ . Apparently, in calculation, the plate should be divided into two units in the direction of  $x$ . Convergence situation of buckling load factor  $\lambda$  of the plate in one-way compression ( $\beta = 1$ ,  $\gamma = 0$ ) corresponding to the collocation point number  $e$  in each unit is shown in Figure 3, in which the letters C, F, S respectively denote the fixed, free and simply supported boundary conditions. As can be seen from the figure, regardless of what kind of boundary condition, load factor  $\lambda$  can quickly converge. We can also see that when the plate has free edge, the convergence is alternating and turbulence-like, and when the plate boundary doesn't have free edge, convergence shows monotone decreasing. Figure 4-6 depicts convergence of the first sixth-order frequency factor of the plate with different boundary conditions. Also, it can be seen that this method has very good convergence. In particular, the first second-order frequency converges very quickly. In general, setting 11 collocation points within a unit can render sufficient accuracy. In the following calculations, set 11 collocation points within each unit. It can be seen from the figure that, when plate has free edge, convergence is poor, remaining turbulence-like.

Figure 3. Convergence situation of critical load factor  $\lambda$  under one-way second-order plate compression.

Figure 4. Convergence situation of inherent frequency factor  $\Omega$  of second-order plate with two opposite edges simply supported.

Figure 5. Convergence situation of inherent frequency factor  $\Omega$  of second-order plate with two opposite free edges.

Figure 6. Convergence situation of inherent frequency factor  $\Omega$  of second-order plate with two opposite fixed edges.

For verification of calculation accuracy, compare critical load factor and vibration frequency factor of second-order thin plate with two opposite edges simply supported, with different relative thicknesses and geometry sizes under one-way compression to the relevant results, as shown in Figure 7. Table 1 and Table 2 are calculation and

comparison results. In calculation of critical load factor, Table 1 shows the critical load factors of thin plates with different relative thicknesses. As can be seen from Table 1, the results coincide with those in other literatures, with good accuracy. In addition, the maximum relative errors between the result in this paper and paper [7], [17], [18] are respectively. Obviously, the values given by Eisenberger and Alexandrov differ from the results of this paper and other literatures. In fact, what they give is third-order buckling load, not the minimum critical load. The result of this paper is correct. Table 2 shows a comparison of inherent frequency, with  $h_1/L = 0.005$ ,  $a = 1$  in calculation of inherent frequency. The table shows inherent frequency factors of plates of different sizes and different relative thickness. As can be seen, the result of this paper is slightly larger than those given by Xiang<sup>[18]</sup> and Yuan<sup>[19]</sup>. Despite the maximum relative errors of, respectively between this result and them, it still has a relatively good calculation accuracy.

Based on the above comparative study of convergence and numerical accuracy, this paper calculates buckling load and inherent frequency of multi-order plates with variable thickness, as listed in Table 3 and Table 4. In calculation,  $h_1/L = 0.1$  is taken. Different combinations of S, F, C in the table represent different boundary conditions. As can be seen from Table 3, along with the enhancement of boundary constraint, critical load factor increases; critical load factor varies little with the order number of plate, as the plate buckling factor is mainly determined by first-order thin plate. We also find that right end boundary condition of plate exerts relatively large influence on critical load factor, but the influence from left end boundary condition is small. This is because flexural rigidity of plate mainly concentrates on the right end. Naturally, the

	6	3.4624	2.5789	3.7350	2.9943	3.1203	3.6069

boundary condition on the end has relatively large influence on buckling factor. Table 4 shows the inherent frequencies of the first six orders of plate. Different from critical load factor, we see that, for the most part, with the increasing order number of plate, inherent frequency factor will decrease, especially high order frequency.

#### 4 CONCLUSION

This paper adopts a new numerical method—Differential Cubature Element method (DCE) and combines Levy solving technique to solve the problem of buckling free vibration of stepped plate with boundary condition of two opposite simply supported edges. By assuming displacement function of order form, it transforms two-dimensional problem into one-dimensional one, and then begins unit division in one-dimensional domain, sets collocation points in each unit, disperses governing equation and boundary conditions into a set of homogeneous linear algebraic equations with differential cubature method and obtains classic eigenvalue problem. Convergence analysis and numerical accuracy study confirms feasibility and effectiveness of the proposed method.

With the characteristics of good convergence, high accuracy of differential cubature method and strong feasibility of finite element method, the method proposed by the paper is good.

M.S. Jiang

Logistics Department of National University of Defence Technology, Changsha, China

**ABSTRACT:** To feature river-crossing and bridging equipment with characteristics such as light weight, fast set up, small storage volume, high load bearing capacity and low construction costs, the Tensairity structure was introduced into the design of bridge section in this paper. By using the Patran/Nastran software, a finite element model of the Tensairity bridge section was established in numerical simulation analysis, the distortion and stress of the structure under the effect of typical wheel load was studied, and the limit of load bearing capacity of the structure was obtained. Studies in this paper provide technical support for the research on new river-crossing and bridging equipment.

**Keywords:** airbag; beam string structure; Tensairity bridge section; numerical simulation

### 1 INTRODUCTION

Traditional river-crossing and bridging equipments have drawbacks such as heavy weight, large volume, slow erection, low load bearing capacity and bulk support personnel and vehicles, which adversely affect its maneuvering characteristics. To meet the requirements of future high-tech warfare and non-military rescue, it is significant to develop new river-crossing and bridging equipment with characteristics like light weight, fast set up, high load bearing capacity and high maneuver. Tensairity structure is a new structure system consisting of airbeams with low internal pressure, flexible cables and rigidity compression elements and is featuring light weight, small size, fast set up and high load bearing capacity, as shown in Figure 1. Tensairity, a blending word coming from the three words “tension”, “air” and “integrity”, was proposed by Dr. Mauro Pedretti, the chief engineer of the Swiss Airlight Co. Ltd. in 2002, whose research has the leadership in the field of structural engineering. Researches on Tensairity structure at home and abroad focus on the structure of one dimension

Figure 1. The basic element of a Tensairity beam.

beam and column. To meet the requirements of the development of river-crossing and bridging equipment, Tensairity structure was brought in section design, and by employing the method of numerical simulation the mechanical properties of the new Tensairity bridge section was analyzed, which provided technical support for the research on new river-crossing and bridging equipment.

### 2 DESIGN OF THE TENSAIRITY BRIDGE SECTION

Against temporary bridges for flood-fighting and emergency rescues and river-crossing and bridging

(A) Front view of a tensairity bridge section

(B) Sectional view of 1/2 segment of a tensairity bridge section

Figure 2. Geometric drawing of a tensairity bridge section.

Table 1. Parameters of elements of a Tensairity bridge section.

Item	Section (mm)	Material	Elasticity modules (MPa)	Yield strength (MPa)
Bridge deck slab	t = 3	Aluminum alloy	$7.0 \times 10^4$	283.55
Upper compression chord	210 × 100 × 10	Steel	$2.1 \times 10^5$	235
Lower cable	R = 6	Stress relieving steel wire	$1.95 \times 10^5$	1570
Airbeam	t = 1.5	PVC	500	100

equipment, based on the theoretical research of Tensairity structure, the present study conducts a primary design of the Tensairity bridge section, whose span and bridge deck width are designed to be 8 meters and 4 meters, respectively. Aluminum alloy sandwich panel is applied to act as bridge deck slab to bear upper vehicle load, and the design of bridge deck slab is based on aluminum alloy pontoon deck panel. Tensairity beam uses rectangular steel tube as upper compression chord, and asymmetric fusiform airbeam, whose radius of center section is 0.5 meter and material is PVC coating and internal pressure is 40 KPa, is applied in this study. Steel strand is used as tension member for lower chord. The design is shown in Figure 2, and parameters of structural elements are listed in Table 1, where t is thickness.

Material constitutive models employed in the numerical simulation are as follows: the ideal elastic-plastic model is applied to PVC and steel wire, the elastic hardening constitutive model is applied to aluminum alloy.

### 3 COMPUTING OF THE TENSIRITY BRIDGE SECTION

The present study selects the representative diaxon wheel-type load LT-20 as the subject of numerical simulation research. Due to the symmetry of the Tensairity bridge section, half of the model is analyzed and the connections between elements in modeling are not considered.

Since the landing area (length × width) of the front wheel of LT-20 vehicles is 0.3 m × 0.2 m, and the back wheel is 0.6 m × 0.2 m, the exact computing model is shown as Figure 3.

#### 3.1 Displacement of Tensairity bridge section under the wheel type load

The Tensairity bridge section forms its stiffness and reached self-balance under the internal pressure and therefore possesses the capacity to stand up to external load. The structural displacement response of the Tensairity bridge section under the typical wheel type load (LT-20) is shown in Figure 4.

Figure 3. Loading pattern of wheel type load (LT-20).

The pictures of displacement of the Tensairity bridge section under the wheel type load, as shown in Figure 4, illustrate that the maximum displacement value lies in 4.4 meters along the direction of bridge span, which means that the maximum vertical distortion occurs on the point that is 20 centimeters length from the back wheel's edge and the maximum displacement is 1.98 centimeters. The top of airbeam is linked to the upper compression chord and has the same displacement, resulting in the expansion outside of both sides of the airbeam with the maximum displacement. The lower cable distorts downward subject to the load and the cable near to the top distorts outward subject to the internal pressure of the airbeam, which lead to the inclination of upward displacement in the middle part of the cable. The displacement of the bridge deck slab and upper compression chord are far more greater than that of the lower cable, which can be attributed to following reasons: first, the internal shearing force of the structure delivers through inflatable airbeams when subjected to external load and therefore the displacement of the lower cable lags behind that of upper compression elements; second, the lower cable stays in the state of compression and bellies out due to the pressure of the top of the airbeam, resulting in the upward inclination of the cable.

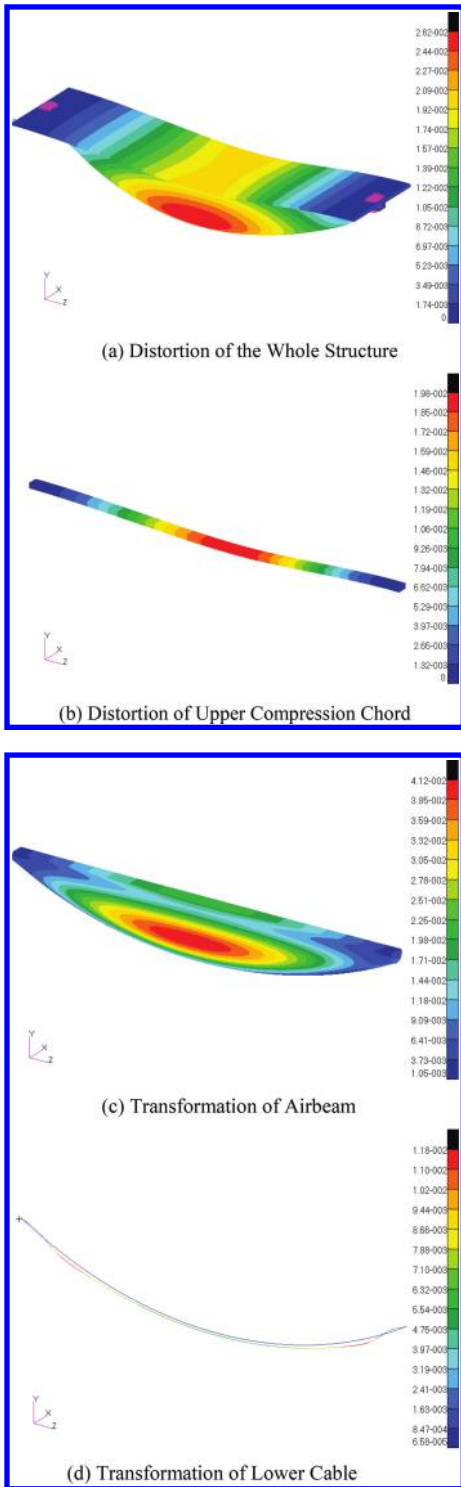

Figure 4. Displacement of a Tensairity bridge section under the wheel type load.

### 3.2 Stress of the Tensairity bridge section under the wheel type load

As to the internal force of the elements of the Tensairity bridge section under the wheel type load, the present study focuses on the stresses of upper bridge deck slab, upper compression chords, airbeams and lower cables. The stresses of the elements of the bridge section are shown in Figure 5.

As shown in Figure 5, under the wheel type load, as for the Tensairity bridge section, stress concentration of the bridge deck slab lies in the landing area of the back wheel and the joint to the top of the cable, the stress is symmetrically distributed. Besides stress concentration of the bridge support, the maximum stress lies in the 4.65 meters along the bridge span of the bottom flange of the upper compression chord, with a stress of 124 MPa. More than being the stiff compression element of the airbeam, the upper compression chord also acts as stiffening ribs of the upper bridge deck slab, therefore, the stress of the upper compression chord increases in spots like the back wheel and joint to the cable. The stress of the bottom flange of the chord is larger than that of the top, which shows that the upper chord bears bending moment. The stress of the airbeam gradually decreases from the middle part to the two sides, and that of the joint of upper compression chord is large.

### 3.3 The limits of load bearing capacity of the Tensairity bridge section under the wheel type load

The load bearing capacity of the bridge structure is one important measurement indicator of the bridge performance. To explore the limits of load bearing capacity of the Tensairity bridge section subject to the wheel type load, the present study assumes that the structure is damaged when any spots of the structure or of the cross section fail to meet the material failure criteria and the corresponding load is defined as the limit of load bearing capacity. If the stiffness requirement of the structure is not met when structure is damaged, the limit of load bearing capacity is the one meeting the stiffness requirement. As for the numerical simulation, considering the nonlinearity of the material and the structure, Mises yield criterion is applied to the aluminum alloy sandwich panel. A heavy load is exerted to the active area of the load of the bridge deck slab and the Newton-Raphson Iteration is employed for calculating. When the calculating terminates, the percentage of convergence ratio multiplying the overall load is the limit of load bearing capacity.

It is shown by the calculating results of numerical simulation that when the value of the load reaches 127.6 KN, the airbeam and the upper compression chord are damaged because the stress

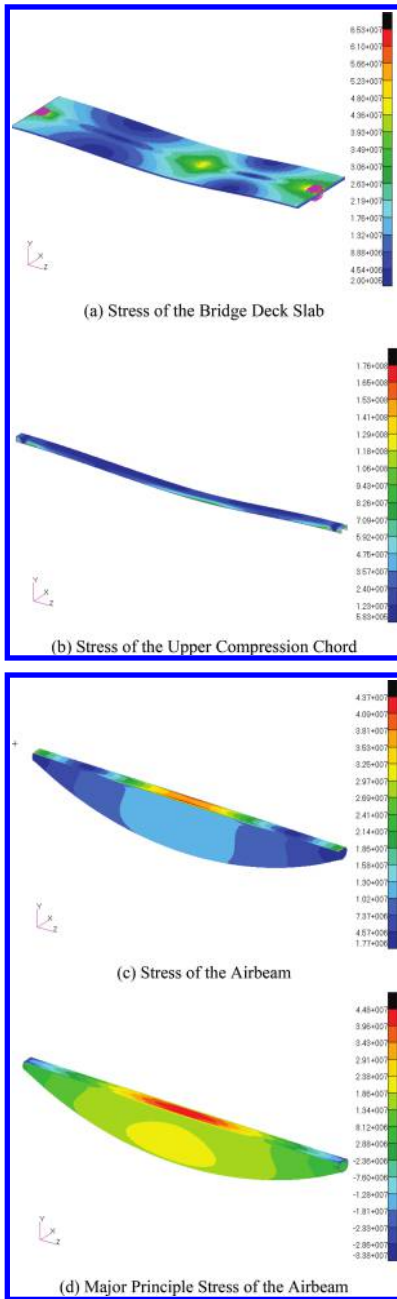

Figure 5. Stress of the Tensairity bridge section under the wheel type load.

of their contact area reaches the yield point. The maximum stress of the midspan of the bridge deck slab is 67 Mpa and the maximum stress of the upper compression chord is 158 Mpa, at the same time, the maximum displacement of the

structure is 3.3 centimeters and the other elements of the structure meet the material requirements and overall stiffness requirements. Therefore, the limit of load bearing capacity is mostly determined by the membrane materials of the airbeam and the limit can be promoted by improving the performance of the membrane materials.

#### 4 CONCLUSION

The Tensairity structure is an innovative expanded structure of the pneumatic membrane, which greatly increases the load bearing capacity of the pneumatic structure by adding lower cable and upper compression chord and at the same time effectively reduces the internal pressure, and therefore, overcomes the contradictions among the inner gas pressure, material strength and load bearing capacity of the pneumatic structure and provides a new means of applying the pneumatic structure. In this paper, we designed the Tensairity bridge section based on the principle of the Tensairity structure, and by employing the method of numerical simulation, analyzed the distortion and stress of the Tensairity bridge section subject to the typical wheel type load, and obtained the limits of load bearing capacity of the structure subject to the load, shown as follows:

1. Under the wheel type load, the maximum displacement of the Tensairity bridge section lies in the 4.4 meters of the direction of bridge span and the maximum stress lies in the 4.65 meters of the direction of bridge span.
2. The limits of load bearing capacity of the 1/2 Tensairity bridge section subject to the wheel type load is 127.6 KN, and the limit is mostly determined by the performance of the membrane materials.

**ABSTRACT:** This paper presents a series of compression tests on steel tubular members fabricated from Q420 high-strength steel plates, to study the compression stability behavior and failure mechanism. The tests were performed over a range of member lengths. The overall geometric imperfections and the material properties were measured prior to the tests. The test specimens were placed between pinned ends and tested in a horizontal way. The Finite Element Analyses (FEA) were conducted to simulate their experimental behavior by using ANSYS, and the Shell elements were used to create the circular hollow sections. Moreover, the test stability coefficients were compared with the design coefficients predicted using different provisions, and the design guidance was also proposed for later use.

**Keywords:** Q420 high-strength steel; circular hollow section; stability bearing capacity; FEA; design guidance

## 1 INTRODUCTION

The steel circular hollow section, with closed cross section, has good integral rigidity, high bearing capacity, and relatively small drag coefficient. It can be designed without framing eccentricities, and is applied widely in engineering structures, such as grid structures, pipe trusses, steel towers and offshore platforms. Due to the development of the power grid and the promotion of loading criterion, increasing amounts of high-capacity, high-voltage and multi-loop transmission lines have been constructed. These impose higher loads on steel towers, both dead loads and wind loads. Q420 high-strength steel tubes have been applied in a large amount of transmission lines, including 500 kV,  $\pm 800$  kV and 1000 kV lines<sup>[1-2]</sup>.

Yang Mei et al.<sup>[3]</sup> adopted a modified CDC method to derive the overall stability coefficients of Q420 and Q460 high-strength steel tubes. Han J.ke et al.<sup>[4]</sup> raised the recommended diameter-to-thickness value of leg members of steel tubular tower, based on the research results of a typical 1000 kV double-circuit transmission tower. Yang Longyu et al.<sup>[5]</sup> performed compression tests on high-strength steel tubular members between pin

ends, with different steel materials and geometric dimensions. He also proposed the reduction methods of local stability strength and slenderness application scope of steel tubes. Gu Q. et al.<sup>[6]</sup> employed the elastoplastic beam-column theory and numerical integration to calculate the load-deflection curves of round and square steel tubes. Chen W.F. et al.<sup>[7]</sup> raised a simplified residual stress mode of circular steel tube, not considering the change of residual stress along the wall thickness. Pan et al.<sup>[8]</sup> used the hole drilling method to measure the residual stress distribution of a welded circular hollow steel section. Demao Yang et al.<sup>[9]</sup> carried out compression tests on high-strength box-shaped columns, and proposed improved column design of high-strength slender sections. Ben Yong et al.<sup>[10]</sup> conducted compression tests of stainless-steel tubular members, and compared test strengths with the design strengths using different codes. Rasmussen and Hancock<sup>[11]</sup> presented a test program comprising high-strength box and I-section specimens, including fix-ended stub columns and pin-ended long columns.

This paper describes a series of compression tests on Q420 steel tubular members. The test stability coefficients are compared with the design coefficients predicted by American, European, and

Chinese standards. Finally, the design recommendations are proposed on the basis of the theoretical research results.

## 2 EXPERIMENTAL INVESTIGATIONS

### 2.1 Test specimens

Due to the field investigation results of steel tubular towers and limited experimental conditions, the steel tubes with a specification of  $\Phi 377 \times 8$  were selected as test specimens. The steel was classified as Q420 to the Chinese standards GB50017<sup>[12]</sup>. The specimens are cold-formed from flat steel sheets and seam-welded with a longitudinal full penetration weld. In order to investigate the influence of the slenderness ratio on compression stability behavior, the slenderness of 30, 40, 50, 60, 80, 100 was chosen for specimens, with three specimens in each group, i.e. 18 specimens in total. Besides, the tensile coupon tests were performed with standard specimens extracted from steel plates used in specimen fabrication and steel tubes used for the test, respectively. The material properties are listed in Table 1. Initial overall geometric imperfections of the specimens were measured, as well as the geometric imperfections along the longitudinal welds. The maximum overall flexural imperfection at mid-length of steel tubes was  $l/1400$ , where  $l$  is the length of the specimen.

### 2.2 Test set-up and procedure

As depicted in Figure 1, the concentric compression was applied horizontally as the effect of self-weight was negligible. Two 6000 kN spherical hinges, with the outer diameter of 450 mm and the total height of 120 mm, were placed at both ends. The square end plates were 500 mm wide to confirm full contact with the hinges and enough local rigidity. A 5000 kN hydraulic jack was employed to apply monotonic

Plate shape	Yield stress (MPa)	Ultimate stress (MPa)	Elastic modulus (MPa)
Flat	439.4	500.2	$2.1 \times 10^5$
Rolled	432.6	505.6	$2.1 \times 10^5$

Figure 1. Compression test set-up.

central loading in one side, with the reaction blocks connecting fixed base using anchor bolts, and the other side was set to contact with the reaction wall.

The compression tests were conducted by applying multi-stage loading, and each load step was held for 1–2 minutes. Prior to the tests, a theodolite was used to ensure that the tubular member was loaded in the center, and electrical strain gauges and displacement transducers were arranged at the typical positions of the test specimens. The strain gauge dimension was  $10.0 \text{ mm} \times 4.0 \text{ mm}$ , with a maximum ultimate strain of 2%–3%.

As illustrated in Figure 2, the strain gauges were mounted on three cross-sections of test members, i.e. mid-section and other two sections with one-eighth lengths from the mid-section. Four displacement meters, with a measuring range of  $\pm 100 \text{ mm}$ , were placed at four corners of the end plate to measure the axial shortening and rotation of the bearing plate during the loading process. At the regular interval, a data acquisition system, named DH3816, was adopted to record the readings of strains and displacements.

### 2.3 Test results

In the early stage of loading, the test members remained elastic, and no obvious deformation was observed. The strain and displacement developed approximately linearly. With the increasing compression, the strains at typical positions bifurcated gradually. When reaching the ultimate bearing capacity, the strains descended immediately, and the axial shortening increased rapidly. Meanwhile, the overall flexural deformation and local buckling developed rapidly.

The failure modes of the test specimens with series slenderness ratios are shown in Figure 3. The experimental failure modes were generally in agreement with the ideal ones. The failure mode of test tubular members was a mixture of overall flexural buckling and local stability. In general, for the test specimen with a slenderness ratio of 30 and 40, the local buckling was more obvious, as shown in Figure 3. For the test specimen with a slenderness more than 50, the overall flexural deformation was

Figure 2. Arrangement of measuring points.

Figure 3. Overall flexural buckling of the specimens.

Figure 4. Local buckling of the specimens.

more obvious, as depicted in Figure 4. As the steel circular hollow section has numerous symmetric axes, the specimens bent freely, just as predicted beforehand. Relative rotation of the end plate was also observed in the test process.

### 3 FINITE ELEMENT ANALYSES

Following the completion of the experimental tests, a nonlinear finite element model was developed using ANSYS, and a four-node Shell181 element was selected to simulate the steel tubes. The Young's modulus was  $2.1 \times 10^5$  MPa, and the Poisson ratio was taken as 0.3. The steel material was modeled by an ideal elastoplastic tri-linear model with actual properties, and the tangent modulus was taken as  $0.1 E$  in the post yield range to ultimate strength, as shown in Figure 5. The end plates were created with Solid45 elements, and their MOE were set as  $2 \times 10^8$  MPa to increase the local stiffness and reduce the local stress concentration in the bearings.

For eigen buckling analyses, the corresponding mode shape was obtained by adopting the Block Lanczos eigenvalue extraction method. Then, the imperfect model was created by adding  $l/1400$  overall flexural deformation, and the residual stress was also taken account. Uniaxial compression forces were

GB 50017	$100(235/f_y)$	55.9
Eurocode 3	$90(235/f_y)$	50.4

applied on the analytical models and a large deformation option was activated. The arc-length method in conjunction with the modified Newton Raphson method is used to accelerate the numerical solution convergence. The model deformation and von Mises stress distribution are depicted in Figure 6.

### 4 THEORETICAL ANALYSES

#### 4.1 Local stability

For compression members, local buckling can not occur before overall stability, i.e. the critical stress of local stability shall be more than that of overall

Table 3. Comparisons of overall stability coefficients.

$d$	$t$	$\lambda$	$\varphi_{\text{exp}}$	$\varphi_{\text{FEA}}$	$\varphi_{\text{exp}}/\varphi_{\text{FEA}}$	GB50017		AISC 360-05 <sup>[13]</sup>	BS EN 1993-1 <sup>[14]</sup>	ASCE 48-11 <sup>[15]</sup>
						$\varphi_a$	$\varphi_b$	$\varphi_{\text{AISC}}$	$\varphi_{\text{BS}}$	$\varphi_{\text{ASCE}}$
377	8	30	0.908	0.924	0.983	0.939	0.895	0.921	0.874	0.951
		40	0.844	0.858	0.984	0.9	0.833	0.864	0.791	0.913
		50	0.795	0.809	0.983	0.849	0.763	0.796	0.701	0.864
		60	0.76	0.738	1.030	0.77	0.675	0.72	0.609	0.804
		80	0.641	0.686	0.934	0.57	0.499	0.558	0.443	0.651
		100	0.501	0.484	1.035	0.397	0.357	0.402	0.322	0.459

stability. In order to meet this stipulation, a limited value of the diameter-to-thickness ratio ( $d/t$ ) is provided in different codes. Table 2 summarizes the limited values of  $d/t$  according to the design standards, with the nominal yield stress, where  $f_y$  is 420 N/mm<sup>2</sup>. The  $d/t$  value of the test specimens was 47.1, which was less than the limited values given in the table.

#### 4.2 Overall stability

Under the axial compression  $P$ , the equilibrium equation of an ideal member with both ends pin supported could be established, based on the small flexural deformation theory. The value of  $y'$  can be taken as 0 due to the small deformation condition, and expression (1) can be obtained. The deformed member presents a half sinusoidal curve shape, and the curvilinear equation can be defined as  $y = A \sin \pi x / l$ . Then, the critical force can be expressed as  $P_{cr} = \pi^2 EI / l^2$ , where  $E$  is the modulus of elasticity and  $l$  is the length of the tubular member:

$$EIy'' + Py = 0 \quad (1)$$

However, various defects exist in the actual compression member inevitably, and member presents flexural deflection even under a small load. The concept of the overall stability coefficient  $\varphi$  was put forward in current design codes, and  $\varphi$  is the ratio of overall critical stress  $\sigma_{cr}$  to design stress  $f$ .

#### 4.3 Comparative analyses

As to the welded tubular member, the residual stress usually generates in the fabrication procedures, such as cold-forming and welding. For the steel tubes with the same geometric dimension, the distributions of residual stresses are similar. On this basis, one can suggest that the effect of residual stresses is less detrimental to the strength of the high-strength steel column than that of the ordinary steel column. For the welded circular steel section investigated here, GB 50017 terms it as the

Figure 7. Comparisons of overall stability coefficients.

b-type section, while other standards do not provide the detail classifications.

The calculated overall stability coefficients calculated from test strengths, simulated strengths and predicted strengths using different design standards are summarized together in Table 3. Meanwhile, the calculated stability coefficients were plotted against the slenderness ratio ( $\lambda$ ), as illustrated in Figure 7. It is obvious that the ASCE standard provides the maximum stability coefficient, while BS offers the minimum values, with the error more than 8%. The test strengths agree well with that obtained from the FEA results, with the ratios ranging from 0.983 to 1.035. For the test specimen with the slenderness ratio more than 60, the stability bearing capacity can be calculated according to AISC 360-05 and GB 50017 (class a section). For the test specimen with the slenderness less than 50, the stability strength can be computed as per GB 50017 (class b section) and BS EN 1993-1.

## 5 CONCLUSIONS

A series of compression tests are performed on Q420 high-strength steel tubular members with

both ends pin supported. Meanwhile, the finite element program, ANSYS, is used to simulate the experimental behavior. Finally, the test stability coefficients are compared with that predicted by different standards. It can be concluded as follows:

1. The failure modes of the test specimens mainly exhibit an extremum behavior, together with obvious local buckling, which shows a similar trend with the analytical results. The failure mode of test tubular members was a mixture of overall flexural buckling and local stability.
2. The test strengths agree well with that obtained from the analytical results, with the ratios ranging from 0.983 to 1.035. Therefore, ANSYS can be used widely to simulate the tubular members with different sizes, which the tests do not cover.
3. Among the design standards, BS code gives the conservative predictions, and ASCE is proved to be not conservative, with the error more than 8%.
4. For Q420 high-strength steel tubular members with the slenderness ratios more than 60, the stability strengths can be calculated according to AISC or GB 50017 (class a section). For the test specimen with the slenderness less than 50, the strengths can be computed as per GB 50017 (class b section) or BS EN 1993-1.

**ABSTRACT:** The slope of the Xiaowan Hydropower Station slope is huge, complex, high, and steep, with a maximum excavation height of nearly 700 m. The structural plane of rock mass along the river is developed and unloads strongly, but the deposit slope has a wide distribution and is unstable. A large number of pre-stressed anchors, anchor bolts, and other measures have been adopted in the slope reinforcement design to improve the safety factor and the slope stability. The pre-stressed anchoring effect is analyzed by studying the monitoring results of slope pre-stressed anchoring. The analysis result provides a scientific basis for slope reinforcement design, construction, and stability evaluation.

**Keywords:** pre-stressed; anchoring effect; anchor load cell

## 1 BRIEF INTRODUCTION TO THE XIAOWAN HYDROPOWER STATION SLOPE ANCHORING PROJECT

Xiaowan Hydropower Station is located in a high-intensity earthquake area with narrow terrain, steep slope, and closely packed buildings. The main projects have mass open excavation and are focused within the range of approximately 3 km<sup>2</sup>. Open excavation forms a 700 m-high slope. The stability of such a high slope is one key technological issue in project construction.

A natural slope in the main slope zone is about 42°. Based on its lithological characteristics, the slope consists of biotite granitic gneiss and amphibole plagioclase gneiss. The rock shows a monoclinic structure, transverse distribution, and steep upstream slope that stretches along the river direction and cuts off crack growth along the slope angle. The Yinshuigou accumulation and the Dachunshu ditch accumulation distributed before the dam on each side of the river. They have a significant impact on engineering owing to their deep-seated coverage and complicated composition natures. The diverse of this rock slope failure have typical slope type reservoir features, and the complicated slope excavation body makes construction more difficult.

Given the complicated geological conditions of excavation slopes, the engineering design adopts a multitude of pre-stressed anchor and supporting measures—about more than 10,000—to meet the stability requirements of slope excavation during construction and operation.

## 2 TEST OF SLOPE ANCHORING PRODUCTION

Slope anchorage of the Xiaowan Hydropower Station is a key construction project with a limited construction period, heavy construction work, and difficult hole-forming. Two test areas were selected from the left and right river banks for anchoring site production testing prior to the start of the project to determine the anchoring materials and construction techniques that meet the project requirement, optimize the design parameters, investigate the construction approach, monitor the accelerating construction progress, and accumulate experience for the large-scale construction. The process included 1) testing the match of the grout in the anchoring segment with the concrete in the outer anchor head, the cement-proof ring, and the material's mechanical properties; 2) measuring pre-stressed

anchoring load and load loss law; 3) testing the stress distribution law of pre-stressed strand in the anchoring and free segments; 4) analyzing the effect of the anchor group by testing the rock deformation law and the influencing range of anchoring tension; and 5) testing the real stretching range of the pre-stressed strand during the tension of each anchoring strand in the right bank after the project started in order to solve rock weathering and the accumulation of anchoring devices, the hole-making method, and the blocking and grouting technique.

### 3 ANALYSIS OF SLOPE ANCHORING STABILITY

#### 3.1 Main monitoring result of slope pre-stressed anchoring

Xiaowan Hydropower Station mainly uses common tension-type anchors as reinforcement

for 1000, 1800, and 3000 KN designed loads. According to monitoring technical requirements, about 3% of pre-stressed anchors are selected based on load level to arrange load cells in vary locations, observe pre-stressed anchoring load and its changes, as well as realize pre-stressed anchoring effect on slope rock and long-term work requirement for safety forecast during construction. The load cell is BGK4900 produced by Geokon Instruments (Beijing) Co., Ltd. Table 1 shows the main technical index of the anchoring load cell.

Excavation of the Xiaowan Hydropower Station slope started in February 2002. By December 2004, slope excavation of more than elevation 1000 m was basically completed. About 10,000 pre-stressed anchors were used on the slope. By the end of December the following year, 285 anchor load cells were installed. Table 2 shows the statistics of pre-stressed anchor monitoring of all the location.

Table 1. Main technical index of the BGK4900 anchor load cell.

	Range (KN)	Over range tension (% FS)	Resolution (% FS)	Accuracy (% FS)
Technical Index	1000 ~10,000	150	±0.025	±0.25 ~±0.5

Table 2. Statistics of pre-stressed anchor monitoring result.

Locations	Tensile load/design load	Locked load/design load	Observation value/design load	Mean locked loss (%)	Mean later loss (%)	Loss range (%)
Slope at the right bank above 1,365 m	1.07	0.97	0.94	9.72	3.22	-9.5~9.2
Slope at the right bank between 1245 m to 1365 m	1.09	1.00	0.95	8.02	4.76	-8.4~12.3
Intake slope at the right bank	1.08	1.003	1.048	7.15	-3.74	-18.3~7.1
Slope at the upstream of the right bank abutment slot	1.09	0.997	0.965	9.03	2.03	-3.3~4.6
Slope at the downstream of the right bank abutment slot	1.12	1.039	0.99	7.27	5.03	2.7~7.4
Slope at the right bank of plunge pool	1.13	1.019	0.969	8.83	4.89	3.6~6.3
Slope at the right bank of tailwater tunnel	1.12	1.027	0.965	8.23	6.11	-0.1~9.0
Slope at the No.4 ridge above 1,380 m	1.18	1.09	1.039	7.73	5.73	2.4~6.0
Slope at the No.4 ridge between 1245 m to 1380 m	1.06	0.995	0.952	6.39	4.87	1.9~16.2
Slope at the left bank of plunge pool	1.11	1.022	0.984	7.53	3.75	0.8~7.8
Slope at the upstream of the left bank abutment slot	1.14	1.06	1.018	6.85	4.25	2.3~7.2
Intake slope of spillway tunnel at the left bank	1.12	1.045	1.004	6.59	3.96	1.6~7.0
High telpher base at the left bank	1.16	1.082	1.051	6.62	2.92	0.3~6.0
Low telpher base at the left bank	1.14	1.057	1.038	7.35	1.75	1.4~2.1
High telpher base at the right bank	1.05	0.967	0.928	7.43	3.97	0~12.4
Low telpher base at the right bank	1.05	0.972	0.94	6.95	3.27	1.3~4.9
Dachushu ditch accumulation slope	1.01	0.942	0.896	6.28	4.30	-19.6~11.9
Yinshuigou accumulation slope	0.995	0.933	0.898	6.34	-1.19	-115.7~24.8

### 3.2 Analysis and evaluation of slope pre-stressed anchoring effect

#### 3.2.1 Prestress loss

For anchoring prestress of the rock slope, the average locked later loss, average loss, and total loss were 6.31%, 3.55%, and 11.16%, respectively. For anchoring prestress of the homogenous slope, figures for such losses were 7.61%, 1.56%, and 9.17%, respectively.

#### 3.2.2 Anchoring load

The ratio of average anchoring load of the rock slope and that of the designed load was 0.986, which was 1.4% lower than the designed load. The ratio of average anchoring load of the homogeneous slope and that of the designed load was 0.897, 10.3% lower than the designed load.

#### 3.2.3 Dynamic change laws of anchoring load

The dynamic change laws of the anchoring load can be summarized as follows:

1. Anchoring load declines slowly and tends toward stability, showing that the pre-stressed anchor is normal and that the slope where the anchor is located deforms slightly.
2. Anchoring load increases due to the occurrence in slopes of certain deformations, such as Yinshuigou accumulation slope and intake slope of the power station. Slope deformation causes anchoring load increasing, which reflects the inhibition of pre-stressed anchor on slope deformation.
3. Anchoring load fluctuates in anchors positioned around those with larger environmental changes, thereby reflecting the impact of environment on slope deformation.
4. Anchoring load suddenly reduces in anchors that are placed in Yinshuigou accumulation slopes. After the anchoring load is locked and unloaded, the load does not increase, but instead continues to decrease because of slope deformation. This finding indicates that rocks in the anchoring section are very complicated.

## 4 ROLE OF PRE-STRESSED ANCHORING MONITORING RESULT IN WARNING AND FORECASTING SLOPE STABILITY

After the pre-stressed anchoring tension is locked, the changes in its load can intuitively reflect the work status of pre-stressed anchor as well as the practical conditions and work features of the slope. In the slope anchoring construction of Xiaowan Hydropower Station, monitoring results of the pre-stressed anchor was fully used for warning and forecasting.

### 4.1 Intake slope forecast

In the intake slope of the station, the height of slope excavation was 106 m below EL. 1245 m, whereas vertical excavation was conducted below EL. 1220 m in the front slope. Vertical slope was 81 m in height. Given the complicated geological conditions, the excavation started from EL. 1245 m in September 2003. The load in the anchor load cell of the intake front slope continued to increase in different degrees on October 15, 2004; by October 26, a crack had appeared between the front slope and the abutment slot slope. The No. 1 intake and the rock pillar were blasted on February 4, 2004. The No.1 to No. 4 slots were dug at EL. 1150 m on December 10. In December 14–19, 2004. The No. 1 to No. 4 slots in the intake front slope were dug up to 1150 m to 1145 m. Load unloading for the slope excavation and maintaining the rock pillar failed, loads of partial anchor load cells in the front slope showed an accelerated increase in different degrees, such that fine cracks occurred in the slope above EL. 1220 m. On December 11, the load rate of the C2B-3IV-PR-32 anchor was up to 26.5 KN/d; on December 12, the supporting

	Nov. 25– Dec. 2	Dec. 2– Dec. 16	Dec. 16– Dec. 9	Jan. 9– Jan. 29	Jan. 29– Feb. 29	Feb. 29– Mar. 15	Mar. 15– Apr. 5
Load rate	-1.18	0.71	2.04	5.49	3.47	2.62	0.74

construction above EL. 1162 m in the intake front slope had been completed. The deformation rate of most monitoring points above EL. 1180 m had slowed, but the rates of monitoring points below 1180 m elevation were still high. The load rate of the C2B-3IV-PR-32 anchor (1171 m in elevation) was up to 5.19 KN/d. Anchoring load was high at 1.10 times the designed load, and deformation rate at this location was also higher. With the completion of the intake slope support and the gradual pouring of the intake tower, intake slope deformation gradually stabilized starting in 2005. Table 3 shows the slope of this location, and Figure 1 shows the typical load–time curve of the anchor load cell.

#### 4.2 Forecast of the Yinshuigou accumulation slope

The Yinshuigou accumulation slope was excavated in the early part of the year 2002. When slope excavation reached the elevation 1276 m on December 14, 2003, displacements at many monitoring points suddenly improved. Moreover, loads in the C2 A-III-PR-04 anchor load cell arranged on the high road at elevation 1389 m increased. A rechecking was followed by explanations to the related parties on December 17. Intensive observations made afterwards for the slope of this location showed that the changes in anchoring load increased after the rain on January 9, 2004, and that the changes showed accelerated development until January 29. Slope stability forecasting was raised again by combining the apparent phenomenon and the inner monitoring result. Real-time monitoring conducted mainly for the changes in anchoring load found that the monitoring load was 1350.0 KN at 1630 h of April 5, within the designed load limitation. Anchoring load was reduced to 1321.8 KN at 2130 h after which the anchor was observed continuously. The anchoring load then reduced to 1122.3 KN and tended to stabilize at 0730 h of April 6. At 2200 h of April 10, the anchoring load was 1120.2 KN, but suddenly changed to 363.4 KN at 0830 h of April 12 and became 363.7 KN at 0400 h. The anchor head was pulled out on April 14 because the anchor was a complete failure. Table 4 shows the load rate statistics of the C2 A-III-PR-04 anchor load cell. Figure 2 refers to the load–time process curve.

Figure 2. Typical load–time curve of the anchor load cell.

## 5 CONCLUSION

1. The greatest excavation height at Xiaowan Hydropower Station is close to 700 m. Numerous pre-stressed anchors were used to reinforce the support for engineering design. Monitoring the slope pre-stressed anchoring plays a very important role in realizing the anchoring effect of pre-stressed anchor on slope rock and its long-term working status, adjusting and optimizing reinforcement parameters, organizing constructions, and accelerating the construction process to ensure engineering safety during the construction period.
2. The monitoring results of pre-stressed anchor in the slope show that the average locked loss of prestress is 6.31%, the average later loss is 3.55%, and the total loss is 11.16%. Anchoring load basically reaches the design requirements.
3. The changes in pre-stressed anchoring load and other monitoring data show that the changes in slope pre-stressed anchoring load meet the practical conditions of all slopes and the specific working features. Slopes are generally stable except for a certain deformation in local slopes.
4. After the pre-stressed anchoring tension is locked, the changes in its load show the work status of pre-stressed anchor as well as the real conditions and work feature of the slope in this location. The Xiaowan Hydropower Station anchoring project made a creative exploration in warning and forecasting slope stability by means of pre-stressed anchor monitoring results. It also provided valuable experience for analysis and evaluation of slope stability of similar engineering projects.

## Study on mode II fracture initiation using the strain energy density criterion

W. Gao, S.N. Wang & Y. Su

*School of Aeronautics, Northwestern Polytechnical University, Xi'an, China*

**ABSTRACT:** The Brazilian disc specimen and the semi-circular bend specimen have been used by many researchers to study mode I, mode II and mixed mode I–II brittle fracture in different materials. However, the mode II fracture toughness obtained experimentally in the past from these two specimens show large inconsistencies compared with the theoretical predictions. In this paper, a modified strain energy density criterion is used to study the effect of  $T$ -stress on the fracture initiation angle and the fracture toughness ratio  $K_{IIc}/K_{Ic}$ , then the theoretical predictions are compared with the relevant published experimental results obtained from fracture tests on the Brazilian disc specimen and the semi-circular bend specimen. A very good agreement is shown between the predicted results and the experimental results.

**Keywords:** brittle fracture; strain energy density criterion; mode II fracture;  $T$ -stress

### 1 INTRODUCTION

Brittle fracture is a major mode of failure in components and structures containing cracks. According to the classic fracture model, for mode II loading condition, the crack propagates if the mode II stress intensity factor  $K_{II}$  reaches its critical value (or mode II fracture toughness,  $K_{IIc}$ ). Therefore, it is important to develop appropriate theoretical and experimental methods for determining mode II fracture toughness  $K_{IIc}$  in brittle materials.

In the past years, many different test specimens have been designed for determining  $K_{IIc}$  for various engineering materials (Erdogan & Sih 1963, Ueda et al. 1983, Awaji & Sato 1978, Chong & Kurrupu 1984). Among those testing specimens the Brazilian Disc (BD) specimen and the semi-circular specimen under three-point bending (SCB) are two of the most favorite specimens for fracture tests in brittle material. Mode I, Mode II and mixed mode I/II could be provided easily for each of these two specimens by setting the crack line in an appropriate angle relative to the loading direction and the test procedures in both the BD specimen and SCB specimen are easy and cost effective.

In addition to the experimental techniques mentioned above for obtaining the fracture toughness of engineering materials, there are several theoretical criteria for predicting mixed mode I/II in cracked bodies. The Maximum Tangential Stress (MTS) criterion (Erdogan & Sih 1963), the Maximum Energy Release Rate (MERR) (Hussain et al. 1963) and the minimum Strain Energy Density criterion (SED) (Sih 1974) are three most

important criteria for brittle fracture under mixed mode loading condition. Among these criteria, the minimum strain energy density criteria has been found to be a powerful tool to predict the fracture and fatigue behavior of cracked and notched components (Sih & Ho 1991, Nobile et al. 2004, Sih & Tang 2005, Berto & Lazzarin 2009). Theoretical predictions based on this criterion suggest that the ratio of mode II fracture toughness  $K_{IIc}$  over mode I fracture toughness  $K_{Ic}$  is a fixed value just depends on the Poisson's ratio  $\nu$ . For example, for  $\nu = 0.3$ , the value of  $K_{IIc}/K_{Ic}$  predicted by the SED criterion is 0.96 and for  $\nu = 0.2$ , the value is 1.07. However, there are many experimental investigations reporting a ratio of  $K_{IIc}/K_{Ic}$  significantly higher or lower than the fixed value. A review of the related papers shows that depending on the tested material and the specimen geometry, the value of  $K_{IIc}/K_{Ic}$  varies typically from 0.42 to 2.2 (Lim et al. 1994a, b, Khan & Al-Shayea 2000, Ayatollahi et al. 2006, Awaji & Sato 1987). Such inconsistencies between the theoretical and experimental results restrict the validity of fracture criteria like the conventional SED criteria to limited geometry and loading conditions. There have been some attempts to justify such large inconsistencies. Liu et al. (1998) suggested that possible formation of shear banding in front of the crack tip prior to the initiation of fracture can be the reason of  $K_{IIc}$  in the epoxy resin being much higher than  $K_{Ic}$ . However, they could provide only a qualitative interpretation of test results.

In this paper, a modified SED criterion is used for predicting brittle fracture in mode II loading.

The modified SED criterion takes into account the effect of non-singular stress term ( $T$ -stress) in addition to the singular stress term. Then, the theoretical predictions calculated from the modified SED criterion are verified by using some experimental results obtained from mode II fracture tests on the BD specimen and SCB specimen in the past.

## 2 MODIFIED MINIMUM STRAIN ENERGY DENSITY CRITERION

Elastic stress field around the crack tip in linear elastic homogeneous and isotropic material for I/II mixed loading can be written as (Williams 1957):

$$\sigma_{xx} = \frac{1}{\sqrt{2\pi r}} \left( K_I \left( \frac{3}{4} \cos \frac{\theta}{2} + \frac{1}{4} \cos \frac{5\theta}{2} \right) - K_{II} \left( \frac{7}{4} \sin \frac{\theta}{2} + \frac{1}{4} \sin \frac{5\theta}{2} \right) \right) + T + O(r^{1/2}) \quad (1.a)$$

$$\sigma_{yy} = \frac{1}{\sqrt{2\pi r}} \left( K_I \left( \frac{5}{4} \cos \frac{\theta}{2} - \frac{1}{4} \cos \frac{5\theta}{2} \right) + K_{II} \left( -\frac{1}{4} \sin \frac{\theta}{2} + \frac{1}{4} \sin \frac{5\theta}{2} \right) \right) + O(r^{1/2}) \quad (1.b)$$

$$\tau_{xy} = \frac{1}{\sqrt{2\pi r}} \left( K_I \left( -\frac{1}{4} \sin \frac{\theta}{2} + \frac{1}{4} \sin \frac{5\theta}{2} \right) + K_{II} \left( \frac{3}{4} \cos \frac{\theta}{2} + \frac{1}{4} \cos \frac{5\theta}{2} \right) \right) + O(r^{1/2}) \quad (1.c)$$

$$\sigma_{zz} = \begin{cases} 0 & \text{for plane stress} \\ \nu(\sigma_{xx} + \sigma_{yy}) & \text{for plane strain} \end{cases} \quad (1.d)$$

where  $r$  and  $\theta$  are the polar coordinates with the origin located at the crack tip,  $K_I$  and  $K_{II}$  are the mode I and mode II intensity factors respectively,  $\nu$  is the Poisson's ratio,  $\sigma_{xx}$ ,  $\sigma_{yy}$ , and  $\sigma_{zz}$ , are the stress in the Cartesian coordinates. The first term in each stress component is singular and the second term  $T$ , is constant and independent of the distance  $r$  from the crack tip. The higher order terms  $O(r^{1/2})$  are often negligible at location very close to the crack tip.

The SED criterion, formulated by Sih (1974), states that the onset of brittle fracture takes place when the strain energy density factor  $S$  at a constant distance  $r_c$  around the crack tip reaches a critical value  $S_c$  and the direction of crack initiation angle  $\theta_0$  coincides with the direction of minimum strain energy density. In mathematical form, the SED criterion can be written as:

$$\left. \frac{\partial S}{\partial \theta} \right|_{\theta=\theta_0} = 0, \quad \frac{\partial^2 S}{\partial \theta^2} > 0 \quad (2)$$

where  $S$  is the strain density factor, defined as:

$$S = r_c \frac{dW}{dV} \quad (3)$$

$$\begin{aligned} \frac{dW}{dV} &= \frac{1}{2E} (\sigma_{xx}^2 + \sigma_{yy}^2 + \sigma_{zz}^2) \\ &\quad - \frac{\nu}{E} (\sigma_{xx}\sigma_{yy} + \sigma_{xx}\sigma_{zz} + \sigma_{yy}\sigma_{zz}) \\ &\quad + \frac{1+\nu}{E} (\tau_{xy}^2 + \tau_{xz}^2 + \tau_{yz}^2) \end{aligned} \quad (4)$$

where  $dW/dV$  is the strain energy density function per unit volume,  $E$  is the modulus of elasticity. Both  $r_c$  and  $S_c$  are assumed to be constant material properties.

The SED criterion in general can be used for pure mode I, pure mode II and mixed mode I/II and the conventional SED criterion only takes into account the singular term in Eq. (1). Here in this paper, the SED criterion is modified by using the stress field (Eq. (1)) considering both the singular term and the  $T$ -stress term. The strain energy density function can be written as:

$$\begin{aligned} S &= \frac{1}{16G\pi} (a_{11}K_I^2 + a_{12}K_I K_{II} + a_{22}K_{II}^2 \\ &\quad + a_{1T}K_I T + a_{2T}K_{II} T + a_T T^2) \end{aligned} \quad (5)$$

where the factors  $a_{ij}$  are functions of the angle  $\theta$ , and defined as:

$$a_{11}(\theta) = (1 + \cos \theta)(\kappa - \cos \theta),$$

$$a_{12}(\theta) = 2 \sin \theta (2 \cos \theta - (\kappa - 1)),$$

$$a_{22}(\theta) = ((\kappa + 1)(1 - \cos \theta) + (\cos \theta + 1)(3 \cos \theta - 1)),$$

$$a_{1T}(\theta) = 2\sqrt{2\pi r_c} \cos \frac{\theta}{2} ((\kappa - 2) - \cos \theta + 2 \cos^2 \theta),$$

$$a_{2T}(\theta) = -2\sqrt{2\pi r_c} \sin \frac{\theta}{2} (\kappa + \cos \theta + 2 \cos^2 \theta),$$

$$a_T(\theta) = (1 + \kappa)\pi r_c.$$

where  $G$  is the modulus of rigidity, for plane strain,  $\kappa = 3 - 4\nu$ , for plane stress,  $\kappa = (3 - \nu)/(1 + \nu)$ .

For pure mode II under plain strain condition,  $K_I = 0$ ,  $\kappa = 3 - 4\nu$ , Eq. (5) can be written as:

$$\begin{aligned} S &= \frac{(1 + \nu)K_{II}^2}{8\pi E} \left( \left( \left( \frac{9}{2} - 4\nu \right) + (4\nu - 2)\cos \theta + \frac{3}{2}\cos 2\theta \right) \right. \\ &\quad \left. - B\alpha \left( (7 - 8\nu)\sin \frac{\theta}{2} + \frac{1}{2}\sin \frac{5\theta}{2} \right) + 2(1 - \nu)(B\alpha)^2 \right) \end{aligned} \quad (6)$$

where  $B$  is the biaxiality ratio (Leevers & Radon 1976) and the definition is:

$$B = \frac{T\sqrt{\pi a}}{K_{II}} \quad (7)$$

and  $\alpha$  in Eq. (7) is defined as:

$$\alpha = \sqrt{\frac{2r_c}{a}} \quad (8)$$

where  $a$  is the crack length for edge cracks and the semi-crack length for center crack,  $r_c$  is the constant distance. The terms involving  $B\alpha$  in Eq. (6) represent the contribution of  $T$ -stress in the near crack-tip strain energy density.

By substituting Eq. (6) into Eq. (2), the fracture initiation angle  $\theta_0$  is determined by solving:

$$2\left((2-4\nu)\sin\theta_0 - 3\sin 2\theta_0\right) - B\alpha\left((7-8\nu)\cos\frac{1}{2}\theta_0 + 5\cos\frac{5}{2}\theta_0\right) = 0 \quad (9)$$

For any given value of  $B\alpha$ , the angle  $\theta_0$  can be calculated from Eq. (9). Figure 1 shows the variation of fracture initiation angle  $-\theta_0$  versus  $B\alpha$  for  $\nu = 0.2, 0.3,$  and  $0.4$ . According to Figure 1, the initiation angle  $-\theta_0$  increases by rising the  $B\alpha$  (or  $T$ -Stress), it's clear from this figure that  $T$ -stress has a significant effect on the initiation angle of mode II fracture.

Then the initiation angle  $\theta_0$  is replaced into Eq. (6) and the conditions related to the onset of crack propagation can be found  $S = S_c$ . Eq. (5) can be written as:

Figure 1. The effect of  $T$ -stress on the fracture initiation angle for different Poisson ratio.

$$S_c = \frac{(1+\nu)K_{IIc}^2}{8\pi E} \left( \left( \frac{9}{2} - 4\nu \right) + (4\nu - 2)\cos\theta_0 + \frac{3}{2}\cos 2\theta_0 \right) - B\alpha \left( (7-8\nu)\sin\frac{\theta_0}{2} + \frac{1}{2}\sin\frac{5\theta_0}{2} \right) + 2(1-\nu)(B\alpha)^2 \quad (10)$$

where  $S_c$  is the critical strain energy density factor and  $K_{IIc}$  is the critical value of mode II stress intensity factor corresponding to the fracture load for plane strain conditions.

Under pure mode I loading the fracture initiation angle is zero, therefore, for  $\theta_0 = 0$  and  $T = 0$ , the critical strain energy density factor  $S_c$  is determined from Eq. (5) as:

$$S_c = \frac{(1+\nu)(1-2\nu)K_{Ic}^2}{2\pi E} \quad (11)$$

Thus, the plane strain mode I fracture toughness can be defined as:

$$K_{Ic} = \sqrt{\frac{2\pi E S_c}{(1+\nu)(1-2\nu)}} \quad (12)$$

If  $S_c$  is considered to be a constant material property, Eq. (10) suggests that  $K_{IIc}$  is not constant but depends on  $B$  or the  $T$ -stress. Using Eq. (10) and Eq. (12), the critical intensity factor of material for different geometry and loading condition is written in terms of  $K_{Ic}$  as:

$$\frac{K_{IIc}}{K_{Ic}} = \left( \frac{(4.5-4\nu) + (4\nu-2)\cos\theta_0 + 1.5\cos 2\theta_0}{4(1-2\nu)} - \frac{B\alpha}{4(1-2\nu)} \left( (7-8\nu)\sin\frac{\theta_0}{2} + \frac{1}{2}\sin\frac{5\theta_0}{2} \right) + \frac{1-\nu}{2(1-2\nu)}(B\alpha)^2 \right)^{-1/2} \quad (13)$$

Figure 2 shows the variation of  $K_{IIc}/K_{Ic}$  versus  $B\alpha$  for plane strain condition. The results are based on different values of Poisson's ratio. It is shown that according to the modified SED criterion, the  $T$ -stress has a considerable influence on the critical mode II intensity factor. As illustrated in Figure 2, when the  $T$ -stress is negative, the critical stress intensity factor first increases by rising the  $T$ -stress ( $B\alpha$ ) till it reaches its maximum value which is dependent on the Poisson's ratio. From this point, a sharp decrease in the critical stress intensity factor of the material can be observed. On the other hand, an increase in the positive  $T$ -stress generally leads

Figure 2. The effect of  $T$ -stress on the critical stress intensity factor for mode II.

to a considerable decrease in the mode II critical intensity factor. The modified SED criterion suggests that the  $T$ -stress plays an important role in calculating the mode II fracture toughness of materials.

### 3 FRACTURE PARAMETERS

As shown in Figure 3, the Brazilian Disc (BD) is a circular disc of radius  $R$  and thickness  $t$  containing a central crack of length  $2a$  and subjected to a diametral compressive load  $P$ . The Semi-Circular Bend (SCB) specimen is a semi-circular disc of radius  $R$  and thickness  $t$  having an edge crack of length  $a$  and subjected to three point bending with a span of  $2S$  for the bottom support distance. For both specimens, the crack makes an angle  $\alpha$  with respect to the loading direction. When the inclined angle  $\alpha$  is zero, both specimens are loaded in pure mode I. By increasing  $\alpha$ , the crack is subjected to a combination of mode I and mode II deformation. Pure mode II are provided in specific angles depending on the crack length ratio  $a/R$  and the loading support ratio  $S/R$ . The crack inclination angle corresponding to pure mode II loading condition typically varies between  $20^\circ$  and  $30^\circ$  for the BD specimen and  $35^\circ$  and  $60^\circ$  for the SCB specimen (Ayatollahi & Aliha 2007).

The stress intensity factors ( $K_I$  and  $K_{II}$ ) and the  $T$ -stress in these specimens are often written as:

$$K_I = \begin{cases} Y_I \frac{P}{Rt} \sqrt{\frac{a}{\pi}} & \text{for BD specimen} \\ Y_I \frac{P\sqrt{\pi a}}{2Rt} & \text{for SCB specimen} \end{cases} \quad (14)$$

Figure 3. (a) Centrally cracked Brazilian disk specimen and (b) semi-circular specimen under three point bending.

$$K_{II} = \begin{cases} Y_{II} \frac{P}{Rt} \sqrt{\frac{a}{\pi}} & \text{for BD specimen} \\ Y_{II} \frac{P\sqrt{\pi a}}{2Rt} & \text{for SCB specimen} \end{cases} \quad (15)$$

$$T = \begin{cases} \frac{T^*P}{\pi Rt(R-a)} & \text{for BD specimen} \\ \frac{T^*P}{2Rt} & \text{for SCB specimen} \end{cases} \quad (16)$$

where  $Y_I$  and  $Y_{II}$  and  $T^*$  are the normalized forms of  $K_I$ ,  $K_{II}$  and  $T$  respectively. These parameters are functions of the crack length, the crack angle and the loading support distance. Different analytical and numerical techniques have been used by researchers calculating the factors  $Y_I$  and  $Y_{II}$  and  $T^*$  for the BD specimen (Awaji & Sato 1987, Atkinson et al. 1982, Ayatollahi & Aliha 2007) and SCB specimen (Ayatollahi & Aliha 2004, 2007, Kuruppu & Chong 1986, Lim et al 1993). Atkinson et al. (1982) have calculated the related mode II angle  $\alpha_{II}$  for the BD specimen with different ratio of  $a/R$ . Fett (2001) calculated the  $T$ -stress for the cracked Brazilian disc specimen by using the boundary collocation method. Theoretical investigations show that the  $T$ -stress in the BD specimen is always negative and in the SCB specimen is always positive when the specimens are subjected to pure mode II (Ayatollahi & Aliha 2004, 2007).

### 4 RESULTS AND DISCUSSION

There have been considerable amount of experimental results reported in the papers for mode I and mode II fracture toughness data obtained from fracture tests on the BD specimen and SBC specimen. A review of the experimental results shows that the fracture ratio,  $K_{IIc}/K_{Ic}$  determined from the

BD specimen is always significant higher than the value predicted by the conventional SED criterion, meanwhile, the value of  $K_{IIc}/K_{Ic}$  determined from the SBC specimen, is always lower than the theoretical predictions.

The reported experimental values for  $K_{IIc}/K_{Ic}$  typically commence from 1.09 for graphite SM-124 (Awaji & Sato 1987) and increase to a figure as high as 2.165 for Saudi Arabian limestone (Khan & Al-Shayea 2000) using the BD specimen. For example, the mode I fracture toughness  $K_{Ic}$  and mode II toughness  $K_{IIc}$  obtained through experiment using the BD specimen for limestone material are  $13.28 \text{ MPa} \cdot \sqrt{\text{mm}}$  and  $29.25 \text{ MPa} \cdot \sqrt{\text{mm}}$  and the value of  $K_{IIc}/K_{Ic}$  is 2.165. The mode I and mode II fracture toughness obtained for grain marble are reported to be  $35.42 \text{ MPa} \cdot \sqrt{\text{mm}}$  and  $71.15 \text{ MPa} \cdot \sqrt{\text{mm}}$  respectively and the ratio of  $K_{IIc}/K_{Ic}$  is 2.009 (Aliha et al. 2006). However, the values of  $K_{IIc}/K_{Ic}$  for limestone and grain marble predicted by the conventional SED criterion are 1.074 and 0.957 which are much lower than the experimental results. Lim et al. (1994a, b) conducted a series of fracture tests on a water-saturated synthetic mudstone called Johnstone using the SCB test configuration. The pure mode II was obtained in their tests at the angle of crack inclination of  $\alpha = 54^\circ$  and by considering  $S/R = 0.5$ ,  $a \approx 16.5 \text{ mm}$ ,  $R \approx 8 \text{ mm}$  and  $w \approx 17.7\%$  (where  $w$  is the percent of saturated water content). The average value of  $K_{IIc}$  obtained from the results of the tests was approximately  $0.935 \text{ MPa} \cdot \sqrt{\text{mm}}$ , and the value of  $K_{Ic}$  obtained from the experiment is  $2.2 \text{ MPa} \cdot \sqrt{\text{mm}}$ . Thus, the ratio of  $K_{IIc}/K_{Ic}$  for Johnstone is about 0.425. The fracture ratio  $K_{IIc}/K_{Ic}$  for PMMA is obtained using the SBC specimen with the values of  $a/R$  and  $S/R$  are 0.3 and 0.43 respectively and the pure mode II could be provided at the crack angle  $\alpha = 50^\circ$ , the reported experimental value of  $K_{IIc}/K_{Ic}$  for PMMA is 0.526 (Ayatollahi et al. 2006). However, the value of  $K_{IIc}/K_{Ic}$  predicted by the conventional SED criterion is 0.811 for PMMA, and for Johnstone, the prediction result is 1.074. The experimental results presented in Lim et al. (1994a, b) and Ayatollahi (2004) show that the values of  $K_{IIc}/K_{Ic}$  obtained from fracture tests on the SBC specimen are significant lower than the results predicted by the

conventional SED criterion. It is pointed that the mode I fracture toughness value used here was taken from a fracture tests in which the loading direction was perpendicular to the bedding planes.

Eq. (9) and Eq. (13) indicate that the value of  $T$ -stress,  $K_{II}$  and  $r_c$  are required for calculating the ratio of  $K_{IIc}/K_{Ic}$ . For the BD specimen and SBC specimen, when the specimen geometry is available, the values of  $T$ -stress and  $K_{II}$  can be extracted from Ayatollahi & Aliha (2004, 2007) or directly calculated by finite element analysis software such as ABAQUS. For some brittle materials, the critical distance  $r_c$  is often approximated by the radius of fracture process zone. Schmidt (1980) proposed a maximum normal stress criterion to predict the size of fracture process zone as:

$$r_c = \frac{1}{2\pi} \left( \frac{K_{IIc}}{\sigma_t} \right)^2 \quad (17)$$

where  $\sigma_t$  is the tensile strength. By replacing  $K_{Ic} = 2.2 \text{ MPa} \cdot \sqrt{\text{mm}}$  and  $\sigma_t = 0.435 \text{ MPa}$  (for  $w \approx 17.7\%$ ) in Eq. (17), the value of  $r_c$  is estimated for Johnstone to be 4 mm. Based on the results of earlier fracture tests reported by Smith et al (2006) the critical radius  $r_c$  for PMMA is about 0.1 mm. The value of  $r_c$  calculated by using the same method is 9 mm and 14 mm for limestone and coarse grain marble respectively.

Table 1 shows the comparison between the experimental results and the theoretical predictions. It can be seen that the modified SED criterion described in this paper can provide very good predictions for mode II fracture test results. For Johnstone, the theoretical predictions based on the modified SED criterion suggests that the value of  $K_{IIc}/K_{Ic}$  is 0.385 that is consistent well with the average of the experimental results  $K_{IIc}/K_{Ic} = 0.425$  as described above. For PMMA, the prediction value of  $K_{IIc}/K_{Ic}$  is 0.538 that also is consistent well with the average of the experimental results 0.542. And for limestone and grain marble, the ratios of  $K_{IIc}/K_{Ic}$  predicted by the modified SED criterion are 2.238 and 1.943 respectively, the average of experimental results are 2.20 and 2.009. Again it is seen that a good agreement exists between the experimental

Table 1. Fracture toughness ratio  $K_{IIc}/K_{Ic}$  predicted from the modified SED criterion.

Specimen	Material	$r_c$ (mm)	$B\alpha$	$K_{IIc}/K_{Ic}$ (predicted by SED criterion)	$K_{IIc}/K_{Ic}$ (predicted by modified SED criterion)	$K_{IIc}/K_{Ic}$ (average of test results)
SBC	Johnstone	4.0	2.100	1.074	0.385	0.425
	PMMA	0.1	0.585	0.811	0.538	0.526
BD	Limestone	9	-1.068	1.074	2.238	2.165
	Marble	14	-0.892	0.957	1.943	2.009

results and the theoretical predictions when the modified SED criterion is used.

The modified SED criterion can be used for predicting the mode II fracture toughness of brittle materials from other mode II crack specimens as well and it provides an appropriate method for calculating the mode II fracture toughness from the mode I fracture toughness, this prevents the expensive and time-consuming procedure required for the design, preparation and conduction of mode II fracture tests. The modified SED criterion suggests that the mode II fracture toughness is significantly dependent on the geometry and loading conditions. The SBC specimen always underestimates the value of mode II fracture toughness in engineering materials. This is because a large positive  $T$ -stress is present in the SBC specimen when the specimen is subjected to mode II. And for the BD specimen, a negative  $T$ -stress is present when the specimen is under mode II loading condition and the absolute value of the  $T$ -stress in a mode II BD specimen is small, the mode II fracture toughness is often overestimated in a mode II BD specimen. Therefore, despite several advantages of the BD specimen and SBC specimen for measuring fracture toughness, in brittle materials, it is important to keep in mind that the mode II fracture toughness determined from these two specimens often overestimates or underestimates the fracture resistance of mode II cracks in engineering components and structures.

## 5 CONCLUSIONS

1. The minimum strain energy density criterion was modified to include the effect of  $T$ -stress in predictions of critical mode II fracture toughness. The modified SED criterion suggests that the  $T$ -stress has a considerable influence on the critical stress intensity factor and the fracture initiation angle of brittle and quasi-brittle materials.
2. The theoretical analysis shows that when the  $T$ -stress is negative the critical stress intensity factor first increases as the magnitude of  $B\alpha$  rises, then it declines after a specific value of  $B\alpha$ . Meanwhile, when the  $T$ -stress is positive, increasing  $B\alpha$  generally leads to decreased values of critical stress intensity factor.
3. The  $T$ -stress in the BD specimen is always negative and in the SCB specimen is always positive when the specimens are subjected to pure mode II. The SBC specimen used to measure the mode II fracture toughness can significantly overestimate the value of  $K_{IIc}$  while the BD specimen, underestimate the value of  $K_{IIc}$  in real structure and components.
4. The modified SED criterion was used to predict the fracture toughness ratio  $K_{IIc}/K_{Ic}$  and the predictions show a good agreement with the experimental results.

## Discussion on methods of strengthening concrete structures

Lijun Dou & Tianyu Chen

*Structure Engineering, Changchun Institute of Technology, Changchun, China*

**ABSTRACT:** Due to various factors, the problem of inadequate carrying capacity may appear in the process of construction or use of concrete structures. In this case, some appropriate strengthening methods must be taken in order to keep the safety of the buildings. An account of the commonly used strengthening methods will be given by the author, and the scope, the advantages, and disadvantages of each method will be discussed to provide reference for practical engineering application.

**Keywords:** concrete structure; strengthening methods; safety

### 1 INTRODUCTION

For years, concrete has been the engineering material which is most widely used in the world. However, due to the influence of the disasters, such as earthquake, hurricane, and fire, or exceeding its service life, the carrying capacity of the construction members of existing buildings will be reduced. In this case, in order to ensure the safety and avoid the resources loss of reconstruction, strengthening ought to be chosen prior and it has valuable practical engineering significance.

Since the 1980s, the amount of building strengthening has risen continuously in the United States, the Great Britain, Sweden, and some other developed countries. A large number of buildings have been strengthened properly. In this century, the proportion of the strengthened buildings has already been more than the new construction. In China, according to statistics, more than 40% of the existing buildings need to be strengthened, of which most are of the concrete structures. Especially after the Wen Chuan earthquake and other serious natural disasters, the state launched a new version of the code for seismic design and other relevant regulations, though some buildings cannot meet the requirements for the new code, seismic strengthening is essential, such as the nationwide seismic strengthening project of primary and secondary school building. Thus, the structural strengthening in China is still a long way, and it brings excellent opportunities for development of structural strengthening industry.

### 2 GENERAL PRINCIPLES OF STRENGTHENING CONCRETE STRUCTURE

There has already been force and deformation before the strengthening work begins. The strengthening process will force the structure second. Thus, it must be very cautious and follow certain principles during the strengthening process in order to ensure that the old and the new structures can work together. There are three general principles of strengthening concrete structure.

First, the destruction of the original structure members should be avoided. The engineering quantities and the negative impact should be minimized as much as possible. It must make sure that the old and the new structure can bear some of the loads at the same time, and mainly by the original structure members.

Second, the function of the building should not be affected. While developing a strengthening program, it must be in conjunction with the identification and the use requirement so that the program is scientific and reasonable. Then, some ill-considered factors and errors can be avoided. The function of the building will keep regular.

Third, the integrity of the structure must be ensured. Due to the force generated by the secondary and hysteresis effect when strengthening, the reasonable structure and the reliable connection must be guaranteed during the process of strengthening, to avoid new weak parts from appearing in the structure, thus resulting in the poor integrity.

Strengthening work is different from the construction of new structure, which needs to be

higher and stricter. The strengthening work staff must be on a high professional level to detect the problems and deal with the actual situation. In China, the strengthening of concrete structure must follow the “Code for design of strengthening concrete structure” (GB50367-2013).

### 3 INTRODUCTION TO THE COMMONLY USED STRENGTHENING METHODS

The strengthening methods of concrete structure are divided into direct strengthening and indirect strengthening. The appropriate method is selected according to the actual conditions and use requirements.

#### 3.1 *Direct strengthening methods*

##### 3.1.1 *Increasing section area*

Structure strengthening with increasing section area is a method, which has a wide scope of application and the obvious strengthening effect. It is mainly used for strengthening the bending and the compression members of concrete structure. The method is to increase section area by adding a layer of concrete on the outside surface of the member. For a beam member, the concrete is added in the compression zone and the rebars are added in the tension zone. For a column member, the rebars are added in its marginal area. Like this, the bearing capacity of cross section and the inflexibility of concrete members get improved.

Now, the technology of this strengthening method is mature and costs low. The bearing capacity of the members improves obviously. The durability and the stability are also superior. However, the method belongs to wet work. It takes a period of time to conserve. So it affects production and life. Besides, as the section area is increasing, the appearance of the building may be affected. The headroom decreases. The weight of structure increases.

##### 3.1.2 *Externally wrapped steel section*

Structure strengthening with externally wrapped steel section is divided into two types: dry work and wet work. It is mainly used for strengthening concrete beam and column. Dry work refers to the section steel and batten plates are directly placed around the member. There is no cementation between steel and concrete member. The reliability of this type is poor, so it is rarely utilized. Wet work refers to stick steel to concrete members tightly with adhesive material. At present, modified epoxy cement is widely utilized which is poured between steel and concrete member. The cement layer can pass stress so that the externally wrapped steel section and the member work together.

The steel section area is increased by a large margin in this strengthening method. At the same time, the bearing capacity and inflexibility are also improved. The technology is simple, the amount of work is small. But the consumption of steel is great, there are some requirements of adhesive material. Thus, the expense is higher.

##### 3.1.3 *Bonded steel plate*

Structure strengthening with bonded steel plate is mainly used for strengthening the bending, the tension and the large eccentric compression members of concrete structure. The specific method is to stick the thin steel plate to the surface of concrete member with adhesive material. Then the steel plate and the original member combine into a combinational member. Like the externally wrapped steel section, the cement layer can pass stress. The steel plate and concrete member can work together well so it has high bearing capacity. The code allows that the strength level of the original member is not less than C15, and the tensile bond strength is not less than 1.5 MPa.

The technology of this method is simple and fast. There is an excellent integrity of the combination. The construction has little impact on normal production and life. There is no obvious impact on the appearance of original structure and the headroom. However, its durability is poor. It costs a lot because the consumption of steel is large. Additionally, it does not apply to the members, which bear dynamic load.

##### 3.1.4 *Concrete displacement*

Structure strengthening with concrete displacement is suitable for strengthening the load-bearing member, for which the strength of compression zone is low or serious defect appears. The specific method is to remove the concrete of the member, which is in poor condition and pour the new concrete. Whether the old and the new combine well or not is the key to the effect of concrete displacement. During the construction, reliable measures must be taken on the concrete joint surface.

According to the rules of the code, there must be effective top support to the original member when strengthening horizon members such as beam and slab. It must make sure that there is no tensile stress on joint surface through checking calculation, observation, and control. The strength level of the concrete which is utilized to displace is one level higher than the original, and not less than C25.

The method is widely suitable. Almost all concrete members can be strengthened by it. The effect is good and the member can keep its original appearance. However, the amount of wet work is large, and it may cause some damages to concrete members.

### 3.1.5 *Bonded carbon fiber material*

Structure strengthening with bonded carbon fiber material is suitable for strengthening the bending, the axial compression, large eccentric compression and the tension concrete member. The method is to use a carbon fiber impregnated with resin adhesive to laminate the concrete structure in the bearing parts. Make the two into one so as to improve the bearing capacity, reduce deformation and control cracks of the member.

This method makes concrete member to have better durability, corrosion resistance, and anti-fatigue performance. Carbon fiber material has little impact on the weight of structure and the maintenance cost is low. However, the fire and high temperature resistance of carbon fiber material are poor. When there is a great temperature difference, concrete may crack as a result of the cohesive force between carbon fiber and concrete is destroyed. Carbon fiber may fissure due to lack of ductility when there is a large deformation.

## 3.2 *Indirect strengthening methods*

### 3.2.1 *Externally prestressed*

Structure strengthening that was externally prestressed is the method which utilizes prestressed steel rod and section steel bar to strengthen the structure. The distribution of internal force changes and stress level decreases through prestressing the steel. Strengthening by this method can effectively avoid the hysteresis of stress and strain in general strengthened structures. It is suitable for strengthening the beam, the slab, the column, and the truss, which has small section, needs to increase load, needs to improve performance or is in a high state of stress and strain.

The prestressed rebar and section steel utilized in this method can enhance the bearing capacity of cross section and oblique section. The strengthened structure can work effectively. The prestress is able to offset some stress, this is beneficial to control the deflection and crack of members. There are also some disadvantages, such as the complex construction process, demanding highly on environment. Stress concentration of prestress rebar is produced in the bolted part or the corner. It may lead to rebar's fissure and flab.

### 3.2.2 *Adding fulcrums*

Structure strengthening with adding fulcrums is suitable for strengthening beams, slabs, and trusses. The method is to diminish the structure's span by adding fulcrums in order to decrease the internal force and enhance the bearing capacity of the structure. The method can be divided into two types according to the different mechanical per-

formances of the support structure: rigid fulcrum strengthening and elastic fulcrum strengthening. Rigid fulcrum strengthening is to exert the load on the fulcrum and pass it to the column and the foundation. Its stress is definite and the bearing capacity is enhanced well. Elastic fulcrum strengthening is to pass the load to support structure indirectly by bending of structure or truss' effect. It cannot enhance the bearing capacity obviously, but there is less impact on inner space than rigid fulcrum. There are some regulations about the connection between original members and new numbers. The wet hoop connection is selected when the support structure is reinforced concrete. The dry hoop connection is selected when the support structure is section steel.

The method is simple, reliable, and effective. However, it is easy to influence the building's appearance and function. Therefore, the method should be selected under certain permission conditions.

In addition to the above strengthening methods, structure strengthening with wire wrapped, adding shear wall, and some other methods are also used in some practical engineering. In the process of strengthening concrete structure, there are some related techniques, such as crack repair, embedded rebars, anchor, antitrust and supporting beams, and demolishing columns. The methods and the techniques are introduced in "Code for design of strengthening concrete structure" (GB50367-2013) and "Configuration diagram for strengthening concrete structure" (13SG311-1).

## 3.3 *Precautions of the method selection*

The selection of strengthening method is the prerequisite of strengthening design. It directly influences the quality and cost of the strengthening work. Therefore, a variety of factors should be considered and analyzed comprehensively when selecting an appropriate method. The following points need to be focused on:

1. Select the method, which is economical, simple, and less-impacted on production and life in the premise of ensuring safety.
2. Figure out the advantages, disadvantages, applicable conditions, and special requirements of each method.
3. Consider the feasibility of the method fully, ensure that it can implement smoothly and meet the requirement of strengthening.
4. Strengthening is a comprehensive technology, which may apply several different methods. The superiority of every method should be taken to achieve the good effect.

#### 4 THE DEVELOPMENT TREND OF STRENGTHENING CONCRETE STRUCTURE

As far as the current development situation, strengthening building structure especially strengthening concrete structure has drawn a widespread attention. As hot field-related academic groups all over the world have carried out a lot of technical exchanges and cooperation. Therefore, its application and development has a very bright future.

In recent years, the application of composite materials leads the strengthening technology a significant progress, such as utilizing the inorganic composite mortar pasting steel mesh to strengthen the members of concrete structure. This new strengthening method has the features of anti-aging, fire resistance and superior durability, and the performance of the composite mortar is better than that of the organic cementing material. Fiber composite material strengthening is also a new method, which has been utilized in some countries. It has superior mechanical properties, durability, corrosion resistance, and wide range of applications. The strengthening work is of high quality and efficiency with it. From now on, the study on fiber composite material will be carried out thoroughly to get over the shortcomings of fiber material and obtain a more perfect strengthening method.

In addition, more and more new strengthening methods will be brought out as the development of new material and technology in civil engineering.

#### 5 CONCLUSION

With the increasing size and the total amount of construction in China, as the development of modern technology and construction industry, strengthening concrete structure has become one of the most promising and dynamic technical branches of modern building technology. In the coming period, the practical engineering experience will constantly promote the progress of its

basic theory and technology. In turn, with the level of study and application improves, some more scientific, safer and more economical strengthening methods will be put forward to service the practical engineering.

# Freeze-thaw damage model for polypropylene fiber concrete

Sheng-ping Chen & Fei Ten

*School of Civil Engineering and Architecture, Hubei University of Technology, Wuhan, China*

**ABSTRACT:** The mechanical performance of polypropylene fiber concrete under cyclic freezing and thawing actions was experimentally conducted in this paper. 100 mm × 100 mm × 100 mm cubic specimens and 100 mm × 100 mm × 400 mm beam specimens were made with two different volume ratio of polypropylene fiber. The compressive strength, bending behavior and dynamic elastic modulus of polypropylene fiber concrete were tested after different freeze-thaw cycles. The experimental results demonstrate that, with the increase of freeze-thaw cycles, the frost damage of polypropylene fiber concrete was cumulated, and the relative dynamic modulus, the compressive strength and flexural strength were reduced. By adding polypropylene fiber to concrete, the loss of dynamic modulus was improved, and the flexural strength was increased obviously, but the compressive strength had no significant variance. Furthermore, a freeze-thaw damage model of polypropylene fiber concrete was established.

**Keywords:** polypropylene fiber concrete; freezing and thawing cycle; damage model; strength; dynamic elastic modulus

## 1 INTRODUCTION

Concrete structure is often damaged by cyclic freeze-thaw actions in cold areas, and the freeze-thaw resistance is regarded as the most important index of concrete durability<sup>[1]</sup>. The freeze-thaw damage can be understood as the internal damage of concrete structure. From the point of view of damage mechanics, the definition of damage variable and the establishment of fiber concrete freeze-thaw damage model under cyclic loading are of important reference value to the prediction of the life of concrete structures in cold area and the evaluation of the durability of concrete structure.

Polypropylene fiber can inhibit crack propagation, prevent crack diffusion, improve the long-term performance of the concrete structure and improve structure durability. The frost resistance of polypropylene fiber reinforced concrete has been obtained a lot of attention. The study on freeze-thaw damage of fiber concrete has obtained certain results in experimental data and damage model<sup>[2-5]</sup>. The damage behavior of polypropylene fiber concrete in freeze-thaw is studied by conducting an experiments of freeze-thaw on the polypropylene fiber concrete specimens. From the macroscopic physical properties, the frost damage is reflected as the loss of dynamic elastic modulus, the reduced mechanical properties, such as the compressive strength, the flexural strength. In this paper, a freeze-thaw damage model is established, which is based on the two parameter Weibull

distribution, and on the basis of the test data from the polypropylene fiber concrete under cyclic freezing and thawing actions.

## 2 FREEZE-THAW TEST

### 2.1 *Experiment materials*

The design strength of polypropylene fiber concrete is C45. The ordinary Portland cement, coarse river sand with a maximum particle size of 20 mm, and polypropylene fiber with a length of 19 mm were used.

### 2.2 *Freeze-thaw test*

The specimens are divided into two series of specimens. The first series are 100 mm × 100 mm × 100 mm cubic specimens, which are used to determine its compressive strength. The second series are 100 mm × 100 mm × 400 mm beam specimens, which are used to measure the relative dynamic elastic modulus, mass loss and flexural strength. Three different volume ratios of fiber contents were made. Fast freezing and thawing test method was adopted according to the Chinese national standard GB/T50082-2009. Freeze-thaw equipment come from Shanghai Sanhao refrigeration equipment factory. Before the experiment, specimen should be soak in the water of 20–25 °C for 4 days to make the specimen come to water saturation state. Every freeze-thaw cycle is about

4 hours, the frozen and melt state transition time is about 10 minutes. The temperature in the center of the specimen under completely frozen is  $-17\text{ }^{\circ}\text{C}$ , and the highest temperature is about  $8\text{ }^{\circ}\text{C}$ .

### 3 EXPERIMENTAL RESULTS AND ANALYSIS

#### 3.1 Experiment phenomena

When the freeze-thaw cycles are 50 times, the three groups of specimens emerge no obvious change, only have a small amount of thin skin loss. The polypropylene fiber concrete was not significantly exposed, and the mass loss of block is small, and even there were some slightly increasing trend. This shows that, after freeze-thaw action, the surface of concrete appear tiny cracks, cause the block absorbs water. The damage in the three groups of specimens are in a lesser degree. When cycle time of freeze-thaw reached 100 times, protective layer on the surface of the block is flaking off, peeling powder particles increased obviously. Due to the effect of polypropylene fiber, surface of fiber concrete cohere residual fragments which is not peeling off completely. When freeze-thaw cycles reached 150 times, protective layer of block surface peels off in great quantities. A majority of internal aggregate has been exposed. Surface damage degree of fiber concrete with 0.75% fiber content is significantly better than that of plain concrete. The polypropylene fiber can alleviate the effect of concrete internal stress because of temperature variance, prevent the expansion of the micro cracks. With the increase of fiber content, the phenomenon is more obvious, and the quality loss rate is smaller. When freeze-thaw cycles reached 200 times, block

surface layer has been exfoliated completely, internal aggregate naked completely. With the increase of fiber content, the damage degree of block surface have no obvious difference.

#### 3.2 The mass loss rate and relative dynamic modulus

Specimen's mass is measured after every 25 times freeze-thaw cycles. The relative dynamic elastic modulus for concrete is expressed:

$$P_n = \frac{f_n^2}{f_0^2} \times 100\% \quad (1)$$

where  $P_n$  represents specimen's relative dynamic elastic modulus after n times freeze-thaw cycles (%);  $f_n$  represents specimen's transverse resonance frequency after n times freeze-thaw cycles (Hz);  $f_0$  represents specimen's transverse resonance frequency before freeze-thaw test (Hz).

Mass loss rate of concrete is expressed:

$$W_n = \frac{G_0 - G_n}{G_0} \times 100\% \quad (2)$$

where  $G_0$  represents specimen's initial mass,  $G_n$  represents specimen's mass after n times freeze-thaw cycles. The test data were shown in [Table 1](#) and [Table 2](#).

The relationship between freeze-thaw cycles and relative dynamic elastic modulus, mass loss rate are shown in [Figure 1](#) and [Figure 2](#), respectively. [Figure 1](#) and [2](#) indicate that, for P1 and P2 group with polypropylene fibers, the loss of dynamic modulus and mass loss of concrete is less than that

Table 1. The mass loss rate.

No.	The mass loss rate							
	25 times	50 times	75 times	100 times	125 times	150 times	175 times	200 times
P1	-0.31	0.56	0.94	1.67	2.32	2.84	3.44	4.15
P2	-0.16	0.43	0.91	1.52	2.20	2.41	2.79	3.39
P3	-0.09	0.28	0.72	1.21	1.67	2.16	2.45	2.84

Table 2. The relative dynamic elastic modulus.

No.	The relative dynamic elastic modulus							
	25 times	50 times	75 times	100 times	125 times	150 times	175 times	200 times
P1	98.21	95.78	91.66	86.40	81.57	75.28	69.49	62.60
P2	98.74	96.86	92.85	88.59	84.13	78.36	73.17	67.77
P3	98.24	98.24	94.90	90.95	87.82	83.65	78.24	76.87

Figure 1. Mass loss for polypropylene fiber concrete.

Figure 2. Relative dynamic elastic modulus for polypropylene fiber concrete.

of plain concrete in each stage of freeze-thaw. And the reinforcing effect of high fiber content is better than that of low fiber content. This shows that polypropylene fiber can improve the frost resistance of concrete materials effectively.

### 3.3 Concrete freeze-thaw strength

With the increase of freeze-thaw cycles, internal damage is accumulated, and concrete compressive strength and flexural strength is decreased, the strength tendency of concrete with different polypropylene fiber volume fractions was reflected in Figure 3 and Figure 4. For the compressive strength, the initial strength of concrete with 0.75% fiber content is enhanced, but with the number of freeze-thaw accumulate, strength decline quickly. Strength is

Figure 3. Compressive strength of polypropylene fiber concrete.

Figure 4. Flexure strength of polypropylene fiber concrete.

least after 200 times freeze-thaw. For the specimens with 1.5% fiber content, strength is higher than plain concrete's under different freeze-thaw cycles. Moreover, 1.5% fiber content is better than 0.75% fiber content. Adding fiber content has a more significant effect for flexural strength. Fiber can significantly increase the content's flexural capacity, and two kinds of concrete of different fiber content have no significant difference for the flexural strength.

## 4 FREEZE-THAW DAMAGE MODEL

### 4.1 Definition of damage variable

The damage variable is defined as:

$$D = 1 - \frac{E_u}{E_0} \quad (3)$$

When  $D$  is the damage variable,  $E_n$  is the dynamic elastic modulus of concrete after  $n$  times freeze-thaw cycles,  $E_0$  is the initial dynamic elastic modulus.

#### 4.2 Freeze-thaw damage model

The Weibull distribution model can be regarded as the life of the material distribution model. According to the two-parameter Weibull probability model, the probability distribution function is:

$$F(N) = 1 - \exp\left[-\left(\frac{N}{\eta}\right)^\beta\right] \quad (4)$$

where  $\eta$  is the characteristic parameter,  $\beta$  is shape parameter.

After  $n$  times of freeze-thaw cycles, the failure probability of concrete is:

$$P_f(n) = 1 - \exp\left[-\left(\frac{n}{\eta}\right)^\beta\right] \quad (5)$$

After  $n$  times freeze-thaw cycle, the damage of concrete is defined as  $D(n)$ . When the freeze-thaw cycles of concrete achieves  $n$ ,  $D(n) = 1$ , it means the failure of concrete material, failure rate  $P_f(N) = 1$ . To concrete material, after  $n$  times freeze-thaw cycles, failure rate of this material is  $P_f(n)$ , while the failure damage of concrete is  $D(n)$ , at this time we can regard failure rate of this material as the amount of damage, thus there be:

$$P_f(n) = D(n) \quad (6)$$

And that also is

$$D(n) = 1 - \exp\left[-\left(\frac{n}{\eta}\right)^\beta\right] \quad (7)$$

From the formula (7):

$$\ln\left(\ln\frac{1}{1-D}\right) = \beta\ln\frac{1}{\eta} + \beta\ln(n) \quad (8)$$

Instruct  $Y = \ln(\ln(1/(1-D)))$ ,  $X = \ln(n)$ , formula (8) can be written as a first order linear function:

$$Y = a + bX \quad (9)$$

Based on the definition of variable damage, the experiment data of the dynamic elastic modulus  $E_n$  can be used as the calculated value of freeze-thaw damage regulation  $D = 1 - E_n/E_0$ .

Table 3. Parameter of linear regression.

No.	a	b ( $\beta$ )	$\eta$	$R^2$
P1	-9.252	1.592	334.153	0.99596
P2	-9.969	1.708	342.630	0.99409
P3	-10.385	1.726	410.264	0.97970

Figure 5. Linear fitting of Weibull distribution.

In order to make the scatter  $(X_i, Y_i)$  reach the best state of linear, we can use maximum likelihood to estimation parameters a, b. Parameter estimation data as shown in Table 3.

Data points fall on a straight line basically as shown in Figure 5. All of the correlation coefficient more than 0.97. This shows that choosing the two-parameter Weibull distribution probability model to establish fiber concrete freeze-thaw damage constitutive model is rational.

Therefore, the freeze-thaw damage equation of different fiber content concrete is established as

$$D(n) = 1 - \exp\left[-\left(\frac{n}{334.153}\right)^{1.592}\right] \quad (10)$$

$$D(n) = 1 - \exp\left[-\left(\frac{n}{342.630}\right)^{1.708}\right] \quad (11)$$

$$D(n) = 1 - \exp\left[-\left(\frac{n}{410.264}\right)^{1.726}\right] \quad (12)$$

## 5 CONCLUSION

1. Polypropylene fibers on the structure hinders the permeate of concrete internal water, the frost resistance of concrete was enhanced from

the internal structure. With the increase of fiber volume, mass loss rate and the concrete of the dynamic modulus loss rate accumulated slowly with freezing thawing cycles. The polypropylene fiber can improve the frost resistance of concrete test piece.

2. Establishing concrete freeze-thaw model by using the Weibull probability distribution equation is feasible. The model can meet the experimental data well and reflect the real environment. So the model can be used as evaluation reference of the fiber concrete life under the action of freeze-thaw.
3. Concrete strength is improved under the action of freeze-thaw by mixing fiber, but with the cumulative number of freeze-thaw, the effect of polypropylene fiber hinder decline of concrete compressive strength is not very obvious, but fibers can improve the flexural strength significantly obviously. Finally, the damage model of polypropylene fiber concrete is established, and the experimental data fitting accuracy is higher. But the damage model still need a lot of test data to verify.

# Design and application of real-time deformation monitoring system for factory building

XiaoDong Pan, ZhiBin Yao & Lei Zhao

College of Civil Engineering, Zhejiang University of Technology, Hangzhou, China

**ABSTRACT:** It is hard to detect the settlement and incline of the structure timely and accurately by the traditional methods of measurement, which use level and total station. This program will establish a set of system for real-time deformation monitoring and safety warning. The whole system consists of sensor module, signal transmission module, signal processing module, and feedback module. The deformation of factory structure can be precisely and continuously monitored in the coming years. If the deformation exceeds warning level, the system will be automatically alarmed. This paper will analyze the components of system and the principle of monitoring. The foundation settlement and inclination of a machine repair workshop is monitored and the feasibility of the system is verified.

**Keywords:** real-time monitoring; sensor; monitoring system; safety warning

## 1 INTRODUCTION

In recent years, we routinely use the total station and other conventional measuring instruments to measure structural settlement and deformation. But the conventional methods have some disadvantages. It will take a long and slow process for them to obtain the deformation. It is difficult to reflect the health and safety of structure in time because the measuring frequency is not enough.

The deformation monitoring is a series of long-term and repetitive measuring work. The key of monitoring is setting monitoring point in the important position of the structure and observing periodically to obtain the information of deformation. Then we need to check and process the deformation data and ensure the safety of the construction. Therefore, it has important significance to establish a structural health monitoring system, which can immediately make the monitoring deformation of structure be done and diagnose its safety.

For that reason, we need to establish a high degree of automation system which can timely measure out the deformation and transmit to the computer. Then through the software system of data processing, the monitoring system will achieve automatic identification and let users have a clear understanding of the deformation condition in a graphical form. The system will automatically be alarmed if the deformation exceeds the alarm value.

## 2 THE MONITORING PRINCIPLE AND SYSTEM COMPOSITION

### 2.1 The monitoring principle

Single-layer factory building is composed of vertical and horizontal framed bents. We generally calculate

Figure 1. Settlement and incline influence to structure.

Figure 2. Design of system structure.

1—monitoring fixed mount, 2—supply for electrical, 3—signal bus, 4—processing system, 5—warning indicating device, 6—static force level, 7—biaxial inclinometer, 8—Benchmark static force level, 9—connecting wire, and 10—remote feedback device.

Table 1. The structure deformation monitoring content.

Monitoring content	Monitoring technology	Monitoring instrument	Monitoring period	Monitoring type
Settlement	Physics sensors	Static force level	Dynamic	Real-time automatic
Inclination	Physics sensors	Biaxial inclinometer	Dynamic	Real-time automatic

the transverse frame bent for structure analysis. So we can choose a representative framework in the whole structure as a calculated element. Uneven settlement and inclination will induce the structural change due to its internal force and cause deformation. The schematic diagram is shown in Figure 1.

At the bottom of each frame column, sensors will be installed and the signal from the sensors will be output to the processing system by transmission module. Then, the results of the settlement and inclination will be displayed on a computer screen in the form of a graph. Finally, the system will output signal to the warning device.

## 2.2 System composition

According to the single-layer factory structure model, a system that can do real-time measurements, settlement, and inclination is designed. The whole system can be divided into four modules: sensor module, signal transmission module, signal processing module, and feedback module. The design of system construction has been shown in Figure 2.

Sensor module: we regard a frame column as a monitoring element, and then install sensors at the bottom of each frame column to get the data of settlement and inclination of every moment. We will get the settlement date from static force level and  $t$  the inclination from biaxial inclinometer. The monitoring content is shown in Table 1.

Signal transmission module: This module is composed of a serial port communication, connecting wire, signal bus, and so on. It can realize the data transmission.

Signal processing module and feedback module: The main function of this module is to manage and collect dates, analyze structure safety, and give signal back to the remote feedback device. We choose Microsoft Visual Studio 2008, which can display monitoring data in the form of dynamic graphic to design the program code of safety warning system. According to the different security level, the system will give the device a corresponding signal. Once the monitoring data have achieved a warning value, the device will be warned.

## 3 FIELD TEST

### 3.1 Engineering background

Due to age, the factory building has been degraded in the process of using and has a hidden trouble

Figure 3. Monitoring point of factory building.

in security issue. The main deformation monitoring work is measuring the settlement and inclination of the factory building. The work has begun in October 2013 and has been finished in March 2014, lasting half-a-year.

### 3.2 Arrangement of measuring points

When we arrange sensor placement for factory building, we should fully consider the influence of the wires on daily work. On this basis, we optimize economic efficiency by the way of choosing sensor wire path which has the shortest and the least interference to the factory daily operation. According to the factory building layout and engineering characteristics, we decorate seven monitoring points and a datum mark. Monitoring points (JX1, JX2, JX3, JX4, JX5, JX6, JX7 and GZ01) are shown in Figure 3.

## 4 MONITORING DATA ANALYSIS

### 4.1 Monitoring data statistics

The factory building has been real-time monitored for more than six months. Monitoring frequency

is twice a day and no less than 50 times a month. According to the surrounding environmental situation, we appropriately increase or decrease monitoring frequency. Based on the monitoring data, we draw the settlement curve in Figure 4 and the biaxial angle statistics in Table 2.

#### 4.2 The summary and rating of monitoring

The settlement points JX1, JX2, JX5, and JX7 are larger than others. The biggest was JX5 whose

accumulated maximum settlement is 11.1 mm and maximum subsidence rate (the ratio of cumulative settlement monitoring and monitoring time) is 0.0845 mm/d. Generally speaking, the settlement point which is close to the road side is bigger than others. The inclination point of JX2 and JX5 are larger; their maximum angle is 0.045 degrees.

According to the current national standard “industrial building reliability appraisal standard” GB 50144-50144, we assess the safety of factory building which is on A level.

Figure 4. The accumulated settlement curve of four monitoring points (JX1, JX2, JX5, and JX7).

Table 2. The biaxial angle statistics of factory building.

	Direction	October–November	November–December	December–January	January–February	February–March	Max inclination
JX1	x	0.02	0.02	0.01	0.01	0.01	0.028
	y	-0.02	-0.01	-0.02	-0.02	-0.02

	y	0.02	0.03	0.03	0.03	0.02	
JX5	x	-0.02	-0.02	-0.02	-0.02	-0.01	0.036
	y	-0.03	-0.02	-0.01	-0.01	-0.02	
JX6	x	-0.01	-0.02	-0.03	-0.04	-0.01	0.045
	y	0.01	0.01	0.01	0.02	0.01	
JX7	x	-0.01	-0.01	0.00	0.00	-0.01	0.032
	y	-0.03	-0.03	-0.03	-0.03	-0.02	

## 5 CONCLUSION

Real-time deformation monitoring system for factory building overcomes the defects of the traditional monitoring which cannot finish timely, long-term monitoring. The interface is simple and users can see the deformation of structure on the remote PC and mobile phones. Monitoring data and warning signs can be displayed in the form of dynamic graphic in time. The feasibility of the system is verified by the application of real-time deformation monitoring system. Monitoring results show that the system is able to coordinate the operation and realize the expected function design. What is more, the system provides a useful data for the structure safety assessment method and accumulates engineering experience for similar deformation monitoring system.

## Analysis for seismic performance of shear wall-steel truss structure system

Weidong Sun, Xinyu Niu & Hongbin Chen

Jilin Key Laboratory of Disaster Prevention and Reduction, Faculty of Civil Engineering, Changchun Institute of Technology, Changchun, China

**ABSTRACT:** In order to reduce the seismic response of concrete shear wall structure and prevent it from brittle failure, concrete shear wall and steel truss are combined to form the shear wall-steel truss structure system, and the steel truss system is equipped with buckling-restrained brace to strengthen the energy consumption capacity of the structure and decrease the seismic response. A framed-tube structure model is used as example in this paper. The tube has ordinary concrete tube structure and shear wall-steel truss structure. Dynamic elastic-plastic time-history analysis method is used to analyze the seismic response of different cases under the rarely met earthquake. The calculation result showed that, seismic response of the shear wall-steel truss structure system's storey shift, speed, acceleration and total shearing force of substrate has been effectively controlled, thus reducing the seismic response of the overall structure.

**Keywords:** shear wall-steel truss structure; seismic response; time history analysis; seismic damping effect

### 1 INTRODUCTION

Concrete shear wall structure is featured by big rigidity and strong anti-lateral force, which is extensively applied in high-rise buildings; the shear wall, however, has big rigidity resulting in stronger seismic response, and easily causes brittle failure. Its main problems are to ensure the shear wall structure to have enough anti-lateral force rigidity under normal operation, and reduce seismic response in case of rarely met earthquake to prevent against brittle failure. Therefore, domestic and foreign scholars have studied many approaches [1, 2]. Current approaches mainly start with the shear wall itself and take measures, leading to more difficult construction and higher cost. The author has proposed, based on the structure system, combining concrete shear wall and steel truss to form shear wall-steel truss structure system, and installing some buckling-restrained brace dampers in the truss system to increase the energy consumption capacity of the structure, and lessen its seismic response [3]. The schematic diagram of shear wall-steel truss structure system is as shown in Figure 1. The buckling-restrained brace has advantages of low cost, good energy consumption, very stable hysteresis property, excellent low cycle fatigue property, strong adaptability to environment and temperature, and long-term stable performance [4]. In normal operation stage, the buckling-restrained brace can be used as ordinary rod; in case of rarely met earthquake, it can be yielded first to play its role in energy consumption. Such structure owns

anti-lateral force rigidity of the shear wall, and the steel truss has excellent ductility and energy consumption capacity, which only needs simple construction, convenient for repair and replacement after earthquake. When a hole opening is required

Figure 1. Schematic diagram of shear wall-steel truss structure system.

for construction, a reasonable support form can be placed for making the hole opening. If the hole is not unnecessary, thermal insulation materials can be filled.

In order to analyze the seismic resistance of shear wall-steel truss structure system, in this paper, a framed-tube structure model is taken as an example. The tube has ordinary concrete tube structure and shear wall-steel truss structure. Dynamic elastic-plastic time-history analysis method is used to analyze the seismic response of different cases under the rarely met earthquake to compare the seismic damping effect of steel truss-shear wall structure.

## 2 CALCULATION MODEL AND CALCULATION CASE

### 2.1 Calculation model

The layout of frame-core tube structure is as shown in Figure 2. The structure has 27 storeys, substrate storey is 4.2 m high, and 2–27 storeys are 3.6 m high. Specific dimensions of columns, beams and wall components are as shown in Table 1. The floor thickness is 0.12 m. The floor's constant standard load is 4 kN/m<sup>2</sup>, standard live load 2.5 kN/m<sup>2</sup>, roof's constant standard load, and standard active load 2 kN/m<sup>2</sup>. The standard linear load of frame beams surrounding the storey is 8.0 kN/m, and the standard linear load of frame beams surrounding the roof is 3.0 kN/m.

### 2.2 Calculation case

3 structural cases are adopted in this paper: CASE1: the tube has ordinary concrete tube structure, and

Figure 2. Structural layout of frame-core tube.

Table 1. Dimension table of calculation model construction members.

Member	Dimension (mm)	Concrete grade	Storey
Column	1000 × 1000	C50	1–5 storeys
	900 × 900		6–10 storeys
	800 × 800		11–15 storeys
	700 × 700		16–20 storeys
	600 × 600		21–27 storeys
Secondary beam	300 × 600	C40	1–27 storeys
Main beam	350 × 750	C40	1–9 storeys
	350 × 700		10–19 storeys
	300 × 700		20–27 storeys
	400	C50	1–9 storeys
	300		10–19 storeys
	200		20–27 storeys

hole openings are made at X and Y directions of the core tube (see Fig. 2), with width 3 m, height of first storey 2.7 m, and height of other storeys 2.4 m. The place with the opening width is installed with ordinary reinforced concrete coupling beams; CASE2: the tube has shear wall-braced frame, and the truss can meet the construction requirements and is arranged for the purpose of reasonable stress and convenient construction. The steel truss is placed at X direction of the tube is as shown in Figure 1. The diagonal web member is equipped with buckling-restrained brace. Y direction of the tube can accomplish the construction functions. The hole width span is broadened, that is, the horizontal span of truss in the middle of the tube is increased. The diagonal web member is arranged as reverse V shape for setting up openings. The schematic diagram of truss is as shown in Figure 3. The diagonal web member also adopts buckling-restrained brace; CASE3: the structural layout same as CASE2 is used. The only difference is that, buckling-restrained brace is only used in truss diagonal web members at 8–12 storeys with big calculation shift in CASE1, and the remaining storeys of truss diagonal web members are ordinary steel rods.

When designing truss rods in CASE2 and CASE3, we will enable two cases inter-storey angle shift under the effect of frequent earthquake to be basically in conformity with CASE1, ensure the deformation capacity of two cases during normal application, and make two cases realize early yield of buckling-restrained brace when the big earthquake happens. Rod types and dimensions of CASE2 and CASE3 got from repeated calculations are as shown in Figure 3 and Figure 4.

Main aim of this paper is to compare the seismic response of three cases in the effect of rarely

Figure 3. Single inclined layout of diagonal web member.

Figure 4. Schematic diagram of reverse V shape layout of diagonal web member.

met earthquake. The buckling-restrained brace and some structural members will enter elastic-plastic stage in the effect of rarely met earthquake, so dynamic elastic-plastic time history analysis method is used for analysis. This case uses components of EL Centro seismic waves in 1940 at south and north directions for dynamic elastic-plastic time history analysis. Maximum acceleration of the seismic wave is  $3.417 \text{ m/s}^2$ . Ground acceleration time history is as shown in Figure 5.

Midas/Gen analysis software is used for dynamic elastic-plastic time history analysis, buckling-restrained brace is simulated with nonlinear linkage unit—hysteresis system in Midas/Gen, and the hysteresis system is consisted of 6 springs with unidirectional plasticity at the degree of freedom. In this project, only  $D_x$  (axial direction) has characteristic

Figure 5. Schematic diagram of components acceleration of EL centro seismic waves at south and north directions.

Figure 6. Model of buckling-restrained brace hysteresis system.

value of spring plasticity. The model of hysteresis system is as shown in Figure 6. According to the early-stage buckling-restrained brace test result, set up elastic rigidity  $k$  of buckling-restrained brace as  $1.24 \times 10^6 \text{ kN/m}$ , yield strength  $F_y$  2632 kN, specific value  $r$  between rigidity and elastic rigidity after yielding of buckling-restrained brace 0.1, and yield index  $s$  of buckling-restrained brace 2. The relational expression of strength  $f$  and deformation  $d$  is:

$$f = r \cdot k \cdot d + (1 - r) F_y \cdot z. \quad (1)$$

### 3 CALCULATION RESULT ANALYSIS

#### 3.1 Comparative analysis of shift, speed and acceleration

The dynamic elastic-plastic time history analysis result of shift, speed and acceleration at top storey and the ninth storey in 3 cases is as shown in Table 2. The curve of shift, speed and acceleration time history curve at the ninth storey is as shown in Figure 7, Figure 8 and Figure 9. According to the analysis result, the seismic response of shear wall-steel truss structure system regarding storey shift, speed and acceleration is smaller than that of ordinary concrete tube structure. Compared with CASE1, average control rate of three indexes in CASE2 and CASE3 is 10%–20%; based on the contrast between CASE3 and CASE2, the average control rate at each storey is similar, indicating that installing buckling-restrained brace at the

Table 2. Analysis result table of shift, speed and acceleration.

Seismic response	CASE1	CASE2	
	Seismic response peak value	Seismic response peak value	Control rate compared with CASE1
Top storey shift (m)	0.169	0.135	18.45%
	-0.143	-0.119	
Top storey speed (m/s)	0.912	0.754	11.65%
	-1.005	-0.945	
Top storey acceleration (m/s <sup>2</sup> )	5.586	4.789	16.49%
	-7.576	-6.158	
9th storey shift (m)	0.033	0.031	13.64%
	-0.033	-0.026	
9th storey speed (m/s)	0.227	0.180	21.03%
	-0.206	-0.162

	-2.212		

Figure 7. Curve graph of 9th storey shift time history.

Figure 8. Curve graph of 9th storey speed time history.

storey with big lateral sway can get good effect. The buckling-restrained brace placed at the storeys with small inter-storey shift is always elastic, stopping the ordinary steel rod from exerting the role of energy consumption and seismic damping. The comparative diagram of inter-storey shift angles of CASE1 and CASE3 is as shown in Figure 10. The correlation curve can show that, under the effect of rarely met earthquake, the inter-storey

shift angle of shear wall-steel truss structure has become smaller than that of ordinary concrete tube structure.

### 3.2 Comparative analysis for total shearing force at the structure substrate

The analysis result of total shearing force at the structure substrate is as shown in Table 3.

Figure 9. Curve graph of 9th storey acceleration time history.

Figure 10. Comparative graph of inter-storey shift angles of CASE1 and CASE3.

Table 3. Table of analysis result of total shearing force at the structure substrate.

CASE	CASE1	CASE2	
Content	Seismic response peak value	Seismic response peak value	Control rate compared with CASE1
Total substrate shearing force (kN) and control rate	50118 -48231	46635 -39678	12.34%
CASE	CASE3		
Content	Seismic response peak value	Control rate compared with CASE1	Control rate compared with CASE2
Total substrate shearing force (kN) and control rate	45531 -36763	16.46%	4.86%

According to the time history analysis result, the total substrate shearing force peak value of shear wall-braced-frame system fell by 12.34% and 16.46% compared with the ordinary concrete tube structure, so the difference between CASE2 and CASE3 is not obvious.

#### 4 SUMMARY

Based on the analysis for dynamic elastic-plastic time history in the effect of rarely met earthquake of three cases, the following conclusion is given below:

- Compared with ordinary reinforced concrete tube structure case, seismic response of the shear wall-steel truss structure system's storey shift, speed, acceleration and total shearing force of substrate has been effectively controlled.
- In the shear wall-steel truss structure system, all storeys are arranged with buckling-restrained brace. Compared with the case that only sets up buckling-restrained brace at the storeys with big inter-storey shift, the difference between their seismic damping effect is not big, indicating that, installing buckling-restrained brace at the storeys with big inter-storey shift can exert stronger seismic damping function. The buckling-restrained brace placed at the storeys with small inter-storey shift is always in elastic stage, so it can only play a role of the normal steel rod, and its energy consumption and seismic damping functions cannot be fully exerted.

# Seismic performance and retrofit for a historic concrete building in Shanghai

H.N. Wang

*College of Civil Engineering, Shanghai Normal University, Shanghai, China*

H.B. Liu

*Shanghai Research Institute of Building Sciences, Shanghai, China*

*Shanghai Key Laboratory of New Technology Research on Engineering Structure, Shanghai, China*

**ABSTRACT:** Seismic retrofitting of the cultural heritage, especially of the historic buildings, requires compliance with the severe restrictions of Code related to the preservation of the original artistic and structural features. In order to meet the rebuilding needs, safety inspection, seismic evaluation and strengthening design for a historic building are carried out. This building, completed in 1930s, was designed without considering the effect of possible earthquakes which cannot meet the current seismic criteria. Safety and seismic behavior are analyzed. According to the evaluation, the design idea and strengthening methods are put forward.

**Keywords:** historic building; seismic evaluation; retrofit; design criteria

## 1 INTRODUCTION

There are many historic buildings in Shanghai. In order to reuse the available existing buildings, structures must be adapted for the new use and upgraded to current building code requirements. However, few historic buildings meet current code seismic requirements for life safety, and most have architecturally significant elements that are threatened by future earthquakes.

The need for evaluating the seismic adequacy of those existing buildings has come into focus following the damage of numerous concrete structures during earthquakes. In particular, the seismic rehabilitation of older concrete buildings, which were designed prior to the advent of modern seismic design codes, is a matter of growing concern.

We know almost everything about earthquakes (in reality every earthquake teaches us something more) and how to mitigate their risks but the major problem are all the buildings erected before the Standards were issued. Seismic retrofitting means improving the resistance of a structure so that it will be in accordance with the seismic standards. Hence, it is necessary to evaluate these building's seismic performance and to retrofit them using appropriate methods.

## 2 APPLICATION EXAMPLE

A typical historic concrete building is selected as an application example to evaluate the seismic

performance of existing historic buildings in Shanghai (see Fig. 1). As many rehabilitation projects, the existing as-built documentation of the structural system was sparse. This structure was designed without considering the effect of possible earthquakes. The seismic design forces are significantly lower than what is now required by the current standard.

A 9-story historic building is located in Shanghai, China, and was designed and constructed in early 1930s per the applicable building codes at the time of construction. It is a reinforced concrete frame building with brick infill walls, and elevator shafts, flues and part of stair well walls are solid reinforced concrete walls. Therefore, the lateral system for the building consists of a non-ductile reinforced concrete frame system. The building is U-shaped in plan, as shown in Figure 1, with two,

Figure 1. Plan view of case study building.

9-story wings almost equally expanded 9.3 m. The 28.88 m tall building is 44.2 m long and 22.2 m wide. The first story height is 3.97 m and the others are 3.05 m. There are four elevators. The building is supported on a pile foundation system.

### 3 EVALUATION OF EXISTING BUILDING

In any retrofit project the foremost problem the structural engineer is faced with is the evaluation of the existing structural strength and deformation capacity. For nonhistoric structures, these issues are not very important since the primary intent of retrofit there is to provide life safety. For historically significant structures, where the performance objective extends beyond those of life safety and includes protection of architectural features, a reliable estimate of the existing structural capacity and of the dynamic characteristics of the structure is important.

#### 3.1 Comprehensive material testing

Coring samples and laboratorial testing for concrete and reinforcing steel was conducted by a licensed testing laboratory.

According to standard requirements, a minimum of three samples of concrete cores and reinforcing steel were extracted from the various structural components and tested. The final testing result shows that the concrete strength ( $f_c$ ) varies from 16.8 MPa to 25 MPa, and the average is 21.6 MPa. The yield strength ( $f_y$ ) of reinforcing steel varies from 500 MPa to 512 MPa. In addition to destructive tests, several site visits and condition assessments investigations were conducted. Concrete members appeared intact with minimal cracking or evidence of reinforcement corrosions. The in-situ dimensions, member sizes, reinforcement sizes, and concrete cover are all measured.

#### 3.2 Modal analysis

Structural analysis was performed to assess the seismic performance of the building and identify deficiencies (see Fig. 2). The analytical model of the building incorporated the dimensions of structural members measured on site. The beam-column joints located around the perimeter of the building are taken as rigid joints. The interior beams of frame are taken as hinged joints due to fewer bars. Except the shear walls of two elevator shafts, others can't link with the ground. Structural walls and floor slabs were modeled using shell elements, whereas line elements were used for the beams and columns. Walls and columns were assumed to be restrained at the foundation level with full fixity.

Figure 2. Model of structure.

#### 3.3 Structural analysis

Seismic fortification intensity is 7 degree. According to the result, the building periods in the x- and y-directions are similar. The first mode is 1.20 s in the X direction. The second one is 1.19 s, which represents the vibration in the Y direction. The third mode is 0.86 s, which represents the torsional vibration of the structures. The maximum story drifts is 1/547 in the X direction and 1/486 in the Y direction. This analysis clearly indicated that the building has lowly torsional response and excessive story drift.

A preliminary evaluation of the building revealed several seismic deficiencies, including the following.

(1) non-ductile detailing, such as lack of beam confinement reinforcement, (2) flexible lateral system with excessive building deflections, and (3) inadequate strength of the shear walls at the stairwells. In addition, the foundation pressure under columns mainly meets the requirements of bearing capacity of foundation soil.

#### 3.4 Structural shortcomings in details

A preliminary investigation of this historic structure was performed to determine the building's ability to adequately respond to future seismic events. The results of analytical investigations showed that the building in its current configuration possessed major seismic deficiencies. The main structural deficiencies are the following:

- Structural system: irregularities in the column grid; the lack of beams at the corridor is an irregularity; discontinuity in vertical lateral

components due to many transfer components. All of these can lead to important damage in this part of the building during an earthquake.

- Reinforcement details: the lack of bars at the end of beams; the lack of hooping in the core area of beam-and-column joint; no bars at the top of slabs.
- Size of member section: part of the columns section is too small; the thickness of elevator shafts walls, which act as shear walls, is small.
- Other details: Inadequate anchorage bars of column reinforcement into the filler walls.

In conclusion, seismic deficiencies that should be evaluated include shear walls that are not properly reinforced; irregular features like concrete walls or columns; components weakened due to less reinforcement and sections; insufficient lateral capacity of the building. The methods described below are commonly used for concrete buildings based on these deficiencies.

## 4 RETROFIT DESIGN

### 4.1 Design criteria

Since the renovation constitutes major structural changes, the structure in the new configuration must comply with the current seismic provisions of 2010 *Code for Seismic Design of Buildings* and 2009 *Technical Specification for seismic strengthening of Buildings* (Ministry of Construction of the People’s Republic of China), which provide guidance for evaluating the seismic performance of existing structures and determining the necessary retrofitting methods to achieve the performance objectives. In addition, since it’s a historical building, it must comply with the more stringent requirements of 2004 *Protective Technology Criterion for Remarkable Historic Architecture in Shanghai*. Furthermore, Shanghai Cultural Relics Protection Law stipulates owners of the protected buildings cannot change the facade, structure or inner decoration of the buildings.

### 4.2 Retrofit objective

The main objective of retrofit is to be cost-effective, applicable and functional solution that upgrades the seismic safety of the building to meet the desired performance criteria. An effective retrofit application should avoid the possibility of non-ductile failure modes by proper precautions.

### 4.3 Strengthening shear walls

To mitigate the above-mentioned seismic deficiencies, a comprehensive retrofit methodology

was investigated. The components of the seismic retrofit are briefly discussed here.

Strengthening shear walls with RC layers is a conventional method of strengthening in China. In this method a mesh of reinforcing bars is first placed in one or both sides of the wall and then it is covered with a thin concrete layer (Fig. 3). The concrete layer and reinforcing bars should be anchored to the wall to ensure that the wall and RC layers work together.

Considering the service requirement of elevator shafts, a 60 mm thick shotcrete cover would be applied to the exterior faces of the perimeter walls. The shotcrete will be reinforced with a horizontal and a vertical mat of closely spaced No. 8 reinforcement. Sufficient dowels will be provided to attach the shotcrete to the existing walls to ensure that the completed unit works in unison. As a result, the effective reinforcement ratio and spacing of reinforcement would then meet the current Code requirements. By extending the shotcrete vertical reinforcement mat through the slab, these bars would be used to provide sufficient anchorage of the slab.

### 4.4 Strengthening beams using Carbon Fiber Reinforced Polymer (CFRP)

The substandard beams would also be retrofitted by externally bonded CFRP. CFRP can be used for increasing beams strength. It is observed that CFRP retrofits increase the flexural and shear strength of beams. In addition to the high strength-to-weight ratio and excellent corrosion resistance of CFRP composites, the bonded CFRP strengthening technique has many advantages, such as its simplicity of construction and minimal impact on the dimensions and service conditions of existing structures. Due to the flexibility of CFRP fabrics, they are also easy to install and can have an advantage when the retrofit is applied at hard-to-reach locations.

One or two horizontal CFRP sheet and fibers oriented in longitudinal direction was first installed

Figure 3. Typical detail of concrete wall strengthening with reinforced concrete layer.

Figure 4. Layout of CFRP strengthening beam.

at each side of the beam web (Fig. 4). Two layers of CFRP bonded at the bottom of the whole beam. The vertical U-shaped CFRP sheets were then applied followed by the installation of a mechanical end anchorage. The U-shaped CFRP sheets had a width of 200 mm and a center-to-center spacing of 400 mm. The web corners were chamfered to a radius of approximately 10 mm prior to CFRP application.

## 5 SUMMARY AND CONCLUSIONS

The traditional historical buildings are generally more affected during earthquakes. For historic buildings, the selection of retrofit should be based on the existing constraints, desired superstructure performance, and the overall economics. There are number of seismic retrofit techniques available for concrete structures, depending on the type and

condition of the deficiencies. It is important to obtain accurate as-built information and analytical data to perform a seismic evaluation of the existing structure and to select the appropriate retrofitting strategy. The selection of retrofit is based on the results of seismic performance evaluation. Furthermore, appropriate seismic retrofit can effectively achieve life safety criteria and minimize damage to the typical architectural features of historic buildings.

## Strength model of FRP confined concrete cylinders

Ji-Shuai Wang & Dong-Sheng Gu

College of Environmental and Civil Engineering, Jiangnan University, China

**ABSTRACT:** Fiber Reinforced Polymer or plastics (FRP) has been widely used as a new material for strengthening existing civil infrastructures, due to their advantages in the high tensile strength, light weight, ease for construction, no addition to dimensions of members etc. There have been a number of studies on the uses of this technique. But theoretic researches of those still drops behind in its applications in construction and the need being further perfected. In order to confirm the calculating method of FRP confined concrete circular columns in engineering practice and based on relevant results of studies, authors have analyzed the representational FRP confined concrete strength models and compared the value of these models with the data of relevant experiments. Analyzed the precision from strength constraint factor and concrete strength, and fitted the collected data for two different forms and then proposed an improved simplified model for calculating axial compressive strength of FRP confined columns. The value of this model could tally with the experimental results. The proposed model may be a reference for practical engineering.

**Keywords:** FRP circular concrete columns; the axial compressive strength; strength calculating model

### 1 INTRODUCTION

FRP confined concrete is of passive constraints. When FRP confined concrete columns under axial pressure and lateral expansion of concrete column results in FRP materials' hoop tension, tension of FRP with hoop strength also, in turn, limits the lateral of the concrete column, which make the restraining affection of concrete column. What's more, making concrete column in the three-way compression state, and the bearing capacity of reinforced concrete columns and ductility can be increased at the same time. Starting from the initial loading stage, the difference of ring expansion deformation between FRP material and concrete was produced because of the difference of stiffness and Poisson's ratio. The deformation of concrete is greater than FRP outsourcing material, and then a squeeze between the two is made, generating constraint stress. Early constraint stress to a certain extent delayed the initial cracks to appear. With the increase of axial load, longitudinal cracks began to appear, and the lateral strain growth is increasing quickly, and this intensifies the squeezing effect between FRP outsourcing material and the core concrete, and due to the increasing of restraint stress, the further development of longitudinal cracks in the concrete gets restricted, and also the compressive strength of the concrete is improved. When load increases to maximum axial load, FRP material is destroyed and the longitudinal stress of the core concrete is also at a peak, eventually it

leads to the destruction of the components. The core concrete in three-way compression state in the whole loading process, and the FRP material in a vertical pressure—ring pull bidirectional stress state in the late stress and FRP materials mainly subject to ring tensile stress. The stress of the FRP material mechanics model is as shown in Figure 1. The thickness of FRP, ultimate tensile strength and the diameter of the core concrete have an effect on the size of the core concrete binding. Through calculations we can get the formula of  $f_i = 2f_j t/D$ ,  $f_j$  on behalf of the FRP binding of circular concrete columns;  $f_j$  and  $t$ , respectively, representing the ultimate tensile strength of FRP materials and thickness;  $D$  representing the diameter of the core concrete.

Figure 1. The stress of the FRP material mechanics model.

## 2 DATA COLLECTION

Since the 1980s, various countries' scholars have done a lot of experimental studies on FRP confined concrete. The author collected 182 groups of experimental data of past scholars. Having established  $f_l/f_{co}$  and  $f_{cc}/f_{co}$  as the X axis and Y axis of rectangular coordinate system as shown in the Figure 2,  $f'_{cc}$  and  $f_{cc}$ , respectively, represent the calculation axial compressive strength and experimental axial compressive strength of FRP confined concrete specimens,  $f_{co}$  represent the axial compressive strength of concrete specimens of no lateral stress constraints.

## 3 THE EXISTING CALCULATION MODELS

1. At present, scholars home and abroad have proposed many strength model. Listed some of them which have representation as follows:

$$\frac{f'_{cc}}{f_{co}} = 1 + 3.4 \left( \frac{f_l}{f_{co}} \right) \quad (1)$$

$$\frac{f'_{cc}}{f_{co}} = 1 + 2.25 \left( \frac{f_l}{f_{co}} \right)^{\frac{5}{4}} \quad (2)$$

$$\frac{f'_{cc}}{f_{co}} = 1 + 2.0 \left( \frac{f_l}{f_{co}} \right) \quad (3)$$

2. To see the difference of calculated value and experimental value, the corresponding charts are listed in the Figure 3. From the chart we can see the calculated value of Wang and Wu's model is larger and the precision of Youssef's

Figure 2. Scholars and their data.

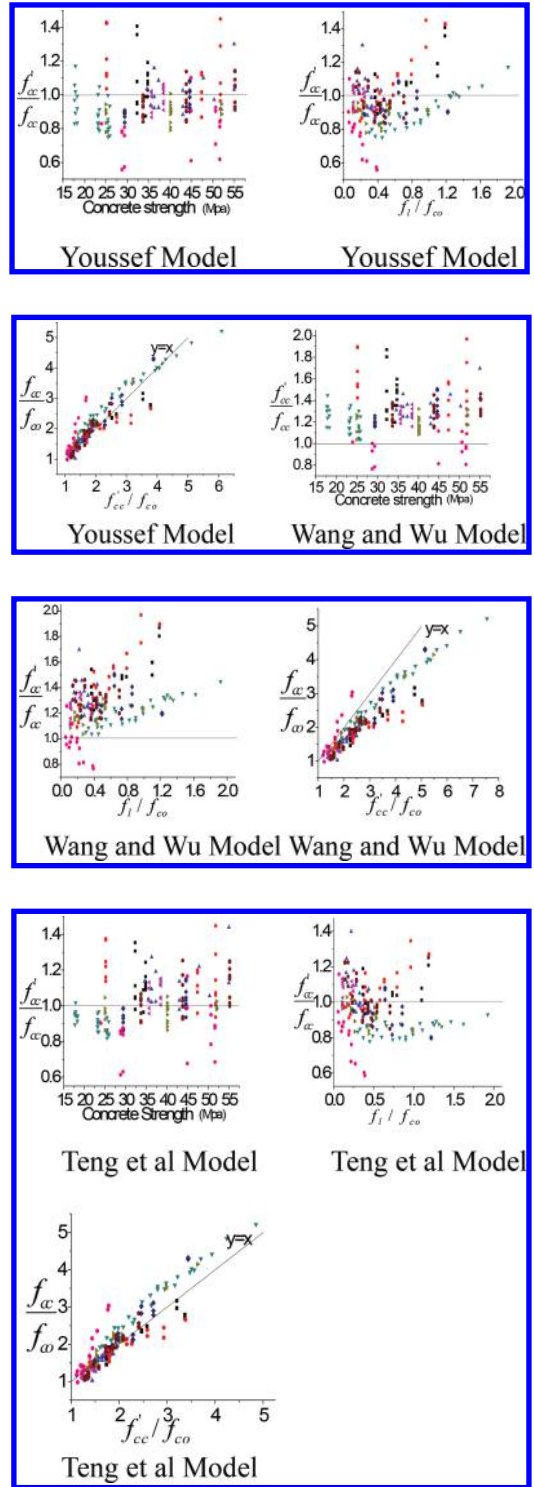

Figure 3. Performance of existing models for circular columns.

and Teng's model is higher than Wang and Wu's model in this data. But the strength calculation value of Youssef's and Teng's model is respectively bigger and smaller than the experimental value. So it is necessary to put forward the precise calculating model which has more extensively applicable scope.

#### 4 FITTING CALCULATION MODEL

In this paper, by fitting the collected data, we get two different forms of strength calculating models listed in the Figure 4 and 5. The accuracy from the aspects of constraint intensity coefficient and strength of concrete are compared. It can be easily obtained by chart, the precision of the two fitting models are similar, and they basically can make all the data scatter evenly distributed on both sides of bisector.

Figure 4. Linear fitting model.

Figure 5. Exponential fitting model.

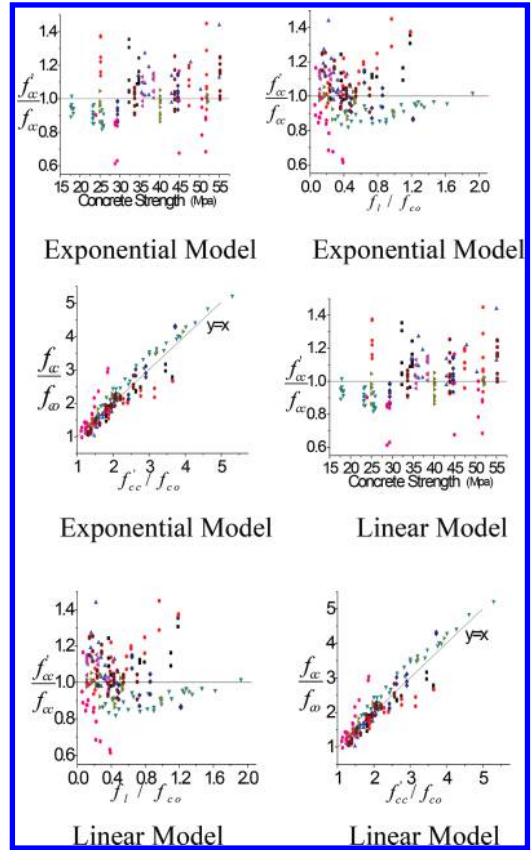

Figure 6. Performance of fitting models for circular columns.

#### 5 MODEL ANALYSIS AND COMPARISON

In order to select the optimum FRP strength calculation model, the average of  $f'_{cc}/f_{co}$ , discrete coefficient (Cv) and  $\Sigma Q$  are listed as follows. We all know that the closer the average is to 1.00, the smaller the discrete coefficient and the smaller the value  $\Sigma Q$ , the degree of discrete is higher. The discrete degree of Wang and Wu's model and Youssef's model is big and the discrete degree of Teng's model and two fitting models is small, the average is closer to 1, therefore, in this paper, the accuracy is significantly better than the first two models, has a better agreement with experimental data.

$$\Sigma Q = \Sigma \left[ \left( \frac{f_{cc}}{f_{co}} \right) - \left( \frac{f'_{cc}}{f_{co}} \right) \right]^2$$

$$\text{Exponential Fit: } \frac{f'_{cc}}{f_{co}} = 64889e^{\frac{\left(\frac{f_l}{f_{co}}\right)}{28924}} - 64888$$

$$\Sigma Q = 17.32 \quad \mu = 1.02 \quad C_v = 0.14 \quad (4)$$

Linear Fit:  $\frac{f'_{cc}}{f_{co}} = 1 + 2.24 \left( \frac{f_l}{f_{co}} \right)$

$$\Sigma Q = 17.32 \quad \mu = 1.02 \quad C_v = 0.14 \quad (5)$$

Wang and Wu model:  $\frac{f'_{cc}}{f_{co}} = 1 + 3.4 \left( \frac{f_l}{f_{co}} \right)$

$$\Sigma Q = 108.74 \quad \mu = 1.27 \quad C_v = 1.24 \quad (6)$$

Youssef et al model:  $\frac{f'_{cc}}{f_{co}} = 1 + 2.25 \left( \frac{f_l}{f_{co}} \right)^{\frac{5}{4}}$

$$\Sigma Q = 22.26 \quad \mu = 0.95 \quad C_v = 0.87 \quad (7)$$

Teng et al model:  $\frac{f'_{cc}}{f_{co}} = 1 + 2.0 \left( \frac{f_l}{f_{co}} \right)$

$$\Sigma Q = 20.81 \quad \mu = 0.97 \quad C_v = 0.13 \quad (8)$$

## 6 CONCLUSIONS

In this paper, the method for calculating the strength of FRP confined concrete model is analyzed, and the collected data was in the form of linear and exponential fitting. Then analyzing and comparing the experimental value and calculating value from two aspects of constraint intensity coefficient and the strength of concrete. The discrete degree of linear fitting model, exponential

fitting model and Teng's model is small and the differences are not big, but the form of exponential fitting model is too complex and Teng's model slant a bit bigger, it is no doubt that the linear fitting model is one of the best in them. With a large number of test results is good and the form of the model is simple, it may be applied to practical engineering.

# Joints transferring forces outside box columns with different beams' height and columns' deviation of verticality—finite element method simulation

Z.G. Xu, R. Yang & Z.B. Zhang

Faculty of Civil Engineering, Guangzhou University, Guangzhou, China

C.G. Deng

Department of Structural Engineering, Tongji University, Shanghai, China

**ABSTRACT:** Design of beams' height in steel frame structure should be based on loads and deformation of structure. It can lead to beams with different heights in the central joints of steel frame. A performance of joint with different beams' height is different from the normal joint. This paper presents a joint transferring force outside box columns with different beams' height. Three groups of specimens were designed to compare with traditional joints by finite element method program ANSYS, considering steel columns' deviation of verticality up to code limits and four times of code limits. By adding force-transforming elements, the results show that joints carrying capacity have greatly increased and the influence of deviation has reduced.

**Keywords:** joints, verticality, force-transforming elements

## 1 INTRODUCTION

In structural design, the height of the beam of a steel frame should be based on loads and deformation of structure<sup>[1]</sup>. As to the central joints of steel frame, the connection between steel beams may be unproportioned to the height of the beams, which will lead to the performance of joint with different beam heights different with that of normal joint. Therefore, it is necessary to carry out stress analysis for joints with different beam heights in steel frame. This paper presents a joint transferring force outside box columns with different beam heights. They are analyzed and compared with the traditional joints by finite element method program ANSYS. In addition, a practical steel structure inevitably has residual stresses, initial deflection, initial deviation of column's location axis, and other defects<sup>[2,3]</sup>. It is also analyzed with steel column verticality deviation by the code limits and four times the limit. We found that adding the force-transforming elements can improve the initial deflection of joints.

## 2 CREATION OF FINITE ELEMENT MODELS

### 2.1 Model design

This paper mainly focuses on research of joints transferring beam forces outside box columns with

different beam heights. Details of the joint are shown in Figures 1 and 2 of lower adding element. The box column with a deviation of verticality is shown in Figure 3. The material of steel specimens is Q345B, with Modulus of elasticity  $E = 2.00 \times 10^5$

Figure 1. Joint transferring beams' forces outside box columns with different beams' height.

Note: 1—Rectangular section steel column; 2—"H" section steel beam; 2'—"H" section steel low beam; 3a—Upper transferring forces plate; 3b—adding element; 3b-1—Upper cover plate; 3b-2—Lower cover plate; 3b-3—Web plate.

Figure 2. Detail of lower adding element.

Figure 3. The box columns with a deviation of verticality  $\Delta$ .

MPa and Poisson's ratio  $\nu = 0.3$ . Three groups of specimens were designed according to the conference<sup>[4]</sup>. The column length is 2 m. The length of the beam is 1.5 m. The other parameters are shown in Table 1. In this ANSYS analysis, material

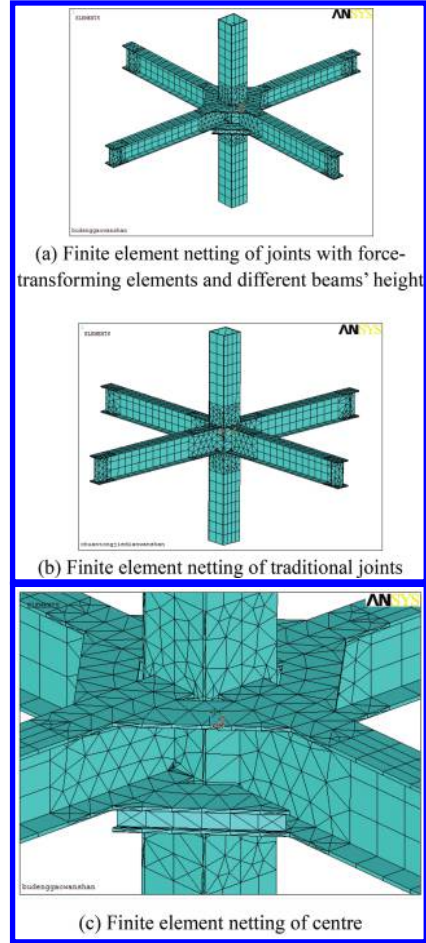

Figure 4. Finite element discretization of the joints.

Table 1. The parameters of test specimens.

Specimens	Upper cover plate (mm)			Lower cover plate (mm)			Web plate (mm)			Vertical deviation (mm)
	Length	Width	Thickness	Length	Width	Thickness	Height	Thickness	Length	
SJ-1a	374.07	125	9	374.07	125	9	50	6	374.07	None
SJ-1b	None			None			None			None
SJ-2a	374.07	125	9	374.07	125	9	50	6	374.07	2
SJ-2b	None			None			None			2
SJ-3a	374.07	125	9	374.07	125	9	50	6	374.07	10
SJ-3b	None			None			None			10

nonlinearity and geometric nonlinearity are considered, and the model of Multilinear Isotropic is selected. SOLID45 with 8 nodes is chosen as the beam-column elements which are far away from the panel zone. The high-precision SOLID95 with 20 nodes is chosen as the beam-column elements and the inner plates, and Von-Mises criterion is chosen as the yielding criterion.

## 2.2 Model discretization

In this paper, we focus on the performance of joint zone, so we create smaller elements of the centre part and bigger elements far away from the panel zone, as shown in Figure 4.

## 2.3 Constraints and loading

To fit for the actual situation in engineering, the constraints along three directions x, y, and z are set at the bottom of the column. Constraints of two directions x and y are set at the top of the column. Vertical load is applied at the top of the column, while concentrated loads are applied onto the top flange of all four steel beams. Slowly loading of the 60 sub-steps is used in this simulation.

## 3 RESULTS OF FINITE ELEMENT ANALYSIS

According to “Code for acceptance of construction quality of steel structures” (GB50205-2001)<sup>[5]</sup>, the deviation of verticality  $\Delta$  of a single column should have an allowable deviation of verticality  $\Delta$  no greater than  $h/100$  (the column length is  $h$ ) and also should not be greater than 10.0 mm. The column length is 2 m in this paper, so the deviation of verticality allowable deviation should not be greater than 2 mm.

### 3.1 The joints transferring beams’ forces outside box columns with different beams’ height and the deviation of verticality is 2 mm—finite element method simulation

Take SJ-2a and SJ-2b columns’ deviation of verticality  $\Delta = 2$  mm on the premise of recent code, and compare the results with those of specimen SJ-1a and SJ-1b, which are perfect traditional joints. Take short beam as the reference points on the flange of the central axis, we got load–displacement curves are shown in Figure 5.

In Figure 5, SJ-1a is a specimen transferring beams’ forces outside box column with different beam height. Comparing with traditional specimen, we find that yielding stresses, stiffness, and ultimate carrying capacity have greatly increased.

Figure 5. Load–displacement curves of SJ-1a, SJ-1b, SJ-2a, SJ-2b.

Figure 6. Load–displacement curves of SJ-1a, SJ-1b, SJ-3a, SJ-3b.

The yielding capacity increases 56.2%, and ultimate carrying capacity increases 40%. It means that adding force-transforming elements can greatly increase performance of joint with different beam heights.

If verticality deviation of steel column is 2 mm, the carrying capacities of the joint transferring beams forces’ outside box columns and the traditional joint which stiffness are decreased, less than 5%, so they can satisfy the need of engineering. It means that the deviation limits of verticality in the code can ensure the sufficient carrying capacity of the joints.

### 3.2 The joints transferring beams’ forces outside box column with different beams’ height and the deviation of verticality is 10 mm—finite element method simulation

In order to get more clear effect of steel columns’ deviation of verticality on its capacity, the deviation of verticality have to be increased to 10 mm and compared its result with that of perfect joint. Take short beam as reference points on the flange of the central axis, we got load–displacement curves are shown in Figure 6.

In Figure 6, if steel column verticality deviation is 10 mm, performance of specimen SJ-3a, which is a joint transferring beams’ forces outside box columns, and traditional joint specimen SJ-3b are

decreased obviously. Comparing with specimen SJ-3a and specimens with perfect joints transferring beams' forces outside box columns, the yielding capacity of SJ-3a decreases by 38.4%, and ultimate the carrying capacity of SJ-3a decreases 28.6%. Comparing SJ-3b and perfect traditional specimen, the yielding capacity of SJ-3b decreases by 73.3%, and the ultimate carrying capacity of SJ-3b decreases by 75%. By adding force-transforming elements, the influence of deviation can be reduced.

#### 4 CONCLUSION

A joint transferring force outside box columns with different beam heights is present. Three groups of specimens were designed to compare with traditional joints by finite element method program ANSYS. Considering columns' deviation of verticality, the conclusions are as follows:

1. Without initial defects, the stiffness, yielding stresses, and ultimate carrying capacity of joints have greatly increased by adding force-transforming elements. Its yielding capacity increases 56.2%, and ultimate carrying capacity increases 40%.
2. If column verticality deviation is 2 mm, stiffness and carrying capacity of the joints transferring beam forces outside box columns and traditional joints are decreased, less than 5%. It means that the deviation within code limits can ensure sufficient carrying capacity of the joint.
3. If column verticality deviation is 10 mm, performance of the joints transferring forces outside box columns and traditional joints will decrease obviously. By adding force-transforming elements, the influence of deviation can be reduced.

# Reliability of non-resonant quasi-integrable Hamiltonian systems under wide-band random excitations

J. Lan, H.Y. Wang & Y.J. Wu

*Department of Engineering Mechanics, Shanghai Jiao Tong University, Shanghai, P.R. China*

**ABSTRACT:** In this paper, the reliability problem based on the first-passage model of non-resonant quasi-integrable Hamiltonian system under wide-band random excitations is studied analytically. By using stochastic averaging method, the equations of motion of the original Hamiltonian system are reduced to a set of averaged Itô stochastic differential equations. The backward Kolmogorov equation governing the conditional reliability function and the Pontryagin equation governing the mean first-passage time are established under appropriate boundary and (or) initial conditions. An example is given to show the accuracy of the analytical method. All results are verified by Monte Carlo simulation.

**Keywords:** stochastic averaging method; reliability function; mean first-passage time; Monte Carlo simulation

## 1 INTRODUCTION

It is widely been recognized that the random excitations are ubiquitous in engineering, such as turbulent wind, seismic ground motion, etc. When investigating the dynamical behavior of a randomly excited structure, a key issue is to determine the probability that the structure works safely and reliably. In general, this problem of dynamical reliability can be converted into the problem that the response of the system stays within a safety domain probabilistically. Failure occurs when the state of the responses leaves the safety domain for the first time. This is the so-called first-passage (excursion, or exit) problem (Goller et al. 2013).

To solve the first-passage problem, a straightforward way is direct simulation, such as Monte Carlo Simulation (MCS). A major defect of MCS is that the computational cost is expensive. The other method is theoretical analysis based on appropriate mathematical model (Ghazizadeh et al. 2012). So far, a well developed theoretically analytical method for solving first-passage problem is built on the theory of diffusive Markovian process. This method requires that the random excitation is modeled as Gaussian White Noise (GWN). However, when the random excitation is not GWN, such as wide-band random noise, bounded noise, or Poisson white noise, the response of the randomly excited system is not diffusive Markovian process. In this case, one can not directly establish the PDEs governing the conditional reliability function and the moment of mean first-passage time. Previous studies have demonstrated that stochastic

averaging method is a powerful tool to overcome this difficult (Wu et al. 2013, Zhu 2006).

Hamiltonian system plays an important role in dynamics analysis. In this work, the reliability problem based on the first-passage model of Many-Degrees-of-Freedom (MDOF) non-resonant quasi-integrable Hamiltonian system under wide-band random excitations is studied analytically. The equations of motion of the original Hamiltonian system are reduced to a set of averaged Itô stochastic differential equations after stochastic averaging. The Backward Kolmogorov (BK) equation governing the conditional reliability function and the Pontryagin equation governing the mean first-passage time are established under appropriate boundary and (or) initial conditions. An example is given to show the accuracy of the analytical method. The reliability function and mean first-passage time are obtained. Monte Carlo simulation is performed to verify the analytical results.

## 2 AVERAGED ITÔ STOCHASTIC DIFFERENTIAL EQUATIONS

Consider the following n-DOF quasi-Hamiltonian system

$$\begin{aligned} \dot{Q}_i &= \frac{\partial H}{\partial P_i}, \\ \dot{P}_i &= -\frac{\partial H}{\partial Q_i} - \varepsilon c_{ij}(\mathbf{Q}, \mathbf{P}) \frac{\partial H}{\partial P_j} + \varepsilon^{1/2} h_{ik}(\mathbf{Q}, \mathbf{P}) \xi_k(t), \\ i, j &= 1, 2, \dots, n; \quad k = 1, 2, \dots, m. \end{aligned} \quad (1)$$

where  $Q_i$  and  $P_i$  are generalized displacements and momenta, respectively;  $H = H(\mathbf{Q}, \mathbf{P})$  is Hamiltonian;  $c_{ij}(\mathbf{Q}, \mathbf{P})$  denote quasi linear damping coefficients;  $h_{ik}(\mathbf{Q}, \mathbf{P})$  denote amplitudes of stochastic excitations;  $\varepsilon$  is a small positive parameter;  $\xi_k(t)$  are stationary wide-band random excitations with correlation functions  $R_{kk}(\tau) = E[\xi_k(t)\xi_k(t + \tau)]$  or spectral density  $S_{kk}(\omega)$ . The repeated subscript denotes summation.

Assume  $H$  is separable and each  $H_i$  can be expressed as

$$H_i(Q_i, P_i) = P_i^2/2 + U_i(Q_i). \quad (2)$$

Hence, system (1) is a quasi-integrable Hamiltonian system.

If the specified conditions in the paper (Cheung & Xu 1995) are satisfied, the solution of Equation (1) can be expressed as the following form of generalized harmonic function

$$\begin{aligned} Q_i(t) &= A_i \cos \Phi_i(t) + B_i, \\ P_i(t) &= -A_i v_i(A_i, \Phi_i) \sin \Phi_i(t), \end{aligned} \quad (3)$$

where

$$\begin{aligned} \Phi_i(t) &= \eta_i(t) + \Theta_i(t), \\ v_i(A_i, \Phi_i) &= \frac{d\eta_i}{dt} \\ &= \sqrt{\frac{2[U_i(A_i + B_i) - U_i(A_i \cos \Phi_i + B_i)]}{A_i^2 \sin^2 \Phi_i}}, \\ U_i(A_i + B_i) &= U_i(-A_i + B_i) = H_i. \end{aligned} \quad (4)$$

$A_i$ ,  $\eta_i$ ,  $v_i$  and  $\Theta_i$  are all stochastic processes.  $A_i$  and  $v_i$  are the amplitude and instantaneous frequency of the  $i$ th sub-system of the system (1), respectively.

If the system is not resonant, according to Stratonovich-Khasminskii limit theory (Khasminskii 1996, Stratonovitch 1963) and performing averaging with respect to the rapidly varying variables  $\Phi$ , one can obtain the following averaged Itô equations about  $\mathbf{A}$

$$\begin{aligned} dA_i &= \varepsilon \bar{m}_i(\mathbf{A})dt + \varepsilon^{1/2} \bar{\sigma}_{ie}(\mathbf{A})dB_e(t), \\ i &= 1, 2, \dots, n; \quad e = 1, 2, \dots, l. \end{aligned} \quad (5)$$

### 3 CONDITIONAL RELIABILITY FUNCTION AND MEAN FIRST-PASSAGE TIME

$\mathbf{A}$  are amplitudes of the original system (1). It is reasonable to assume that first-passage occurs once  $A_i(t)$  exceeds a certain critical value  $A_{ic}$  for the first time. The conditional reliability function,

denoted by  $R(t | \mathbf{A}_0)$ , is defined as the probability of  $\mathbf{A}(t)$  being in the safety domain  $\Omega_s$  within interval  $(0, t]$  given initial state being in  $\Omega_s$ .  $R(t | \mathbf{A}_0)$  is determined by the following BK equation:

$$\frac{\partial R}{\partial t} = \varepsilon \bar{m}_{i0} \frac{\partial R}{\partial A_{i0}} + \frac{1}{2} \varepsilon \bar{b}_{ij0} \frac{\partial^2 R}{\partial A_{i0} \partial A_{j0}}, \quad (6)$$

where

$$\bar{m}_{i0} = \bar{m}_i |_{\mathbf{A}=\mathbf{A}_0}, \quad \bar{b}_{ij0} = \bar{\sigma}_{ie} \bar{\sigma}_{je} |_{\mathbf{A}=\mathbf{A}_0}. \quad (7)$$

The initial and boundary conditions of Equation (6) are

$$\begin{aligned} R(0 | \mathbf{A}_0) &= 1, \quad A_{i0} \in [0, A_{ic}), \\ R(t | \mathbf{A}_0) &= 0, \quad A_{i0} = A_{ic}, \\ R(t | \mathbf{0}) &= \text{finite}. \end{aligned} \quad (8)$$

The conditional Mean First-Passage Time (MFPT)  $T(\mathbf{A}_0)$  is also a function of the initial state  $\mathbf{A}_0$ .  $T$  is determined by the following Pontryagin equation:

$$-1 = \varepsilon \bar{m}_{i0} \frac{\partial T}{\partial A_{i0}} + \frac{1}{2} \varepsilon \bar{b}_{ij0} \frac{\partial^2 T}{\partial A_{i0} \partial A_{j0}}, \quad (9)$$

The boundary conditions of Equation (9) are

$$\begin{aligned} T(\mathbf{A}_0) &= 0, \quad A_{i0} = A_{ic}, \\ T(\mathbf{0}) &= \text{finite}. \end{aligned} \quad (10)$$

Solving the partial differential equations (6) and (9) by finite difference method, one can obtain the approximate reliability function and mean first-passage time of the original system (1).

## 4 NUMERICAL EXAMPLE

Consider the following 5-DOF coupled Duffing-van der Pol system.

$$\begin{aligned} \dot{Q}_i &= P_i, \\ \dot{P}_i &= -(\beta_{i0} + \beta_{ij} Q_j^2) P_i + \omega_{i0}^2 Q_i + \alpha_i Q_i^3 \\ &= \xi_{i1}(t) + Q_i \xi_{i2}(t), \quad (i, j = 1, \dots, 5). \end{aligned} \quad (11)$$

Herein,  $\xi_{ik}(t)$  are independent wide-band random excitations with the following spectral density function:

$$S_{ik}(\omega) = \frac{D_{ik}}{\pi} \frac{1}{\omega^2 + \omega_{ik}^2}, \quad i = 1, \dots, 5; \quad k = 1, 2. \quad (12)$$

The parameters are chosen as:  $A_{ic} = 0.5$ ,  $\beta_{i0} = -0.01$ ,  $\beta_{ij} = 0.01$ ,  $\omega_{01}=1.0$ ,  $\omega_{02} = \sqrt{3}$ ,  $\omega_{03} = \sqrt{5}$ ,  $\omega_{04} = \sqrt{7}$ ,  $\omega_{05} = \sqrt{10}$ ,  $\omega_{ik} = 50$ ,  $D_{ik} = 12$  ( $i, j = 1, \dots, 5$ ;  $k = 1, 2$ ). There is no resonance in system (11). The averaged Itô stochastic differential equations are:

$$dA_i = \bar{m}_i(A)dt + \bar{\sigma}_{ik}dB_k(t), \quad (k = 1, 2). \quad (13)$$

The drift coefficients are

$$\begin{aligned} \bar{m}_i &= \bar{s}_i + \bar{m}_{i1} + \bar{m}_{i2} + \bar{m}_{i3} + \bar{m}_{i4}, \\ \bar{s}_i &= -A_i \left[ \left( 2\beta_{i0} + \sum_{j=1, j \neq i}^5 A_j^2 \beta_{ij} \right) (8\omega_{0i}^2 + 5A_i^2 \alpha_i) \right. \\ &\quad \left. + A_i^2 \beta_{ii} (3A_i^2 \alpha_i + 4\omega_{0i}^2) \right] / \left[ 32(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ \bar{m}_{i1} &= m_{i11} S_{i1}(\omega_i(A_i)) + m_{i13} S_{i1}(3\omega_i(A_i)) \\ &\quad + m_{i15} S_{i1}(5\omega_i(A_i)) + m_{i17} S_{i1}(7\omega_i(A_i)), \\ \bar{m}_{i3} &= m_{i31} S_{i1}(\omega_i(A_i)) + m_{i33} S_{i1}(3\omega_i(A_i)) \\ &\quad + m_{i35} S_{i1}(5\omega_i(A_i)) + m_{i37} S_{i1}(7\omega_i(A_i)), \\ \bar{m}_{i2} &= m_{i22} S_{i2}(2\omega_i(A_i)) + m_{i24} S_{i2}(4\omega_i(A_i)) \\ &\quad + m_{i26} S_{i2}(6\omega_i(A_i)) + m_{i28} S_{i2}(8\omega_i(A_i)), \\ \bar{m}_{i4} &= m_{i42} S_{i2}(2\omega_i(A_i)) + m_{i44} S_{i2}(4\omega_i(A_i)) \\ &\quad + m_{i46} S_{i2}(6\omega_i(A_i)) + m_{i48} S_{i2}(8\omega_i(A_i)), \\ m_{i11} &= \pi [2b_{i0}(A_i) - b_{i2}(A_i)] \\ &\quad \times \frac{d}{dA_i} \left[ \frac{2b_{i0}(A_i) - b_{i2}(A_i)}{A_i^2 \alpha_i + \omega_{0i}^2} \right] / \left[ 8(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i13} &= \pi [b_{i2}(A_i) - b_{i4}(A_i)] \\ &\quad \times \frac{d}{dA_i} \left[ \frac{b_{i2}(A_i) - b_{i4}(A_i)}{A_i^2 \alpha_i + \omega_{0i}^2} \right] / \left[ 8(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i15} &= \pi [b_{i4}(A_i) - b_{i6}(A_i)] \\ &\quad \times \frac{d}{dA_i} \left[ \frac{b_{i4}(A_i) - b_{i6}(A_i)}{A_i^2 \alpha_i + \omega_{0i}^2} \right] / \left[ 8(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i17} &= \pi b_{i6}(A_i) \frac{d}{dA_i} \left[ \frac{b_{i6}(A_i)}{A_i^2 \alpha_i + \omega_{0i}^2} \right] / \left[ 8(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i22} &= \pi A_i [2b_{i0}(A_i) - b_{i4}(A_i)] \\ &\quad \times \frac{d}{dA_i} \left\{ \frac{[2b_{i0}(A_i) - b_{i4}(A_i)] A_i}{A_i^2 \alpha_i + \omega_{0i}^2} \right\} / \left[ 32(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i24} &= \pi A_i [b_{i2}(A_i) - b_{i6}(A_i)] \\ &\quad \times \frac{d}{dA_i} \left\{ \frac{[b_{i2}(A_i) - b_{i6}(A_i)] A_i}{A_i^2 \alpha_i + \omega_{0i}^2} \right\} / \left[ 32(A_i^2 \alpha_i + \omega_{0i}^2) \right], \end{aligned}$$

$$\begin{aligned} m_{i26} &= \pi A_i b_{i4}(A_i) \frac{d}{dA_i} \left[ \frac{b_{i4}(A_i) A_i}{A_i^2 \alpha_i + \omega_{0i}^2} \right] / \left[ 32(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i28} &= \pi A_i b_{i6}(A_i) \frac{d}{dA_i} \left[ \frac{b_{i6}(A_i) A_i}{A_i^2 \alpha_i + \omega_{0i}^2} \right] / \left[ 32(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i31} &= \pi [4b_{i0}^2(A_i) - b_{i2}^2(A_i)] / \left[ 8A_i (A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i33} &= 3\pi [b_{i2}^2(A_i) - b_{i4}^2(A_i)] / \left[ 8A_i (A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i35} &= 5\pi [b_{i4}^2(A_i) - b_{i6}^2(A_i)] / \left[ 8A_i (A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i37} &= 7\pi b_{i6}^2(A_i) / \left[ 8A_i (A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i42} &= \pi A_i [2b_{i0}(A_i) - b_{i4}(A_i)] \\ &\quad \times [2b_{i0}(A_i) + 2b_{i2}(A_i) + b_{i4}(A_i)] / \left[ 16(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i44} &= \pi A_i [b_{i2}(A_i) - b_{i6}(A_i)] \\ &\quad \times [b_{i2}(A_i) + 2b_{i4}(A_i) + b_{i6}(A_i)] / \left[ 8(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i46} &= 3\pi A_i b_{i4}(A_i) \\ &\quad \times [b_{i4}(A_i) + 2b_{i6}(A_i)] / \left[ 16(A_i^2 \alpha_i + \omega_{0i}^2) \right], \\ m_{i48} &= \pi A_i b_{i6}^2(A_i) / \left[ 4(A_i^2 \alpha_i + \omega_{0i}^2) \right]. \end{aligned} \quad (14)$$

The diffusion coefficients are

$$\begin{aligned} \bar{b}_{ii} &= \bar{\sigma}_{i1}(A_i) \bar{\sigma}_{i1}(A_i) + \bar{\sigma}_{i2}(A_i) \bar{\sigma}_{i2}(A_i) = \bar{b}_{i11} + \bar{b}_{i22}, \\ \bar{b}_{i11} &= b_{i11} S_{i1}(\omega_i(A_i)) + b_{i13} S_{i1}(3\omega_i(A_i)) \\ &\quad + b_{i15} S_{i1}(5\omega_i(A_i)) + b_{i17} S_{i1}(7\omega_i(A_i)), \\ \bar{b}_{i22} &= b_{i22} S_{i2}(2\omega_i(A_i)) + b_{i24} S_{i2}(4\omega_i(A_i)) \\ &\quad + b_{i26} S_{i2}(6\omega_i(A_i)) + b_{i28} S_{i2}(8\omega_i(A_i)), \\ \bar{b}_{i11} &= \pi [b_{i2}(A_i) - 2b_{i0}(A_i)]^2 / \left[ 4(\alpha_i A_i^2 + \omega_{0i}^2) \right], \\ \bar{b}_{i13} &= \pi [b_{i2}(A_i) - b_{i4}(A_i)]^2 / \left[ 4(\alpha_i A_i^2 + \omega_{0i}^2) \right], \\ \bar{b}_{i15} &= \pi [b_{i4}(A_i) - b_{i6}(A_i)]^2 / \left[ 4(\alpha_i A_i^2 + \omega_{0i}^2) \right], \\ \bar{b}_{i17} &= \pi b_{i6}^2(A_i) / \left[ 4(\alpha_i A_i^2 + \omega_{0i}^2) \right], \\ \bar{b}_{i22} &= \pi A_i^2 [b_{i4}(A_i) - 2b_{i0}(A_i)]^2 / \left[ 16(\alpha_i A_i^2 + \omega_{0i}^2) \right], \\ \bar{b}_{i24} &= \pi A_i^2 [b_{i2}(A_i) - b_{i6}(A_i)]^2 / \left[ 16(\alpha_i A_i^2 + \omega_{0i}^2) \right], \\ \bar{b}_{i26} &= \pi A_i^2 b_{i4}^2(A_i) / \left[ 16(\alpha_i A_i^2 + \omega_{0i}^2) \right], \\ \bar{b}_{i28} &= \pi A_i^2 b_{i6}^2(A_i) / \left[ 16(\alpha_i A_i^2 + \omega_{0i}^2) \right], \end{aligned}$$

$$\begin{aligned}
b_{i0}(A_i) &= (\omega_{0i}^2 + 3\alpha_i A_i^2/4)^{1/2} (1 - \lambda_i^2/16), \\
b_{i2}(A_i) &= (\omega_{0i}^2 + 3\alpha_i A_i^2/4)^{1/2} (\lambda_i/2 + \lambda_i^3/64), \\
b_{i4}(A_i) &= (\omega_{0i}^2 + 3\alpha_i A_i^2/4)^{1/2} (-\lambda_i^2/16), \\
b_{i6}(A_i) &= (\omega_{0i}^2 + 3\alpha_i A_i^2/4)^{1/2} (\lambda_i^3/64), \\
\lambda_i &= \alpha_i A_i^2/4 (\omega_{0i}^2 + 3\alpha_i A_i^2/4).
\end{aligned} \tag{15}$$

The BK equation associated with the averaged system (13) is

$$\frac{\partial R}{\partial t} = \bar{m}_{i0} \frac{\partial R}{\partial A_{i0}} + \frac{1}{2} \bar{b}_{i0} \frac{\partial^2 R}{\partial A_{i0}^2}, \quad (i = 1, 2, 3, 4, 5). \tag{16}$$

The initial and boundary conditions of Equation (16) are

$$\begin{aligned}
R(0 | \mathbf{A}_0) &= 1, \quad A_{i0} \in [0, A_{ic}), \\
R(t | \mathbf{A}_0) &= 0, \quad A_{i0} = A_{ic}, \\
\frac{\partial R}{\partial A_{i0}} &= 0, \quad A_{i0} = 0.
\end{aligned} \tag{17}$$

The Pontryagin equation associated with the averaged system (13) is

$$-1 = \bar{m}_{i0} \frac{\partial T}{\partial A_{i0}} + \frac{1}{2} \bar{b}_{i0} \frac{\partial^2 T}{\partial A_{i0}^2}, \quad (i = 1, 2, 3, 4, 5). \tag{18}$$

The boundary conditions of Equation (18) are

$$\begin{aligned}
T(\mathbf{A}_0) &= 0, \quad A_{i0} = A_{ic}, \\
\frac{\partial T}{\partial A_{i0}} &= 0, \quad A_{i0} = 0.
\end{aligned} \tag{19}$$

Figure 1. Conditional reliability functions of the system (11) ( $A_0 = 0$ ).

Figure 2. MFPT of the system (10).  $A_{i0}$  is a variable.

Solving the 5+1-dimensional BK Equation (16) and 5-dimensional Pontryagin equation (18), we obtain the conditional reliability function and mean first-passage time of the system (11), respectively. Figure 1 shows results of conditional reliability function. The solid lines are analytical results while the discrete symbols are results from Monte Carlo simulation. Obviously, the agreement is very good. Figure 2 shows that the mean first-passage time is a decreasing function of the initial state. This is physically meaningful because first-passage happens more easily when the initial state is closer to the threshold.

## 5 CONCLUSIONS

In the present paper, the reliability problem of MDOF strongly nonlinear quasi-integrable Hamiltonian systems is studied. The BK equation and the Pontryagin equation are established to determine the conditional reliability function and the conditional mean first-passage time, respectively. A 5-DOF coupled Duffing-van der Pol system is given to illustrate the application of the analytical method. The 5+1-dimensional BK equation and 5-dimensional Pontryagin equation are solved under suitable initial and boundary conditions. It is seen that the agreement between the analytical method and MCS is very good.

**ABSTRACT:** Diaphragm-through joint of Concrete-Filled Square Steel Tube and steel beam is a form of rigid joints. It has the characteristics of good seismic behavior, high bearing capacity, and good ductility. The research progress in China of this kind of joint is reviewed from both experimental study and theoretical analysis, including the forms of direct welding type, side plate strengthen type, circular fillet type, fillet slope type, circular slope combination type, and Steel beam end clap and board bolted type. The form of this kind of joint adopted in Chinese specification is also introduced. Finally, the problems existing in the current research and those that needed to be further studied are pointed out.

**Keywords:** concrete filled steel tubular; diaphragm-through; joint; experimental study; theoretical analysis

## 1 INTRODUCTION

Concrete Filled Steel Tube (CFST) gives full play to the advantages of them, and has high bearing capacity, good plasticity and high toughness etc. It can meet the needs of large span, tall, heavy-duty and other structures, so it has been widely used in engineering (Shantong Z., 2003). According to the different cross-section forms, CFST can be divided into round, square and polygon section concrete filled steel tube, etc. Among them, the round and square ones are widely applied. In the CFST structure, beam-column joint plays a role of passing moment and shear force between beam and column, which is the key part of design and is also difficult in construction. To meet the project needs, different scholars have put forward many kinds of joints for connecting CFST and beam, including inner diaphragm joints, strengthening ring plate joints, vertical stiffener joints and diaphragm-through joints. Among them, the diaphragm-through joint is one

of the forms of joint recommended by Chinese specification (Xilin et al, 2004). In the following, the forms of Diaphragm-Through Joint (DJ) of Concrete Filled Square Steel Tube (CFSST) and Steel Beam (SB) and the research progress of it in China will be reviewed, which will provide reference for designing this kind of joint.

## 2 FORMS OF DJ OF CFSST-SB

DJ of CFSST and SB is made by the following steps: the steel tube and SB are connected by two diaphragms, in which part of the two diaphragms pass through and are welded in the tube; the flanges ends of SB are welded or bolted on the diaphragms; the web of SB are welded or bolted on one ends of a steel plates; the other end of the plates is welded on the steel tube. It has the forms of direct welding type, side plate strengthen type, circular fillet type, fillet slope type and circular

slope combination type, Steel beam end clap and board bolted type, as shown in Figures 1–6. These developments and changes in the forms of joints solve the problems of large welding residual stress between the beam end and diaphragm, and meet the requirements of engineering function.

Direct welding type, as shown in Figure 1, means that the beam flange and diaphragm are welded directly without any transition method, which is the structure form recommended by Chinese rectangle steel tube concrete specification. It is convenient for construction and the amount of steel used for connection is small, but the stress concentration between the beam flanges and the diaphragm is large. It needs high requirements for welding quality. Side plate strengthen type, as shown in Figure 2, means that side panels are welded on both sides of the flanges at the beam

Figure 1. Direct welding type.

Figure 2. Side plate strengthen type.

Figure 3. Circular fillet type.

Figure 4. Fillet slope type.

Figure 5. Circular slope combination type.

Figure 6. Full-bolt type.

end additionally, of which the lateral plate and the beam flange are located on the same plane or close to the inner beam flange, so as to reduce the stress concentration of the weld place, and prevent the occurrence of brittle failure. But it has large amount of welding and is difficult for machining and site weld, and the beam flange edge are easy to be torn in the lateral plate ends. So there are a lot of project risks. Circular fillet type, as shown in Figure 3, is a kind of structure setting an arc transition at the connections of steel beam flange and diaphragm. Circular fillet can effectively reduce stress concentration at the end of beam flange edge, and it is beneficial to improve the ductility and seismic energy dissipation of joints. Fillet slope type, as shown in Figure 4, makes diaphragm from two sides turn into slope angle less than 1:4, and sets an arc transition at variable cross-section. This kind of structure cannot only effectively reduce the stress concentration of connections for the slope angle is small, but also have no problems in wallboard installation. Circular slope combination type, as shown in Figure 5, means that it adopts a processing mode of fillet slope at up diaphragm plane and adopts a processing mode of circular fillet at down diaphragm plane of joint. The diaphragm and beam flanges are connected with groove welding, and the beam web and the steel pipe column wall are connected by high-strength bolt. Increasing diaphragm size will not affect the beauty of architecture structure; instead, it provides a certain condition for concealment of the upper structure and join processing. Thus it is convenient to install bolt and connection plate (Liang W., 2009). Steel beam end clap and board bolted type, as shown in Figure 6, means that steel beam is inserted among the up and down diaphragms, then the steel beam flange

and diaphragm are connected by bolts. Compared with the above joints, there is no problem of stress concentration at the beam end due to welding, but as a result of diaphragm extruding beam flange, this causes some difficulties in installation.

### 3 RESEARCH ON DJ OF CFSST-SB

#### 3.1 Experimental study

Experimental study about DJ of CFSST-SB is mainly carried out after 2005 in China, including static tensile test, low-reversed cyclic loading test. The static tensile test aims to test the tension force on the beam flange in the diaphragm, diaphragm and cylindrical wall weld, transfer and destruction of the weld, and the influencing factors. The low-reversed cyclic loading test aims to test the joint's seismic performance, failure mode, and influence factors. The experimental study is carried out mainly as follows. Hong F. & Lihua X. & Guofeng D. (2007) have done experimental study about nine side plate strengthen diaphragm-through joints specimens under low-reversed cyclic load and static tensile test in 2007 and 2008. The results show the hysteresis curves attained in the experiment are full and the connections have a good energy dissipation capacity. The width to thickness ratio of the column has little influence on the bearing capacity of the connection, but it has a little influence on the stains of the gusset plate. The stress distributing can be ameliorated and the ductility of the connections can also be improved through welding the additional plates to both sides of the flanges. Jikui M. & Bin R. & Xinliang J. & Zhihua C. (2008, 2009, 2012) have investigated thirty specimens subjected to low-reversed cyclic load and static tensile test. It was found that tensile load from steel beam flange was mainly shared by square steel tube and diaphragm and there were 3 kinds of failure modes: steel beam flange fracture, weld fracture, and joint broken. For steel square tube, plastic zone appeared around intersections between steel square tube and diaphragm. However, for diaphragm, plastic zone appeared along the cross-section lines enclosed by steel square tube. Joints of circular fillet type and fillet slope type have high load-bearing capacity and good ductility. Details of the steel beam flange with the diaphragm have obvious effect on the ductility, energy dissipation and rigidity degeneration, and the seismic performance of joint of circular fillet type and fillet slope type are better than those reinforced by taper plate welded to the beam flanges and diaphragm. Since all the specimens fail in the beam, diaphragm thickness, diameter of concrete cast hole and width to thickness ratio of the tube have less influence on joint seismic behavior, however, the concrete filled in the tube can greatly reduce bearing deformation of joint panel zone, improve the joint stiffness and the

seismic performance of it. Zilin L. et al (2014) have done experiment of six full-scale specimens under low-reversed cyclic load. The result of the experiment shows that the joint is characterized by good seismic behavior, high bearing capacity, and full hysteresis curve. The eccentric specimens failed due to the cracking of corner bolt hole on the diaphragm, and the specimens without eccentricity failed due to the cracking of diaphragm. Welded diaphragm had no effect on the bearing capacity. The end of the beam, and stress focus phenomena were easily seen at the connection of the partition and the beam.

#### 3.2 Theoretical analysis

Theoretical analysis about DJ of CFSST-SB is mainly carried out after 2005 in China, mainly using the software of ANSYS and ABAQUS. In addition to the problem considered in the above experiment, study should also include further finite element simulation results for establishing simplified calculation method for designing. The theoretical analysis carried out mainly as follows.

Lei Z. (2006) has done theoretical analysis and finite element calculation, the result shows that the seismic design method used in current structural design specification is suitable for the joints discussed in the paper. And its strength formula and thickness requirement are proposed. It is also analyzed the influence of diaphragm thickness, extend length, and axial compression ratio on joint behavior. Jikui M. (2008) analyzed the joint under low-reversed cyclic load and static tensile load by finite element method. The yield mechanism is studied, formula for calculating tensile capacity is proposed, which take account of the force that transferred to the diaphragm plate and tube. Stress distribution in the joint panel zone and the damage mechanism is simulated. Some suggestions for improving joint design are presented. Qin L. (2010) simulated the seismic performance of the side plate strengthen of the joint under low-reversed cyclic load by the finite element simulation method. The results showed the joints have good strength, stiffness, ductility, and the hysteresis curves attained are full. Jingjing B. (2012) researched the seismic performance of the joints with fillet and slope at the connecting zone. The results demonstrated that stress concentration

Figure 7. Overhanging inner diaphragm connection.

occurred at the areas like the diaphragm edge spot, the soldering hole, the welded area between diaphragm and beam. More attention should be paid to the soldering hole design and processing.

#### 4 RECOMMENDED FORM IN CHINESE SPECIFICATION

The forms of the joint of CFST and SB recommended in Chinese code CECS 159: 2004 (Xilin et al, 2004) include sinner diaphragm connection, overhanging inner diaphragm connection, outer diaphragm connection, and inner diaphragm connection with short beam. In which, the overhanging inner diaphragm connection is the form of DJ of CFSST and SB, as shown in Figure 7.

It is required in the specification that in the principle of design, the form of joints should be with simple structure, good integrity, clear force transmission path, safe, reliability, saving material, and convenient for construction. In joint design, it should make the joint accomplish reasonable structure and have the necessary ductility, which can guarantee welding quality and avoid the stress concentration and large constraint stress. When calculating the rigid welded joint between CFSST with internal diaphragms and SB, in addition to check the strength of the weld seam and high strength bolt, it should check the bending and shear bearing capacity of the joint.

It can be seen from the above specification, the form of DJ of CFSST-SB is single, and it's only considered the influence of the material strength in the method for checking the bending and shear bearing capacity of the joint, while such factors as the steel ratio, axial compression ratio, etc., are not considered.

#### 5 CONCLUSIONS

From the above reviewing, it can be seen:

1. For DJ of CFSST and SB, in the design, the main problems needed to be considered include how to solve much stress between the beam end and diaphragm, reduce the number of welding and meet the requirements of architectural appearance.
2. DJ of CFSST and SB has direct welding type, side plate strengthen diaphragm-through joint type, circular fillet type, fillet slope type, and circular slope combination type, which solves the larger welding residual stress between the beam end and diaphragm and meets the requirements of architectural function.
3. It has been made much research achievements for DJ of CFSST and SB in China, but in Chinese specification, the recommended form of DJ of CFSST and SB is single, and in the

process of checking, such factors as the steel ratio, axial compression ratio, etc., are not considered. These problems need to be further studied in the future.

**ABSTRACT:** In reinforced concrete Frame-shear Wall Structure (FWS), Coupling Beam (CB) of shear wall and the corresponding frame beam up to it, i.e., Frame Coupling Beam (FCB), has a stage of cooperative working under horizontal load. It will be helpful for knowing the whole working mechanism of FWS if the working mechanism of that stage is deeply analyzed. So, the parallel double coupling beams with different widths composed of CB and FCB, briefly called Double Beams (DBs), is taken as a research object. The load-bearing process of 11 DBs under low-cycle repeated loads are simulated with finite element simulation method. How the stiffness degradation of DBs are influenced by different influencing factors are analyzed. The results show that the span-depth ratio of FCB and the span-depth ratio of SCB have the largest and second largest influence on the stiffness degradation of DBs separately, yet the width of FCB, the strength of concrete, and the reinforced area ratio of DBs has no less effect on the stiffness degradation of DBs.

**Keywords:** double coupling beams; frame coupling beam; shear coupling beam; stiffness degradation

## 1 INTRODUCTION

In reinforced concrete Frame-shear Wall Structure (FWS), there are Parallel Double Coupling Beams (PDCB) of different size, which are composed of part of Frame Coupling Beam (FCB) and Coupling Beam (CB) of shear wall in FWS. In shear wall structure, there are also PDCB, which is composed of two coupling beams with the same width. But these two kinds of PDCB are different not only because of the width of the beams, but also because of their reinforcement requirements (Cui J.J., 2012). Many different kinds of coupling beam are promoted by different researchers through changing reinforcement arrangement, taking new structure measurement or changing material etc, and much research work is also done on them accordingly (Cao W.L. et al. 2010, Shuai J., 2011, Zhou J.H. et al. 2012, Jia L.G. et al. 2013 &

Paulay T. et al. 1999). But little study is done on the PDCB in FWS. Therefore, it becomes one of the focuses of civil engineers on how the force behavior of parallel double coupling beams with different widths is (Li M. et al. 2013). So, in this paper, the factors influenced the stiffness degradation of it will be analyzed.

## 2 DESIGNED SPECIMENS

The factors that influence the stiffness degradation of PDCB mainly includes the Span Length (SL) of the CB and the FCB, the Section Height (SH), the Section Thickness (ST), the Span-Depth Ratio (SDR) of the beams, the Concrete Strength (CS), and the Reinforced Area Ratio (RAR) which is the area ratio of longitudinal reinforcement in the CB and the FB. In order to analyze how these factors

Table 1. List of the specimens.

No	FCB				CB				CS	RAR
	SL (mm)	SH (mm)	ST (mm)	SDR	SL (mm)	SH (mm)	ST (mm)	SDR		
1	1200	800	300	1.5	1200	400	200	3	14.3	2
2	1200	480	300	2.5	1200	400	200	3	14.3	2
3	1200	600	300	2	1200	400	200	3	14.3	2
4	1200	600	300	2	1200	800	200	1.5	14.3	2
5	1200	600	300	2	1200	550	200	2.2	14.3	2
6	1200	600	400	2	1200	400	200	3	14.3	2
7	1200	600	250	2	1200	400	200	3	14.3	2
8	1200	480	300	2.5	1200	400	200	3	C25	2
9	1200	480	300	2.5	1200	400	200	3	C35	2
10	1200	480	300	2.5	1200	400	200	3	C30	2.5
11	1200	480	300	2.5	1200	400	200	3	14.3	1.5

influence the stiffness degradation, 11 specimens are designed shown in Table 1. The longitudinal bars of the CB and the FCB are all HRB335 and the stirrups of them are all HPB300.

### 3 FINITE ELEMENT SIMULATION

In order to simulate the load-bearing process of PDCB, blocks are set at both of the beam ends to make it easy to apply low cyclic load, shown in Figure 1. The loading process of the PDCB is simulated by finite element software. In simulation: the stress-strain curve of the concrete is plastic damage model; eight-node reduced integration of the three-dimensional solid elements (C3D8R) are used to simulate the concrete and upper and lower blocks. TRUSS elements are used to simulate steel. The “embedded” is used to simulate the contact between steel and concrete (Zhu Z.F., 2013, Zhang B.B., 2005, Dai F.T., 2006 & Jia Y.G. et al, 2005). The lower block is consolidated by limiting displacement of all-directions. The vertical displacement and internal and external plane rotation of the upper block is limited, which makes it can solid along the horizontal direction. Anti-symmetric low cyclic loading is applied on both ends of the upper block. Newton-Raphson iteration method is adopted to solve the problem. The finite element model is shown in Figure 2.

### 4 STIFFNESS DEGRADATION OF DBS INFLUENCING FACTORS

Under cyclic loads, the stiffness degradation is characteristic that stiffness of the structure lower with the load displacement amplitude and the number of cycles increases. In this paper, stiffness degradation characteristics of structure under low

Figure 1. Designed PDCB.

Figure 2. Finite element model of PDCB.

cycle reciprocating load denoted loop stiffness of the first cycle of the corresponding under the same level displacement loading. The diagram of specimen stiffness calculation method is shown in Figure 3.  $K_i$  is the stiffness degradation coefficient,  $P_A, P_B$  is load values of peak point,  $\Delta_A$  and  $\Delta_B$  is displacement values of peak point. Calculated stiffness changes of specimens under different loading cycles are shown in Figure 4 to Figure 8.

#### 4.1 Influence of the span-depth ratio $\alpha$

The stiffness degradation curve of double beams numbered 1, 2 and 3 under low cycle reciprocating load are shown in Figure 4, of which other parameters are unchanged, but the span-depth ratio of FB is changed. It's 1.5, 2, and 2.5 respectively. It can be seen from Figure 3 that span-depth ratio of FB influences the initial ring stiffness of DB greatly, with the increase of span-depth ratio of FBs, the corresponding stiffness of DB is decreases obviously. When the span-depth ratio changes from 1.5 to 2.5, the initial ring corresponding stiffness

Figure 3. Schematic of how to calculate stiffness.

Figure 4. Influence of  $\alpha$  to the stiffness degradation of DB.

Figure 5. The influence of  $\beta$  to stiffness degradation of DB.

Figure 6. The influence of  $B$  to stiffness degradation of DB.

Figure 7. Influence of  $f_{ck}$  to the stiffness degradation of DB.

decreases by about 50%. With the increase of cycle number, the influence of span-depth ratio of FB decreases, when the loop reaches the 7 ring, the corresponding DB stiffness of every SDR is almost the same. Accordingly, the span-depth ratio of FB

Figure 8. The influence of  $R$  to the stiffness degradation of DB.

is an important parameter which influences stiffness degradation of DB.

#### 4.2 Influence of span-depth ratio $\beta$

The stiffness degradation curve numbered 3, 4 and 5 under low cycle reciprocating load are shown in Figure 5, of which other parameters are unchanged and the span-depth ratio of CB is changed, it is 3, 2.2, and 1.5, respectively. It can be seen from the Figure 4, the stiffness of DB influenced by the span-depth ratio of SWB, but it isn't obvious compared with FB, when the SDR changes from 1.5 to 3, the first ring corresponding stiffness decreases by about 20%, and the span-depth ratio of SWB changes from 2.2 to 3, very close to stiffness degradation curve of DB, however, when the cycle number increases to the 8 ring, the stiffness of DB that different span-depth ratio of SWB is almost the same. From this we can conclude that the span-depth ratio of SWB influences stiffness degradation of DB but it isn't obvious compared with FB.

#### 4.3 Influence of the section width $B$

The stiffness degradation curve of frame beams numbered 6, 3 and 7 under low cycle reciprocating load are shown in Figure 6, of which other parameters are unchanged and the Section Width (SW) of FB is changed, it is 400 mm, 300 mm, and 250 mm, respectively. It can be seen from the figures, the first lap of the DB with 250 mm section width of FB has the largest stiffness, about 1.3 times of FB with 400 mm and 300 mm section width, the 2 ring later, stiffness degradation curve of DB that width of FB is 250 mm, 300 mm and 400 mm is almost the same. And stiffness degradation curve of DB that width of FB is 300 mm and 400 mm always close to each other. Therefore, only when the frame beam width is small and close to

the shear wall width, the section width of FB have influences in the first ring stiffness of DB, beyond this scope, the width of frame beam almost had no effect on stiffness degradation of DB.

#### 4.4 Influence of concrete strength $f_{ck}$

The stiffness degradation curve of frame beams numbered 8, 10 and 9 under low cycle reciprocating load are shown in Figure 7, of which other parameters are unchanged and the CS is changed, it is 11.9 Mpa (C25), 14.3 Mpa (C30), and 16.9 Mpa (C35) respectively. It can be seen from the figures, generally, the higher the CS, the greater the stiffness of the double beam, but the change is not big, the first ring corresponding stiffness of DB that concrete strength is 16.9 Mpa is 1.13 times of CS with 11.9 Mpa, and the first ring corresponding stiffness of DB that concrete strength is 16.9 Mpa is almost the same with the CS is 14.3 Mpa. It shows that concrete strength has a little effect on DB stiffness degradation.

#### 4.5 Influence of reinforced area ratio $R$

The stiffness degradation curve of frame beams numbered 11, 2, and 10 under low cycle reciprocating loads are shown in Figure 8, of which other parameters are unchanged and the reinforced area ratio is changed. It is 1.5, 2, and 2.5, respectively. It can be seen from the figures, the larger the reinforced area ratio, the greater the double beam stiffness. The first ring corresponding stiffness of DB that RAR is 2.5 is 1.1 times of RAR with 1.5, but when the RAR increases to a certain extent, it only has a little influence in the stiffness of DB. It shows that with the increase of the reinforced area ratio, the stiffness of DB has increased, but it isn't obvious.

## 5 SUMMARY

Based on the above analysis, the following conclusions can be drawn:

1. The largest factor that influence the stiffness degradation of DB is the SDR of FB, and the span-depth ratio of CB is the secondary. With the increase of span-depth ratio of FB and CB, the stiffness of DB decreases, therefore, the degree of the decrease is reducer with the increase of the number of cycles. When the number of cycle increases to a certain extent, the span-depth ratio of the FB and the CB has almost no effect on stiffness of DB.
2. The stiffness degradation is influenced by the section width of FB, concrete strength and RAR. With the increase of the section width of FB, concrete strength and increase of RAR, the stiffness of DB increases, but the increase is a little.

# Study on parameter optimization of static performance for long-span elliptic suspended dome structure

K.R. Shi & Z.R. Jiang

State Key Laboratory of Subtropical Building Science, South China University of Technology, Guangzhou, China

**ABSTRACT:** Taking the new type hybrid structure of elliptic suspended dome as the analytical object, the parameter optimization of static performance is studied in detail. By the method of nonlinear static analysis, the effects of different parameters on the static performance are systematically analyzed i.e. rise-span ratio, plane shape factor, prestress and strut's length. The results show that rise-span ratio and strut's length have greater effects on the structural static performance than plane shape factor and prestress. The smaller rise-span ratio and the larger plane shape factor are good for improving static performance. Prestress should be rational as over-high prestress or over-low prestress would cause disadvantageous problems. The longer strut can improve static performance, but over-long strut affects stability and reduces head room of the building.

**Keywords:** elliptic suspended dome; static performance; nonlinear analysis; prestress; parameter optimal analysis

## 1 INTRODUCTION

Analysis of structural static performance provides basic theoretical foundation for structure design, which offers necessary reference for other kinds of analysis such as dynamics performance analysis, stability analysis and so on [1]. There are some studies on static performance of circle suspended dome [2–8], however, only few studies are about elliptic suspended dome [9–10]. Elliptic suspended dome is a new structure form, and its structural performance becomes more complex with the increase of structural span. To meet the requirements of engineering practice, this paper is going to research on parameters optimization of static performance for large-span elliptic suspended dome by utilizing a typical calculation example, which aims at achieving regular conclusions and giving rational suggestions.

## 2 CALCULATION MODEL AND PLAN OF PARAMETRIC ANALYSIS

### 2.1 Calculation model

The calculation model should be representative and able to reflect general character of homogeneous structures. So the following typical model is chosen, namely, a long-span elliptic suspended dome (Fig. 1). The span of long axis of the model is  $2a = 80$  m, and the span of short axis

is  $2b = 64$  m. The relevant plane shape factor is  $\delta = 0.8$ . Its surface shape is an elliptic paraboloid with the arch rise of  $f = 6.667$  m. The upper chord layer is a single-layer latticed shell, whose members are made of the steel pipes of 203 mm in diameter and 10 mm in thickness. The characteristic value of yield strength of the steel pipe members is 345 MPa, which connected by rigid joint. The lower cable-strut system consists of three-ring hoop cables, radial cables and struts, whose hoop cables are set at a ring interval and struts at a joint interval. The twisted-type parallel steel-wire cables are used, whose ultimate tensile strength is 1670 MPa, and the diameter of each steel-wire is 5 mm. The section types of the hoop cables are respectively PES C5-61, PES C5-91, PES C5-121 from the inner ring to the outer ring, and the section type of all the radial cables is PES C5-55. The struts are used the steel pipes of 168 mm in diameter and 8 mm in thickness with the characteristic value of yield strength of 345 MPa. The lengths of the struts are respectively 4.889 m, 5.723 m, 6.556 m from the inner ring to the outer ring. The anchor joints of the cable-strut system are fixed.

Figure 1. Calculation model of elliptic suspended dome ( $\delta = 0.8$ ).

The Young's modulus of the steel pipes and cables are  $2.06 \times 10^5$  MPa and  $1.95 \times 10^5$  MPa, respectively. The initial prestress of the hoop cables are respectively 315.6 kN, 472.8 kN and 731.9 kN from the inner ring to the outer ring. The radial sliding supports are used in the suspended dome model. For conveniently description, the suspended dome model is called 'basic model'.

### 2.2 Load condition

Take common roof load conditions: characteristic values of permanent load  $g = 1.0$  kN/m<sup>2</sup> (including structure self-weight) and characteristic values of live load  $p = 0.5$  kN/m<sup>2</sup>. According to the structural characteristics of elliptic suspended dome, loading state analyses by 3 kinds of load combination are conducted.

### 2.3 Parameter selection

Compared comprehensively, influences of four main parameters on the structural stability are taken into account, i.e. rise-span ratio, plane shape factor, prestress and strut's length. Among these parameters, the plane shape factor is the ratio of short-axis's length and long-axis's length in horizontal projection of the elliptic suspended dome, that is:

$$\delta = \frac{b}{a} \quad (1)$$

where,  $a$  is half length of elliptic long-axis and  $b$  is half length of elliptic short-axis.

## 3 PARAMETER INFLUENCE ANALYSIS OF STRUCTURAL STATIC PERFORMANCE

### 3.1 Influence of rise-span ratio

In order to get different rise-span ratio, only the arch rise is changed while other parameters keep unchanged (Table 2). In the Table 2, the rise-span ratio of long-axis of the 'basic model' is 1/12, and the corresponding rise-span ratio of long-axis is 1/9.6.

Figures 2-6 shows influences of different rise-span ratio on vertical deformation, horizontal radial displacement of support, axial force of member in the upper shell and internal force of cable-strut system.

1. According to Figure 2, rise-span ratio makes a great difference on the vertical deformation of suspended dome, the maximum vertical displacement of node decreases as the rise-span ratio increases. However, the influence is gradually weaken as rise-span ratio becomes larger. The maximum vertical displacement of node all appears in load Comb-III, which shows half span live load distribution (on short-axis) controls vertical deformation of the structure. Also, differences of the maximum vertical displacement of node among the three load combinations decrease with the increase of rise-span ratio. Horizontal radial displacement of support also obeys the similar rules (Fig. 3).
2. According to Figure 4, the change of rise-span ratio makes a great difference on axial force of the upper member, and the effects from different load combinations on the maximum tensile force

Table 1. Load combination.

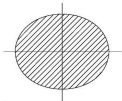

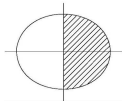

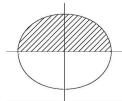

Code	Comb-I	Comb-II	Comb-III
Combination	All span permanent load + all span live load	All span permanent load + half span live load (on long-axis)	All span permanent load + half span live load (on short-axis)
Live load distribution chart			

Table 2. Different values of rise-span ratio.

Arch rise	4 m	6.667 m	8 m	10 m	16 m
Rise-span ratio of long-axis	1/20	1/12	1/10	1/8	1/5
Rise-span ratio of short-axis	1/16	1/9.6	1/8	1/6.4	1/4

Figure 2. Influence of rise-span ratio on vertical deformation.

Figure 3. Influence of rise-span ratio on support displacement.

and compressive force differ. If rise-span ratio is relatively small, unsymmetrical distribution of live load is not critical to the maximum tensile force of the upper member. When rise-span ratio increases to a certain degree (for the proposed example, when its rise-span ratio of long-axis is more than 1/8), the maximum tensile force occurs in Comb-III (half span live load distribution along the short-axis), and the maximum compressive force of the upper member occurs in Comb-III regardless of the value of rise-span ratio.

- Similarly, the internal force of cable-strut system decreases with the increase of rise-span ratio, and the smaller rise-span ratio makes a greater difference (Figs. 5-6). Cable force and axial compressive force of strut are larger when the suspended dome has smaller rise-span ratio, which makes full use of the high-strength materials and advantages of elastic support of the strut. However, the maximum internal force of cable-strut system occurs in Comb-I.

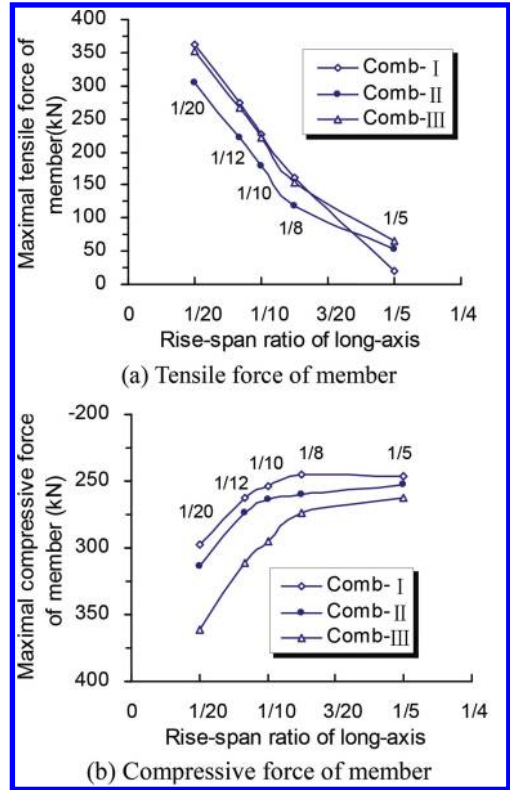

Figure 4. Influence of rise-span ratio on axial force of member.

- As shown in Figures 2-6, Comb-II (half span live load distribution on the long-axis) controls neither structural deformation nor internal force of member.

In summary, rise-span ratio has obvious influence on static performance of suspended dome, and suspended dome with smaller rise-span ratio takes more advantages of this structural system.

### 3.2 Influence of ratio plane shape factor

Base on the 'basic model' ( $\delta = 0.8$ ), as shown in Table 3, the values of plane shape factor change from 0.6 to 1.0 while the span of long-axis (80 m), the arch rise (6.667 m) and other parameters keep unchanged.

Figures 7-11 shows influences of different plane shape factors on vertical deformation, horizontal radial displacement of support, axial force of member in the upper shell and internal force of cable-strut system.

Figure 5. Influence of rise-span ratio on cable force.

Figure 6. Influence of rise-span ratio on internal force of strut.

Table 3. Different values of plane shape factor.

Plane shape factor $\delta$	0.6	0.7	0.8	0.9	1.0
Span of long-axis (m)	80	80	80	80	80
Span of short-axis (m)	48	56	64	72	80

1. According to Figure 7, plane shape factor makes a great difference on the vertical deformation of suspended dome, the vertical displacement of node increases with the increase of plane shape factors. Increase speed of the maximum vertical displacement of node differs in each load combination, Comb-I and Comb-III are basically same, Comb-II is the fastest. When  $\delta$  increases to 1.0, horizontal projection of suspended dome changes into a circle and calculation results of Comb-II and Comb-III are the same.

Figure 7. Influence of plane shape factor on vertical deformation.

2. According to Figure 8, the maximum horizontal radial displacement of support all increases with the increase of  $\delta$  under each load combination. Among the three load combinations, displacement keeps linear growth in Comb-I and Comb-III, while in Comb-II, the displacement increases faster and faster with the increase of  $\delta$  and it is equal to the displacement of Comb-III when  $\delta$  reaches 1.
3. Similarly, plane shape factor has an obvious effect on axis force of the upper member and internal force of the lower cable-strut system (Fig. 9–11).
4. It is the same with the parameter analysis results of rise-span ratio that load combination II (half span live load on the long-axis) controls neither transformation nor stress.

In summary, plane shape factor makes a great difference on static performance of suspended dome, and the increase of plane shape factor is helpful for improving structural performance.

### 3.3 Influence of prestress

Base on the ‘basic model’ ( $\delta = 0.8$ ), the influences of different prestress values on vertical deformation, horizontal radial displacement of support, axial force of member in the upper shell and internal force of cable-strut system are studied.

Figures 12–16 shows the calculation results of different prestress values, among which the prestress value of the ‘basic model’ is set to Unit 1.

1. According to Figure 12, prestress makes a great difference on the vertical deformation of suspended dome. The maximum vertical displacement of node decreases with the increase of prestress and it keeps linear growth under different load combinations. It is showed that prestress can adjust structural deformation effectively

Figure 8. Influence of plane shape factor on support displacement.

Figure 10. Influence of plane shape factor on cable force.

Figure 9. Influence of plane shape factor on axis force of member.

and nonlinear characteristic of formed structure is inconspicuous.

- According to Figure 13, the influence of prestress on support displacement is obvious. The maximum horizontal radial displacement of support decreases linearly with the increase of prestress.

Figure 11. Influence of plane shape factor on internal force of strut.

- According to Figure 14, increase of prestress reduces the maximum tensile force of member in the upper shell obviously and makes the maximum compressive force of member increase. However, over-high prestress not only can't improve structural static performance, but also increases the burden of the structure itself. However, over-low prestress can't take full advantage of suspended dome system.
- Change of prestress has effect on the internal force of cable-strut system naturally, as shown in Figure 15 and Figure 16. The maximum cable force and the maximum axial compressive force of strut keep linear growth with the increase of prestress.

In summary, prestress has obvious influence on static performance of the suspended dome. Furthermore, only reasonable prestress can improve structural performance.

Figure 12. Influence of prestress on vertical deformation.

Figure 13. Influence of prestress on support displacement.

### 3.4 Influence of strut's length

As shown in Table 4, strut's length is changed by adjusting the angle between radial cable and horizontal plane in long-axis direction, among which the angle of the 'basic model' is 20 degree.

Figures 17~21 shows influences of different strut's length on vertical deformation, horizontal radial displacement of support, axial force of member in the upper shell and internal force of cable-strut system.

1. According to Figure 17 and Figure 18, strut's length makes a great difference on the vertical deformation of suspended dome and support displacement, the maximum vertical displacement of node and horizontal displacement on support decreases continuously with the increase of strut's length. It is concluded that increase of strut's length largens strut's vertical component of forces with the same prestress (Fig. 21). Sequentially, it reduces vertical deformation and horizontal displacement effectively, which is no longer obvious as strut's length

(a) Tensile force of member

(b) Compressive force of member

Figure 14. Influence of prestress on axial force of member.

Figure 15. Influence of prestress on cable force.

Figure 16. Influence of prestress on internal force of strut.

Figure 17. Influence of strut's length on vertical deformation.

Figure 20. Influence of strut's length on cable force.

Figure 18. Influence of strut's length on support displacement.

Figure 21. Influence of strut's length on internal force of strut.

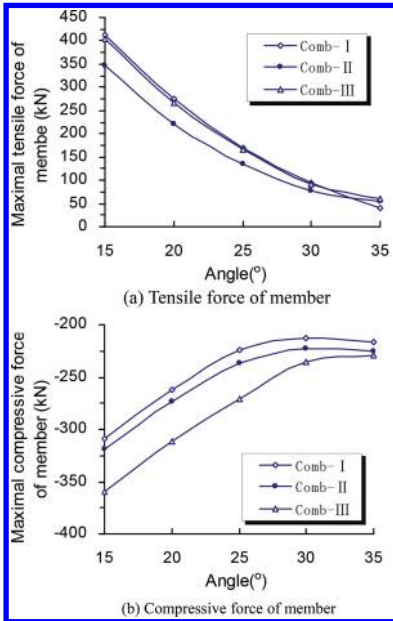

Figure 19. Influence of strut's length on axial force of member.

reaches to a certain degree. Therefore, strut's length should be chosen rationally just like the prestress. What's more, stability of over-long strut must be noticed.

2. According to Figures 19-21, increase of strut's length reduced peak of internal force of structural member. Similarly, effect on reducing inner-force peak is no longer obvious as strut's length increases to a certain degree.

In summary, strut's length has an obvious influence on static performance of suspended dome. The longer strut improved structural static performance effectively, but over-long strut is bad for strut's stability and reduces head room of the building.

#### 4 CONCLUSIONS

1. Rise-span ratio has a significant influence on static performance of suspended dome, and smaller rise-span ratio takes more advantages of this structural system.

2. Plane shape factor has a notable influence on static performance of elliptic suspended dome, and increase of plane shape factor is helpful for improving structural performance.
3. Prestress has obvious influence on static performance of suspended dome. Furthermore, only reasonable prestress can improve structural performance.
4. Strut's length makes a great difference on static performance of suspended dome. The longer strut improved structural static performance effectively, but over-long strut is bad for strut's stability and reduces head room of the building.

**ABSTRACT:** From the aspects of mechanics effect, foundation pit excavation is a kind of unloading of excavation on the surrounding environment. This will cause displacement of the surrounding soils and change the internal structure of the corresponding, using different tools and methods for studying the influence of the foundation pit excavation has become a hot topic in academia. Combined with the analysis of the influence of excavation on the surrounding environment, the paper uses the DCFEM method and two-stage analysis method to study this influence.

**Keywords:** foundation pit excavation; two-stage method for analyzing; soil settlement; impact analysis

## 1 INTRODUCTION

The utilization rate of the city land resources continuous improvement, the continuous development of underground space, and the development of foundation pit engineering gradually to the ultra deep is being done on a large scale with the continuous expansion of the city.

Foundation pit engineering is a traditional topic in the construction of foundation and underground engineering. At the same time, it also has strong comprehensive geotechnical engineering problems. It is not only related to the typical strength problems of soil mechanics and deformation problems, but also involves the interaction of soil and support structure of support. The soil around the foundation pit is affected by different disturbances in the process of excavation of foundation pit; this is called environmental effect. If this situation is handled properly, it will not only cause a waste of resources, but also casualties and significant economic losses. There have been many engineering accidents that have caused destruction of the surrounding buildings, underground pipelines, and facilities by the excavation of foundation pit. It is visible, there is a great risk in the process of foundation pit excavation, It is an urgent need for this topic for more in-depth research about the impact on the surrounding environment of foundation pit excavation. In this paper, through the research of the research status on the foundation pit of domestic and foreign, According to the problems

about the failure of surrounding environment in the process of foundation pit, to study using the method of finite element method and data analysis to solve different kinds of problems.

## 2 CHINA AND ABROAD RESEARCH STATUS

Terzaghi and Peck et al have begun to study geotechnical engineering problems in Foundation Pit Engineering and put forward the total stress method that can estimate the stability degree of excavation and support load size. The principle of this theory has been used until now after constant improvement and revision.

Bjeruum and Eide presented a method of analysis of deep foundation pit in uplift set in the 1950's. They began monitoring deep foundation pit engineering in soft clay in Oslo and the city of Mexico in 1960's, which play a role in promoting to improve the accuracy of prediction.

Lambe believes that there are 8 factors on the deformation of soil around the pit through the research in 1970's: the length of excavation, the width and depth of excavation, soil conditions of pit, groundwater level, the exposure time of pit, support system, the order of the excavation and support, the adjacent structures, and facilities and construction load.

Leung analysis of a set of uniform distribution that reflects the maximum horizontal displacement

and the maximum settlement of the surface and the relationship between the stiffness of a bracing system and those, comparing the research results of Peck, Mana, Clough, and Long.

The ground loss method that was put forward by Professor Hou Xueyuan can be used to estimate the settlement of the soil around deep foundation and calculate subsidence displacement of ground based on the related principle of ground movement area of wall displacement and ground settlement.

Gong Xiaonan et al deduct a calculation method that calculation of ultimate resistance before and after excavation based on the classical resistance formula of clayey soil pile. He also analyzes the change rule of coefficient of resistance is reduced under the condition of different excavation depth, excavation length, length width ratio and pile length, through comparing the results of theory with the measured data, the results of finite element analysis and other methods.

Obviously, the research about the foundation pit supporting has been relatively mature, but there are few researches on the effect of pit excavation on the surrounding environment. The theoretical research on the topic has aroused the attention of many scholars at home and abroad. Increasing the research in this area will increase the safety of excavation engineering, and promote the development of the theory of foundation pit engineering.

### 3 THEORETICAL ANALYSIS METHODS

Over the past ten years, the foundation pit engineering has been rapidly developing in our country, with the basic construction of our country and a large area of old city transformation like a raging fire. The problems in excavation engineering are increasing more and more, and even more and more complex. Foundation pit engineering is excavating deeper foundation pits, larger excavation areas, surrounding environment is more complex. The unknown risks in excavation also increased, especially to the surrounding structures and surrounding buildings, underground pipelines etc. in the process of excavation. The following will introduce and analyze the changes of the surrounding environment caused by excavation.

#### 3.1 *The uneven settlement of soil around the foundation due to pit excavation*

In the process of construction of deep foundation pit engineering, the surrounding soil will be disturbed by different degree, this will affect the normal use of the surrounding buildings, structures and underground pipeline, even cause engineering accident. The uneven subsidence of the surrounding surface is one of the important influence which caused by excavation. Factors of

ground settlement: the state of stress and strain of the soil around changes, the displacement of surrounding soil, strata consolidation caused by well point precipitation, sand loss, sand flow, piping loss caused by pumping.

#### 3.2 *Analysis of the surrounding soil stress-strain state change*

The main way of impact that the excavation to adjacent underground structure is that the surrounding soil will be disturbed, and that will lead the stress and strain state of the surrounding soil to change, eventually leading to stress and strain state of neighboring structures to change. The reason for the change of soil strain state is that plastic deformation of the soil caused by stress perturbations and the strain caused by soil creep. However, the strain of soil is mainly remolded. Soil turns to reconsolidation soil. With the depth of excavation increasing, the internal forces of the soil around the pit increasing, the soil around the foundation pit will produce a large plastic zone, the lateral soil of the foundation pit will cause a destructive sliding toward the foundation pit. Eventually, the foundation pit becomes unstable and a lot of subsidence is generated around the foundation pit. These subsidence can cause a large margin of formation loss. This is also an important factor arises engineering accident.

#### 3.3 *Analysis of displacement of soil around foundation pit*

The stability of the soil is weakened when the excavation plane push down, the shear force of the soil will be increased. When the strain of the soil is greater than the shear strain, the structure of soil is damaged, the surrounding soil is moved, so, the unstable state region is appeared in the surrounding soil. In particular, when the stress change region between two underground engineering is in a whole, this area will have a large loose range of soil. The soil between the two underground engineering will be unstable, at the same time, the retaining structure will change. This change will vary according to the width of the separation zone between the adjacent underground engineering. The results show that the width of separation zone is set to two times excavation depth, the mutual influence of deep foundation pit construction can be reduced effectively. This kind of interaction has some relationships with the excavation sequence of adjacent foundation pit and effect of variable position of supporting structure and so on.

#### 3.4 *Analysis of settlement caused by foundation pit precipitation*

During foundation pit excavation, when the water level of the groundwater level is reduced too low

or the structure of the retaining structure is too large, it can reduce subsidence of ground around the foundation pit. If the uneven settlement is too large, There may also cause buildings tilt, crack of wall, road and underground pipeline cracking, and other serious problems.

The amount of moisture content in the soil directly affects the mechanical properties of the soil structure. When the moisture changes in the soil body, the soil will generate a reshaping. Experiment shows, for the same kind of soil, the mechanical properties of undisturbed soil samples are very different with remodeling soil samples. During the excavation of foundation pit, the constant drainage causes the groundwater level fall. The moisture content of soil around the foundation pit is changed, and the stress state of the soil also changes. This will cause the remodeling of the structure of soil around the foundation pit, the mechanical properties of soil are changed. This remodelled soil will produce uneven settlement under the same load, especially in soft soil region, this performance is more obvious, the great harm, because the soil moisture content is high, the soil loses the moisture, the soil produces the consolidation.

#### 4 RESEARCH ON SOME OUTSTANDING ISSUES

##### 4.1 Analysis of the influence of foundation pit excavation on the foundation of near buildings

Research on the influence of foundation pit excavation near pile foundation has been studied by domestic and foreign scholars with different methods. Leung et al. has discussed the influence of foundation pit excavation on the foundation of adjacent piles under no support conditions through centrifugal model test, and has analyzed the influence to single pile and group piles with different piles. Pan et al. and Miao et al. has discussed deformation and mechanical properties of passive single piles and extracted P-y curve of single pile uniform soil under horizontal displacement condition.

The influence of foundation pit excavation on the foundation of adjacent buildings is a passive pile problem. Zhu Xiaoyu et al. has discussed the influence of the foundation pit excavation to the single pile and the group pile at the different distance with DCFEM (finite element method control the displacement, the simplified method has been applied to the analysis of environmental impact of underground excavation). Then, they also compared the test results of influence of foundation pit excavation on adjacent piles with results of centrifugal model test.

Figure 1 (a) and (b) are the comparison of results between DCFEM and centrifuge tests, The displacement of the piles obtained by DCFEM

Figure 1. Comparison of results between DCFEM and centrifuge tests.

method is more than that of the centrifugal model. The calculated moment is smaller than the centrifugal test result. But the displacement curves and bending moment curves of the two methods are similar, the displacement values are all at the top of the pile, and the maximum bending moment is located in middle of the pile body.

##### 4.2 Analysis of the influence of excavation on near metro tunnel

People's living standards improved with the rapid development of economy. City traffic is becoming increasingly congested. The trend is that the Metro has become construction of urban transport. But in this times of land-scarcity, It is inevitable that excavation pit near the subway will be used to construct high-rise buildings. The subway track has strict requirement for the soil mass below the orbit. This gives the study of the excavation of the subway tunnel important significance. The research on the influence of the excavation to the subway tunnel is not a new problem. Domestic scholars have carried out a thorough study on the subject.

Zhang Zhiguo et al. have adopted a two-stage analysis method which can consider unloading effects at the bottom and around the pit wall soil due to excavation. This method is based on the Winkler foundation model to establish the basic differential equation of the longitudinal deformation of the subway tunnel. According to the Galerkin method, the equation is converted to a one-dimensional finite element equation for calculation. At the same time, they have studied the factors of the longitudinal deformation of tunnel: different tunnel depth, distance from the excavation site, different foundation soil and different tunnel diameter, and so on. The results of this method are compared with the field measurement data. The results were in good consistency.

## 5 THE DIRECTION OF THE FUTURE RESEARCH ON THE ENVIRONMENT INFLUENCED BY THE EXCAVATION OF FOUNDATION PIT

Foundation pit is as temporary structure, strength safety reserve is also lower relative to the main body structure, at the same time, the external environment factors of foundation pit is so many, for example, geological conditions and different sites of different regions, even though the same sites are not the same in different regions, many factors make it a comprehensive system engineering. Whether the surrounding environment is influenced by foundation pit excavation is also a comprehensive study, the engineering situation around the foundation pit will be more and more complex in future studies. With the continuous progress of Technology, we can apply professional software to study the interaction between foundation pit and buildings, select the appropriate constitutive model of soil, and combine with the surrounding engineering situation to simulate construction and forecast construction risk. This can ensure the safety of the construction, at the same time, it can also speed up the construction progress to make up for foundation pit temporary problem. The data fed back through the construction process can verify the correctness of the simulation. The combination of theory, software and construction site is the ultimate design through the continuous improvement. Eventually, we will design a more safe and efficient construction scheme.

## 6 CONCLUSION

In the era of vigorous economic development, The foundation pit engineering continuously develop to deeper and larger area, which is also the opportunity and challenge for geotechnical workers.

Many geotechnical workers have made remarkable achievements in the foundation pit after years of unremitting efforts and development, but in recent years, some technical problems of foundation pit engineering are still waiting to be resolved. Applying the theory of foundation pit to guide practice, we will verify the correctness of theory from practice, it also helps to achieve a greater breakthrough in theory at the other way round. There are some another problems and valuable research results of foundation pit engineering are not reflected in this paper due to the limited level and space, I hope that scholars give me some criticisms.

# A detailed analysis of the steel strand corrosion effect on serviceability state of PC continuous rigid frame bridges

Peng Wang, Fumin Wang, Li Zhang & Zanpeng Zhang

China Merchants Chongqing Communications Technology Research and Design Institute Co. Ltd.,  
Chongqing, China

**ABSTRACT:** Based on the degradation model for sectional area and mechanical properties of corroded steel strands, a detailed analysis is done to find the effect of steel strand corrosion on serviceability state of PC continuous rigid frame bridge by finite element method. The result shows that corrosion of steel strands have very serious effects on the prestress reserves, especially the upper steel tendons in the top slab and the steel tendons in the bottom slab of the box girder. It is an important cause for long-term deflection and cracks of this kind of bridge.

**Keywords:** Prestressed Concrete; continuous rigid frame bridge; steel strands; corrosion; crack; deflection

## 1 INTRODUCTION

PC (Prestressed Concrete) continuous rigid frame bridges have advantages such as high stiffness, seismic resistance, and less expansion joints. So they are widely used. There are two kinds of common diseases in the girder of the bridge, which should be paid attention to: one is concrete cracking and the other is excessive deflection under long-term load effect. Both often go together and enhance mutually.

There are long-term deflection data of 15 bridges listed in Figure 1 a). It can be seen that the deflection-to-span ratios are between 1/393 and 1/4242, most of them are more than the expected value. The average annual increment of deflection under long-term load effect of some bridges are shown in Figure 1 b), most of them are between 1 cm/a and 5 cm/a. They have no clear relationship with the length of the bridge span.

The causes for cracks and long-term deflections are complex, and thus a debatable problem. The corrosion of steel tendons may be one reason for it to cause reduction of the cross-sectional area, strength, elastic modulus, and elongation of steel tendon, it also leads to reduction of the prestress reserve and bearing capacity of the girder, but the degree of the effect still needs further research.

## 2 MECHANICAL PROPERTIES OF CORROSION STEEL STRANDS [1]

**Corrosion rate.** The corrosion rate of a piece of steel strand can be determined by weight or average cross-sectional area after corrosion.

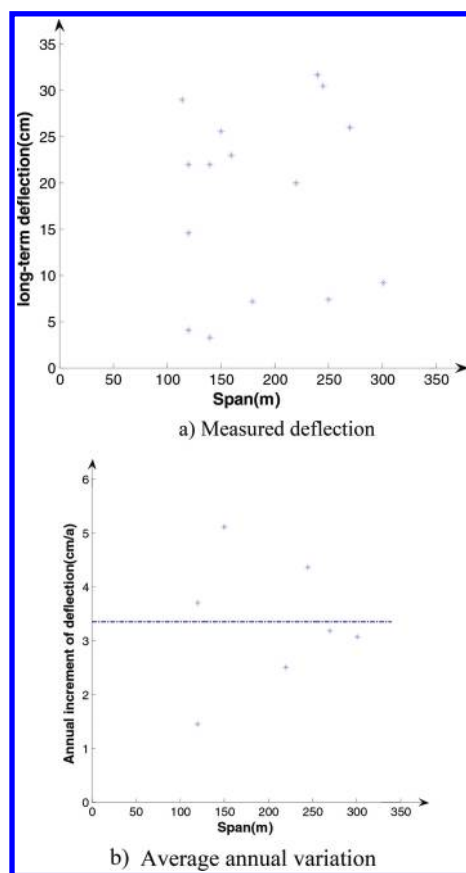

Figure 1. Statistics of long-term deflection of PC continuous rigid frame bridges.

$$\rho_w = \frac{g_0 - g_t}{g_0} = \frac{A_p - A_{pt}}{A_p} \quad (1)$$

where:  $g_0$ ,  $g_t$  is the weight of steel strand before and after corrosion respectively,  $A_p$ ,  $A_{pt}$  is the average cross-sectional area of steel strand before and after corrosion respectively.

**Nominal ultimate strength.** A model for the nominal ultimate strength of corroded steel strands is as formula (2).

$$f_{ul} = (1 - 8.422\rho_w^{1.351})f_u \quad (2)$$

where,  $0 < \rho_w < 10.4\%$ ,  $f_{ul}$  is the nominal ultimate strength of corroded steel strands;  $f_u$  is the ultimate strength of un-corroded steel strands.

**Nominal elastic modulus.** A model for the nominal elastic modulus of corroded steel strands is as formula (3).

$$E_{p1} = (1 - 40.4633\rho_w^{2.366})E_p \quad (3)$$

where,  $E_{p1}$  is the nominal elastic modulus of corroded strands;  $E_p$  is the elastic modulus of un-corroded strands.

### 3 EFFECT OF STRAND CORROSION ON PC CONTINUOUS RIGID FRAME BRIDGE

**Project case.** A PC continuous rigid frame bridge is adopted for analysis, detailed dimensions of the bridge are shown in Figure 2. The girder is built with concrete C55 according to Chinese Code. It has a three-dimension prestressing system, in which the longitudinal prestressing tendons are the most important part, they consist of top slab tendons, web tendons, bottom slab tendons as shown in Figure 3.

According to Figure 3, the upper tendons in the top slab are prone to corrode for they are closer to external environment and traffic loading; the lower tendons in the top slab are protected by thicker concrete cover, so they are affected by external environment more weakly than the upper tendons. The corrosion order of the steel tendons in the girder may be the upper tendons in the top slab firstly, the lower tendons in the top slab secondly, and the last are the

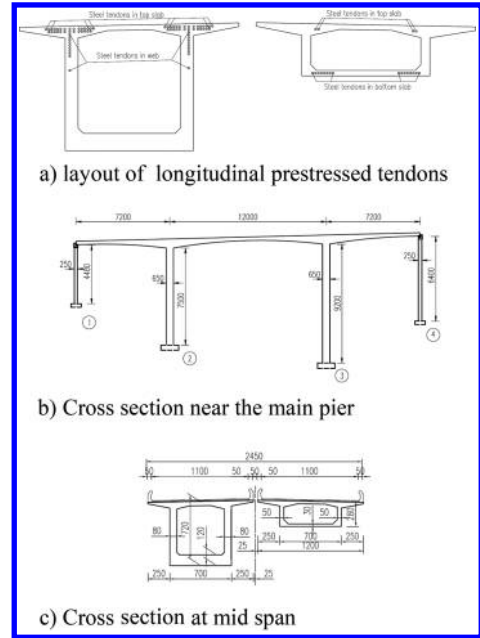

Figure 3. Layout of longitudinal prestressing tendons.

Table 1. Section area and mechanical properties of corroded tendons.

Corrosion rate	$E_p$ [MPa]	$F_{pk}$ [MPa]	$A_p$ [mm <sup>2</sup> ]

0.06	184856.2	1509.9	2090.6	1698.6	2482.5
0.08	174964.2	1343.6	2046.1	1662.4	2429.7
0.10	161030.0	1161.9	2001.6	1626.3	2376.9
0.12	142707.6	966.9	1957.1	1590.2	2324.1

bottom slab tendons. But because the bottom slab cracks sometimes in the early age of the girder, tendons in the bottom slab may corrode firstly. All the cases above are considered in this paper.

According to formula (1) to (3), mechanical properties of corroded tendons can be obtained under various corrosion rates, which are listed in Table 1.

Because the PC continuous rigid frame bridge is a hyperstatic structure, the internal force will redistribute if steel tendons corrode, it is a complex problem, so the corrosion effect analysis is carried out by finite element method. The FE model is shown in Figure 4.

Figure 2. Layout of PC continuous rigid frame bridge.

Figure 4. FE model.

**Corrosion effect of the upper tendons in the top slab.** Analyses are carried out to calculate the deflection of the middle span, the principal tensile stress of the webs, normal stress of the bottom slab, and effective prestress of the corroded steel tendons.

As shown in Figure 5, the deflection under long-term load effect increases along with the increasing of the corrosion rate of the upper tendons, and the increase tends to accelerate. When the corrosion rate is 10%, the deflection reaches  $-19.16$  mm, which is  $1/6263$  of the main span. When the corrosion rate is 12%, the deflection reaches to a  $-25.35$  mm, which is  $1/4734$  of the main span. Herein brittle fracture may happen when corrosion rate is more than 10%, so 12% is only for reference.

When the corrosion rate is 10%, the nominal ultimate strength decreases to 1161.9 MPa, approximately to effective prestress of normal steel tendons; when the corrosion rate is 12%, the strength decreases to 966.9 MPa, lower than the effective prestress. When the corrosion rate is between 10% and 12%, tendon fracture is likely to happen, so prestress reserved and bearing capacity of the girder will decrease rapidly, and long-term deflection will become worse.

As shown in Figure 6a), principal tensile stress under short-term load effect is in proportion to the corrosion rate of the upper tendons in the top slab. When the corrosion rate is 10%, the tensile stress reaches 0.95 MPa, when the corrosion rate is 12%, the tensile stress reaches 0.98 MPa, getting close to the limit value of the tensile stress of 1.096 MPa. As shown in Figure 6b), normal stress at the bottom of the mid span increases along with the increasing of the corrosion rate.

As shown in Figure 7, the effective prestress of tendons decreases along with the increasing of the corrosion rate of the upper tendons. When the corrosion rate is 10%, the effective prestress drops from 1172.1 MPa to 1110.8 MPa, and the prestress loss rate is 14% considering section area loss of the tendons. When the corrosion rate is 12%, the loss rate reaches 18%.

**Corrosion effect of the lower tendons in the top slab.** Assuming that the upper prestressing tendons have been corroded, the corrosion rate is 10%. The

Figure 5. Corrosion effect of the upper tendons on deflection.

Figure 6. Corrosion effect of the upper tendons on the stress.

corrosion rate of the lower tendons grows from 0 to 10%, and then the deflection drops from  $-19.16$  mm to  $-22.78$  mm, reduced by 3.61 mm in total. Stress at the bottom of mid span rises from  $-1.79$  MPa to  $-1.67$  MPa, increased by 0.12 MPa in total under short-term load effect, and the principal stress of the web at the 1/4 span drops from 0.95 MPa to 0.93 MPa, decreased by 0.02 MPa in total.

**Corrosion effect of the web tendons.** Assuming all the prestressed tendons of the top slab have been corroded, the corrosion rate is 10%. The

Figure 7. Corrosion effect of the upper tendons on the effective prestress.

Figure 8. Corrosion effect of the bottom slab tendons.

corrosion rates of tendons in the web grows from 0 to 10%, then the deflection drops from  $-22.78$  mm to  $-24.74$  mm, reduced by  $1.96$  mm. Stress at the bottom of mid span rises from  $-1.67$  MPa to  $-1.61$  MPa, increased by  $0.05$  MPa under short-term load effect, the principal stress of the web at the  $1/4$  span rises from  $0.93$  MPa to  $0.95$  MPa, increased by  $0.02$  MPa.

**Corrosion effect of the bottom slab tendons.**

When tendons in the bottom slab corrodes individually, the corrosion rate of the tendons in the bottom slab grows from 0 to 10%, the deflection rises from 0 to  $-4.72$  mm, as shown in Figure 8, and normal stress at the bottom of mid span rises from  $-2.22$  MPa to  $-1.5$  MPa, increased by  $0.72$  MPa under the short-term load effect. In addition, the principal stress of the web at the  $1/4$  span drops from  $0.87$  MPa to  $0.86$  MPa, reduced by  $0.01$  MPa.

If the top slab tendons have been corroded, and the bottom slab begins to corrode, insignificant rebound of deflection might occur due to redistribution of the internal force.

**Some tendons are corroded and fractured.** As mentioned above, when the corrosion rate is more than 10%, steel strand might be fractured. For example, when the upper tendons of the top slab corrode alone, in which 3 pieces of strand of each tendon ( $16\phi^{15.2}$ ) get fractured, while the corrosion rate of other strands is 10%, the girder deflection drops from  $-19.16$  mm to  $-37.24$  mm, the principal

tensile stress of the web at  $1/4$  span reaches  $1.08$  MPa under short-term load effect, close to the limited value. When there are 6 fractured strands, the girder deflection rises to  $-58.98$  mm, the principal tensile stress of the web at  $1/4$  span will reach  $1.26$  MPa, exceeding limited value, while the stress at the bottom slab of mid span reaches  $0.6$  MPa, the webs and the bottom slab crack, resulting in the decrease of the girder stiffness and accelerated growth of the long-term deflection.

**4 SUMMARY**

In this paper, research is carried out to analyze the effect of steel tendon corrosion on a PC continuous rigid frame bridge. It is concluded that:

1. The corrosion effect of the upper tendons on the long-term deflection and principal tensile stress of the web is most significant, but the effect on the normal stress of the bottom slab is slightly lower than that of the bottom slab tendons. The corrosion effect of the lower tendons and the web tendons is insignificant. The corrosion of the tendons in the bottom slab exerts the most significant effect on the stress of the bottom slab.
2. PC continuous rigid frame bridge is a hyperstatic structure with complicated prestressed system. When the tendons in the top slab have

been corroded and the tendons of bottom slab begins to corrode, insignificant re-bounce of deflection might occur due to redistribution of the internal force.

3. When part of the tendons especially the upper tendons of the top slab corrode and fracture, the prestress reserved decreases rapidly, diagonal cracks will appear on the web, and lateral cracks might appear at the bottom of mid span, resulting in accelerated growth of the deflection.

All in all, steel tendons corrosion is one of the important reasons for a long-term deflection and crack of PC continuous rigid frame bridge.

**ABSTRACT:** The nature of affordable housing industrialized building system is to realize its large-scale and industrial production in the field of urban construction. Its core is changing the housing construction projects from the traditional field construction to factory manufacturing. To achieve these objectives we need to standardize, modularize, and serialize its key assemble parts, design, and produce the matching mould, and assemble the mode parts. Mould plays a connecting role in these aspects, its applicability and advanced nature, directly affect the degree of the factory automation and efficiency of field installation and parts quality, mould design optimization problem should be taken seriously enough. On the foundation of the detailed investigation and study, the composite wallboard mould was analyzed, concluded, and summarized, which requires multiple groups of pouring in the northern area.

**Keywords:** composite wallboard; mould; group technology

## 1 INTRODUCTION

Industrialization of buildings is an inevitable trend in the construction industry [1]. The prefabricated building structures has to achieve the most efficient industrial production structure. Precast concrete is the main way of concrete construction, comparing with cast-in-place concrete, its features include factory construction, construction convenient, low impact on the surrounding environment, the surface roughness, the exact appearance of size, short construction period and fast return on investment [2–3]. With the continuous development of the technology of prefabricate concrete, the demand of mould is increasing, so mould design optimization problem should be taken seriously enough.

## 2 THE PROBLEMS OF PREFABRICATED MOULD AT PRESENT

The formwork Engineering is an important part of the reinforced concrete structural engineering [4]. With the continuous development of the technology of prefabricate concrete, the demand of mould is increasing. But there are several questions of the traditional mould of precast wall:

1. Severe deformation during the life of the interior wall mould.
2. The mould is difficult to disassemble.

3. A mold can only produce a wall, this mode of production wastes material.

## 3 CONNECTION OF COMPOSITE WALLBOARD MOULD

Composite wallboard in fixed mould is composed of the following parts, they are bottom mold steel base, the bottom bracket and the bottom mold steel mold, mold wall outer leaves, inner leaf mold wall, and window mode. These parts are assembled into a unified whole composite wallboard production process.

Dies use reasonable connection, the quality of the connection design affects productivity of compound wall and quality of the mold. Currently there are connections of mold including weld connections and bolted connections [5]. With fixed steel pedestal base mold, according to the actual support cases, desirable on both sides of the support or the support sides to be calculated.

## 4 CONNECTION DESIGN OF MOULD

In order to facilitate, this mold will make a list of standard components involved in schematic (see [Table 1](#)) text, part of the direct use of its number.

Floorplan of window mould and bottom mould is Figures 8 and 9.

## 5 CONCLUSIONS

This paper describes the design principle of the mold connected, and the technical characteristics

of composite wall in northern China, and the original mold problems were analyzed and summarized. On the foundation of the detailed investigation and study, the composite wallboard mould was analyzed, concluded and summarized, which requires multiple groups of pouring in the northern area. Its design theory and calculation method were elaborated. The author optimized the mould design in the area of the original mould composition and connection structure using three-dimensional design software SKETCHUP and AUTOCAD plane drawing combination design method that provide the basis for other similar structure design.

**ABSTRACT:** The dominant vibration period is one of the most important behavioral parameters of the structures that are widely used in most of the seismic design codes of structures. The proposed methods by the Codes and Standards for calculation of the dominant vibration period are only dependent to Structure's height, and are obtained based on the first vibration mode. Thus, in cases with a small ratio of height to span of the structure, could not give sufficient accurate results. In this paper, we have studied the effects of height and the span of structures on the vibration periods and the mass participation ratios in higher vibration modes after performing the modal analysis for several steel moment resistant frames. Then, we have developed a simplified formula, based on the results. The relations presented in this article, besides considering the effect of the height and span of structure in estimating the first and second vibration modes, have no certain complexity and could present a good alternative for the formulae incorporated in the codes.

**Keywords:** modal analysis; vibration period; mass participation ratio; first and second vibration modes; codes formulae

## 1 INTRODUCTION

Many structures should be designed against the seismic loads due to their special functionality. The full dynamic analysis of structures could not be utilized inclusively because of its time-consuming solution process and computational complexity (Goel & Chopra 1997). Therefore, the seismic design codes of structures have tended towards the "quasi-static method". This method is based on the substitution of seismic loads by the base shear force at the base level and its distribution over the height of the building (Salama 2014), and it has been introduced by most of the structural design codes such as the International Building Code (IBC) or Euro code (IBC 2000, Eurocode 2004).

Calculating the base shear coefficient is based on the several proposed factors, including behavior factor (R), response factor (B), importance factor (I) and design base acceleration ratio (A) (Chopra 2011).

B, the response factor, which is obtained from the standard design response spectrum, shows that what

percentage of seismic acceleration at the building floor level, enters the structure and affects the mass of different floor levels. For calculating this factor, the dominant structural vibration period should be calculated first, and then, using the standard design response spectrum, the response factor could be read (Chopra & Goel 2000).

To calculate the dominant vibration period, the Codes have provided several empirical relationships for conventional structures, but each of them has its own deficiencies (Carrillo & Alcocer 2013). For example, these relationships are just a function of structure height. In other words, the only factor in determining the dominant vibration period of a structure is the height of the structure, while other factors such as span of the structure and architectural configuration of the structure can also be effective. On the other hand, in calculating the dominant vibration period, only, the first vibration mode of structure is considered, and the effects of higher vibration modes are neglected. While by increasing the height of structure (H), or the height-to-span ratio of structure (H/L), the

effects of higher vibration modes will be significant, and the seismic behavior of structure is highly affected by them. For instance, a structure, which is considered as “mid-rise building”, may have a large height-to-span ratio because of the smallness of the span, and therefore, in this case, the effect of higher vibration periods on the seismic behavior of the structure is impressive. That is why the proposed Codes formulae do not provide an accurate estimate of the structural vibration period.

In this paper, twelve steel structures with moment resistant frames at different heights and spans have been examined, and then, using modal analysis, the first and second vibration modes of these structures have been extracted. Next, the effects of height—to- span ratio on the vibration period and mass participation factor have been studied, and finally, considering the height and span of structures, some simplified equations have been developed to estimate the dominant vibration period of structures for the first and second vibration modes. In addition to the proposed simplified formulae, the relative accuracy of the formulae included in the Code has also been studied and compared for different kinds of structures.

## 2 REVIEW OF TECHNICAL LITERATURE

The existing deficiencies in the seismic design of structures codes, including not covering all types of the structures in engineering constructions, neglecting the effects of higher vibration modes and ignoring the geometric characteristics of structures in estimating the dominant period have led many researches to estimate the vibration periods for the seismic behavior of structures during earthquakes.

In this regard, Skinner et al. (1993) studied the use of the seismic isolation systems to improve the seismic behavior of structures. They stated that using seismic isolation systems, increases the dominant period and damping of the structures, and as a result, reduces the input seismic demand of the structure. They evaluated the period of structures, before and after using seismic isolators and studied the reduction of higher modes' effects after rehabilitation of the structures with seismic isolation systems.

Chun et al. (2000) assessed the accuracy of Korean Building Code of 1988 in calculating the dominant period of the reinforced concrete buildings with shear wall systems. For this purpose, they conducted some full-scale measurements for 50 different buildings and compared the results of the measurements with the dynamic modeled ones, and also formulae proposed by Codes. The results of this study showed that the stiffness of the tested buildings is different from the results obtained

from the formulae in Codes. At the end of the study, to have a better estimation of the stiffness, they proposed an expression to calculate the shear wall period of the reinforced concrete buildings.

Balkaya & Kalkan (2013), using three-dimensional finite element dynamic analysis, studied the behavior of tunnel form concrete buildings with shear walls, and then, using the obtained results, tried to investigate the effects of architectural configuration, roof weight and arrangement of shear walls on the dominant period of analytical models.

Balkaya & Kalkan (2004) studied the behavior factor ( $R$ ) and dominant period of tunnel form structures with concrete shear walls. They discussed the flow of transferring load from shear walls to foundation and studied the effects of Structures' vibration modes on the plastic behavior.

Bratosin et al. (2009), using the Kelvin-Voigt nonlinear model, proposed a method for modeling the resonance peaks in the nonlinear analysis of site materials. He, in addition to studying the dynamic behavior of rock and soil media and magnification of seismic waves, tried to provide a better estimate of the Environment's dominant period and its effect on the site-structure resonance.

This research, after modeling and designing of several steel structures with moment resistant frames at different heights and spans, used modal analysis to examine the shape modes of structures in higher vibration modes. It evaluated the effects of height and span of structures on the mass participation factor and dominant period in different vibration modes. Finally, some simplified equations were provided to estimate the dominant period of structures in the first and second vibration modes and evaluate the accuracy of Code formulae in estimating the dominant period of steel structures.

## 3 PROBLEM SOLVING METHODOLOGY

The governing dynamic motion equation in a multi-degree of freedom system with viscous damping is (Chopra 2011),

$$M\ddot{U} + D\dot{U} + KU = F \quad (1)$$

where  $U$ ,  $\dot{U}$  and  $\ddot{U}$  are displacement, velocity and acceleration vectors, respectively, and  $F$  is the external load vector in the system.  $M$ ,  $D$  and  $K$  represent the mass, damping and stiffness matrixes of the system, respectively. The free vibration equation of the system without damping could be written as follows,

$$M\ddot{U} + KU = 0 \quad (2)$$

Assuming a cosine harmonic response as  $U = \varphi \cos(\omega t - \theta)$  for this differential equation, the solution will be,

$$[-M\omega^2 + K]\varphi = 0 \quad (3)$$

Eq. (3) is a linear system of “n-equations, n-unknown parameters” which has answer only if the determinant of the coefficient matrix is zero (Eq. 4).

$$\Delta = |-M\omega^2 + K| = 0 \quad (4)$$

Eq. (4) that is called characteristic equation of the system, is a linear function of  $\omega^2 = \lambda$  (Eq. 5).

$$\begin{aligned} \Delta = 0 &= a_0 + a_1\omega^2 + a_2\omega^4 + \dots + a_{2n}\omega^{2n} \\ &= a_0 + \sum_{i=1}^n (a_i\lambda^i) \end{aligned} \quad (5)$$

This linear equation has n roots as  $\{\lambda_k\}_{k=1,2,\dots,n}$  or  $\{\pm\omega_k\}_{k=1,2,\dots,n}$ , where  $\lambda$  is the Eigen value of coefficient matrix and  $\omega$  ( $\omega = \pm\lambda^{1/2}$ ) is the natural frequency of the system. Thus, by calculating n values for  $\omega$ , n values for natural period are calculated in accordance with Eq. (6).

$$T = \frac{2\pi}{\omega} \quad (6)$$

As it is shown in Eq. (7), corresponding to any values of natural frequencies (or Eigen values), there is a natural mode vector (or Eigen vector),

$$[-M\lambda_i + K]\varphi_i = 0, \quad i = 1, 2, \dots, n \quad (7)$$

The ratio between the components of eigenvectors obtained from the above equation forms the mode shape matrix which reflects the system vibration.

$$\Phi = \begin{bmatrix} \varphi_{11} & \varphi_{12} & \dots & \varphi_{1n} \\ \varphi_{21} & \varphi_{22} & \dots & \varphi_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ \varphi_{n1} & \varphi_{n2} & \dots & \varphi_{nn} \end{bmatrix} \quad (8)$$

The following equation shows the percentage of mass participation, which represents the percentage of structure mass involved in the structure's vibration mode.

$$[-M\lambda_i + K]\varphi_i = 0, \quad i = 1, 2, \dots, n \quad (9)$$

#### 4 MODELING AND ANALYSIS

Twelve steel moment resistant frames, including four five-story structures, four twelve-story structures, and four twenty-story structures were analyzed by SAP2000 software to examine the vibration period changes against structure geometry. In this regard, seismic loading and designing of these structures were considered in accordance with the Iranian Code of practice for seismic resistant design of building (Code 2800, 2005). The results of this design are shown in Tables 1 to 3.

In the next step, the structures were analyzed by the modal analysis method and the dominant period and mass participation factor of the first and second vibration modes were calculated.

To compare the results from modeling by software, and the results from Code prescribed equations (Eq. 10), apart from the modal analysis results, the dominant vibration period was calculated for all the structures with proposed equations, prescribed in Code 2800 (Code 2800, 2005). The results, then, were presented in Table 4 with respect to the structures' geometry (number of stories and spans), structures' height (H), structures' span length (L), periods calculated by Code 2800 ( $T_{2800}$ ), periods of the first vibration mode calculated by the modal analysis ( $T_{\text{mode1}}$ ), periods of second vibration mode calculated by the modal analysis ( $T_{\text{mode2}}$ ), mass participation factors of the first vibration mode ( $L_1$ ), mass participation factors of the second vibration mode ( $L_2$ ) and total mass participation factors of the first and second vibration modes ( $L_1 + L_2$ ).

$$T = 0.08H^{\frac{3}{4}} \quad (10)$$

\* First number is the story number, and the second one is the span number.

The diagram of Figure 1 compares the periods obtained by the modal analyses in the first and second vibration modes and the values obtained by Code 2800 (Code 2800, 2005). It can be seen that in all structures, the period estimated by Code 2800 is between the periods of first and second vibration modes obtained from the modal analysis. It can also be seen that with higher structures, the difference between the periods of the first and second vibration modes is greater.

We arrange values in Table 4 in terms of structure's height-to-span ratio (H/L), to examine changes in the vibration period of the structure, compared with geometric characteristics of the structure (Table 5).

Figure 1. Comparing the results of modal analysis and Code 2800 formula.

9	1.17576	2.37125	0.81863	0.76	0.12	0.88
15	1.72466	3.47091	1.12826	0.75	0.12	0.87

Figure 2. Changes in mass participation factor of first mode to H/L.

Figure 2 shows the change of mass participation factor in the first vibration mode against height-to-span ratio of the structure (H/L). As it could be seen, by increasing the height-to-span ratio (H/L), the mass participation factor will decrease sharply. When the height increases, higher modes will have a greater effect on the structural response, therefore, actual behavior of structure could not be modeled just by considering the first vibration mode.

In Figure 3, the sum of mass participation factor in the first and second vibration modes (i.e.  $L_1 + L_2$ ) is plotted against the height-to-span ratio of the structure (H/L). As it is seen from this diagram, the total mass participation of the two first modes has a downward trend. In other words, there are some cases in which more than one vibration mode is effective on the structural response. Therefore, to estimate the dynamic structural behavior, higher vibration modes of the structure might also need to be considered.

As previously mentioned, Code formulae are just a function of structure height and only calculate the period of first vibration mode. To solve

Figure 3. Changes in mass participation factor of two first modes against H/L.

Figure 4. The relationship between height to span ratio and period of first vibration mode.

Figure 5. The relationship between height to span ratio and period of second vibration mode.

this problem, according to Figures 4 and 5, by fitting a curve to the results from the modeling software, two simplified equations are developed. These equations could be used to determine the first and second vibration periods considering the height-to-span ratio of the structures.

We can use the provided equations instead of Code formulae in order to calculate the vibration period of steel structures with moment resistant frames (Eqs. 11 and 12). These equations could be used to calculate the vibration periods of the first and second modes as a function of height-to-span ratio of the structure.

$$T_{model1} = 1.1567 \left( \frac{H}{L} \right)^{0.5008} \quad (11)$$

$$T_{model2} = 0.394 \left( \frac{H}{L} \right)^{0.4996} \quad (12)$$

The Table 6 is provided in order to investigate the relative error of equations proposed by Code compared to equations proposed by this paper. In this Table, there are three error ranges of 0 and 10%, 10 to 30% and over 30%.

## 5 CONCLUSION

Codes formulae provided for calculation of the period are only a function of structure's height. In other words, the only factor, affecting the variation of the period of a structure, is its height, while adding a span to the structure can change its stiffness extremely, and therefore, the period of the structure changes, without any change in its height. Apart

from this issue, by increasing the height-to-span ratio of the structure, the effect of higher vibration modes in structural behavior are consequently increased, and we cannot calculate the period, by just relying on the first vibration mode. Hence, in this paper, using the modal analysis of steel structures with moment resistant frames, we have studied the effect of structure height-to-span ratio on period and mass participation factor of the first and second vibration modes and developed two simplified equations for this purpose. Comparing the results of Code relationships and equations proposed in this paper, relative error percentage is presented in Table 7 in terms of the height and the span length of different structures. According to this table, the error percentage at lower heights is less than 10% while this amount is over 30% for higher heights.

Regarding the assumptions used in this article, and to continue working on this paper, some points and suggestions are offered as follows:

- This paper discussed the steel moment resistant frames with different spans and heights. Other types of structures including concrete or steel structures such as bracing steel frame and double steel frames can be studied in the same way.
- In this study, steel frames are modeled and analyzed in two-dimensional form. To examine issues such as irregularity in plan and height, this study should be done using a three-dimensional modeling tool.
- In seismic rehabilitation of the structures, utilizing passive controllers such as dampers or seismic isolators, estimating the vibration period of the structure before and after the rehabilitation is necessary. Therefore, the current study can be developed for seismic rehabilitation of structures as a new research project.

# Installation study of transverse brace of stacked tied arch bridges for safety of out-plane buckling

Youjun Niu

Gansu First Installation Engineering Co. Ltd., Lanzhou, China

Pengzhen Lin

School of Civil Engineering, Lanzhou Jiaotong University, Lanzhou, China

**ABSTRACT:** Stacked arch bridge is a new bridge system, based on four different styles of installation of transverse brace of a stacked tied arch bridge. Out-of-plane buckling is analyzed according to different position and different form of installation of transverse brace; the safety factor of stability and buckling model of each analysis models are get, the more important influence factors to out-of-plane buckling are analyzed, the results have reference value to same bridge application.

**Keywords:** bridges; stacked arch bridges; tie arch bridges; transverse brace; out-of-plane buckling; safety factor

## 1 INTRODUCTION

Stacked arch bridge is a new bridge system. It means its upper and lower arch ribs of main arch rib are separated and the skewbacks (support points) are set up on the different piers, which is shown in Figure 1. In Japan, the similar system of the bridge existed. The main arch ribs of stacked arch bridge is composed of upper and lower arch ribs, separation sections, dumbbell sections, and web members. Suspender is anchored in arch rib. In order to balance their horizontal thrust, tie bar is anchored in skewback of the upper and lower arch rib by batch. This system bears vertical loads, which is transferred by suspender. The dumbbell section and web member can coordinate the stress distribution of arch rib. The main arch rib separates into some parts in-plane, which makes the style of bridge unique, increases grandeur of the bridge and gives a person with strong space aesthetic feeling.

To the stacked tied arch bridge, a single arch rib can be considered to be composed of upper and lower two arch ribs. The setting location of lateral connection systems in the upper and lower two arch ribs and the structure of installation of transverse brace all can influence the whole out-plane buckling. Comparing with the most four intuitive styles of the transverse brace of a stacked tied arch bridge, the safety factor of stability and buckling model are analyzed with different setting positions and forms of the transverse brace under three kinds of load condition at the finished bridge state. The more obvious form of the transverse brace can be

Figure 1. Stacked tied arch bridges system (unit: cm).

obtained, which influences out-of-plane stability. The results have reference value to same bridge application.

## 2 ANALYSIS OF THE MODEL

### 2.1 Basic information

A bridge's preliminary scheme is that the stacked arch bridge structure system uses concrete filled steel tubular. The bridge is bi-directional four-lane design. Its main span is 12 m + 86 m + 12 m and deck width is 20 m. According to comprehensive analysis of mechanics and styles of the arch rib, choosing upper arch rib's rise-span ratio is 1/5 and lower rise-span ratio is 1/4.15. Both upper and lower arch ribs use concrete filled circular steel tubular and the thickness of steel pipe wall is  $t = 10$  mm, diameter  $\Phi = 900$  mm. The cross-section of main arch's dome roof is dumbbell-shaped (Fig. 2). Away from the vault at 12.3 m, upper and lower ribs are separated by dumbbell-shaped and intermediate connecting rods and vertical diagonals which are made up of steel pipe, with thickness of 10 mm, diameter 500 mm.

Figure 2. Section of the main arch vault (unit: cm).

Figure 3. Section of prestressed concrete beam (unit: cm).

Tie bar is rigid and longitudinal beam is prestressed concrete box girder (Fig. 3). Middle cross beam uses prestressed concrete T-shape beam. To facilitate anchoring steel strands of suspender and cross-beam, middle cross beam needs to be thickened to 50 cm at the intersection of the middle cross beam and longitudinal beam. The spaces of middle cross beam and suspender are 6 m. Close to the lower arch foot, the distance between middle cross beam and the arch foot end beam is 10 m. Installation of transverse brace uses steel pipe is 10 mm thick with a diameter of 600 mm.

## 2.2 Finite element model

ANSYS8.1 is used to analyze the model. Arch rib uses BEAM4. Composite sectional characteristic is used for calculating sectional characteristic, and

conversion elastic modulus is put to use. Longitudinal beam and crossbeam employ BEAM4. The prestressed of longitudinal beam should be taken into account when it shares nodes with LINK10. Suspender uses LINK10 and initial tension should be taken into consideration. Tie bar and installation of transverse brace use BEAM4 as well. Supporting way is a continuous beam support method. Upper arch foot is a movable support, and one side of lower arch foot is a fixed support, the other side is movable support. Simulation of dumbbell-shaped section is realized through coupling the corresponding node-freedom degree of the upper and lower arch rib at the dumbbell section.

## 2.3 Loading conditions

According to lane loading calculation, the live load and dead load must be considered at the finished bridge state. Considering that the lower arch rib needs to bear large axial force and the lower rise-span ratio is larger, the axial force influence-line loading calculation was carried out on arch rib and arch foot. The lane load is highways-I-level. Uniform load is 10.5 KN/m and concentrated force is 432 KN (taken shear force calculation value).

Loading condition can be classified into 3 kinds:

1. Only taken the dead load into account (concluding structure weight, the prestressed of tie beam, suspender initial tension).
2. The dead load, crowd load, wind force, and transverse live load, which loads by influence-line of four-lane (considering transverse reduction). Loads are combined by ultimate limit states.
3. The dead load, crowd load, wind force, and transverse live load, which loads by influence-line of two-lane (considering transverse reduction). Loads are combined by ultimate limit states.

## 2.4 Analysis patterns

Comparative analysis is carried out through the following four modes for different settings of installation of transverse brace.

- a. Both upper and lower arch ribs set 5 transverse braces, which are located on the lower arch rib. The corresponding setting positions are 1/6, 1/3, 1/2, 2/3, 5/6 span of the lower arch rib. Installation of transverse braces at mid-span are “\*” shapes, set on the webs of the dumbbell section. Other transverse braces are “K” shapes (Fig. 4).
- b. On the basis of “a” model, the transverse brace located in the lower arch rib is removed, and the transverse brace of upper arch ribs and mid-span is unchanged.
- c. On the basis of “a” model, the transverse brace located in the lower arch rib is removed, and the

Figure 4. Finite element model for stability analysis.

transverse brace of lower arch ribs and mid-span is unchanged.

- d. Change the “\*” shape to the “I” shape on the basis of “c” model.

In 4 kinds of cases: “a” reflects that setting transverse braces of upper and lower arch ribs have an impact on the overall out-plane buckling; “b” and “c”, respectively, reflect that setting transverse braces of upper and lower arch ribs have an influence on the overall out-plane instability; “d” reflects that the forms of transverse braces at mid-span influence the overall out-plane instability.

### 3 BUCKLING ANALYSIS

#### 3.1 Linear buckling analysis theory

According to the theory of linear buckling, the structure buckling load can come down to solve equation (1)’s eigenvalue under the action of the external load  $F$ :

$$(K + \lambda S)\delta = 0 \quad (1)$$

In which:  $K$  is the structural stiffness matrix;  $S$  is the initial stress stiffness matrix;  $\lambda$  is characteristic values;  $\delta$  is buckling mode.

If the equation (1) is  $n^{\text{th}}$ -order linear differential equation, Then theoretically exist  $n$  eigenvalues— $\lambda_1, \lambda_2 \dots \lambda_r$ . But for the engineering issues discussed, only the smallest eigenvalue is also the minimum safety factor has actual significance.

Assuming the critical eigenvalues is  $\lambda_{cr}$  and critical load is  $\lambda_{cr}$ . If the equation (1) is the spatial model, then the eigenvalues and modes include the in-plane and out-plane buckling.

#### 3.2 Buckling analysis

Critical eigenvalues of the analysis modes and the corresponding instability modes are shown in Table 1 and Figure 5.

Table 1. Stability analysis of mode  $\lambda_{cr}$ .

Mode	Load pattern		
	I	II	III
a	12.50	8.86	9.23
b	9.62	7.09	7.35
c	11.66	8.25	8.60
d	7.84	5.63	5.88

Figure 5. The main each sidewise buckling mode.

As can be seen in Table 1 and Figure 5, the first-order of structural instability is due to plane instability under the load of conditions and calculation modes, and also of the first-order sidewise instability safety factors and modals can be obtained from different transverse braces. But at the same installation of transverse brace setting mode, loading case only affects the safety factor and has nothing to do with the first-order instability mode. All in all, dead load cases the largest buckling safety factor, followed by a two-lane loading conditions, and the four-lane is minimum. So in this paper a four-lane loading is the most unfavorable way at the operating conditions. Operating conditions can meet standard buckling safety factor, which is greater than the safety factor of 4 to 6, except the d mode.

When the transverse braces of upper and lower rib are set, the overall lateral stiffness of structure is larger and the sidewise buckling safety factor is largest—dead load is 12.5, four-lane 8.86, two-lane 9.23. As the number of transverse braces decreased, the buckling safety factor of the second mode decreases compared to the first mode at the 3 kinds of loading condition. The first condition is reduced by 23%, and the second and the third cases are decreased by 20%. But the instability mode and the first mode are basically the same.

For another reduction of transverse braces, when only the lower arch ribs set transverse braces (third mode), the sidewise instability safety factor is larger than the transverse braces that are set on the upper arch ribs (second mode) under each loading condition. The first condition is reduced by 21.2%. The second condition is decreased by 16%, and the

third case is decreased by 20%. Under this mode, the structural instability mode is anti-symmetric.

In the fourth mode, when the “\*” shape transverse brace is changed into “I” shape, the sidewise instability safety factors are reduced. The first condition is reduced by 33%, and the second and the third cases are decreased by 32%. But the instability mode is the same as the “\*” shape.

In view of the above analysis, the overall stability of structure is most outstanding that is influenced by the lateral stability of lower arch rib. Meanwhile, the power transverse connection system is also important to sidewise instability at the mid-span. Therefore, they should be strengthening in design.

#### 4 CONCLUSIONS

Compared to the different transverse braces of stacked tied arch bridge in this paper, we can obtain the following conclusions.

1. Different forms of transverse brace have a certain gap to the out-plane sidewise safety factor, also to the sidewise buckling mode. Setting a number of transverse braces on the upper and lower arch ribs can get the maximum safety factor, and four-lane loading is the most unfavorable instability condition.
2. Under the circumstances of setting transverse braces on the upper or lower arch ribs, the sidewise buckling safety factor is more larger when the transverse brace is only set on the lower arch rib. In this paper, when the transverse brace is set on the lower arch rib, the safety factor can be increased by 1.2 times as compared with setting on the upper arch rib.
3. Setting a number of rigid transverse braces at the mid-span have a prominent influence on sidewise safety factor, and the safety factor is increased by about 1.5 time when the “\*” shape is set at the mid-span compared to the “I” shape.
4. Setting location of transverse brace has an impact on first-order lateral instability mode. When setting transverse braces on upper arch ribs, the out-plane first-order structural instability mode is symmetric, but on the lower arch ribs is anti-symmetric.

Setting transverse braces on upper and lower arch ribs can get the maximum safety factor, but third form is the best. Not only can we obtain the safety factor which is closer to the first condition, but also it is the most economical one.

# Experimental study on mechanical properties of stabilized clay soils used in hydraulic engineering

Jie Chen, Jie Leng, Yongjing Mao, Yubao Yang & Yuepeng Pan

College of Harbor, Coastal and Offshore Engineering, Hohai University, Nanjing, China

**ABSTRACT:** In order to produce stabilized clay soils, which can be applied into harbor and coastal engineering locally as a substitute for concrete, inorganic cementitious materials including cement, Ground Granulated Blastfurnace Slag (GGBS), gypsum, and lime were mixed by semi-dry finished form with same dosage of clay soil. Experimental results shows that the best mixing ratio for materials used in clay stabilization is 65% clay soil, 18% cement, 12% GGBS, 2.5% gypsum, and 2.5% lime. The compressive, tensile, and softening strength of this stabilized clay soil at 28 day is 25.6 MPa, 2.4 MPa, and 7 MPa, respectively, meeting the demand of hydraulic engineering and can be used in harbor and coastal engineering.

## 1 INTRODUCTION

Soil stabilization is a measure that solidifies the detrital soil grain into solid matter with certain strength level and the soil stabilized called stabilized soil<sup>[1]</sup>. For their relative stable physical and chemical property, cementitious materials such as cement, gypsum, lime, and GGBS is a kind of stabilizer. Tomohisa<sup>[2]</sup> has ever proposed that concrete powder, GGBS and volcanic ash can be used to strengthen soil with high water and organic contend; Zalihe<sup>[3]</sup> proved that gypsum and GGBS can effectively stabilized the organic swelling clay; Shirazl<sup>[4]</sup> pointed that the mixture of gypsum and GGBS is able to eliminate warping and cracking caused by concrete shrinkage; Wenzhong Song<sup>[5]</sup> proved that the mixture of cement, gypsum, and lime can excite the activity of GGBS and improve its initial setting time and strength; Shanghua Jia<sup>[6]</sup> researched the effect of the lime on the physical filling, hydration, coagulation, and ion exchange of cement, which increases the unconfined compressive strength of soil; Some other inorganic and organic materials are also taken into consideration concerning soil stabilization. Renjian Shao<sup>[7]</sup> has made some relevant research in this area and a good result is obtained. In conclusion, the most of the research productions mentioned has been applied into road engineering, and little of which is applied into harbor and waterway engineering.

In this paper, the stabilized clay soils used in hydraulic engineering to substitutes concrete of grade C20 was studied. The lowest cement content under this premise was determined first. Then substitutes cement with the mixture of gypsum, lime, and GGBS to research on the best optimal composition of the stabilizer.

## 2 EXPERIMENTAL MATERIALS AND METHODS

### 2.1 Experimental raw materials

The water content of clay soil sample used in this experiment is 25.2% and its PH value is 7.6. The physical and chemical properties of the soil are shown in Table 1.

As is shown in Table 1, SiO<sub>2</sub> is the main substance in soil sample, the percentage of which is 55.37%, followed by Al<sub>2</sub>O<sub>3</sub> (19.13%) and the proportion of other substances are all less than 10%. During these chemical substances, SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, CaO and Fe<sub>2</sub>O<sub>3</sub> play a decisive role in the physical and chemical properties of the soil.

Raw materials include Portland cement produced by Conch Corporation, GGBS with S95 standard produced by Meibao construction materials co, ordinary lime in bulk with 98% purity and gypsum with 98% purity.

Table 1. Chemical composition of clay soil sample.

Ingredients	Average value (%)
SiO <sub>2</sub>	55.37
Al <sub>2</sub> O <sub>3</sub>	19.13
Fe <sub>2</sub> O <sub>3</sub>	7.47
CaO	8.03
MgO	3.92
K <sub>2</sub> O	3.28
Na <sub>2</sub> O	0.81
TiO <sub>2</sub>	1.07
SO <sub>3</sub>	0.41

## 2.2 Experimental methods

Before experiment, the clay soil is grinded into powder after air drying and then be filtrated by sieve pit (1.8 mm). Then all materials are weighed precisely according to mix proportion, then, they are put into JJ-5 cement mortar mixer and mixed well. Third, the materials are pouring into 70.7 mm × 70.7 mm × 110 mm steel mold and made into specimens by vibration compression.

The concrete proposal is as follows: in first step, the mold is filled with materials and the pressure on the mold increased to 2 MPa with velocity of 400 NV/s, then the remainder is poured into mold and pressed again. At this step, the pressure rise to 10 MPa with velocity of 400 N/s and maintain in this level for 2 minutes, after that, the pressure keeps rising to 20 MPa with the same velocity and maintained in peak for two minutes. Two minutes later, the pressure is removed and the specimens are taken out with approximately 70 mm × 70 mm × 110 mm size.

After being cured for 28 days in standard conditions, specimens are put in universal testing machine to be test for the compressive strength, tensile strength and water stability followed by corresponding standard. The water stability is tested by detecting its softening strength.

## 3 OPTIMUM MIXTURE RATIO

### 3.1 The determination of optimum dosage of cementitious materials

Cement first acts as the only cementitious material to be mixed with clay soil sample and then the lowest dosage of cement is determined while the compressive strength and tensile strength of clay stabilized material is more than 20 MPa, and the softening strength is above 2.4 MPa. The result is shown in Table 2.

As is shown in Table 2, when the dosage of cement is larger than 35%, the strength of clay

Table 2. Influence of cement content on strength of clay soil stabilized after 28 days.

Number	1	2	3	4	5	6
Clay soil (%)	95	85	75	70	60	65
Cement (%)	5	15	25	30	35	40
Water (%)	15.5	15.5	15.5	15.5	15.5	15.5
Compressive strength (MPa)	/	8.1	14.3	18.7	23.3	26.7
Tensile strength (MPa)	/	1.1	1.52	1.87	2.36	2.5
Softening strength (MPa)	/	5.7	11.9	16.3	21.0	23.8

stabilized can be up to the standard. Every factor taken into consideration, the optimum proportion is 35% cementitious material and 65% clay soil.

### 3.2 The determination of optimum dosage of other materials

#### 3.2.1 The influence of cement and GGBS's mixing ratio on stabilized clay soil

In this group of experiment, content of lime and gypsum is unchanged (3% and 4% respectively). Changing the content of cement and GGBS, a curve of compressive strength, tensile strength and softening strength with different mixing ratio can be plotted, which is shown in Figure 1.

As is shown in Figure 1, with the increase of content of cement and the decrease of content of GGBS, the curve of strength rise first and decline later. When the content of cement is under 20%, the compressive strength fluctuates little and maintain in the level over 20 MPa. If too much cement is mixed with clay soil, the water-cement ratio will decline, which results in lower strength.

GGBS has pozzolanic effect and more active silica, alumina and higher ash activity than clay soil used in experiment. In alkaline environment, GGBS can generate C-S-H gel structure, which has strong cementing power. P.V. Sivapullaiah<sup>[8]</sup> pointed that adding some materials with pozzolanic effect can effectively enhance the unconfined compressive strength of stabilized soil. GGBS can also mediate the compressive and tensile strength to some degree.

However, too much or less GGBS can undermine the strength and GGBS with content of 8%~16% has the best effect on compressive and tensile strength. The softening strength showed in Figure 1 gradually grows over compressive strength, which means that the water stability of clay stabilized rises with the increase of GGBS's dosage.

Every factor taken into consideration, the optimum mixing ratio of cement and GGBS is 16:12.

Figure 1. The influence of cement and GGBS's mixing ratio on strength of stabilized soil.

### 3.2.2 The influence of gypsum and GGBS's mixing ratio on clay soil stabilized

In this experiment, content of cement and lime is unchanged (18% and 4% respectively). Changing the content of GGBS and gypsum, the change of compressive strength, tensile strength, and softening strength with different mixing ratio of gypsum and lime is showed in Figure 2.

Hydration structure of test sample is not compact and it has much interspace, as well as many unhydrated mineral powder particles. At the same time, because of the mixture of flue gas desulfurization gypsum which excites the activity of cement and GGBS, Aft is turned into AFm and the hydraulic degree deepens<sup>[9]</sup>.

With the existence of GGBS, Hydrated calcium aluminate can react with plaster and generate hydrated calcium aluminate. The main property of ettringite is expansibility and the existence of interspace allows the ettringite to expand after cement hydration, which enhance the strength.

As is shown in Figure 2, with the increase of gypsum's dosage and the decrease of GGBS, the compressive strength rises at first and declines later. If the quantity of gypsum is too small, calcium sulfoaluminate hydrates will be generated, on the contrary, if the quantity of which is too large, gypsum cannot be consumed and the strength can be undermined as well. As for the hydra stability, gypsum is not the main influence. Every factor taken into consideration, the optimum mixing ratio of gypsum and GGBS is 11:2.

### 3.2.3 The influence of gypsum and GGBS's mixing ratio on clay stabilized

In this experiment, content of cement and GGBS is unchanged (18% and 12% respectively). Changing the content of gypsum and lime, the change of compressive strength, tensile strength, and softening strength with different mixing ratio can be plotted, which is shown in Figure 3.

As it is mentioned before, SiO<sub>2</sub> is the main ingredient which takes percentage of 55.37%,

Figure 2. The influence of GGBS and gypsum mixing ratio on strength of stabilized soil.

Figure 3. The influence of gypsum and lime mixing ratio on strength of stabilized soil.

followed by Al<sub>2</sub>O<sub>3</sub> (19.13%). SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub> are likely to react with alkaline substance and can generate Ca(OH)<sub>2</sub> after the addition of lime, which can hydrolysis and released Ca<sup>2+</sup> that will later exchange with K<sup>+</sup>, Na<sup>+</sup> and H<sup>+</sup> and thin the capillary film. This phenomenon can contribute to the decrease of soil's dispersibility and viscoplasticity. Because of this, the strength and stability of soil particle can be enhanced. Also Ca(OH)<sub>2</sub> can react with active silica and alumina, which can generate hydrated calcium silicate gel and hydrated calcium aluminate gel. The two products reduce the interspace among particles and the water permeability, as well as improving the compactness and increase the velocity and degree of reaction of ash.

As is shown in Figure 3, with the increase of content of lime, the strength of clay stabilized decreased and reasons can be divided into two main aspects. First, with more lime is added into clay soil, the more carbonization reaction mainly occurs on the surface of specimens, the compact carbon film generated prevents CO<sub>2</sub> and O<sub>2</sub> from entering inside and the harden process slows; Second, the lime slaking consumes huge quantity of water, which contributes interspace after the evaporation of water and the strength is undermined. Though more lime is harmful to strength, when the percentage of lime and gypsum is 3% and 4% respectively, the strength of clay stabilized can still go up to 20 MPa. In construction, appropriate amount of lime can improve the post-strength of concrete and can operate under more stress. As is shown in Figure 3, the dosage of lime is beneficial to clay soil's hydra stability. Every factor taken into consideration, the optimum cementitious materials mixing ratio is 3% lime, 4% gypsum.

As a conclusion, the optimum proportion of cement and GGBS is 16:12, which of GGBS and gypsum is 11:2. Optimal content of gypsum and lime is 4:3. Overall, the proportion of four ingredients (cement, GGBS, gypsum and lime) is 52%, 34%, 6.9%, and 1%, respectively. Considering economy, the proportion can be adjusted into 52%,

Table 3. Law of development of various properties of clay stabilized.

Curing days	7 d	28 d	90 d
Compression strength (MPa)	10.1	25.6	28.1
Tensile strength (MPa)	1.0	2.4	2.7
Softening strength (MPa)	9.5	7	3.2
Dry-shrinkage ratio (%)	0.01	0.008	0.002
Volume density (%)	2.15	2.14	2.13
Water absorption (%)	9.1	7	3.2

34%, 7%, and 7%, respectively. Since the percentage of clay soil is 65%, the optimum mixing ratio of cementitious materials is cement (18%), GGBS (12%), gypsum (2.5%), and lime (2.5%).

#### 4 PERFORMANCE TEST FOR CLAY STABILIZER IN OPTIMUM CEMENTITIOUS MATERIALS MIXING RATIO

The physical and mechanical properties of the stabilized material with the optimal proportion obtained from above experiment were tested in this section. Produced follow the optimum mixing ratio and cured 7, 28 and 56 days, respectively, the properties of specimens such as compressed, tensile, and softening strength, dry-shrinkage ratio, volume density and water absorption were tested at 7, 28, and 56 days, respectively. The result is shown in [Table 3](#).

As is shown in [Table 3](#), compressive, tensile strength of clay stabilized can achieve standard of 20 MPa at 28 days. The strength of the material is qualified, as well as the growth of later strength. Also the later softening strength of clay stabilized is good, which means high hydra stability and adaptation to the construction of hydraulic engineering. [Table 3](#) also demonstrates that the dry-shrinkage ratio and water absorption of clay stabilized declines gradually, while the volume density is almost unchanged, which contributes to the stability of property.

#### 5 CONCLUSION

1. It is feasible to use waste clay to produce specimens by stabilization. The production made in this way has enough compressive, tensile, and softening strength, as well as good

water stability. It can substitute concrete to be applied to hydraulic engineering.

2. Among cementitious materials used in clay stabilization, with the increase of cement's content, the strength of stabilized clay grows while the utilization of clay soil declines and the optimum dosage of cement is 18%. Right amount of gypsum is helpful to generate ettringite to enhance the strength and the best dosage of gypsum is 2%. Lime is involved in the chemical reaction of generating high-early-strength calcium aluminate, which is beneficial to strength and the optimum dosage of lime is 6%. The dosage of GGBS can reduce the content of cement and the best dosage of GGBS is 12%.
3. When the content of waste clay soil is 60% and the dosage of cement, GGBS, gypsum, and lime is 18%, 12%, 4%, and 6%, respectively, the softening strength after 28 days of stabilized clay soil is over 22 MPa and the tensile strength of which is 2.4 MPa, meeting the standard of materials used in hydraulic engineering.

# Experimental study on the interior joints of the unsymmetrical hybrid connection

P.X. Liang

Nanjing Institute of Technology, Nanjing, China

H. Zhang & M.G. Sun

JinKen College of Technology, Nanjing, China

**ABSTRACT:** Unsymmetrical hybrid connection consists of precast members, unbonded post-tensioned tendons, and mild steel bars that are only placed on the upside of the beam section. The mild steel bars are set partly unbonded near the interface to prevent from the bars. The experiment for three interior joints under low reversed cyclic loading is introduced. Results of experiment show that the unsymmetrical hybrid connection has good performance of seismic resisting.

**Keywords:** unsymmetrical hybrid connection; energy-dissipation component; interior joints; performance of seismic resisting

## 1 INTRODUCTION

Unsymmetrical hybrid frame (Fig. 1) evolves from the hybrid frame (Stanton, 1997) which consists of precast members, post-tensioned prestressed tendon, and bonded mild steel bars. For simplifying the construction and increasing the speed of assembly in place, there are no mild steel bars as energy-dissipation component on the bottom of the beam in unsymmetrical hybrid connection. According to the suggestion of PRESS (Jubum, 2005), prestressed tendon should be designed to be unbonded near the interface. There are two mechanisms in unsymmetrical hybrid connection. First, the post-tensioned prestressed tendons keep elastic all along and restore the frame to its original configuration and maintain continuity between beam and column after the earthquake. In other words, the post-tensioned tendon is used to clamp the beam against

the column, providing the shear resistance through friction developed at the beam–column interface. Second, mild steel bars dissipate energy by yielding in tension and compression. Because the function of the mild steel bars is to dissipate energy, the energy-dissipation capability of unsymmetrical hybrid connection is weaker than the hybrid connection.

## 2 EXPERIMENT DESIGN

### 2.1 Design of experiment members

Three full size interior joints (Fig. 2) are fabricated for the experiment. Several design parameters list in Table 1. The intensity of concrete's is  $f_{cu} = 43.9$  MPa, and the high strength grout is  $f_{cu} = 37.7$  MPa (in 7 d). The low looseness steel strand with the intensity of 1860 MPa is used as prestressed tendon. The mild steel bars are grouted in holes. After the high strength grout is daubed on the surface of the interface of the members, the beam, and column are integrated by prestressing the sand. Then the mild steel bars are put on the top of the beam and grouted. High strength grout is also used to fill up the beam and maintained to the designed intensity. The mild steel bars are set partly unbonded, near the interface by daubing butter and wrapping with plastic paper.

### 2.2 Experiment loading

The axial load of the column is applied to the value ( $\mu = 0.25$ ), then the jacks are used to apply positive

Figure 1. Unsymmetrical hybrid frame.

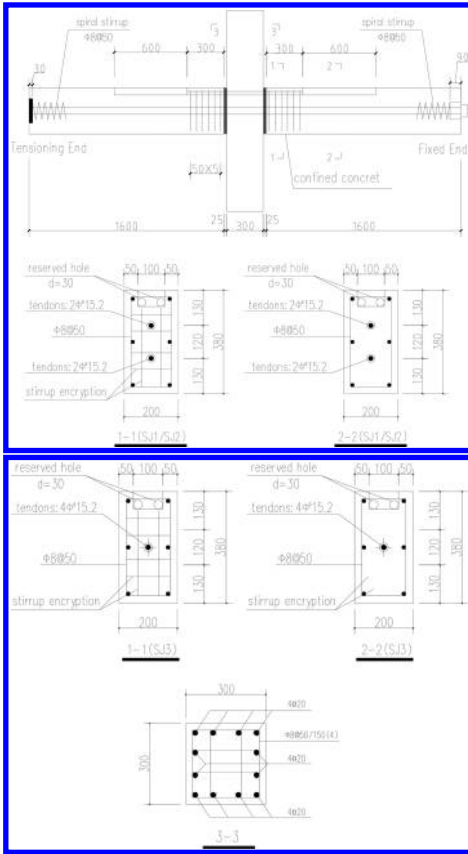

Figure 2. Design of experiment members.

Table 1. Main design parameters of experiment members.

Joint number	Beam stress (MPa)	Mild steel bars	Unbonded length of mild steel (mm)
SJ-1	2.88	2C20	200
SJ-2	2.98	2C20	250
SJ-3	2.98	2C20	200

and negative loads at the end of the beam. The displacement control method of reverse cyclic loading is applied in the experiment. The load-controlling method is applied before the beam section of the interface yield, and after the section yielding the displacement-controlling method is applied. The data collection system that can measure and auto-record consists of a sensor, a data-collection apparatus, and a computer. The positive loading refers to loading down and the negative loading refers to loading upon.

### 3 RESULTS AND ANALYSIS OF EXPERIMENT

#### 3.1 Joint behavior of damage

Under the reverse cyclic loading, the whole process of the experiment can divide into four stages: elastic, cracking, yielding, and damage. The damage modes of the joints all belong to beam plastic-hinge mode, and damage concentrates near the beam-column interface; however, beam and column remain elastic with few cracks (Fig. 3). Crossing inclined cracks

Figure 3. The load-displacement cycling curves of the experiment joints.

Table 2. Main experiment data.

Joints number	Cracking load $P_c$ (kN)	Yielding load $P_y$ (kN)	Yielding displacement $\Delta_y$ (mm)	Peak load $P_u$ (kN)	Ultimate displacement $\Delta_u$ (mm)
SJ-1	-22.4/29.97	-22.05/29.3	10.0/-10.0	-32.2/77.59	60/-60
SJ-2	-31.39/42.38	-71/59	16.0/-16.0	-92.91/61.41	78/-78
SJ-3	-32.77/39.12	41.4/-52.9	14.0/-14.0	-71.72/49.68	60/-60

occur at the end of the loading and close when unloading in the joint core of SJ-1, SJ-2, and SJ-3. The cover concrete shells off, and the length  $h$  is 180 mm ~ 200 mm, which is about 1/2 of the beam height. A gap opens at the bottom or top of the interface under loading and closes when interface under loading and closes when unloading, and the residual deformation is small. The main experiment data list is given in Table 2 (“+” and “-” refers to positive loading and negative loading, respectively).

### 3.2 Cycling curves

Figure 4 is the load-displacement ( $P-\Delta$ ) cycling curves. There are several common features: All the curves show the “s” shape and the prestressing effect is very clear. The curves are unsymmetrical and show plumper under positive loading. Before the crack occurs, the area of cycling loop is small its shape is near straight line, and the residual deformation is small. From the crack occurring to the connection yielding, the shape of cycling loop begins to show curvilinear, the area of cycling loop gradually increases. The shape of the cycling curves shows from “S” to arched under positive loading, and displays some features of the joint cast-in-place. When unloading, the curves look sharp, and the joints have strong ability of restoring to its original configuration, and show distinctly the features of prestressed concrete joint.

The difference of the cycling curves can be concluded as: (1) After the SJ-1 yielding, the strength of the main cycling loop kept increasing, while the displacement of the beam increasing. When the displacement arrived at 60 mm of the second cycle, the strength dropped to 85% of the peak load value and the joint damaged. (2) SJ-2’s storey drift arrived at 0.034. When the displacement arrived at 78 mm of the second cycle, the strength dropped to 85% of the peak load value and SJ-2 damaged. (3) SJ-3’s storey drift arrived at 0.0144, its deformation ability is weaker than SJ-2’s. Its skeleton curve shows clearly declining shape. After SJ-3 yielding, the area of cycling loop gradually increased, however, because of the different ways of tension in the SJ-3, the area cycling loop of SJ-3 is less than the area of SJ-1 or SJ-2.

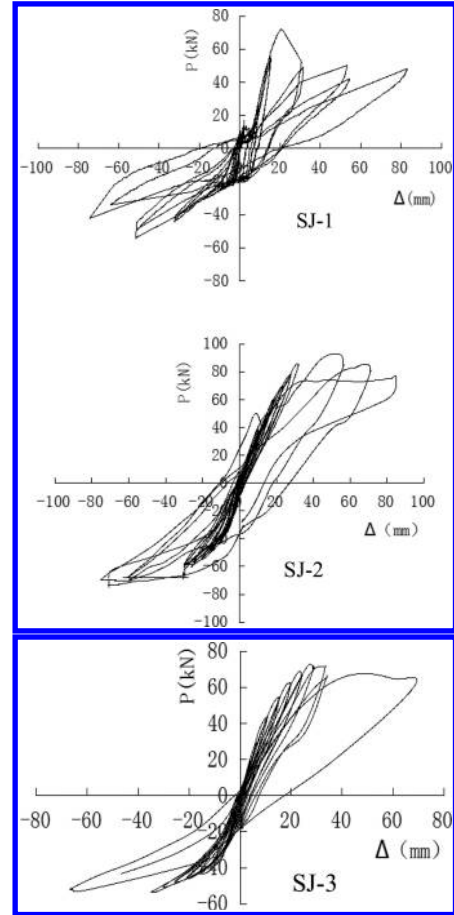

Figure 4. The load-displacement cycling curves of the experiment joints.

### 3.3 Displacement ductility

Table 3 is the displacement ductility coefficient of SJ-1 ~ SJ-3. The displacement ductility coefficients of the joints are between 4.29 ~ 6.0, which is near the coefficient of reinforced concrete structure. Axial forces in the beam reduce the ductility of the joint. The relation of displacement ductility

Table 3. Ductility coefficient of displacement.

Joints number	Yielding displacement $\Delta_y$ (mm)	Ultimate displacement $\Delta_u$ (mm)	Displacement ductility coefficient $\mu_\Delta$
SJ-1	10.0	60.0	6.0
SJ-2	16.0	78.0	4.88
SJ-3	14.0	60.0	4.29

Table 4. Equivalent viscous damping.

Joints number	SJ-1	SJ-2	SJ-3
$h_e$	6%	5.8%	7.6%

is:  $SJ-1 > SJ-2$ . So, the longer the unbonded length is the lower displacement ductility the joint has.

### 3.4 Energy-dissipation ability

Equivalent viscous damping (Zhenzheng Fang, 2005) ( $h_e$ ) is used to express the energy dissipation ability of the joint. Table 4 shows the equivalent viscous damping of the joints in different stage. Table 4 shows that: (1) As equivalent viscous damping gradually increased, and the energy dissipation of the connection also increased. The equivalent viscous damping of SJ1 and SJ2 is approximate. (2) The equivalent viscous damping of SJ-3 is largest, which shows SJ-3 has the strongest energy dissipation ability. The prestressing degree of SJ-1 is higher than that of SJ-2, so the SJ-2's ductility is weaker.

## 4 SUMMARY

Through the experiment for three unbonded post-tensioned unsymmetrical hybrid joints under

reverse cyclic loading, some features of the connection are acquired. The main contents are as follows:

1. The damage modes of the joints belong to beam plastic-hinge mode. Damage concentrates near the beam-column interface, however, beam and column remain elastic with few cracks; There is no slip between the interfaces, which proved that the shearing forces of the beam being carried by the friction is available.
2. The unbonded length of mild steel affects the connection, the shorter the unbonded length of mild steel is, the lower ductility the joint has.
3. The cycling curves are unsymmetrical and show plumper under positive loading because of the unsymmetrical mild steel bars. The energy dissipation ability under positive loading is stronger than under negative loading.
4. As the displacement increased, equivalent viscous damping gradually increased, and the energy dissipation of the connection also increased. The equivalent viscous damping of unsymmetrical connection is about 6% ~ 8%.

This work was supported by the General Project of Natural Science Foundation research of College and University in Jiangsu Province of China (Found Number: 12KJB560001), also by the Cyanine Project in Jiangsu Province of China in 2014.

# Application and numerical simulation of polyurethane insulation board in concrete lining canal

Yingzi Yin & Dong Zhang

The School of Architecture and Civil Engineering, Inner Mongolia University of Science and Technology, Baotou, China

**ABSTRACT:** At present, polyurethane board has been widely used as insulation material in lining canal. Yet, it is hard to scientifically define the thickness of polyurethane board in different positions of a canal. Based on the site test research of polyurethane board in the south main canal in Linhe Area of Inner Mongolia, we utilize the ANSYS to analyze the influence of various insulation board thicknesses on canal's temperature and displacement field, and obtain frost heaving values at different positions of the canal. The calculated value is consistent with measured data, which provides technical support for the thickness of polyurethane board in the lining canal construction.

**Keywords:** polyurethane; canal; application; numerical simulation

## 1 INTRODUCTION

The north canals located in the seasonal frozen soil area are very easy to frost heave due to the long frozen period every winter. The temperature rises and thaws the soil out after the freeze. The concrete channel rigid lining is very easy to damage under these kinds of repeated freeze-thaw cycles. In recent years, the integrity of the concrete lining canal is improved through adopting some antifreeze bilge and heat preservation measures. With the development of the geotechnical material science, there has been a lot of heat preservation materials used in channel lining. The thermal insulation material proposed in this paper is being heavily promoted in the current canals-polyurethane insulation board. This material has a small coefficient of thermal conductivity, light weight, ageing resistance, convenient transportation, and construction. Due to different areas such as climate and soil conditions, the reasonable thickness of these kinds of polyurethane insulation board is still not calculated. Now just to do a field test, and then according to the monitoring results determine the reasonable thickness of the insulation board in the regional channels.

### 1.1 Project overview

The South Main Canal is located in Shuanghe town, Linhe district of Inner Mongolia. It is east-west and has a high underground water level. The channel soil with strong frost heave belongs to seasonal frozen soil. The cross section of the South Main Canal in Linhe is trapezoidal. A thickness of

6 cm precast concrete panel lining is used to prevent water seepage. The channel cross section and the frost heaven measured data are respectively shown in Figure 1 and Table 1.

According to the demand for lining channel insulation board of national standard *the Canal Seepage Control Engineering Technical Specifications (SL 18-2006)*, the test using polyurethane insulation board density is about 45 Kg/m<sup>3</sup>.

Figure 1. The cross section of the South Main Canal.

The mechanical properties of polyurethane insulation board are shown in Table 2.

## 2 FINITE ELEMENT ANALYSIS

### 2.1 Finite element model

Through the comprehensive analysis of the south main canal soil, climate and the trapezoidal channel mechanism of frost heave in the Inner Mongolia Linhe district, canal bed is heavy silty loam soil. Finite element model is shown in Figure 2. Take 1.0 m along the vertical direction of the slope, take 4.6 m along the length direction of the slope, and establish a two-dimensional plane model.

In the calculation of temperature field, the temperature boundary conditions imposed by the data in Table 3, left and right boundary are thermal insulation.

In the calculation of stress field, the constraint conditions for both sides of the model vertical section are x constraints, the horizontal section of model bottom is y constraints, top boundary is free, the rest are x and y constraints.

### 2.2 Parameter selection

The calculation of temperature field only related to the coefficient of thermal conductivity, regard the linear expansion coefficient of the frozen soil as a negative value at the thermal coupling calculation. Freezing temperature is close to 0°C and 0°C which is adopted as a benchmark. Due to the limited measured parameters, regardless of the difference of the vertical and horizontal directions, take the  $\eta/T$  for the unified frost heaving coefficient, the  $\eta$  is the frost heave rate, refer to Table 1, T is temperature. Foundation soil modulus of elasticity and poisson's ratio are determined according to the reference [5]. Material mechanics parameters are shown in Tables 4 and 5.

## 3 THE COMPUTER SIMULATION RESULTS AND ANALYSIS

### 3.1 Temperature field analysis

It is can be seen in Figure 3, the zero temperature lines in temperature field rise significantly after

Figure 2. Finite element model.

Temperature (°C)	0	-1	-2	-3	-5
Elastic modulus (Pa)	11e6	19e6	26e6	33e6	46e6

laying the different thicknesses of polyurethane insulation board on the slopes. The thicker the plate is, the higher the zero line temperature rises. The polyurethane insulation board has heat preservation effect, abates the transmission of ground temperature, and raises the ground temperature obviously.

### 3.2 Displacement field analysis

It is can be seen in Figure 4, the maximal displacement of model 1 is 14.5 cm on the shady slope. The upper maximal displacements of model 2 and model 3 are respectively 2.9 cm and 3.7 cm, and the below maximal displacements of model 2 and model 3 are respectively 1.7 cm and 2.8 cm on the shady slope. The maximal displacement of model 1 is 6.7 cm on the sunny slope. The upper maximal displacements of model 2 and model 3 are respectively 1.7 cm and 2.9 cm, and the below maximal displacements of model 2 and model 3 are respectively 0.5 cm and 0.2 cm on the sunny slope. In theory, the thicker the insulation board is, the smaller the frost heaving

Table 5. Material mechanics parameters.

Item	Thermal conductivity (w/(m°C))	Elastic modulus (Pa)	Poisson's ratio	Thermal expansion Coefficient (1/°C)
Polyurethane	0.029	$2.1 \times 10^9$	0.4	$1.4 \times 10^{-4}$
Mortar	1.54	$2.0 \times 10^{10}$	0.2	$1.1 \times 10^{-5}$
Concrete	1.58	$2.4 \times 10^{10}$	0.167	$1.1 \times 10^{-5}$
Frozen soil	1.987		0.330	$\eta/T$
Unfrozen soil	1.320	$1.5 \times 10^7$	0.375	0

Figure 3. The temperature field distribution of various measures (unit: °C).

Figure 4. The normal displacement field distribution of various models (unit: °C).

amount is. But the frost heave is affected by the underground water level in practical channels. The below frost heaving amount on both slopes is greater than the upper because of the high underground water level and the rich soil water content. And the software simulation results only consider a single temperature, and don't take the moisture content into account. So the result of simulation is that the thicker the insulation board is, the smaller the frost heaving amount is. The numerical simulation results accord with basic monitoring data. The different thicknesses of the insulation board cut the different frost heaving amounts.

#### 4 CONCLUSIONS

1. The canal frost heave is influenced by adjacent foundation soil temperature field; therefore, we suggest laying polyurethane insulation board in certain ranges of canal top and bottom, so that the canal concrete rigid lining is protected perfectly.
2. At present the software simulation results only consider a single temperature field, and don't take the moisture content and soil property into account. Though the numerical simulation results accord with basically monitoring data, it

can be only approximately referenced for actual construction. The several factors are considered in the future frost heaving simulation.

3. Many simulation parameters can be selected only according to references due to the limited test condition. Sometimes those parameters do not reflect the real value of the region, so establishing a perfect material parameters database is proposed.
4. Many monitoring data is manual measuring due to the limited site conditions, this may lead to inaccurate measurements. So the test conditions should be improved and reducing artificial operation makes results more accurate.

**ABSTRACT:** The influences of cement content (ratio of cement weight to dry weight of soils) and confining pressure on the mechanical properties of cement-treated sandy soil are investigated by consolidated-undrained triaxial compression tests. Cement contents adopted in the tests are 0%, 2.5%, 5%, 7.5% and 10%. Confining pressures applied around specimens are as follows: unconfined, 30, 100 and 200 kPa. The test results show that the addition of cement or a high confining pressure can significantly improve the compression strength of the soil. It is observed from stress-strain behaviors that a transition of failure type from ductility to brittleness occurs with the increasing cement content, and the soil at higher confining pressure presents better ductility than at lower confining pressure with the same cement content. Furthermore, cement content and confining pressure both present perfect linear relationships with the compression strength of the soil. A linear expression of such linear relationship is obtained through the multiple regression analysis. The axial stiffness of the soil increases with increasing cement content and confining pressure, whereas the yield strain of the soil decreases with increasing confining pressure only for the cemented soil.

**Keywords:** sandy soil; compressive strength; cement content; confining pressure; triaxial compression test

### 1 INTRODUCTION

To achieve the purpose of saving the construction cost, instead of completely replacing the original local soils with high-quality materials, soil stabilization techniques have been adopted in practice to improve the mechanical properties of bad soils. Several kinds of additives such as cement, lime, fly ash, polymers and fibers have attracted much concern under various geology conditions. Comparing with other stabilization techniques, cement treatment has many beneficial effects on engineering behavior for a wide range of soils (Uddin et al. 1997, Lo & Wardani 2002, Lorenzo & Bergado 2004), such as rapid stabilization, constructing convenience and cost saving. So, the cement treatment technique based on the laboratory test

has attracted much attention in the last decades. Sariosseiri et al. (2009, 2011) investigated the influence of cement content addition on the soil in the State of Washington by using consolidated-undrained triaxial compression tests. The results showed a significant improvement in drying rates, workability, unconfined compressive strength and shear strength of the soil, and pointed out that the brittle type of failure may appear in high-cement content cases. Ajorloo et al. (2012) and Schnaid et al. (2001, 2003) quantified the effects of cementation on the stress-strain behavior, stiffness and shear strength of sand by using triaxial tests, and indicated that higher confining pressure or higher cement content, or both can apparently improve the stiffness and strength of the sand. The brittle behavior of the cemented sand appeared

at lower confining pressure and higher cement content. da Fonseca et al. (2009) studied the stabilization effects of cement content on Osorio sand and Botucatu residual sandstone. The results are in close agreement with the aforementioned conclusions. Moreover, a general formulation that was used to evaluate unconfined compression strength as a function of absolute volume of voids divided by absolute volume of cement was presented. Pantazopoulos et al. (2012) presented the influences of cement type and gradation on the stress-strain-strength behavior of sands. It concluded that microfine cement can improve the strength higher than ordinary cement.

Although the aforementioned research results show similar conclusions, for one soil type, targeted test investigation also have to be performed to quantify the influence of factors on its mechanical properties. The present study focuses on the mechanical properties of subgrade soil of the Beijing-Harbin railway. The influences of cement content and confining pressure on the stress-strain behavior and compression strength of the soil are investigated and quantified in this study.

## 2 MATERIALS AND TEST PROCEDURES

### 2.1 Materials

The soil used in this study was sampled from the roadbed of the Beijing-Harbin railway, in northern China. It was dried and screened using a sieve with a diameter of 2 mm, in accordance with the “Test Methods of Soils for Highway Engineering”. The grain size distribution curve of the soil is shown in Figure 1. According to the “Standard of Engineering Classification of Soil”, the soil is classified as poorly graded sandy soil. The physical properties of the soil are listed in Table 1. Portland cement type II-Tehran determined by ASTM C150-07, as

Figure 1. Grain size distribution curve of the sandy soil.

Table 1. Physical properties of the soil used in this study.

Property	Value
Specific gravity (G)	2.54
Constrained grain size (D60) (mm)	0.23
Effective grain size (D10) (mm)	0.085
Uniformity coefficient (Cu)	10.4
Curvature coefficient (Cc)	7.62
Maximum void ratio (emax)	0.65
Minimum void ratio (emin)	0.51
Optimum water content (%)	8.7

Table 2. Composition of the cement type II-Tehran (%).

CaO	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	MgO	Fe <sub>2</sub> O <sub>3</sub>	SO <sub>3</sub>	K <sub>2</sub> O
62.24	20.65	4.26	3.72	3.14	1.6	0.93

the additive, is adopted in this study, and the composition is listed in Table 2.

### 2.2 Test procedures

The specimens were prepared by remodeling the sample soils in cylindrical molds of diameter 50 mm and height 100 mm. The dry density of the specimens is 1.69 g/cm<sup>3</sup>, and the optimum water content is 9.5% on the basis of the average values obtained from standard Proctor compaction tests carried out on uncemented soils. The specimens were then stored in a curing chamber for 28 days before testing.

An automatic data acquisition triaxial compression test apparatus model GSZ302 was used to measure the stress-strain behavior data of the specimens. The uncemented specimens were consolidated for 2 hours at the corresponding confining pressure. Then, consolidated-undrained tests were undertaken to measure the stress-strain behavior of the specimens. The tests were performed in the strain control mode and the axial movement control at a velocity of 0.002 mm/min. Four cement content scenarios (0%, 2.5%, 5%, 7.5% and 10%) and five confining pressure scenarios (unconfined, 30, 100 and 200 kPa) were adopted, and the corresponding 20 specimens were prepared herein.

## 3 RESULTS AND DISCUSSION

### 3.1 Stress-strain behavior

Figure 2 shows the curves between the shear stress and shear strain of the specimens with different

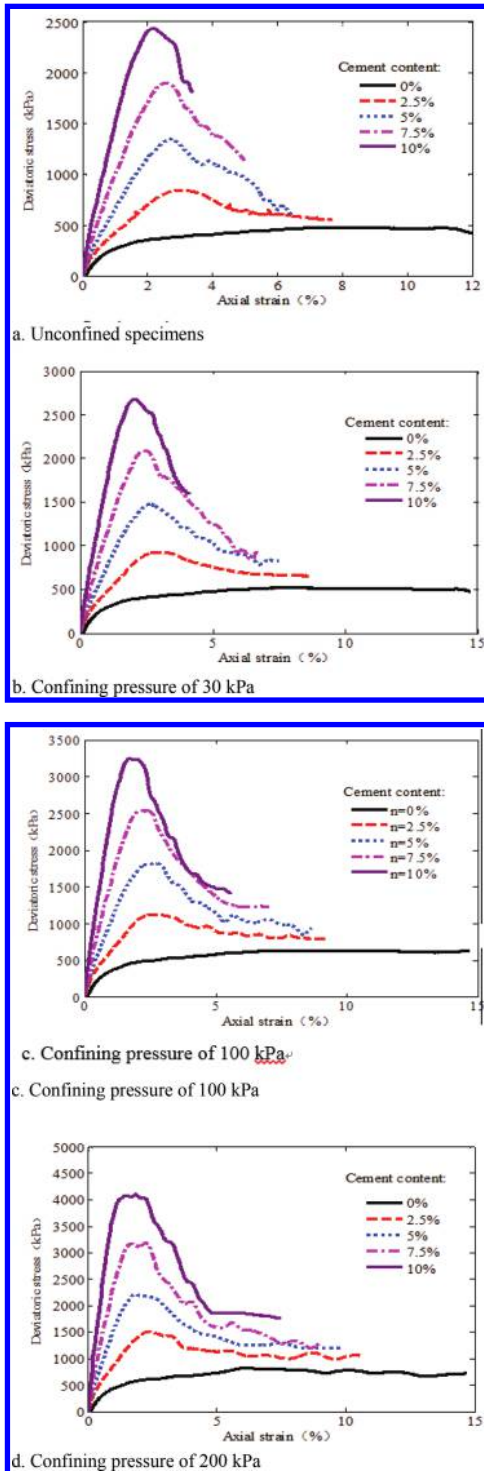

Figure 2. Deviatoric stress-axial strain behavior of uncemented and cemented sandy soils at confining pressures of 30, 100 and 200 kPa, after 28 days curing.

cement contents at the corresponding confining pressure after 28 days curing. It can be observed that the enhancement effect of cement addition is strongly dependent on cement content in this study. The stress-strain behaviors of all the cemented soils, compared with uncemented soils, are linear up to the peak point stress and then enter the plastic states until failure. Furthermore, the slopes of the stress-strain curves at a low strain area (below 0.025) increase with increasing cement content. As cement content increases, the deviatoric stress increases at the same strain. The peak point stresses do not achieve at the same strain; instead, the strain rates of the peak point stresses decreases with increasing cement content. On the other hand, comparing the peak stresses of specimens in Figure 2, as confining pressure increases, the peak stress of the specimen increases with the same cement content.

The failure types of specimens varied apparently with different cement contents. The specimens of uncemented, 2.5% and 10% cement content presented ductile, planar, and brittle type of failure, respectively, for unconfined scenarios (Figure 2a), whereas at a confining pressure of 200 kPa (Figure 2d), the specimens of uncemented and cement content of 2.5% exhibited the ductile type of failure and those of 10% cement content displayed the tendency to planar type of failure. This illustrates the transition of failure type from ductile to brittle that occurs with increasing cement content from uncemented to 10%, whereas with increasing confining pressure, the transition of failure type from brittleness to ductility occurs.

It should be noted that the compression strength of the specimen at a constant confining pressure increases with increasing cement content. A well-defined linear relationship between shear strength and cement content is obtained in the tests. Also, the relationships between compression strength and confining pressure of the specimens illustrate that compression strength appears to be linear to confining pressure. In order to quantify the influences of cement content and confining pressure on the compression strength of the soil, multiple regression analysis of compression strength as a linear function of cement content and confining pressure is performed, and the regression equation is obtained as follows:

$$S_{eq,p} = 2.52C_c + 4.86\sigma_3 + 125 \quad (1)$$

Where  $S_{eq,p}$  is the equivalent compression strength;  $C_c$  is the cement content and  $\sigma_3$  is the confining pressure.

The influence of cement content and confining pressure on the compressive strength and the corresponding regression plan is shown in Figure 3.

Figure 3. Variation of compressive strength of sandy soil with cement content and confining pressure.

It should be noted that the correlation coefficient of the regression is equal to 0.982, which illustrates that the relationship between compression strength and the two test parameters is highly linear dependent.

### 3.2 Secant modulus

Secant modulus is generally adopted to evaluate the stiffness of the soil through processing of the test data. In order to investigate the dependence of stiffness on cement content and confining pressure, secant moduli versus axial strain in logarithmic scale curves are plotted in Figure 4. It can be found that for all the scenarios, as the axial strain increases, the secant moduli almost keep at a constant value at a small strain area followed by gradual attenuations. It is easy to understand that the horizontal lines of the curves indicate the linear elastic stage of the soils, and the break points of curves define the yield secant moduli of the soils. It should be noted that the curves of cemented specimens (Fig. 4b) present a longer linear stage (below 1%) than those (below 0.1%) of uncemented specimens (Fig. 4a), which means that the addition of cement can significantly improve the linear elastic performance of the soil. On the other hand, as confining pressure increases, the secant modulus of either the uncemented or the cemented soil increases, which illustrates that under a higher confining pressure, the stiffness of the soils can be improved effectively. During the variation of confining pressure from 30 to 200 kPa, the secant modulus of uncemented specimens (Fig. 4a) at a linear elastic stage is enhanced by a ratio of 0.2–0.7, and the secant modulus of cemented specimens (Fig. 4b) with a cement content of 7.5% at a linear elastic stage is enhanced by a ratio of 0.25–1.8. It should be noted that the break points

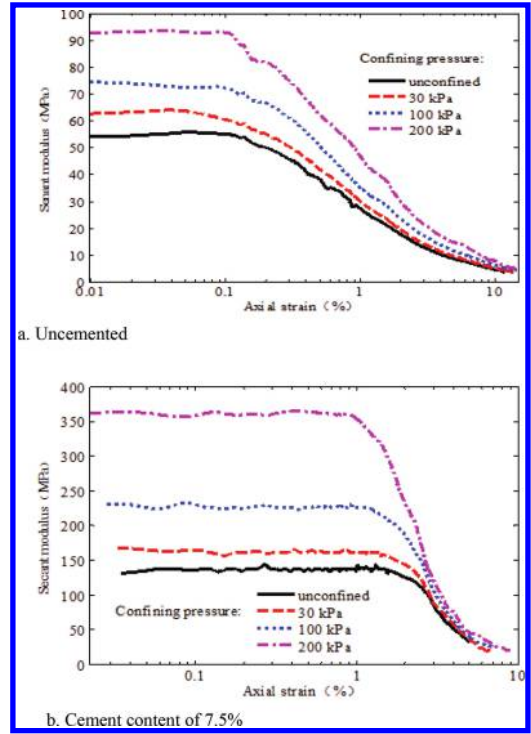

Figure 4. Secant modulus versus axial strain on the logarithmic scale for uncemented and cemented soils with a cement content of 7.5%.

in the curves of uncemented specimens at different confining pressures almost keep at a constant value of axial strain (0.1%), whereas for cemented specimens with a cement content of 7.5%, the axial strain at the break point decreases with increasing confining pressure. It means that the yield strain of the soil is not expected to improve dramatically with increasing confining pressure under the uncemented condition.

## 4 CONCLUSIONS

The present study aims at investigating the influences of cement content and confining pressure on the mechanical properties of cemented soils in the roadbed of the Beijing-Harbin railway. On the basis of the present results, the following conclusions can be drawn.

Addition of cement as the additive can significantly improve the strength of sandy soils. The compression strength increases with increasing cement content, whereas the failure type of soil varied from ductility to brittleness with increasing cement content from uncemented to 10%.

As confining pressure increases, the compression strength of the soil increases and a positive effect occurs on failure type: brittleness reduction or ductility improvement.

A linear relationship between compression strength and cement content, as well as the confining pressure, is observed and a linear equation of such linear relationship is obtained through the multiple regression analysis, by which the compressive strength of the soil can be easily evaluated.

Axial stiffness of the sandy soil increases with increasing cement content and confining pressure. The yield strain of the soil decreases with increasing confining pressure for the cemented soil, but not for the uncemented one.

# Influence factors analysis of settlement characteristic of CFG pile-net composite foundation during embankment construction

Hong Zhang, Jian-jia Wu & Xian-ming Huang

*Department of Civil Engineering and Architecture, Nanchang Institute of Technology, Nanchang, China*

Li-ping Zhang & Xiao-ming Yang

*Jiangxi Highway Development Corporation, Nanchang, China*

**ABSTRACT:** This paper took a deep soft foundation section in the project of CFG pile-net composite structure treatment of a highway in Jiangxi province as the research object. The influence of design parameters on the settlement of pile-net composite foundation during embankment construction was analyzed by using the finite difference software FLAC3D, including pile length, pile spacing, cushioning layer thickness and geogrid layers. The calculation results are as follows: the influence of pile spacing on settlement of soft foundation is very significant, the settlement of subgrade surface increases by 71.86% with pile spacing varying from 3 d to 8 d; pile length affects obviously the settlement of soft foundation, the settlement of subgrade surface decreases by 38.30% with pile length varying from 15 m to 21 m; the influence degree of cushioning layer thickness and geogrid layers on the settlement of soft foundation is relatively smaller.

**Keywords:** expressway; pile-net composite foundation; embankment construction; settlement; numerical analysis

## 1 INTRODUCTION

Due to the advantages of small settlements, high stability, short duration and convenient construction, the pile-net composite foundation is widely used in construction, highway, railway and other engineering fields, and good economic benefits were obtained (Dai et al. 2010, Sun et al. 2013). While the working mechanism of pile-net composite foundation is very complicated, theoretical research is far behind the engineering practice, and there is no mature design calculation method today. As a result, a large number of scholars at home and abroad studied the pile-net composite foundation on engineering test, theory study, numerical simulation and other aspects, and obtained some achievements (Cao et al. 2006, Chen et al. 2004, Cai et al. 2010, Huang et al. 2013). Hewlett (1998) put forward the calculation formula of pile-soil load share ratio through the indoor model test. Rao et al. (2001) considered the specific situation of pile-net composite foundation, and then deduced the three point method to calculate the amount of post-construction settlement. Xue et al. (2014) carried on the finite element analysis of pile-net composite foundation in highway widening engineering, and the results indicated that pile-net composite foundation treatment technology solved

the problems of differential settlements caused by new and old subgrade. This paper took a deep soft soil foundation test section in the project of CFG pile-net composite structure treatment of the Jiu-jiang ring expressway A1 block in the city of Jiu-jiang in Jiangxi province as the research object. The finite difference software FLAC3D was carried to analyze the influence of pile length, pile spacing, cushioning layer thickness and geogrid layers on the deformation of pile-net composite foundation, and the design parameters were to be optimized.

## 2 ENGINEERING SITUATION

Jiu-jiang ring expressway whose route crosses the soft soil district of Poyang Lake is located in the city of Jiu-jiang, Jiangxi province. The depth of soft soil foundation is from 12 m to 20 m in the A1 block of the ring expressway. The reinforcement design scheme of the soft soil foundation test section makes use of the cement flyash gravel pile (CFG pile) and geogrid net to deal with it. The CFG pile average length is 20 m, pile diameter is 0.5 m and pile spacing is 2 m, strength grade of concrete is C15; cushioning layer takes gravel whose thickness is 0.5 m, and geogrid net laying on the cushioning layer is 1 layer.

### 3 CALCULATION MODEL AND PARAMETER SELECTION

This paper assumed that each soil layer distributed uniformly along the depth direction in the calculation model, the effect of mechanical load during construction period was not considered when the model was analyzed. The Mohr-Coulomb constitutive model was adopted by assuming that the soft soil foundation and gravel cushion were elastic-plastic material. The calculation depth of foundation adopted 40 m, it is divided into three layers, the first layer is plastic silty clay whose thickness is 4 m, the middle layer is soft plastic silty clay whose thickness is 16 m, the last layer is hard plastic silty clay whose thickness is 20 m. Horizontal calculation width of foundation model adopted 100 m, and the longitudinal length adopted 10 m. With the symmetry on the geometric model of soft road embankment, the 1/2 model was adopted to calculate and analyze. Geogrid and CFG pile adopted geogrid unit and pile unit which were from inside of FLAC3D. Calculation model is shown in Figure 1. Model calculation parameters of soft soil, embankment and gravel cushioning are shown in Table 1.

Figure 1. Calculation model of soft foundation.

Table 1. Physical-mechanical properties of foundation filling of every layer.

	Thickness/m	Bulk modulus (K/MPa)	Shear modulus (G/MPa)	Density ( $\rho$ /KN/m <sup>3</sup> )	Cohesion (c/KPa)	Angle of internal friction/ $^{\circ}$

### 4 CALCULATION RESULTS ANALYSIS

#### 4.1 The influence of different pile length on the subgrade deformation

In order to study the influence degree of different pile length on the subgrade deformation, this paper took the CFG pile-net composite foundation as the basic model (cushioning thickness is 0.5 m, geogrid layer is one layer, pile diameter is 0.5 m and pile spacing is 2.00 m). Three different CFG pile length were selected to carry on the numerical simulation: (1) the pile length is 21 m (2) the pile length is 15 m (3) the pile length is mixed 15 m with 20 m (the pile length adopt 15 m except shoulder of the road). After the construction load the calculation results are shown in Figure 2.

The Figure 2 shows that the settlement of subgrade surface decreases with the increase of pile length. The maximum settlement value of subgrade surface are respectively 20.60 cm, 12.71 cm and 12.96 cm under the situation of pile length are respectively 15 m, 21 m and 15 m mixed with 20 m. The maximum settlement value of subgrade surface reduces by 38.30% when the pile length varies from 15 m to 20 m, which indicates that the increase of pile length has a better control effect on subgrade settlement. Compared with the situation that pile length is 21 m, the settlement of subgrade surface is slightly larger under the condition of pile length mixing 15 m with 21 m, but mixed pile can greatly reduce the project cost.

#### 4.2 The influence of different pile spacing on the subgrade deformation

In order to study the influence degree of different pile spacing on the subgrade deformation, this paper took the CFG pile-net composite foundation as the basic model. Four different CFG pile spacing were selected to carry on the numerical simulation: (1) the pile spacing is 3d (2) the pile spacing is 4d (3) the pile spacing is 6d (4) the pile spacing is 8d (d is the pile diameter). After the construction load the calculation results are shown in Figure 3.

Figure 2. Accumulative settlement distribute curve of subgrade surface with different pile length.

Figure 4. Accumulative settlement distribute curve of subgrade surface with different cushioning layer thickness.

Figure 3. Accumulative settlement distribute curve of subgrade surface with different pile spacing.

The Figure 3 shows that the settlement of subgrade surface increases with the increase of pile spacing. The maximum settlement value of subgrade surface are respectively 12.51 cm, 12.71 cm, 17.13 cm and 21.50 cm under the situation of pile spacing are respectively 3d, 4d, 6d and 8d. The maximum settlement value of subgrade surface increases by 71.86% when the pile spacing varies from 3d to 8d, which indicates that the increase of pile spacing has a significant control effect on subgrade settlement.

#### 4.3 The influence of different cushioning layer thickness on subgrade deformation

In order to study the influence degree of different cushioning layer thickness on the subgrade deformation, this paper took the CFG pile-net

composite foundation as the basic model (geogrid layer is one layer, pile length is 21 m and pile spacing is 4d). Four different cushioning layer thickness were selected to carry on the numerical simulation: (1) no cushioning layer (2) cushioning layer thickness is 0.3 m (3) cushioning layer thickness is 0.4 m (4) cushioning layer thickness is 0.5 m. After the construction load the calculation results are shown in Figure 4.

The Figure 4 shows that the settlement of subgrade surface increases with the increase of cushioning layer thickness under the situation of different cushioning layer thickness. The maximum settlement value of subgrade surface are respectively 10.96 cm, 12.52 cm, 12.71 cm and 13.15 cm under the situation of cushioning layer thickness are respectively 0, 0.3 m, 0.4 m and 0.5 m. The maximum settlement value of subgrade surface increases by 19.98% when the cushioning layer thickness varies from 0 to 0.5 m, which indicates that the increase of cushioning layer thickness has a certain degree effect on subgrade settlement.

#### 4.4 The influence of different geogrid layers on subgrade deformation

In order to study the influence degree of different geogrid layers on the subgrade deformation, this paper took the CFG pile-net composite foundation as the basic model. Four different geogrid layers were selected to carry on the numerical simulation: (1) no geogrid (2) one layer geogrid (3) two layers geogrid (4) three layers geogrid. After the construction load the calculation results are shown in Figure 5.

The Figure 5 shows that the settlement distribution curves of subgrade surface are basically

Figure 5. Accumulative settlement distribute curve of subgrade surface with different geogrid layers.

same under the situation of different geogrid layers; Under the situation of no geogrid, the settlement of subgrade surface is slightly larger than the other situations. The maximum settlement value of subgrade surface are respectively 13.48 cm, 12.71 cm, 12.64 cm and 12.65 cm under the situation of geogrid layers are respectively 0, one, two and three, which indicates that influence degree of geogrid layers on the settlement of pile-net composite foundation is relatively smaller.

## 5 CONCLUSION

Based on the analysis on the settlement of soft foundation test section of the Jiu-jiang ring expressway reinforced by CFG pile-net composite structure, design parameters of the CFG pile-net composite foundation are optimized with considering the cost factors of construction. We can adopt the reinforcement program that the pile length is mixed 15 m with 21 m, pile spacing is 2.00 m, cushioning layer thickness is 0.4 m and geogrid layer is one layer.

# Construction analysis of cellular sheet piles in thick clay condition

Y.Z. Bai

China Harbor Engineering Company Ltd., Beijing, China

**ABSTRACT:** Cellular structures constructed of interlocking steel sheet piles are used in marine environments as cofferdams, bulkheads, mooring dolphins, and lock guide walls. During the construction process, great difficulty is occasionally met because interlock forces between sheet piles surge when sheet piles penetrate specific geological layer such as hard clay. This paper presents a new method to evaluate the impact of geological condition on cellular sheet pile construction. A new parameter based on CPT tests is applied to determine the difficulty of penetrating process of sheet piles. Total 26 cellular sheet piles are evaluated in according with this method. The results show that this method supplies a new idea for evaluation of cellular structure construction.

**Keywords:** cellular sheet pile; construction analysis; clay

## 1 INTRODUCTION

A sheet-pile cellular structure is constructed by arranging straight web sheet piles in a cylindrical shape. The structure may be used singly as a mooring structure in a harbor, or several may be interconnected to form a retaining structure or cofferdam. With the growing requirement for environment protection and construction efficiency, this new technology is more and more often applied in many Chinese projects as different as Guangzhou Xinscha Harbor, Sutong Bridge pile support. Based on its wide application, Great achievements have been made both in design and construction areas. On the design side, many researchers applied finite element analyses and instrumentation measurements to study cellular structure's safety against sliding, bearing failure, overturning, and tilting, as well as sheet pile interlock rupture<sup>[1][2]</sup>. On the construction side, powerful vibrating hammers have been invented and incorporated into the penetrating process of sheet pile to dense sand layer. But for penetrating hard clay, there is still great difficulty met in the vibrating process because of the sharp increase of interlock forces between sheet piles. How to evaluate the impact of geological condition on cellular sheet pile construction is a key task in front of researchers and engineers.

## 2 GEOLOGICAL CONDITION

Water depth in construction site is between 4 m to 12 m and 11~28 m marine deposit is underneath sea bed with levels on a range from -2.5 mPD

to -10 mPD. Under the marine deposit, alluvium is followed. Specific physical and strength parameters of soil layers are shown in Table 1.

Due to environmentally friendly requirement, non-dredging measures such as cellular sheet piles and stone column are taken to form the seawall and improve ground. With the driving of vibrating hammer, cellular sheet piles pass through 15~25 m marine deposit and penetrates into 10~18 m alluvium. Its low stiffness makes it difficult to combine each sheet pile into a cellular structure.

Table 1. Physical and strength parameters of soils.

Parameters	Soil types	Recommended values
Bulk density	Marine deposits	1.50 Mg/m <sup>3</sup>
	Alluvium	1.90 Mg/m <sup>3</sup>
	Decomposed rock	1.90 Mg/m <sup>3</sup>
Drained shear strength	Marine deposits	$C' = 4 \text{ kPa}, \Phi' = 24^\circ$
	Alluvium (Clay)	$C' = 7 \text{ kPa}, \Phi' = 26^\circ$
	Alluvium (Silt)	$C' = 3 \text{ kPa}, \Phi' = 30^\circ$
	Alluvium (Sand)	$C' = 0 \text{ kPa}, \Phi' = 35^\circ$
Undrained shear strength, $C_u$	Marine clay	$C_u = 1+1.1z$ , for depth $z$
	Alluvium clay	$C_u = 2+1.3z$ , for depth $z$
Soil stiffness	Alluvium	$E = 0.9z-1$ (MPa), reduced level $z$
Coefficient of consolidation, $C_v$	Marine deposits	0.67 m <sup>2</sup> /year
	Alluvium clay/alluvium silt	1.50 m <sup>2</sup> /year

Every disturbance of vibrating operation and geotechnical change will cause large deformation, thus resulting in great difficulty of driving cellular sheet pile.

### 3 THE IMPACT OF GEOLOGICAL CONDITION ON CELLULAR SHEET PILE CONSTRUCTION

The Site composed mainly of marine deposit, alluvial sand alluvial clay layers. In view of its relatively low strength, the Contractor encounters no difficulty so far when driving the sheet piles through the marine deposit layer. The Contractor however concerns the difficulty encountered during the process of driving sheet piles into the alluvial sand and alluvial clay layers. Table 2 compares the construction mechanism of driving sheet piles into alluvial sand and alluvial clay layers.

In view of the explanation provided in Table 2 and because of the fundamental difference in geological structure, the alluvial sand can be liquefied when the sheet piles are being driven down causing the frictional resistance between the sheet piles and the surrounding liquefied sand to be reduced, which in turn facilitates further penetration of the sheet piles. The occurrence of liquefaction in alluvial sand layers is the main reason as to why it is relatively easier for cellular structures, where the

subsoil has high proportion of sand, to achieve the toe levels as determined by the Engineer.

Unlike alluvial sand, there is in general no occurrence of liquefaction in alluvial clay layers. Hence, both the strong cohesion amongst the clay particles as well as the friction between the sheet piles and the surrounding clay particles resist the downward force exerted by the vibratory hammer and the self-weight of the sheet piles. During the vibrating and penetrating process of sheet pile, its deformation occurs and is transferred and accumulated by the interlock among sheet piles. This will cause immense difficulty to the installation of main cell which is composed of a series of sheet piles.

### 4 RESISTANCE TO DRIVING OF SHEET PILES IN ALLUVIAL CLAY

The resistance to driving of sheet piles in alluvial clay mainly comes from the friction between the sheet piles and the clay. According to de Ruiter and Beringen<sup>[3]</sup>, the unit frictional resistance can be determined by the following equation:

$$f_s = \alpha \times S_u \quad (1)$$

where,

$\alpha = 1$  (normally consolidated clay)

Table 2. Mechanism of driving sheet piles into alluvial sand and alluvial clay.

Geological stratum	Alluvial sand	Alluvial clay
Net cone resistance (qnet)	1~20 MPa	0.5~2.5 MPa
Characteristics	There is no cohesion between the soil particle sand the strength mainly comes from the interlocking and the frictional resistance developed between the soil particles in contact with each other. The denser the soil, the higher the net cone resistance.	There is strong cohesion between the soil particles and the strength mainly comes from this cohesive force. The stiffer the soil, the higher the net cone resistance.
Source of downward force	The force exerted by the vibrating hammer at the top of the sheet piles and the self-weight of the sheet piles.	
Resistance to downward force	Friction between the sheet piles and sand particles.	Friction between the sheet piles and clay particles.
Any liquefaction occurred during sheet pile driving?	The high frequency vibration during sheet pile driving causes the surrounding sand layers to liquefy. The liquefied sand particles suspend in the water, and thus, greatly reduce the coefficient of friction between the sand layers and the surface of the sheet piles.	The high-frequency vibration during sheet pile driving cannot cause the surrounding clay layers to liquefy, and thus, cannot reduce the coefficient of friction between the clay layers and the surface of the sheet piles.
Change of frictional resistance	Due to liquefaction, significant reduction in frictional resistance to the driving of sheet piles.	Because of no liquefaction, minimal reduction in frictional resistance to the driving of sheet piles.
Comparison of frictional resistance	After liquefaction, the frictional resistance of the alluvial sand layer to the driving of sheet piles is smaller than that before liquefaction, and is also much smaller than that of the alluvial clay layer to the driving of sheet piles.	

$\alpha = 0.5$  (over-consolidated clay)  
 $S_u =$  undrained shear strength.

Senneset (1982)<sup>[4]</sup> established the following equation to estimate the undrained shear strength of clay based on the net cone resistance obtained for cone penetration test:-

$$S_u = \frac{q_e}{N_{ke}} \quad (2)$$

where,  
 $N_{ke}$  is a constant in the range of  $9 \pm 3$ .  
 Here,  $N_{ke}$  can be adopted as 12.

Combining (1) and (2), the unit frictional resistance can be determined by the following equation:

$$f_s = \alpha \times \frac{q_e}{N_{ke}} \quad (3)$$

Hence, the total frictional resistance experienced by the sheet pile in alluvial clay can be determined by the following equation:-

$$F = f_s A = \alpha \times \frac{q_e}{N_{ke}} \times B \times H \quad (4)$$

where,  
 $B =$  width of the sheet pile,  
 $H =$  length of penetration of sheet pile into the alluvial clay layer.

As the width of the sheet pile is constant, the total frictional resistance experienced by the sheet pile is therefore determined by  $q_e \times H$ , or the product of the average net cone resistance of the alluvial clay and the length of penetration of the sheet pile.

Based on the average values summarized in Table 3, the product of the average net cone resistance of the alluvial clay and the length of penetration of the sheet pile for the as-installed cellular structures are graphically presented in Figure 1.

As demonstrated in Figure 1, when the product of the average net cone resistance of alluvial clay and the length of penetration of sheet pile reaches certain level, the process of downward force overcoming the total frictional resistance between the sheet pile and the alluvial clay will cause large deformation thus increasing the interlock force between sheet piles. Cellular structures cannot be driven any further down to achieve designed toe levels. The specific information is shown in Table 4 based on the experience gained so far from the as-installed cellular structures.

Table 3. Average thickness and strength of the layered alluvial sand and alluvial clay.

Cellular structure no.	Top level of alluvium (mPD)			Average top level of alluvium (mPD)	Toe level determined by the engineer (mPD)	Average embedment into alluvium (m)	Alluvial sand			Alluvial clay

**ABSTRACT:** Soil structural properties are the intrinsic factors which determine the dynamic characteristic of the soil. Firstly, on the basis of previous studies, this paper analyzes the substance of conventional soil dynamic structural parameters, namely, the dynamic structural property of soil in any state is the dynamic shear secant modulus of it. It is discovered that the description of the dynamic structure of soil by using dynamic shear secant modulus is quite different from the fact. Secondly, the paper suggests using the dynamic structural parameters based on the view of equivalent elastomer that is dynamic tangent modulus. Thirdly, the paper defines the soil dynamic structural residual degrees to reflect the three external effects on soil structure: disturbance, loading and humidification. Lastly, the paper gives the expression of dynamic structural residual degrees based on Hardin-Drnevich hyperbola model when external condition varies.

**Keywords:** dynamic structure; dynamic tangent modulus; dynamic structural residual degrees

## 1 INTRODUCTION

To study the dynamic characteristics of soil is one of the soil dynamics research tasks. From the structural point of view, the soil structural properties which show the physical condition of soil (Xie and Qi, 1999) are the intrinsic factors determining the mechanical properties of soil (Qi, 1999). The soil dynamic characteristics are the outward manifestation of the change or destruction of soil structural characteristics under the coupled action of dynamic load and other external forces. Therefore, it is necessary to research soil structural characteristics under the coupled action of dynamic load and other external forces (hereinafter referred to as soil dynamic structure) in order to further reveal the change laws of soil dynamic characteristics.

At present, there are three basic ways to study structural properties of soil (Xie and Qi, 1999): Firstly, the microstructure morphology methods; Secondly, solid mechanics methods; thirdly, soil mechanics methods. Among them, soil mechanics methods demonstrate great potentialities and developmental prospect. Since Xie ding-yi and Qi ji-lin mooted to determine soil structural quantitative parameters based on releasing soil structure potential the correlative research is in the ascendant. Structural research scholars firstly obtain a wealth of achievements under static conditions about soil

structural characteristics (Luo et al., 2004; Shao et al., 2004; Xia, 2005; Chen et al., 2007; Chen and Gao, 2006; Chen et al., 2006). Meanwhile, Luo Ya-sheng, et al. (Luo, 2003; Wang et al., 2010) extend this method to the field of soil dynamics and establish the soil dynamic structural parameters based on dynamic shear stress method. The structural parameters obtained from static mechanics through simple and clear experiment method and mechanism can reflect some effects on soil structure.

However, the determination of these parameters are dependent on one or more of the three external function—disturbance, loading and humidification. Therefore, to some certain questions, these parameters cannot well provide direct answers. Here are three questions: First, what are the change rules in the soil structure when the soil is immersed? Second, what are the change rules in the soil structure when the soil is only disturbed? Third, what are the change rules in the soil structure when the soil is both disturbed and immersed? Because the soil dynamic structural parameters are derived from static structure parameters, the above problems still exist in the soil dynamic structural parameter research.

In light of this, through analyzing the soil dynamic structural parameters based on the same dynamic shear stress method, the paper proposes soil dynamic structural parameters based

on equivalent elastomer views, and defines the dynamic structural residual degrees. The paper also gives the expression of dynamic structural residual degrees based on Hardin-Drnevich hyperbola model according to different external conditions.

## 2 THE SOIL DYNAMIC STRUCTURAL PARAMETERS BASED ON THE VIEW OF EQUIVALENT ELASTOMER

### 2.1 The essence of the traditional soil dynamic structure parameters

At present, many soil dynamic structural parameters under the dynamic loading conditions proposed by Xie Dingyi and Qi Jilin are gained from the generalizing of soil structural parameters under the static load conditions. The idea is to seek structural quantitative indicator by releasing structure potential. Soil dynamic structural parameters based on the same dynamic shear stress method are firstly proposed in Luo Ya-sehng's doctoral thesis titled *structural constitutive relation of unsaturated loess under static and dynamic complex stress conditions*. Its expression is:

$$m_{\gamma d} = \tau_{do}^2 / (\tau_{ds} \tau_{dr}) \quad (1)$$

where  $m_{\gamma d}$  is the soil dynamic structural quantitative parameter based on the dynamic shear stress;  $\tau_{do}$  is undisturbed soil dynamic shear stress at dynamic shear strain  $\gamma_d$ ;  $\tau_{ds}$  is undisturbed saturated soil dynamic shear stress at dynamic shear strain  $\gamma_d$ ;  $\tau_{dr}$  is disturbed soil dynamic shear stress at dynamic shear strain  $\gamma_d$ .

Considering that  $\tau_{do}$ ,  $\tau_{ds}$  and  $\tau_{dr}$  are soil dynamic shear stress at the same dynamic shear strain  $\gamma_d$ , the Formula 1 can be further simplified as:

$$m_{\gamma d} = \frac{\tau_{do}^2}{\tau_{ds} \tau_{dr}} = \frac{G_{do}^2 \gamma_d^2}{G_{dr} \gamma_d G_{ds} \gamma_d} = \frac{G_{do}^2}{G_{dr} G_{ds}} \quad (2)$$

where  $G_{do}$  is undisturbed soil dynamic shear secant modulus at dynamic shear strain  $\gamma_d$ ;  $G_{ds}$  is undisturbed saturated soil dynamic shear secant modulus at dynamic shear strain  $\gamma_d$ ;  $G_{dr}$  is disturbed soil dynamic shear secant modulus at dynamic shear strain  $\gamma_d$ .

The simplification of soil structural quantitative parameters based on the same dynamic shear strain method can get the same result:

$$m_{\tau d} = \frac{\gamma_r \gamma_s}{\gamma_o^2} = \frac{\tau_d \tau_d}{G_{dr} G_{ds}} = \frac{G_{do}^2}{\left(\frac{\tau_d}{G_{do}}\right)^2 G_{dr} G_{ds}} \quad (3)$$

where:  $\gamma_o$  is undisturbed soil dynamic shear strain at dynamic shear stress  $\tau_d$ ;  $\gamma_s$  is undisturbed saturated soil dynamic shear strain at dynamic shear stress  $\tau_d$ ;  $\gamma_r$  is disturbed soil dynamic shear strain at dynamic shear stress  $\tau_d$ ;  $G_{do}$  is undisturbed soil dynamic shear secant modulus at dynamic shear stress  $\tau_d$ ;  $G_{ds}$  is undisturbed saturated soil dynamic shear secant modulus at dynamic shear stress  $\tau_d$ ;  $G_{dr}$  is disturbed soil dynamic shear secant modulus at dynamic shear stress  $\tau_d$ .

According to the definition of soil dynamic structural parameters  $m_{\gamma d}$ :

$$m_{\gamma d} = m_1 / m_2 \quad (4)$$

Among them,  $m_1 = \tau_d / \tau_s$  shows the size of the structural variability, which is the release of soil inherent dilatant-consolidatory potentials by immersion;  $m_2 = \tau_r / \tau_o$  shows the size of the structural stability, which is the release of soil coupling effect by disturbing.  $m_1$  and  $m_2$  can be further simplified as:

$$m_1 = G_{do} / G_{ds} \quad (5)$$

$$m_2 = G_{dr} / G_{do} \quad (6)$$

Through the above analysis, the essence of soil dynamic structural parameters based on the same dynamic shear stress method and the same dynamic shear strain method can be found is the soil dynamic structural changes, which can be reflected by loading, disturbance and water immersion.

The dynamic structural property of soil in any state is the soil dynamic shear secant modulus  $G_d$ , which corresponds to the state. Then type 5 means that under the same dynamic shear strain, the reciprocal of the ratio between the residual structural property after water immersion and the structural property before water immersion can be used to reflect the extent to which the water immersion influences on the soil dynamic structural property. Water immersion causes the chemicals weakening, dissolving and suction connection losing. The wedging action of water film can release soil inherent shear-shrinkage potential, namely, water immersion influences structural variability. Thus, type 5 can be used to measure the size of structural variability. Type 6 means that under the same dynamic shear strain, the ratio between the residual structural property after disturbance and the structural property before water immersion can be used to reflect the extent to which the disturbance influences on the soil dynamic structural property. By damaging the soil coupling effect, disturbance reduces the coupling strength between the soil particles, influencing the structural stability. Therefore, type 6 can be used to measure the size of structural stability.

## 2.2 The proposal of the soil dynamic structural parameters on the view of equivalent elastomer

Soil is the elastic-plastic body. Supposing that soil elastic part and plastic part were independent of each other, then the dynamic shear secant modulus  $G_d$  can only represent the elastic property of soil. Obviously, there is a huge difference between the soil dynamic structural property described by dynamic shear secant modulus  $G_d$  and the real soil structural property. Therefore, using dynamic shear tangent modulus to describe soil dynamic structural is recommended.

Dynamic shear tangent modulus  $G_t$  is the first-order derivative of dynamic shear stress to dynamic shear strain at any point of the dynamic shear stress—dynamic shear strain curve. Compared with dynamic shear secant modulus  $G_d$  which is the ratio between dynamic shear stress and dynamic shear strain, dynamic shear tangent modulus  $G_t$  is more inclusive to soil elastic part and plastic part of soil. Soil dynamic shear tangent modulus describing soil structural properties can be understood as follows: if soil dynamic structural properties which own the dynamic shear tangent modulus  $G_t$  can be equivalently described by the dynamic shear tangent modulus  $G_{t1}$  ( $G_{t1} = G_t$ ) of elastomer, then, the soil structural property of any state has a correspondently equivalent structural property of elastomer. It is called the equivalent elastic elastomer view. Based on this view, soil dynamic structural parameters can be described by the dynamic shear tangent modulus.

## 3 SOIL DYNAMIC STRUCTURAL RESIDUAL DEGREE

The soil mechanics research through ages has revealed that the fundamental way to change or destroy soil structural properties is disturbance, loading and water immersion. Disturbance can damage the soil coupling effect, reducing the coupling strength between the soil particles; loading can change arrangement mode as well as coupling characteristics of soil particles; water immersion can make the chemicals in the soil weakened, dissolved and the suction connection lost. Water film wedging action can release the soil inherent shear shrinkage potential. In order to quantitatively describe these three external effects to soil dynamic structural properties, the paper defines a new coefficient—soil dynamic structural residual degree  $n_m$ .

For one or more external effects, the soil dynamic structural has (or not) residue in the soil after the initial soil dynamic structural changes (or destruction). The residual degree of soil dynamic

structural in the external effect is the ratio of between dynamic structural parameters (dynamic shear tangent modulus)  $G_t$  and initial soil dynamic structural parameters (initial dynamic shear tangent modulus)  $G_{t0}$ , that is:

$$n_m = G_t/G_{t0} \quad (7)$$

By formula (7) it can be seen that the value of  $n_m$  is 1-centered, changing away from 1 in two directions. Without any external effect,  $n_m = 1$ , namely, the original soil dynamic structural property is invariant; when  $n_m > 1$ , the soil dynamic structural property is strengthened under external effect, such as dehumidification; when  $n_m < 1$ , the soil dynamic structural property is weakened under external effect, such as immersion.

If the initial state of the soil is unloaded, the moisture content is  $w_0$ , and the initial dynamic structural parameter (initial dynamic shear tangent modulus) of undisturbed soil is  $G_{t0}$ , then the residual degree under different external effects is:

1. The soil dynamic structural residual degree under load

$$n_m = G_{td}/G_{t0} \quad (8)$$

where  $G_{td}$  is the dynamic structural parameter of undisturbed soil (dynamic shear tangent modulus) for moisture content  $w_0$  when the dynamic shear stress is  $\tau_d$ .

2. The soil dynamic structural residual degree in immersion (the answer of the first question in the introduction)

$$n_m = G_{tw}/G_{t0} \quad (9)$$

where  $G_{tw}$  is the dynamic structural parameter of undisturbed soil (dynamic shear tangent modulus) for water immersion to  $w$ .

3. The soil dynamic structural residual degree of disturbance (the answer of the second question in the introduction)

$$n_m = G_{td}/G_{t0} \quad (10)$$

where  $G_{td}$  is the dynamic structural parameter of soil (dynamic shear tangent modulus) for moisture content  $w_0$  after disturbance.

4. The soil dynamic structural residual degree under the coupling effect of loading and immersion

$$n_m = G_{tdw}/G_{t0} \quad (11)$$

where  $G_{tdw}$  is the dynamic structural parameter of soil (dynamic shear tangent modulus) for water immersion to  $w$  after disturbance when dynamic shear stress is  $\tau_d$ .

5. The soil dynamic structural residual degree under the coupling effect of loading and disturbance

$$n_m = G_{irzd}/G_{io} \quad (12)$$

where  $G_{irzd}$  is the dynamic structural parameter of soil (dynamic shear tangent modulus) for water immersion to  $w_0$  after disturbance when dynamic shear stress is  $\tau_d$ .

6. The soil dynamic structural residual degree under the coupling effect of water immersion and disturbance (the answer of the third question in the introduction)

$$n_m = G_{irw}/G_{io} \quad (13)$$

where  $G_{irw}$  is soil dynamic structural parameters (dynamic shear tangent modulus) for water immersion to  $w$  after disturbance.

7. The soil dynamic structural residual degree under the coupling effect of loading, water immersion and disturbance

$$n_m = G_{irzdw}/G_{io} \quad (14)$$

where  $G_{irzdw}$  is the dynamic structural parameter of soil (dynamic shear tangent modulus) for water immersion to  $w$  after disturbance when dynamic shear stress is  $\tau_d$ .

#### 4 THE EXPRESSION OF DYNAMIC STRUCTURAL RESIDUAL DEGREES BASED ON HARDIN-DRNEVICH HYPERBOLA MODEL

The curve showing the relationship between dynamic shear stress amplitude and dynamic shear strain amplitude is named backbone curve. A large number of experiments show that backbone curve under loading is hyperbolic, displaying non-linear characteristics, which can be described by Hardin-Drnevich hyperbola model (Xie, 2007), as is shown in formula 15:

$$\tau_d = \gamma_d / (a + b\gamma_d) \quad (15)$$

where  $a, b$  are test constants.

Its dynamic shear tangent modulus equation is:

$$G_t = a / (a + b\gamma_d)^2 \quad (16)$$

The initial dynamic shear tangent modulus (structural parameters for the initial state) is:

$$G_{io} = 1/a \quad (17)$$

According to equations from (8) to (14) and from (16) to (17), can obtain the expressions of soil dynamic structural residual degrees under different external effects in Table 1.

Table 1. Under different external conditions, soil dynamic structural residual degrees list.

External effect	Dynamic structural residual degrees	Expression	Note
Loading	$\frac{G_{irzd}}{G_{io}}$	$\frac{a^2}{(a + b\gamma_d)^2}$	$a, b$ are test constants of undisturbed soil based on Hardin-Drnevich hyperbola model experiment at moisture content $w_0$ .
Immersion	$\frac{G_{irw}}{G_{io}}$	$\frac{a}{a_1}$	$a_1$ is test constant of undisturbed soil based on Hardin-Drnevich hyperbola model experiment for water immersion to moisture content $w$ .
Disturbance	$\frac{G_{ir}}{G_{io}}$	$\frac{a}{a_2}$	$a_2$ is test constant of soil based on Hardin-Drnevich hyperbola model experiment for disturbance to moisture content $w_0$ .
Loading and immersion	$\frac{G_{irzd,w}}{G_{io}}$	$\frac{a_1 a}{(a_1 + b_1 \gamma_d)^2}$	$a_1, b_1$ are test constants of undisturbed soil based on Hardin-Drnevich hyperbola model experiment for loading and immersion to moisture content $w$ .
Loading and disturbance	$\frac{G_{irzd}}{G_{io}}$	$\frac{a_2 a}{(a_2 + b_2 \gamma_d)^2}$	$a_2, b_2$ are test constants of soil based on Hardin-Drnevich hyperbola model experiment for loading and disturbance to moisture content $w_0$ .
Disturbance and immersion	$\frac{G_{irw}}{G_{io}}$	$\frac{a}{a_3}$	$a_3$ is test constant of soil based on Hardin-Drnevich hyperbola model experiment for disturbance and immersion to moisture content $w$ .
Loading, disturbance and immersion	$\frac{G_{irzdw}}{G_{io}}$	$\frac{a_3 a}{(a_3 + b_3 \gamma_d)^2}$	$a_3, b_3$ are test constants of soil based on Hardin-Drnevich hyperbola model experiment for loading, disturbance and immersion to moisture content $w$ .

## 5 CONCLUSIONS

This paper analyzes substance of soil dynamic structural parameters on the basis of previous research about soil structural properties. It is deemed that soil dynamic structural changes can be reflected in loading, disturbing and water immersing. In addition, the soil dynamic structural property is its dynamic shear secant modulus in any state. It is discovered that the description of soil dynamic structural properties by using dynamic shear secant modulus is quite different from its real structural properties. The paper suggests using the dynamic structural parameters based on the view of equivalent elastomer (dynamic tangent modulus), which defines the soil dynamic structural residual degrees that reflect impact of the disturbance, load and humidification on soil structural properties. This paper also gives the expression of dynamic structural residual degrees based on Hardin—Drnevich hyperbola model in different external conditions.

Yunqing Liu, Qingrui Lu, Shijun Chen & Weiwei Bian

*Architectural College, East China Institute of Technology, Nanchang, China*

**ABSTRACT:** A comparative study on the mechanical properties of clay rock in Tamusu region and abroad was carried out, by collecting relevant data and by conducting point-loading test, uniaxial tension test and rock triaxial tests. The research indicates that the mechanical strength of clay rock in Tamusu region is superior to that of clay rock from abroad. The clay rock in Tamusu region takes on the brittle deformation as a whole, and takes on plastic deformation only when subject to high temperature and large pressure. In addition, the tensile strength of clay rock in Tamusu region is similar to that of Callovo-Oxfordian rock in France, and decreases with the increasing depth. The research is intended for providing certain technical support for the site selection of high-level radioactive waste repository in China.

**Keywords:** high-level radioactive waste; deep geological repository; clay rock; mechanical properties

## 1 INTRODUCTION

High-level radioactive waste deep geological repository is considered as a type of the most complex deep underground projects being studied by the nuclear-armed countries, while the subjects on deep rock mechanical properties are becoming the research hotspots during site selection, design, construction and operation of underground laboratories and deep geological repositories of high-level waste<sup>[1]</sup>. The research at home and abroad shows that both the granite and clay rocks are suitable for the deep disposal of high-level radioactive wastes<sup>[2]</sup>. For example, Amann et al. conducted the research on the brittle behavior of deep Opalinus clay rocks in Switzerland<sup>[3-4]</sup>, and Brapi et al. investigated the fracture mechanics of the Opalinus clay rock<sup>[5]</sup>. In China, Liu Y et al. studied the basic physical mechanics and time-temperature effect of granite in Beishan area, Gansu province<sup>[6]</sup>. However, few researches on the mechanical behavior of clay rock for the site selection of deep disposal repositories have been performed in China. In view of this, a series of tests on the mechanical properties of deep clay rock in Tamusu region of Inner Mongolia Gobi have been carried out, together with comparing its mechanical behavior with that of foreign clay rock, with the aim of

providing valuable data for the research on the construction conditions of geological repositories for high-level radioactive waste.

## 2 COMPARISON ON THE BASIC BACKGROUND

The adopted clay rock in this paper was taken from the southern part of Tamusu region, Bayingobi basin of Inner Mongolia. It was formed in the Middle stage of Early Cretaceous with warm and humid climate, and the environment can be regarded as typical lakeshore delta facies. The gray clay rock that we selected was formed by the sedimentary of grey continental debris of the Lower Cretaceous Bayingobi Group, with a buried depth ranging from 550 to 650 m. The rock can be characterized mainly by horizontal bedding, and the petrographic composition is comparatively uniform, with asphalt in some local area. The formation age can be considered as 120 Ma, which is earlier than the Boom Clay of Belgium (Oligocene, 30 Ma<sup>[1,6]</sup>), as shown in [Table 1](#), and later than the Callovo-Oxfordian Clay of France (Middle Jurassic—late Jurassic, 145 Ma) and the Opalinus Clay of Switzerland (Middle Jurassic, 180 Ma). Both its formation age and buried depth

Table 1. Main characteristics of the different geological media for high-level waste from abroad<sup>[11–15]</sup>.

	Opalinus clay	Callovo-Oxfordian clay	Boom clay
Thickness (m)	80–120	135	100
Buried depth (m)	500–1000	300–600	1800
Density (g/cm <sup>3</sup> )	2.5–2.6	2.32–2.61 (2.42)	2.67
Uniaxial compression strength (MPa)	4–8	12–49 (26)	2.0–2.2
Tensile strength (MPa)	1–2	0.9–5.4 (2.6)	–
Young's modulus (MPa)	2000–3000	4000–5600 (4900)	200–400 (300)
Poisson's ratio	–	0.3	0.125
Internal friction angle (°)	23–25(24)	–	18
Formation age	Aalenian (Dogger) 180 Ma	Middle Callovian to lower Oxfordian 145 Ma	Rupelian 30 Ma

are close to that of the Callovo-Oxfordian Clay of France.

### 3 COMPARISON OF BASIC MECHANICAL PROPERTIES

The fundamental parameters of mechanical properties of clay rock such as point-loading strength, elastic modulus, Poisson's ratio, tensile strength, triaxial compression strength, internal friction angle and cohesion were determined by a series of tests. The rock samples were prepared according to the provisions of Rock Physical and Mechanical Properties Test (GB/T9966-2001) and Suggested Methods of Rock Mechanics Laboratory Tests by the International Society for Rock Mechanics.

#### 3.1 Tensile strength

Tensile strength was determined using point-loading test estimation and Brazilian tests. With the rock samples taken at the buried depth of 650 m and 555 m, respectively, the point loading strength of vertical bedding was obtained at the range of 3.52–5.49 MPa, while that of horizontal bedding ranged from 2.61 to 3.21 MPa.

It can be inferred from the point loading strength that the tensile strength of vertical bedding is about 3.3–5.3 MPa, and for horizontal bedding is about 2.1–3.1 MPa, which show little discrepancy in the two directions, and therefore the anisotropy is not clear. Meanwhile, the estimated tensile strength is distinctly smaller than the estimated compressive strength, and the discrepancy almost reaches 25 times. The estimated compressive strength is about 80–140 MPa, much larger than that of Opalinus Clay (4–8 MPa), Callovo-Oxfordian Clay (12–49 MPa) and Boom Clay (2–2.2 MPa).

Brazilian test can be used indirectly to determine the tensile strength of rock. According to their

buried depth, the rock samples were divided into 2 groups. For the sample at the depth of 641 m, the tensile strength ranges from 1.77 to 2.14 MPa, and for the sample of 627 m, the tensile strength reaches 2.05–2.62 MPa, which is shown in Table 2.

The comparison shows that the result obtained from Brazilian test is relatively smaller than the estimated value of the point loading tests; however, the tensile strength for vertical bedding of clay rock in Tamusu region is in the range of 2–3 MPa, which falls into the range of that of the Callovo-Oxfordian clay rock, and 1 time higher than that of the Opalinus clay rock (1–2 MPa). Moreover, the tensile strength gradually decreases with the increasing depth, and the varying characteristic with depth should be further studied.

#### 3.2 Triaxial compression strength

Using the microprocessor control Electro-hydraulic servo rock triaxial testing machine TAW-2000 of East China Institute of Technology, we performed a series of tests for which the radial deformation was controlled, and the testing data were recorded automatically by the computer. Due to that the nuclear waste generally releases heat during the operation of high-level geological repositories, the triaxial tests were conducted under a high temperature and high pressure. With the temperature controlled at 60°C, the confining pressures at 10 MPa, 20 MPa and 30 MPa were, respectively, fixed, and the corresponding mechanical parameters can therefore be determined as shown in Table 3. Poisson's ratio falls within the range of 0.023–0.038, which is much lower than that of the foreign clay rock, and therefore little anisotropy can be proved by the point loading tests. The elastic modulus ranges from 2800 to 3100 MPa, similar to that of Opalinus Clay, lower than that of Callovo-Oxfordian Clay, and 8–10 times higher than that of Boom Clay.

Table 2. Results of Brazilian test.

Dimension of samples						Tensile strength		
Rock type	Sample numbering	Depth/m	Forced direction	Diameter D/mm	Height H/mm	Ultimate load/kN	Single value/Mpa	Average value/Mpa
Rock clay	16-16-L1	641	Radial	49.50	25.48	3.5	1.77	2.00
	16-16-L2			49.50	25.48	4.26	2.14	
	16-16-L3			49.58	25.00	4.04	2.08	
Rock clay	8-14-L1	627	Radial	49.60	25.00	3.99	2.05	2.26
	8-14-L2			49.58	25.54	5.21	2.62	
	0-16-L1	630.5		49.58	25.62	4.19	2.10	

Table 3. Results of triaxial compression test.

Temperature	Samples numbering	Mass of samples M/g	Volume	Density	Pressure $\sigma^3$	Axial ultimate load P	Ultimate axial stress $\sigma_1$	Elastic modulus MPa	Poisson's ratio	Internal friction angle $\varphi^\circ$
60°C	32-19	178.00	449.15	2.51	10	83.75	45.69	—	—	54.72
	32-19-1	177.29	452.8	2.55	20	372.30	202.10	3100	0.038	
	36-32	178.24	435.89	2.45	30	478.05	265.06	2800	0.028	

Figure 1. Stress-strain curves under different confining pressures at 60°C.

Figure 1 shows stress-strain curves under different confining pressures at 60°C. It can be inferred that the rock samples manifest distinct brittleness. Especially under the confining pressure of 10 MPa, an obvious brittle failure can be noticed. With the increasing confining pressure, the samples show brittleness at the beginning, and plastic deformation occurs in the later stage. The strain and compressive strength increases sharply when the samples break. The compressive strength of clay rock in Tamusu region,

no matter estimated from point loading test or determined by triaxial tests, is higher than that of foreign clay rock. As a result, from the mechanical point of view, the clay rock in Tamusu region can be used as the geological medium for high-level waste.

#### 4 CONCLUSIONS

By comparing the conducted tests and the foreign data, we can draw the following conclusions about the clay rock in Tamusu region: 1) the mechanical strength is superior to that of foreign clay rock as a whole; however, it shows distinct brittleness. Little discrepancy exists between horizontal and vertical beddings, and the anisotropy is not obvious; 2) the estimated compressive strength is 25 times of tensile strength, and much higher than that of foreign clay rock; 3) tensile strength is obtained as about 2 MPa, similar to that of the Callovo-Oxfordian clay from France. Tensile strength decreases with the depth, of which the varying tendency needs to be further studied; 4) the triaxial data show that the strength increases sharply with the increasing confining pressure, and plastic failure occurs in the later stage. However, because the discreteness is notable, the varying pattern of elastic modulus and Poisson's ratio with confining pressure needs to be further investigated.

# Study on the simulation test for Osterberg cell test of large pile foundation

Lina Xu

Jilin Jianzhu University, Changchun, China

**ABSTRACT:** This paper makes a comparative study on the methods to determine the bearing capacity of all kinds of pile foundations. Based on the study, it analyses the advantages of Osterberg cell test. Based on the field test data obtained on the Lanqi Songhua River Bridge of Jilin province, this paper applies the simulated test to simulate the Osterberg cell test, and the results show that the simulation and field measurements are highly consistent. Meanwhile, the load characteristics, including the load bearing features of pile foundation and the distribution features of displacement field of rock-soil mass around the pile, could be studied through the simulation. It can make up for a lack of field tests and laboratory tests. This illustrates that the method has certain feasibility and is of certain reference value for the future study on the bearing capacity of pile foundation.

**Keywords:** pile foundation; bearing capacity; Osterberg cell test; simulation

## 1 INTRODUCTION

At present, a large amount of pile foundations are used in key projects in China such as railway, bridge, high-rise buildings and others. Determining the bearing capacity of pile foundation in a correct and reasonable manner can enhance the economic performance on the basis of achieving a quality construction.

As the development of science and technology, the methods used to determine the bearing capacity of pile foundation are continuously improved as well. In particular, the rapid development of computer technology also drives the study on the pile foundation in simulated aspects. I. Said et al. (2009), Chen Lun et al. (2002), Wang Lijuan (2003), and Li Jin et al. (2004) conducted a study on the load transfer mechanism targeted at different types of piles by applying different numerical simulation software programs, respectively. Ottaviani (1975), Emilioms M. Comdromos et al. (2003), Panich Voottipiyex et al. (2011) carried out the study on bearing features of grouped piles. Wang Youqing et al. (2002), and Zhou Gang et al. (2010) conducted the numerical simulation study on the mechanism of action between the pile and soil.

This paper has first carried out a comparative study on the methods used to determine the bearing loads of pile foundation and analyzed the

advantages and disadvantages of these methods. Based on the field test data obtained on the Lanqi Songhua River Bridge of Jilin province, this paper applies the simulated test to simulate the Osterberg cell test, and the results show that the results of simulation and field measurements are highly consistent. Meanwhile, the load characteristics, including the load bearing features of pile foundation and the distribution features of displacement field of rock-soil mass around the pile, could be studied through the simulation. This illustrates that the method has certain feasibility and is of certain reference value for the future study on the bearing capacity of pile foundation.

## 2 STUDY ON THE METHODS TO MEASURE THE BEARING LOADS OF LARGE PILE FOUNDATION

At present, the methods used to measure the bearing loads of pile foundation mainly include single pile static load test, Osterberg cell test, dynamic test method (low strain detection method and high strain detection method), static-dynamic method, sound wave transmission method, model test method, simulation test and others. All these methods have displayed their own advantages and limitations during long term uses, as shown in [Table 1](#).

Table 1. Comparison of different methods to measure the bearing loads of all the pile foundations.

	Static load test	Osterberg cell test	Model test method	Simulation test
Advantages	The most reliable, accurate and direct method recognized internationally to determine the bearing capacity of single pile	Has avoided the problem of stacking in static load. Can directly measure the resistance of tip and side of pile; 3. Has a relatively lower requirement for the site	Being more targeted and purpose oriented during the research on the interaction of pile-soil, and conducting comparative study through changing the design parameters	Being able to simulate the complex mechanics and transformation features during the interaction of pile and soil. And the interaction process between pile and soil visually can be capable of observing through computer software
Limitations	Hard to set up the counter force device and require an open and flat site. The test piles can no longer be used as the engineering piles	Not able to carry out the random sample detection. And it is difficult to determine the correct position of loading box	It is hard to simultaneously achieve the similarity in size, physics and environment of the model	Results are affected by the selection of parameters and simulation model
			Dynamic test method	
	Static-dynamic method	Sound wave transmission method	Low strain detection method	High strain detection method
Advantages	Being low in cost, short in duration and convenient and flexible	It serves as an efficient method to inspect the internal defects of the concrete cast-in-place pile and assess its integrity, and it is not limited by the site and possesses high test accuracy	It is used to detect the integrity of pile body structure. It can be used to calculate the location of defect, distinguish the hole shrinkage from the hole enlargement, and discover the shallow defects or tiny horizontal fracture	It can have a relatively clear reflection on the deeper pile body. It can be used to detect the integrity of pile body, test the vertical compressive capacity of single pile and monitor the piling process
Limitations	Static-dynamic method is still a dynamic test method; the dynamic phenomenon still exists and a certain hypothesis is required to adjust the data; meanwhile, it also has the limitations existing in dynamic test methods	It only applies to the cast-in-place pile with the diameter of pile being 0.6–0.8 m and the sounding pipe is required to be embedded and the sampling is bad in randomness	This method is not suitable for piles such as deformed pile, pile with branches and plates, root pile, and the pile in which the resistance of pile body differs little from that of soil around the pile	It is inadvisable to be used alone in the acceptance check of engineering pile alone, and can only be used in the test pile for verification, not in test pile for design

### 3 COMPUTER SIMULATION ANALYSIS

The application of computer-based simulation technology can better simulate the features of strain and displacement changes in the process of pile-soil interaction.

#### 3.1 Overview of the Lanqi Songhua River Bridge

Jilin Lanqi Songhua River Grand Bridge is located in the Lanqi–Jiangmifeng section of Jilin ring expressway and also in the connection section of national road Chang-Hui highway and the national road Hei-Da highway; the bridge starts from Lanqi village located in the west line of Ji-Feng highway and ends at Yongqing village located in the east line of Ji-Feng highway with an overall length of 625 m, spanning the second Songhua River; the cast-in-situ bored piles are adopted for all the design foundation of the main bridge. Three piles are selected, and a self-balancing test method is adopted for static load test.

#### 3.2 Numerical calculation model

In this paper, FLAC3D is adopted to establish the numerical calculation model, and the size of the model is 30 m × 60 m × 80 m, with 9587 panel points and 8020 units in total. As the test pile belongs to an overlong and large diameter pile owing to its length of 50 m and diameter of 2 m, both the pile and rock-soil mass adopt the physical model. Besides, the rock-soil mass adopts the Mohr-Coulomb Model and the pile body adopts the Elastic Model. Laboratory test can be used to obtain the material parameters of all the soil layers, as shown in Figure 1.

#### 3.3 Load application

During the loading of Osterberg cell test on site, the estimated load value is 2 × 33000 kN and the load value of each grade is 1/11 of the limit value. In order to reflect the results of Osterberg cell test on site in the real manner, the loading procedure used in Osterberg cell test shall be adopted during simulation, and the load values of each grade are given in Table 2.

#### 3.4 Analysis of simulation results

##### 3.4.1 Comparison of numerical simulation and Osterberg cell test

Figure 2 shows the relations between loads and the displacement.

As shown in Figure 2, the results obtained from the numerical simulation are rather identical with that measured actually on site, and the change

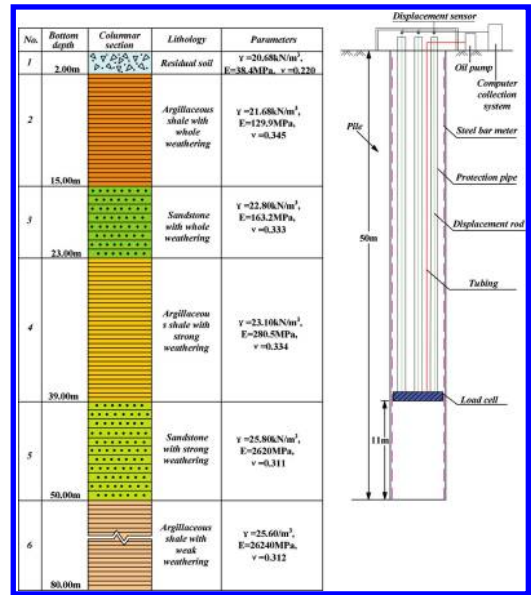

Figure 1. Engineering geologic columnar profile and pile foundation self-balancing loading system.

Table 2. Grading of estimated load value.

Series of loading	Load value (kN)
1	6000
2	9000
3	12000
4	15000
5	18000
6	21000
7	24000
8	27000
9	30000
10	33000

Figure 2. Curve graph showing the relations between loads and displacement.

rules are consistent. As the loads are exerted, all displacements increase accordingly. The displacement of the upper segment of the pile is larger than that of the lower segment of the pile, which shows that the side friction on the upper section of the pile body plays a better role than that on the lower section. When the load reaches 33000 kN, the upward displacement of the upper segment of the pile increases dramatically, which shows that the side friction on the upper segment of the pile plays to its limit. In the process of numerical simulation, when the load of the last grade is exerted, the displacement of the upper segment of the pile increases continuously and the calculation is hard to be converged, and this can be explained by the fact that the ultimate bearing capacity is approached at this moment. The displacement of the lower segment of the pile is relatively smaller due to the combined action of the side friction of the pile and the resistance on the tip of the pile and always shows a linear variation.

### 3.4.2 Study on transmission rules of loads

#### 1. Distribution features of the axial force of the pile body

Figure 3 shows the distribution rules of axial forces of the pile body at different elevations under the effect of loads of all levels. From the figure, it can be seen that the results obtained from the numerical simulation has the same

variation trend as that measured in the Osterberg cell test. When being exerted by the same load, the maximum axial force of the pile body is generated at the load cell, and if the upper segment of the pile is affected by the side friction, the axial force decreases gradually and the axial force on top of the pile reaches the minimum. As for the upper segment of the pile, the axial force of the pile body decreases more rapidly along with the increase of loads. This is because the side resistance of the pile will increase as well along with the increase of loads.

#### 2. Distribution features of displacement field of geotechnical body around the pile

As the loads are exerted, the displacement of the upper segment of the pile and that of the lower segment of the pile increase continuously and the geotechnical body around the pile also brings about the displacement accordingly. Figure 4 shows the contour maps showing the displacement fields of geotechnical body around the pile when the loads 6000 kN and 15000 kN are exerted, respectively. It can be seen from it that the geotechnical body around the upper segment of the pile brings about the upward displacement, which decreases gradually from the top of the load cell to the ground surface and the side friction also plays its role gradually from the loading box to the top of

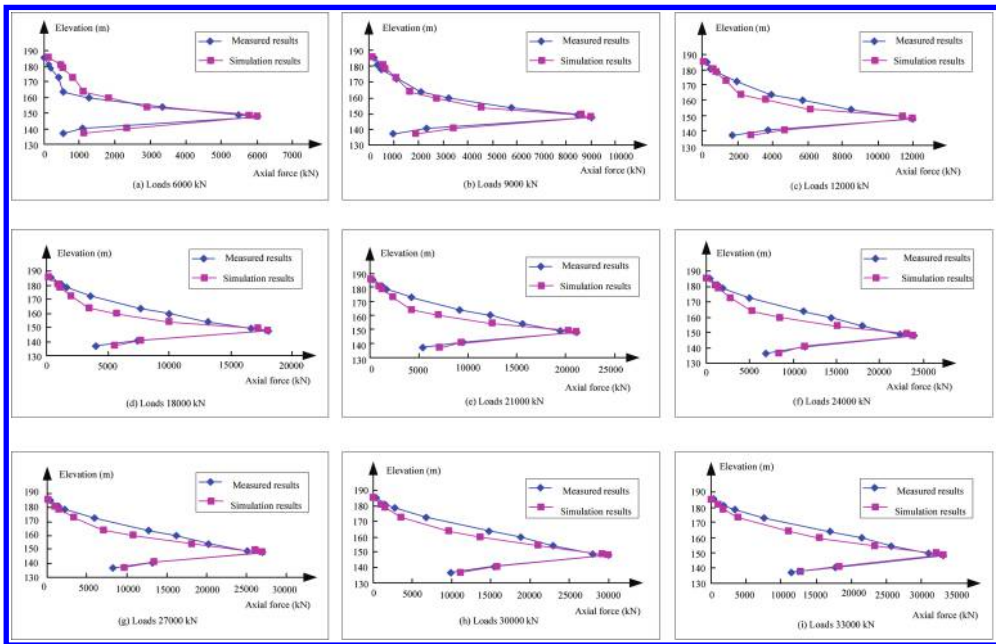

Figure 3. Distribution rules of axial forces of pile body.

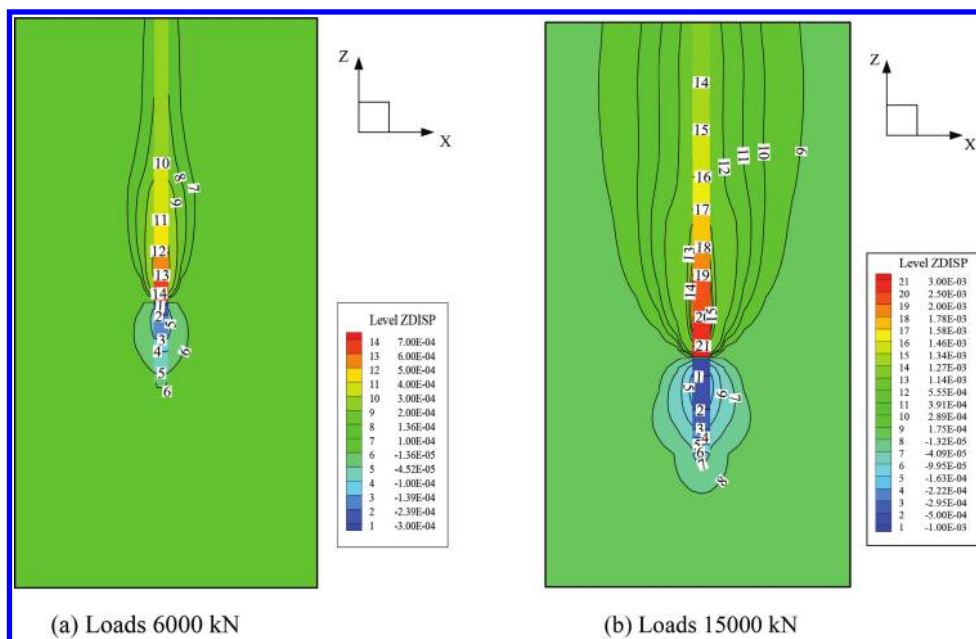

Figure 4. Contour map showing the distribution of displacement field of rock-soil mass around the pile under the action of different loads (Unit: m).

the pile. As the loads exerted increase, the displacement of the geotechnical body around the pile will be brought about in larger areas. This is because as the side friction of the pile plays its role gradually, the friction exerted on the geotechnical body that is on the lateral side of the pile increases gradually as well. In this way, the upward displacement of the soil increases, which affects even larger areas as well. The geotechnical body around the lower segment of the pile brings about the upward displacement which decreases gradually from the bottom of the load cell to the bottom of the pile. The numerical simulation analysis can be used to observe variation rules and distribution features of displacement of rock-soil mass around the pile. It is extremely necessary to understand the distribution features of the displacement field of geotechnical body mass around the pile in the intensive study of interactions between the load transmission mechanism and pile-soil in the Osterberg cell test method.

#### 4 CONCLUSIONS

This paper has carried out a study on the bearing features of pile foundation through numerical simulation and the following conclusions can be drawn:

1. Through the comparative study on all kinds of test methods used to determine the bearing capacity of pile foundation, the advantages and shortcomings of the various test methods have been summarized and the back analysis based simulation test method used to determine the bearing capacity of pile foundation has been put forward.
2. Through the numerical simulation test, the bearing features of pile foundation can be better simulated, including the relations between displacement and loads, the distribution features of axial force of pile body and others. Besides, the test can help to visually observe the distribution features of displacement field of rock-soil mass around the pile, which cannot be achieved by using the field test and the laboratory test.

# Numerical analysis of settlement of the soft clay foundation

Xiaocheng Jiang

Henan Electric Power Survey and Design Institute, Zhengzhou, China

Yongquan Li

College of Civil Engineering and Architecture, Henan University of Technology, Zhengzhou, China

**ABSTRACT:** The Modified Cam-clay Model and the Drucker-Prager Creep Model are deduced and dealt with in detail. The two model are applied to the finite element calculation of soft foundation treatment of a dam. It shows that the results calculated are similar and close to the monitoring data with those two models. By comparison, it can be got that the displacement calculated by the Drucker-Prager Creep Model is closer to monitoring data than that calculated by the Modified Cam-clay Model. It demonstrates the reasonableness and efficiency of the viscoelasto-plastic model.

**Keywords:** soft clay; Modified Cam-clay model; Drucker-Prager creep model; finite element

## 1 INTRODUCTION

Soil has various properties, including elastoplasticity, dilatation, shear contraction, stickiness and so on<sup>[1-2]</sup>. At present, a lot of constitutive models have been developed, but they have their own merits, defects and application limits. Rheology is one obvious and important mechanical property of soft soil, so it must be taken into account when it comes to engineering in soft soil.

Based on Drucker-Prager creep model, this paper deals with the improvement of it in consideration of Rheology<sup>[3-4]</sup>, by which the displacement of soft soil is calculated and compared to that calculated by general modified Cam-Clay model. In addition, the method of transferring to equivalent sand wall is introduced when soft soil is treated by plastic drainage plate.

## 2 MODIFIED CAM-CLAY MODEL

The Cam-clay model proposed by ROSCOE et al is the first critical-state model for describe clay soil. ROSCOE and BURLAND amend the shape of the yield curve and obtained the modified Cam-clay model. The Modified Cam-clay model is based on few parameters which can be obtained from conventional laboratory tests. Since then the Modified Cam-clay model is widely referenced and has now been widely used in solving boundary value problems in geotechnical engineering practice.

The yield function formula of the Cam-clay model can be expressed:

$$f(\sigma) = p \left( 1 + \frac{\eta^2}{M^2} \right) - p_0 = 0 \quad (1)$$

In above formula,  $\eta = q/p$ ,  $p$ ,  $q$  are respectively the average stress and the shear stress which can be expressed below.

$$p = \frac{1}{3}(\sigma_z + 2\sigma_x) \quad (2)$$

$$q = \sqrt{(\sigma_x - \sigma_z)^2 + 3\tau_{xz}^2} \quad (3)$$

$M$  is the stress ratio which equals  $\eta$  when soil failure happens.  $M$  can be calculated by below expression.

$$M = \frac{6 \sin \phi'}{3 - \sin \phi'} \quad (4)$$

When only volume is considered, the total volumetric strain increment includes two parts.

$$\Delta \varepsilon_v = \Delta \varepsilon_v^e + \Delta \varepsilon_v^p \quad (5)$$

Plastic volumetric strain increment can be described:

$$\Delta \varepsilon_v^p = A \frac{\partial f}{\partial p} \Delta p_0 \quad (6)$$

$A$  is plastic parameter. Plastic volumetric strain increment can be got from  $\varepsilon_v - \ln p$  curve:

$$\Delta \varepsilon_v^p = (\lambda - \kappa) \ln \frac{p_0}{p_i} \quad (7)$$

where  $p_i$  is the initial stress. The plastic parameter  $A$  can be concluded:

$$A = \frac{\lambda - \kappa}{p_0 \frac{\partial f}{\partial p}} \quad (8)$$

where  $\lambda$  and  $\kappa$  are respectively Volume compression index and Volume rebound index.

$$\varepsilon_v^e = \kappa \ln \frac{p_0}{p_i} \quad (9)$$

Volume rebound modulus  $M_v$  can be expressed by:

$$M_v = \frac{3\Delta p_0}{\Delta \varepsilon_v^e} = \frac{3p_0}{\kappa} \quad (10)$$

Through associated flow rule, elastic-plastic matrix can be got by:

$$[D]_{ep} = [D] - \frac{[D] \left\{ \frac{\partial f}{\partial \sigma} \right\} \left\{ \frac{\partial f}{\partial \sigma} \right\}^T [D]}{\frac{1}{A} + \left\{ \frac{\partial f}{\partial \sigma} \right\}^T [D] \left\{ \frac{\partial f}{\partial \sigma} \right\}} \quad (11)$$

where

$$\left\{ \frac{\partial f}{\partial \sigma} \right\} = \begin{Bmatrix} \frac{\partial f}{\partial \sigma_x} \\ \frac{\partial f}{\partial \sigma_z} \\ \frac{\partial f}{\partial \tau_{xz}} \end{Bmatrix} = \begin{Bmatrix} \frac{2}{3} \left[ 1 + \frac{6p(\sigma_x - \sigma_z) - q^2}{M^2 p^2} \right] \\ \frac{1}{3} \left[ 1 + \frac{6p(\sigma_z - \sigma_x) - q^2}{M^2 p^2} \right] \\ \frac{6\tau_{xz}}{M^2 p} \end{Bmatrix} \quad (12)$$

$1/A$  can be calculated by:

$$\frac{1}{A} = \frac{1}{\lambda - \kappa} \left[ p \left( 1 + \frac{\eta^2}{M^2} \right) \left( 1 + \frac{2p(\sigma_x - \sigma_z) - q^2}{M^2 p^2} \right) \right] \quad (13)$$

### 3 DRUCKER-PRAGER CREEP MODEL

Drucker-Prager creep model implies that the Drucker-Prager plasticity model uses isotropic

linear elasticity, a hyperbolic plastic flow potential, and the linear Drucker-Prager yield surface with a circular yield surface in the deviatoric plane ( $K = 1$ ). The creep laws for the Drucker-Prager creep models are written in terms of an equivalent creep stress, which is a measure of the creep "intensity" of the state of stress at a material point. The definition of depends upon the type of hardening (compression, tension, or shear) used with the linear Drucker-Prager plasticity model, but in all cases  $\bar{\sigma}^{cr} = \bar{\sigma}^{cr}(q, p, \beta)$ :

$$\bar{\sigma}^{cr} = \frac{(q - p \tan \beta)}{(1 - (1/3) \tan \beta)} \quad (\text{compression}) \quad (14)$$

$$= \frac{(q - p \tan \beta)}{(1 + (1/3) \tan \beta)} \quad (\text{tension}) \quad (15)$$

$$= (q - p \tan \beta) \quad (\text{shear}) \quad (16)$$

There is a cone in the meridional plane in which no creep deformation will occur. The default creep laws provided are simple and are intended to model these condary creep of the material. Use this creep law when the stress in the material remains essentially constant:

$$\dot{\bar{\varepsilon}}^{cr} = A (\bar{\sigma}^{cr})^n t^m \quad (17)$$

Use this creep law when the stress in the material varies during the analysis:

$$\dot{\bar{\varepsilon}}^{cr} = \left( A (\bar{\sigma}^{cr})^n \left[ (m+1) \bar{\varepsilon}^{cr} \right]^m \right)^{\frac{1}{m+1}} \quad (18)$$

Use this creep law when an exponential relationship between stress and creep strain rate is needed:

$$\dot{\bar{\varepsilon}}^{cr} = A e^{(\alpha \bar{\sigma}^{cr})} (t/t)^m \quad (19)$$

The Drucker-Prager creep model uses a hyperbolic creep flow potential that ensures the creep (deformation) flow direction is always defined uniquely:

$$G^{cr} = \sqrt{(\varepsilon \bar{\sigma}|_0 \tan \Psi)^2 + q^2} - p \tan \Psi \quad (20)$$

### 4 ENGINEERING APPLICATION

A soil dam is built above a recently sedimentary silt of a lake base, with a depth of 8–10 m, underlying by a 8 m depth of clayey loam and base rock.

The physical and mechanical properties of the foundation soil are shown in Table 1 and Table 2. The width of the dam base is 44 m, the ratio of the slope is 1:2, the thickness of filling soil is 10 m, and the period of operation is 180 d. The plastic drainage plate method is applied to consolidate

Table 1. Parameters of Cam-clay model.

Material	Filling (silty clay)	Soft clay
$\gamma_d$ (KN/m <sup>3</sup> )	18.5	17.5
$v$ (°)	0.29	0.29
$\kappa$	0.007	0.012
$\lambda$	0.06	0.05
$M$	1.3	1.32
$e$	0.8	0.9
$k_z$ (m/s)	$5.8 \times 10^{-9}$	$3.4 \times 10^{-9}$
$k_r$ (m/s)	$6.7 \times 10^{-9}$	$4.9 \times 10^{-9}$

Table 2. Parameters of Drucker-Prager creep model.

Material	Filling (silty clay)	Soft clay
$\varphi$ (°)	28.6	8.5
$m$	7.8	7.5
$n$	10.5	3.5
$k_z$ (m/s)	$5.8 \times 10^{-9}$	$3.4 \times 10^{-9}$
$k_r$ (m/s)	$6.7 \times 10^{-9}$	$4.9 \times 10^{-9}$

Figure 1. Finite element mesh for the dam.

Figure 2. Relationship between vertical displacement and time at the centre of the dam.

Figure 3. Relationship between horizontal displacement and time at the toe of the dam.

the foundation. First, a cofferdam was constructed and fluidized silt discharged by mud pump. Then a layer of 1 m silt clay was laid to enhance the strength of the ground to enable the movement of the plastic plate plugging machine. A cushion layer of 50 cm medium to coarse sand was laid over the silt clay as the path of horizontal drainage. The distribution of the plastic drainage plate is club, with an interval of 1.5 m. The plate is placed about 0.5 m in the mild clay.

## 5 CONCLUSIONS

The Modified Cam-clay model and the Drucker-Prager creep model are applied in the 2 dimension finite element calculation respectively. FE mesh of the dam is showed in Figure 1. Then the results of surface settlement at the center of the soil dam and displacement of slop toe are compared with field monitoring data, shown in Figure 2 and Figure 3. The conclusion can be drawn that the results calculated are similar and close to the monitoring data with those two models. Thus those two models are also suited to soft soil. In addition, the results also show that the results calculated with the Drucker-Prager creep model are closer to the monitoring data.

# Numerical analysis of bearing capacity of single pile under axial loading

Xianfeng Zhang

Henan Electric Power Survey and Design Institute, Zhengzhou, China

Yongquan Li

College of Civil Engineering and Architecture, Henan University of Technology, Zhengzhou, China

**ABSTRACT:** A finite element model has been developed to simulate single pile under axial loading via Drucker-Prager model. Pile-soil interaction is analyzed by Mohr-Coulomb formula. Based on the results of the analysis, the bearing capacity of single pile and the scope of plastic zone can be got. Those results gained by numerical method may provide reference to pile engineering practice.

**Keywords:** soil-pile interaction; axial loading; Drucker-Prager; finite element

## 1 INTRODUCTION

Soil-pile interaction is an important topic in the development of a performance based design procedure. With the rapid advances of computing technology, finite element analysis is assuming more important role in engineering practice. The advantage of finite element analysis lies in its ability to accommodate complex soil stratigraphy and its potential for solving three-dimensional soil-structure interaction problems. However, to be successfully used in practical design, the soil model should be simple and can be easily calibrated by conventional field or lab testing. On the other hand, the model should be able to realistically capture the most important aspects of soil-structure nonlinearities. Since it was first introduced, Drucker-Prager type model has been successfully adopted in analysis of geomaterials due to its relative simplicity<sup>[1-2]</sup>. For example, a comprehensive nonlinear finite element analysis of vertically loaded pile was carried out using ABAQUS TM. In this study, the surrounding soil was modeled using extended Drucker-Prager plasticity while the piles were modeled as linearly elastic material. Yang and Jeremi used non-associative Drucker-Prager for cohesionless soil and von Mises criterion for cohesive soil, and developed p-y curves for laterally loaded piles in multi-layered soil profiles<sup>[3-4]</sup>. Although these previous analyses dealt with pile-soil interaction with various degrees of success, detailed information on model assumptions and uncertainties associated with model selection are not available. In the following sections, we describe a parametric study of the various factors associated with simple model simulation.

## 2 MODEL FORMULATION

Pressure-sensitive failure mechanism of soil is represented by a cone-shape yield surface:

$$F = \alpha I_1 + \sqrt{J_2} - Y = 0 \quad (1)$$

where  $I_1$  is the first invariant of stress tensor and  $J_2 = (1/2)S_{ij}S_{ij}$  is the second invariant of deviatoric stress tensor  $S_{ij} = \sigma_{ij} - (1/3)I_1\delta_{ij}$ .  $\alpha$  and  $Y$  are material parameters related to the soil friction angle and the cohesion.

For small strain formulation, strain rate is usually additively decomposed into elastic and plastic components,

$$\dot{\epsilon}_{ij} = \dot{\epsilon}_{ij}^e + \dot{\epsilon}_{ij}^p \quad (2)$$

such that rate form of stress-strain relation can be written as

$$\dot{\sigma}_{ij} = C_{ijkl}(\dot{\epsilon}_{kl}^e - \dot{\epsilon}_{kl}^p) \quad (3)$$

To better describe volumetric behavior of soil, non-associative flow rule is usually adopted. The plastic flow is defined through potential surface  $Q$  with parameter  $\beta$  controlling soil dilatancy,

$$Q = \beta I_1 + \sqrt{J_2} - Y \quad (4)$$

Plastic strain rate is defined normal to the potential surface via

$$\dot{\epsilon}_{ij}^p = \lambda \frac{\partial Q}{\partial \sigma_{ij}} = \lambda \left( \frac{s_{ij}}{2\sqrt{J_2}} + \frac{1}{3}\beta\delta_{ij} \right) \quad (5)$$

where  $\lambda$  is plastic multiplier and can be determined by consistency condition.

### 3 PILE-SOIL INTERACTION

An extended version of the classical isotropic Coulomb friction model is provided in Abaqus for use with all contact analysis. The extensions include an additional limit on the allowable shear stress, anisotropy, and the definition of a “secant” friction coefficient. A special case of friction in Abaqus/Standard is so-called rough friction, where it is assumed that there is no bound on the shear stress; that is, no relative motion can occur as long as the surfaces are in contact. Rough friction is implemented with the Lagrange multiplier method.

In Abaqus/Explicit the relative motion in the absence of slip is always equal to zero if the kinematic contact algorithm is used with hard tangential surface behavior; at the end of each increment the positions of the nodes on the contact surfaces are adjusted so that the relative motion is zero. With the penalty contact algorithm in Abaqus/Explicit the relative motion in the absence of slip is equal to the friction force divided by the penalty stiffness.

Pile-Soil interaction is stimulated by Mohr-Coulomb formula.

$$\tau_{lim} = \mu \cdot P + b, \quad |\tau| \leq \tau_{lim} \quad (6)$$

where:  $\tau_{lim}$ —critical sliding shear stress;  
 $\tau$ —equivalent shear stress;  
 $\mu$ —friction coefficient;  
 $P$ —contact normal stress;  
 $b$ —contact cohesion.

### 4 ENGINEERING APPLICATION

To demonstrate the capacity of Drucker-Prager model prediction, consider a 0.75 meter circular concrete pier installed to 20 meter of depth in sand. The pile is vertically loaded on its top under drained condition. A finite element model was developed to simulate the pile behavior. Due to axisymmetry of this problem, only one quarter of the cross section is meshed using axisymmetric bilinear element. The mesh, shown in Figure 1. The base of the mesh is fixed and only vertical movement is allowed along right hand side of the mesh and the axis of symmetry (the left hand side of the mesh). The pile is modeled with linearly elastic elements with a Young’s modulus  $E_p = 20\ 106\ \text{kPa}$  and Poisson’s ratio  $\nu_p = 0.1$ . Elastic parameter and density are defined and for soil by elastic, density and Mohr coulomb. Where  $c = 45\ \text{kPa}$  and friction and dilation angle are equal to zero. After assigning sections and meshing each

Figure 1. Finite element mesh.

Figure 2. Diagram of the vertical stress ( $S_2$ ).

part, two parts are assembled together and an interface is created between pipe and soil. Tangential and normal behavior is used for interface. And friction coefficient is 0.6. There is an initial step where the boundary conditions are defined and then a geostatic step where the gravity load is applied to whole model. the pile is constrained in the three direction ( $U1 = U2 = U3 = 0$ ) at the Geostatic step and then release it in the next step. Analysis is separated in three different steps. Step 1: Geostatic. In this step, we consider only the soil element and deactivated the pipe element as mentioned above. Step 2: Static, General. In this step you can activate the interface between pipe and soil by released the pipe. Step 3: Static, General. In this step, you

can perform loading, displacement. etc. dam shell is 21.7 cm. When the slaking deformation is considered, the uplift move diminishes manifestly, and the maximal value is only 13.4 m, which obviously contains the weakening impact caused by the slaking deformation.

When single pile is loaded by 1400 KN, from Figure 2, the stress of piles and soils decreases gradually with the increase of depth, which is in accordance with the general Soil-pile interaction law. From Figure 3, Figure 4, and Figure 5, it can be seen that the pile end soil is effected in vertical 6D depth and in radial 2D depth. Besides, Plastic zone  $r_p = 1.44$  can be seen. For the soil is not damaged, the bearing capacity of single pile is approximately 1400 KN.

In general, pile end resistance give full play which need large displacement. Pile end cone angle

Figure 5. Diagram of plastic zone for pile end.

Figure 3. Diagram of the radial stress ( $S_x$ ).

Figure 4. The vertical displacement contour after completing the dam construction (m).

is smaller, pile end resistance need greater displacement value to give play. This shows that the pile end cone angle is smaller, the pile tip penetration is more conducive, the radial displacement of pile end soil is smaller, namely the region of influence is smaller on pile end bearing layer; The load transmission process can be divided into the following four stages of of pile under step loading process: ① Pile side friction playing ② Pile side friction and end resistance of the pile sharing ③ pile end resistance bearing ④ Pile bearing stratum plastic state is reached or the pile structure damage.

## 5 CONCLUSIONS

Drucker-Prager type plastic model has been developed to simulate vertically loaded pile response in cohesionless soil. Pile-soil interaction is analyzed by Mohr-Coulomb formula. Based on the results of the analysis, the bearing capacity of single pile and the scope of plastic zone can be got. Those results gained by numerical method may provide reference to pile engineering practice.

# Analysis of dynamic responses of loess slope by compaction loads

Zhijie Sun, Jianbin Zhao & Lishan Dong

*Key Laboratory of Highway Construction and Maintenance Technology in Loess Region,  
Ministry of Transport, P.R. China*

*Shanxi Key Laboratory of Highway Construction and Maintenance Technology in Loess Region,  
Shanxi Transportation Research Institute, Taiyuan, China*

**ABSTRACT:** Through the project example, the finite element software GTS was used to simulate change rules of dynamic properties and dynamic response of expressway loess slopes on compaction loads. The results showed that the amplitude of the dynamic response for loess slopes in dynamic compaction fades out rapidly with the impact loading effect, and the amplitude of the horizontal dynamic response and the amplitude vertical dynamic response take place at the same time. The slope has an amplification effect on the horizontal dynamic response, and the amplification effect increases with the increase in the height of slope. The amplification phenomenon of amplitude vibration in the upper and central parts of the slope surface is obvious compared with the internal part of the slope. In conclusion, the dynamic response amplitude fades out with the depth increasing, the horizontal dynamic response amplitude decays faster than the vertical dynamic response amplitude, the decay rate decreases with the increase in the height of slope.

**Keywords:** compaction; soil slope; dynamic performance; acceleration; displacement

## 1 INTRODUCTION

The construction of dynamic compaction will produce a larger vibration shock wave, which will bring certain harm on the construction site and nearby buildings. The commonly used “Blasting Safety Regulations” [6] evaluate the dynamic environment caused by dynamic compaction, and then determine the safe construction distance. It will draw different conclusions according to the energy of dynamic compaction, shape of hammer, site conditions and the shape of adjacent structures, which different engineering projects need to be determined individually according to the corresponding conditions. In recent years, scholars at home and abroad conducted a series of research work for the compaction of the adjacent building by dynamic compaction, and proposed the safety distance of vibration and formula of vibration attenuation [7–12].

But the study on the construction of loess engineering on the condition of dynamic compaction, especially the dynamic response problem of the adjacent slope, is scarce.

Therefore, the numerical simulation was used to simulate the dynamic response on the condition of the dynamic compaction in this paper, and the rules of dynamic parameters such as acceleration, velocity and displacement were studied, so as to provide instructive reference for

the engineering design and construction in loess regions.

## 2 PROJECT OVERVIEW

Taking the natural loess slopes in the Xiangnnng area as the investigation object, focusing on the survey and statistics of loess slope height around 20 M, as shown in [Figure 1](#), with its lithology being loess  $Q_3$ , the slope can be approximated as linear, undisturbed loess of different parts in slope, which were considered to perform an indoor physical mechanics parameter test.

Figure 1. Loess slope.

### 3 COMPUTATIONAL MODEL

The dynamic model of the slope focuses on the simulations of boundary conditions. Under the condition of static analysis, boundary conditions of the infinite soil model can be established to some extent; however, for dynamic analysis, the general boundary conditions, which are the same as the static boundary conditions, can cause large errors due to the wave of reflection. So, in order to resolve this issue, we used the viscous boundary condition proposed in 1972 by Lysmer and Wass (Viscous Boundary). The finite element model is shown in Figure 2.

The material used in the model was the loess soil of the Xiangning section in the Jixian-Hejin expressway. The loess soil is mainly Q3 loess, and the mechanical properties are according to indoor physical tests. The physical and mechanical indices of the average value are listed in Table 1.

In the single-point tamping energy 600 kN·m model, the tamping load is simulated to the node dynamic load, and the compaction process is simulated to the dynamic load function by time history.

For the dynamic response law analysis of the slope in different parts and at different soil depths, the profile is set, as shown in Figure 4, and the feature points on the slope are used to research on the dynamic characteristics under compaction

Figure 2. Dynamic finite element model.

load disturbances. The slope geometry and monitoring sections are shown in Figure 3.

### 4 DYNAMIC ANALYSIS RESULTS

In order to study the dynamic response of loess slope caused by compaction vibration, and to investigate on the dynamic responses of the surface of the slope and different positions inside the slope and slope into different positions, the analysis of the loess slope stability on the dynamic compaction effect is carried out. The analysis focuses on acceleration, velocity and displacement, monitoring sites, mainly including the top, middle and toe of the slope, surface and below about 10 m depth of the slope.

#### 4.1 Typical waveforms

To reveal the effect of the tamping load on the slope, we select the monitoring section II with H/2 height of the slope. Extraction of the acceleration, velocity and displacement time history curves in horizontal and vertical directions is performed. The curves are shown in Figure 4.

In Figure 4, the vibration variation of monitoring point in the middle of the slope is that the acceleration, velocity and displacement of both horizontal and vertical directions occurs with compaction load and rapid decay with the disappearance of compaction load. In a period ( $T = 0.1$  s) of compaction load, the horizontal dynamic response and vertical dynamic response occur in the same time.

Due to the impact load applied to the vertical direction, the vertical dynamic amplitude is larger than the horizontal dynamic amplitude. The vertical acceleration amplitude of the monitoring point is  $0.4 \text{ m/s}^2$ , and the horizontal acceleration amplitude of the monitoring point is  $0.26 \text{ m/s}^2$ . The vertical velocity amplitude of the monitoring point is  $0.75 \text{ mm/s}$ , and the horizontal velocity amplitude of the monitoring point is  $0.34 \text{ mm/s}$ . The vertical displacement amplitude of the monitoring point is  $0.17 \text{ mm}$ , and the horizontal displacement amplitude of the monitoring point is  $0.085 \text{ mm}$ .

#### 4.2 Variation of acceleration along the surface of the slope

The acceleration amplitude curves in horizontal and vertical directions with the height of the slope are shown in Figure 5. Hmax represents the horizontal acceleration amplitude, and Vmax the vertical acceleration amplitude.

The vertical acceleration amplitude decreases gradually from the toe of the slope to the shoulder of the slope, whose maximum vertical acceleration amplitude is  $0.61 \text{ m/s}^2$  in the toe of the slope. The attenuation amplitude is maximum in the range of 5 m of slope height. The horizontal acceleration

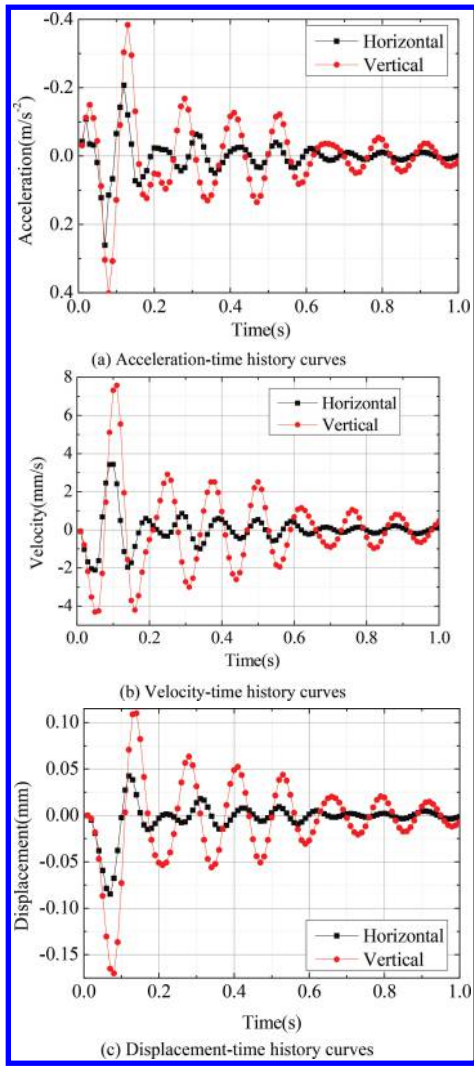

Figure 4. Dynamic response time curves in section II.

Figure 5. The acceleration amplitude curves along the slope surface.

amplitude increases from the toe of the slope to the shoulder of the slope, whose maximum horizontal acceleration amplitude is  $0.37 \text{ m/s}^2$  in the slope shoulder. The slope has an amplification effect on the horizontal acceleration.

#### 4.3 Variation of acceleration along inside of the slope

The variation curves of acceleration amplitude along the depth in the toe of the slope are shown in Figure 6.

As shown in Figure 6, the horizontal acceleration amplitude and vertical acceleration amplitude were gradually increased with the depth increasing in the range below 7 m depth of the slope surface. When the depth is more than 7 m, the vertical acceleration attenuates and the horizontal acceleration continues to increase.

The horizontal acceleration amplitude increases from the toe of the slope to the shoulder of the slope, whose maximum horizontal acceleration amplitude is  $0.17 \text{ m/s}^2$  in the slope shoulder. The soil depth has an amplification effect on the toe of the horizontal acceleration.

From the surface to the inside of 10 m depth of the slope, the vertical acceleration amplitude ranges from  $0.55 \text{ m/s}^2$  to  $0.68 \text{ m/s}^2$ , and the horizontal acceleration amplitude ranges from  $0.11 \text{ m/s}^2$  to  $0.17 \text{ m/s}^2$ .

The variation curves of the acceleration amplitude along the depth in the middle of the slope are shown in Figure 7.

As shown in Figure 7, from the surface to the inside of 6 m depth of the slope, the horizontal acceleration amplitude and vertical acceleration amplitude were gradually decreased with the depth increasing. When the depth is more than 6 m, the horizontal acceleration attenuation continues to decrease, while the vertical acceleration increases slowly.

From the surface to the inside of 10 m depth of the slope, the vertical acceleration amplitude ranges from  $0.36 \text{ m/s}^2$  to  $0.40 \text{ m/s}^2$ , and the horizontal acceleration amplitude ranges from  $0.084 \text{ m/s}^2$  to  $0.26 \text{ m/s}^2$ .

Figure 6. The acceleration curves of the toe of the slope.

Figure 7. The acceleration curves of the middle of the slope.

Figure 8. The acceleration curves of the shoulder of the slope.

The variation curves of the acceleration amplitude along the depth in the shoulder of the slope are shown in Figure 8.

As shown in Figure 8, the acceleration law of the slope shoulder is different from that of the toe and middle of the slope, with both horizontal and vertical acceleration decreasing with the increasing depth.

From the surface to the inside of 10 m depth of the slope, the vertical acceleration amplitude ranges from 0.30 m/s<sup>2</sup> to 0.34 m/s<sup>2</sup>, and the horizontal acceleration amplitude ranges from 0.19 m/s<sup>2</sup> to 0.36 m/s<sup>2</sup>.

## 5 CONCLUSION

Through the study on the change rules of dynamic properties and dynamic response of expressway loess slopes on compaction loads, the research results show that:

1. The amplitude of dynamic response for loess slope in dynamic compaction fades out rapidly with the impact loading effect, and the amplitude of horizontal dynamic response and the amplitude vertical dynamic response take place in the same time.
2. The slope has an amplification effect on the horizontal dynamic response, and the amplification effect increases with the increase in the height of the slope.

3. The amplification phenomenon of amplitude vibration in the upper and central parts of the slope surface is obvious compared with the internal part of the slope. The dynamic response amplitude fades out with the depth increasing, the horizontal dynamic response amplitude decays faster than the vertical dynamic response amplitude, and the decay rate decreases with the increase in the height of the slope.

The simulation results are helpful to reveal the dynamic response rules of loess slope under the condition of dynamic compaction, which provide instructive reference for the engineering design and construction in loess regions.

**ABSTRACT:** A new type of composite column called concrete-cored sand-gravel column has been proposed, which consists of a prefabricated inner pile and surrounding sand-gravel materials. The engineering practices have demonstrated that the concrete-cored sand-gravel columns can be used to improve bearing capacity and accelerate consolidation of soft soil effectively. To theoretically analyze the characteristics of consolidation of the composite foundation, the equal strain assumption is modified and the differential equations for consolidation of the composite foundation under time-dependent loading were established considering both horizontal and vertical flows. The general analytical solutions for consolidation equations were derived, and the solutions under multi-staged linear loading were developed. To verify the validity of the proposed solutions, a case history of embankment supported by concrete-cored sand-gravel columns was analyzed. The predicted ground settlements at the centerline of embankment base agreed well with the field data.

**Keywords:** concrete-cored sand-gravel column; composite foundation; time-dependent loading; consolidation; analytical solution

### 1 INTRODUCTION

Due to the rapid development of soft soil improvement technique, some new ground improvement methods have been proposed, such as soil-cement columns combining with PVDs (Ye et al. 2012, 2013), stiffened deep cement mixing piles (Ye & Cai 2012) and concrete-cored sand-gravel columns (Chen et al. 2007, Tang et al. 2010). The concrete-cored sand-gravel column is composed of a prefabricated inner concrete pile and surrounding sand-gravel materials. The prefabricated inner piles can be used to improve bearing capacity of the composite foundation, and the sand-gravel annulus can shorten drainage paths and accelerate consolidation of subsoil.

The concrete-cored sand-gravel columns have been used in practical projects successfully. Chen et al. (2007) and Tang et al. (2010) presented a series of field test results in Zhen-Li highway, China, including pile-soil stress ratio, ground settlement and differential settlement between pile and soil, lateral displacement, excess pore water pressure, etc. Cheng et al. (2007) studied the embankment strengthening effects by the concrete-cored sand-gravel columns in Shenzhen River estuary, China.

Limited theoretical researches of consolidation of concrete-cored sand-gravel columns improved

composite foundation have been conducted so far. Yu et al. (2012) proposed analytical solutions for low-grade concrete-cored sand-gravel column composite foundation. Shi et al. (2013) derived the theoretical solutions for the concrete-cored sand-gravel column composite foundation, considering both radial and vertical flows within the sand-gravel annulus.

For composite foundation improved by granular columns (Han & Ye 2001, 2002) or flexible columns (Ye et al. 2012), the upward penetration into cushion and downward penetration into substratum of columns are inconsiderable due to small modulus difference between columns and subsoil, so the application of equal strain assumption between columns and subsoil is reasonable. However, the equal strain assumption is unsuitable for the rigid pile composite foundation because of considerable penetration of rigid piles caused by great modulus difference between rigid piles and subsoil. The prefabricated inner pile belongs to rigid pile. Thus, the analytical solutions of concrete-cored sand-gravel columns improved composite foundation derived by Yu et al. (2012) and Shi et al. (2013) based on equal strain assumption are inappropriate.

The equal strain assumption is modified for the concrete-cored sand-gravel column composite

foundation in this study. The analytical solutions of concrete-cored sand-gravel columns improved composite foundation under time-dependent loading are derived based on the modified equal strain assumption. A history case is analyzed to verify the validity of the proposed analytical solutions, and the predicted ground settlements agree well with the field measurements.

## 2 CONSOLIDATION OF THE COMPOSITE FOUNDATION

### 2.1 Consolidation problem

The schematic diagram of the concrete-cored sand-gravel column composite foundation is shown in Figure 1. The consolidation model of the composite foundation is axisymmetric and cylindrical coordinates are adopted, in which  $P(t)$  = time-dependent loading;  $H$  = improvement depth of concrete-cored sand-gravel column;  $r_e$ ,  $r_s$ ,  $r_w$  and  $r_c$  = radius of influential zone, smear zone, sand-gravel annulus and inner pile, respectively;  $E_c$ ,  $E_s$ ,  $E_w$  and  $E_p$  = modulus of cushion, subsoil, sand-gravel annulus and inner pile, respectively;  $k_h$  and  $k_s$  = horizontal conductivity of undisturbed zone and smear zone, respectively;  $k_w$  and  $k_v$  = vertical conductivity of sand-gravel annulus and subsoil, respectively.

The main assumptions made in the analysis are summarized below:

1. Modified equal strain assumption and only vertical strain are considered;
2. The soil is fully saturated, and the water flows obey the Darcy's law;

Figure 1. Schematic diagram of calculation model.

3. The permeability and modulus of subsoil are assumed to be constant during consolidation.

### 2.2 Modified equal strain assumption

Li et al. (2014) developed a theoretical solution of consolidation of rigid pile composite foundation, which took the modulus of cushion, pile and subsoil into consideration. Based on the research results of Li et al. (2014), the equal strain assumption for the concrete-cored sand-gravel column composite foundation is modified.

In this study, the concrete-cored sand-gravel columns are sat on hard substratum, and the penetration of column tip into substratum is not considered. According to deformation compatibility, the compression of subsoil in improvement depth equals to upward penetration into cushion and compression of inner pile, i.e.

$$S_S = S_P + S_T \quad (1)$$

where  $S_S$  = compression of subsoil in improvement depth;  $S_P$  = compression of inner pile shaft;  $S_T$  = upward penetration into cushion.

The upward penetration of inner pile into cushion can be calculated using vertical surface displacement of rigid circle footing on semi-infinite mass by Poulos & Davis (1974):

$$S_T = \frac{\pi}{2} (1 - \nu_c^2) \frac{P_a r_p}{E_c} \quad (2)$$

where  $E_c$ ,  $\nu_c$  = compression modulus and Poisson's ratio of cushion, respectively;  $p_a$  = vertical pressure on inner pile head;  $r_p$  = radius of inner pile.

The compression of inner pile shaft can be computed by

$$S_P = \int_0^H \frac{p(z)}{E_p} dz \quad (3)$$

where  $p(z)$  = vertical stress along pile shaft; and  $E_p$  = elastic modulus of inner pile.

When side friction of pile is not taken into consideration,  $p(z)$  is a constant value along pile shaft, i.e.

$$p(z) = p_a \quad (4)$$

Assuming that only positive side friction  $\tau$  is considered, and  $\tau$  is constant along pile shaft,

$$p(z) = p_a - \frac{\tau \cdot 2z}{r_p} \quad (5)$$

Since the distribution of side friction of pile is very complicated, Equation 6 is adopted in this

study to simplify the calculation of compression of inner pile.

$$S_p = \psi \frac{P_a}{E_p} H \quad (6)$$

where  $\psi$  is an empirical coefficient relating to overloading, length and modulus of pile, and site conditions, etc.

Combining Equations 1–2, 6 yields

$$\varepsilon_v = \frac{S_s}{H} = \frac{S_p + S_T}{H} = \psi \frac{P_a}{E_p} + \frac{\pi}{2} (1 - \nu_c^2) \frac{P_a r_p}{H E_c} \quad (7)$$

where  $\varepsilon_v$  = volumetric strain of subsoil.

As a consequence, the equivalent modulus of inner pile can be defined as

$$E_p^{eq} = \frac{P_a}{\varepsilon_v} = \left[ \frac{\psi}{E_p} + \frac{\pi}{2} (1 - \nu_c^2) \frac{r_p}{H E_c} \right]^{-1} \quad (8)$$

Due to high strength of inner concrete pile, the compression of pile is insignificant compared to upward penetration, and the influence of  $\psi$  on equivalent modulus of inner pile is unimportant. As a result, the value of  $\psi$  can be taken as unity for simplicity. The detailed discussions about  $\psi$  can be seen later.

Thus, the equal strain assumption for the concrete-cored sand-gravel column composite foundation can be expressed as

$$\frac{\bar{\sigma}_s - \bar{u}_s}{E_s} = \frac{\bar{\sigma}_w - u_w}{E_w} = \frac{\bar{\sigma}_p}{E_p^{eq}} = \varepsilon_v \quad (9)$$

In the above equation  $\bar{\sigma}_s, \bar{\sigma}_w, \bar{\sigma}_p$  = average total additional stress at any depth within subsoil, sand-gravel annulus and inner pile, respectively;  $\bar{u}_s$  = average excess pore water pressure in subsoil at any depth;  $u_w$  = excess pore water pressure within sand-gravel annulus at any depth.

### 2.3 Deduction of differential equations

At any time, the subsoil, the sand-gravel annulus and the inner pile carry the applied loads, i.e.

$$\pi(r_c^2 - r_w^2) \bar{\sigma}_s + \pi(r_w^2 - r_p^2) \bar{\sigma}_w + \pi r_p^2 \bar{\sigma}_p = \pi r_c^2 P(t) \quad (10)$$

The partial differential equations in subsoil can be expressed as

$$-\frac{k_s}{\gamma_w} \left( \frac{1}{r} \frac{\partial u_m}{\partial r} + \frac{\partial^2 u_m}{\partial r^2} \right) - \frac{k_v}{\gamma_w} \frac{\partial^2 \bar{u}_s}{\partial z^2} = \frac{\partial \varepsilon_v}{\partial t} \quad r_w \leq r \leq r_s \quad (11a)$$

$$-\frac{k_h}{\gamma_w} \left( \frac{1}{r} \frac{\partial u_n}{\partial r} + \frac{\partial^2 u_n}{\partial r^2} \right) - \frac{k_v}{\gamma_w} \frac{\partial^2 \bar{u}_s}{\partial z^2} = \frac{\partial \varepsilon_v}{\partial t} \quad r_s \leq r \leq r_c \quad (11b)$$

where  $u_m, u_n$  = excess pore water pressure at any point in smear zone and undisturbed zone, respectively;  $\gamma_w$  = unit weight of water.

The average excess pore water pressures of the subsoil and the composite foundation, respectively, can be defined as follows:

$$\bar{u}_s = \frac{1}{\pi(r_c^2 - r_w^2)} \left[ \int_{r_w}^{r_s} 2\pi r u_m dr + \int_{r_s}^{r_c} 2\pi r u_n dr \right] \quad (12)$$

$$\begin{aligned} \bar{u} &= \frac{1}{\pi(r_c^2 - r_p^2)} \left[ \int_{r_p}^{r_w} 2\pi r u_w dr + \int_{r_w}^{r_s} 2\pi r u_m dr \right] \\ &= \frac{1}{(n^2 - m^2)} \left[ (1 - m^2) u_w + (n^2 - 1) \bar{u}_s \right] \end{aligned} \quad (13)$$

where  $n = r_c/r_w$ ;  $m = r_p/r_w$ .

Xie et al. (2009) pointed out that the quantity of water flowing into the column through the disturbed zone is not equal to that flowing out from the column and the difference between them is equal to the volume change of the column. Thus, for the concrete-cored sand-gravel composite foundation,

$$-\frac{2}{(1 - m^2)} \frac{1}{r_w} \left( \frac{k_s}{\gamma_w} \frac{\partial u_m}{\partial r} \right) \Big|_{r=r_w} - \frac{k_w}{\gamma_w} \frac{\partial^2 u_w}{\partial z^2} = \frac{\partial \varepsilon_v}{\partial t} \quad (14)$$

The boundary conditions and initial conditions of Equations 11a, b are described as follows:

$$\text{As } r = r_c, \quad \frac{\partial u_n}{\partial r} = 0; \quad (15a)$$

$$\text{As } r = r_s, \quad u_m = u_n, \quad \frac{k_s}{\gamma_w} \frac{\partial u_m}{\partial r} = \frac{k_h}{\gamma_w} \frac{\partial u_n}{\partial r}; \quad (15b)$$

$$\text{As } r = r_w, \quad u_m = u_w; \quad (15c)$$

$$\text{As } z = 0, \quad \bar{u} = 0; \quad (15d)$$

$$\text{As } z = H, \quad \frac{\partial \bar{u}}{\partial z} = 0; \quad (15e)$$

$$\text{As } t = 0, \quad \bar{u} = \sigma_0(z); \quad (15f)$$

where  $\sigma_0(z)$  = initial excess pore water pressure at depth  $z$ .

Let  $Y_1 = E_p^{eq}/E_s$  and  $Y_2 = E_w/E_s$ , combining Equations 9–10, substituting Equation 13 and getting derivative with respect to time  $t$  yields

$$\frac{\partial \mathcal{E}_v}{\partial t} = \frac{n^2 \frac{dP(t)}{dt} - (n^2 - m^2) \frac{\partial \bar{u}}{\partial t}}{\left[ m^2 Y_1 + (1 - m^2) Y_2 + (n^2 - 1) \right] E_s} \quad (16)$$

Integrating Equations 11a, b and using the boundary conditions 15a, b and c, the following equations can be derived

$$\frac{\partial u_m}{\partial r} = \frac{\gamma_w}{2k_s} \left( \frac{\partial \mathcal{E}_v}{\partial t} + \frac{k_v}{\gamma_w} \frac{\partial^2 \bar{u}_s}{\partial z^2} \right) \left( \frac{r_e^2}{r} - r \right) \quad (17)$$

$$u_m = \frac{\gamma_w}{2k_s} \left( \frac{\partial \mathcal{E}_v}{\partial t} + \frac{k_v}{\gamma_w} \frac{\partial^2 \bar{u}_s}{\partial z^2} \right) \left( r_e^2 \ln \frac{r}{r_w} - \frac{r^2 - r_w^2}{2} \right) + u_w \quad (18a)$$

$$u_n = \left[ \frac{\gamma_w}{2k_h} \left( r_e^2 \ln \frac{r}{r_s} - \frac{r^2 - r_s^2}{2} \right) + \frac{\gamma_w}{2k_s} \left( r_e^2 \ln \frac{r_s}{r_w} - \frac{r_s^2 - r_w^2}{2} \right) \right] \left( \frac{\partial \mathcal{E}_v}{\partial t} + \frac{k_v}{\gamma_w} \frac{\partial^2 \bar{u}_s}{\partial z^2} \right) + u_w \quad (18b)$$

Substituting Equations 18a, b into Equation 12 yields

$$\bar{u}_s = \frac{\gamma_w r_e^2 F_a}{2k_h} \left( \frac{\partial \mathcal{E}_v}{\partial t} + \frac{k_v}{\gamma_w} \frac{\partial^2 \bar{u}_s}{\partial z^2} \right) + u_w \quad (19)$$

In the above equation

$$F_a = \left( \ln \frac{n}{s} + \frac{k_h}{k_s} \ln s - \frac{3}{4} \right) \frac{n^2}{n^2 - 1} + \frac{s^2}{n^2 - 1} \left( 1 - \frac{k_h}{k_s} \right) \left( 1 - \frac{s^2}{4n^2} \right) + \frac{k_h}{k_s} \frac{1}{n^2 - 1} \left( 1 - \frac{1}{4n^2} \right) \quad (20)$$

where  $s = r_s/r_w$ .

By substituting Equation 17 into Equation 14, the following equation can be obtained

$$-\frac{n^2 - 1}{n^2 - m^2} \frac{k_v}{\gamma_w} \frac{\partial^2 \bar{u}_s}{\partial z^2} - \frac{1 - m^2}{n^2 - m^2} \frac{k_w}{\gamma_w} \frac{\partial^2 u_w}{\partial z^2} = \frac{\partial \mathcal{E}_v}{\partial t} \quad (21)$$

Substituting Equation 13 into Equation 19 and Equation 21, respectively, the following equations can be derived

$$\frac{\partial \mathcal{E}_v}{\partial t} = \frac{n^2 - m^2}{n^2 - 1} \frac{2k_h}{\gamma_w r_e^2 F_a} (\bar{u} - u_w) - \frac{n^2 - m^2}{n^2 - 1} \frac{k_v}{\gamma_w} \frac{\partial^2 \bar{u}}{\partial z^2} + \frac{1 - m^2}{n^2 - 1} \frac{k_v}{\gamma_w} \frac{\partial^2 u_w}{\partial z^2} \quad (22)$$

$$\frac{\partial \mathcal{E}_v}{\partial t} = -\frac{k_v}{\gamma_w} \frac{\partial^2 \bar{u}}{\partial z^2} - \frac{1 - m^2}{n^2 - m^2} \frac{k_w - k_v}{\gamma_w} \frac{\partial^2 u_w}{\partial z^2} \quad (23)$$

Combining Equations 22–23, and then substituting the result into Equation 16, Equation 16 can be solved as

$$u_w = \bar{u} - A \frac{\partial^2 \bar{u}}{\partial z^2} + B \frac{\partial \bar{u}}{\partial t} - C \frac{dP(t)}{dt} \quad (24)$$

In the above equation

$$A = \frac{\gamma_w r_e^2 F_a}{2k_h} \frac{k_w}{k_w - k_v} \frac{k_v}{\gamma_w} \quad (25)$$

$$B = \frac{r_e^2 F_a}{2C_h} \left( \frac{n^2 - 1}{n^2 - m^2} + \frac{k_v}{k_w - k_v} \right) \times \frac{n^2 - m^2}{m^2 Y_1 + (1 - m^2) Y_2 + (n^2 - 1)} \quad (26)$$

$$C = \frac{r_e^2 F_a}{2C_h} \left( \frac{n^2 - 1}{n^2 - m^2} + \frac{k_v}{k_w - k_v} \right) \times \frac{n^2}{m^2 Y_1 + (1 - m^2) Y_2 + (n^2 - 1)} \quad (27)$$

where  $C_h = k_h E_s / \gamma_w$  is coefficient of consolidation of subsoil in the horizontal direction.

Substituting Equations 16, 24 into Equation 23 yields

$$D \frac{\partial^4 \bar{u}}{\partial z^4} - E \frac{\partial^3 \bar{u}}{\partial z^2 \partial t} - F \frac{\partial^2 \bar{u}}{\partial z^2} + G \frac{\partial \bar{u}}{\partial t} = \frac{dP(t)}{dt} \quad (28)$$

In the above equation

$$D = \frac{k_w k_v E_s r_e^2 F_a}{2\gamma_w k_h} \frac{1 - m^2}{n^2 - m^2} \frac{m^2 Y_1 + (1 - m^2) Y_2 + (n^2 - 1)}{n^2} \quad (29)$$

$$E = \frac{r_e^2 F_a}{2} \frac{k_v}{k_h} \left[ \frac{n^2 - 1}{n^2 - m^2} \left( \frac{k_w}{k_v} - 1 \right) + 1 \right] \frac{1 - m^2}{n^2} \quad (30)$$

$$F = \left[ 1 + \frac{1 - m^2}{n^2 - m^2} \left( \frac{k_w}{k_v} - 1 \right) \right] \times \frac{m^2 Y_1 + (1 - m^2) Y_2 + (n^2 - 1)}{n^2} C_v \quad (31)$$

$$G = \frac{n^2 - m^2}{n^2} \quad (32)$$

where  $C_v = k_v E_s / \gamma_w$  is coefficient of consolidation of subsoil in the vertical direction.

#### 2.4 Analytical solutions

According to the intrinsic function method of non-homogeneous equations, the intrinsic function corresponding to Equation 28 is  $\sin(Mz/H)$  where

$$M = (2k + 1)\pi/2, k = 0, 1, 2 \dots$$

In Equation 28,  $dP(t)/dt$  can be developed as the Fourier series at  $[0, H]$  on the basis of the intrinsic function

$$\frac{dP(t)}{dt} = \sum_{k=0}^{\infty} f_k(t) \sin\left(\frac{M}{H}z\right) \quad (33)$$

In the equation

$$f_k(t) = \frac{\int_0^H P'(t) \sin\left(\frac{M}{H}z\right) dz}{\int_0^H \sin^2\left(\frac{M}{H}z\right) dz} = \frac{2}{M} P'(t). \quad (34)$$

Using the intrinsic function method of non-homogeneous equations, the solution to Equation 28 can be assumed to have the following form, which satisfies boundary conditions 15d, e.

$$\bar{u} = \sum_{k=0}^{\infty} V_k(t) \sin\left(\frac{M}{H}z\right) \quad (35)$$

Substituting Equations 33, 35 into Equation 28,  $V_k(t)$  can be derived as

$$V_k(t) = \left\{ \frac{2}{M} \int_0^t P'(\tau) e^{\beta_m \tau} d\tau + C_1 \right\} e^{-\beta_m t} \quad (36)$$

where  $\beta_m = [D(M/H)^4 + F(M/H)^2]/[E(M/H)^2 + G]$ ;  $C_1 =$  arbitrary constant.

Thus, the solution to Equation 28 can be obtained as

$$\bar{u} = \sum_{k=0}^{\infty} \left\{ \frac{2}{M} \int_0^t P'(\tau) e^{\beta_m \tau} d\tau + C_1 \right\} \sin\left(\frac{M}{H}z\right) e^{-\beta_m t} \quad (37)$$

Using initial condition 15f, and the orthogonality of the Fourier series, the average excess pore water pressure  $\bar{u}$  can be expressed as

$$\bar{u} = \sum_{k=0}^{\infty} \sin\left(\frac{M}{H}z\right) e^{-\beta_m t} \left\{ \frac{2}{H} \int_0^H \sigma_0(l) \sin\left(\frac{M}{H}l\right) dl + \frac{2}{M} \left[ \int_0^t P'(\tau) e^{\beta_m \tau} d\tau - \int_0^t P'(\tau) e^{\beta_m \tau} d\tau \Big|_{t=0} \right] \right\} \quad (38)$$

The overall average degree of consolidation in terms of stress is defined as the ratio of average effective stress at time  $t$  to time  $t = \infty$  in a composite foundation.

$$\bar{U}(t) = \frac{\int_0^H (P_u + \sigma_0(z) - \bar{u}_s - P_0) dz}{\int_0^H (P_u + \sigma_0(z) - P_0) dz} \quad (39)$$

where  $P_0 =$  initial loading;  $P_u =$  ultimate loading.

### 3 SOLUTIONS FOR SPECIAL CASE

The external loading is assumed to vary linearly with time as shown in Figure 2, and can be expressed as

$$P(t) = \begin{cases} R_1 t & 0 \leq t < t_1 \\ \sum_{i=1}^j R_i (t_i - t_{i-1}) + R_{j+1} (t - t_j) & t_j \leq t < t_{j+1} \\ \sum_{i=1}^n \Delta P & t_n \leq t \end{cases} \quad (40)$$

where  $i, j =$  loading stage;  $t_{i-1}, t_i =$  initial time and terminal time of loading stage  $i$ ;  $R_i =$  loading rate at loading stage  $i$ ;  $\sum \Delta P =$  accumulated value of loading at all stages;  $n =$  the last loading stage. The initial excess pore water pressure  $\sigma_0(z)$  is zero.

By substituting Function 40 into Equations 38 and 39, the solutions of average excess pore water

Figure 2. Multi-staged linear loading.

pressure and average degree of consolidation under multi-staged linear loading can be obtained.

As  $0 \leq t < t_1$ ,

$$\bar{u} = \sum_{k=0}^{\infty} \frac{2}{M} \sin\left(\frac{M}{H} z\right) \frac{R_1}{\beta_m} (1 - e^{-\beta_m t}) \quad (41)$$

$$\bar{U}(t) = \frac{1}{\sum \Delta P} \left[ R_1 t - \sum_{k=0}^{\infty} \frac{2}{M^2} \frac{R_1}{\beta_m} (1 - e^{-\beta_m t}) \right] \quad (42)$$

As  $t_j \leq t < t_{j+1}$ ,

$$\bar{u} = \sum_{k=0}^{\infty} \frac{2}{M} \frac{1}{\beta_m} \sin\left(\frac{M}{H} z\right) e^{-\beta_m t} \cdot \left[ \sum_{i=1}^j R_i (e^{\beta_m t_i} - e^{\beta_m t_{i-1}}) + R_{j+1} (e^{\beta_m t} - e^{\beta_m t_j}) \right] \quad (43)$$

$$\bar{U}(t) = \frac{1}{\sum \Delta P} \left\{ \left[ \sum_{i=1}^j R_i (t_i - t_{i-1}) + R_{j+1} (t - t_j) \right] - \sum_{k=0}^{\infty} \frac{2}{M^2} \frac{1}{\beta_m} e^{-\beta_m t} \right\} \cdot \left[ \sum_{i=1}^j R_i (e^{\beta_m t_i} - e^{\beta_m t_{i-1}}) + R_{j+1} (e^{\beta_m t} - e^{\beta_m t_j}) \right] \quad (44)$$

As  $t \geq t_n$ ,

$$\bar{u} = \sum_{k=0}^{\infty} \frac{2}{M} \frac{1}{\beta_m} \sin\left(\frac{M}{H} z\right) e^{-\beta_m t} \sum_{i=1}^n R_i (e^{\beta_m t_i} - e^{\beta_m t_{i-1}}) \quad (45)$$

$$\bar{U}(t) = 1 - \frac{\sum_{k=0}^{\infty} \frac{2}{M^2} \frac{1}{\beta_m} e^{-\beta_m t} \sum_{i=1}^n R_i (e^{\beta_m t_i} - e^{\beta_m t_{i-1}})}{\sum \Delta P} \quad (46)$$

## 4 CASE APPLICATION

The field experiment described by Chen et al. (2007) and Tang et al. (2010) was conducted at stations K63 + 046 – K63 + 066 on the Zhen-Li expressway in Jiangsu Province, China. The soft soil was improved by the concrete-cored sand-gravel columns, which were installed a triangular pattern at a spacing of 2.1 m and a depth of 20 m. The C20 concrete was used to prefabricate the square inner piles with cross-sectional dimensions of 200 mm × 200 mm. The outer diameter of the sand-gravel annulus was 0.5 m. The gravel cushion was 0.5 m thick including a layer of geo-grid. The physical and mechanical properties of soils at the site are listed in Table 1. Section K63 + 056 was taken as the monitoring cross section. The loading process and instrumentation were introduced by Chen et al. (2007) and Tang et al. (2010).

Figure 3 shows the steel bar stresses monitored at the center of K63 + 056 cross section. Table 3 lists the compression of inner pile calculated using axial stresses along pile shaft and soil pressures at pile head, respectively. The axial stresses along pile shaft are calculated from steel bar stresses monitored as shown in Figure 3. The value of  $\psi$  is back-calculated by comparing the compression results computed from equations  $S_p = \int_0^H p(z) E_p dz$  and  $S_p = p_a / E_p H$ .

At 112 days when embankment filling is completed, the upward penetration of inner pile into cushion is 78 mm as shown in Table 2, while the compression of inner pile is 5.39 mm; at 269 days, the upward penetration of inner pile into cushion is 112 mm, while the compression of inner pile is only 7.16 mm. It can be seen that the compression of inner pile is far less than the upward penetration into cushion due to high strength of rigid inner pile, thus the effects of compression of inner pile on calculation of composite modulus are insignificant. The value of  $\psi$  converges quickly with time and verges on

Differential settlement/mm	13	63	78	109	112

Table 3. Compression of inner pile.

Time/d	31	61	96	112	133	269
$S_p = \int_0^H \frac{p(z)}{E_p} dz$	2.50	3.39	4.32	5.39	6.38	7.16
$S_p = \frac{p_a}{E_p} H$	0.50	1.56	2.27	3.67	4.74	5.41
$\psi$	5	2.17	1.90	1.47	1.35	1.33

Figure 4. Variation of settlement with time.

unity. Due to the insignificant effects of compression of inner pile and variation trend of  $\psi$ , the value of  $\psi$  can be taken as unity for simplicity when predicting the degree of consolidation of the concrete-cored sand-gravel column composite foundation.

Figure 4 shows a comparison of the calculated results and the measured ground settlements at the center of K63 + 056 cross section. It can be seen that the predicted settlements agree well with the monitored field results, which verifies the validity of the proposed solutions for concrete-cored sand-gravel columns improved composite foundation.

## 5 CONCLUSIONS

The analytical solutions of the concrete-cored sand-gravel column composite foundation under time-dependent loading are derived considering the modified equal strain assumption. The value of  $\psi$  can be taken as unity for simplicity in practical application. The analytical solutions have been used for predicting ground settlements of a history case successfully, which verifies the feasibility and reasonability of the proposed analytical solutions. Only upward penetration of pile into cushion is considered in this study. Both upward penetration into cushion and downward penetration into substratum of pile are expected to be taken into account in the further study.

## Application of the correlation method on the analysis of the influence factor of heading blast vibration

Li Yan

*School of Architecture and Civil Engineering, Chengdu University, Chengdu, Sichuan, China*

**ABSTRACT:** In order to reduce the size of the heading blast vibration strength and control vibration hazard, blasting vibration influence factors on the basis of the Gray Relation Analysis (GRA) are analyzed. At first, vibration velocity is determined, and the main vibration frequency and vibration duration are regarded as the systematic characteristic variables. The total explosive charge, maximum explosive, medicine chamber length, principal piece sewn dosage, segments, blasting pitch, and minimum delay interval time are taken as related factor variables. In combination with heading blast monitoring data of dam foundation in Longbeiwang hydropower station, gray correlation calculation is done. Finally, the results of the systematic characteristic variable correlation degree are sorted and its advantages are analyzed. The order of blasting vibration effect factors is obtained as follows: total dosage and the main segment sewed dosage are the first influence factors, and the second ones are medicine chamber length and the most explosive. In conclusion, the theoretical basis can be provided to control blasting vibration effectively by using the method of GRA to determine the main influencing factors of blasting vibration.

**Keywords:** heading blast; blast vibration revision; Gray Correlation Analysis (GRA); characteristics variables; related factor variable

### 1 INTRODUCTION

The method of chamber blasting is attended by more people with the development of the Engineering construction and energy resources in China. However, the adverse effects are resulted from the influence of blasting vibration on the surrounding environment and structure when blasting is done. The main influential factors of blasting vibration are analyzed to reduce the hazard of blasting vibration effectively. Both the blasting resources and route of transmission are included in these factors. The common action of both factors influences the strength of blasting vibration (Huo 2003, Zhang 2007, Zhang 2005). The total dose, the maximum dose of single segment, the direction of resistance line, segment number of the blasting, the interval time of the segment, hole parameters, and the number of free surface are included in the factor of blasting resources. The distance, altitude difference, and geological condition are included in the route of transmission. Influential level of different factors are analyzed and compared for each factor. The main influential factors are determined, and thus it is prerequisite to control the blasting vibration effectively.

Influential degree of the factors of blasting has been investigated by many researchers at home and abroad. According to the actual data in engineering,

the influence of the total dose and distance from the blasting center on the blasting vibration is analyzed using both linear and nonlinear regression in MATLAB by Zhang Guang Zhou, etc (Zhang 2005). The hierarchical structure of different factors is analyzed using the hierarchical analytical method by Yuan Mei (Yuan & Wang 2010). The main factors of influence on the blasting vibration velocity are selected to build a BP neural network model, and the blasting vibration velocity peak of particles is predicted by Tang Ha (Tang 2004, Cai 1997, Xu 1998, Wang 2003). The method of numerical simulation is used to analyze the blasting vibration, and concluded that the distance from the blasting center has a great influence on the blasting vibration velocity. The distance is the main factor to affect blasting vibration, and concluded on the basis of Brazil yatfai greenstone quarry blasting data in combination with the method of probability and statistics. The influential factor analysis of blasting vibration is done using the method of field experiment in combination with the numerical simulation in a open pit mining field in India by Venkatesh H.S (Venkatesh H.S 2005). It was concluded that the total dose is irrelevant to the blasting vibration when the distance from the blasting center is between 100 and 3000 meters.

However, the above methods have still some shortcomings: first, a large amount of data are

needed because using few data is difficult to find out the statistical law; second, a certain distribution of typical probability is required to obey for the sample; third, amount of calculation is large, and quantitative results are inconsistent with qualitative analysis. From the perspective of system engineering, the effect of the blasting vibration is actually the gray system including a part of known information and part unknown information, so the method by using gray correlation is more reasonable to analyze the degree of the influence factors of blasting vibration. Gray Relational Analysis (GRA Gray) was first proposed in 1984 by Professor Deng Julong. The advantages of this method can make up for the lack of mathematical statistical analytical methods. Only a small amount of the sample is supplied, and a typical distribution (Deng 2002, 2005; Liu, 2010) is not needed. The relationship between the primary and secondary influence factors of blasting vibration can be determined accurately. So, blasting parameters are optimized, and the hazard of the blasting vibration is reduced.

## 2 THE PRINCIPLE AND STEPS OF GRAY CORRELATION METHOD

The relationship between the data can be found out, and the major and minor relation and magnitude of influence degree in a system containing a variety of factors are analyzed. The close degree is judged according to the similar degree of sequential curve geometry. Its basic characteristics are as follows: the curve is close to the corresponding sequence; the correlation between the corresponding sequences is larger; and it can reflect the proximate degree of the discrete space.

### 2.1 The choice of the variable between characteristic factors and related factors

$Y_j(k)$ ,  $X_i(k)$  represent the  $j$ th systematic feature vector and the  $i$ th relevant factor variable, respectively in  $k$ th tests. The main influential factors of the systematic feature vector are determined by using the tests' data. Then, the corresponding data in the test form the sequence of relevant factors and systematic feature variable sequence, namely:

$$X_i = [X_i(1), X_i(2), \dots, X_i(n)] \quad (1)$$

$$Y_j = [Y_j(1), Y_j(2), \dots, Y_j(n)] \quad (2)$$

### 2.2 The original data standardization

Because of different dimensions and magnitude of various factors, the data is not comparable,

Dimensionless data sequence is demanded to assure the accuracy of the relevant degree. So, these factors must be transformed numerically.

The usually dimensionless methods include the following: initialization method, equalization method and interval value method. Equalization method is adopted in the text.  $X$  and  $Y$  are intervalled by using the interval operators  $D_i$  and  $D'_i$ , and the interval value is as follows:

$$X'_i = X_i D_i = [x'_i(1), x'_i(2), \dots, x'_i(k), \dots, x'_i(n)] \quad (3)$$

$$Y'_j = Y_j D'_j = [y'_j(1), y'_j(2), \dots, y'_j(k), \dots, y'_j(n)] \quad (4)$$

where

$$x'_i(k) = \frac{x_i(k)}{\bar{x}_i}, \quad \bar{x}_i = \frac{1}{n} \sum_{k=1}^n x_i(k), \quad (5)$$

$$y'_j(k) = \frac{y_j(k)}{\bar{y}_j}, \quad \bar{y}_j = \frac{1}{n} \sum_{k=1}^n y_j(k)$$

### 2.3 Gray correlation calculation

After the data is dimensionless, characteristic variables data sequence and related factors data sequence are  $x'_i(k)$  and  $y'_j(k)$ , respectively. According to the definition,

$$\gamma(x'_i(k), y'_j(k)) = \frac{\Delta_{\min} + \zeta \cdot \Delta_{\max}}{\Delta_{ij}(k) + \zeta \cdot \Delta_{\max}} \quad (6)$$

where  $x'_i(k), y'_j(k)$  are gray correlation coefficient, respectively.

$\Delta_{ij}(k) = |x'_i(k) - y'_j(k)|$  is the absolute difference,  $\Delta_{\min} = \min_i \min_k \Delta_{ij}(k)$  is the smallest difference, and  $\Delta_{\max} = \max_i \max_k \Delta_{ij}(k)$  is the biggest difference.  $\zeta$  is the distinguish coefficient, with general  $\text{agv}$  is  $[0,1]$ , In the practical application,  $\zeta = 0.5$ : the smaller the value of  $\zeta$ , the greater the resolution ratio. It actually proves that its value of change will only change the size of the relative value, but will not affect the ranking of the gray correlation degree.

### 2.4 Solving the correlation

The formula can be obtained as follows:

$$\gamma(y_j(k), x_i(k)) = \frac{1}{n} \sum_{k=1}^n \gamma_{ij}(k) \quad (7)$$

where  $i = 1, 2, \dots, s; j = 1, 2, \dots, m$ .

### 2.5 Analysis of the correlation matrix results

Gray correlation matrix is given by

$$\Gamma = (\gamma_{ij}) = \begin{bmatrix} \gamma_{11} & \gamma_{12} & \cdots & \gamma_{1m} \\ \gamma_{21} & \gamma_{22} & \cdots & \gamma_{2m} \\ \cdots & \cdots & \cdots & \cdots \\ \gamma_{s1} & \gamma_{s2} & \cdots & \gamma_{sm} \end{bmatrix} \quad (8)$$

The effect of related and characteristic factors is judged based on the size of gray correlation of rows and columns in Equation (8). The main and secondary factors are analyzed, and the main influence factors are called advantage factors among them.

If there is  $a, b \in \{1, 2, \dots, j\}$ , it meet  $\gamma_{ia} \geq \gamma_{ib}$ ,  $i = 1, 2, \dots, s$ . The factor  $X_a$  is better than  $X_b$ ; if it meet  $\sum_{i=1}^s \gamma_{ia} \geq \sum_{i=1}^s \gamma_{ib}$ ,  $i = 1, 2, \dots, s$ . The factor  $X_a$  is quasi superior to  $X_b$ .

If there is  $j \in \{1, 2, \dots, m\}, j = 1, 2, \dots, m, j \neq h, X_h$  is superior to  $X_j$ , then the factor  $X_h$  is the optimal factor; if  $i \in \{1, 2, \dots, n\}, i \neq h, X_h$  is quasi superior to  $X_i$ , then the factor  $X_h$  is a quasi-optimal factor.

### 3 CAVERN BLASTING ENGINEERING EXAMPLE

#### 3.1 Determining the system feature variables and related factors

As blasting seismic wave parameters, vibration peak parameters are used only to judge the size of the vibration, and not the duration of

the vibration. Vibration frequency also plays an important role on vibration intensity, so three factors are taken as systematic feature factors. In combination with the Longbeiwang hydropower station cavern blasting test site, in the design of blasting parameters, the relevant factors including the total amount, the number of segments, maximum explosive, blasting distance and elevation difference are selected, and the chamber length and the main line charge should also be considered due to the cavern blasting.

Therefore, the total amount and maximum explosive, chamber length, main line charge and the number of segments, blasting distance and the minimum delay time interval elevation difference were regarded as related variables, and recorded for  $X_i$  ( $i = 1, 2, 3, \dots, 8$ ), respectively. The monitoring data of a cavern blasting vibration in Hubei is established in this paper. Part of the monitoring data is presented in Table 1.

#### 3.2 Calculated gray correlation

##### 3.2.1 The original data, the cavern blasting vibration velocity, the main vibration frequency and the duration of blasting vibration testing data

It can be seen from Table 2, the system characteristics variable sequence is  $Y1 = [10.24 \ 5.184 \ 5.158 \ 10.98 \ 6.507 \ 4.064]$ ,  $Y2 = [8.673 \ 9.363 \ 11.17 \ 11.01 \ 11.35 \ 4.792]$  and  $Y3 = [0.7466 \ 0.6843 \ 1.057 \ 0.870$

Table 2. Monitoring data samples of blasting vibration.

System characteristics variable	Y <sub>1</sub>	Vibrate velocity /cm/s	10.24	5.18	5.16	10.98	6.50	4.06
	Y <sub>2</sub>	Main frequency /Hz	8.67	9.36	11.17	11.01	11.35	4.79
	Y <sub>3</sub>	The duration /s	0.75	0.68	1.06	0.87	0.59	0.74

0.5966 0.7434]. The associated factors variable matrix is shown as follows:

$$X' = \begin{bmatrix} 1.12 & 1.16 & 0.95 & 0.85 & 0.82 & 1.12 \\ 1.11 & 1.15 & 0.96 & 0.84 & 0.83 & 1.10 \\ 0.93 & 1.13 & 0.92 & 0.92 & 0.64 & 1.46 \\ 1.11 & 1.00 & 1.11 & 0.89 & 0.67 & 1.22 \\ 0.38 & 0.38 & 0.75 & 1.13 & 1.50 & 1.88 \\ 0.88 & 1.22 & 1.10 & 0.64 & 1.35 & 0.80 \\ 1.33 & 1.22 & 0.78 & 0.74 & 0.52 & 1.42 \\ 0.30 & 0.60 & 0.90 & 1.20 & 1.50 & 1.50 \end{bmatrix} \quad (9)$$

### 3.2.2 Using the average method to dimensionless data

Average method is used to dimensionless Equations (4) and (5), and the matrix  $X'$  of the new matrix  $X$  can be obtained as Equation (10):

$$X = \begin{bmatrix} 14700 & 15330 & 12570 & 11280 & 10830 & 14850 \\ 4412 & 4600 & 3772 & 3384 & 3248 & 4456 \\ 18.36 & 22.30 & 18.30 & 18.18 & 12.74 & 28.91 \\ 240.0 & 216.0 & 240.0 & 192.0 & 144.0 & 264.0 \\ 2.000 & 2.000 & 4.000 & 6.000 & 8.000 & 10.00 \\ 356.2 & 494.1 & 447.9 & 259.1 & 545.9 & 325.3 \\ 72.00 & 66.00 & 42.00 & 40.00 & 28.00 & 77.00 \\ 50.00 & 100.0 & 150.0 & 200.0 & 250.0 & 250.0 \end{bmatrix} \quad (10)$$

### 3.2.3 Calculating the correlation

Excel is used and combined with Equations (6) and (7) to calculate the correlation degree of the characteristic vector sequence  $Y$  and influencing factors of the variable  $X$ , as given in Table 3.

### 3.3 The result analysis

1. The order of the influence of various factors on blasting vibration velocity is as follows: total amount, maximum explosive, elevation difference, main line charge, delay time interval, number of segments, chamber length, and blast-

ing distance. The major role is played in cavern blasting vibration strength.

- The order of the influence of various factors on blasting vibration frequency is as follows: blasting distance, main line charge, chamber length and maximum explosive, total amount, delay time interval, number of segments, elevation difference among them, effect of blasting distance is the largest, maximum explosive takes the second place, and influence of the elevation difference is relatively small.
- The order of the influence of various factors on duration of blasting vibration is as follows: main line charge, chamber length, total amount, maximum explosive, blasting distance, number of segments, delay time interval, elevation difference, associated value of the main line charge and chamber length is much bigger than other factors in the main influence factors on the duration.
- As three parameters were chosen to be systematical characteristics variables of blasting vibration, the sum value of correlation degree of vibration velocity and vibration frequency and duration of vibration are adopted to evaluate the impact degree of various factors on blasting vibration, and the result is relatively reasonable. The major influence factors of the cavern blasting vibration intensity are the total amount and the main line charge, that is to say, in the cavern blasting, their influence of blasting vibration should be considered first.
- Based on past experience in blasting engineering, it was found that the total amount and the maximum explosive have great influences on blasting vibration. It can be seen from the gray correlation calculation results that the total amount and the maximum explosive play an important role in the influence of blasting vibration. This result is consistent with related projects basically. Therefore, the blasting vibration on slope rock mass can be reduced and slope rock mass stability is protected by controlling

Table 3. Correlation results (non-dimensional).

	Total amount	Maximum explosive	Chamber length	Main line charge	Segment	Blasting distance	Elevation difference	Delay time interval
Vibration velocity	0.730	0.728	0.619	0.656	0.622	0.597	0.710	0.625

Duarte time	0.784	0.784	0.834	0.835	0.551	0.715	0.586	0.587
Summation	2.126	2.124	2.098	2.2	1.692	2.069	1.774	1.795

the total amount and the maximum explosive in the future.

#### 4 CONCLUSIONS

Through the above application, the gray relational analysis method can be used to analyze the influencing factors of blasting vibration in a cavern, and the following conclusions can be obtained:

1. Gray relational analysis method can be used for fewer samples to identify the primary and secondary relations of a variety of factors that affect the blasting vibration under a certain blasting condition. It provides scientific evidence for the reasonable control of blasting vibration. Moreover, it is a simple and effective method.
2. When the influence factors of blasting vibration were analyzed, it is found to be more reliable and multiple feature variables were chosen to analyze. When multiple blasting characteristics variables were used, different situations of different blasting characteristic variables of the optimal factor often appeared, and then the size of the blasting characteristics and values of correlation between variables were considered to determine the factors that influence the blasting. Thus, more reasonable results can be obtained.
3. The above results of the gray correlation and analysis advantages were sorted and can be seen from the correlation. Cavern blasting is different from other blasting. The main period of feeds and the medicine chamber length effect on the size of the vibration strength is more important. So, in the cavern blasting, the effect of the two factors on the influence of blasting vibration should be considered.

#### 5 DISCUSSION

1. In order to control the blasting vibration, the domestic and foreign scholars are basically focused on the design of blasting parameters. However, the influence of the topography and geomorphology, geological conditions on blasting vibration is ignored. Although there are some scholars who began to pay attention to this problem, the results are mainly amplified with the lash effect and site effect. However, the influence of and the form and geological conditions on blasting vibration will be the trend of the blasting vibration research.
2. At present, a lot of methods are used to study the influence factors of blasting vibration, but commons area involve analyzing the influence degree of various factors, single affect peak speed, duration of vibration, and the main vibration frequency, respectively. The coupling effect between the influence factors cannot be considered, and the research on the coupling action is very effective on controlling the blasting vibration.

# Study on the dynamic deformation characteristics of loess landslide

X.M. Cui & X.H. Sun

*School of Geology Engineering and Surveying, Chang'an University, Xi'an, Shaanxi, China*

**ABSTRACT:** Dangjiacha landslide was triggered by Haiyuan earthquake. Based on the site investigation, representative soils on the sliding surface were collected for soil tests. By using the advanced dynamic torsional shear triaxial apparatus, a series of shear tests were carried out to study the loess's dynamic characteristics of Dangjiacha landslide. The dynamic torsional shear test results show that the dynamic shear stress-strain curves can be described with hyperbola under complex stress conditions. Consolidation confining pressure influences the dynamic shear stress-strain relationship curve obviously, but the influence of vibration frequency is not obvious. The relationship between the dynamic shear modulus and dynamic shear strain is little influenced by consolidation confining pressure and vibration frequency. The dynamic shear modulus attenuates quickly when the dynamic shear strain is in the range of 0–1. However, when the dynamic shear strain is larger than 3, the dynamic shear modulus attenuates very slowly.

**Keywords:** Haiyuan earthquake; Dangjiacha landslide; dynamic torsional shear triaxial apparatus; consolidation stress; vibration frequency

## 1 INTRODUCTION

Loess is covered with more than 9.3 percent of the world's land mass, with a total area of about 13 million. The most typical loess is located in China. In China, the area of loess region is about 640,000 km<sup>2</sup>. It is one of the main areas of seismic activity. Previous strong earthquakes have caused a lot of landslides, subsidence due to earthquake, cracks and other disasters, which is a threat to human life and property seriously (Wan 2003). Thus, the study of the loess structural characteristics under seismic forces is significant for earthquake disaster reduction, economic and social development in the loess area.

In view of this, loess dynamic characteristics under the earthquake have been studied by many scholars. Some have studied using the seismic wave and random wave exerted on a standard specimen to study the dynamic strength and deformation characteristics of loess (Duan, Zhang, and Li 1990; Wang and Zhang 1991; Wang, Zhang, and Wang 1994). Others have studied by considering the simplified earthquake wave as an equivalent sine wave, and then exerted the equivalent sine wave on the soil samples. The test result has been carried out on similar dynamic strength—dynamic strain rules (Wu and Xie 1987, 1994; Xie 2001). Dynamic stress-strain relationship, the dynamic elastic modulus, dynamic strength and damping ratio of loess in different regions under different consolidation stresses and different moisture contents have also been studied by other scholars (Chen, He, and Gao 2006;

Luo 2000; Luo and Tian 2005; Luo, Xie, and Li 2000; Tian, Zhang, and Zhang 2004). However, the study on the dynamic characteristics of loess under complex stress conditions is still not sufficient.

This paper aims to disclose the dynamic characteristics of loess earthquake landslide. Dangjiacha landslide triggered by Haiyuan earthquake was selected as the research object. Representative loess on the sliding surface was collected for soil tests. By using the advanced dynamic torsional shear triaxial apparatus, a series of shear tests were carried out.

## 2 DANGJIACHA LANDSLIDE BACKGROUND

Dangjiacha landslide was one of the typical high-speed remote loess landslides triggered by Haiyuan earthquake in 1920. It is located in Dangjiacha

Figure 1. Dangjiacha landslide (Sun et al. 2009).

Table 1. Physical property indices of intact loess.

Density g/cm <sup>3</sup>	Specific gravity	Liquid limit %	Plastic limit %	Plastic index %	Particle composition		
					Sand %	Silt %	Clay %
1.3	2.71	31.1	21.4	9.7	13.0	71.9	15.1

Figure 2. Stress state of the sample.

village, Xiji County, Ningxia Autonomous Region (Fig. 1). The landslide is mainly composed of Late Pleistocene Malan loess (Q3), and the sliding surface shape looks like a chair. The sliding direction is 295°, and the average slope angle is about 25 m. When the earthquake occurred, the landslide moved down to the Nilan River, and formed a lake (Sun et al. 2009).

### 3 TEST DESIGN

#### 3.1 Soil sample preparation

Representative loess on the sliding surface was collected for soil tests. Its indices of physical properties are listed in Table 1. Using specialized tools, the soil was collected into hollow cylindrical specimens of height 100 mm, outer diameter 70 mm, and inner diameter 30 mm. The hollow cylindrical specimens were sealed with plastic wrap to prevent evaporation.

The stress state of the specimen is shown in Figure 2. The hollow cylindrical sample bears internal and external confining pressure, the axial load and vibration torque on the cross section. These forces can simulate the radial stress, circumferential stress, axial normal stress and torsional shear stress. Using the to and fro movement, the dynamic test can be implemented.

#### 3.2 Test apparatus and design

The dynamic torsional shear triaxial apparatus developed by Japan HiTi Ltd was used in this

experiment. This apparatus composed of the host, pressure control system, power control system and measurement system. The measurement system automatically collected the data every 0.03 s. During the test, data on static pressure, dynamic pore water pressure, axial deformation, dynamic torque and dynamic angle were recorded.

In this test, the consolidation ratio was 1.5, and confining pressures were 100 kPa, 200 kPa, 300 kPa. Under each confining pressure, five vibration frequencies were selected in this test (Cui 2011).

## 4 ANALYSIS OF THE TEST RESULTS

### 4.1 Relationship of dynamic shear stress and shear strain of intact loess

Dynamic torsional shear tests of intact loess under different consolidation stresses and vibrational frequencies were carried out. Through the analysis of the test results, a series of dynamic shear stress ( $\tau_d$ ), dynamic shear strain ( $\gamma_d$ ) relation curves, dynamic shear modulus ( $G_d$ ), and dynamic shear strain ( $\gamma_d$ ) relation curves were obtained (Figs. 3 and 4).

It can be seen from Figure 3 that consolidation confining pressure influences the  $\tau_d$ - $\gamma_d$  relation curves obviously, but the influence of vibration frequency is not obvious. With the decrease in the consolidation confining pressure, the relationship curve has a downward trend. This means that dynamic stress decreases with the decrease in the consolidation confining pressure under the same dynamic strain. The relation curves exhibit no cross phenomenon under different confining pressures. During the vibration frequency at 0.5 Hz, 1 Hz, 2 Hz, the  $\tau_d$ - $\gamma_d$  relationship curves concentrated in a very narrow stripe. During the vibration frequency at 5 Hz, 10 Hz, the  $\tau_d$ - $\gamma_d$  relationship curves moved up.

This is because the loess has a loose structure, and the soil density increases with the increasing consolidation pressure. So, to produce the same dynamic shear strain, they need a bigger dynamic shear stress. Moreover, the smaller the vibration frequency, the greater the corresponding amplitude, and the soil structure can be easily damaged.

Figure 4 shows the  $1/G_d$ - $\gamma_d$  relation curves of intact loess under different test conditions. It can be seen that  $1/G_d$ - $\gamma_d$  relation curves conform to the linear relationship. Its expression is given as follows:

Figure 3.  $\tau_d-\gamma_d$  relationship curves.

Figure 4.  $1/G_d-\gamma_d$  relationship curves.

$$\frac{1}{G_d} = a + b\gamma_d \quad (1)$$

where

$G_d$  is the dynamic shear modulus;  
 $\gamma_d$  is the dynamic shear strains;  
 $a = 1/G_0$  is the  $1/G_d-\gamma_d$  curve in the y intercept;  
 $b = 1/\tau_{dmax}$  is the  $1/G_d-\gamma_d$  relation curves' slope;  
 $G_0$  is the maximum dynamic shear modulus or the initial dynamic shear modulus; and  $\tau_{dmax}$  is the maximum dynamic shear stress.

Moreover, substituting  $1/G_d = \gamma_d/\tau_d$  into (1) equation, it becomes

$$\tau_d = \frac{\gamma_d}{\frac{1}{G_0} + \frac{\gamma_d}{\tau_{dmax}}} = \frac{\gamma_d}{a + b\gamma_d} \quad (2)$$

Thus,  $\tau_d-\gamma_d$  relation curves conform to the hyperbolic model.

#### 4.2 Dynamic shear modulus

The dynamic shear modulus of the soil is the dynamic shear stress required to produce units of dynamic shear strain. It can be expressed by the ratio of dynamic shear stress and shear strain. It is the ability of the soil to resistant dynamic shear deformation. It is an important index to evaluate soil seismic performance.

Figure 5 shows  $G_d-\gamma_d$  relation curves. It shows that the dynamic shear modulus ( $G_d$ ) decreases with the increase in the dynamic shear strain. The attenuation of  $G_d$  within the range of 0–1 of the dynamic shear strain is rapid. When the dynamic shear strain is  $\geq 3$ , the attenuation of  $G_d$  almost close to zero. The value of  $G_d$  is distributed within a very narrow strip under different consolidation confining pressures and different vibration frequencies. Therefore, the consolidation confining pressure and the vibration frequency have little influence on the  $G_d-\gamma_d$  relation curves.

#### 4.3 The initial dynamic shear modulus and the maximum dynamic shear stress

From the above findings, we can see that the initial dynamic shear modulus ( $G_0$ ) is the reciprocal of  $1/G_d-\gamma_d$  relation curve on the vertical intercept, and the reciprocal of the slope of  $1/G_d-\gamma_d$  relation curve is the maximum dynamic shear stress ( $\tau_{dmax}$ ). The initial dynamic shear modulus and the maximum dynamic shear stress can be obtained from the test. The results are summarized in Table 2 and Table 3.

Figure 5.  $G_d-\gamma_d$  relationship curves.

Table 2. The initial dynamic shear modulus of intact loess.

Vibration frequency	Initial dynamic shear modulus $G_0$		
	$\sigma_3 = 100$ kPa	$\sigma_3 = 200$ kPa	$\sigma_3 = 300$ kPa
0.5 Hz	161	370	384
1 Hz	142	312	357
2 Hz	192	384	500
5 Hz	163	370	400
10 Hz	238	333	625

Table 3. The maximum dynamic shear stress of intact loess.

Vibration frequency	Maximum dynamic shear stress $\tau_{dmax}$		
	$\sigma_3 = 100$ kPa	$\sigma_3 = 200$ kPa	$\sigma_3 = 300$ kPa
0.5 Hz	100	111.11	135.14
1 Hz	98.04	109.89	156.25
2 Hz	92.59	113.64	188.68
5 Hz	105.26	156.25	188.63
10 Hz	84.75	163.93	125

It can be seen from Tables 2 and 3, under the same vibration frequency, the greater the consolidation stress, the larger the initial dynamic shear modulus and the maximum dynamic shear stress. This is because the loess is a kind of unsaturated and under consolidated soil, and has macro pores and vertical fissures. Therefore, loess is consolidated under a certain consolidation confining pressure: the larger the pressure is, the better the loess consolidation will be, and the greater the loess dynamic strength will become. Under a certain consolidation confining pressure, applying different vibration frequencies on soil specimens, the value of the initial dynamic shear modulus and the maximum dynamic shear stress becomes more dispersed and has no obvious regularity.

## 5 CONCLUSION

In this paper, we take the loess under different consolidation confining pressures and different vibration frequencies as the research subject, and using the dynamic torsional shear triaxial apparatus, we studied the dynamic characteristics of the intact loess of Dangjiacha landslide. The main result can be summarized as follows:

1. The dynamic shear stress and dynamic shear strain relation curves conform to a hyperbolic model under different consolidation confining pressures and vibration frequencies. Consolidation confining pressure influences the  $\tau_d-\gamma_d$  relationship curve obviously, but the influence of vibration frequency is not obvious. The influence can be described by the changing rules of the initial dynamic shear modulus and the maximum dynamic shear stress under complex stress conditions. These characteristics of landslide soil are consistent with the previous research results of loess.
2. Dynamic shear modulus and dynamic shear strain have little influence on the relationship between the dynamic shear modulus and dynamic shear strain. The dynamic shear modulus attenuates quickly when the dynamic shear strain is in the range of 0–1; however, when the dynamic shear strain is much larger than 3, the dynamic shear modulus attenuates very slowly.
3. The initial dynamic shear modulus and the maximum dynamic shear stress increase with the increase in consolidation confining pressures. Under a certain consolidation confining pressure, applying different vibration frequencies on soil specimens, the value of the initial dynamic shear modulus and the maximum dynamic shear stress becomes more dispersed and has no obvious regularity.

# The deformation characteristics of Xi'an aquifer sand under high-stress condition

X.H. Sun & X.M. Cui

*School of Geology Engineering and Surveying, Chang'an University, Xi'an, China*

**ABSTRACT:** By using self-designed high-pressure consolidation system, one dimensional consolidation test on aquifer sand under high-stress state is conducted. The test simulates the process of compaction and expansion of aquifer caused by fluctuation of water table in confined aquifer. The relationship between the deformations of aquifer sand sample and pore water pressure was analyzed. Test results show that: aquifer sands present complex deformation characteristics under different stress state. When pore pressure drops, the aquifer sand is compacted. Most of the deformation is plastic and creep characteristic is obvious. When pore pressure arises, the aquifer sand expands very little and the deformation is mainly elastic. There are significant differences between the particle size distribution curves before and after the test. The rupture and crush of sand particle can be seen in The SEM images directly. The sand deformation is related to the rupture and sand particles as well.

**Keywords:** aquifer compaction; high-stress state; sand deformation; land subsidence; water table decline

## 1 INTRODUCTION

Excessive withdrawal of groundwater has caused severe land subsidence in Xi'an, China (Lee, et al., 1996). In the process of land subsidence both the aquifer and the aquitard have been compacted (Galloway, et al., 1999). In the early stage of land subsidence, many researchers have put great emphasis on the deformation of aquitard (Holzer, 1995, Shearer, 1998). Some researchers take the view that majority of permanent deformation is caused by the compression of aquitard which is composed of fine-grain sediment (Ortega-Guerrero, et al., 1999). The compaction of coarse-grain sediment (such as sand) during the process of subsidence is very small and recoverable (Tolman and Poland, 1940). With the accumulation of extensometer and laboratory data, it was found that deformation of aquifer can take up more than 50% of the total subsidence and become the main compaction layer (Zhang, et al., 2006). Thus, the deformation of aquifer sand gradually aroused research's attention and the study of sand deformation increase gradually (Hoffmann, et al., 2003).

In the initial stage of groundwater exploitation, the pumpage is relative small and depths of wells are shallow, the compacted layers mainly located in shallow strata. Aquifer sand is under low-stress state and its deformation characteristic is clarity known by researchers. As the increase of groundwater demand, aquifer system loses

balance between recharge and discharge. Long-term ground-water withdrawal caused significant drop of water table in confined aquifers. The aquifer sand is gradually influenced by pumping and produces deformation. In Xi'an, a long history of ground-water withdrawal have created severe land subsidence hazard. According to the monitor data of extensometer group which located in the southern suburb of Xi'an, all of the hydrostratigraphic units within 300 m depth were compressed obviously (Peng, 2012). In this context, understanding the deformation characteristics of each stratum has become a necessary condition for calculating land subsidence (Sun, 2014). Under different stress state, the deformation characteristics of the aquifer sand vary greatly. How to simulate the in-situ stress state of aquifer which buried deep under the ground become the key difficulties to test (Xue, 2003). For the stress conditions is strict and difficult to meet, there are a few related research have been conducted (Huang, 2007, Li, et al., 2007, Ma, et al., 2008, Shi, et al., 2007). The degree of the research is still not enough.

The medium-fine sand in Xi'an aquifer is selected as sample in this test. Self-designed high-pressure consolidation system is used to accurately simulate the in-situ stress condition of aquifer and fluctuation of water table caused by groundwater withdrawal. Deformation characteristics of aquifer sand are detail analyzed after the test.

## 2 HIGH-PRESSURE CONSOLIDATION TEST

### 2.1 Testing devices

The test is performed on self-designed high-pressure consolidation system (Fig. 1). The total stress (axial stress) in the test is applied by the axial stress loading parts (part 2). The pore water pressure is applied by pore pressure loading parts (part 3). The confining chamber is a hollow drum shape cylinder and soil sample is placed in it. Its inner diameter is 125 mm and the internal height is 440 mm. The confining chamber is made of stain steel and it can withstand 10 MPa pressure during the test. During the test the specimen is always under the water to maintain saturation. There are four pore transducer installed on wall of confining chamber to measure pore pressure.

### 2.2 Test sample

The main lithology of Xi'an aquifers is medium-fine sand. The sample chosen for this test is sampling from a 5 m-deep pit which located in the western suburbs of Xi'an. The basic characteristics of sand

sample are as follows: specific gravity  $G_s = 2.675$ , effective size  $d_{10} = 0.223$  mm and average size  $d_{50} = 0.614$  mm.

### 2.3 Stress levels and loading methods

Based on the monitor data of extensometer group, the stratum which buried from 0 to -300 m are main compaction layers and their compression accounted for 89% of the total land subsidence.

Therefore, this test is mainly to consider the deformation of aquifer which buried shallower than -300 m. The depth of Xi'an confined aquifer mainly located in the depth from -100 to -300 m. The total stress of aquifer sand is proportional to the depth they was buried. When the bulk density is assumed equal to 20 kN/m, the total stress is from 2 MPa to 6 MPa. Total stress is applied by means of axial stress in the test. The pore water pressure is proportional to water table of aquifer. The water table is assumed equal to -50 m before ground water has been heavily pumped. And gradually decline to depth they are buried and then recovery to the initial depth. Thus the pore pressure applied in the test related to the aquifer depth and range from 0.5 MPa to 2 MPa (Table 1).

Figure 1. High-pressure consolidation system.

Table 1. Stress applied in the test.

Stage	Axial stress (MPa)	Simulated depth (m)	Pore pressure (MPa)	Simulated water table(m)
1	2	-100	0.5→0→0.5	-50→-100→-50
2	3	-150	1→0→1	-50→-150→-50
3	4	-200	1.5→0→1.5	-50→-200→-50
4	5	-250	2→0→2	-50→-250→-50
5	6	-300	2.5→0→2.5	-50→-300→-50

Figure 2. Stress levels and sequence in the test.

The staged loading method is adopted in this test. To simulate the total stress and water pressure in reality, the axial stress and pore pressure are independent applied by part 2 and part 3 of the high-pressure consolidation system respectively. Keeping the axial stress unchanged, change the pore water pressure step by step after the deformation of sand sample become stable. When the pore pressure restores to the original value in this stage, increase the axial stress to the next stage level. According to the difference in axial stress, the test can be divided into five loading stages. From stage 1 to stage 5, the magnitude of axis stress were 2, 3, 4 and 5 MPa respective (Fig. 2).

### 3 RESULTS OF HIGH-PRESSURE CONSOLIDATION TEST

Through applying a series of stress on the sand sample strain-time and strain-stress characteristics of sample can be determined.

#### 3.1 Strain-time curves

The stage 3 in Figure 2 was selected as typical case for analysis in this stage. The test results can be drawing into form of strain-time curve. The axial stress keeping unchanged at 4 MPa, and pore pressure dropped progressively from 1.5 Mpa to 1.2, 0.9, 0.6, 0.3 and 0 Mpa, then gradual return to 1.5 MPa (Fig. 3). During the process of pore pressure fluctuation, the aquifer sand shows complex deformation characteristics. (1) During the whole process of pore pressure fluctuation, the majority of deformation of sand sample is unrecoverable. it means the deformation of sand is plastic rather than elastic. The plastic deformation of the vertical strain is about 0.7%. (2) The deformation of sand is not finished instantaneous. When the pore

Figure 3. Stress applied in Stage 3.

Figure 4. Strain-time curves in Stage 3 (axial stress = 4 Mpa).

pressure drops from 0.9 MPa to 0.6 MPa and from 0.6 MPa to 0.3 MPa, the delay compaction caused by consolidation can be ignored due to high permeability coefficient of sand. Deformations of sand sample stabilize in more than 20 hours after pore pressure changed is caused by creep (Fig. 4). (3) When the pore pressure was arising the sand expands so small.

#### 3.2 Strain-stress curve

After the test is finished, the plot of the effective stress (calculated from axial stress and pore pressure) versus the corresponding compaction strain of each stress state can be drawn (Fig. 5).

The Figure 5 shows, deformation of the sand is not only related to the effective stress, but also related to the stress history of sand. When pore pressure drops but higher than any previous value (preconsolidation stress), the change of pore pressure creates

Figure 5. Strain-stress relations curve.

only a small deformation. When the pore pressure drops and lower than previous value, the sand may undergo significant, permanent compaction. The compaction includes elastic, plastic and viscose components. When pore pressure arises, along with the effective stress reducing, the sand sample has a small amount of expansion. It is inconsistent with the traditional view on sand deformation.

#### 4 MICROSCOPIC ANALYSIS OF THE TEST

##### 4.1 Laser particle size analysis

In order to explore the deformation mechanism of Xi'an aquifer sand, laser particle analyses were conducted (Fig. 6).

Through the comparisons of particle size distribution curve before and after the test, it can be seen that the sand particle size distribution curves have changed markedly. The percentage of coarse particles with diameter larger than 0.36 mm was reduced after the test. The percentage of sand with diameter smaller than 0.36 mm was rising meanwhile. This phenomenon shows that sand has various deformation mechanisms under high-stress state. Besides mutual slip between the particles, the sand grains may crack during the compression. This phenomenon is more common for large size of the sand particles.

##### 4.2 Images of SEM

High-precision Scanning Electron Microscope (SEM) was used to observe the microstructure of sample after the test. It can easily found and directly observed cracks and scratches in the surface of sand grain in SEM images (Fig. 7).

##### 4.3 Mechanism of sand deformation under high-stress state

Prior to the deformation of sand, arrangement of sand grains are loose and the soil skeleton is

Figure 6. Particle size distribution curve in the test.

Figure 7a. Sand after test (magnify = 200).

Figure 7b. Sand after test (magnify = 600).

not stable. There are a lot of pores with different size spread over the soil body. After effective stress is applied, soil skeleton start to deform, and sand particles start to move. In the process of grain moving, some small sand particles filled into the

big pores lead to quickly decrease in sand porosity and high-rate deformation. With the increasing number of big pores are filled gradually, space for sand particles moving is limited. As the resistance increases gradually, the moving speed of particles slow down. In macroscopic, the rate of sand deformation changes from fast to slow as time goes on. With the increase of effective stress, the acting force between soil particles increases accordingly. Usually, the interfaces between sand particles are not Surface-to-surface contact, but face-angular contact or angular-angular contact.

So there is a large stress concentration in contact position. When effective stress is large enough, the sand particles with shape of flake, columnar, angular, and larger particle are prone to rupture, crushing or grinding. A big particle may crush into some smaller particles. The smaller particles filled into the spaces between larger particles and soil begins to further deformation. For both the sand particles moving and crushing are need some time to finished, thus the sand exhibit creep characteristics. In unloading process (pore pressure arise), the small particles that have been crushed before cannot be re-cemented and returned to its original position (McDowell, 2003). So the sand has large irrecoverable plastic compaction.

## 5 CONCLUSION

In this paper, the deformations of aquifer sand under high-stress state are the main research subject. By using high-pressure consolidation system, characteristics of sand sample are analyzed and the mechanism of sand deformation is discussed. The main result summarized as follows:

1. The deformation characteristics of sand under high stress are complex. The compaction includes not only elastic and plastic deformation, but the viscous deformation as well.
2. Deformation characteristics of sand are related to changing patterns of pore pressure. When pore water pressure drops. Sand creeps and most of the deformation are irreversible. When pore pressure arises, sand compression stops or takes very slight expansion.
3. Sand deformation not only related to the slip between the particles but also to the crushed or fractured of some particles as well.

# Experiment research on the creep model of aquifer sand in Xi'an

X.H. Sun & X.M. Cui

School of Geology Engineering and Surveying, Chang'an University, Xi'an, China

**ABSTRACT:** The long history of ground-water pumping has caused a severe land subsidence hazard in Xi'an, China. During the process of ground-water pumping, deformation of confined aquifer has an influence on the total subsidence. In order to ascertain the deformation characteristics of aquifer, which is mainly composed of sand, a series of tests were conducted. By using a self-designed high-pressure consolidation system, the *in situ* stress states of aquifers were simulated in the test. The test results show that the sand of aquifer expresses a complex deformation characteristic under high-stress states. The aquifer sand shows a remarkable creep characteristic when the water table drops. When the water table arises, the creep of sand is not obvious. When the water table drops, the stress-strain and strain-time relation curves of sand can be described by the Generalized Kelvin Model with five components. Five rheological parameters in the Generalized Kelvin Model are not constant but varied, which are related to effective stress.

**Keywords:** aquifer sand; creep model; land subsidence; high-pressure consolidation system; Xi'an

## 1 INTRODUCTION

Xi'an is located in the northwestern of China where the amount of annual rainfall is often less than 400 mm (Lee et al., 1996). The industrial and municipal use of water depends almost entirely on groundwater. The amount of explored ground water began to increase substantially after 1960s (Peng, 2012). The long history of groundwater pumpage has caused a severe land subsidence hazard. In the early stage of land subsidence research, many researchers have put great effort on the deformation of aquitard. It was usually thought that the land subsidence was caused by the compaction of aquitard, which composed of fine-grained sediments primarily. Almost all of the subsidence is caused by compaction of clay layers (Holzer, 1995; Ortega-Guerrero et al., 1999; Shearer, 1998). Comparatively, the compaction of sand or coarser-grained sediments is elastic and small that can be negligible (Tolman and Poland, 1940).

With the accumulation of monitoring data, researchers have gradually realized that the aquifer can also be compacted substantially. The coarser-grained sediments (e.g. sand) and fine-grained sediments (e.g. clay and silty clay) have differences in compressibility. However, when the accumulative thickness of sand layers was large enough, the total compression of sand layers may be remarkable (Liu et al., 1994). Thus, the deformation of aquifer should be calculated in the land subsidence model (Hoffmann et al., 2003).

In reality, the aquifer system is buried deep under the ground. The total stress of the aquifer is

equal to the weight of the overlying stratum. The pore water pressure is related to the change in the water table. Long-term ground-water withdrawal from confined aquifers reduces fluid pressures and causes the sand layer to compact. Since the change in the water table is very slow and cyclical, both the changing patterns of effective stress and deformation characteristics of the sand layer are different from that under the low-stress state in the conventional consolidation test (Zhang et al., 2012). Under the high-stress state, the aquifer sand has complex deformation characteristics (Sun, 2014). It not only depends on the magnitude of the effective stress and impose orders, but also is related to time. Compared with the low-stress state, the aquifer deforms plastically and deformation lags behind the change in pore water pressure in them. It shows the characteristics of creep. Concisely, it describes the deformation characteristics of aquifer sand during compaction, and the expansion process is the key factor in land subsidence modeling.

Recent years, many researchers have taken these complex deformation characteristics of the aquifer sand into consideration, and have finished some field and laboratory tests. However, there are no creep models to describe such deformation characteristics of aquifer sand under *in situ* stress conditions for Xi'an yet. Therefore, a self-designed high-pressure consolidation system was used to accurately simulate the *in situ* stress condition of aquifer and fluctuation of water table caused by groundwater withdrawal. By simulating the stress changes, the deformation was measured. Furthermore, the deformation characteristics of

aquifer sand were analyzed and a new creep model was constructed.

## 2 ONE-DIMENSIONAL CREEP TEST

### 2.1 Testing device

Creep test is conducted on a self-designed high-pressure consolidation system. This system mainly composed of axis stress applying parts, pore pressure applying parts and confining chamber. The confining chamber is the key components of the high-pressure consolidation system. Soil sample is placed inside the stain steel cylinder. Axial stress is applied to the specimen through a rigid piston and porous stone located on the top of the soil specimen (Fig. 1). The advantage of the test system is that it can control the magnitude of axial stress and pore pressure independently, and thus it can be used to simulate the overlaying load and pore water pressure, respectively.

### 2.2 Test sample

The main lithology of Xi'an aquifers is a medium-fine sand. The sample sand chosen for this experiment is sampled from a 5 m-deep pit, which is located in the western suburbs of Xi'an. The basic characteristics of the sand sample are as follows: specific gravity  $G_s = 2.675$ , effective size  $d_{10} = 0.223$  mm and average size  $d_{50} = 0.614$  mm. During the test, the temperature is set as  $15 \pm 5^\circ\text{C}$ .

### 2.3 Stress levels and loading methods

The test used the staged loading method. There were four loading stages in the test. From stage 1 to stage 4, the magnitude of axis stress was 1.72, 2.99, 4.25 and 4.88 MPa, respectively. For each stage, the

Figure 1. Confining chamber.

Figure 2. Axial stress and pore pressure in the test.

pore pressure was applied from an initial value that was gradually reduced to 0, and then progressively restored to its original value (Fig. 2). It then took stage 2 as example. The axial stress was 2.99 MPa, and approximately equal to the total stress of the aquifer, which was buried 150 m under the ground. Pore pressure had an initial value of 1 MPa, and then stepped down to 0 MPa and gradually returned to 1 MPa. The fluctuation of pore pressure simulated the process of the water table in Xi'an confined aquifer, which dropped from  $-50$  m to  $-150$  m depth and then returned to  $-50$  m. In the test, changing either the axial stress or the pore pressure of the aquifer sand sample reached a stable state. The criterion for the sand sample to reach a stable state is the rate of deformation less than  $0.001$  mm/h.

The axis stress, pore pressure, the sand sample's compression or expansion and time were all documented during the whole test.

## 3 RESULTS OF THE CREEP TEST

The result of the test is expressed by the plots of strain versus time in minutes, as shown in Figure 3.

From the strain-time curves under the multi-level stress state, some features different from the low-stress state can be found.

When changing the pore pressure each time, the compression of the sand sample increased with time rapidly, but the rate of compression decreased gradually. The deformation process of the aquifer sand can be divided into two phases.

In the first phase, the change in the pore pressure caused the same magnitude change in effective stress. Sand began to consolidate and made large deformation. Due to high permeability, the

Figure 3a. Creep curve in stage 1, axis stress = 1.72 Mpa.

Figure 3d. Creep curve in stage 4, axis stress = 4.88 Mpa.

Figure 3b. Creep curve in stage 2, axis stress = 2.99 Mpa.

Figure 3c. Creep curve in stage 3, axis stress = 4.25 Mpa.

excessive pore water pressure in the sand sample dissipated immediately after the pore pressure changed. So, the first phase lasted for a very short time and instantaneous compaction was caused by consolidation.

In the second phase, the aquifer sand sample was under constant effective stress, but its deformation continued to grow as time increased. Aquifer sand began to creep obviously.

When the pore pressure was increasing, the sand expanded so small that the strain curve was almost horizontal. In other words, Xi'an aquifer sand had a creep feature only when loading or the water table dropped.

#### 4 RESULTS OF THE CREEP TEST

Based on the test results, it is found that the deformation of Xi'an aquifer sand has the characteristics of elastic, plastic and viscosity. In order to apply these features to land subsidence calculation model, a creep model should be constructed for the deformation of Xi'an aquifer sands. Based on the rheological model theory, the aquifer sand can be seen as a homogeneous continuum with elastic, plastic and viscosity. Some basic rheological components are combined to fit the complex characteristic of aquifer sand in the test. These basic rheological components include the Hook model, the Newton model, and the St Venant model (Fig. 4a-c).

##### 4.1 Selection of the creep model

The deformation of aquifer sand has some instantaneous compaction. It should have the Hook model in the creep model, and the hook model should be connected in series with other components. The rate of sand compression decreases gradually. And creep deformation tends to a limit value. It should have components that have a decaying creep feature, such as Kelvin model (Fig. 4d). Merchant model can fit the above requirements. Due to steep parts of creep curves, the Merchant model cannot quite

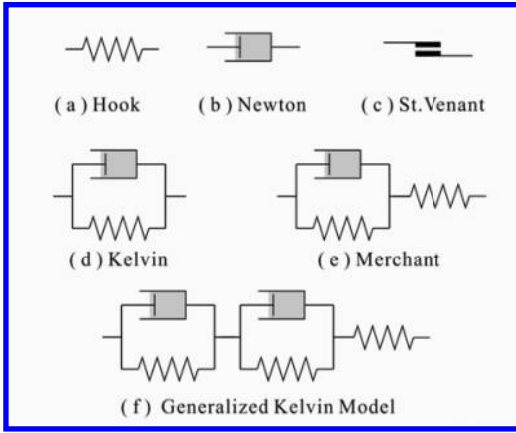

Figure 4. Creep model for the deformation of aquifer sand.

fit the first phase of sand deformation (Fig. 4e). Multiple Kelvin model connected in series can avoid the above shortcomings. The more the Kelvin body in series, the steeper the initial stage of the creep curve is. Land subsidence is a regional geological hazard. Many parameters of the rheological model may be hard to obtain in reality. Thus, the components used in the constructed creep model should be as little as possible. A generalized Kelvin model with five components is used to describe the characteristics of aquifer sand deformation (Fig. 4f).

#### 4.2 Model parameter fitting

The generalized Kelvin model, which is used in this article, is composed of two Kelvin bodies and a Hook body in series, so the relation between strain and stress can be expressed as follows:

$$\sigma_1 = \sigma_2 = \sigma_3 = \sigma \quad (1)$$

$$\sigma_1 = \sigma = E_H \varepsilon_1 \quad (2)$$

$$\sigma_2 = \sigma = E_{K1} \varepsilon_2 + \eta_{K1} \dot{\varepsilon}_2 \quad (3)$$

$$\sigma_3 = \sigma = E_{K2} \varepsilon_3 + \eta_{K2} \dot{\varepsilon}_3 \quad (4)$$

where  $E_H$ ,  $E_{K1}$ ,  $E_{K2}$  are the modulus of elasticity, and  $\eta_{K1}$ ,  $\eta_{K2}$  are the coefficient of viscosity.

From Equation (2), we obtain

$$\varepsilon_1 = \frac{\sigma}{E_H} \quad (5)$$

And from Equation (3), we obtain

$$\varepsilon_2 = e^{-\int \frac{E_{K1}}{\eta_{K1}} dt} \left( c + \int \frac{E_{K1}}{\eta_{K1}} \frac{\sigma}{E_{K1}} dt \right) \quad (6)$$

When  $t = 0$ ,  $\varepsilon_2 = 0$ , we thus obtain

$$c = -\frac{\sigma}{E_{K1}} \quad (7)$$

Equation (6) becomes

$$\varepsilon_2 = \frac{\sigma}{E_{K1}} \left( 1 - e^{-\frac{E_{K1}t}{\eta_{K1}}} \right) \quad (8)$$

Similarly,

$$\varepsilon_3 = \frac{\sigma}{E_{K2}} \left( 1 - e^{-\frac{E_{K2}t}{\eta_{K2}}} \right) \quad (9)$$

So, the strain of the generalized Kelvin model can be expressed as follows:

$$\varepsilon = \frac{\sigma}{E_H} + \frac{\sigma}{E_{K1}} \left( 1 - e^{-\frac{E_{K1}t}{\eta_{K1}}} \right) + \frac{\sigma}{E_{K2}} \left( 1 - e^{-\frac{E_{K2}t}{\eta_{K2}}} \right) \quad (10)$$

Table 1. Parameters of the generalized Kelvin model.

Axis stress/MPa	2.99		
Pore pressure/MPa	0	0.6	1
$E_H$ /MPa	227.3	238.1	312.5
$E_{K1}$ /MPa	1639.3	2941.2	1470.6
$E_{K2}$ /MPa	3636.4	2040.8	434.8
$\eta_{K1}$ /MPa · d	2180.3	382.7	102.6
$\eta_{K2}$ /MPa · d	203.5	4617.5	6680.4
Correlation coefficient	0.9934	0.995	0.9774

Figure 5. Fitting curves of stage 2 by using the generalized Kelvin model.

Table 2. The correlated coefficient of the generalized Kelvin model under different stress states.

Axial stress (MPa)	Pore pressure (MPa)	Correlation coefficient
1.72	0.4	0.9523
	0.2	0.9384
	0	0.9635
4.25	1.6	0.9702
	0.8	0.9798
	0	0.9237

Deformation can be calculated by using Equation (10). We choose the creep curve in stage 2 as representation. According to the test data, the parameters in the generalized Kelvin model were determined. Each value is given in Table 1, and the fitting curves are shown in Figure 5.

It can be seen from Table 1 that the five parameters of the generalized Kelvin model under different effective stress conditions vary. So, the parameters of the generalized Kelvin model are not constant, but vary with the change in effective stress.

Table 2 lists the correlation coefficient of the generalized Kelvin model in fitting each stress state curve in the test. The generalized Kelvin model can thus describe the deformation feature under *in situ* stress states.

## 5 CONCLUSION

In this paper, the deformations of aquifer sand under high stress states are the main research subject. By using a high-pressure consolidation system, the characteristics of the sand sample are analyzed and a creep model is constructed. The main result can be summarized as follows:

1. Xi'an aquifer sand showed a significant creep characteristic when the water level dropped. And no creep occurred when the water table arose.

2. Generalized Kelvin model was composed of five components. It could describe the complex compaction characteristic of Xi'an aquifer sand.
3. The parameters of the creep model of Xi'an aquifer sand were not constant but varied. By using the variable parameter model, it could improve the model precision.

# Fractal study of debris flow provenance granularity in Qinling temple valley

X.C. Xue, D. Han, L.Y. Zhang, P.B. Yang, L.J. Shi, S.Y. Huang & Y.C. Zhang  
*College of Geology and Environment, Xi'an University of Science and Technology, Xi'an, China*

**ABSTRACT:** The research of debris flow provenance and deposit granularity is one of the debris flow researches in the field of basic content and the characteristics of fractal theory solution of complex problems are widely used. The fractal dimension of provenance granularity of mine debris flow is one of the important structure indexes of potential landslide, which reflects the formation mechanism and dynamics, kinematics characteristics of debris flow. This paper based on fractal theory studies the debris flow provenance of Qinling mountain temple valley mine, and based on the obtained debris flow provenance granularity fractal dimension value in the study area offers the date to support the prevention of debris flow disasters in the study area.

**Keywords:** Qinling; temple valley; mine debris flow; provenance granularity; the fractal

## 1 INTRODUCTION

Debris flow is one of the common geological disasters in mountain. It has the characteristics of sudden, ferocious, briefly, scouring and silting in large scale, devastating, and often caused great damage to people's life and property<sup>[1]</sup>. In the mineral resources area, there has been massive artificial loose solid material, increased in the natural ground slope, which has made the non-debris flow gully turn into debris flow gully, from fewer area into high incidence and formed the mine debris flow disaster due to large-scale mining beneficiation activities, solid waste emissions and burden, such as solid waste emissions and burden.

Affected by multiphase tectonic movement and weathering denudation of joint action for a long time, the mine debris flow gully topography in the study area is various, and the grain composition of wasted slag is complex. In order to explore the nonlinear characteristic of the main controlling factors of the mine debris flow in the study area, we made a fractal study of wasted slag based on on-site measurement, photographs, measurements, graphics, statistics, and sampling tests.

## 2 INTRODUCTION OF FRACTAL DIMENSION

Fractal dimension is a value that is used to measure a set of irregular and broken degree of geometrical or natural object and usually expressed in scores or

decimal number. Fractal theory is put forward by American B.B.M andelbrot at first in the 1970s<sup>[2]</sup>. It can be used to research no characteristic length but has self-similarity of graphics and phenomena in the nature. Fractal dimension can be given a quantitative description to complex configuration that the traditional mathematics is difficult to answer in the nature<sup>[3]</sup>.

## 3 GRANULARITY FRACTAL DIMENSION CALCULATION

Granularity fractal dimension generally has the following several kinds of calculation methods: calculating the fractal dimension by changing the size of observation, analyzing the granularity of provenance, calculating the fractal dimension according to the measure dimension and according to the correlation function and dimension, etc<sup>[4]</sup>. This paper selects changing the size of observation and analyzes the granularity of provenance to realize the Debris flow provenance granularity fractal calculation.

### 3.1 Changing the size of observation

Changing the size of observation is also called Box counting method<sup>[5]</sup>. It is the use of different lengths of a square grid to cover the object under the test. When a square grid length changes, the number  $N(r)$  of grid covered with the object has inevitable changes. When the lengths of a square grid are  $r_1$ ,

$r_2, r_3, \dots$ , fairly  $r_k$ , the number of square grid is covered with measured object corresponding to  $N(r_1), N(r_2), N(r_3), \dots N(\text{fairly } r_k)$ , we can calculate the granularity fractal dimension by formula (1):

$$\lg N(r) = -D \lg r + A \quad (1)$$

Type: A is undetermined constants and D is the dimensions of the measured object; its value is equal to the absolute value of the type slope value.

### 3.2 Analysis of the granularity provenance

The formation process of debris flow is a very complicated nonlinear process and the composition particle of debris flow is a no characteristic length structure graph. The fractal of debris flow is a self-similar particle size distribution based on a statistical sense. The fractal dimension of particle is calculated by using formula (2):

$$D = b - 3 \quad (2)$$

According to the analysis results of granularity of debris flow, we can find a straight line from the particle size of log-log graph of cumulative percentage of the particle and particle size, then search for a straight line segment of slope, and get the Granularity fractal dimension of wasted slag sources<sup>[6]</sup>.

## 4 THE RESEARCH OF PROVENANCE GRANULARITY FRACTAL

### 4.1 The fractal features of coarse particle

We adopted “changing the size of observation” to calculate the fractal dimension of coarse particles whose diameter is larger than 1 cm of debris flow source. The specific methods: choosing coarse particle with diameter greater than a certain grain size as the research object, and determining the measurement scale by blockiness size. Generally, we called the particles whose diameter is larger than 20 cm as rubble, and called the diameter between 1 cm and 20 cm as crushed stone. Particle dimension is 1 cm that can be used as a lower bound of the scale of the field fractal measurement.

Since the statistical work progress is slow, in order to get more accurate data, we took massive photos of debris flow source using a high-resolution digital camera (Fig. 1). Then, we measured the maximum diameter of each stone using the AutoCAD software, and calculated the actual diameter through certain proportion relationship with the tools of Excel. Finally, we acquired grain-size statistical results in the study area (Table 1).

We took the logarithm of measure as abscissa and the logarithm of the count of aggregate that

Figure 1. The statistical photo of source.

Table 1. The statistical table of wasted slag granularity.

r (cm)	>50	>25	>12.5	>6.25
N (1-2)	0	0	21	105
N (1-3)	0	0	14	122
N (1-4)	0	0	30	98
N (1-5)	0	1	24	95
N (2-1)	0	0	8	83
N (3-1)	0	1	6	58
N (3-2)	0	1	17	80
N (3-3)	0	0	9	70
N (4-1)	0	2	37	101
N (4-4)	0	0	8	85

Note: r—particle size, cm; N—the accumulative frequency of the rubble whose diameter is greater than r; 1-2, 1-3 point number of photos or sample.

corresponds to scale as ordinate. Then, we can obtain a set of data and put all data in the rectangular plane coordinate system. According to the definition of fractal, if the object of study in accordance with fractal rule, the point will land on a straight line; if the object of study in a certain interval in accordance with the law of fractal, and in other interval does not conform to the fractal rule, then the point in the range of fractal will fall on a straight line. According to “Change the size of observation” and Table (1), the absolute value of straight slope is the fractal dimension of the particle size in the study area.

According to the above principles, finished the fractal calculation of 10 samples, we can obtain fractal dimension of samples in the study area (Table 2).

### 4.2 The fractal features of granule

The diameter of grain between 0.0625 mm ~ 1 cm of the debris flow provenance, we used the sieving to get grain composition and then we calculated

Table 2. The fractal dimension of coarse particle of wasted slag in Temple ditch mine.

Sample	1-2	1-3	1-4	1-5
Fractal dimension	1.504	1.964	1.096	1.149
Related coefficient	0.911	0.896	0.906	0.850

Table 3. The granularity cumulative percentage distribution table of granule.

Sample	r	The percentage of grain $\eta$ (%)		
		<0.066	<0.090	<0.100
1	m (g)	0.50	59.50	77.30
	$\eta$ (%)	0.03	3.90	5.06
2	m (g)	0.10	3.90	37.70
	$\eta$ (%)	0.01	0.13	1.27
3	m (g)	0.80	41.10	31.00
	$\eta$ (%)	0.04	2.10	1.58
4	m (g)	0.30	26.90	35.90
	$\eta$ (%)	0.02	1.55	2.07

Note: r—particle size, mm;m—the cumulative of particles of the wasted slag, g;  $\eta$ —the cumulative percentage,%

Table 4. The fractal dimension of granule of wasted slag in Temple ditch mine.

Sample	1	2	3	Average
Fractal dimension	2.6033	2.5277	2.4310	2.4439
Related coefficient	0.9687	0.9941	0.9948	0.9870

the fractal dimension by “analysis the granularity of provenance”. Through sieving, we let diameter of slag to be 3.2, 2, 1, 0.5, 0.4, 0.25, 0.2, 0.1, 0.09, and 0.066 mm standard sample sieve, and obtained grain size distribution data of various samples (Table 3).

According to sieving result of sample, we can get the slope of the straight line and obtained the granularity of the fractal dimension according to formula (2) (Table 4).

#### 4.3 The fractal features of particle

To the diameter of the grain less than 0.0625 mm of debris flow provenance, we gained grain composition by using a laser diffract instrument. The particle size of wasted slag ranged from 20 to 80 microns. Then, we calculated the fractal dimension by “principle of granularity analysis”. According to the formula (2), it is not difficult to draw fractal dimension of wasted slag (Table 5).

Table 5. The fractal dimension of the particle of wasted slag in Temple ditch mine.

Sample	1	2	3	Average
Fractal dimension	2.2361	2.3220	2.4152	2.3078
Related coefficient	0.9976	0.9978	0.9922	0.9964

## 5 CONCLUSION

Through the fractal research of debris flow provenance granularity multi-scale, we can draw the following conclusions:

1. Mine debris flow provenance whether large particles, medium particles, or micro particles, can be characterized by fractal dimension; a variety of particle scales have good fractal characteristics.
2. From the point of fractal dimension, the fractal dimension of coarse particles tend to be scattered (1.012~2.929), and the mean value is 1.926; the fractal dimension of granule is relatively concentrated, and the mean value is 2.511. The fractal dimension of particle is concentrated, and the mean value is 2.309. These values indicate that the larger particle has the smaller fractal dimension. From the correlation coefficient, the fractal dimensions of the average correlation coefficient of the three particles are 0.909, 0.974, and 0.996. That indicated the particle of debris flow source has more obvious fractal characteristics.
3. The fractal dimension of provenance granularity of mine debris flow is one of the important structure indexes of potential landslide, which reflects the formation mechanism and dynamics, kinematics characteristics of debris flow. The greater the provenance granularity fractal dimension the more the particles in clay composition has, which the probability of viscous debris flow is greater, the higher the risk of the mine debris flow at the same time, the stability is worse.

**ABSTRACT:** For this study, a soil–rock mixture slope was taken, for example, the coupled stress and seepage field and stability characteristic during rising and drawdown of reservoir water level were studied based on finite element model. Proper calculation parameters were selected in the landslide simulation according to the engineering condition. The results indicated that groundwater levels in different lithological mediums varied at different speeds; variation of groundwater level was lagged behind the variation of reservoir level when the reservoir is filling fast. But it was not so different from that of the reservoir level during the drainage process. In addition, the sudden rise of the reservoir water level did affect the stability of the slope greatly, and the decreasing value of the safety factor will increase with the amplitude of the increase of the water level. The stability of the landslide fell down during the rising of the level, and fell down at first and then rise during the falling of the level.

**Keywords:** stress field; seepage field; geostudio; landslide; stability

## 1 INTRODUCTION

Landslide on the reservoir bank caused by water–rock interaction (Louis C. 1974) is a kind of geological hazard, which is a long-time difficult problem. As is accepted, the change of water-level is the main reason of landslide. In recent years, more and more researches have been focused on landslide, and have made some desirable results (Morgerns Stern N. 1963; Berilgen M.M. 2007; Liao Hong-jian et al. 2005). Failure of slope contains many factors such as stress field, chemical field, temperature field, seepage field, etc. Coupling typically exists between different factors (Wang Xue-wu et al. 2006). Seepage field will be primarily affected when the water-level changes, then the stress field variation may lead to instability and failure of the slope (Xu W.J. et al. 2009). In recent years, with the application and popularization of finite element method and computer technologies, another effective way was found to calculate and analyze problems of landslide (Guo Ming-wei et al. 2012; Yang Jin et al. 2012; Huang Man et al. 2013; Pan Guo-lin et al. 2015).

In order to ensure the safe operation of the reservoir, it is necessary to check the stability of the dam. Seepage low and WRI were researched first

in this article and, based on this, the effect to the slope stability in rising and drawdown of water level was researched, some preliminary conclusions were drawn and those may provide helpful reference for related research.

## 2 GEOLOGICAL CHARACTERISTICS

### 2.1 Landform of the reservoir

The reservoir bank consists of oblique layered rocks, the top-down view is like an asymmetric pear, 260 meters as trailing edge height of the landslide mass, 190 meters as width, 770 meters as the leading edge width, 12–57 meters as thickness, 0.37 square kilometres as area,  $824 \times 104$  cubic meters as volume, and  $70^\circ$  as main sliding direction. The terrain in the middle to low part of the landslide mass slopes gently and there is no negative volcanic form.

### 2.2 Physical character of the rock

The landslide mass consists of soil with macadam, gravelly soil, and pebbly silty clay from front to back in turn. The whole structure has an initial medium dense and weathering weakens from the

surface to the centre. Gray pebbly silty clay is the major component of the slip band whose thickness varies from 0.7 to 1.5 meters; 30% of the pebbly is sandstone and marlstone which have a diameter of 20–100 mm and water content of the silty clay is 10.8%–18.3%, the compression ratio is 0.602. Through many shear strength tests show that cohesion can take a value from 14 to 16 kilo Pascal and internal friction angle usually varies from 18 to 25.5. In addition, inclination of the landslide bed varies from 30 to 80.

### 3 ANALYSIS OF SEEPAGE CHARACTERISTICS

#### 3.1 Calculation model

Select a section of the reservoir dam to build model, as shown in Figure 1.

The landslide mass is mainly composed of gravelly soil and the landslide bed consists of mudstone and marlstone.

#### 3.2 Parameter selection

Hydraulic conductivity and water content were indispensable for dam seepage simulation; changing curves of conductivity and water content with pressure are shown in Figure 2. Confining boundary is adopted for slip plane while variable water head boundary was applied to the model.

#### 3.3 Calculation results and analysis

##### 3.3.1 Storage process

Groundwater level will elevate as a result of reservoir storage, so this process was simulated using the transient method. According to actual condition, the water level rises from 145 to 175 meters within a month, then the water rise speed should be 1 meter per day. Calculation result using SEEP/W module was shown in Figure 3.

All Seepage lines of the dam curve left, which illustrates that “backflow” appears inside the

Figure 1. Calculation model of seepage.

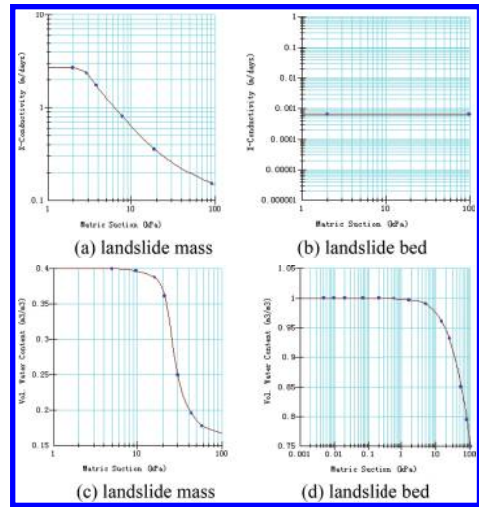

Figure 2. Conductivity and water content curves.

Figure 3(a). Seepage lines during storage process.

Figure 3(b). Seepage lines during drainage process.

landslide mass. Groundwater level rises quickly in the initial impoundment period and changes to be steady on later stage. Although the landslide mass has good conductivity, the variation of groundwater level was generally delayed relating to that of the reservoir level when the reservoir is filling fast.

Figure 4. Distribution of the minor principal stress during drainage process.

### 3.3.2 Drainage process

It took 180 days for the reservoir level to decrease from 175 to 135 meters, and hence the velocity of water level drawdown should be 5 meter per month. Adopt the same module as in the previous section and the result was shown in Figure 4.

As the landslide mass has good conductivity, and the reservoir level dropped very slowly, so the variation of groundwater level was not so different from that of the reservoir level.

## 4 SLOPE STABILITY ANALYSIS

### 4.1 WRI analysis

Characteristic of water–rock interaction was researched based on coupled stress and seepage field. Variation of seepage causes the variation of water load, and then lead to the change of stress field.

The same calculation model as previous section was applied in this section, and expected preferences are shown in Table 1.

The calculation showed that the maximum principal stress was characterized by compressive stress, which increased with the rise in reservoir water level and was nearly parallel to the bank slope. The minor principal stress varied along the bank slope. Also, minor principal stress above the sliding surface was greater than that below the sliding surface that may lead to some destruction (see Fig. 4). The maximum shear stress decreased with the falling of water level and reached the maximum at the bottom rear of the dam, so pull apart plane may form easily at this point.

### 4.2 Calculation result during storage process

Traditional limit equilibrium method is adopted by SLOPE/W program, and slope stability in this article was calculated using the following methods: the Janbu method, Bishop method, and Morgenstern–Price method. The result of storage process was shown in Figure 5.

The exported safe factors of the most dangerous slip surface were shown in Table 2. The Bishop

Table 1. Coupling analysis parameters.

Parameters	Landslide mass	landslide bed
Unit weight (KN/m <sup>3</sup> )	18	26
Deformation modulus (Mpa)	0.03	0.85
Internal friction angle	20°	34°

Figure 5. Calculation result of landslide stability (30 d).

Table 2. Safe factors with different methods.

Time/d	M-price	Janbu	Bishop
0	1.275	1.179	1.338
5	1.231	1.143	1.294
10	1.206	1.112	1.261
15	1.187	1.095	1.237
20	1.178	1.083	1.22
25	1.175	1.08	1.218
30	1.175	1.08	1.218

method gave the largest safe factor and Janbu method gave the smallest ones, but the variation trends of those three methods were similar.

Line graph could describe the variation more intuitively (see Fig. 5).

Figure 6 shows that the safe factor decreased slowly during storage process, so the stability of the landslide will fall down during the rising of the level.

### 4.3 Calculation result during drainage process

Similarly, the result of drainage process was shown in Figure 7 and the variation of safe factors in Figure 8.

Figure 8 shows that the stability decreased in the first 30 days and then rebound slowly in the following 150 days. The cause of the above phenomenon was that the gravity and sliding force of the slope was aggravated by hydrodynamic pressure. As the landslide mass has good conductivity, and the reservoir level dropped very slowly, the hydrodynamic pressure was decreased fast.

Figure 6. Variation of safe factors.

Figure 7. Calculation result of landslide stability (180 d).

Figure 8. Variation of safe factors.

## 5 CONCLUSION

Seepage low and WRI were researched first in this article and then discussed the distortion-destruction mechanism of slope, finally studied the effect to bank slope in rising and drawdown of water level. Major results can be concluded as follows:

1. Groundwater levels in different lithological mediums varied in different speed. Mainly composed of sandstone, the landslide mass has better permeability than that of the landslide bed which consists mainly of marlstone.

2. The variation of groundwater level was generally delayed relating to that of the reservoir level when the reservoir is filling fast. While, the variation of groundwater level was not so different from that of the reservoir level during the drainage process.
3. Due to the sudden rise and slow fall of the water level, rising water level gave a more obvious effect on the bank slope than those in decreasing of the water level.
4. The stability of the landslide fell down during the rising of the level, and fell down at first and then rise during the falling of the level of style is very important. Note the spacing, punctuation and caps in all the examples below.

**ABSTRACT:** To meet the needs of scientific calculation of subsidence caused by dewatering of pit, on the basis of the previous work and fully integrated with numerical simulation technology, the scientificity of Area Sink Method (ASM) in calculating subsidence is studied theoretically, and numerically realized by PM software, which is especially focused on. Then, by a set of numerical examples, the subsidence caused by dewatering is calculated by ASM, and by comparing with sophisticated Point Well Method (PWM), the accuracy and efficiency of ASM are analyzed. Finally, the applicability and practicability of ASM in calculating subsidence caused by dewatering is summarized systematically.

**Keywords:** dewatering of pit; subsidence; PWM; ASM

### 1 INTRODUCTION

Calculation of subsidence induced by dewatering of pit is a classical problem in geotechnical engineering. In some guides or standards, it is required, and the most popularized method is called Layer-Wise Summation Method (LSM), but LSM is too idealized to analyze more complex problems, such as dewatering through multilayered aquifers or dewatering under cut-off walls, or some unsteady problems, etc. In order to solve the problems beyond LSM, numerical method becomes more and more necessary.

With the development of numerical method, especially in the field of regional subsidence induced by widespread exploitation of groundwater for water resource, many complex problems can be accurately modeled by softwares, the most popularized one of which is Processing Modflow (PM) which has two unique modules: WELL (Point Well Method, abbrev PWM) and IBS (inter-bedded system). In the recent 10 years, PM has tried to model subsidence induced by dewatering in pits, but only the simple problem can be accurately modeled, such as dewatering in single aquifer without cut-offs. With the development of deep pits, PM is faced 2 major difficulties in modeling subsidence induced by dewatering with the module Well as follows: 1) Multiscale problems in pretreatments

and calculations. On one hand, the extent of models is always very large, which are dependent on the radius of influence, sometimes 1000 meters or even more. On the other hand, the spacing of wells is very small, which is usually between 6–8m. So, in order to accurately characterize the dewatering condition, the model should be divided into many meshes, which will increase numerical calculations, or even make convergence difficulties. 2) Drainage of aquifer. As it is known, the WELL module in PM cannot model drainage of aquifers with the water table declining near to the bottom of the aquifer, WELL module will stop working, and numerical calculation of the drawdown will be wrong, thus making numerical errors in modeling the subsidence with IBS according to the principle of effective stress.

The two problems in the WELL module above greatly retarded further popularized PM in modeling subsidence. So some simplification of wells in pretreatment is very important, which will improve the efficiency of numerical calculation as highly as possible, under the premise that the accuracy is enough for engineering evaluation.

Recently upon previous work, with systematical numerical tests, Wang Junhui (2015) has introduced an equivalent method called Area Sink Method (ASM) to approximate wells for calculating discharge rate of put-upon which a series of

valuable conclusion has been made. Can wells also be treated by ASM approximately in modeling subsidence induced by dewatering? (Some mathematical derivation and systematical numerical tests has been done from which the efficiency of simulation for subsidence with ASM is proved and tested.

## 2 MATHEMATICAL THEORY

### 2.1 Mathematical deduction

As it is shown in the **Figure 1**, the dewatering domain is  $\Omega_1$ , whose boundary is  $\Gamma_1$  (slightly larger than the pit), inside which dewatering is carried out, and the required drawdown is  $s_d(x, y)$ , which is also called designed drawdown.  $\Omega_2$  indicates the model domain, whose boundary is  $\Gamma_2$ .

On curve  $\Gamma_1$ , a group of wells are assigned, the flow rate of the well  $i$  ( $i = 1, 2, 3 \dots n$ ) is  $Q_i$  correspondingly.

With PWM, a drawdown distribution approximately designed to drawdown can be derived, thus

$$s^P(x, y) = s_d(x, y) \quad x, y \in \Omega_1 \quad (1)$$

where  $s^P(x, y)$  indicates distribution of drawdown by PWM;  $s_d(x, y)$  indicates distribution of designed drawdown for dewatering.

And with AWM, whose flow rate is  $q(x, y)$  (shown as the dashed area in **Fig. 1**), another drawdown distribution approximated to the designed drawdown can also be derived, thus

$$s^A(x, y) = s_d(x, y) \quad x, y \in \Omega_1 \quad (2)$$

where  $s^A(x, y)$  indicates the distribution of drawdown by ASM.

By using formulas (1) and (2), we can derive that,

Figure 1. Sketch map of ASM and PWM.

$$s^A(x, y) = s^P(x, y) \quad x, y \in \Omega_1 \quad (3)$$

For convenience, a new function on  $\Omega_2$  is just introduced as follows:

$$F(x, y) = s^P(x, y) - s^A(x, y) \quad x, y \in \Omega_2 \quad (4)$$

With (3) and (4), the following can be concluded:

$$F(x, y) = 0 \quad x, y \in \Omega_1 \quad (5)$$

As it is known, the contribution of any well  $Q_1$  to an arbitrary point  $(x, y)$  in  $\Omega_2$  has the same mechanism, so the mathematical formula of  $s^P(x, y)$  is identical throughout  $\Omega_2$ . According to the principle of superposition,  $s^A(x, y)$  by ASM can be regarded as the results of superposition by innumerable imaginary point wells, from which it can be concluded that the formulation of  $s^A(x, y)$  is also identical on  $\Omega_2$ . Upon above deduction, it can be derived that the formulation of function  $F(x, y)$  is identical throughout  $\Omega_2$ .

Upon above discussion and according to (5),  $F(x, y)$  is a constant function equal to zero, thus

$$F(x, y) \equiv 0 \quad x, y \in \Omega_2 \quad (6)$$

With (4) and (6), it can be derived as

$$s^A(x, y) = s^P(x, y) \quad x, y \in \Omega_2 \quad (7)$$

According to principle of effective stress and (7), it can be concluded that the subsidence calculated by PWM and ASM is identical theoretically, thus

$$sub^A(x, y) = sub^P(x, y) \quad x, y \in \Omega_2 \quad (8)$$

where  $sub^P(x, y)$  indicates distribution of subsidence by PWM;  $sub^A(x, y)$  indicates distribution of subsidence by ASM.

### 2.2 Numerical solutions by PM

In the software PM,<sup>[12]</sup> there are some modules that can be used as ASM indirectly by setting appropriate parameters, such as Drain and Evaporation.

#### 1. With module Drain

In the module Drain, in order to make the designed water level after dewatering, approaching the Elevation of drainage, the calculation of the distribution of Drain hydraulic conductance can be made, from which subsidence can be easily calculated.

#### 2. With module Evaporation

By setting Elevation of the ET surface as the bottom of aquifer, ET Extinction Depth at 0.5–1.0m below the bottom of pit, adjusting

the value of the maximum ET rate the calculated water level approaches the designed water level.

### 3 NUMERICAL TEST

#### 3.1 Project overview

There is a square pit with the scale of  $50\text{m} \times 50\text{m}$ , and the depth of its bottom is 30m.

The elevation of site is 25m, there exists a confined aquifer between the depth of 15–40m, whose lithology is fine sand, hydraulic conductivity is 50m/d, specific storage is 0.0001/m, specific yield

Figure 2. Sketch map of relationship between wells distribution and the pit.

is 0.12, radius of influence is 400m, and the depth of water level is 5m.

In the dewatering schedule, 112 tube wells are arranged, the spacing of wells on the edges and inside of the pit is 8m and 40m respectively, and the elevation of designed water level is 6m.

In order to evaluate the subsidence induced by dewatering, PWM and ASM are applied, respectively.

#### 3.2 Pretreatment and efficiency of PWM against ASM

PWM and ASM are implemented by the module Well and the module Drain, respectively. According to radius of influence and the scale of the pit, the model domain is defined as a square of  $1000\text{m} \times 1000\text{m}$ . In order to ensure the accuracy and efficiency of calculation, the density of grids should be high near the pit and low far away from the pit.

As it is known, the tube well should be located accurately in PWM, so the spacing of tube well should be as small as possible near the pit, the smallest of which is within 2m, the total number of grids in PWM is  $158 \times 158$  as is shown in Figure 3(a). While the geometrical characteristic in ASM is much more simple than PWM, the spacing of tube wells can be enlarged properly, the spacing of grids near the pit is 10m, the total number of grids is  $62 \times 62$ , which is only 15% of PWM, as is shown in Figure 4(b).

Since the number of grids in ASM is much lesser than that of PWM, so, in theory, the efficiency of calculation by ASM is much higher than by PWM. From the unsteady dewatering numerical tests with 200 steps, it is found that, the calculation time

Figure 3. Preprocessing of PWM and ASM (P1 to P8 indicates the reference points from the borderline of pit to outward).

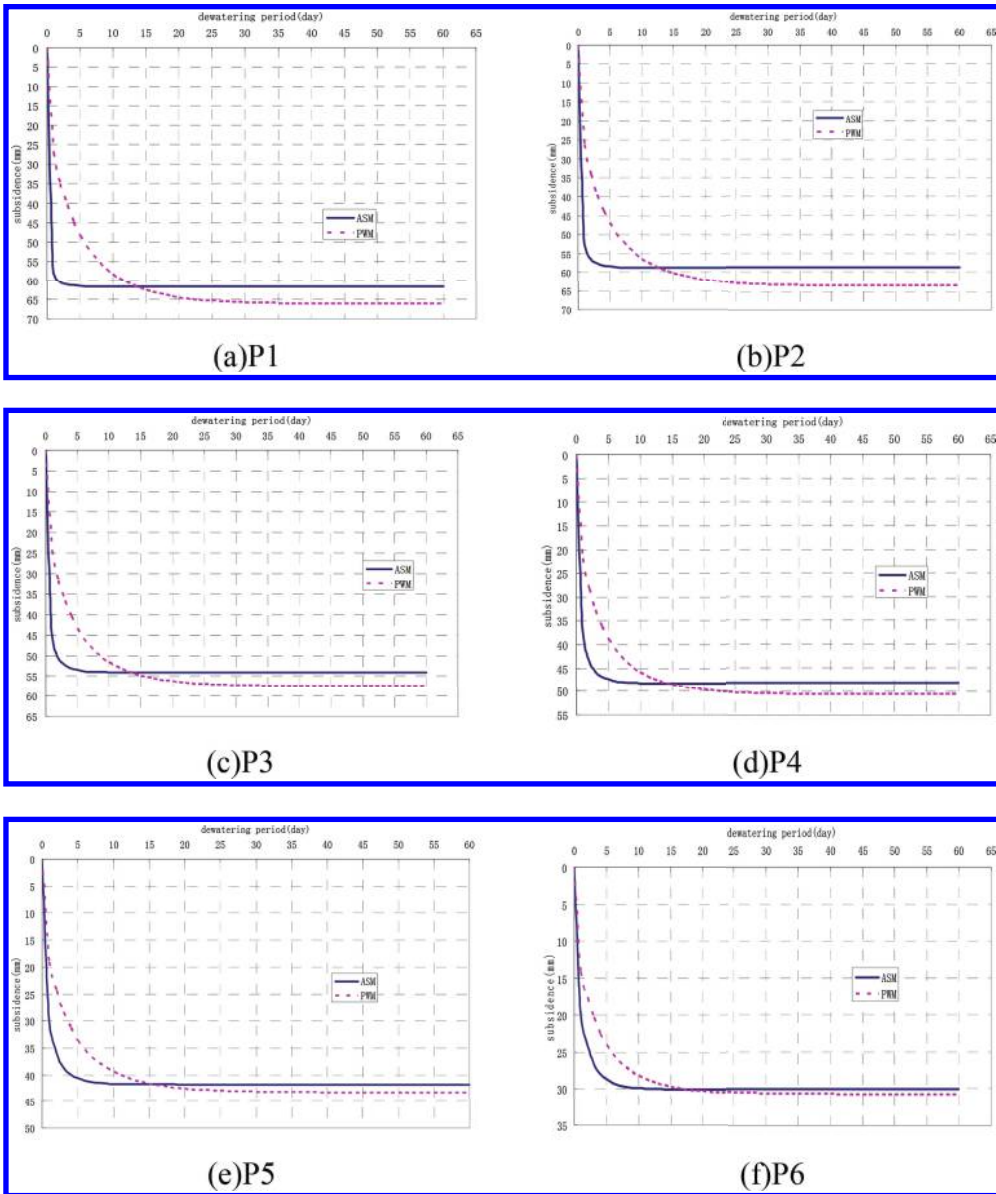

Figure 4. Dynamic curve of subsidence calculated by PWM versus ASM.

consumed by PWM is 75 seconds, while the calculation time consumed by ASM is only 6 seconds, from which it can be also concluded that the efficiency of calculation by ASM is much higher than by PWM.

### 3.3 Errors between PSM and ASM

Figure 4 shows the subsidence calculated by ASM and PWM, at different distance from the pit edge.

From Figure 4, you can see that nearer to the pit more errors between PWM and ASM are found. With the distance from pit increasing, the calculation results by ASM approached to that by PWM. (P5 and P6).

In fact, the final subsidence is more significant for engineering, while the maximum relative error of final subsidence is calculated by ASM to PWM within 10% (Fig. 4), so the accuracy of ASM is sufficient for engineering.

## 4 CONCLUSION

By the deduction and numerical tests, ASM is more efficient in calculating subsidence induced by dewatering of pit than PWM, under the premise of sufficient accuracy for engineering.

## Statistical study on bond strength of rock anchor

Mengxiong Tang, Hesong Hu & Chenglin Zhang

Guangzhou Institute of Building Science Co. Ltd., Guangzhou, China

**ABSTRACT:** Comparisons between the hyperbolic model and exponential model prediction effect have been made and the exponential model is selected to analyze P-S curve of rock anchor test data. Ultimate bearing capacity of anchor is predicted by exponential model firstly then the bond strength of rock anchor is calculated and these results are classified according to the hardness degree of rock. It is shown that bond strength of rock anchor recommended in the code is larger than 20% the statistic on the soft rock condition and both are in agreement on the hard rock condition.

**Keywords:** exponential model; rock anchor; bond strength; statistic

### 1 INTRODUCTION

Rock anchor is widely used in excavation pit supporting, slope reinforcement, underground anti-floating structures, and other projects.

It is required to determine the ultimate bearing capacity according to anchor rod pull-out test for building foundation design level in grade A and according to specification recommended value of the bond strength between the mortar and rock for other grades. The core issue of the engineering design reasonably determines the bond strength between the mortar and rock. Existing specifications recommended by the characteristic value of bond strength between mortar and rock recommended are relatively general, and brought the security risks to engineering application. It is necessary to get a more reasonable and reliable value of experience by statistically analyzing the bonding strength between mortar and rock through a lot of experimental data in different geological conditions.

It costs a lot of time and money to get the rock anchor ultimate bearing capacity by destructive test.

As an alternative, reasonable theoretical model can be chosen to fit the rock anchor inspection  $p$ - $s$  curve and forecasting the ultimate bearing capacity of rock anchor in practical application and theoretical analysis, due to the rock bolt destructive testing data is scarcer than acceptance test data. Then the bond strength between mortar and rock in different geological conditions can be calculated inversely. The results of inversion calculated can be used in improving the exiting standards.

### 2 COMPARISON FOR MATHEMATICAL MODEL

$p$ - $s$  curve of rock anchor and pile to be similar and include the fallow stages: elastic stage, elastic-plastic deformation, damage evolution. It is usually to fit the  $p$ - $s$  curve of pile by hyperbolic model and exponential model. Hyperbolic model and exponential model is used to describe the  $p$ - $s$  curve of rock bolt in this paper and according to the basic experimental data of an engineering project to the discussion of the applicability of the two models.

#### 2.1 Hyperbolic model

Assume that  $p$ - $s$  curve accords with hyperbolic equation.

$$p = \frac{s}{as + b} \quad (1)$$

$p$  is the load ( $kN$ ),  $s$  is the anchor displacement ( $mm$ ), and  $a$  and  $b$  are the fitting parameters. Ultimate bearing capacity is as follows:

$$P_u = \lim_{s \rightarrow \infty} \frac{S}{aS + b} = \frac{1}{a} \quad (2)$$

Assuming that  $y = s/p$ ,  $x = s$ , after transformation to get the linear equation:

$$y = ax + b \quad (3)$$

Using the least squares fitting, can calculate parameters  $a$ ,  $b$ .

## 2.2 Exponential model

Assume that  $p$ - $s$  curve accords with exponential equation.

$$P = P_{max} (1 - e^{-as}) \quad (4)$$

$P_{max}$  is the solvable load of rock anchor ( $kN$ );  $a$  is the subsidence attenuation factor ( $mm^{-1}$ ); unknown parameters  $P_{max}$  and  $a$  can be determined by computer analyzing the pull-out test data, *matlab* *n l in fit* function was used to write the corresponding program.

After confirming the  $P_{max}$  and  $a$  can be plugged into our index equation and get the fitting  $p$ - $s$  curve equations. The ultimate bearing capacity  $P_u$  of the pile can be to write as follow according to  $(\Delta S_{i+1}/\Delta P_{i+1}) \geq 0.1 mm/kN$ .

$$P_u = P_{max} - 10/a \quad (5)$$

## 2.3 Comparison of the model results and measured data

Reinforced pull-out rock bolt was set in a 2-layer bottom central in the anti-floating design on the Guangzhou Pearl river new town core area of

municipal traffic projects. Medium and weakly weathered rocks anchor the body. The anchor hole diameter is 150 mm, anchor length is 6 ~ 15 m, All the rod material is 428 steel. The engineering rock anti-floating anchor test measured data was used to fit the hyperbolic model and exponential model respectively to predict the ultimate bearing capacity and test the applicability of the two models. Comparison results are shown in Table 1 and Figures 1–5.

The ultimate bearing capacity is determined by assuming that the values of the displacement are at infinity for the hyperbolic model, so do not tally with the actual project and affect the fitting precision of the hyperbolic model. The result of predicting the ultimate bearing capacity of the rock bolt is not ideal by using the hyperbolic model, error in the range of 20% ~ 30%. Exponential model fitting precision of rock bolt bearing capacity is accurate; the error is very small, in the range of 3% ~ 13%.

## 3 STATISTICAL ANALYSIS OF ROCK BOLT PULLING TEST DATA

The upliftment bearing capacity's characteristic value can be calculated according to the bond

Table 1. Comparison between two models prediction effect.

Bolt	Measured/ $kN$	Exponential/ $kN$	Error/%	Hyperbolic/ $kN$	Error/%

strength between the cement mortar or concrete and rock anchor, its formula is:

$$R_t = 0.8\pi d_1 \sum l_i f_i \quad (6)$$

$f_i$  is the bond strength characteristic value between the cement mortar and concrete rock layers  $i$  ( $kPa$ ).  $d_1$  is the anchor diameter (mm).  $l_i$  is the length of anchoring section.

The exponential mathematical model was used to fit the rock anchor rod pull-out test  $p$ - $s$  data according to the previous conclusions and predict the ultimate bearing capacity of the rock bolt, thus get  $f_i$  values according to the calculated by formula (6). 380 bolts testing data in 38 projects were selected to analyze, including 160 anchors in soft rock geology, 93 anchors in less soft rock geology and 127 anchors in hard rock geological.

Numerous experimental data were statistically analyzed by writing a batch program in *Matlab* and get the distribution of bond strength characteristic value between the cement mortar or concrete and rock. As shown in Figures 6–8. The bond strength of rock anchor can be gained by getting in the corresponding 90% cumulative frequency.

As can be seen from the Figure 6, for soft rock geology, rock bolt bond strength of mortar or concrete are mainly distributed in less than 210  $kN$  area, which accounts for 90.63% of the total. It is suggested that bond strength of rock bolt mortar can be assigned a value in 110 ~ 160  $kPa$  for the middle weathered soft rock and assigned a value in 110 ~ 160  $kPa$  for the lightly weathered soft rock.

As can be seen from the Figure 7, for less soft rock geology, rock bolt bond strength of mortar or concrete are mainly distributed in less than 330  $kN$  area, accounting for 89.25% of the total. It is suggested that bond strength of rock bolt mortar can be assigned a value in 180 ~ 230  $kPa$  for the middle weathered soft rock and assigned a value in 230 ~ 330  $kPa$  for the lightly weathered soft rock.

Figure 6. Histograms of bond strength of rock anchor on soft rock condition (160 anchors).

Figure 7. Histograms of bond strength of rock anchor on less soft rock condition (93 anchors).

Figure 8. Histograms of bond strength of rock anchor on hard rock condition (127 anchors).

Table 2. Comparison between bond strength of rock anchor recommended in the code and statistic.

Stiffness	Representative	Weathered	Code value (kPa)	Statistics (kPa)
Soft rock	Mudstone	Middle weathered	150~200	110~160
		Lightly weathered	200~250	160~210
Less soft rock	Tufa	Middle weathered	200~250	180~230
		Lightly weathered	250~400	230~330
Hard rock	Granite	Middle ~ lightly weathered	400~600	400~600

As can be seen from the Figure 8, for hard rock geology, rock bolt bond strength of mortar or concrete are mainly distributed in less than 600 kN area, accounting for 89.75% of the total. It is suggested that bond strength of rock bolt mortar can be assigned a value in 400 ~ 600 kPa for the hard rock.

#### 4 CONCLUSION

The appropriate mathematical model was selected in this paper to statistically analyze the rock bolt acceptance test data and get the following conclusion:

1. Described by the exponential model of rock bolt  $p$ - $s$  curve to predict the ultimate bearing capacity is feasible, small error and good stability, meeting the precision requirement in engineering and providing the convenient for researching the bond strength of the rock anchor.
2. The bond strength of mortar or concrete and rock can be back calculated by the exponential model to predict the ultimate bearing capacity of anchor. The statistical results show that in the soft rock and less soft rock geological conditions, specification recommends value is 20% larger than the statistics, the specification values match the statistics suggested in hard rock geological conditions.

Results in this paper have been submitted to the standard specifications for design of building foundation of Guangdong province DBJ (15-31-2003) revised group for reference.

# Particle breakage characteristics of calcareous sand under P-wave

Xue-Yong Xu, Xiao-Fen Chen, Guo-Hai Chen, Sheng-Jie Di & Wan-Qiang Cheng  
*Power China Huadong Engineering Corporation Limited, Hangzhou, China*

**ABSTRACT:** Calcareous sand is a special marine geotechnical medium that exhibits interesting physical and mechanical properties resulting from its composition and structure. Calcareous sand particles are fragile and irregular and thus, may break under common stress such as the overpressure from an explosion in a nearby field. In the current paper, the particle breakage characteristics of calcareous sand under explosion were studied through mini-explosion experiments and the measurement method of Hardin was adopted to estimate the degree of particle breakage. The results show that calcareous sand exhibits strong absorption and attenuation effects on the P-wave because of its particle breakage characteristics. The relative degrees of particle breakage of the calcareous sand are 0.532, 0.217 and 0.06, at the distance from blasting source center position 5 cm, 10 cm and 15 cm. Many particles were broken near the blasting zone. The broken, compress, and damage zones are formed, which consume most of the energy and result in an increase in the attenuation effect. Through theoretical calculations, the energy for the formation of the broken, compress, and damage zones is found to consume 25% of the total energy.

**Keywords:** marine geotechnical medium; calcareous sand; P-wave; particle breakage; relative degree

## 1 INTRODUCTION

Calcareous sand is a special marine geotechnical medium composed primarily of calcium carbonate. The special sedimentary environment of calcareous sand, particularly its deposition process which does not involve long-distance transport, resulted in the preservation of the small pores in the original skeleton<sup>[1-2]</sup>. Studies have shown that the irregular shape and particle breakage characteristics of calcareous sand account for its engineering properties, which are significantly different from those of other terrestrial sand<sup>[3-5]</sup>.

At present, docks, airport runways, collecting tanks, and other kinds of civil and military infrastructures are constructed on coral reefs because of necessity, as well as for protection and the development of marine resources. These infrastructures potentially cause accidental and man-made explosions. Thus, studies on explosion safety and protection for these buildings are becoming increasingly significant.

Calcareous sand is the most common material medium on coral reefs, and its mechanical properties significantly affect the propagation and attenuation of the explosion wave. In recent decades, extensive studies on the dynamic characteristics of terrestrial sand or soil have been conducted. For example, Gohl W.B. et al. (2000)<sup>[6]</sup>, Dontsov V.E. et al. (2001)<sup>[7]</sup>, WANG Ming-yang et al. (2002)<sup>[8]</sup>, Qu Jun-tong et al. (2006)<sup>[9]</sup>, MU

Chao-min et al. (2010)<sup>[10]</sup>. These studies can be classified into two categories, namely, the experimental method and numerical simulations. The experimental method obtains the relationship between the material medium parameter and the explosion load. For example, different densities, grain compositions, and sand saturation exhibit different characteristics in response to explosions. On the other hand, numerical simulations are mostly performed by establishing physical models based on experimental test results and then using the ANSYS/LS-DYNA software to imitate the explosive process<sup>[12]</sup>. Studies on the dynamic response characteristics of calcareous sand under explosion are rare. Hence, the conduct of research on this field is necessary. Understanding the explosion compression wave propagation and attenuation can provide basic information for engineering constructions. In the current paper, the explosion compression wave propagation of calcareous sand would be examined through indoor explosion experiments. In addition, the particle breakage characteristics would be analyzed.

## 2 EXPERIMENT MATERIAL

The calcareous sand used in this experiment was sampled from China Nansha Islands. The physical parameters were determined and a granulometric

Table 1. Physical properties of calcareous sand.

$D_{60}$ (mm)	$D_{30}$ (mm)	$D_{10}$ (mm)	$e_{max}$	$e_{min}$	$d_s$
0.876	0.579	0.112	1.405	0.766	2.76

Figure 1. Granulometric analysis of calcareous sand.

analysis experiment was conducted prior to the indoor explosion experiment. The results show that 50% of the particles have sizes larger than 0.5 mm, and the non-uniform coefficient is 7.83, indicating that the samples could be classified as coarse sand. Table 1 and Figure 1 show the detailed physical properties of the calcareous sand and the results of the granulometric analysis experiment, respectively.

### 3 MEASUREMENT OF PARTICLE BREAKAGE

A previous study has shown that soil particles are incompressible, and that soil deformation results from the reduction of gas and water in the soil pores and the recombination of soil particles. The study also showed that the intensity theory is based on the friction and slippage between soil particles.

However, experiments showed that soil particles may partially or wholly break when they are subjected to stress from an external force greater than their own strength. Calcareous sand particles are fragile and irregular and thus, may break under common stress such as the overpressure from an explosion in a nearby field, which can exceed up to several hundred MPa. As such, the strong impact can cause a large number of calcareous sand particles to break.

After the explosion experiments, the samples were obtained from the area 5 cm to 20 cm from the blast center. Granulometric analysis was then conducted, and a granulometric analysis curve before and after the explosion was drawn. The calcareous sand particle breakage characteristics were

also described, and the measurement method of Hardin (1985) was adopted to estimate the degree of particle breakage of calcareous sand under an explosion. Finally, the value of the explosion energy loss in forming the crush, compression, and damage zones of calcareous sand were calculated.

### 4 TEST RESULTS

After the explosion experiments, the samples obtained at 5 cm, 10 cm, and 15 cm from the center of the explosion were subjected to granulometric analysis, and the granulometric analysis curve before and after the explosion was drawn. The results are shown in Figure 2.

Figure 2. Granulometric analysis results of the samples at different distances.

In the examination of the particle breakage characteristics, many different methods of measuring the degree of particle breakage were proposed based on the study objectives. These methods are mostly empirical. In the current paper, the measurement method of Hardin (1985) was used to estimate the degree of calcareous sand particle breakage under explosion. This model proposed the concept of breakage potential by assuming that 0.074 mm is the minimum particle breakage size and is greater than the size of all particles, which have varying degrees of potential for breakage.

$$b_p = \log_{10} \left[ \frac{D \text{ mm}}{0.074 \text{ mm}} \right] \quad (1)$$

where  $D$  is the particle size, and when  $D < 0.074$  mm,  $b_p = 0$ .

For the samples, the potential for breakage ( $B_p$ ) is defined as follows:

$$B_p = \int_0^1 b_p df \quad (2)$$

For the tests before and after the break, the overall potential for fragmentation or the overall potential for breakage is defined as  $B_t$ , as shown in Eq. (3).

$$B_t = \int_0^1 (b_{p0} - b_{pt}) df \quad (3)$$

where  $b_{p0}$  and  $b_{pt}$  are the potential for breakage before and after the explosion, respectively. Meanwhile,  $B_r$  is defined as the relative degree of particle breakage, as expressed in Eq. (4).

$$B_r = \frac{B_t}{B_{p0}} \quad (4)$$

The relative degrees of particle breakage of the calcareous sand at different distances from the center of the explosion can be obtained from the results and are presented in Table 2.

A large number of calcareous sand particle breakage occur within a certain range, especially near the explosion site, which result in the formation of the crush, compression, and damage zones. An immense energy blast is consumed during the formation of these regions, and the explosive stress wave propagation is also affected.

Table 2.  $B_r$  at different distances from the center.

Distance (cm)	5	10	15
$B_r$	0.532	0.217	0.06

## 5 CALCULATION OF THE ENERGY LOSS

The total chemical energy of the blasting agent for the experiment can be expressed as follows:

$$E_0 = mQ \quad (5)$$

where  $E_0$  is the total energy released by the blasting agent,  $m$  is the quality of the blasting agent, and  $Q$  is the detonation heat of the unit plastic blasting agent, which is the constant (3.545 kJ/g) for the current experiment.

Some assumptions are made to simplify the calculation process, such as the spherical shape of the broken, compress, and damage zones. Therefore, the relationship of the energy conservation for a one-dimensional blasting wave can be expressed as

$$e + \frac{p}{\rho} + \frac{1}{2}(D-u)^2 = e_0 + \frac{p_0}{\rho_0} + \frac{1}{2}(D-u_0)^2 \quad (6)$$

where  $e_0$ ,  $p_0$ ,  $\rho_0$ , and  $u_0$  and  $e$ ,  $p$ ,  $\rho$ , and  $u$  are the internal energy, pressure, density, and velocity of the mass point before and after the action of the blasting wave, respectively.  $D$  is the propagation velocity of the shock wave front, and  $v = 1/\rho$ . The energy relationship between the energy and the unit volume change can then be derived as

$$\Delta e = \frac{1}{2}(p + p_0)(v + v_0) \approx \frac{3(1+2\gamma)p^2}{2\rho_0 E} \quad (7)$$

where  $\gamma$  and  $E$  are Poisson's ratio and the elastic modulus, respectively, where as  $p$  is the stress wave attenuation formula in calcareous sand. Eq. (7) can then be rearranged as follows:

$$\Delta e = 32.5 \left( \sqrt[3]{Q/R} \right)^{2.95} \quad (8)$$

Therefore, the energy consumed by the compression zone can be expressed as

$$e = \frac{1}{2} \Delta e \frac{4}{3} \pi R_d^3 \rho \quad (9)$$

where  $R_d$  is the radius of the compression zone.

The calculated total energy of the blasting agent and the consumed energy from the broken, compress, and damage zones are shown in Table 3.

A previous study has shown that the consumed energies for the broken, compress, and damage zones are 8~15% of the total energy for rock and cement material, but the value is approximately 25% for calcareous sand. These results indicate that particle breakage consumes a large amount of

Table 3. Reference table for all kinds of energy.

Q/g	$E_0$ /kJ	$e$ /kJ	$e/E_0$
1.5	5.318	1.432	0.269
3.0	10.636	2.675	0.252

blasting energy that can lead to the formation of these zones and the increased attenuation of the compression wave.

## 6 CONCLUSIONS AND DISCUSSIONS

The particle breakage characteristic was analyzed through indoor explosion experiments, main conclusions are summarized as follows:

1. Calcareous sand is a special marine geotechnical medium. Exploring saturated calcareous soil explosion compacting mechanism and effect through the experimental study have great theoretical and practical significance to engineering construction in calcareous soil area.
2. A large number of calcareous sand particle breakage occur within a certain range, especially near the explosion site, which result in the formation of the crush, compression, and damage zones. An immense energy blast was consumed during the formation of these regions, and the explosive stress wave propagation was also affected. The results show that relative degrees of particle breakage of the calcareous sand are 0.532, 0.217 and 0.06, at the distance from blasting source center position 5 cm, 10 cm and 15 cm.
3. Under the effect of a blasting load, many particles were broken near the blasting zone. The broken, compress, and damage zones are formed, which consume most of the energy and result in an increase in the attenuation effect. Through theoretical calculations, the energy for the formation of the broken, compress, and damage zones is found to consume 25% of the total energy.

# Parameter sensitivity analysis of marine steel pipe pile in sandy soil foundation based on $p$ - $y$ curve method

Sheng-jie Di, Xue-yong Xu & Xiao-fen Chen

Power China Huadong Engineering Corporation Limited, Hangzhou, China

Xiang Wang & Ling-fang Bu

Power China Zhejiang Huadong Construction Engineering Corporation Limited, Hangzhou, China

**ABSTRACT:** Each parameter of pile and soil in marine sandy soil foundation is analyzed based on  $p$ - $y$  curve method, including qualitative analysis and quantitative analysis. With engineering design index such as the displacement and deflection slope of pile top, max moment and max shear of pile shaft, max soil pressure to judge standard, we distinguish the sensitivity factors and the non-sensitivity factors. Research conclusions are as follows: the internal friction angle  $\phi$  and the bending stiffness  $EI$  of pile are sensitivity factor, the effective unit weight  $\gamma$  is moderate sensitivity factor, and the effective unit weight  $\gamma$  is relative insensitive factor. Research results can provide beneficial reference for engineering surveyors and designers.

**Keywords:** sandy soil foundation; pile and soil interaction;  $p$ - $y$  curve method; parameter sensitivity

## 1 INTRODUCTION

Coastal and offshore engineering including harbor and wharf engineering, breakwater engineering, offshore drilling platform engineering, offshore wind farm engineering, anti-collision pier engineering and so on, these structures are supported by pile foundation subjected to horizontal load performance. The horizontal load performance is the control factor to design those pile foundations. The pile foundations can bear part of the action of horizontal loading, and the soil around the pile can also bear the rest action of loading. The combinations of pile-soil interaction mechanical properties have the ability to resist the whole horizontal deformation of the pile body [1, 2].

The internationally recognized effective analysis method of pile foundation with large deformation is the  $p$ - $y$  curve method; this method has been used widely by the American Petroleum Institute (API) and Det Norske Veritas (DNV) [3, 4].  $p$ - $y$  curve analysis method is also used by the Chinese standard code for Specifications for offshore Platform Engineering Geology investigation (GB/T 17503-2009) and the industry standard for Code for Pile Foundation of Harbor Engineering (JTS 167-4-2012) [5, 6]. The method can better simulate the response of piles and soil elastic-plastic development process.

At the offshore engineering site in the southeast of the yellow sea in China, shallow strata have a wide range of sand distribution; state of structure

from loose to close-grained is complex. Their mechanical property is the key to influence the survey and design of pile foundation engineering. Statistical analysis and reading values of the shear strength parameters are more important. The parameters of  $p$ - $y$  curve method also are crucial. However, the discussion of the content and research are few reported so far. All these are matters worthy of attention.

Only after the sensitivity of the pile foundation design index have been confirmed and obtained will the engineers of in-situ test and indoor experiments be granted access to hold the key of the problem. No matter from sampling, sample preparation, transport, in situ test, indoor test and parameter statistics, all should be strictly implement the relevant regulations, and striving for accuracy.

## 2 CALCULATION METHOD

In the conventional engineering design, the mechanical responses of pile foundation under the load combination are commonly used as the design indexes, such as the deflection at pile top or at the mudline, deflection slope of pile, maximum bending moment, maximum shear force, and the maximum soil pressure. The  $p$ - $y$  curve method and its principle with sandy soil foundations are shown in the reference [3]. Based on the  $p$ - $y$  curve method, assume that the soil reaction  $p$  is the function of

the pile depth  $z$  and the pile deflection  $y$ , the function is shown as  $p = p(z, y)$ . At the same time, the both side of pile at the unit  $dz$  are respectively distributed load  $q(z)$  and soil counterforce  $p(z, y)$ , and the shear force in the cross section of pile is  $S$ , bending moment is  $M$ . For the balance of the unit  $dz$ , the sum of the horizontal force should be zero. Therefore, the following equations can be derived:

$$(S + dS) - S - p(z, y)dz + q(z)dz = 0 \quad (1)$$

$$\frac{dS}{dz} = p(z, y) - q(z) \quad (2)$$

$$S = \frac{dM}{dz} \quad (3)$$

$$\frac{dS}{dz} = \frac{d^2M}{dz^2} = p(z, y) - q(z) \quad (4)$$

According to the mechanics of materials, the symbols of second order differential  $d^2y/dz^2$  and bending moment  $M$  are opposite, so it can be concluded that the bending moment differential equations as follows:

$$EI \frac{d^2y}{dz^2} = -M \quad (5)$$

where  $E$  is elasticity modulus,  $I$  is geometrical moment of inertia, and  $EI$  is the bending stiffness of pile.

$$EI \frac{d^4y}{dz^4} = -p(z, y) + q(z) \quad (6)$$

The [equation \(6\)](#) is the deflection differential equation of pile in the soil foundation. For general structure foundation under the horizontal load effect, the interface between soil and pile has the trend of separating, at the same time, the cohesion force between pile and soil is smaller than the effect force in the direction of attack, so it can be generally assumed to  $q(z) = 0$ , so the [equation \(6\)](#) can be expressed as:

$$EI \frac{d^4y}{dz^4} + p(z, y) = 0 \quad (7)$$

Regardless of the soil foundation is elastic or inelastic, the deflection differential [equation \(7\)](#) is always founded.

According to each division point deflection  $y$  of pile body, the rest indexes including the bending moment  $M$ , the shear force  $S$ , deflection slope  $St$  and the soil pressure  $R$  can be obtained from deflection at any unit of pile, which can be expressed as follows:

$$EI \left( \frac{d^2y}{dz^2} \right) = M \quad (8)$$

where  $z$  is depth of calculation point, and  $y$  is deflection of pile at the depth  $z$ .

$$EI \left( \frac{d^3y}{dz^3} \right) = S \quad (9)$$

$$\frac{dy}{dz} = St \quad (10)$$

$$EI \left( \frac{d^4y}{dz^4} \right) = R \quad (11)$$

It can be programmed through the above relations to obtain the design indexes.

### 3 ANALYSIS SCHEME

Take a large diameter steel pipe pile in offshore sandy soil ground for an example. The pile diameter  $D = 1.2$  m, pipe thickness  $t$  is 19 mm, the height of the pile above the mud line  $H$  is 7.9 m, the depth of pile under the mud line  $L$  is 45 m, the bending stiffness of pile  $EI = 2.46 \times 10^6$  kN/m<sup>2</sup>, soil effective unit weight  $\gamma = 9$  kN/m<sup>3</sup>, and internal friction angle of soil  $\phi = 35^\circ$ . Under the horizontal load  $F = 400$  kN at the top of pile, the deflection of pile top is 13 mm, and the maximum bending moment of pile is 3700 kNm. Based on the  $p$ - $y$  curve method, through calculation and analysis, the pile top deflection  $y = 14.7$  mm, the maximum bending moment  $M = 3880$  kNm. These design indexes of pile under different horizontal loads are shown in [Figure 1](#). In addition, the calculation result is basically corresponding to the measured value. Therefore, the computational results show that the method and the program we developed are correct and available.

In order to make the sensitivity analysis on some parameters under different horizontal loads, we develop the analysis scheme. The load changes at the range of 50 kN to 400 kN under different internal friction angles  $\phi$  of sandy soil. The reference value of  $\phi$  is set to be  $35^\circ$ , the corresponding design indexes can be obtained respectively according to the increment of 50%, -50% and -70% (corresponding to the internal friction angles  $\phi = 52.5^\circ$ ,  $17.5^\circ$  and  $10.5^\circ$  respectively).

For the sandy soil parameters  $\phi$ ,  $\gamma$  and pile structure parameter  $EI$ , we use the reference values mentioned above to fluctuate 20% and 5% interval as calculating parameters. Therefore, the sensitivity analysis of a certain parameter is made when the rest parameters are constant, so it can be to determine the quantitative influence of each single parameter.

Figure 1. Design indexes of pile under different horizontal loads.

#### 4 ANALYSIS RESULTS

The curves of pile design indexes under different internal friction angles and different horizontal loads are shown in Figure 2. From the curves, we can easily and clearly to obtain the rules. Under the same increase and decrease amplitude, the shapes of curves are significantly different. The sensitivity of internal friction angle to the deflection is greater than the maximum bending moment of pile.

Parameter sensitivity analysis curves of sandy soil and pile structure are shown in Figure 3

Figure 2. Design indexes of pile with different internal friction angles of sandy soil and horizontal loads.

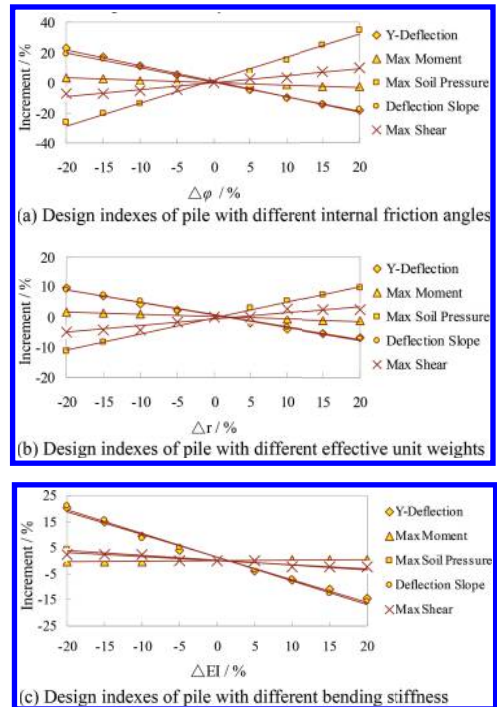

Figure 3. Parameter sensitivity analysis curves.

42.00	12.0	-18.37	3770	-2.84	830.2	10.0	73.13	35.00	-0.0087	-17.61

and Table 1. Within  $\pm 20\%$  of internal friction angle, the maximum horizontal deflection at pile top is in  $-18.37\%$ ~ $23.00\%$ . In the meantime, the changing of the slope at pile top are similar to the deflection, it is about  $-17.61\%$ ~ $19.22\%$ .

The biggest impact of indexes is the maximum soil pressure, and its maximum amplitude value can reach  $35.00\%$ . In terms of internal friction angle, the influence of effective unit weight is reduced. Therefore, for the sandy soil, we can determine that the internal friction angle is sensitive factor, and the unit weight is relative less sensitive factor.

In addition, for the deflection and slope at pile top, the bending stiffness  $EI$  is sensitive factor, the change range is  $12.60\%$ ~ $17.70\%$ . However, for the design indexes shear force and bending moment,  $EI$  is the relative less sensitive factor, the change amplitude is less than  $5\%$ .

## 5 CONCLUSIONS AND DISCUSSIONS

Through the parameter sensitivity analysis of marine sandy soil and pile, main conclusions are summarized as follows:

1. Through the design indexes of pile foundation as the judgment standard, the parameter sensitivity analysis results are more clearly, the conclusions can provide a reference for engineering survey and design engineer directly.
2. The sensitivity factors and less sensitivity factors studied are distinguished. Among them, internal friction angle  $\varphi$  of sandy soil is the most critical parameter, and pile bending stiffness  $EI$  is basically as important as  $\varphi$ . At the same time, effective unit weight  $\gamma$  of sandy soil is relatively less critical, but it also has major impact.
3. Because the influence of the pile bending stiffness is greater, so under the premise of

unimproved foundation soil, we can improve the pile bending stiffness to control the deflection and deflection slope of pile under the horizontal load, such as expansion of pile diameter or grouting in the pile pipe.

# Kinematic analysis of slope failure modes based on stereographic projection

S. Xiao, Y.T. Gao, S.C. Wu, B. Liu & Q.M. Tian

*Key Laboratory of Ministry of Education for Efficient Mining and Safety of Metal Mine, University of Science and Technology Beijing, Beijing, China*

**ABSTRACT:** On the basis of surveying and mapping data of joints and structural planes in Muliashi Open Pit, the kinematic analysis of slope failure modes was carried out on the tenth survey area (Area 10) of this open pit, using stereographic projection. The key points in graphic analysis process, criterion of potential failure modes and corresponding probabilities of the four kinds of slope failure modes, including planar sliding, wedge sliding, flexural toppling and direct toppling, were analyzed in detail. The results obtained in Area 10 were compared with the actual situation of instability slope on site. Comparison results show that this method could effectively identify potential slope failure mode. Furthermore, all slopes within the survey areas of the open pit were statistical analyzed, and results showed that wedge sliding failure in the open pit was most likely slope failure mode, successively followed by the toppling failure in northern slopes and the planar sliding failure in southern slopes. This method could identify potential slope instability mode effectively, and has important guiding significance for slope stability analysis and instability slope treatment.

**Keywords:** stereographic projection; kinematic analysis, failure mode; open pit slope

## 1 INTRODUCTION

Stereographic projection, widely used in structural geology and rock geotechnical engineering, is a method of reflecting objects' three-dimensional geometric elements (etc. line, polygon) onto the projection plane for further research (He 1965; Sun et al. 1980). It has been extensively documented that stereographic projection can be applied well in slope stability analysis by reflecting the spatial relationships between slope plane and joint planes (Hoek 1977; Goodman 1980; Hudson et al. 1997).

Kinematic analysis refers to analyzing the movement of object only from its spatial relationship and geometry and meanwhile ignoring the mass and external force. Kinematic analysis has been used to analyze the instabilities of discontinuity-controlled rock slopes (Aksoy et al. 2007), as well as the probability of block toppling failure and planar sliding. This method also can be applied for finding stable blocks within the Fraser's Hill granite slopes (Wangsa et al. 2008).

Combined use of stereographic projection and kinematic analysis has been recently proposed to analyze the potential failure modes and corresponding probabilities based on the spatial relationship between the slope surface and the joint planes. Specifically, by using the methods of

stereographic projection and kinematic analysis, Wang et al. (2011) analyzed the maximum safe excavation slope angle of double free face slopes, Smith et al. (2015) studied the instability of structural slopes under local stress trajectories, and moreover Admassu et al. (2013) analyzed the potential failure probability under different failure modes. All these researches promote the combined application of the stereographic projection and kinematic analysis.

In the present study, stereographic projection was used to map survey data of joints and structural planes from Muliashi Open Pit onto equatorial plane. Furthermore, four kinds of slope failure modes—planar sliding, wedge sliding, flexural toppling and direct toppling, were discussed in details using kinematic analysis focus on three aspects, including graphic analysis process, criterion of potential failure and corresponding probabilities. Research works have important guiding significance for slope stability analysis and instability treatment.

## 2 PROJECT OVERVIEW

Muliashi Open Pit (Fig. 1) located in Luanshya, Zambia, which is a deep open pit with a design

Figure 1. Muliashi open pit (partial).

mining depth of 175 m. The border elevation is 1280 m, and has mined to platform of 1190 m. The bench height is 15 m, which will be 30 m after benches combination. The instability phenomena such as small and medium scale collapse occurred to the southern slope during upper mining.

The rock mass of the open pit has developmental joints and structural planes. Site investigation found that the main cause of failure was ill-structure planes, especially the existence of multiple sets of structural planes cutting the rock mass, or the tendency of structural planes which were consistent with the tendency of slope, which would greatly reduce the slope stability.

In order to study the influence of rock joints on slope stability, mapping of joints and structural planes of slope rock mass has been made, which could effectively expose the distributing features of joints and structural planes in mine rock slope. In addition, it was conducive to know the distribution of lithology, characteristics of geological engineering, the rock group division, the engineering geological zoning, and etc. All these could provide guidance for the treatment of instability slope.

### 3 FIELD SURVEYING OF JOINTS AND STRUCTURAL PLANES

According to Code for Investigation of Geotechnical Engineering in China (GB50021-2001), weak intercalations and the distribution, composition, degree of consolidation and the features of the structure should be investigated in the engineering survey. The occurrence, crack width and persistence of joints should be measured by different parts of rock.

Fifty scan lines were layout in the outcrops in Muliashi Open Pit to get statistical materials of geological and geometric features of joints, which divided the open pit into 12 areas according to

different area conditions and lithology of rock mass. Projection diagram of joints occurrence poles and the favorite joint sets were illustrated. And then, the slope failure modes could be analyzed. The preliminary results are shown in Figure 2.

## 4 STEREOGRAPHIC PROJECTION KINEMATIC ANALYSIS

Given the relationship between the rock joints occurrence and slope plane, the stereographic projection kinematics analysis method was used to analyze the potential failure modes and the corresponding probabilities. The Area 10 in Figure 2 was cohosted to take analysis in detail.

### 4.1 Failure modes analysis of Area 10

The Area 10 with development joints and structural planes is located in southern slope, which belongs to the orebody footwall. The region slope angle is 65 degrees, and the average dip direction is 30 degrees. According to the regional joint survey data, four failure modes, including planar sliding, wedge sliding, flexural toppling and direct toppling, were applied to analyze the potential instability probability.

#### 4.1.1 Planar sliding

If planar sliding occurred, the dip direction of joint plane and the slope plane must have a same tendency. Also, the structural plane angle must be greater than the friction angle of rock mass, but be smaller than the slope angle.

The analysis graph of planar sliding mode is shown in Figure 3. The friction angle of rock mass in the slope is the friction angle cone in Figure 3 which set to 23 degree from the project materials. Based on empirical observations, a typically value of 20 to 30 degrees was assigned to the lateral limits. According to the stereographic projection kinematic analysis theory, the red zone is the critical pole vector zone for planar sliding. Joint poles in this area would easily cause planar sliding. The statistical analysis showed that the critical poles in red zone are 66, which accounted for 10.38% in the all joints. The analysis results are shown in Table 1.

#### 4.1.2 Wedge sliding

Wedge sliding includes double (along the line of intersection) and single sliding plane (if one plane has a more favorable orientation for sliding than the line of intersection). Wedge sliding is based on the analysis of joint plants intersections.

When two joint planes intersect together, they will form a three dimensional intersecting line which will form a intersection point with the polar

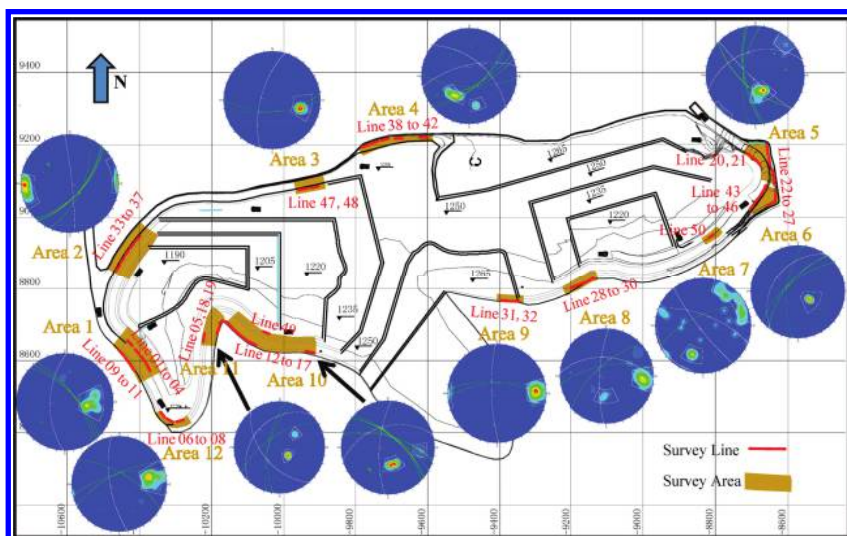

Figure 2. Field joint survey results.

Figure 3. Graphic analysis of planar sliding mode.

Table 1. Analysis results of planar sliding mode.

Type	Critical poles	All poles	Percentage of critical poles/%
Planar sliding	66	636	10.38

projection ball. If the intersection point falls in the red area in Figure 5, the intersection of two joint planes could cause a wedge sliding.

There are totally 188932 intersections formed by the entire joint planes, the number of which fall into the red zone is 139992, accounting for

Figure 4. Graphic analysis of wedge sliding mode.

74.10% (Table 2). The results show that the collapse of slope is likely caused by wedge sliding.

#### 4.1.3 Flexural toppling

The slip limit plane is defined in the flexural toppling failure according to Goodman's (1980). If slip occurs, the bedding normal must be inclined less steeply than a line inclined at an angle equivalent to the friction angle above the slope. The dip direction of the slip limit plane is equal to the slope, and the dip angle is equal to the results of slope angle minus the rock mass friction angle.

The red zone in Figure 6 represented the critical pole vector zone of flexural toppling mode. There is

Figure 5. Graphic analysis of flexural toppling mode.

Table 2. Analysis results of wedge sliding mode.

Type	Critical intersections	All intersections	Percentage of critical intersections/%
Wedge sliding	139992	188932	74.10

Figure 6. Graphic analysis of direct toppling mode.

only one joint pole in this zone, accounting for 0.16% in the entire poles (Table 3). The results proved the low possibility of flexural toppling damage.

#### 4.1.4 Direct toppling

The analysis of direct toppling is based on two conditions. Firstly, two joint sets intersect so that the intersection lines dip into the slope and form

Table 3. Analysis results of flexural toppling mode.

Type	Critical poles	All poles	Percentage of critical poles/%
Flexural toppling	1	636	0.16

Figure 7. Failure slope on site.

Table 4. Analysis results of direct toppling mode.

Type	Critical intersections	All intersections	Percentage of critical intersections/%
Forward	3654	188932	1.93
Oblique	903	188932	0.48%

discrete toppling blocks. Then, a third joint set exists, which act as release or sliding planes, allowing the blocks to topple. The damage mode can be further subdivided into forward toppling and oblique toppling by the relationship between sliding block and slope dip direction.

The red and yellow zones in Figure 7 are likely to generate positive toppling and oblique toppling, respectively. The statistical analysis showed that the proportion of forward toppling and oblique toppling were 1.93% and 0.48% (Table 4), respectively.

#### 4.1.5 Results discussion of Area 10

According to the stereographic projection kinematic analysis of slope within the Area 10, the probabilities of planar sliding, wedge sliding, flexural toppling, forward toppling and oblique toppling were 10.38%, 74.10%, 0.16%, 1.93% and 0.48%, respectively. The probability of wedge sliding in Area 10 is the greatest, followed by planar sliding.

The failure slope on site of Area 10 is showed in Figure 7. The sliding rock mass was controlled by the two intersecting joint planes, and caused a wedge sliding failure. The analysis result is consistent with the fundamental instability of site conditions, proving the effectiveness of this analysis method.

10	10.38%	74.10%	0.16%	1.93%	0.48%	Wedge sliding, planar sliding
11	64.24%	74.34%	0.61%	0.55%	0.00%	Wedge sliding, planar sliding
12	0.00%	22.27%	0.00%	13.24%	1.94%	Wedge sliding, forward toppling

#### 4.2 Analysis results of the open pit

The method of stereographic projection kinematic analysis was used to analyze the 12 areas of open pit slope from the four failure modes. Results are shown in Table 5.

The Area from 2 to 4 belonging to the northern slope (ore body hanging wall) have a maximum possibility of wedge sliding, followed by toppling failure. The Area from 6 to 11 belonging to the southern slope (Ore body footwall slope) have a maximum possibility of wedge sliding, followed by planar sliding.

The analysis results could be a preliminary identification of potential instability of slope, which has important guiding significance for slope stability analysis and slope engineering management treatment.

## 5 CONCLUSION

By stereographic projection kinematic analysis of Muliashi Open Pit, we've got basic conclusions as follows:

1. The probability of wedge sliding is the greatest in Area 10, followed by planar sliding. The analysis result is consistent with the fundamental instability of site conditions, proving the effectiveness of this analysis method.
2. The northern slope has a maximum possibility of wedge sliding, followed by toppling failure. The southern slope has a maximum possibility of wedge sliding, followed by planar sliding.
3. The analysis results could be a preliminary identification of potential instability of slope, which

has important guiding significance for slope stability analysis and slope engineering management treatment.

**ABSTRACT:** Based on Terzaghi's one-dimensional consolidation theory, this study was carried out on oedometer test, with further analysis in comparing the numerical simulations of the finite difference method using a numerical simulation program written in C++. The results show that the proposed numerical simulation procedure could simulate the oedometer test well, which have a certain theoretical value and practical significance for revealing the deformation of soft soil consolidation.

**Keywords:** soft clay; oedometer test; numerical simulation; finite difference method

## 1 INTRODUCTION

In consolidation of soft clay, many areas of modern construction were involved. It occupies a very important position in civil engineering. The consolidation test of soil was established according to the classic Terzaghi consolidation theory. At present, the incremental hierarchical loading method is the standard method commonly used at home and abroad. The essence of this method is when the last level of loading reaches stability, then it is applied to the next level of loading [1]. Because of the time reaching to the needed level is long, usually it is completed in several days or 10 more days, it is difficult to accurately determine the value of pre-consolidation pressure with less and discontinuous test data. Therefore, this paper applies a numerical analysis to the continuous loading compression test. In addition, in the incremental hierarchical loading experiment, there is an uneven distribution of effective stress on the horizontal planes, which along the height of the specimen, will lead to a very uneven compression. In this case, the specimen's structures are susceptible to damage and the test cycle is long.

In order to overcome the above disadvantages, foreign scholars have conducted intense researches on the consolidation test from the end of the 60s and developed the continuous loading consolidation test. According to different control conditions in the tests, the successive loading consolidation test can be divided into equivalent lumped

parameter method (Smith & Wahls [2], 1969), control the pore pressure gradient consolidation (Lowe [3], 1969), loading rate such as consolidation test (Aboshi [4], 1970; Von Fay [5], 1986), control the degree of consolidation test (Janbu [6]), control of hydraulic gradient strain consolidation test (Attasit Korchaiya-pruk [7], 2007).

Meanwhile, experimental results have a lot of discreteness due to the man-made factors on the consolidation test [8]. In this paper, we use Terzaghi as a one-dimensional consolidation theory [9], combining the constant strain consolidation test and the control of hydraulic gradient constant strain consolidation test, to analyze the control hydraulic gradient of constant strain consolidation test (GCRS), and to compile numerical simulation program of the indoor consolidation test using C++ programming language, the correctness of the simulation program according to the pre-existing experimental results was verified.

## 2 THE THEORY AND PROGRAM OF MERICAL SIMULATION

### 2.1 Basic idea

In GCRS consolidation test, the pore pressure of the specimen is the sum of the pore pressure of consolidation deformation and generated by the additional hydraulic gradient. The flow direction of pore water is determined by strain rate and additional hydraulic gradient of the base.

In order to simulate GCRS consolidation test, the specimen is divided into two parts, the upper part and the lower part, and the interface of the two parts is in the middle plane. Then two parts are further divided into several sub layers respectively (generally 20 or more).

## 2.2 Basic theory

At the beginning of GCRS consolidation simulation test, assuming that the middle plane occupies the center of the sample, namely

$$(NA \text{ Location})_{initial} = \frac{H_0}{2} \quad (1)$$

$$H_{Ti} = H_{Bi} = \frac{H_0}{2} \quad (2)$$

where,  $H_{Ti}$  and  $H_{Bi}$  is the height of upper and lower part of the specimen. Every part of the specimen is divided into  $n$  layers, the thickness of each layer is

$$H_{TLi} = H_{TBi} = \frac{H_{Ti}}{n} = \frac{H_{Bi}}{n} \quad (3)$$

where,  $H_{TLi}$ ,  $H_{TBi}$  is the thickness of upper and lower sublayer;  $n$  is the number of sublayers in each part. At the beginning of the simulation test, a void ratio was assumed after a period of consolidation settlement according to the initial void ratio of specimen. In the process of simulation, the mathematical convergence method was applied, thereby, to ensure that the specimen deformation simulated values are equal to the calculated values. The height of each sublayer after the consolidation can be calculated according to the assumed void ratio:

$$H_s = \frac{H_T}{(1+e_0) \cdot n} = \frac{H_{TLi}}{(1+e_0)} \quad (4)$$

$$H_{Lf} = H_{Li} - \left[ \frac{(H_{Li} - H_s)}{H_s} - e_{fa} \right] \cdot H_s \quad (5)$$

where,  $H_{Lf}$  is sublayers high after  $\Delta t$  consolidation;  $e_{fa}$  is sample's void ratio after  $\Delta t$  consolidation;  $H_s$ ,  $e_0$  is high of sample solid phase and initial void ratio; All the sub-layers have the same initial void ratio and height at the beginning of the simulation test.

Sub-layer's permeability coefficient can be obtained by:

$$C_k = \frac{\Delta e}{\Delta \log(k)} = \frac{e_{fa} - e_i}{[\log(k_L) - \log(k_0)]} \quad (6)$$

$$C_k [\log(k_L) - \log(k_0)] = e_{fa} - e_i \quad (7)$$

$$\log(k_L) = \frac{[e_{fa} - e_i + C_k \cdot \log(k_0)]}{C_k} \quad (8)$$

$$k_L = 10^{\left[ \frac{e_{fa} - e_i + C_k \cdot \log(k_0)}{C_k} \right]} \quad (9)$$

where,  $C_k$  is  $e \sim \log k$  curve's slope;  $k_L$  is Sub-layer's permeability coefficient;  $k_0$  is initial permeability coefficient.

Based on the deformation of soil layer, we can get the calculating formula of seepage velocity:

$$V_d = \frac{q}{A} \quad (10)$$

$$V_d = \frac{\Delta Volume}{\Delta t \cdot A} = \frac{\Delta H \cdot A}{\Delta t \cdot A} = \frac{\Delta H}{\Delta t} \quad (11)$$

where  $V_d$  is the seepage velocity caused by the soil deformation,  $q$  is the seepage flow, and  $\Delta t$  is the time increment.

In addition, another part of the seepage is due to the additional hydraulic gradient at the bottom of the specimen, which can be calculated by

$$i = \frac{\Delta u_b}{H} \cdot \frac{1}{\gamma_w} \quad (12)$$

$$V_i = k \cdot i \quad (13)$$

$$V_i = k_L \cdot \left( \frac{\Delta u_b}{H} \cdot \frac{1}{\gamma_w} \right) \quad (14)$$

where  $\Delta u_b$  is the excess pore water pressure at the bottom of the sample and  $\gamma_w$  is the severe of water.

Therefore, the total seepage flow velocity of sample is the sum of two parts, namely

$$V = V_d + V_i \quad (15)$$

The average excess pore water pressure will be achieved based on the calculation formula of hydraulic gradient and flow velocity, for

$$V = k \cdot i \quad (16)$$

$$V = k_L \cdot \left( \frac{\Delta u_L}{H_L} \right) \cdot \frac{1}{\gamma_w} \quad (17)$$

$$\Delta u_L = \frac{V \cdot H_L \cdot \gamma_w}{k_L} \quad (18)$$

where  $\Delta u_L$  is excess pore water pressure of each soil layer.

By (18), we can calculate the mean effective stress with the normal orientation of each layer:

$$\sigma'_{vL(avg)} = \sigma_v - \Delta u_L = \sigma_v - \frac{V \cdot H_L \cdot \gamma_w}{k_L} \quad (19)$$

where  $\sigma'_{vL(avg)}$  is the mean effective stress with the normal orientation of soil layer, and  $\sigma_v$  is the total stress. Therefore, we can calculate the new void ratio,

$$C_c = \frac{\Delta e}{\Delta \log(\sigma'_v)} \quad (20)$$

$$C_c \cdot [\log(\sigma'_{vL(avg)}) - \log(\sigma'_{v0(avg)})] = e_n - e_i \quad (21)$$

$$e_n = e_i + C_c \cdot [\log(\sigma'_{vL(avg)}) - \log(\sigma'_{v0(avg)})] \quad (22)$$

where  $C_c$  is the compression index,  $\sigma'_{v0(avg)}$  is effective stress for the average initial method, and  $e_n$  is the new calculated void ratio.

Using the new void ratio, the deformation of soil layer can be calculated. Each soil layer (from top layer to middle plane) has the same calculation process.

The simulation process of the lower part of the specimen is the same to that of the upper part except that the calculation of soil layer is from the base to middle plane, step by step. Therefore, after  $\Delta t$  consolidation, the height of the sample becomes

$$H_f = H_{Tf} + H_{Bf} \quad (23)$$

Comparing the calculated sample height with the theoretical value (calculated by strain rate and time increment). If their difference is beyond the setting error range showing that hypothesis void ratio is not correspondent with practice and needs to be corrected. Therefore, we should modify the void ratio constantly in the process of simulation using iteration method until the calculated height is equal to the theoretical value. The void ratio is modified by the convergence algorithm,

$$e_{update} = \frac{e_a}{\left[ \frac{H_f(\text{predicted})}{H_f(\text{expected})} \right]} \quad (24)$$

Not only the deformation conditions should be satisfied, but the boundary conditions, including the excess pore water pressure at the top of the sample  $\Delta u_t$ , the excess pore water pressure at the bottom of sample  $\Delta u_b$ , the excess pore water pressure of the boundaries of the sample  $\Delta u_{NA(t)}$ ,  $\Delta u_{NA(b)}$ . If the value of  $\Delta u_{NA(t)}$  is not equal to  $\Delta u_{NA(b)}$ , it shows the middle plane, which divided the specimen into the upper and the lower parts disagrees with the practical and we need to modify it. If the value of  $\Delta u_{NA(t)}$  is greater than  $\Delta u_{NA(b)}$ , it shows that the middle plane is lower, and should be up-regulated;

Table 1. Summary of the input parameters for CGC simulation.

Parameter	Physical meaning
$H_0$	Initial drainage height
$\dot{\epsilon}$	Strain rate
$e_0$	Initial void ratio
$k_0$	Initial permeability coefficient
$C_k$	Slope of $e \sim \log(k)$
$C_c$	Compression index
$\Delta u_b$	Pore pressure
$\Delta t$	Time increment

if the value of  $\Delta u_{NA(t)}$  is less than  $\Delta u_{NA(b)}$ , it shows that the middle plane is higher, and should be down-regulate. The correction calculation formula of middle plane position is as follows:

$$\Delta(NA) = NA_i \pm \frac{H_i}{m} \quad (25)$$

where  $\Delta(NA)$  is the correction value of middle plane position,  $NA_i$  is the initial set of middle plane position,  $H_i$  is total height of the sample, and  $m$  is correction coefficient of the middle plane position.

The value of  $m$  controls the middle plane's extent of variation. In order to get the appropriate correction value, the set value of  $m$  should be larger (100 or more). After the new middle plane is determined, dividing the upper and lower part of the sample into  $n$  layers separately, and conducting the simulation experiment until boundary conditions of the deformation condition and the excess pore water pressure are met, then the simulation experiment of  $\Delta t$  is finished.

### 2.3 The numerical simulation parameters

Based on the simulation theory above, the main simulation parameters includes: the drainage height of specimen, the strain rate, the initial void ratio, the permeability coefficient, the curve's slope, the compression index of pore pressure, etc. Table 1 shows the simulation parameters and physical meaning of them.

## 3 ANALYSIS OF EXPERIMENT RESULT

In the range of experimental error, the deformation index measured by the GCRS test is equivalent to the one which is measured by the routine consolidation test. Judging from the comprehensive technical and economical comparison, we can expect that GCRS test is superior to routine consolidation test.

### 3.1 Compression curve drawing

In the continuous load test, take semi-continuous observation into normal stress, sedimentation, and pore water pressure. Calculating the void ratio basis on the current load, and then a compression curve using the effective stress, the void ratio can then be obtained.

### 3.2 To solve the $c_v$ , $m_v$ , $k_v$

The coefficient of consolidation could be obtained by the theory

$$c_v = \frac{\Delta\sigma}{\Delta t} \cdot \frac{H^2}{2\Delta u_b} \quad (26)$$

Therefore, as long as we know the normal pressure increment  $\Delta\sigma$  within a tiny period,  $\Delta t$  we can calculate the coefficient of consolidation  $c_v$  directly by formula (26), and have no more need of mapping. At the same, we can calculate the average void ratio  $c_v$  at any time.

In addition, the volume compressibility coefficient and the permeability coefficient can be calculated directly by the following formula:

$$m_v = \frac{1}{H} \cdot \frac{\Delta\delta/\Delta t}{\Delta\sigma/\Delta t} \quad (27)$$

$$k = \frac{\gamma_w H}{2u_b} \cdot \frac{\Delta\delta}{\Delta t} \quad (28)$$

where  $\Delta\delta$  is the normal increment of deformation and  $\gamma_w$  is the volume weight of water.

## 4 THE RESULT OF NUMERICAL ANALYSIS

Conduct the above simulation program on sample of consolidated soil. The simulation parameters of soil sample are shown in Table 2:

Table 2. Input parameter values for oedometer simulation.

Parameter	Value
$H_0$	2.54 cm
$\dot{\epsilon}$	0.002
$e_0$	1.0
$k_0$	$6 \times 10^{-5}$ cm/s
$C_k$	0.4478
$C_c$	-0.4478
$\Delta u_b$	20 kPa
$\Delta t$	120 s

### 1. Compression Curve

We can get the relation curve of the void ratio changes along with axial stress by the simulation results, namely the compression curve. As shown in Figure 1 and Figure 2, they are the relation curve of  $e \sim p$  and  $e \sim \log p$ , respectively.

The same as the conventional consolidation test, we can calculate the consolidation parameters such as modulus of compressibility  $E$ , coefficient of volume compressibility  $m_v$ , and compression index  $C_c$  and so on by relation curve of  $e \sim p$  and  $e \sim \log p$ . However, due to the graphic solution will produce some error; here we adopt to point the coordinate to solve the problem directly.

### 2. Consolidation Parameters

After the simulation test was conducted  $\Delta t = 120$  s, increment of normal pressure  $\Delta\sigma = 30.5981 - 30.0 = 0.5981$  kPa, the applied pore water pressure is 20 kPa, coefficient of consolidation can be calculated by the formula (26). And by the simulation results, we can get

Figure 1. Relation curve of  $e \sim p$ .

Figure 2. Relation curve of  $e \sim \log p$ .

Table 3. Engineering characteristics of saturated loess.

The category of the soil	Dry density	The content of water	The initial void ratio	The proportion of soil particles	Saturation
The saturated loess	1.353 g/cm <sup>3</sup>	34%	0.996	2.7	92.2%

Table 4. Comparison of experimental data and simulation data.

The axial stress (kPa)	50	100	200	400	800
The test results of void ratio	0.8967	0.8388	0.7695	0.6977	0.6265
The simulated results of void ratio	0.9131	0.8538	0.7804	0.6986	0.6121

Figure 3. Comparison of experiment and simulation  $e \sim p$  curve.

Figure 4. Comparison of experiment and simulation  $e \sim \log p$  curve.

the normal deformation  $\Delta\delta = 4.8 \times 10^{-3} \text{ cm}$ . Then, coefficient of volume compressibility  $m_v$  and coefficient of permeability  $k$  will be calculated separately by formulas (27) and (28).

$$c_v = \frac{\Delta\sigma}{\Delta t} \cdot \frac{H^2}{2\Delta u_b} = \frac{0.5981}{120} \times \frac{4.0^2}{2 \times 20} = 0.00199 \text{ cm}^2/\text{s}$$

$$m_v = \frac{1}{H} \cdot \frac{\Delta\delta/\Delta t}{\Delta\sigma/\Delta t} = \frac{1}{4.0} \times \frac{4.8 \times 10^{-3}/120}{0.5981/120} = 0.2006 \text{ MPa}$$

$$k_v = \frac{\gamma_w H}{2u_b} \cdot \frac{\Delta\delta}{\Delta t} = 3.924 \times 10^{-5} \text{ cmls}$$

## 5 EXAMPLE OF VERIFICATION

This paper refers to Beibei-Yao's [10] parameters of saturated remodeling loess consolidation test under continuous load, as shown in Table 3, using the proposed GCRS numerical simulation program to test the engineering properties of saturated loess.

According to simulation results, take the void ratio where the axial stress is 25 kPa, 50 kPa, 100 kPa, 200 kPa, 400 kPa, and 800 kPa to compare with the test results, and the comparison results which are shown in the Table 4. Then drawing the simulated curve by simulated results, and taking the simulated curve and test curve into comparison, as shown in Figure 3 and Figure 4.

By the two comparisons of the data and curve changes, the axial strain test values are close to simulated values when the per level load is stable, moreover, the curve's coincidence is very high. This shows the correctness of the simulation program, which was put forward in this paper, can be used for indoor consolidation simulation test of saturated soil, as well as be able to use the results of simulation to calculate consolidation parameters.

## 6 CONCLUSIONS

This paper, based on Terzaghi's one-dimensional consolidation theory, conducted the finite difference method for numerical simulation on the

consolidation test control hydraulic gradient, discussed the strain rate, sample size, permeability coefficient, pore pressure and other parameters that effect the consolidation test results. Research results show as follows:

1. The numerical simulation program presented in this paper can be applied to control hydraulic gradient consolidation simulation test with different sizes of the sample.
2. The results of the control hydraulic gradient consolidation simulation test shows that the void ratio change value obtained by numerical simulation is very close to the test data, and it has verified the rationality and correctness of approach which was proposed by this paper.

# A calculating model for acid load settlement based on mass transfer process of AMD corrosion

L.C. Jiang

*School of Civil Engineering and Transportation, South China University of Technology, Guangzhou, China*

W.W. Li & J.J. Zeng

*School of Mechanical and Automotive Engineering, South China University of Technology, Guangzhou, China*

**ABSTRACT:** Analyze mass transfer process of AMD corrosion and put forward the calculating model for acid load on the base of the experiment on AMD corrosion and the mechanism of sulfide oxidation. The model could be used to get AMD corrosion load while measuring instant concentration of corrosion solution. The corrosion load settlement of a slope is analyzed applying this model. The analysis results shows that: (1) in the puddle, water storage, fracture and other mineral water gathering areas, the acid load settlement is very serious, reaching more than 500 mg/L, significantly higher than other regions; (2) on the position of slope surface, due to AMD corrosion effect in a relative short time, the acid load is between 166–300 mg/L, relatively low; (3) away from the mines, such as streams, the acid load is below 20 mg/L, the lowest.

**Keywords:** AMD corrosion; AMD corrosion experiment; mass transfer process; calculating model for acid load settlement

## 1 INTRODUCTION

In the chemical, metal and coal mines that exploit sulfide ore, AMD (Acid Mine Drainage) action is the remarkable effects of slope failure. Sulfide and its residue oxidize with air and water, and then produce AMD solution that contains heavy metal ions (Wang, J. et al. 2007).

AMD solution is with strong corrosion capability. Long-term corrosion reaction and stress corrosion eventually lead to the structure destruction of the rock mass.

The water-rock chemical interaction is a hot spot research area in the civil engineering in recent years (Xiang, R.J. et al. 2012, Feng, X.T. et al. 2002). Related researches mainly focus on the damage to the environment by acid liquor, the influence on the mechanical parameters of rock or soil mass, and the influence on slope stability, etc. AMD corrosion is obviously different from the chemical interaction with common acid liquor, so as the mechanism (Tang, L.S. et al. 2000). Corrosion action makes the instability mechanism of side slope complicated at the sulfide mine (Jiang, L.C. et al. 2013), main stability analysis belongs to the qualitative analysis. In order to quantify AMD corrosion influence on sulfide mine, mass transfer process of AMD corrosion reaction needs to be analyzed and then investigate acid load of

AMD corrosion, which the current research hasn't involved in yet.

With a large-scale domestic pyrite mine slope as the study object, on the basis of the related experiments, starting with the research of the oxidation mechanism of the sulfide minerals, this paper has analyzed AMD chemical mass transfer behavior and carried out the researches on the settlement calculation for acid load in the process of AMD corrosion.

## 2 AMD CORROSION EXPERIMENT

The engineering study object of this paper is the slope located in a large-scale domestic open-pit pyrite mine. The slope rock mass mainly contains quartz sandstone, diorite, dioritic porphyrite and a small amount of limestone in some area.

The standard specimen is processed (Fig. 1) according to the Specifications for Rock Tests in Water Conservancy and Hydroelectric Engineering (SL264-2001), and the AMD solution collected at the bottom of mining pit (Fig. 2).

Specimens are soaked for 25 days and the interval time for sampling collection is 5 days. The indoor temperature is kept stable during the test process. Table 1 shows the concentration of major ions of AMD solution before vs. after the test.

Figure 1. Rock samples.

Figure 2. AMD solution of mine.

Table 1. Composition variation of AMD solution before vs. after the corrosion reaction.

AMD solution		The concentration of major ions (mg/L)					
		SO <sub>4</sub> <sup>2-</sup>	Fe <sup>2+</sup>	Ca <sup>2+</sup>	Mg <sup>2+</sup>	K <sup>+</sup>	Na <sup>+</sup>
pH=1.25	before corrosion	3.7×10 <sup>3</sup>	43.7	137.1	45.4	1.1	4.7
	after corrosion	5.3×10 <sup>3</sup>	60.8	458.1	71.3	3.0	8.2
pH=3.38	before corrosion	2.7×10 <sup>3</sup>	39.9	124.0	42.8	0.8	4.4
	after corrosion	4.1×10 <sup>3</sup>	54.3	352.6	55.6	2.2	6.3

The results show that the concentration of the ion varies obviously in the solution after corrosion, and the concentration of Ca<sup>2+</sup>, Fe<sup>2+</sup> and SO<sub>4</sub><sup>2-</sup> is significantly increased.

After SEM scanning, a large number of pores and cavity appears in the specimen, which shows

the soluble calcium salt (CaCO<sub>3</sub>), mudstone and sulfide minerals (FeS<sub>2</sub>) are dissolved between the joints of the specimen. AMD corrosion is the process of chemical mass transfer of mineral.

### 3 MASS TRANSFER PROCESS ANALYSIS OF AMD CORROSION

AMD solution consists of multiple acid liquors and its pH value is generally between 2 and 5 with high conductivity, and the high conductivity of AMD solution increased the rhythm of ion replacement which will increase the corrosion rate. The essence of the slope damage process by AMD corrosion is the process of ion exchange; the ion exchange rate directly affects the corrosion rate.

According to microcosmic chemical mass transfer principle, the dissolved minerals flux caused by ion exchange can be expressed by fluid velocity of pore rocks (Jiang, L.C. 2012) and AMD solution concentration as

$$J_{adv} = v^*(nc) = vc \quad (1)$$

where  $J_{adv}$  is the solute flux, namely the damage quantity of slope rock mass;  $v$  is the fluid velocity of corrosion liquid;  $c$  is local concentration of ion in AMD solution;  $n$  is the porosity which shows the influence of the integrity of rock mass on corrosion;  $v^*$  is the fluid velocity of liquid in the pore.

The diffusion (or dispersion) flux of the solute can be represented as

$$J_s = D_s \frac{\partial C}{\partial n} \quad (2)$$

where  $J_s$  is diffusion flux;  $C$  is the overall concentration of the solution;  $D_s$  is the diffusion coefficient;  $\bar{n}$  is the normal vector.

When minerals of rock mass are dissolved or new attachments are generated on rock surface, the dissolution rate can be expressed as

$$\text{Rate}_i = r_i \frac{A_0}{V} \left( \frac{m_i}{m_{i0}} \right)^n \quad (3)$$

There into,

$$r_i = k_i \left[ 1 - \left( \frac{IAP}{K_k} \right)^\sigma \right] \quad (4)$$

where  $r_i$  is the specific speed of medium;  $A_0$  is the initial surface area of rock mass;  $V$  is the volume of the solution;  $m_{i0}$  is the initial molar coefficient

of minerals;  $m_i$  is the molar coefficient of minerals at  $t$  moment;  $IAP$  is ion product;  $K_k$  is chemical equilibrium constant;  $\sigma$  is non-dimensional coefficient.

During the process of AMD corrosion, the expression for the porosity of rock mass is

$$\left. \begin{aligned} \frac{dn_i}{dt} &= \gamma V_i Rate_i \\ n &= n_0 + \sum_{i=1}^{M_i} Rate_i \end{aligned} \right\} \quad (5)$$

Thus, mathematical expressions of mineral dissolution quantity of AMD corrosion are

$$\left. \begin{aligned} \frac{\partial(nC_i)}{\partial t} &= D \frac{\partial^2(nC_i)}{\partial n^2} - v \frac{\partial(nC_i)}{\partial t} + \sum_{i=1}^{M_i} Rate_i \\ Rate_i &= r_i \frac{A_0}{V} \left( \frac{m_i}{m_{i0}} \right)^n \\ C_i(x, y, z)_{t=0} &= 0 \\ C_i(t) &= C_0 - \gamma Rate_i \end{aligned} \right\} \quad (6)$$

where  $C_i(x, y, z)$  is the boundary conditions of corrosion concentration at  $t$  moment.

The mathematical model includes the main exchange process between corrosion solution and the rock mass, dynamic change of the solution characterization represents the AMD corrosion process.

Analyzing the solution acid load can effectively evaluate the degree of AMD corrosion.

#### 4 SETTLEMENT CALCULATION FOR ACID LOAD OF AMD CORROSION

The field investigation results show that, in the process of sulfide mineral mining, along with the change of the ore bodies exposed area, depth, slope runoff and the external rainfall, AMD acidity will also continue to change. But within a certain time period  $t$ , the acid settlement quantity in the mine pit area is relatively stable. On the basis of chemical mass transfer process, the researches on the acid load for slope rock mass by the AMD corrosion have been carried out.

##### 4.1 The chemical process of acid generation

The main mining product is sulfide minerals ( $FeS_2$ ), and under the strong acid environment, acid production action of hydration of Fe element in pyrite will be restrained (Feng, X.T. 2010). Meanwhile, during the acid settlement processing, hydrolytic acidification of basic group positive ion and hydrolytic acidification action of carbonate are difficult

to proceed. Based on the analysis, acid generation of AMD corrosion mainly comes from the oxidation process of S element.

The main oxidation reaction of pyrite in water environment is as follows

According to the Equation (6) which is the mass transfer of AMD corrosion, the velocity of  $H_2SO_4$  by AMD corrosion is calculated.

Supposed that the reaction rates of Equation (7) to (10) respectively correspond to  $R_1$ ,  $R_2$ ,  $R_3$  and  $R_4$ ; the solute concentration at  $t$  moment is  $C_{it}$  and the mass is  $m_{it}$ . Based on the chemical dynamics theory, the reaction constant of the four equations can be obtained as Equation (11):

$$\left. \begin{aligned} R_1 &= \gamma_1 (C_{FeSO_4 0} - C_{FeSO_4 t}) (C_{H_2SO_4 0} - C_{H_2SO_4 t}) \\ R_2 &= \gamma_2 (C_{Fe_2(SO_4)_3 0} - C_{Fe_2(SO_4)_3 t}) \\ R_3 &= \gamma_3 (C_{FeSO_4 0} - C_{FeSO_4 t}) (m_{s0} - m_{st}) \\ R_4 &= \gamma_4 (C_{H_2SO_4 0} - C_{H_2SO_4 t}) (m_{s0} - m_{st}) \end{aligned} \right\} \quad (11)$$

where  $\gamma_1$ ,  $\gamma_2$ ,  $\gamma_3$  and  $\gamma_4$  are reaction coefficients that can be acquired according to reaction temperature (Jiang, L.C. 2007).

Thus, in the process of analyzing the load settlement of AMD corrosion, for simplifying the calculation, the influence of AMD corrosion on the slope body is evaluated by corrosion settlement rate by means of the measurement of PH variation.

##### 4.2 Dimensionless method of parameter

When calculating the generation amount of  $H_2SO_4$  by AMD corrosion, Equation (6) can be transferred to the response numerical model characterized by porosity.

Assumed the initial porosity is  $\phi_0$  and the dimensionless of the porosity is

$$\phi = \frac{\phi_t}{\phi_0} \quad (12)$$

The dimensionless of the flow velocity is

$$v = \frac{1 - \phi_t}{1 - \phi_0} \quad (13)$$

Similarly, related concentration parameters of AMD corrosion solution can be processed with dimensionless method.

## 5 CALCULATION OF AMD ACID LOAD

Because of the Equation (9) shows no acid production or consumption, it should not be taken into consideration during calculation. Other components such as oxygen, moisture and Fe<sub>2</sub>S are regarded as sufficient, and their dimensionless parameters are set to 1.

Based on the previous analysis, the influence of the initial medium parameters mainly divides into two aspects including temperature and concentration. The influence value of temperature and concentration can be represented by the Damkoler number of  $\zeta_1$ ,  $\zeta_2$ ,  $\zeta_3$  and  $\zeta_4$  whose range is [0,1]. The calculation process can refer to Wang, N. et al. (2012) and Michaela, S. (2011). Substitute each dimensionless parameter into Equation (6), the formula of the acid production of AMD corrosion can be obtained as

$$\begin{aligned} \frac{\partial C_{H_2SO_4}}{\partial t} = & -\frac{1-\phi_t}{1-\phi_0} \left[ \gamma_3 \zeta_3 (m_{S_0} - m_{S_t}) (1 - C_{FeSO_4}) \right] \\ & + \gamma_1 \zeta_1 (1 - C_{FeSO_4}) (1 - C_{H_2SO_4}) \\ & + \gamma_4 \zeta_4 (m_{S_0} - m_{S_t}) (1 - C_{H_2SO_4}) \end{aligned} \quad (14)$$

where the 1st item is the consumption amount of sulfuric acid for Equation (8), and this process mainly takes place near the pore which is mostly influenced by pore fluid velocity parameters; the 2nd item is the amount of acid production by Equation (7); the 3rd item corresponds with the amount of acid production for Equation (10).

During the reaction process, the products and reactants of sulfide minerals interact as basis, then the constrained relation can be established with Damkoler number from Equation (7) to (10):

$$\zeta_1 + \zeta_2 + \zeta_3 + \zeta_4 = 1 \quad (15)$$

In the Equation (14), the generation rate of Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> and FeSO<sub>4</sub> are

$$\begin{aligned} \frac{\partial C_{FeSO_4}}{\partial t} = & -\frac{1-\phi_t}{1-\phi_0} \left[ \gamma_2 \zeta_2 (1 - C_{Fe_2(SO_4)_3}) \right] \\ & + \gamma_1 \zeta_1 (1 - C_{FeSO_4}) (1 - C_{H_2SO_4}) \\ & + \gamma_4 \zeta_4 (m_{S_0} - m_{S_t}) C_{H_2SO_4} \end{aligned} \quad (16)$$

$$\begin{aligned} \frac{\partial C_{Fe_2(SO_4)_3}}{\partial t} = & -\frac{1-\phi_t}{1-\phi_0} \left[ \gamma_3 \zeta_3 (m_{S_0} - m_{S_t}) (1 - C_{FeSO_4}) \right] \\ & + \gamma_4 \zeta_4 (m_{S_0} - m_{S_t}) C_{H_2SO_4} \\ & + \gamma_2 \zeta_2 (1 - C_{Fe_2(SO_4)_3}) \end{aligned} \quad (17)$$

The Equation (14) to (17) constitute the model of calculation for acid load.

On this basis, with the calculation program compiled by the CAD and measurement of real time concentration of the corrosion solution, the load value of AMD corrosion, namely the concentration of H<sub>2</sub>SO<sub>4</sub>, is then obtained.

## 6 ENGINEERING APPLICATION

In a large domestic pyrite mine slope, the sulfide ore bodies is adhere to the location between Huanglong group and Chuanshan group limestone, whose baseboard consists of the arenaceous shales of Gaolishan group and quartz sand, and roof with diorite, Qixia limestone and Chuanshan limestone. The ore body mainly consists of the pyrite (FeS<sub>2</sub>). In the process of mining, the acid corrosion is serious.

In order to evaluate the corrosion status of slope rock mass at the mine, the water areas near line11 to line 19 are selected as study object, including seepage water of slope surface, water in mining pit, acid water sump, the nearby stream and so on (Guo, J.C. et al. 2005). Part of the sample composition is shown in Table 2 (test temperature is 25 °C). Locations include: ①Seepage water of slope surface on +23 m; ②Seepage water of slope surface on -24 m; ③Water in the middle mining pit on -48 m; ④Water warehouse in mining pit on -48 m; ⑤East No.1 dewatering well; ⑥Seepage water of slope surface on +24 m; ⑦Gutterway outside the stope; ⑧Upstream of the Xinxi River.

Table 2. Slope water composition (unit: mg/L).

Locations	pH	SO <sub>4</sub> <sup>2-</sup>	TFe	Cu
①	4.81	171	0.03	0.35
②	4.31	199	0.03	0.35
③	1.03	284	86	24.90
④	2.27	374	105	20.90
⑤	4.20	523	0.04	13.70
⑥*	4.60	500	1.27	1.36
⑦	6.00	261	0.022	0.13
⑧	6.80	118	0.20	0.04

\*+24 m slope surface is on the main crack F<sub>13</sub> of the slope

Based on the concentration of the reactants and the environment temperature, the undetermined parameter value in the corrosion load formula can be acquired by table look-up. Time nodes are subject to pore 0.1 (Jiang, L.C. et al. 2011) to 0.25 (Du, Y.J. et al. 2014). The  $H_2SO_4$  settlement of slope corrosion solution and the content of  $Fe_2(SO_4)_3$  and  $FeSO_4$  can be obtained by calculation, as shown in Table 3.

Data in the table shows that there is a significant difference of AMD corrosion load at the different sections of the slope: the most powerful acid settlement appears at East No. 1 dewatering well and +24 m slope surface, which are up to 500 mg/L or more; acid settlement at the upstream of Xinxi River is minimum, which is less than 20 mg/L. The amount of acid production near the slope region is between 166~300 mg/L.

Based on the analysis of the phenomenon above, AMD corrosion solution is converged at the locations such as sump and well, which cumulative settlement of AMD acid load. Thus the acid load at those locations, where the most severe location of corrosion of rock happens, is higher than other locations. +24 m step is on the main crack  $F_{13}$  of the slope. Since the water has been contacted with the sulfide ore body for a long period, acid generation amount has reached 505 mg/L with significant destruction of corrosion. At the remaining regions of the slope, infiltration of main surface water and ground water has formed AMD corrosion solution. With short duration of reaction and the lower acid generation, there is weak corrosion interaction. Streams far away from the mines have not been affected by acid oxidation of sulfide minerals and the acidification load is extremely low.

Data in Table 3 can be converted into a histogram as shown in Figure 3 which intuitively represents the settlement of  $H_2SO_4$ ,  $Fe_2(SO_4)_3$  and  $FeSO_4$  under the corrosion at different locations.

As the analysis, the concentration of  $Fe_2(SO_4)_3$  and the  $FeSO_4$  in the sump or dipole is more obvious while not in the remaining positions of

Figure 3. Basic material relationship of the corrosion solution.

the measurement, which matches well with the mine actual situation. The main reason is that the remaining areas of the measuring position are all small catchment areas and they are limited to the production  $Fe_2(SO_4)_3$  and  $FeSO_4$ . Since the confluence time of AMD in the catchment is longer, the amounts of the three corrosion products by AMD are a bit higher than those in the dipole. Therefore, the conclusion is the model calculation results is consist with mine actual situation.

## 7 CONCLUSIONS

According to the oxidation mechanism of sulfide minerals, the chemical mass transfer of AMD corrosion has been researched. By introducing the concept of acid load settlement, the acidification model of AMD corrosion is established and has applied into some large-scale sulfide mining slope. This research reaches conclusions as follows:

1. Based on the conservation of S content element, the chemical mass transfer behavior of AMD has been analyzed. The dynamic acidification model of AMD corrosion was established by studying the calculation formula of dynamic changes of concentration of  $H_2SO_4$ ,  $Fe_2(SO_4)_3$  and  $FeSO_4$  solutions.
2. The analysis of slope acid corrosion shows that the sumps, wells and structural surfaces of slope are the weak areas of land slide. It provides evidence for putting forward the relevant effective control strategies.
3. The settlement analysis of acid load for corrosion indicates that the settlement in slope catchment area is the most obvious area where corrosion settlement is above 500 mg/L, and acid production this area around the slope ranges from 166 to 300 mg/L.

Table 3.  $H_2SO_4$  settlement of slope corrosion solution (unit: mg/L).

**ABSTRACT:** The stress alteration in the course of tunneling through soft rocks is simulated when under predetermined pressure from the strata and by fixing first and radical unloading second, a tri-axial creeping experiment is conducted. The tri-axial unloading shearing experiment indicates that with the shearing stress decreasing, the creeping rate will apparently go down. When the shearing stress reaches a value (It turns out to be 0.5 MPa in the present experiment) below the critical point, the axial creeping almost approaches zero. When the shearing stress exceeds a critical value (It turns out to be 3.5 MPa in the present experiment), the creep of the cretaceous strata will experience the different damages composed of such three stages as those of decelerating, being constant and accelerating. In accordance with the experiments results, a constitutive model is constructed for the visco-elasto-plastic cretaceous soft rock stratum creeping. Then the secondary development is conducted of the finite element procedure and then the constitutive model we have developed is embedded in the large non-linear finite element program ADINA8.3. Upon the completion of the above-mentioned work, a numerical simulation experiment is conducted with the supporting process while tunneling in the soft rock strata in a coal mine in Inner Mongolia. The experiment indicates that the constitutive model for the elasto-visco-plastic creeping can tell the deformation characteristics of soft rock strata rather precisely. And the experiment results are well comparable with those of the numerical simulation, showing that our experiment results can be employed as a reference for the design of roadways in cretaceous soft rock strata and the corresponding tunneling performance.

*Keywords:* experiment with creeping deformation affected by unloading; cretaceous formation; soft-rock roadway; secondary development of finite element

### 1 INTRODUCTION

Most of the coal mines in the Western regions of China traverse the Cretaceous and Jurassic Formations of the Mesozoic Strata, characterized by argillaceous cementation, low strength and apparent creeping. In deep underground roadway supporting, no one can afford to neglect such important phenomenon as soft rock deformation. Therefore, investigations into the phenomenon are increasingly conducted with rich and satisfactory results obtained. By turning to experiments, component model theories and finite element methods, scholars abroad have founded constitutive models for soft rock creeping and developed soft rock engineering calculation procedures. However, most of the models cannot be used to describe the stages of the creeping<sup>[1-3]</sup>. Taking this

into account, scientific researchers at home and abroad are devoting themselves to the study of the phenomenon by turning to soft rock experiments and theoretic deduction, aiming to find a satisfactory solution.

For example, Liu Yeke, Deng Zhibin, Cao Ping, et al<sup>[4]</sup> from Central South University have carried out experiments with sticky clay in the lab, aiming to reveal the tri-axial creeping characteristics by turning to cascade loading method and obtained rich experiment data and curves. By improving on the Burgers soft rock creeping model, which has taken into consideration the impacts exercised by soft rock parameter deterioration, Yang Wendong, Zhang Qiangyong, Zhang Jianguo, et al<sup>[5]</sup> have perfected the FLAC-3D finite element model database. By deriving from the constitutive formulae for the Kelvin creeping model and

combining the soft rock constitutive model with the non-linear mechanics theory, Jiang Binsong, Cai Meifeng, et al<sup>[6]</sup> have proved that the deep underground soft rock creeping is characterized by chaotic behaviors and described the conditions for the chaotic behavior to occur. She Chengxue, et al<sup>[7-9]</sup> have clarified the characteristics for mudstone creeping by gradual loading. Based on their soft rock creeping experiment results, Wang Yongyan, et al<sup>[10-12]</sup> have established a constitutive model for creeping under high pressure in deep underground mines. Xian Xuefu, Jiang Yongdong, et al<sup>[13-15]</sup> have founded a constitutive model for sandstone creeping, providing references for rock engineering design and supporting. By conducting experiments with mudstone creeping under different conditions, Yang Chunhe, et al<sup>[16-18]</sup> have analyzed the laws governing the impacts moisture content exercise on mudstone creeping characteristics. By experimental investigation into tri-axial rheological mechanic characteristics under the impact of breccia penetration, Wang Rubin, Xu Weiya, et al<sup>[19]</sup> have discovered that when the stress is greater or less or approaching the stress for rocks to break, apparent creeping can be witnessed. Wang Deng ke, Yin Guangzhi, et al<sup>[20]</sup> have founded a constitutive model for creeping under different loads, different stratum pressures and different gas pressures. Tang Mingming, Wang Zhiyin, et al<sup>[21]</sup> have conducted experiments with three kinds of core samples from rock salt, pure salt rock and pure mudstone to investigate the tri-axial shearing creeping under different stratum pressures and discovered the laws governing the creeping with corresponding creeping formulae established. Through experiments, Zhao Yangsheng, et al<sup>[22]</sup> have come to know how creeping rate is closely related to the composition and structure, to find that the rate for stable creeping of bedded rock salt can be described by turning to power function.

In recent years, scholars at home and abroad have conducted numerous investigations into constitutive relations for soft rocks with rich results obtained. However, reports have not been published with regard to the rheological properties of soft rocks in the Cretaceous formation under stress induced by engineering construction, nor has any report been published with regard to researches conducted by turning to finite numerical simulation. By carrying out main in a deep underground mine in the Western region of China investigations into soft rock behaviors under unloading impacts induced by roadway tunneling, we have founded a constitutive mechanic model for elastic, sticky and plastic soft rock. And the model is applied on a large non-linear finite element procedure ADINA8.3.

## 2 EXPERIMENTS WITH THE TRI-AXIAL CREEPING OF MUDSTONE IN THE CRETACEOUS FORMATION IN THE STRESS APPLICATION DIRECTION

The experiments with the tri-axial creeping of mudstones in the Cretaceous Formation along stress are carried out by turning to the tri-axial shearing creeping experiment system developed by ourselves. To be specific, the device is developed jointly by The State Engineering Laboratory for Deep Underground Coal Mine Construction Technology and Xi'an Lichuang Facilities. And it can be employed to simulate tri-axial creeping deformation behaviors when the axial and radical loads are applied to the pre-consolidated sample. For the tri-axial creeping experiment system, the maximal axial load is 1200 kN, the stratum pressure is 60 MPa and the fluctuation range is confined to  $\pm 10$  kPa. The experiment system is composed of a loading system, a computer-aided automatic sampling system and a controlling system.

### 2.1 Preparation of experiment samples

The samples used in the tri-axial creeping laboratory experiment are obtained from the mudstone strata in the Cretaceous Formation in a coal mine in Inner Mongolia. The raw sample is then turned into a cylindrical sample of  $\phi 50$  mm  $\times$  100 mm. The sample processing craft and precision are compatible to *Methods and Standards for Engineering Rock Mechanics Experiment* (GB/50266-99). The processed specimen for the experiment has a side flatness confined within 0.02 mm, with the surface error confined within  $\pm 0.05$  mm. The specimen contains as much moisture as it did when it lay in the mine. Then the specimens are weighed and numbered. The physical parameters such as moisture content, density and the like are listed in [Table 1](#).

### 2.2 The experiment procedure

To simulate the process for coal mine roadway tunneling and supporting in soft rocks, the following tri-axial shearing creeping experiment procedure is designed:

Table 1. Basic physical parameters of the muddy soft rock specimen.

Burial depth (m)	Moisture content (%)	Saturated uniaxial strength (MPa)	Plastic limit index	Liquid limit index	Saturation degree (%)
550	24.5	4.65	16.2	-0.21	95.6

1. In the process of the creeping experiment, three values for the pre-consolidated stratum are selected and of the three, the value in the middle position is obtained by calculating the weight of the soil. The three values for the consolidated stratum pressure are  $(p-1)$  MPa,  $(p)$  MPa and  $(p+1)$  MPa respectively.
2. Consolidation is carried out in the condition that the predetermined stratum pressure  $\sigma_2 = \sigma_3$ . And it is required by the experiment that when the deformation is not greater than 0.005 mm/h, the experiment should stop.
3. To obtain creeping parameters, series of creeping curve families should be established. And for the success of the experiment, different stress coefficients  $k_i$  should be determined.
4. To carry out the tri-axial shearing creeping experiment under the impact of radial unloading while the axial pressure is kept constant, the value for the load should be determined according to  $k_i \sigma_s$ , where  $\sigma_s$  is the strength for the tri-axial shearing of the soft rock, to be obtained through tri-axial shearing strength experiment.
5. When the specimen deformation is stabilized for more than 24h (when  $d\epsilon/dt \leq 0.0005h^{-1}$  and it is the first degree stabilized creeping) or when the specimen is damaged (and it is the second degree accelerating creeping), the experiment should come to an end.
6. With stratum pressure and axial pressure gradually unloaded, take out the specimen and describe its damage, and measure the moisture content and density of the frozen soil specimen after the experiment.
7. Repeat the experiments specified by the 1–6 steps of the procedure.

The experiments with the tri-axial shearing creeping under the impact of unloading the stratum pressure after consolidation shed much light on the dynamic stress variation process under the impact of roadway tunneling in Cretaceous soft rocks. Through the derivation with time as a function of the tri-axial shearing creeping stress, time as a function of creeping rate can be obtained as shown in Figure 3.

The tri-axial shearing creeping experiment by turning to consolidating and radical unloading in sequence, the laws governing Cretaceous soft rock deformation are obtained as follows:

1. The curves (as shown in Fig. 2) for time as a function of Cretaceous soft rock creeping under the impact of radical unloading shows that when the shearing stress is smaller than a critical value (or 0.5 MPa as obtained by our experiment), the axial creeping rate approaches 0. When the shearing stress is greater than a critical value (or 3.5 MPa as obtained by our experiment), the Cretaceous soft rock creeping process is marked by

Figure 1. The samples model.

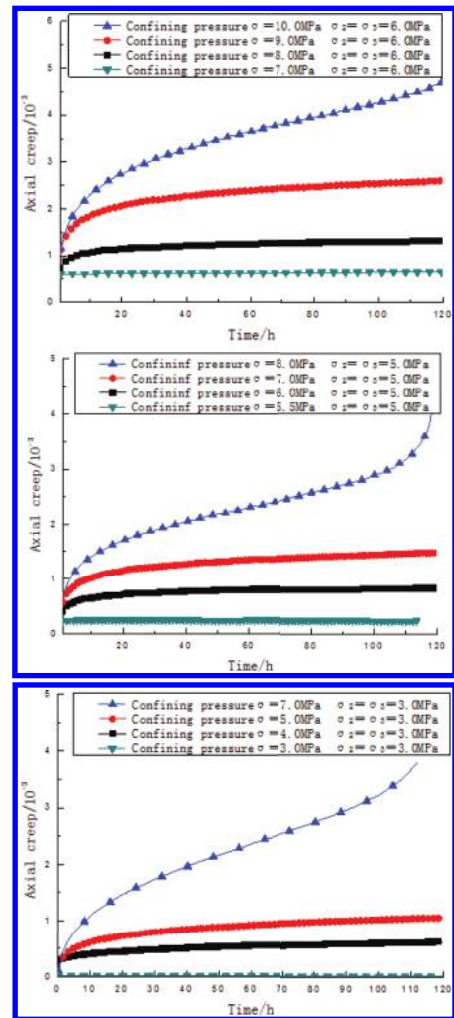

Figure 2. Curves for Cretaceous mudstone creeping under the impact of radial unloading.

Figure 3. Relation between axial creep rate and creep time.

such three stages as accelerating, being constant and decelerating. This shows that there should be a threshold for the Cretaceous soft rock creeping stress at the beginning of the creeping and a critical stress for creeping to do damage.

- As shown in Figure 3(b), when the creeping stress is smaller than  $\sigma_1 = \sigma_3 < 3.5 \text{ MPa}$ , no apparent creeping is witnessed in the Cretaceous formation; when it reaches  $3.5 \text{ MPa} > \sigma_1 - \sigma_3 \geq 0.5 \text{ MPa}$ , the deformation in the Cretaceous soft rock stratum is marked by decelerating creeping; when it reaches  $\sigma_1 = \sigma_3 \geq 3.5 \text{ MPa}$ , the deformation in the Cretaceous soft rock stratum is marked by accelerating creeping, pointing to the conclusion that the creeping has experienced the decelerating, being constant and accelerating stages.

### 3 THE CONSTITUTIVE MODEL FOR CRETACEOUS SOFT ROCKS AND THE DEVELOPMENT OF FINITE ELEMENT PROCEDURE

#### 3.1 The mathematics for the Cretaceous soft rock creeping model

By sorting out the tri-axial shearing creeping data for Cretaceous soft rocks, we have obtained isochronous stress-strain curves as shown in

Figure 4 and the enveloping line for the creeping strength as shown in Figure 5.

- As shown in Figure 4, the isochronous stress-strain curves for Cretaceous soft rocks indicate that when the deviatoric stress is not strong, the stress-strain curves become straight lines. But when the deviatoric stress is rather strong, they become parabolas. Therefore, isochronous stress-strain deformation behaviors of soft rock can be described by turning to the laws governing visco-elasto-plastic deformation.
- As shown in Figure 5, the enveloping lines for Cretaceous soft rock creeping strengths indicate that the Drucker-Prager criterion function can be used to describe the yielding of the soft rock creeping strength. In the application of the criterion function, the initial critical stress function can be selected by turning to Mohr-Coulomb strength function by taking the experiment results into consideration.

As shown in Figure 6, the results obtained from the experiments with tri-axial creeping point to the

Figure 4. The isochronous stress-strain curves for Cretaceous muddy soft rocks.

Figure 5. The creeping strength enveloping line for Cretaceous muddy soft rocks.

Figure 6. The elasto-visco-plastic constitutive model for mudstone.

possibility that by using the basic component combinations, the laws governing Cretaceous soft rock tri-axial creeping deformation under the impact of unloading can be well simulated.

From the constitutive model as shown in Figure 6, the mathematic expression for the constitutive model of the Cretaceous soft rock creeping under the impact of radical unloading can be derived as follows:

$$\begin{aligned} \{\varepsilon\} = & \frac{1}{E_0}\{\sigma\} + \frac{1}{E_1}(1 - e^{-E_1 t/\eta_1}) < \frac{F_1}{F_0} > \{\sigma\} \\ & + < \frac{F_2}{F_0} > \frac{t}{\eta_2} \{\sigma\} \end{aligned} \quad (1)$$

where  $E_0$  stands for the elastic modulus (MPa) for Cretaceous soft rocks;  $E_1$  stands for the damping deformation modulus (MPa) for Cretaceous soft rocks;  $\eta_1, \eta_2$  stand for visco-elastic and visco-plastic coefficients for Cretaceous soft rocks (MPa.min) and  $t$  stands for the external loading time (min).

$$F_1 = \frac{\sin \phi}{3} \times I_1 + \sqrt{J_2} \left( \cos \theta - \frac{\sqrt{3}}{3} \sin \theta \sin \phi \right) - c \cos \phi \quad (2)$$

$$F_2 = \frac{6 \sin \phi}{(3 - \sin \phi)} \sigma_m + \sqrt{3} J_2 - \frac{6c \cos \phi}{(3 - \sin \phi)} \quad (3)$$

### 3.2 The compliance matrix for the finite element calculation

From soft rock rheological mechanics, we know that the total stress  $\{\varepsilon\}$  is the sum total of instantaneous elastic strain  $\{\varepsilon\}^e$ , the visco-elastic strain  $\{\varepsilon\}_t^e$  and the visco-plastic strain  $\{\varepsilon\}_t^p$ :

$$\{\varepsilon\} = \{\varepsilon\}^e + \{\varepsilon\}_t^e + \{\varepsilon\}_t^p \quad (4)$$

From Formulae (1) and (4), the compliance matrix for instantaneous elasticity  $[C]^e$ , that for visco-elasticity  $[C]_t^e$  and that for visco-plasticity  $[C]_t^p$  can be derived.

1. When  $F_1 \leq 0$ , only instantaneous elastic deformation of Cretaceous soft rocks can be witnessed. From elastic mechanics and the finite element theory, the elastic compliance matrix  $[C]^e$  can be derived as follows:

$$[C]^e = \frac{1}{E_0} [R] \quad (5)$$

$$[R] = \begin{bmatrix} 1 & -\mu & -\mu & 0 & 0 & 0 \\ -\mu & 1 & -\mu & 0 & 0 & 0 \\ -\mu & -\mu & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2(1+\mu) & 0 & 0 \\ 0 & 0 & 0 & 0 & 2(1+\mu) & 0 \\ 0 & 0 & 0 & 0 & 0 & 2(1+\mu) \end{bmatrix} \quad (6)$$

where  $\mu$  stands for the Poisson's ratio, determined by uniaxial compression experiments.

2. When  $F_1 > 0$  and  $F_2 \leq 0$ , visco-elastic deformation of the soft rock can be witnessed. From elastic mechanics and the mechanic principle for creeping, the following can be derived:

$$\{\varepsilon_{ij}\}_t^e = [C]_t^e \{\sigma_{ij}\} \quad (7)$$

where  $[C]_t^e$  stands for visco-elastic compliance matrix, determined by the formula below:

$$[C]_t^e = \frac{1}{E_1} (1 - e^{-E_1 t/\eta_1}) [R] \quad (8)$$

3. When  $F_2 > 0$ , visco-plastic deformation of the soft rock is witnessed. By turning to the finite element for calculation, generally, implicit integration is used to determine the relations between the visco-plastic strain and stress as components. At time  $t^n$  the displacement for each node  $\{\delta^n\}$  and the stresses for all the nodes  $\{\sigma^n\}$  are derived. Within the time step  $\Delta t = t^{n+1} - t^n$ , the creeping strain increment in the soft rock can be calculated by turning to Formula (9):

$$\{\Delta \varepsilon_{vp}\}_t = \{\varepsilon_{vp}'\}_t \Delta t + [C]_t^p \{\Delta \sigma\}_t \quad (9)$$

where,  $\{\Delta \sigma\}$  stands for the strain increment within time  $\Delta t$ ,  $[C]_t^p$  stands for the visco-plastic compliance matrix. Then from rheological mechanics and the calculation methods it contains, the visco-plastic compliance matrix can be derived as follows:

$$[C]_t^p = \left\{ \frac{\partial \dot{\varepsilon}^p}{\partial \sigma} \right\} = \frac{1}{\eta_2} \left\{ \left( \frac{\partial F_2}{\partial \sigma} \right) \left( \frac{\partial F_2}{\partial \sigma} \right)^T + F_2 \frac{\partial^2 F_2}{\partial \sigma^2} \right\} \quad (10)$$

where:

$$\frac{\partial F}{\partial \{\sigma\}} = \left\{ \alpha \frac{[P]}{9\sigma_m} + \frac{[Q]}{2\sqrt{J_2}} \right\} \{\sigma\} \quad (11)$$

$$\left( \frac{\partial F}{\partial \sigma} \right) \left( \frac{\partial F}{\partial \sigma} \right)^T = \left\{ \alpha \frac{[P]}{27\sigma_m^2} + \frac{1}{4J_2} [S] \right\} \{\sigma\} \quad (12)$$

$$\frac{\partial^2 F}{\partial \{\sigma\}^2} = - \left\{ \frac{\alpha}{3} \frac{[P]}{(\sigma_m)^2} + \frac{[S]}{4J_2\sqrt{J_2}} \right\} \{\sigma\} \quad (13)$$

where  $[P]$ ,  $[R]$  and  $[S]$  stand for coefficient.

$$[P] = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (14)$$

$$[Q] = \frac{1}{3} \begin{bmatrix} 2 & -1 & -1 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 \\ -1 & -1 & 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 6 & 0 & 0 \\ 0 & 0 & 0 & 0 & 6 & 0 \\ 0 & 0 & 0 & 0 & 0 & 6 \end{bmatrix} \quad (15)$$

$$[S] = \frac{1}{3} \begin{bmatrix} 2 & -1 & -1 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 \\ -1 & -1 & 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 12 & 0 & 0 \\ 0 & 0 & 0 & 0 & 12 & 0 \\ 0 & 0 & 0 & 0 & 0 & 12 \end{bmatrix} \quad (16)$$

Therefore, Formulae (5), (8) and (10) perfect visco-plastic compliance matrixes for soft rock and different matrixes can be selected to perform finite element calculation operations in accordance with different states for stress.

### 3.3 The flow chart for ADINA constitutive procedure development

ADINA provides the users with a rich possibility for the secondary development, allowing them to define in the time of need various functions such as constructing material constitutive models, developing contact elements, judging material breakage, calculating crack expansion, determining users' boundary conditions and ranges of load, etc.

By turning to Fortran, the constitutive model is compiled in accordance with the flowing process as shown in Figure 7. And the environment for ADINA development is Compaq Visual Fortran6.6 A. In the development, by turning to Makefile provided by ADINA, various \*.f files will be automatically linked to generate a dynamically linking file library.

The process for the secondary development of the soft rock constitutive model is as follows:

1. By turning to the flow chart shown in Figure 7, compile the soft rock visco-elsasto-plastic constitutive model by using Fortran;
2. Compile Makefile by modifying its parameters  
`MAT2D_OBJ = ovl30u_user.obj`  
`MAT2D_OBJ = ovl40u_user.obj`  
 Where user stands for the file name selected or defined by the user;
3. Compile the. dll file by following the procedure below:  
`cd D:\program files\df98\bin`  
`cd c:\program files\ADINA\user.dll`
4. bstitute the. dll file in the linking library to be compiled by the user for the user in nmake/f Makefile.user;
5. Add the. dll file generated by the user to the content of bin.

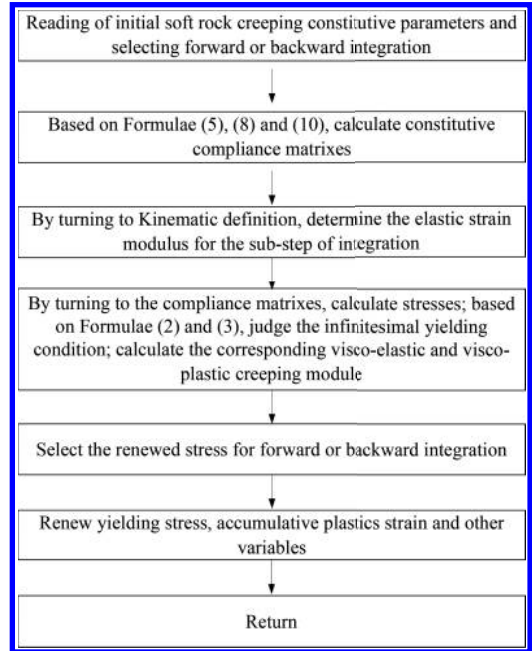

Figure 7. The flow chart for the development of the soft rock visco-elasto-plastic constitutive finite element procedure.

#### 4 ENGINEERING NUMERICAL SIMULATION AND CONCLUSION

The cross-section of the roadway in the mine of Inner Mongolia is a vertical wall semicircular in shape, whose tunneling area  $S_{\text{dig}} = 11.6 \text{ m}^2$  and net area  $S_{\text{net}} = 10.6 \text{ m}^2$ . The roadway is supported by the combination of anchoring rods and cables with concrete sprayed. The layout is shown in Figure 8, where mm is used as the measuring unit. And the roadway is located in the muddy soft rock strata.

As shown in Table 2, by turning to the experiment method presented in the present paper, the parameters for the soft rock constitutive model can be obtained.

By turning to ADINA numerical simulation, the law governing the distribution of anchoring rods and cables in the soft rock roadway can be obtained (as shown in Fig. 9a) and so can the distribution for the vertical displacement of the roadway (as shown in Fig. 9b).

As shown in Table 3, the results obtained from numerical simulation and on-spot measuring for the roadway anchoring rod and cable convergence displacement are compared. And the results obtained by numerical simulation and laws governing on-spot measuring with regard to the road side convergence displacement are shown in Figure 10.

By turning to numerous experiments with soft rock creeping and corresponding numerical simulation, the following conclusions are drawn:

- ① With Mohr-Coulomb and Drucker-Prager strength functions introduced into the element model and through analysis of the experiments with the soft rock creeping under the impact of tri-axial unloading and the rheological model

Figure 8. The illustrated cross-section of a roadway in soft rock strata.

Table 2. The calculation parameters for the soft rock constitutive model.

$E_1/$ MPa	$E_2/$ MPa	$\eta_1/$ MPa · min	$\eta_2/$ MPa · min	$c/$ MPa	$\phi/$
180	265	4 035	6 150	3.15	26

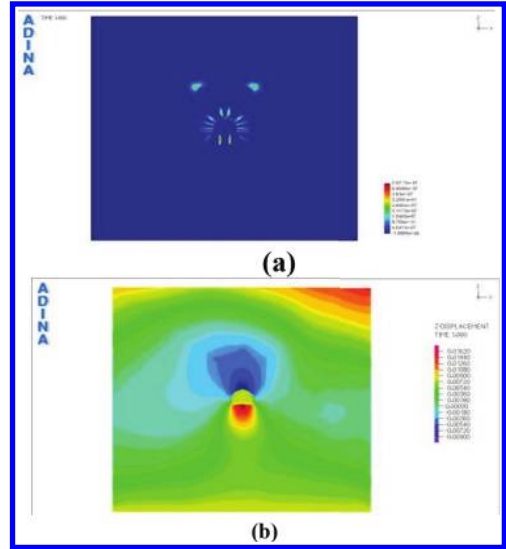

Figure 9. Results of the numeral simulation.

Table 3. The comparison of the results obtained by numerical simulation and on-spot measuring.

Items for comparison	Numerical simulation	On-spot measuring
The maximal pulling force for the anchoring rod/kN	6.95	6.80
The maximal pulling force for the anchoring cable/kN	51.8	46.20
Convergence value/cm	25.4	22.6

- for the element, a constitutive model is founded for Cretaceous soft rock non-linear creeping.
- ② Numerical simulations are conducted of the internal force of the anchoring rod, the stress for the anchoring cable, the roadway displacement distribution and the roadway stress distribution. The results point to the fact that the laws revealed by numerical simulation and those by on-spot measuring are in perfect agreement. And for this reason, the foundation of a soft rock constitutive model is justified.
- ③ By turning to the secondary development of the finite element procedure, the soft rock constitutive

Figure 10. Comparison of the convergences for the two sides of the roadway obtained by numerical simulation and by on-spot measuring.

model is embedded into ADINA finite element procedure. Consequently, the database for the ADINA is enlarged, making it possible to carry out numerical simulation of the soft rock roadway, to monitor and predict the roadway stress field and displacement. All these can provide a guarantee for the scientific tunneling.

**ABSTRACT:** Saline soil disaster is one of the environmental geological problems in the construction of Yanqing new town. In this paper, the saline soil distribution area, chemical composition, and causes of Saline soil in new town area were described, the types of saline soil were divided, and the salt expansion and corrosion were evaluated, which provides the basis for the planning and construction of Yanqing new town and the prevention of disasters.

**Keywords:** saline soil; causes; salinization degree; evaluation of salt expansion and corrosion

### 1 INTRODUCTION

Yanqing new town is located near the Guanting Reservoir and the southeast bank of Caijia River, where saline soil distributes relatively wide about 7.33 km<sup>2</sup> on area. The saline soil disaster is one of the environmental and geological problems in the construction of the new town. Soil salinization has seriously restricted the development of local agriculture. In the past, the land on banks of Guanting Reservoir and Caijia River could have produced 150~200 kg of corn or wheat per acre every year, but now the production has reduced and there were only about 50 kg per acre every year, also no production due to consecutive years of drought. In addition, in the soil salinization area, due to the effect of salt expansion, the foundation bearing capacity reduced, which caused cracks in some houses. In this paper, based on the field survey, the distribution, chemical composition and causes of saline soil in Yanqing new town area were analyzed, the salt expansion and corrosion of saline soil were evaluated, which provides for the basis for the planning and construction of Yanqing new town and the prevention of disasters.

### 2 DISTRIBUTION AND CHARACTERISTICS OF SALINE SOIL

The saline soil in Yanqing new town is mainly distributed in the low-lying area near the Guanting

Reservoir and Caijia River. Through the investigation, the terrain is a flat low-lying area around Guanting Reservoir and on both sides of Caijia River, and due to the water storage of Guanting Reservoir, the groundwater dammed up in the surrounding area, where the depth groundwater is relatively shallow (about 1.3 to 3.0 meters), the hydraulic gradient decreased and the underground runoff slowed even at a standstill. The chemical type of the groundwater under the bank of reservoir and river is sodium chloride-sulfuric water, whose degree of mineralization is 1.0 to 2.5 g/L. The soil above the saline soil is mainly silt, sticky silt and silty-fine sand about 0.5 to 1.0 m thick. Formed by long-term evaporation salt accumulation, the saline soil belongs to secondary-primary saline soil [1].

Through investigation, the soil samples were made at different depths (0 to 0.05 m, 0.5 to 0.55 m, and 1.0 to 1.05 m) in 24 typical districts in the saline soil distribution area to carry out soluble salt tests. Among them, Y1, Y2, Y3, Y4, Y6, and Y7 are sampling points along Caijia River, Y5, Y8, and Y9 are sampling points near Guanting Reservoir. The results of chemical composition tests of the soil (Fig. 1) show that: in the majority of the surface area within 0 to 0.05 m depth, the chemical composition of the soil is mainly chloride-carbonic acid-sulfuric acid type; within 0.5 to 0.55 m depth, the chemical composition of the soil is sulfuric acid-carbonated. According to the classification standard in “Code for Investigation of Geotechnical

Engineering” [2], the saline soil in this area belongs to sulfite or sulfate saline soil (Table 1).

In the new town area, the degree of soil salinization decreases with depth (Fig. 2). The salinity is relatively higher in the 0 to 0.05 m depth, generally in 0.3% to 0.54%, where the degree of salinization is relatively high, of which the highest can reach to 1.17%; within 0.5 to 0.55 m, the salinity is 0.06% to 0.08%, where the highest is 0.19%; within 1.0 to

1.05, the salinity is less than 0.06%. It can be seen that the soil salinization in this area mainly occurs within 0 to 0.5 m under surface, and below 0.5 m the degree of salinization is relatively low. According to the standard in “Code for Investigation of Geotechnical Engineering” sixth chapter, soil within 0 to 0.5 m under the surface of new town area is mainly moderate saline soil, and the lower soil within 0.5 to 1.0 m depth is weak saline soil. The distribution area of moderate salinity in shallow surface is 6.98 km<sup>2</sup>, where the weak salinity is 0.35 km<sup>2</sup>.

Figure 1. The chemical composition of soil in different places in Yanqing new town area.

### 3 ANALYSIS ON THE CAUSES OF SALINE SOIL

The formation conditions of saline soil are: firstly, high salinity of groundwater, which can provide adequate salt; secondly, high water table, which can reach or be close to the surface by capillary action and to be affected by evaporation; thirdly, relatively dry climate, generally where annual evaporation is greater than rainfall, which is easy to form saline soil. Saline soil is the product of combined effects of multiple factors like climate, geology, geomorphology, and hydrogeological conditions and so on.

#### 3.1 Climatic factors

Climatic conditions on the formation of saline soil are mainly drought, large evaporation. Yanqing area is in the transition zone in semiarid and sub-humid climate zone. Over the years of drought, evaporation is about 10 times of precipitation. In the summer hot environment, with evaporation the salt in the shallow groundwater near the Guanting Reservoir and Caijia River banks, it migrates endlessly to the surface and aggregates to form surface salt accumulation; while in cold winter, the lowest temperature below zero, because the salt solubility in aqueous

Figure 2. The salinity of saline soil change with depth.

decreases with decreasing temperature, the salt can be saturated and separated by crystallization.

### 3.2 Soil properties

The height and speed of the capillary action are determined by soil properties which also control the groundwater flow conditions, thus affecting the accumulation and transport of salts in the soil and groundwater. When the level and quality of water are roughly the same, the capillary action of silty-fine sand and sticky silt is relatively strong, and the salinization degree is relatively high. The soil in the survey area near the Guanting Reservoir and Caijia River is in the Quaternary system, Holocene series. Alluvial soil is mainly composed of silt and sticky silt whose capillary action is strong, which is conducive to the formation of saline soil.

### 3.3 Hydrogeological conditions

Hydrogeological conditions which include groundwater depth, runoff conditions, and salinity are the decisive factors in the formation and development of the saline soil. Shallow groundwater and strong evaporation are favorable conditions for the formation of saline soil. Under normal circumstances, when the phreatic level is within 2.5 to 3 m depth, the surface salinization is relatively weak; when within 3 to 5 m depth, the surface salinization is extremely weak; when deeper than 5 m, the soil is non-saline soil; when within 2 to 2.5 m depth, different degrees of salinization occur in the soil; and when within 1 to 2 m depth, the soil salinity content increases sharply and the soil can form sulfuric acid-chloride type and chloride-sulfuric acid type of saline soil and solonchak soil. While highly mineralized water is the main material source of the formation of saline soil, and under the condition of same water depth, the salinization degree is heavier in the high mineralized groundwater distribution area. In addition,

runoff conditions also influence the degree of soil salinization, and when the runoff is slow, the salt in the groundwater is easy to accumulate. In the planning area near the banks of Guanting Reservoir and Caijia River, the surface water is closely related to the groundwater hydraulic. Especially after the construction and water storage of reservoir, the groundwater got supplies, which raises the level of groundwater near the reservoir bank and river bank, and as the groundwater depth reduces, groundwater overflows to the surface in low-lying places, which can form wetlands. Because the terrain is relatively flat, the underground runoff slows down and the groundwater salinity increases, coupled with the regional climate drought for years, different degrees of salinization occurs to the soil.

It is worth noting that the trend of soil salinization is closely related to the environmental conditions. If the climate in this area is drought with little rainfall in the future, the evaporation of groundwater will increase, and the soil salinization will show an increasing trend; when the drought climate weakens and the rainfall intensity increases, infiltration dripping effect of the rain is enhanced, and the salinity of groundwater decreases, which is not conducive to the accumulation of soil salinity and weakening the salinization.

## 4 EVALUATION ON SALT EXPANSION AND CORROSION OF SALINE SOIL

The saline soil in this area which is harmful to the construction of new town area is mainly due to salt expansion and corrosion.

### 4.1 Evaluation on salt expansion

Salt expansion mainly occurs in the saline soil containing sulfate which absorbs water forming crystals and increases its volume when the temperature decreases, causing the soil expansion. When the temperature rises, the sulfate loses water and becomes smaller, resulting in loose soil, which causes thaw collapse. The harm to the saline soil salt expansion and thaw collapse to the construction of planning area is mainly caused by expansion of building foundation, causing building deformation damage and difficulties in construction and transportation.

According to the result of a lot of investigation, the soil that occurred in volume expansion is always within 1 m under the surface. When the foundation depth is more than 1 m, generally the salt expansion hazards do not occur. The test results show that when the base pressure is above 50 kPa, the expansion is not obvious. So for salt expansion of foundation soil it is enough to consider only the soil about 2 m below the surface. The thickness of saline soil in this area is small, within 0 to 1 m depth, the salinization degree is

Table 2. Risk evaluation results of saline soil hazards in the new town planning area.

Location	Saline soil type	Total salt content/%	Saline soil designations	Degree of harm	Risk
<i>Guanting reservoir bank</i>					
Y5	Sulfuric acid type	0.10	Weak saline soil	Slight	Low
Y9		0.23	Weak saline soil	Slight	Low
Y8		0.22	Weak saline soil	Slight	Low
<i>Near Caijia river</i>					
Y1	Sulfurous acid type	0.12	Weak saline soil	Slight	Low
Y2		0.62	Moderate saline soil	Moderate	Middle
Y3		0.39	Moderate saline soil	Moderate	Middle
Y4		0.25	Weak saline soil	Slight	Low
Y6		0.32	Moderate saline soil	Moderate	Middle
Y7	Sulfuric acid type	0.17	Weak saline soil	Slight	Low

\*The total salt content is the average within 0 to 1 m depth.

Table 3. Evaluation results of groundwater corrosion to concrete and steel in the new town saline soil area.

Location	Water depth/m	PH	Cl <sup>-</sup> /mg/L	SO <sub>4</sub> <sup>2-</sup> /mg/L	Cl <sup>-</sup> + SO <sub>4</sub> <sup>2-</sup> /mg/L	Corrosion degree to concrete	Corrosion degree to steel
Guanting reservoir bank	3.8–5.0	7.76	55.8	18.6	70.5	Weak	Weak
<i>Near Caijia river</i>							
Tiansongyin	3.6	7.65	19.5	27.9	47.4	Weak	Weak
Upstream	4.5	7.54	12.1	12.0	24.1	Weak	Weak
Midstream	4.1 m	7.66	697.7	341.0	1038.7	Weak	Moderate
Downstream	5.2	7.84	53.2	16.3	69.5	Weak	Weak

weak to moderate (Table 2), and the depth of building foundation is generally greater than 1.0 m, so the harm of saline soil to the new town construction is slight, and the risk for hazards is low.

#### 4.2 Evaluation on corrosion

Corrosion is mainly caused by the high mineralized water and the soluble salts in saline soil, which can cause corrosion to the concrete structures and the steel structures. Based on “Code for Investigation of Geotechnical Engineering”, the corrosivity of saline soil was evaluated, of which the results are shown (Table 3). The groundwater in the location of saline soil in the new town area can cause weak crystallinity corrosion to the concrete structure, and mostly weak corrosion to the steel structure, moderate degree of corrosion only in the middle reaches of Caijia River. On the whole, the harm degree is slight to moderate.

## 5 CONCLUSION

In Yanqing new town area, the saline soil distributed within 0 to 1.2 m depth belonging to sulfate or sulfite saline soil, where the degree of salinization is mainly from slight to partly moderate, and has partly

influence on constructions and crops. So it is recommended to take the following control measures.

In the engineering construction, due to the shallow depth of saline soil, the saline soil can be directly excavated and replaced by easy compacted coarse-grained soil (such as sand), which can cut off the rise of harmful capillary water; more than 30 cm thick of compacted orthod should be laid on the top to isolate the infiltration of surface water, which can remove the salt expansion and corrosion harm of saline soil.

For the saline soil of farmland, according to the actual situation, crop species can be adjusted, farming methods can be changed, and appropriate measures of irrigation and drainage could be taken. For moderate saline soil, freshwater washing salt method and biological improvement method are combined to control harm.

**ABSTRACT:** Pile foundation is used widely because of good applicability for foundation soil. However, there are still some problems in the appliance of pile foundation, such as Negative Skin Friction (NSF). A series of model tests which aimed at the NSF on the pile under different soil conditions were carried out. Pile stress, displacement of pile head and layered settlement of soil were tested under different surcharge load. The influences of soil characteristics on the NSF on single pile were analyzed mainly, and the relationship between the depth of neutral plane and surcharge load was also research. The results of test can provide references for the related experiment research.

**Keywords:** pile; negative skin friction; model test; soil characteristic; settlement

## 1 INTRODUCTION

Negative Skin Friction (NSF) may occurred by downward vertical soil stress near the pile transferred to the pile shaft when the soil next to a pile settles more than the pile under surface load or groundwater lowering conditions. Because of the development of additional compressive force in a pile and excessive pile settlement, NSF could cause serious problem in pile integrity and maintenance of the structure supported (Fellenius 1998, Acar et al. 1994, Davisson, M.T. 1993).

Some researchers have conducted field tests to study the behavior of pile subject to NSF (Endo et al. 1969, Walker & Darvall 1970, Briaud 1997, Fellenius 2006), which were aimed mostly at NSF on single pile with different kinds of the soil surround the pile. In recent years, some model tests have been carried out to research the NSF on piles (Huang et al. 2013, Leung et al. 2004, Kong et al. 2009). Ng et al. (2008) reported the results of four centrifuge model tests which investigated the response of a single pile subjected to NSF with different pile tip location with respect to the end-bearing stratum layer.

As discussed above, these studies are very helpful for understanding the behavior of pile subjected to NSF. However, the mechanism is still not well understood and existing design methods

are mainly empirical in nature. The literatures on such studies on the influences of soil characteristics (type of the soil around pile, rigidity of end-bearing stratum) on NSF are relatively less. Based on model tests, this paper research the influences of soil characteristics on the NSF on single pile.

## 2 EXPERIMENTAL PROGRAM

### 2.1 Test description

In order to study the difference of NSF on pile in sand and in clay and the influence of pile end-bearing stratum rigidity, two test groups were designed in this work as summarized in Table 1. All the tests were performed in a steel tank (2000 mm × 2000 mm × 1400 mm) with 10 mm in thickness, which was large enough to reduce of the effect of the edges. Reinforcing bands was welded on tank side to reduce the tank deformation caused by applying surcharge load on soil. There were 4 drain valves on the bottom of the tank side, which pore size was 20 mm for drained consolidation.

The model piles were embedded in 1 m thick homogeneous saturated sand bed. The parameters of saturated sand for test are listed in Table 2. In order to ensure the consistency of sand bed in each test, the sand was filled into the tank with the compactness controlled at 45% by weighing

Table 1. Summary of tests.

Test No	Soil type	End-bearing stratum simulation	End-bearing stratum thickness/mm	Surcharge Load/kPa	Pile head load/kN
1	Sand	Gravelly sand	50	120	0.25
2	Sand	Rubber gasket	40	120	3.35

Table 2. Summary of tests.

Internal friction angle/°	Wet density/ $g \cdot cm^{-3}$	Minimum dry density/ $g \cdot cm^{-3}$	Maximum dry density/ $g \cdot cm^{-3}$	Permeability coefficient/ $10^{-6} cm/s$
34.52	1.649	1.249	1.682	934.57

Figure 1. Experiment set-up and pile arrangement: 1-counterforce frame; 2-lower loading plate; 3-upper loading plate; 4-reinforcing band; 5-balance beam; 6-drain valve; 7-model pile; 8-steel plate; 9-settlement standard; 10-dial gauge; 11-dead load; 12-hydraulic jack.

and compaction. To simulate different rigidities of the end-bearing stratum, gravel sand stratum layers with thickness 50 mm and rubber gaskets with thickness 40 mm were installed below the pile tip as end-bearing stratum. The Young's modulus of rubber gasket is about 22.59 MPa.

Model piles were prepared from thin-wall steel pipes of 1.4 m length, 40 mm outer diameter, and 1.18 mm thickness with strain gauges on the inner wall of the pipe piles. The length of embedment of pile (L) in sand bed was 1 m. The modulus of pile was  $2.1 \times 10^5$  MPa. Strain gauges and wires were

arranged on the inner wall of the pipe that can protect the test element not be damaged and can avoid the surrounding soil influenced by test element.

## 2.2 Test procedure

First, the drain valves were closed and gravel sand was put into the tank. Secondly, model piles were arranged on designed position, and then the saturated sand or saturated clay was pushed into the tank. Thirdly, the drain valves were opened and the process of saturated sand consolidation was finished by self-weight after the burying process and standing for 12 h. Fourthly, the drain valves were closed again and 0.3 m thickness dry sand was put into tank as the surcharge load. Finally, the down and up loading plate were successively put on soil surface, and pile cap and bearing plate were successively set on the pile.

The model pile was step-loaded every 15 min by using weight (Test 1) or hydraulic jack (Test 2). After pile head loaded, the surcharge load on soil surface was applied. For the test in sand, the next surcharge load grade was applied when the soil settlement rate was less than 0.01 mm/10 min. However, the next surcharge load was loaded to 80 kPa directly for the test in clay.

## 3 RESULTS AND DISCUSSION

Pile stress, pile head displacement, and the layered settlement of the soil were tested under different surcharge loads.

The test result of single pile in sand is shown in Figure 2 which S means soil settlement and P means p settlement. Figure 2(a) shows the layered settlement of soil increases with the increase of surcharge load, but the increment decreases. The neutral plane is the intersection point between layered soil settlement curve and pile settlement curve

Figure 2. The test result of the pile with gravelly sand layer: (a) The layered settlement of soil and the single pile settlement; (b) The relationship between axial force of pile and surcharge load.

(pile head settlement equals pile bottom settlement because of the less compression of steel model pile), which depth increases with the increase of surcharge load. The axial force of pile indicates that the neutral point varies from 0.8 L to 0.95 L and dragload (subtract the pile head load from the max. axial force) varies from 0.77 kN to 2.64 kN as shown in Figure 2(b). Because the increment of soil is larger than that of pile when the surcharge load increases, the neutral plane shifts down.

For the single pile with rubber gasket stratum layer, the settlement of the pile head under pile head load is shown in Figure 3(a), and the pile head settlement under different surcharge loads is shown in Figure 3(b). Because the rigidity of gravel sand stratum layer is much larger than that

Figure 3. The settlement of pile: (a) Curves of pile head load vs. pile head settlement; (b) Curves of surcharge load vs. pile head settlement.

Figure 4. Curves of axial force vs. pile depth.

of rubber gasket, the pile head settlement was much larger than that of pile with gravel sand stratum.

Figure 4 shows the distribution of axial force in the pile shaft with pile depth. The axial force in the

pile shaft of Test 2 reached to the maximum values of 5.34 kN, respectively, when the surcharge load was 120 kPa. When the surcharge load was zero, the decreasing rate of the axial force in the pile shaft was low because of the low effective stress in the soil. As the surcharge load increased, the axial force decreased more obviously with increasing depth because of the high effective stress. Based on test result, the neutral plane depth changed from 0.4 to 0.6 L. When the surcharge load remained constant, the depth of the neutral plane increased with the decrease in  $K_r$ . Furthermore, the depth of the neutral plane decreased with increasing surcharge load for constant  $K_r$ .

Based on the above experimental results, it can be found that the influences of the end-bearing stratum rigidity on neutral plane depth and dragload are significant. Therefore, it is important for engineering designers to carefully consider pile settlement controls and NSF action when choosing the end-bearing stratum during pile foundation design.

#### 4 CONCLUSIONS

Based on the results of model tests, some useful conclusions can be obtained.

1. The layered settlement of soil increases with the increase of surcharge load, but the increment decreases.
2. The neutral plane depth increases with surcharge load, and the axial force varies more obviously with increasing depth as the surcharge load increased.
3. Neutral plane depth increases with increasing end-bearing stratum rigidity under the same test load conditions. The influences of the end-bearing stratum rigidity on neutral plane depth and dragload are significant.

# Numerical analysis of pile uplift bearing capacity with enlarged head

F.F. Li, H.F. Qian, H.R. Qin & T.Q. Zhou

College of Environmental and Civil Engineering, Jiangnan University, Wuxi, China

**ABSTRACT:** Determination of the ultimate uplift capacity for tension piles is an important part in engineering design. Adopting the contact modeling for the pile-soil interface, the elasto-plastic finite element method is proposed to analyze the uplift pile with enlarged head. The simulated results are in good accordance with the field test data. The plastic region is like the semielliptical curve starting from the enlarged pile tip to the pile shaft. The friction resistance in the enlarged pile tip greatly improves the limit uplift bearing capacity.

**Keywords:** uplift bearing capacity; pile; enlarged head; finite element analysis

## 1 INTRODUCTION

The enlarged piles are widely used in underground structural engineering for uplift resistance design. Compared with the common piles, the enlarged pile has the characteristic of higher uplift bearing capacity with fewer materials. In most situations the ability of a foundation to resist uplift loading is the critical design criterion considerably. Both experimental and numerical analysis is performed to investigate the mechanism of uplift bearing capacity. Based on the uplift centrifugal test of enlarged piles, Dickin[1] used the limit equilibrium method to develop the enlarged pile uplift bearing capacity calculation method. Wu Jiangbin[2] and Huang Maosong[3] used the asymmetrical finite element model to analyze the enlarged pile uplift bearing characteristic.

In the paper, the finite element model for the enlarged pile is developed using ABAQUS. The contact option is used to model the interaction between the pile and the soil. The nonlinear geometric analysis is used to analyze the problem. The relation between the uplift force and the displacement is analyzed. Also the plastic zone of the soil is investigated to model the bearing capacity mechanism.

## 2 FINITE ELEMENT MODELLING USING ABAQUS

With consideration of symmetry of structural, soil and loading condition, half finite element model of the pile-soil is modeled, as shown in Figure 1. The two dimensional reduced integration solid element C2D4R is used to model the soil. The bottom

boundary condition is restrained in x, y directions. The side boundary is restrained in x direction. The Mohr-Coulomb yield criterion is used to model the soil behavior. The elastic model is used to model the pile. The calculation region is taken as 20 times of pile radius in radial direction and 15 times of pile length in depth direction.

### 2.1 Contact

In ABAQUS, the contact pair calculation method is used to model the interaction. In the model, the master-slave surface method is used to model the interaction between the pile and the soil. In the computation, the contact state is determined

Figure 1. Finite element model.

Stratum	Density/ KN/m <sup>3</sup>	Cohesion/ KPa	Depth/m	Friction angle/°	Elastic modulus/MPa	Possion (μ)
①	18.0	0	1.6	22	10.0	0.40
②	17.4	2	1.4	22	8.0	0.40
③	16.6	12	7.0	18	15.0	0.40
④	16.8	16	2.5	12	21.0	0.35
⑤	19.6	15	7.4	20	32.0	0.32
⑥	19.3	36	5.1	33	40.0	0.30
⑦	19.4	5	5.0	43	100.0	0.25
Pile	25.0				28000.0	0.16

using the normal stress between the pile and soil. When the normal stress is tensile stress, the separation occurs between the pile and the soil. When the normal stress is compressive stress, the contact is maintained between the pile and soil. The interface frictional force is determined using Coulomb friction model, determined as:  $f_{crit} = \mu p$ .

When the tangential stress is less than critical value of  $f_{crit}$ , the relative slip occurs in the contact interface. When the contact interface changes from the stick state to the slip state, the discontinuity occur, which causes the finite element analysis failure. In order to solve the problem, the penalty stiffness method is used in ABAQUS. The elastic slip penalty stiffness factor is introduced to allow for the elastic relative slip occurring in the stick state contact interface.

### 2.2 Selection of loading type

In analogous to the model experiment, the force control method or the displacement control method is used in the finite element calculation and analysis. Compared with the force control method, the more accurate force-displacement curve could be obtained using the displacement control method. Another advantage of displacement control method is that when the force amounts to the limit uplift bearing capacity, the accurate limit bearing capacity could be obtained using the displacement control method. When using the force control method, the force loading is not effective when the external force exceeds the limit bearing capacity, which causes the calculation failure. In the paper, the displacement control method is used to apply the loading to obtain limit uplift bearing capacity.

## 3 FINITE ELEMENT ANALYSIS

The uplift bearing capacity of engineering pile full scale experiment in Shanghai is used as the

Figure 2. FEM simulation results of Q-S curve.

numerical analysis with pile length of 27 m and pile diameter 450 mm. The enlarged pile diameter is 0.45 m. The friction coefficient between the pile and soil is taken as 0.2. The displacement control method is used to apply the loading. The soil geological information and the soil mechanical parameter is shown in Table 1.

The computed Q-S curve is shown in Figure 2. As shown in Figure 2, the computed uplift bearing capacity is about 1180 KN, which is close to the experimental value of 1100 KN.

The computed soil displacement and soil vertical stress is shown in Figure 3 and Figure 4 respectively.

The soil yield zone and the plastic distribution is shown in Figure 5 and Figure 6 respectively.

As shown in Figure 5 and Figure 6, the plastic region is like the semielliptical curve starting from the enlarged pile tip to the pile shaft. The enlarged pile tip has the effect of compressing the surrounding soil locally, which causes the local shear failure of soil.

The computed friction resistance distribution along depth of piles during uplift is shown in Figure 7. It can be seen from Figure 7 that the friction resistance in the enlarged pile tip increases greatly, which contributes a lot to the limit uplift bearing capacity.

Figure 3. Soil displacement.

Figure 7. Distribution of friction resistance along depth of piles during uplift.

#### 4 CONCLUSIONS

The numerical analysis is performed to investigate the uplift behavior of enlarged pile. The plastic region is like the semielliptical curve starting from the enlarged pile tip to the pile shaft. The enlarged pile tip has the effect of compressing the surrounding soil locally, which causes the local shear failure of soil. The friction resistance in the enlarged pile tip greatly improves the limit uplift bearing capacity.

## 1 INTRODUCTION

Reinforced gabion retaining walls are essentially semi rigid structures that can generally accommodate large lateral and vertical movements without excessive structural distress. Because of this inherent feature, they offer technical and economical advantage over the conventional concrete gravity retaining walls. Although they can be constructed either as gravity type or reinforced soil type, this work mainly deals with reinforced gabion retaining walls as they are more suitable to larger heights.

Experiments were conducted on small scale models of reinforced gabion retaining walls. While doing so, an attempt was made to explore the possibility of reducing the cost of construction by using quarry dust as a gabion fill material. The most attractive feature of the gabion walls is their cost effectiveness. Gabion walls can achieve around 30–60% savings when compared to Reinforced cement concrete walls constructed in similar situations. Even though the structure is a cost effective one, it can be seen that the stone filling used inside gabion boxes increases the cost of construction. In this work, an attempt is made to examine the effects of replacement of the stone filling in the gabion boxes with a mixture of stone and rock waste. The use of rock waste would relieve some of the problems associated with its

disposal and it may turn into an inexpensive and advantageous construction product. It can also be noted that there is an added advantage in the use of rock waste from the quarries in the sense that the otherwise colossal cost of the conventional retaining structures is reduced to a very low value. Different experiments were carried out for determining the load deformation behaviour of the walls using gabions with different combinations of fill materials [1].

## 2 MODEL STUDIES

In gabion walls, gravity force (self weight) is the predominant stabilizing force, which depends on the unit weight of the material ( $\gamma_m$ ) used for construction, which in turn is dependent on the specific gravity ( $G$ ) of the material by the relation,  $\gamma_m = G \cdot \gamma_w$ , where  $\gamma_w$  is the unit weight of water. The specific gravity of rock waste is nearly equal to that of stone. Therefore, gravity force is not affected by the replacement of stone with rock waste. Considering all these points, rock waste was selected as a substitute for stone filling in this work. To represent the rock waste in the model studies, quarry dust, which is one of the easily and cheaply available waste materials, was used. Similarly stone filling was represented by 20 mm coarse aggregate filling inside

the gabion boxes. Instead of the actual gabion wall with stone filling, the one with a combination of stone filling and quarry dust was considered for the studies. Five different combinations were tried by varying the quantities of quarry dust and stone filling. Load tests were conducted on model gabion retaining walls to study the deformation characteristics of gabion faced retaining walls. The purpose of this study was to find out an optimum combination of quarry dust and stone filling, to replace the stone filling in gabion boxes and thus, further reduce the cost of construction of gabion wall. For this, five different combinations of quarry dust and coarse aggregate were used in the gabion fill supporting the model retaining wall. The combinations were varied by percentage weight of the filling materials in gabion boxes [2].

### 3 FIELD MODEL STUDIES

#### 3.1 Construction of model gabion wall

For the reinforcement purpose the base of the gabion boxes are provided with an extension. Generally 0.6 to 0.8 times the height of the wall is taken as the reinforcement extension including the base of the box. The extension and boxes act monolithically. Boxes are provided with a top cover and internal partitions called as diaphragms to prevent bulging of the box. The model gabion wall was constructed over a length of 2 m. The height of the wall was fixed as 1 m. The wall was constructed at a distance of 2.5 m from the natural slope and the space was filled with sand, which acted as a backfill to the wall. Brick bays were constructed on either side to limit the length of the wall. Sixteen numbers of gabion boxes each of size  $0.5 \text{ m} \times 0.25 \text{ m} \times 0.25 \text{ m}$  were used to retain the backfill. Boxes were provided with an extension of 0.55 m at the base. Top cover was also provided. Because of the small size of the box, diaphragm walls were avoided.

For the load tests, using coarse aggregate as filling material, the above described model gabion boxes were used as such. But for the quarry dust and other combinations of quarry dust and coarse aggregate as filling material, the inner sides of the gabion boxes were stitched with geotextile Terram 1000. Nylon wires were used for stitching. The geotextile prevents the escape of quarry dust through the mesh openings.

The ground was levelled and 5 cm thick layer of sea sand was spread over it. The first layer of four boxes was placed on the levelled ground surface where the wall had to be constructed. The boxes were connected together with steel wires so that they behave as a single unit. The extensions of the boxes were spread over the sand layer. Boxes were

filled with filling material corresponding to the cases considered. In the case of combination filling, the quarry dust and coarse aggregate were filled in the boxes after mixing them properly in the required proportions. Filling was done with proper compaction to achieve the required unit weight of  $15 \text{ kN/m}^3$ . After filling the boxes, the top cover was closed and tightly connected to the sides of the boxes using steel wires. Behind the boxes, geotextile was placed in order to avoid the entry of granular backfill into the boxes. Then backfilling of sand was done up to the height of the boxes. The backfill sand was compacted in each layer to get an average unit weight of  $17.6 \text{ kN/m}^3$ . Each layer of the fill was compacted to get the same density by controlling the weight of soil and thickness of layer. After levelling the backfill, the next layer of gabion boxes was placed above the first layer and the two layers were stitched with steel wires and the procedure was continued up to the required level. Since the height of the wall was fixed as 1 m, four layers of boxes each of height 0.25 m were placed to complete the construction. Markings were made on the front of each box of the facing unit for taking measurement due to surcharge loading [3].

#### 3.2 Loading set up

After the construction of wall using gabion boxes loading was done with sand bags. Before placing the sand bags a concrete slab was placed over the retaining wall to enable the surcharge loads to give a uniform pressure as well as to act as a loading platform. Sand bags were placed in layers. Each layer constituted of 25 bags filled with sand. Each layer provides a surcharge pressure of 2 kPa. The load for the first layer of sand bag (2 kPa) and load from the concrete slab (1 kPa) was taken as the seating load and the initial deformations were noted. An aluminium rod was placed above gabion wall, supported by the brick walls of the bay. This was used as a reference mark to measure the deformations.

In order to measure the lateral deflection the outer edge of the aluminium rod was used as the datum point. A plumb bob was hung down vertical from the outer edge of aluminium bar. Using a metre scale the initial position of wall and the changed position after loading, were measured. The difference between these values gave the lateral deformation at each point. In total, six layers of sand bags were placed one over the other, above the retaining wall. Thus at the end of loading a total pressure of 13 kPa was acting on the wall. After placing each layer of sand bag the loading was kept undisturbed till the deformations stabilized. Before placing the next layer of sand bags, lateral deformations were measured. The walls were not loaded to failure due to the practical difficulty of increasing the height of dead load.

## 4 LABORATORY MODEL STUDIES

### 4.1 Experimental set up

The experiments consisted of studies on model gabion retaining wall constructed in a steel tank of size  $1\text{ m} \times 1\text{ m} \times 1\text{ m}$  in the Geotechnical Engineering laboratory. The height of the wall was fixed as  $0.6\text{ m}$  and the dimensions of the boxes and basal extension were designed using the physical properties of backfill soil and steel mesh which were obtained from laboratory experiments. Sixteen numbers of gabion boxes each  $0.25\text{ m}$  long,  $0.15\text{ m}$  wide and  $0.15\text{ m}$  high and with basal reinforcement of  $0.35\text{ m}$  were used to retain the sand backfill inside the tank. The boxes were fabricated by stitching steel mesh panels to get the required shape.

Four such boxes were stitched one beside the other to form a layer such that they behave as a single unit. Four layers were placed one above the other to form the wall. The horizontal deformations at the front face of the wall were measured using dial gauges.

For the load tests using coarse aggregate alone as the filling material, the above described model gabion boxes were used as such. But for the cases where quarry dust is also used as filling material, the inner sides of the gabion boxes were stitched with geotextile Terram 1000. Nylon wires were used for stitching. The geotextile prevents the escape of quarry dust through the mesh openings. The filling material in the boxes was filled at an average unit weight of  $15\text{ kN/m}^3$ . In this laboratory experiment, the combination filling was done in layers. The required proportion of quarry dust was placed as the bottom layer and the coarse aggregate as the top layer, the separation between the two being made using the geotextile material. The backfill sand was compacted in each layer to get an average unit weight of  $16\text{ kN/m}^3$ . Each layer of the fill was compacted to get the same density by controlling the weight of soil and thickness of layer. After leveling the backfill, the next layer of gabion boxes was placed above the first layer and they were stitched with nylon wires and the procedure was continued up to the required level. Four layers of boxes each of height  $0.15\text{ m}$  were placed one above the other to complete the construction. The layers were also interconnected using steel wires such that the entire wall behaves as a single block. Markings with small metal strips were made on the front face of the circled boxes at the centre for taking deformation measurements with dial gauges.

### 4.2 Loading set up

After the construction of the wall using gabion boxes, loading is done using hydraulic jack and lever arrangement. The loading pattern used is of

two-point loading acting on a  $25\text{ mm}$  thick and  $0.2\text{ m}$  wide strip placed over the sand backfill parallel to the gabion wall. Load was applied using a hydraulic jack, in increments of  $3\text{ kN}$  till failure. After applying each increment, the load was kept constant till the deformations stabilized. Prior to next increment lateral deformations were measured using dial gauges.

## 5 LOAD DEFORMATION CHARACTERISTICS

An account of the results obtained from the experimental studies is presented in this paper.

The field model experiment was loaded up to  $13\text{ kPa}$  which included a seating load of  $3\text{ kPa}$  and initial deformations were measured only after stabilization of the deformations due to the seating load. For the laboratory model experiment, the wall was kept undisturbed for a day for the stabilization of post construction deformations and loading was done on the succeeding day in increments. The load—deformation measurements were noted till failure.

The effective replacement of stone filling in gabion boxes by a cheaper material is the focus of the study and is done by comparing the load deformation behaviour of the five different walls. Figure 1 shows the load deformation characteristics for field model experiment in which the deformation is expressed in terms of a dimensionless quantity, top sway factor,  $\delta_1$  which is defined as  $U_1/H$  where  $H$  is the wall height and  $U_1$  is the top lateral deformation of the wall at the midsection. Although  $U_1$  is referred as top lateral deformation, it is measured as the average of the lateral deformations at the centre of gabion boxes. From the figures, it can be seen that as the load increases, the lateral deformation also increases, as expected.

Figure 1. Load deformation behaviour after seat load (Field model experiment).

The quarry dust filled gabion walls show more lateral deformation than that of the coarse aggregate filled gabion walls. The combinations showed intermediate deformations. This may be due to the low stiffness characteristics of quarry dust filled gabions. As a result, as the percentage of quarry dust increased, top lateral deformation also increased. The 50–50 combination shows a top lateral deformation less than that of quarry dust alone and 70% quarry dust and 30% coarse aggregate combination [4].

## 6 BULGING PATTERNS

The variation of lateral deformation along the height of the wall which is termed as “bulging pattern”, also show the behaviour of retaining walls. The lateral deformations at the mid length of the wall ( $U_2$ ) in all the four layers at a specific load value were measured in the experiments to understand the behaviour of the fill materials in the wall facings. The bulging patterns are plotted with the sway factor,  $\delta_s = U_2/H$  along the x-axis and the wall elevation along the y-axis. The bulging patterns are studied for a uniform surcharge load of  $13 \text{ kN/m}^3$ .

Figure 2 shows the bulging patterns of the model gabion walls for different combinations of fill. As the percentage of quarry dust increased bulging was observed to increase. It is seen that, the top layer experienced more bulging than the lower layer for the first three walls with lesser quantity of quarry dust. The other two walls with larger quantity of quarry dust showed an intermediate bulging in the third layer. An inference can be made at this point that the walls with lesser quantity of quarry dust behave in a stiffer manner than the other walls with higher quantities of quarry dust [5].

Figure 2. Bulging of front face of walls (Field model experiment).

The difference between the two sets of experiments lies in the loading difference and the mode of filling the boxes. Even with these differences, the results are found to be comparable near to the failure points. From this, it can be inferred that the mode of filling has no effect on the load deformation behaviour of the system.

On quantifying the increase in top lateral deformation of the quarry dust filled walls with respect to coarse aggregate filled wall, it is seen from the experiment that filling 30% quarry dust increases the top lateral deformation approximately by 35%. When quarry dust is increased to 50%, almost 70% hike is seen in the deformation value. In general, as the quantity of quarry dust increased, the deformation also increased.

## 7 CONCLUSIONS

Experiments were conducted on small scale model walls in the field and in the laboratory to investigate the effects of replacement of the stone filling in the gabion boxes used as facing in gabion walls, with a mixture of stone and rock waste. To find an optimum mixture of stone and rock waste to be filled in the gabion boxes, walls were constructed with different combinations of stone and rock waste and were loaded to study the variation in the deformation behaviour of the system.

As the load increases, the lateral deformation of reinforced earth retaining wall also increases. The quarry dust filled gabion walls show more lateral deformation than that of the coarse aggregate filled gabion walls. As the percentage of quarry dust increased, top lateral deformation also increased. As the percentage of quarry dust increased, bulging was observed to increase. An inference can be made that the walls with lesser quantity of quarry dust behave in a stiffer manner than the other walls with higher quantities of quarry dust.

**ABSTRACT:** Conventional design procedures of retaining walls in general, do not take into account wall deformation which is usually considered as a minor criterion in design. But in the present trend, a deformation study for retaining walls is important. Finite element analyses were carried out for different reinforcement spacings, reinforcement lengths and facing widths on low, medium, and high walls. The relation between those geometric parameters and the effect of the earth pressure acting on the wall and the facing deformation are discussed in detail in this paper. Moreover, the optimum values have been suggested as follows: the ideal spacing of reinforcement may be fixed as  $0.1 H$ – $0.2 H$ ; the ideal reinforcement length may be fixed as  $0.4 H$ – $0.6 H$ ; the facing width may be fixed as  $0.1 H$ – $0.15 H$ ; the most ideal position for placing the strip loading is at least  $1.5 L$  away from the back face of the wall.

**Keywords:** gabion; reinforced earth retaining wall; deformation behaviour; geometric parameters; finite element method

## 1 INTRODUCTION

Reinforced gabion retaining walls are essentially semi rigid structures that can generally accommodate large lateral and vertical movements without excessive structural distress. Because of this inherent feature, they offer technical and economical advantage over the conventional concrete gravity retaining walls.

Conventional wall design procedures are primarily stress based and do not consider deformations separately. Reason for the same being, deformations are relatively insignificant for the typical conditions of wall geometry and loading for which the design procedures were developed. But in circumstances where walls with non—standard geometry or loading cannot be avoided, deformation criteria should be carefully considered. For example, the use of shortened reinforcement layers due to topographic or economic constraints will cause increased deformations which would otherwise become critical, if avoided. Walls with large external loading or sloping backfills, walls where performance criteria requires very small deformations etc., are some other examples where deformations have more or less equal importance to stresses. Hence this work concentrates on deformation studies [1, 2].

This paper explains the analyses conducted on gabion faced reinforced soil walls of three different wall heights—3 m, 6 m and 9 m representing the low, medium and high walls respectively. Finite element studies were performed by varying the spacing as well as the length of reinforcement and the width of gabion facing. The effect of the position of strip loading on the behavior of walls was also investigated.

## 2 FE MODEL FOR THE PARAMETRIC STUDIES

The reinforcement extending into the soil was assumed to be of same length through out the height of the wall and was taken as equal to  $H$  (the height of Reinforced gabion retaining walls) in the basic system chosen for the parametric study. The wall facing at the bottom was assumed to have an embedment of  $0.15 H$  into the soft clay. Horizontal translation was restricted for the nodes on the left and right end boundaries and all the bottom nodes were completely restrained. The geometry of the model was kept the same for all the parametric studies and only the parameter to be studied was varied accordingly. The FE mesh was fixed such

that the same mesh could be used for all the parametric studies performed.

The basal reinforcing mesh of the gabion boxes extending into the soil were modelled using 288 two noded truss elements with axial stiffness only, assuming linear stress strain relationship. The properties of the gabion mesh were determined in the laboratory by conducting tension tests on a sample specimen of the gabion mesh. The gabion wall facing was modelled as a composite material assigning properties obtained from literature. The soil material was modelled using 2066 four noded isoparametric quadrilateral elements. The non linear stress—strain behaviour of soil was simulated using Duncan and Chang hyperbolic model following Mohr—Coulomb failure criterion. The backfill was assumed to be beach sand and the foundation was assumed to be clayey silt. In reinforced soil structures, the main criterion adopted in the design is that the desirable failure mode is pullout failure rather than the breaking of reinforcement. This is because the failure due to rupture can reduce the shear strength of the structure to a very low value which may cause catastrophic effects to the structure. Hence the failure of reinforcement was not modelled here and it was assumed that the system does not fail by the rupture of reinforcement. The pullout failure of the reinforcement was modelled using four noded zero thickness interface elements at the top and bottom of the reinforcement. The interface elements were also used behind the vertical face of the gabion wall in contact with the back fill, at the base and in the front face (foundation) in contact with the foundation soil. The interface elements were modelled such that the shear stiffness is governed by a hyperbolic rule similar to that of the soil model and related the interface shear stress and displacement [3].

### 3 EFFECT OF REINFORCEMENT SPACING

It is a common practice in the construction of gabion faced walls to provide the reinforcement at uniform spacing. Considering the economic aspects, varied spacing can be more advantageous than uniform spacing. Hence an attempt is made here to study the influence of spacing of reinforcement on the behaviour of gabion faced reinforced soil walls and to arrive at an optimum value of spacing.

For this, different configurations of reinforcement have been chosen, studies were conducted varying reinforcement spacing ( $h$ ) as  $0.08 H$ ,  $0.17 H$ ,  $0.25 H$ ,  $0.33 H$  and  $0.50 H$ . The horizontal deformations of the facing for all the configurations were noted and plotted as shown in figure,

which shows the variation of lateral deformation of gabion wall facing for the different models discussed above for  $H = 6$  m. The lateral deformation increases as the spacing of the basal reinforcement increases, in all the cases, there is not much variation of lateral deformation in the embedded portion of the wall since the outward deformation is restricted by the foundation soil. The shape of the facing deformation changes from a linear form to a bow shaped form as the spacing of basal reinforcement of the reinforced gabion walls decreases and the maximum deformation is as low as  $0.0036 H$ . It is also seen that for medium to large spacings, namely  $h/H = 0.25$  to  $0.5$ , the deformation increases almost linearly with height from bottom to top and the maximum deformation at top is nearly  $0.012 H$  for  $h/H = 0.25$  and  $0.04 H$  for  $h/H = 0.5$ .

The reduction in deformation of reinforced gabion faced walls are plotted against the normalized spacing for the case  $L/H = 1.00$ , where  $L$  is the reinforcement length. Here, the percentage reduction in deformation is defined as,

$$\Delta u = (u_0 - u_1) / u_0 \times 100\% \quad (1)$$

where  $u_0$  is the maximum lateral deformation in the unreinforced case;  $u_1$  is the maximum lateral deformation in the different reinforced cases. As expected, as the spacing becomes smaller the percentage reduction in deformation increases (Fig. 1).

The percentage reduction in deformation is seen to be smaller for low height walls and it increases as the height increases. The variation in percentage reduction in deformation between walls of 3 m height and 6 m (or 9 m) height, is larger for smaller spacings and decreases gradually as spacing increases. The values become almost constant for walls of all heights at large spacings. From the

Figure 1. Effect of reinforcement spacing.

above discussions, it may be concluded that for any wall height, the ideal spacing of reinforcement may be fixed as,  $h = 0.1 H$  to  $0.2 H$ , as observed from Figure 1.

#### 4 EFFECT OF REINFORCEMENT LENGTH

To explore the reasonable reinforcement length in gabion faced reinforced soil walls, studies were conducted varying the lengths of reinforcement as  $0.125 H$ ,  $0.25 H$ ,  $0.5 H$ ,  $0.75 H$  and  $1.00 H$ .

As the length of reinforcement increases, percentage increase in lateral force with respect to the unreinforced case increases. In other words, as the quantity of reinforcement increases, the earth pressure exerted on the back face of the wall increases, indicating the transformation of the state of earth pressure from below active condition to near to at-rest condition, the system changes from an unstable to a stable state which is clearly indicated by the reduction in deflection values with the increase in the quantity of reinforcement [4, 5].

The variation in length was plotted against the change in deformations with respect to the unreinforced case (Fig. 2). Here also, as expected, as the length of reinforcement increases, the reduction in displacement increases.

As the wall height increases, the percentage increase in lateral force increases, but the variation is very small. The percentage reduction in deformation is lower for low height walls and it increases gradually for walls of larger heights and the variation is nominal for medium and high walls. Moreover, observing from Figure 2, the ideal reinforcement length for gabion faced reinforced soil walls may be fixed as  $0.4 H$ – $0.6 H$ , beyond which the deformation variations are seen to be constant.

Figure 2. Effect of reinforcement length.

Figure 3. Effect of facing width.

#### 5 EFFECT OF FACING WIDTH

In order to investigate the effect of the width of gabion facing on the behaviour of gabion faced reinforced soil walls, the same was varied keeping all the other parameters constant. Studies were conducted varying the widths of gabion facing as  $0.025 H$ ,  $0.05 H$ ,  $0.10 H$ ,  $0.15 H$ ,  $0.20 H$ ,  $0.25 H$  and  $0.30 H$ .

Results show that as the facing width increases, there is not much variation in the lateral force exerted at the back face of the wall. This means that the facing rigidity has not much effect on the lateral force developed in the backfill. The variation in facing width has also been plotted against the maximum lateral deflection with respect to the unreinforced case (Fig. 3). Here it is seen that the increase in facing width decreases the maximum lateral displacement. For very thin facings, the displacements are seen to be maximum. For  $b/H \geq 0.1$ , the displacement values are almost constant giving a linear horizontal shape to the latter part of the plot.

As the wall height increases, the lateral force and the displacement values also increase (Fig. 3). The variation in lateral force is nominal for medium and high walls. In the case of displacements, for thin facings, the variation in displacements with increase in wall height is seen to be large. For thicker facings, the corresponding variations are small. To summarise the study, the facing width may be fixed as  $0.1 H$ – $0.15 H$ , beyond which the effect of deformations are seen to be marginal.

#### 6 EFFECT OF POSITION OF STRIP LOADING

Strip loads like pipelines, edges of bridge seating, cranes, compactors etc., are commonly seen at a retaining wall project site. These are permanent loadings and before the placement of these loads

over the structure in the case of a gabion faced reinforced soil wall, the behaviour of the walls should be studied under the action of these loads.

For this, FE studies were conducted by applying strip load of same intensity (35 kN/m which is the usual load taken for the design of bridges etc.), but of varying widths at various positions and maximum lateral deformation is noted. Strip width is denoted as  $B$  and the position is denoted as  $D_e$ .  $D_e$  denotes the distance of the start of strip load from back face of wall.

Strip was varied in position at different values of  $D_e/L = 0.25, 0.50, 0.75, 1.00, 1.25, 1.50, 1.75$  and  $2.00$ . The strip width was varied at values of  $B/L = 0.10, 0.20, 0.30, 0.50, 0.75$  and  $1.00$  for the parametric studies. The deformation is expressed in terms of percentage increase in deformation with respect to the case with no strip loading.

The variation of top lateral deformation of the facing with change of strip position from back face of wall for different width of strip loading was achieved. As expected, the deformation increases with increase in width of strip loads. Regarding the strip position, the ratio  $D_e/L = 0$ , represents that the start of the strip loading is at the back face of the wall. Results show that it is the most critical loading position as the percentage increase in deformation with respect to the unloaded case is maximum here. One more critical plane can be identified from the result where all the curves show a peak. This is at  $D_e/L = 1$ , where the percentage increase in deformation is found to be more compared to other positions. The best position of strip loading can also be identified which is  $D_e/L > 1.5$ . Another suitable position range may also be located from as  $D_e/L = 0.5$  to  $0.75$ . It is at these two positions where the percentage increase in deformation is lesser compared to other positions.

Thus the critical planes where the strip loading should not be placed are the beginning and end of the reinforcement lengths. The most ideal position for placing the strip loading is at least  $1.5 L$  away from the back face of the wall, where  $L$  is the length of the reinforcement. Strip should be placed away from the reinforced region. If in any case, the strip has to be placed inside the reinforced area, the best position is that the start of the strip loading should be within the range  $0.5 L - 0.75 L$  from the back face of the wall. The results of the FE studies performed here were replotted to develop a design chart from which the position of strip loading may be fixed by considering the deformation criteria.

With the aid of this chart, knowing the limiting deformation and strip width, the ideal position of strip loading can be selected.

## 7 CONCLUSIONS

FE analyses of gabion faced reinforced soil retaining walls were carried out for different reinforcement spacings, reinforcement lengths and facing widths on low (3 m), medium (6 m) and high (9 m) walls. The relation between those geometric parameters and the effect of the earth pressure acting on the wall and the facing deformation are discussed in detail in this paper.

Moreover, the optimum values have been suggested in each case. Suggestions are as follows:

For any wall height, the ideal spacing of reinforcement may be fixed as  $0.1 H - 0.2 H$ . The ideal reinforcement length for gabion faced reinforced soil walls may be fixed as  $0.4 H - 0.6 H$ , beyond which the deformation variations are seen to be constant. The facing width may be fixed as  $0.1 H - 0.15 H$ , beyond which the effect of deformations are seen to be marginal.

The strip loading should not be placed at the beginning and end of the reinforcement lengths. The most ideal position for placing the strip loading is at least  $1.5 L$  away from the back face of the wall, where  $L$  is the length of the reinforcement. If the strip has to be placed inside the reinforced area, the best position is that the start of the strip loading should be within the range  $0.5 L - 0.75 L$  from the back face of the wall.

**ABSTRACT:** To simulate the process of expansive soil fissure cracking correctly under the action of the rainfall evaporation, we changed the moisture content of expansive soil in the laboratory. To observe and analyze fracture characteristics of the key factors, we used Matlab software to get the binary cracks image to calculate and analyze the fracture rate under different moisture content of different cycle times, such as the area of the fracture rate, width, quantity, and so on. In addition, this experiment also uses the method of pouring wax to get fracture model. Combined with two-dimensional and three-dimensional analyses, this research makes the results more reliable. The research results show that in the process of a dry-wet circulation, cracks generated quickly, and then slow over time, eventually achieving stability. In five dry-wet circulation processes, the number of fractures appear increasingly at end of each cycle. Gradually, fractures ultimately achieve stability after five dry-wet circulations.

**Keywords:** expansive soil; dry-wet circulation; fracture patterns; binarization; fracture model

## 1 INTRODUCTION

Expansive soil has the characteristics of fractures, over consolidation, and expansion; these three properties are closely related with water content of expansive soil. The soil fissures destroy the integrity of actual engineering, which is one of the most difficult problems in engineering. Previous study of expansive soil fissure was mostly on the qualitative analysis. Quantitative analysis was gradually being taken seriously in recent years. This paper takes the highway-ring around Nanjing weak expansive soil roadbed as the research object. We study cracks in the expansive soil generated under the influence of the climate and those generated in the expansive soil in the laboratory simulation process of natural rainfall dry-wet circulation. We compare the qualitative and quantitative observation statistics to determine key factors of fracture characteristics. Through the representative area of expansive soil in the laboratory on small dry-wet circulation, we observe the expansive soil fracture process and geometric feature of the network. With a larger workload and a small representative area, observation of scene fracture statistics and measurement with a certain randomness is not easy. Crack observation statistics to determine geometrical characteristics of the fracture network is one of the key factors that can greatly reduce the field work of all the

crack observation and statistics and human error, and provide convenience for the follow-up study of expansive soil.

## 2 EXPANSIVE SOIL CRACKS GENERATED TEST

### 2.1 Test tool

Expansive soil for test: the Nanjing highway-ring roadbed weak expansive soil; two same specification (30 mm × 40 mm) of the iron plate (A is used for test photos, B is used for weighing the soil quality change); the camera; the computer; watering can; platform scale.

### 2.2 Test procedure

The basic data:

Plate weight: 2250 g, soil weight 5151 g, water Weight 1199 g, total quality 7401 g, initial moisture content: 23.28%, the dry density: 1.47 g/cm<sup>3</sup>.

To determine the initial moisture content of 23%, calculated with the content of expansive soil and water, and then mixed the original expansive soil with water, so that conforms to the moisture content in soil moisture content, and iron soil compacted. After a period of time with the surface of the expansive soil both A and B generating

cracks, A plate is used to take photos with camera at definite time, B plate is used to record the soil and the iron plate quality on time. To take off the soil surface crack at an appropriate time when the crack no longer change, with watering the surface simulate nature rainfall until the fracture healing, record water supply volume before the next cracks generated. Then do five dry-wet cycles test like this. After five loops by the test results before fracture is basically stable, so this test selects five times of the dry-wet circulation.

### 2.3 Test phenomenon

As shown in Figure 1, in a dehumidifying process experiment, no any cracks are generated in expansive soil surface, except when the soil gradually becomes dry at the beginning after a period of time. As time goes by, expansive soil surface begins to produce small cracks. Then the cracks gradually become wider. Big cracks connect with each other and bestrew the surface of the earth. The whole expansive soil surface will divide into several pieces in different kinds of size and shape and tends to be stable in the end.

In the process of five dry-wet circulations as shown in Figure 2, along with the increase in number of dry-wet circulation, the fracture number on the surface of expansive soil increasing constantly, the block number is also gradually becoming more, and fissure between connected more thoroughly. However, the average width of fissure is reducing, the change of amplitude decreases with the increase of cycling time, finally reached a steady.

When simulated nature rainfall make fissure healing, expansive soil surface become moist and soft gradually. Along with the increase in quantity of water added, accompanied with the collapse of the surface soil particle and the water flow into the crack and crack healing slowly. The healing speed increases as water added quickly before they are

Figure 1. A dehumidifying process of fracture development.

Figure 2. The final fracture after five times dry-wet circulation.

Figure 3. Fissure healing process.

gradually slow down. It was not until after the expansive soil saturated water stop adding water, soil surface eventually become a bit uneven, no longer like initial moisture level.

Expansive soil dry hard before sprinkler, soil surface is relatively smooth, fissure is clearly visible, mutual penetrated. During the preliminary stage of watering the fracture did not heal, but the process of expansive soil surface get Moist and soften gradually, gave a name to this process: the first stage of crack healing when expansive soil get Moist and soften stage. A period of time after watering, the surface of the expansive soil gets more humid, part of the cracks begin to be filled by the expansive soil fine particles which are softening in water. During this period, the speed of crack healing is fastest, gave a name to this process: the second stage of crack healing, the stage of fracture healing. Water after crack healing will have little impact on the crack. A period of time after watering when Fracture surface is almost flush with the soil horizontal plane which can think fissure expansive soils water saturated, gave a name to this process: the third stage of crack healing, the fissure water saturation stage. A period of time after Complete with water, the expansive soil surface will remain some white minerals which are mainly concentrated in on both sides of the original crack. Where there are more cracks, there are more white minerals.

## 3 TEST RESULT ANALYSIS

### 3.1 The relationship between the moisture content and fractures during a cycle process

The chart that the test record of the data analysis to obtain one circulation process with the change of moisture content.

Select two representative point analysis:  $(t_0, w_0)$  and  $(t_1, w_1)$ . Among them: the initial moisture content  $w_0 = 23\%$ , the critical moisture content  $w_1 = 21\%$ ; Moment  $t_0$ : 22:40 when to start to take off the wet, moment  $t_1$ : 1:00 just produce crack. Obtained from experiments:

- $t \in \langle t_0, t_1 \rangle$ , the fitting function:  $y = 0.0028t + 0.3261$ , the moisture content between  $(w_0, w_1)$ , Water content ( $w$ ) decreases and is proportional to the time ( $t$ ).
- $t \in \langle t_1, t_2 \rangle$ , the fitting function:  $y = 0.079 \ln x + 0.079$ , the moisture content

Figure 4. The change of moisture content within a cyclic process.

between  $(w_1, w_2)$ , which is a fissure development period, the speed of moisture content ( $w$ ) reduce speed up before slow down.

Under the invariable conditions of outside air velocity and temperature, the generation of crack is associated with the factors such as development of soil, soil moisture evaporation rate, the stress state, and expansive soil shrinkage characteristics [1]. The shrinkage characteristics associated with the composition of expansive soil and the soil moisture evaporation rate and the stress state are related to the moisture content of soil. When outside conditions are unchanged and expansive soil moisture content is large enough (greater than 21%), the evaporation rate of water is smooth and steady, the soil stress state is hardly changed, and there will be no cracks. When the moisture content of expansive soil is less than the crack generating critical moisture content (21%), the smaller the moisture content, the better the permeability of soil mass becomes, the faster evaporation, soil mass stress state changes, and the easier the soil fissure development. However, when the moisture content is below a certain value (3%), soil moisture content change is not obvious; there is almost no soil mass stress state change and fractures are largely discontinued.

When a crack starts generating, the whole airport surface area increases. This increases the evaporation surface greatly, thus accelerating the speed of internal moisture content reduction. In addition, in the local scope around the fissure, water evaporation rate is faster than the place without cracks, which led to increase the speed of the moisture content reduction of expansive soil in the local scope and new secondary fractures will develop around the main crack.

At the moment of taking off the wet, expansive soil began to produce crack moment, which is puberty before the crack. Water content ( $w$ ) decreases and is almost proportional to the time ( $t$ ). The expansive soil does not produce during fracture. When the moisture content decreased to critical moisture content, ( $w_1$ ) begins to

produce crack. Just produce crack to the ground to a halt is fissure development period, the speed of moisture content ( $w$ ) reduce, the length and speed of the growth rate of Crack change over time quickly before they are slow. When the moisture content down to smaller critical moisture content ( $w_2$ ) the fracture morphology become stable and Fracture largely discontinued, which is a period of fracture stability.

### 3.2 A dehumidifying process fracture characteristics

In the process of one cycle, Matlab software is used to analyze the crack image to get the area change rate and the total length of line chart as shown: (note: crack length in the soil use pixel as units).

In the process of a dry-wet circulation, with the growth of the dehumidifying time, the crack area ratio and the total length does not appear from the moment of  $t = 0$ . That is to say there is no crack generation in the early stages of the dehumidifying process. When cracks began to appear, the crack area ratio and the total length is not starting growth from 0 because the soil surface crack begins to generate at the same time in several locations. The total crack length and area ratio gradually accelerate after a period of time, increase its speed, and finally stabilize.

### 3.3 Analysis of fissure characteristics under the dry-wet circulation

Cutting Test pictures that five dry-wet cycles after each crack completely stability into the same size in the same area, then using Matlab software to get the binary fissure images (morphology theory).

Figure 5. The relationship between crack area ratio and the total length over time.

Programming analysis to calculate the area of the crack rate and the length of the crack will get the data into a line chart, as shown in Figure 6.

After the first time adding water, internal stress of expansive soil changes obviously, degree of expansive soil shrinkage increases sharply. After the second time adding water, degree of expansive soil shrinkage increases lesser, and shrinkage degree reaches the maximum. After the third time adding water, soil structure has changed and become relatively loose, lead to reduce the shrinkage space inside of the soil. After the fourth time adding water, internal structure of the soil changes more which reduces potential energy reserves of the expansive soil and the soil become fluffier.

With the increase of dry-wet cycles, crack area ratio and the total length is increased in the beginning and then decreases, this is due to dry-wet circulations make the internal structure of soil shrinkage stress space and irreversible changes have taken place. Expansive soil to dehydrate contraction, make its internal close-grained, result in fracture. Making the soil samples that complete dehumidified to water saturation again, cracks will be healed, but the soil is not back to the original state before the test, the crack healing doesn't make the place of tensile strength of soil restoration, the original cracks in the structure stress and tensile properties of soil have been destroyed. Under the influence of dry-wet circulation over and over again, the destruction of soil structure gradually accumulated, and internal tectonic stress of soil changes greatly, making the soil loose, plastic

deformation and plastic deformation accumulated with the dry-wet circulation of soil gradually [3], the internal structure, stress and dehumidifying space of soil become more complicated. Therefore, when soil samples to take off the wet process again, the expansive soil generates new crack more easily. Due to the soil dry shrinkage deformation space is limited, and the new crack share some space which cause the crack width on average decreases. The area of the crack rate has maximum, the maximum is associated with the function of internal force and contraction space of soil.

In the process of one cycle, the width of crack has showed a trend of increase with the decrease of the moisture content. And in the process of multiple cycles, the average width of the eventually stabilized crack showed a trend of decrease with the increase of cycling times. And the more cycles, the less number of fractures which width more than 5 mm, what's more, the average width of fracture for the first time cycle is the largest. It is obvious that crack width has close relationship with the area and the length of the crack.

#### 4 FISSURE PARAFFIN WAX MODEL

So far, there are several crack observation methods such as photographic technique, sketch method, conductivity method, CT method and ultrasonic method. Photographic technique and sketch method called direct observations of fracture, the operation is simple but greatly influenced by artificial factors and can only be observed in a crack in the two-dimensional plane [2]. This experiment solid paraffin wax with sand bath, and then pouring liquid paraffin to the expansive soil after dry-wet circulations (as shown in Fig. 7).

Separating the expansive soil and paraffin wax crack model after waiting for a certain period of time that paraffin wax fully solidified, than we can

Figure 6. The eventually crack area ratio and length after five times dry-wet circulation.

Figure 7. Original fracture of expansive soil.

Figure 8. The process of irrigation wax test.

Figure 9. The details of fissure paraffin wax model.

get the three-dimensional expansive soil fracture paraffin model.

Crack model appears grid and spread around, divided the whole model into several blocks in different size. Most fractures are arrived at the bottom of the test plate except a few cracks still not. The fractures that arrived at the bottom are coarser and longer. Most of these are connected together and belong to the main crack. The fractures that have not arrived at the bottom are finer and shorter, and most of the fine fissures are not connected to the main crack on both ends of the crack, which belong to secondary fractures. Crack is not always distributed vertically; there are some that bend from top to bottom, and the fissure walls are uneven. Some fractures have bifurcation phenomenon at the bottom, formatting two or more

fine fissures. Fracture thickness has a tendency of becoming narrower from top to the bottom, looking like a “V” glyph.

Comparing four dry-wet circulation models, the crack block number of the second test article is significantly more than the first, which illustrates that the more cycles, the more fractures. The main fracture number accounts for the vast majority of the total number of fractures. (There is a greater difference between the data of model 1 and model 2; the main reason is not stirring well when making model of expansive soil). The average width of twelve randomly selected typical cracks at the bottom of the model was measured.

Small crack width is less than 1.5 mm, the average width of the main fracture usually between 1.5~5.0 mm. It is obvious that the average width of main fractures is bigger than secondary fractures (small crack). We can saw cracks in the three-dimensional space form more intuitively, and the fracture internal structural is clearer through fissure paraffin model. Crack width decreases from the soil surface to the bottom (looks like “V” glyph). Crack is not always perpendicular to the surface of soil; some cracks even grow sideways; some fractures surface appear on a curved surface and generate new fractures in the fracture surface, which illustrates the internal structure, stress state, non-uniform shrinkage properties of expansive soil. The generation of crack also has certain order which indirectly illustrates the in homogeneity of internal moisture content of soil that proved the correctness of the test results.

## 5 CONCLUSION AND PROSPECT

In the process of one dry-wet circulation, the production and development of expansive soil crack is roughly divided into three stages: crack not puberty, crack development, and crack stop development.

Fractures' influence on expansive soil depends mainly on the strength of expansive soil. Cracks damaged the integrity of the soil and changed the stress state of the soil internal structures. Dry-wet circulation even exacerbated the impacts that form a vicious circle. These bad properties of expansive soil caused much trouble in practical engineering, which is also a headache. Therefore, the importance of studying the crack of expansive soil, the necessity, and urgency is self-evident. Research in the future on expansive soil should be divided into two directions: one is to study from the angle of the micro analysis of the internal structure of expansive soil or its physical and chemical biology and the other is from the macroscopic angle to improve bad properties of expansive soil itself to meet the

needs of the project. This experiment was carried out on expansive soil using dry-wet circulation by simulation to research and analyze expansive soil fissures' "generate—development—healing" characteristics of the cycle for the further research of expansive soil foundation.

# Finite element analysis of reinforced soil retaining wall

Q. Wang, F.F. Li, H.F. Qian, H.R. Qin & T.Q. Zhou

College of Environmental and Civil Engineering, Jiangnan University, Wuxi, China

**ABSTRACT:** The deformation and bearing capacity mechanism is important for the engineering design of reinforced soil retaining wall. Adopting embed modeling for the interaction between the reinforced bar and the soil, the elasto-plastic finite element method is proposed to analyze the behavior of reinforced soil retaining wall. The simulated results are in good accordance with the experimental test data. The plastic region in the retaining wall coincides with the Rankin assumption. The reinforced bar resistance in the retaining wall greatly improves the limit bearing capacity.

**Keywords:** bearing capacity; reinforced soil retaining wall; finite element analysis

## 1 INTRODUCTION

The application of reinforced earth retaining wall has gained great popularity in hydraulic engineering, civil engineering, and transportation construction engineering. The finite element method is a versatile tool to analyze the complex structural mechanical characteristics. The finite element analysis has been performed to examine the behavior of reinforced earth retaining wall since 1970's. Most of the research results were based on nonlinear elastic or simple elasto-plastic model. Liu Huabei [1] used an elasto-plastic model with bounding surface to investigate the geogrid reinforced soil retaining wall. Based on the wedge failure mode of the reinforced soil retaining wall, Lv Wenliang, Yanshuwang and Liu Run [2] used the Mohr-Coulomb material to model the soil and used the ideal plastic spring to model the reinforced bar. The numerical analysis proved that the method was effective and accurate to understand the behavior of the retaining wall.

In the paper, the finite element model for the reinforced soil retaining wall is developed using ABAQUS. The embed option is used to model the interaction between the reinforced bar and the soil. Nonlinear geometric analysis is used to analyze the problem. The plastic zone of the soil is investigated to model the bearing capacity mechanism. Also, the deformation behavior of the retaining wall facing is examined.

## 2 FINITE ELEMENT MODELLING USING ABAQUS

### 2.1 Finite element model

Considering the symmetry of structure, soil, and loading condition, the plain strain finite element

model of the reinforced soil retaining wall is modeled, as shown in Figure 1. The two-dimensional reduced integration solid element C2D4R is used to model the soil. The bottom boundary condition is restrained in x, y directions. The side boundary is restrained in x direction. The Mohr-Coulomb yield criterion is used to model the soil behavior. The elastic model is used to model the pile. The calculation region is taken as 20 times the pile radius in the longitudinal direction. The reinforced rib is assumed to be contact with soil. The embedded option is used to model full contact between reinforced rib and sand.

### 2.2 Boundary and loading

The side view of the reinforced rib distribution is shown in Figure 2. As it can be seen from the figure, the length of the reinforced rib varies in depth. The longer reinforced rib is used in the upper region while the shorter reinforced rib is used in the lower region.

Figure 1. Finite element model.

Figure 2. Side view of the reinforced rib (unit: mm).

Figure 3. Boundary condition.

Figure 4. The applied loading.

The boundary condition for the finite element analysis is shown in Figure 3. The bottom of the retaining wall is restrained in x and y directions. The right side of the retaining wall is restrained in y direction.

In geotechnical analysis, the geostatic analysis is performed firstly to establish the initial stress condition corresponding to the establishment of the reinforced soil retaining wall construction. In the geostatic analysis, gravity loading is applied to the soil region while the initial stress is defined in equilibrium with gravity. Then the loading on the top of the retaining wall is applied in the loading step, as shown in Figure 4.

### 3 FINITE ELEMENT ANALYSIS

The Mohr-Coulomb model is used to model the sand with cohesion  $c = 0$  KPa and friction angle  $35^\circ$ .

The computed Q-s curve is shown in Figure 2. As shown in Figure 2, the computed uplift bearing capacity is about 1180 KN, which is close to the experimental value of 1100 KN.

The computed soil displacement and soil vertical stress is shown in Figure 5 and Figure 6, respectively.

The soil yield zone and the plastic distribution is shown in Figure 7 and Figure 8, respectively.

As shown in Figure 7 and Figure 8, the plastic region limit is like the log-spiral curve starting from the top of the retaining wall to the bottom of the reinforced rib. When the plastic limit forms, the global failure will occur.

Figure 5. Vertical displacement distribution.

Figure 6. Total displacement distribution.

Figure 7. Mises stress distribution.

Figure 8. Plasticity distribution.

Figure 9. Distribution of face displacement along retaining wall depth.

The computed face horizontal displacement distribution along retaining wall depth is shown in Figure 9. It can be seen from Figure 9 that the plastic region in the retaining wall coincides with the Rankin assumption. The reinforced bar resistance in the retaining wall greatly improves the limit bearing capacity.

#### 4 CONCLUSIONS

The numerical analysis is performed to investigate the deformation behavior of reinforced soil retaining wall. The plastic region limit is like the log-spiral curve starting from the top of the retaining wall to the bottom reinforced rib. The plastic region in the retaining wall coincides with the Rankin assumption. The reinforced bar resistance in the retaining wall greatly improves the limit bearing capacity.

#### ACKNOWLEDGMENT

# The research progress of water-salt mechanism and migration model

Guang-li Zhu, Long Zhu & Chao Yu

*Transportation Design Co. Ltd., Wuhai Shi-da Inner Mongolia, P.R. China*

**ABSTRACT:** Soil salinization is one hot issue of numerous interdisciplinary research which involved soil science, environmental science, and geotechnical engineering. Scientific understanding of water-salt migration model and mechanism in soil has great significance for solving soil salinity in agricultural engineering and preventing subgrade salinization in subgrade engineering. Widely accepted at home and abroad; agricultural engineering water migration model (capillarity force hypothesis, film water migration hypothesis, crystallization force hypothesis and adsorption-film capillarity); migration mode of ion in saline soil (seepage flow migration, diffusive migration and seepage-diffusive migration); and water-heat, water-salt, water-heat-salt migration model, and mechanism in soil are introduced. And also the research progress in the area of road engineering is introduced. Principle, similarities and differences, advantages and disadvantages, and applicability and application status of correlation model are analyzed and evaluated.

**Keywords:** soil; salinization; migration mechanism; model

## 1 INTRODUCTION

Yield in arid and semiarid area are affected by soil salinization, especially with the increase of the population in the world, there is an unprecedented pressure for maintaining grain yield. For our country (China), farmland salinization makes great population and less arable land contradiction fierce. In addition, in arid and semiarid area, secondary salinization of subgrade soil leads to pavement disease and reduces performance of pavement. Therefore, research on water-salt migration model and salt accumulation mechanism in soil and subgrade have great significance for solving soil salinity in agricultural engineering and preventing subgrade salinization in subgrade engineering.

## 2 WATER-SALT MIGRATION MODEL

Water-salt migration is a complicated process. From classic literature data motive power hypothesis, which is suitable for water migration in saline soil include following types: (1) capillarity force hypothesis: water transfers to the cold end along the fractures and void in soil with the capillarity force. This theory is suitable for the soil with larger water content. (2) Film water migration hypothesis: Coupling effect of temperature field and water field as cooling progress is the reason for water

migration and redistribution that is water migration with the effect of temperature gradient. Water migration changes the original water distribution in soil and produces uneven distribution of spatial position of soil framework-water-crystal. Physical and mechanical properties of soil are changed. The theory is suitable for fine saline soil. (3) Crystallization force hypothesis: In the cooling progress of soil, solubility of the cold end is lower and more crystal precipitated. Due to the precipitation absorbs 10 crystal water moleculars, water content of the end with more precipitation decreases which causes hydraulic gradient and water transfers from the end with higher water content to the lower. (4) Adsorption-film capillarity: water molecules and salt molecules transfer from point more active and with thicker hydration film to the point more stable and with thinner hydration film. Under natural conditions, the migration of water depends on comprehensive effect of mechanics, physics, and physical chemistry. Each hypothesis mentioned above can represent water migration motive power only at certain conditions.

The migration of ions in saline soil at present research is considered as mainly three types: (1) Seepage flow migration: salt transfers as water in seepage flow. (2) Diffusive migration: salt transfers with the effect of gravity and temperature gradient. (3) Seepage-diffusive migration: At cooling process, salt transfers with the mixing effect of seepage flow and diffusive.

### 3 THE MECHANISM OF SOIL WATER AND SALT MOVEMENT IN AGRICULTURE ENGINEERING

#### 3.1 *The mechanism of soil water and salt movement*

The theory of Soil Water and Salt Movement originated from Darcy's law, and the equation of the advent of solid heat conduction provides the basis for soil solute transport. Since Buckingham (1907) introduced the concept of energy into soil water, Richards (1931)<sup>[1]</sup> described the operation of the unsaturated soil water by using partial differential equation, established the basic equation for water flow in porous media, then the quantitative research of the soil moisture began. Because of the salt movement and the soil moisture migration occurred at the same time, as a result, the soil solute migration equation is developed by soil moisture equation. The common of these equations is that they all analyze the soil water and salt movement with dynamics views, material, and energy balance principle.

The initial research took isothermal conditions as assumptions, and mostly only considered gravity potential and matric potential in water, salt convection and dispersion interaction, and rarely involved other interactions between water and salt, such as the effects of salt concentration gradient on moisture migration, in fact, the salt concentration has an important role on soil water movement. In unsaturated soil, especially the heavy clay, the osmotic potential of the soil is an important driver of soil water movement. Many experiments and simulation results show that the water-holding capacity of the soil is greatly influenced by soil temperature; the water temperature effect of the surface tension is one of the main reasons for this impact. In the mathematical simulation of soil water movement, if the temperature effects of the soil hydraulic properties are ignored, it will produce large prediction error. Therefore, since the 1950s, the soil water movement equation in non-isothermal conditions to be taken seriously and developed, in which it mainly started from the temperature effect of soil hydraulic properties.

In the Middle and Late 1970s, the mechanism studies of water and salt movement began to pay attention to the actual situation in the complex field, for example, for the way of soil water and salt movement with good structure, it not only considered the convection and diffusion, also considered the movable and immobile water, macropore flow, preferential flow and pipe flow, etc. and set up a two-area model of the soil water and salt migration. In two-region model, Van Genuchten considered the solute in the pore between movable

water and immobile water can transport between two region, and considered the effect of moving and immobile water and influenced each other, which is more practical. It can be used to describe the migration of salts in the soil column, and the solute migration under the adsorption condition.

Melsen (1985) introduced the theory of soil spatial variability, put forward theories and method about how to determine the average of soil parameters, the variance and correlation scale. Afterwards, many scholars had set up random logarithmic convection model which includes random convection diffusion model, obtained the probability distribution function of solute transport speed, and the average concentration distribution. This model is suitable for the research of unsaturated soil solute migration in the wild field, which has better results, but it lacks of the measured data validation, still needs further improvement.

The domestic and foreign researchers have done a lot of work about Movement Law of Water and Salt under the condition of evaporation. Recent research demonstrates that plastic film mulching has the role of increasing temperature, keep moisture, water saving, and salt restraint. Through the study of farmland soil water and salt migration under the condition of mulching, aimed at to provide theoretical basis and technical guidance for observing in the field, developing and improving in saline-alkali land and film hole irrigation technology.

#### 3.2 *Soil moisture, heat and salt coupling transport model*

Soil moisture, heat and salt coupling transport models built up on the basis of moisture isothermal model. LA Richards (1931) applied continuity theorem to Darcy flow equation and used a continuous flow equation instead of the instantaneous flow equation to study unsaturated flow in soil, which is known as the basic equation of soil water movement—*isotherm equation*. Klute (1952) changed L.A. Richards' isothermal equation into non-isothermal diffusion flow equation and then a lot of researchers used the equation to determine the diffusion rate of the liquid under the action of the temperature difference. Two types of coupling numerical model, the model based on mass-energy balance and linear equations on the basis of irreversible thermodynamics, are developed.

Philip & De Vries<sup>[2]</sup> (1957), De Vries (1958) proposed the migration of water vapor thermal coupling theory on the basis of the establishment of the mass and energy balance and built soil liquid and gas two-phase flow of water sports model under the influence of precipitation and elevation gradient. Their hydrothermal coupled equation is

a function in which water content and temperature is unknown. Due to the change in temperature can cause a phase change of soil water, such as under freeze-thaw conditions, the liquid and solid state water make mutual conversion and in the evaporation, liquid water change into gaseous water, etc. It is more realistic to use soil water potential and temperature as an unknown function of the equation to indicate the soil moisture and heat conservation process. Milly<sup>[3]</sup> etc. (1982, 1984) improved the mode of Philip (1957). Milly<sup>[4]</sup> used the matric potential gradient instead of moisture gradient to make the modified model applicable to heterogeneity soil. They thought that model can well in line with the actual situation in the complex soil environment and parameters of equations can be obtained from theoretical or empirical equations. Based on Philip (1957) model, Nassar<sup>[5]</sup> etc. (1989, 1992) used moisture, heat and salt transport equations (that is Darcy, Fourier, Fick's law) and continuity equation to establish moisture, heat and solute three coupling shift model and studied moisture, heat and solute simultaneous transport in closed soil column affected by the temperature gradient.

Thermodynamic model was first proposed in 1985. It created expressions and equations about corresponding free energy and dissipated energy of multi-phase medium on the basis of mass conservation, energy conservation and entropy inequality about three-phase medium including soil, ice, water in frozen soil micro unit. Suction of void was caused by a soil frost heave, moisture and heat transfer and water freeze in the thermodynamic model and it is not required to determine the relationship between the water content and negative temperature. Clausius-Clapeyron equation was introduced to seek soil water potential in the process of model derivation. Generally, this type of model is only applicable to a limited freezing temperatures range in the soil. For the low negative temperature, the applicability of this model has not yet been verified.

Flerchinger & Saxton (1989) set up SHAV model to simulate the transmission among water content, heat and the flux of the solute during the process of soil freezing and thawing. Flerchinger & Hanson (1989) used SHAW model to simulate frozen depth of soil, snow layer, and soil temperature in the ranch under three different climatic conditions in America. Nassar & Horton etc. (2000) used SHAW model to study the transmission among water, heat, and the solute in saline and non-saline soil of closed soil columns and analyze the temperature distribution of two soils. Besides, both observed value and predicted value of the water distribution of the non-solute soil showed that water aggregate to 40 cm in soil and frozen

depth in this type of soil is about 45–65 cm. There is no obvious migration of solute in saline soil and slight water decrease at 20 cm. Compared with non-saline soil, solute concentration decreased the freezing temperature.

#### 4 PROSPECT

In summary, there are more research on the unilateral combination of water and salt or water and heat in the study of soil water, heat, salt migration, especially, more achievements in the agricultural engineering, while the research on relationships and interactions between soil moisture, heat, and salt migration are a little. For the salinization of subgrade soil in road engineering, it is some different from agricultural engineering because of the effect of road coverage. Therefore, on the basis of referring to migration law on natural soil water, heat, and salt. We urgently need to research the law of water and salt movement deeply and systematically under the conditions of the road surface coverage to reveal salt accumulation mechanism in highway engineering.

# Application of strain softening model to numerical analysis of deep tunnel

X.H. Diao, S.X. Yang & K. Wang

*School of Civil Engineering and Architecture, East China Jiaotong University, Nanchang, Jiangxi, China*

**ABSTRACT:** According to the incremental theory, the expression of plastic parameter of strain-softening model was deduced in this paper. Based on the In line fish language of FLAC3D, the program which is used to compute the safety factor of surrounding rock was compiled. At the same time, two experiments about uniaxial numerical were designed to compare and analyze Mohr-Coulomb elastic-plastic model and strain softening model, finding the differences of the stress-strain law of the rock under different constitutive conditions. Numerical simulation of a deep buried roadway in an iron mine is carried out as the engineering background. The law of displacement, plastic area distribution of surrounding rock under different constitutive were analyzed, and the surrounding rock stability under different constitutive model were evaluated.

**Keywords:** deep tunnel; surrounding rock softening; numerical analysis; safety factor

## 1 INTRODUCTION

With the rapid development of underground engineering in our country, more and more underground engineering safety problems occur and need to be solved. The problem of deep engineering rock mechanics is one of research directions to be studied, intensively. During the process of excavating the tunnel, due to the deep engineering is in high stress conditions the stress in rock will be distributed again. And it will cause concentration phenomenon by the surrounding roadway, as well as surrounding rock deformation. However, the deformation is often non-linear, and it when reaches a certain degree, it will cause the failure of surrounding rock.

Research shows that during the excavation of deep buried rock, due to the continuous expansion of micro crack in the rock, strength parameters in the nonlinear phase will obviously decrease, which is called rock softening phenomenon [1–4]. When the rock stress reached peak strength, as the deformation continues to increase, the material degradation phenomenon becomes more obvious. Many scholars work at numerical simulation and strain softening theory in order to establish the constitutive relationship, which can reflect the rock nonlinear mechanical response [5–8]. The rock strain softening problem has been paid much attention for the engineering field. However, in Mohr-Coulomb elastic-plastic model, when the parameters of the material are presented as constant value, they often can not reflect the softening effect of deep buried

rock, which is caused by the change of the parameters of surrounding rock [9–11].

To solve this problem, this paper carried out a comparative study by using the strain softening model and Mohr-Coulomb elastic-plastic model which are carried by FLAC3D, analyzed the surrounding rock in two different constitutions under the mechanical response and displacement of different state, and evaluated the stability of surrounding rock under different constitutive relations. The findings of the study have some significant guiding for engineering practice.

## 2 STUDY ON STRAIN SOFTENING MODEL

In FLAC3D, the stage of elastic strain of softening model and Mohr-Coulomb elastic-plastic model are exactly identical [12]. The difference between the two models is that after the plastic yield, in the strain softening model with the increasing of plastic strain, material cohesion, internal friction angle, dilatancy angle, tensile strength will decay. In the process of application, the user can customize these material parameters as a function of plastic strain, the tri-linear softening law is used more common (Fig. 1). Strain softening model in each time step increases the hardening parameter to calculate the total plastic shear strain and tensile strain, thus making consistent the material properties and the material function which the users define. The strain softening model of yield

Figure 1. Stress-strain relation of strain-soft model.

function, flow rule, stress correction are compatible with Mohr-Coulomb model.

From Figure 1, before reaching the yield point, only the elastic strain exists, there is:

$$\varepsilon = \varepsilon^e \quad (1)$$

After reaching the yield point, the strain is equivalent to the sum of elastic strain and plastic strain, where:

$$\varepsilon = \varepsilon^e + \varepsilon^p \quad (2)$$

The plastic strain is divided into plastic shear strain and the plastic tensile strain, where:

$$\varepsilon^p = \varepsilon^{ps} + \varepsilon^{pt} \quad (3)$$

Then formula (2) can be transformed to:

$$\varepsilon = \varepsilon^e + \varepsilon^{ps} + \varepsilon^{pt} \quad (4)$$

### 2.1 Elastic law

The expression of Hooke's law and the main form of stress strain form are expressed as following.

$$\begin{cases} \Delta\sigma_1 = \alpha_1\Delta\varepsilon_1^e + \alpha_2(\Delta\varepsilon_2^e + \Delta\varepsilon_3^e) \\ \Delta\sigma_2 = \alpha_1\Delta\varepsilon_2^e + \alpha_2(\Delta\varepsilon_1^e + \Delta\varepsilon_3^e) \\ \Delta\sigma_3 = \alpha_1\Delta\varepsilon_3^e + \alpha_2(\Delta\varepsilon_1^e + \Delta\varepsilon_2^e) \end{cases} \quad (5)$$

### 2.2 The yield function and potential function

In FLAC3D, the function of shear strain softening model, there is,

$$F^s = \sigma_1 - \sigma_3 N_\varphi + 2c\sqrt{N_\varphi} \quad (6)$$

In the formula  $N_\varphi = \frac{1+\sin\varphi}{1-\sin\varphi}$ , where  $c$  = cohesion force,  $\varphi$  = angle of internal friction,  $\sigma_1$  = the first principal stress,  $\sigma_3$  = the third principal stress.

The tensile yield function as following description.

$$F^t = \sigma_t - \sigma_3 \quad (7)$$

Shear plastic potential function is based on the non-associated flow rule, while the tensile plastic potential function is based on the associated flow rule.

The shear plastic potential function, there is,

$$g^s = \sigma_1 - \sigma_3 N_\varphi \quad (8)$$

The tensile plastic potential function, where:

$$g^t = -\sigma_3 \quad (9)$$

### 2.3 Plastic correction

When the shear failure, there exists orthogonal flow rule:

$$\Delta\varepsilon_i^p = \lambda^s \frac{\partial g^s}{\partial \sigma_i} \quad (10)$$

The tensile failure flow rule:

$$\Delta\varepsilon_i^p = \lambda^t \frac{\partial g^t}{\partial \sigma_i} \quad (11)$$

$\lambda^s, \lambda^t$  are plastic parameters.

To expand formula (10) and (11), there exists:

$$\begin{cases} \Delta e_1^{ps} = \lambda^s \\ \Delta e_2^{ps} = 0 \\ \Delta e_3^{ps} = -\lambda^s N_\varphi \end{cases} \quad (12)$$

$$\begin{cases} \Delta e_1^{pt} = 0 \\ \Delta e_2^{pt} = 0 \\ \Delta e_3^{pt} = -\lambda^t \end{cases} \quad (13)$$

Putting the formula (12) into the incremental elastic law (5) can be obtained as below.

Shear failure stress correction are:

$$\begin{cases} \sigma_1^N = \sigma_1^I - \lambda^s(\alpha_1 - \alpha_2 N_\varphi) \\ \sigma_2^N = \sigma_2^I - \alpha_2 \lambda^s(1 - N_\varphi) \\ \sigma_3^N = \sigma_3^I - \lambda^s(\alpha_2 - \alpha_1 N_\varphi) \end{cases} \quad (14)$$

Among  $N_\psi = \frac{1+\sin\psi}{1-\sin\psi}$ ,  $\psi$  = dilatancy angle. The superscript N, I are represented the unit of new and old state of stress.

Combining formula (14) with (6) by method of substitution:

$$[\sigma_1^I - \lambda^s(\alpha_1 - \alpha_2 N_\psi)] - [\sigma_3^I - \lambda^s(\alpha_2 - \alpha_1 N_\psi)] N_\phi + 2c\sqrt{N_\phi} = 0 \quad (15)$$

Then the solution is:

$$\lambda^s = \frac{f^{sI}}{(\alpha_1 - \alpha_2 N_\psi) - (\alpha_2 - \alpha_1 N_\psi) N_\phi} \quad (16)$$

Similarly, putting the type (13) into the incremental elastic law (5) leads to tensile failure stress correction:

$$\begin{cases} \sigma_1^N = \sigma_1^I + \lambda^I \alpha_2 \\ \sigma_2^N = \sigma_2^I + \lambda^I \alpha_2 \\ \sigma_3^N = \sigma_3^I + \lambda^I \alpha_1 \end{cases} \quad (17)$$

Substitute equation (17) into equation, there is

$$\sigma^I - \sigma_3^I - \lambda^I \alpha_1 = 0 \quad (18)$$

The solution is:

$$\lambda^I = \frac{f^{tI}}{\alpha_1} \quad (19)$$

### 3 ENGINEERING APPLICATION

#### 3.1 Project overview

Xiaoguangzhuang Iron Mine is one of the three iron mine beds which spread in half round in the plunging end of mine arc anticline in Laiwu Graben Basin, belonging to high temperature hydrothermal contact Metasomatic skarn Magnetite deposit generated by the invasion of Diorite magma into Ordovician limestone. The strike of the orebody is NE17°, and the dip of the orebody is NW73°. The buried depth of orebody ranges from 420 to 100 m, the length along the strike is 2150 m, and the thickness of the orebody is 25 to 50 m, up to 80 meters in some parts. The average grade stands at 46.42%. The ore is moderately stable, with the roof of orebody made of tertiary-conglomerates and clayey sandstone and the floor mainly made of altered diorite which is extremely unstable. There are relatively more interlayers which are mainly made

of diorite-porphyrite and serpentinized marble, while conglomerate, clayey sandstone and hornstone constitute the easy-collapse wall rocks near the orebody which have poor stability, loose structure and well-developed cleavage fracture.

#### 3.2 The related parameters and the calculation model

A deep buried scraper tunnel was selected for the numerical analysis. The net cross section of the main roadway is 2.0 m wide, 2.5 meters high and the top is a circular arc shape, arc radius is 1.8 m. The size of the roadway both vertical and horizontal are about 10 m, the longitudinal is 2 m and the buried depth is 1000 meters. The roadway cross-section is shown in Figure 2. Mohr-Coulomb elastic-plastic model and strain softening model are adopted, respectively, in the following paper to analyze and evaluate the displacement, plastic zone distribution and safety factor of surrounding rock.

##### 1. The parameters of the rock

The analysis adopts a kind of rock material. The numerical model of the surrounding rock parameters is shown in Table 1.

##### 2. Calculation model

The calculation model and mesh size as shown in Figure 2 and Figure 3.

Calculating model of node is divided into 5327, and 4344 units.

##### 3. Geostress stress conditions

The model is applied gravity stress in vertical direction, while the horizontal stress field is applied with lateral pressure coefficient. According to the results of geostress measurement, the horizontal stress is greater than the vertical stress, horizontal and vertical stress ratio is about 2.

Figure 2. Cross section of tunnel (unit:m).

Table 1. Mechanical parameter of surrounding rock numerical model.

Modulus of elasticity/ GPa	Poisson's ratio	Cohesion/ MPa	Internal friction angle/(°)	Density/ (Kg/m <sup>3</sup> )	Tensile strength/ MPa
1.2	0.22	2.0	42	2500	0.5

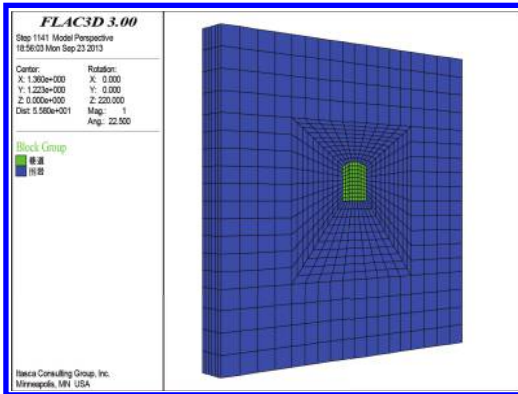

Figure 3. Computation model of tunnel.

### 3.3 Analysis of displacement of surrounding rock

Horizontal displacement to the right is positive, negative to the left. Vertical displacement to the upward is positive, downward is negative. Vertical displacement of surrounding rock calculation results, as shown in Figures 4(a) and (b).

From analysis of Figure 4, in strain softening model the calculation of the maximum vertical displacement is 45 mm, while in Mohr-Coulomb elastic-plastic model the maximum vertical displacement of calculation is about 5 mm. The calculation results of vertical displacement in strain softening model is obviously greater than Mohr-Coulomb elastic-plastic.

The calculation results of horizontal displacement of surrounding rock are shown in Figures 5 (a), (b).

From the analysis of Figure 5, in strain softening model the calculation of maximum horizontal displacement is about 20 mm, while the maximum value of horizontal displacement calculated by Mohr-Coulomb elastic-plastic model is about 10 mm. Two models of roadway under the horizontal deformation are basically symmetrical, the results of horizontal displacement in strain softening model was significantly larger than the Mohr-Coulomb elastic-plastic model.

Analyzing Figures 4 and 5 comprehensive, the overall trend of the calculated displacement of surrounding rock of two models is identity, but the calculated results of displacement in strain

Figure 4. Horizontal displacement of surrounding rock (unit:mm).

softening model is obviously greater than the Mohr-Coulomb elastic-plastic model. In the strain softening model, the deformation of rock softening was reflected obviously.

### 3.4 Analysis of surrounding rock plastic zone

The distribution of plastic zone of surrounding rock is shown in Figure 6 (a), (b).

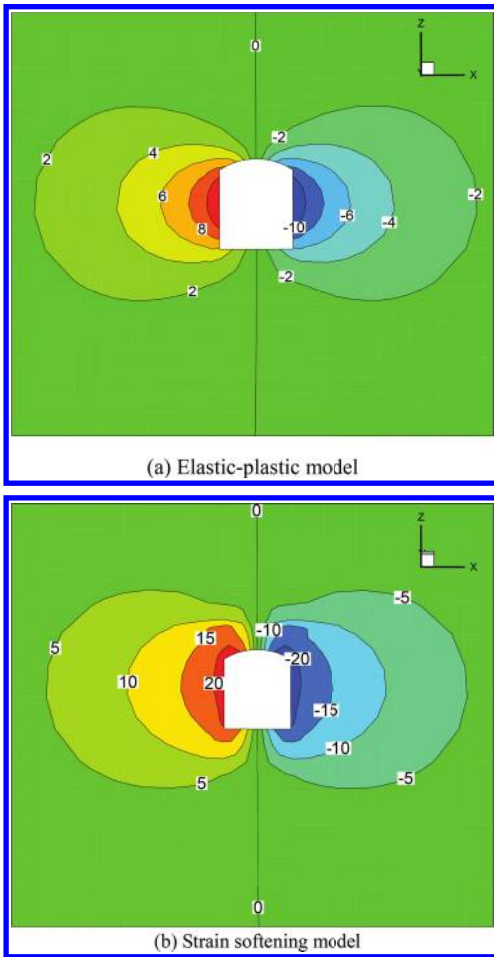

Figure 5. Vertical displacement of surrounding rock mass sample (unit: mm).

From Figures 6 (a), (b) can be seen, in the calculation of elastic-plastic model the plastic zone is mainly distributed in the vault and spandrel, the thickness of plastic zone is 0.5 ~ 1 m. While in strain softening model the plastic zone is mainly distributed in the vault, spandrel and the bottom of arch, the plastic zone extended to the entire area of the side wall on both sides. The distribution range of plastic zone is wider than the elastic-plastic model, and the distribution depth is deeper than the elastic-plastic model. The thickness of plastic zone is about 1.5 ~ 2.5 m.

### 3.5 Stability analysis of surrounding rock

According to the calculation results of stress, Mohr-Coulomb yield criterion is applied to calculate the safety factor of surrounding rock [13–14].

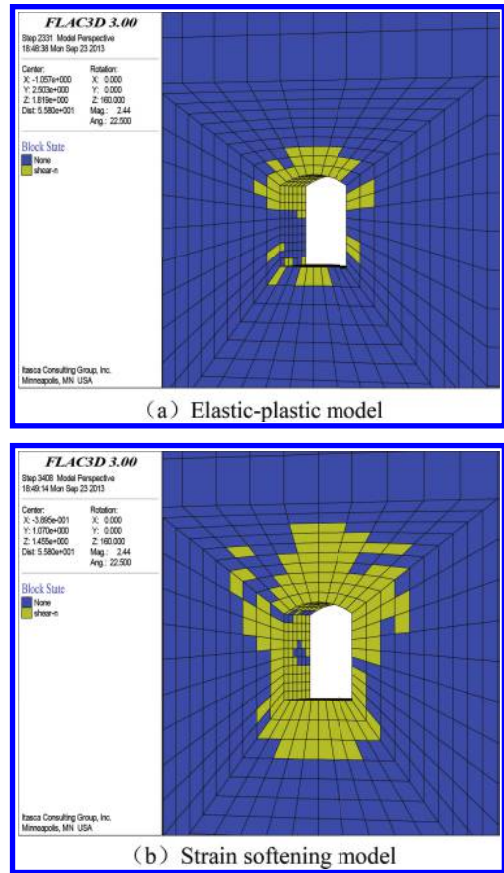

Figure 6. Plastic zone distribution of surrounding rock.

Based on the In line fish language of FLAC3D, the point safety factor of calculating program is compiled. The calculated safety factor of different constitutive models, as shown in Figure 7 (a) and (b).

Two conclusions can be drew From Figures 7 (a) and (b):

1. The point safety factor is calculated by strain softening model is smaller than that of elastic-plastic model.
2. The unstable region of the surrounding rock, which is calculated by Strain softening model is larger than Mohr-Coulomb elastic-plastic model. For deep engineering, comparing and analyzing strain softening model and ideal elastic-plastic constitutive model, the results show that, when ignoring the strength softening characteristic it will partial to unsafe for engineering. When the strain softening model is adopted the stress and deformation of surrounding rock can be reflected more reasonable.

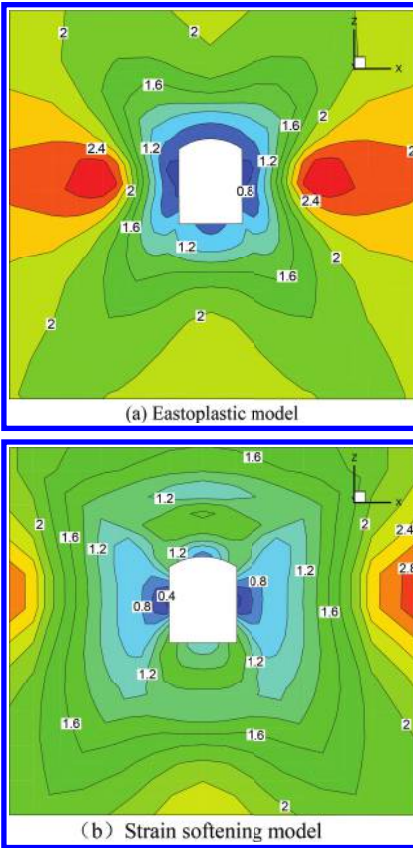

Figure 7. Safety factor of surrounding rock.

#### 4 CONCLUSIONS

1. In the process of deep buried tunnel excavation, the strength parameters of surrounding rock will be decreased continuously, which is caused by stress concentration and redistribution in rock micro crack expansion. In the numerical calculation process of deep buried tunnel, if the classic Mohr-Coulomb model was adopted, the mechanical characteristics of surrounding rock will not be able to response the change.
2. The results of the total deformation of surrounding rock that calculated by using the strain softening model is larger than adopting the elastic-plastic model, and have the greater scope of excavation disturbance. The central tendency of plastic zone of surrounding rock which is calculated by strain softening model and Mohr-Coulomb model are basically same, but its distribution range and thickness would be wider and deeper.
3. When the elastic-plastic model is adopted to calculate the excavation of deep buried tunnel stability

problem, the results are conservative. However, it cannot reflect the true state of rock mechanics and displacement. The strain softening model is recommended to the simulation analysis of deep engineering, in order to evaluate the deformation and support strength of rock mass accurately.

**ABSTRACT:** Rock samples of different sizes have different uniaxial compressive strengths. In this study, based on actual project, we process samples of different sizes and measure their uniaxial compressive strength. Contrastive analysis shows that uniaxial compressive strength decreases with the increase of sample size. Through fitting, we get the relation formula between uniaxial compressive strength and size effect. When side length of sample is 30 mm, the uniaxial compressive strength is close to the standard strength defined in the code. In actual project, if sample size can not meet the required finish size of the code due to limitation of project conditions, we can process 30 mm samples, measure its uniaxial compressive strength, and then calculate the compressive strength of standard samples using the formula.

**Keywords:** size effect; cube sample; uniaxial compressive strength

## 1 INTRODUCTION

Rocks are the product of earth formation and crustal activity. With wide existence in the nature, rocks are often used as building foundation, building materials or surrounding rock. In geotechnical engineering investigation design, the carrying capacity of bedrock, stability of rock slope, stress distribution, stabilization, and deformation of surrounding rocks in underground chamber (tunnel, etc) excavation are all closely related to physical and mechanical property of rocks. Rock uniaxial compressive strength test mainly focuses on the ultimate load per unit area borne by regular-shaped rock samples (e.g. cylindrical sample of building foundation, cubic sample of bridge engineering, or samples of both shapes in pavement engineering), when compression failure is caused by axial compressive force without lateral confinement. That is to say, the ratio between ultimate load and the section area perpendicular to loading direction under sample failure is an important parameter to reflect the physical and mechanical property of rocks.

Factors influencing rock compressive strength can be classified into two aspects: (1) rock conditions, such as diagenesis model, weathering degree,

mineral composition, stratification, fracture direction, etc; (2) test conditions, such as sample processing method, shape, size, load rate, etc.

Sample state includes shape, size, and height-diameter ratio. The influences of the three factors on test result are called size effect. The application of standard samples can eliminate influence of samples with different states, and thus facilitate the comparison of test results. In actual project, influenced by various factors, samples are of different sizes, so some samples can not be processed into standard sized samples. To get rock compressive strength, we need to modify samples with non-standard sizes. In this way, we can get the compressive strength of their corresponding standard samples.

## 2 ENGINEERING BACKGROUND

In this study, we process samples of various sizes for compressive strength test. By analyzing test results, we explore the law of rock compressive strength at different rock sizes, and provide evidence for the relation between compressive strength and rock size.

### 2.1 Petrological characteristics

The samples, gray, are collected from moderately weathered limestone in the exploration field of an expressway in Yunnan Province. The main component is calcite, with other components less than 5%. Dense and hard in texture, the rocks have developed fractures, and most of the fractures are closed. Rock cores are mostly long-column in shape, and knot length is generally 15 ~ 30 cm. The rocks distribute extensively in the field, and constitute the major rock of the field.

### 2.2 Processing of samples

Test Methods of Rock for Highway Engineering (JTGE41-2005) (TMRHE) and Standard for Test Methods of Engineering Rock Mass (GB/T50266-1999) (STMERM) defines that: Stones and rocks used in pavement engineering should adopt cylinder or cube samples. The diameter/side length and height should be  $50\text{ mm} \pm 2\text{ mm}$ .

For this test, we adopt cube samples, with 6 samples as a group. As our purpose is to study the influence of rock size effect, so we process samples of other sizes except for samples with conventional sizes. All the samples are cubic, with sizes of  $30\text{ mm} \pm 2\text{ mm}$ ,  $70\text{ mm} \pm 2\text{ mm}$  and

$100\text{ mm} \pm 2\text{ mm}$ . As limestone particles are fine and small, the sample sizes meet the requirement of “diameter of compressive strength test samples should be 10 times larger than the maximum particle diameter of the rock” defined in TMRHE and STMERM. To avoid influence of chemical blasting on rock property, samples are excavated with manpower from the pit, and then moved indoor for processing. Samples of the same size ( $n = 12$ ) are divided into 2 groups: air-dried group and water-saturated group. Electronic drying cabinet is used for air drying, with the temperature controlled between  $100^\circ\text{C} \pm 5^\circ\text{C}$  and drying time of 8 h. Free water absorption is used for water-saturation, with absorption time of 48 h.

### 2.3 Test method

The samples are put on 200 t–500 t press machine and exerted with longitudinal load (axial direction) under no lateral confinement. To be specific, put the samples at the center of bearing plate of the press machine. Adjust the bearing plate to make sure the samples receive even stress. Exert load at a rate of 0.5–1 MPa/s until the samples are damaged.

Table 1. Strengths of rocks with different side length.

Diameter (mm)	Moisture state	The compressive strength value (Mpa)						Average strength (Mpa)
30±2	Air dry	75.3	78.9	78.6	77.2	76.0	74.8	76.8

Table 3. Point load test value of water-saturated rocks.

Measuring points number	Moisture state	Load orientation	Failure load(KN)	Load spacingD (mm)	Width of failure surface Wf (mm)		Average width (mm)	Equivalent circle square diameter(mm <sup>2</sup> )	Point load strength (MPa)	Size amend coefficient	Convert compressive strength(MPa)
1	Saturated water	Radial	12.7	55.60	73.76	76.41	75.1	5318.1	2.39	1.19	55.9
2	Saturated water	Radial	13.8	47.64	81.75	83.24	82.5	5006.4	2.76	1.17	
3	Saturated water	Radial	13.2	34.09	75.31	73.92	74.6	3240.3	4.07	1.06	
4	Saturated water	Radial	12.0	24.85	75.98	76.82	76.4	2418.5	4.96	0.99	
5	Saturated water	Radial	11.9	45.21	85.11	84.55	84.8	4885.6	2.44	1.16	
6	Saturated water	Radial	10.5	47.25	67.91	69.08	68.5	4122.8	2.55	1.12	

2.4 Test result analysis

For the 4 rock groups of different side lengths, the average saturated water absorption is 0.44%. Longitudinal wave velocity is 4.8 ~ 5.6 km/s, and the average value is 5.3 km/s. The dynamic poisson ratio is 0.22. The Table 1 and Figure 1 present the result of uniaxial compressive strength test.

From the Table 1 and Figure 1 shows above, we can lean with side length at 30 mm, the softening coefficients of rocks in the same group are of remarkable difference; With side length at 100 mm, due to rock sample’s own limitation, uniformity is worse. For cube limestone rock samples, the strength of rocks with 30 mm side length is closest to that of rocks with standard 50 mm side length. Compressive strength takes on a descending trend with the increase of side length.

To better measure the true-value of compressive strength of rocks in the sampling location, we also collect relatively intact rocks for point load test. The Tables 2 and 3 set forth the test result.

From the Tables 2 and 3, we can lean that the strength value calculated from the point load test result is basically identical with the strength value of standard samples. This shows that sample processing and test result are safe and reliable.

3 CONCLUSION

We conduct contrastive analysis to various-sized samples and fit out the relation between rock uniaxial compressive strength and size effect, and derive a new non linear formula:

$$Y = e^{(49.8-6.4/x-7/\ln x)}$$

The samples for the formula above are collected from limestone. Considering differences of regions and rock properties please modify the formula through experiment or relevant experience when you use it.

# Displacement response of buildings under debris flow impact load

J.X. Cao, F.L. Zhang & M.H. Zhou

Research Institute of Structural Engineering and Disaster Reduction, Tongji University, China

**ABSTRACT:** This paper presents the work on investigating the damage buildings including burying and collapse under debris flow, on the basis of investigation in Sanyan Valley. The impact load of debris flow is simplified into triangular impulse load, rectangular impulse load and spike impulse load, through theoretical derivation, the results show that: when the ratio of impulse duration to natural vibration period of building  $\beta$  is less than 0.15, for spike impulse load, the displacement response ratio  $R_{max}$  is much larger than 2, especially when the  $\beta$  is less than 0.02. While  $\beta$  is more than 0.15, for all of three impulse load,  $R_{max}$  is less than or equal to 2, the maximum displacement amplitude  $v_{max}$  only depends on the magnitude of impulse load, thus it is recommended to set the displacement response ratio  $R_{max} = 2$  to estimate the maximum impact load, which could provide reference for future engineering design.

**Keywords:** debris flow; building in town; impulse load; displacement response ratio

## 1 INTRODUCTION

Debris flow is a complex multiphase fluid with huge energy when it happens, which may cause severe damage to nearby buildings, especially in some mountainous areas. Due to natural conditions and economy, structural styles of buildings in mountainous areas are simple, which are unable to effectively resist the impact of debris flow. In August 2010, a severe debris flow ruined more than 5500 houses in Zhouqu, Gansu Province, China and the Yueyuan Village was almost completely buried (Yu et al. 2010). In July 2013, a debris flow destroyed more than 90% houses in Qipangou gully, Sichuan Province, China (Yang et al. 2014). It has drawn much attention in the past few decades due to the large number of disasters.

In China, some research on the impact load of debris flow have been carried out: ① Investigation: Hu et al. (2012) surveyed the Zhouqu severe debris flow, and summarized buildings damage characteristics and suggested some measures to reduce damage. Zeng et al. (2014) derived some static calculation formula, on the basis of 98 building samples in Qipan gully. ② Numerical simulation: Liu (2013) simulated the damage of masonry structure under the debris flow by LS-DYNA software and proposed some measures from the perspective of failure mechanism and energy. Di (2012) simulated the displacement of a second-floor frame structure under the impact of debris flow and contrasted different conditions. Due to the complexity of debris flow component, and the randomness of its impact loading, numerical simulation is certainly

different from the actual situation. ③ Model experiment: Zhang et al. (2006) tested the wall of brick-concrete structure. The experiment could simulate the actual situation, but there is only a piece of walls which neglect the integrity of structure, so they can not completely reflect the real damage under debris flow.

This paper is organized as follow: Section 2 analyzes the damage characteristics of buildings in debris flow prone areas on the basis of investigation in Sanyan Valley. In Section 3, taking triangular impulse load, rectangular impulse load and spike impulse load as debris flow impact load, the dynamic response of buildings is derived. And the maximum impact load of buildings is estimated by a numerical example. The paper will be concluded in Section 4.

## 2 DAMAGE CHARACTERISTICS OF BUILDINGS

Sanyan Valley is situated on the left of Bailongjiang River, north of Zhouqu County. The whole valley looks like “funnel”, which consists of Dayan ditch and Xiaoyan ditch. In August 7, 2010, Sanyan valley basin suffered from heavy rainfall, causing large debris flow disaster. This debris flow is reported to be viscous mud-flow (Hu et al. 2010).

The buildings in Sanyan Valley show two kinds of failure modes: ① Burying. Burying (Fig. 1) refers to the debris flow going into the building interior, and the building is basically intact but lose its function. In nature, the buildings damage caused

a)

b)

Figure 1. Burying of frame structure.

Figure 2. Global overturning of masonry structure.

by debris flow is the process of energy conversion. When the impact energy of debris flow is higher than deformation energy of building, building will show impact damage. Oppositely, the buildings will not damage but its function may lose. © Collapse.

Figure 3. Partial collapse of masonry structure.

Collapse includes overturning collapse and vertical collapse according to the final collapse mode. Overturning collapse (Fig. 2) is due to the weakness of the lateral stiffness, leading to large deformation with the gravity of the two order effect. Vertical collapse (Fig. 3) is defined as the damage of main load-bearing components and unable to resist the weight of building. Actually, both two models appear in many collapse buildings.

### 3 THE DYNAMIC RESPONSE OF BUILDING UNDER DEBRIS FLOW IMPACT LOAD

#### 3.1 Introduction

Impact load is not only the main factor of building damage, but also the important parameter of dynamic response and the debris flow control project design. Wu (1990) generally summarizes the impact load into three types: zigzag impulse (Fig. 4), rectangular impulse (Fig. 5) and spike impulse (Fig. 6). In order to obtain the dynamic response of buildings under impact load, the hypothesis is established: 1) The buildings in town are always one floor, so it can be simplified to be a single degree of freedom. 2) As the duration of impulse load is short, and the damping effect on the structural response is small, so this effect can be neglected.

Based on the above assumptions, the displacement response of building under impact load is derived from Duhamel integral:

$$x(t) = \frac{1}{m\omega} \int_0^t P(\tau) \sin \omega(t - \tau) d\tau \quad (1)$$

where  $x(t)$  is the displacement response of building;  $m$  is the mass of building;  $\omega$  is natural vibration

Figure 4. Zigzag impulse.

Figure 6. Spike impulse.

Figure 5. Rectangular impulse.

Figure 7. Rectangular impulse load.

frequency of building;  $t$  is the time of impulse load;  $P(\tau)$  is impulse load.

### 3.2 Dynamic response of buildings under rectangular impulse loads

The mathematical expression of rectangular impulse load is given by:

$$P(t) = \begin{cases} P_0, & t \leq t_0 \\ 0, & t > t_0 \end{cases} \quad (2)$$

where  $P_0$  is impulse load,  $t_0$  is duration of impulse load. As shown in Figure 7.

when  $0 \leq t \leq t_0$ ,

$$x(t) = \frac{1}{m\omega} \int_0^t P_0 \sin \omega(t - \tau) d\tau \quad (3)$$

Integration by fraction, the displacement of building can be calculated as follow:

$$x(t) = \frac{P_0}{m\omega^2} (1 - \cos(\omega t)) \quad (4)$$

when  $t > t_0$ ,

$$x(t) = \frac{1}{m\omega} \int_0^{t_0} P_0 \sin \omega(t - \tau) d\tau \quad (5)$$

Integration by fraction, the displacement of building can be calculated as follow:

$$x(t) = \frac{P_0}{m\omega^2} \sin(\omega t) \sin(\omega t_0) + \frac{P_0}{m\omega^2} \cos(\omega t) (\cos(\omega t_0) - 1) \quad (6)$$

The ratio of response (Clough, 1981) is defined as the ratio of dynamic displacement to displacement causing by static load, as shown in Eq. (7), which is a measurement of dynamic load:

$$R(t) \equiv \frac{x(t)}{x_{st}} = \frac{x(t)}{P_0/k} \quad (7)$$

where  $x_{st}$  is the displacement of structure under static load,  $k$  is stiffness of structure.

Set  $\alpha = (t/t_0)$ ,  $\beta = (t_0/T)$ , where  $T$  is natural vibration period of building. The ratio of response is

$$R(t) = \begin{cases} 1 - \cos(2\pi\alpha\beta), & \alpha \leq 1 \\ \sin(2\pi\alpha\beta)\sin(2\pi\beta) + \cos(2\pi\alpha\beta)\cos(2\pi\beta) \\ - \cos(2\pi\alpha\beta), & \alpha > 1 \end{cases} \quad (8)$$

Taking  $\beta$  and  $R(t)$  as horizontal coordinate and longitudinal coordinate, respectively, and  $\alpha$  is ranged from 0.1 to 1.9 with 0.2 as increasing step, Figure 8 can be obtained. From this figure, it shows that: under rectangular impulse load, when  $\beta < 0.17$ ,  $R_{max} < 1$ ; while for any value of  $\alpha$  and  $\beta$ ,  $R_{max} \leq 2$ .

### 3.3 Dynamic response of buildings under triangle impulse loads

The mathematical expression of triangle impulse load is given by:

$$P(t) = \begin{cases} P_0(1 - t/t_0), & t \leq t_0 \\ 0, & t > t_0 \end{cases} \quad (9)$$

as shown in Figure 9.

Figure 8. Displacement response of building under rectangular impulse load.

Figure 9. Triangle impulse load.

when  $0 \leq t \leq t_0$ ,

$$x(t) = \frac{1}{m\omega} \int_0^t P_0 \left(1 - \frac{\tau}{t_0}\right) \sin \omega(t - \tau) d\tau \quad (10)$$

Similarly, integration by fraction, the displacement of buildings can be calculated as follow:

$$x(t) = \frac{P_0}{m\omega^2} \left(1 - \frac{t}{t_0} + \frac{1}{\omega t_0} \sin(\omega t) - \cos(\omega t)\right) \quad (11)$$

when  $t > t_0$ ,

$$x(t) = \frac{1}{m\omega} \int_0^{t_0} P_0 \left(1 - \frac{\tau}{t_0}\right) \sin \omega(t - \tau) d\tau \quad (12)$$

Integration by fraction, the displacement of buildings can be calculated as follow:

$$x(t) = \frac{P_0}{m\omega^2} \sin(\omega t) \frac{1}{\omega t_0} (1 - \cos(\omega t_0)) + \frac{P_0}{m\omega^2} \cos(\omega t) \left( \frac{1}{\omega t_0} \sin(\omega t_0) - 1 \right) \quad (13)$$

Set  $\alpha = (t/t_0)$ ,  $\beta = (t_0/T)$ , the ratio of response is

$$R(t) = \begin{cases} 1 - \alpha + \frac{1}{2\pi\beta} \sin(2\pi\alpha\beta) - \cos(2\pi\alpha\beta), & \alpha \geq 1 \\ \frac{1}{2\pi\beta} (1 - \cos(2\pi\alpha\beta)) \sin(2\pi\beta) \\ + \frac{1}{2\pi\beta} \sin(2\pi\beta) \cos(2\pi\alpha\beta) \\ - \cos(2\pi\alpha\beta), & \alpha > 1 \end{cases} \quad (14)$$

Taking  $\beta$  and  $R(t)$  as horizontal coordinate and longitudinal coordinate, respectively, and

$\alpha$  is ranged from 0.1 to 1.9 with 0.2 as increasing step, Figure 10 can be obtained. From this figure, it shows that: under triangle impulse load, when  $\beta < 0.37$ ,  $R_{\max} < 1$ ; while for any value of  $\alpha$  and  $\beta$ ,  $R_{\max} \leq 1.704$ .

### 3.4 Dynamic response of buildings under spike impulse load

The mathematical expression of spike impulse load is given by:

$$P(t) = \begin{cases} P_0 \cdot t/t_0, & t \leq t_0 \\ (2 - t/t_0), & t_0 \leq t \leq 2t_0 \\ 0, & t > 2t_0 \end{cases} \quad (15)$$

as shown in Figure 11.

when  $0 \leq t \leq t_0$ ,

$$x(t) = \frac{1}{m\omega} \int_0^t P_0 \frac{\tau}{t_0} \sin \omega(t - \tau) d\tau \quad (16)$$

Similarly, integration by fraction, the displacement of building can be calculated as follow:

$$x(t) = \frac{P_0}{m\omega^2} \left( \frac{t}{t_0} - \frac{1}{\omega t_0} \sin(\omega t) \right) \quad (17)$$

when  $t_0 < t < 2t_0$ ,

$$x(t) = \frac{1}{m\omega} \int_0^{t_0} P_0 \frac{\tau}{t_0} \sin \omega(t - \tau) d\tau + \frac{1}{m\omega} \int_{t_0}^t P_0 \left( 2 - \frac{\tau}{t_0} \right) \sin \omega(t - \tau) d\tau \quad (18)$$

Figure 10. Displacement response of building under triangle impulse load.

Figure 11. Spike impulse load.

Integration by fraction, the displacement of building can be calculated as follow:

$$x(t) = \frac{P_0}{m\omega^2} \left( \frac{2}{\omega t_0} \sin(\omega t) \cos(\omega t_0) - \frac{2}{\omega t_0} \cos(\omega t) \sin(\omega t_0) + 2 - \frac{t}{t_0} - \frac{1}{\omega t_0} \sin(\omega t) \right) \quad (19)$$

when  $t > 2t_0$ ,

$$x(t) = \frac{1}{m\omega} \int_0^{t_0} P_0 \frac{\tau}{t_0} \sin \omega(t - \tau) d\tau + \frac{1}{m\omega} \int_{t_0}^{2t_0} P_0 \left( 2 - \frac{\tau}{t_0} \right) \sin \omega(t - \tau) d\tau \quad (20)$$

Integration by fraction, the displacement of building can be calculated as follow:

$$x(t) = \frac{P}{m\omega^3 t_0} (\sin(2\omega t_0) \cos(\omega t) - \cos(2\omega t_0) \sin(\omega t) - 2 \sin(\omega t_0) \cos(\omega t) - \sin(\omega t)) \quad (21)$$

Set  $\alpha = (t/t_0)$ ,  $\beta = (t_0/T)$ , the ratio of response is. when  $\alpha < 1$ ,

$$R(t) = \alpha - \frac{1}{2\pi\beta} \sin(2\pi\alpha) \quad (22)$$

when  $1 < \alpha < 2$ ,

$$R(t) = \frac{1}{\pi\beta}(\sin(2\pi\alpha\beta)\cos(2\pi\beta) - \cos(2\pi\alpha\beta)\sin(2\pi\beta)) + 2 - \alpha - \frac{1}{2\pi\beta}\sin(2\pi\alpha\beta) \quad (23)$$

when  $\alpha > 2$ ,

$$R(t) = \frac{1}{2\pi\beta}((\sin(4\pi\beta) - 2\sin(2\pi\beta))\cos(2\pi\alpha\beta) - \frac{1}{2\pi\beta}(\cos(4\pi\beta) + 1)\sin(2\pi\alpha\beta)) \quad (24)$$

Taking  $\beta$  and  $R(t)$  as horizontal coordinate and longitudinal coordinate, respectively,  $\beta$  is ranged from 0.01 to 0.15 with 0.01 as increasing step and  $\alpha$  is ranged from 0.1 to 3.9 with 0.2 as increasing step, Figure 12 can be obtained. From this figure, it shows that: under spike impulse load, when  $\beta < 0.15$ ,  $R_{\max} > 2$ ; Furthermore, with decreasing of  $\beta$ ,  $R_{\max}$  is larger, especially  $\beta < 0.02$ ,  $R_{\max} > 5$ .

Meanwhile, taking  $\beta$  and  $R(t)$  as horizontal coordinate and longitudinal coordinate, respectively,  $\beta$  is ranged from 0.15 to 3 with 0.2 and  $\alpha$  is ranged from 0.1 to 3.9 with 0.2 as increasing step, Figure 13 can be obtained. From this figure, it shows that: under spike impulse load, when  $\beta > 0.15$ ,  $R_{\max} < 2$ , Furthermore, when  $\beta > 1$ ,  $R_{\max} < 1$ .

Based on the above observation, it is found that for rectangular impulse load, triangular impulse load and spike impulse load, displacement response of structure is related to  $\alpha$ ,  $\beta$ . When  $\beta < 0.15$ , for rectangular impulse load and triangular impulse load, the ratio of response  $R_{\max} \leq 2$ , for spike impulse load, the ratio of response  $R_{\max}$  becomes very large. While  $\beta > 0.15$ , for all of the three impulse load, the ratio of response  $R_{\max} \leq 2$ .

Figure 12. Displacement response of building under spike impulse load.

Figure 13. Displacement response of building under spike impulse load.

Figure 14. A sketch of building.

Thus the maximum impact load on buildings can be predicted.

### 3.5 Illustrative example

A building located in debris flow prone area is simulated as shown in Figure 11. The total weight of building is all focused on the beam, i.e.,  $G = 2 \times 10^6 \text{ N}$  while the total stiffness of building  $k = 2 \times 10^8 \text{ N/m}$ . Assume the displacement is limited to 5 mm. Based on the above discussion the maximum impact load on building can be calculated when, (1)  $t_0 = 0.03 \text{ s}$ , (2)  $t_0 = 0.3 \text{ s}$ .

The natural frequency of building can be given by

$$\omega = \sqrt{\frac{k}{M}} = 31.6 \text{ rad/s}$$

with the period of  $T = 2\pi/\omega = 0.2 \text{ s}$ .

The ratio of response  $R_{\max}$  can be obtained as

1.  $\beta = t_0/T = 0.15$   
 When triangle impulse load is applied on building,  $R_{\max} = 0.46$   
 When rectangular impulse load is applied on building,  $R_{\max} = 0.91$   
 When spike impulse load is applied on building,  $R_{\max} = 1.71$
2.  $\beta = t_0/T = 1.5$   
 When triangle impulse load is applied on building,  $R_{\max} = 1.69$   
 When rectangular pulse load is applied on building,  $R_{\max} = 2$   
 When spike impulse load is applied on building,  $R_{\max} = 1.1575$
- c. Calculate the maximum impact load on building according to:  

$$v_{\max} = R_{\max} \cdot P_0/k$$

Thus

1. when  $\beta = 0.15$ ,  $R_{\max} = 1.71$   

$$P_0 = v_{\max} \cdot k/R_{\max} = 584 \text{ kN}$$
2. when  $\beta = 1.5$ ,  $R_{\max} = 2$   

$$P_0 = v_{\max} \cdot k/R_{\max} = 500 \text{ kN}$$

From the result of illustrative example, it shows that: when  $\beta > 0.15$ , the ratio of response  $R_{\max} \leq 2$ , the maximum displacement amplitude  $v_{\max}$  depends on the magnitude of the pulse load. For engineering design, it is suggested to select  $R_{\max} = 2$  to estimate the maximum impact load.

#### 4 CONCLUSIONS

Based on field investigation, this paper analyzes the damage characteristics of buildings under debris flow, and displacement response of buildings under impact load is also discussed. The following conclusions are obtained:

1. Displacement response of structure is only related to  $\alpha, \beta$  under impact load. When the impact load is simplified into a triangular impulse load or rectangular impulse load, the ratio of response  $R_{\max}$  is less than or equal to 2, when it is simplified into a spike impulse load, the ratio of response  $R_{\max}$  is very large if  $\beta$  is less than 0.15. Thus it is very important to select a suitable impulse load, which may affect the result.

2. For the impact load of debris flow, when  $\beta$  is large than 0.15, the ratio of response  $R_{\max}$  is less than or equal to 2, the maximum displacement amplitude  $v_{\max}$  only depends on the magnitude of impulse load. For engineering design, it is suggested to select  $R_{\max} = 2$  to estimate the maximum impact load, which buildings can resist.
3. For spike impulse load, when  $\beta$  is less than 0.15, the ratio of response  $R_{\max}$  especially large. Thus it is recommended to control the natural vibration period of structure, which can reduce the ratio of response.

# Displacement analytic solution of a deep elliptical tunnel in a transversely isotropic rock mass considering the shear stress effect

Zhizeng Zhang & Xiaochang Li

School of Civil Engineering and Architecture, Zhongyuan University of Technology, Zhengzhou, China

**ABSTRACT:** Sedimentary rocks with a layered structure account for two-thirds of the global land area, and this proportion is 77.3% in China. Many metamorphic rocks also have significant features of layered structure, so there are a large number of stability problems about layered rock mass in mining engineering. Layered rock mass is generally considered to be transversely isotropic solid in mechanics. Based on the complex variable expression of displacement components of transverse isotropy, the displacement analytical solution of a deep elliptical tunnel in a transversely isotropic rock mass considering the shear stress effect is derived by the conformal mapping method.

**Keywords:** shear stress; transversely isotropic; elliptical tunnel; displacement; analytical solution

## 1 INTRODUCTION

The displacement about deep tunnels is often of interest to the geotechnical engineers and to be studied. There exist many elliptical tunnels in mining and rock engineering. In order to analyze the stability of elliptical tunnels and research the maintenance measures, it is significant to get the accurate stress and displacement solutions.

Muskhelishvili (1953) gave the stress and displacement distribution of an elliptic tunnel on an infinite plane under tensile, compressive and shear stress conditions, respectively. Cai (2008) obtained the stress and displacement analytic formulae by using the conformal mapping method.

In the above literature, the surrounding rock was regarded as isotropic. Due to the complexity of rock anisotropy, there were only a few papers on the displacement analytic solution of a tunnel in anisotropic rock mass. Lekhnitskii (1981) gave the displacement analytic solution of a circular silo in a transversely isotropic rock mass under the axisymmetric ground stress condition. Zhang (2010, 2012) derived the displacement analytic solutions for tunnels with an arbitrary and elliptical cross-section in two unequal normal stresses, and also gave the complex variable expression of displacement components of transverse isotropy, which helps to obtain the displacement analytic solution of complex tunnels. However, the displacement solution may become more complex when the shear stress effect is considered in a transversely isotropic rock mass.

Based on the above research, this paper attempts to derive the displacement analytic solution of a

deep elliptical tunnel in a transversely isotropic rock mass considering the shear stress effect.

## 2 PROBLEM DESCRIPTION

The following assumptions are made for the model used in this paper:

(1) the surrounding rock is continuous, homogeneous, linear elastic and transversely isotropic, and the displacement and strain are small; (2) the cross-section of the tunnel is elliptical and parallel to the isotropic plane, the length of the long and short axis is, respectively,  $2a$  and  $2b$ ; (3) the length of the tunnel is much larger than the size of the cross-section, so the plane strain condition is

Figure 1. Model of a deep elliptical tunnel.

used; (4) the tunnel is deep; (5) the initial stress in the ground is idealized as a normal stress  $p$ , which acts in the vertical direction, and a normal stress  $q$ , which acts in the horizontal direction, and a shear stress  $\tau$ , (6) compared with the initial stress, the rock weight is small and is ignored in the deduction. Figure 1 shows an ideal model of a deep elliptical tunnel in a transversely isotropic rock mass.

### 3 PHYSICS EQUATIONS OF TRANSVERSE ISOTROPY

A model of a transversely isotropic solid is shown in Figure 2, in which the  $xoy$ -plane and  $oz$  is regarded, respectively, as the isotropic plane and symmetry axis. The generalized Hooke's law equations for transverse isotropy are as follows (Ding, 2006):

$$\begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_z \\ \gamma_{yz} \\ \gamma_{xz} \\ \gamma_{xy} \end{Bmatrix} = \begin{bmatrix} S_{11} & S_{12} & S_{13} \\ S_{12} & S_{11} & S_{13} \\ S_{13} & S_{13} & S_{33} \\ & & & S_{44} \\ & & & & S_{44} \\ & & & & & S_{66} \end{bmatrix} \begin{Bmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \\ \tau_{yz} \\ \tau_{xz} \\ \tau_{xy} \end{Bmatrix} \quad (1)$$

where the parameter  $S_{ij}$  is related to the elastic constants as follows:

$$\begin{aligned} S_{11} &= \frac{1}{E}, \quad S_{12} = -\frac{\mu}{E}, \quad S_{13} = -\frac{\mu'}{E'}, \quad S_{33} = \frac{1}{E'}, \\ S_{44} &= \frac{1}{G}, \quad S_{66} = \frac{1}{G} \end{aligned} \quad (2)$$

where  $E$ ,  $\mu$  and  $G$  are, respectively, the elastic modulus, the Poisson ratio and the shear modulus in the isotropic plane, and  $E'$ ,  $\mu'$  and  $G'$  are those in the direction normal to the isotropic plane.

Figure 2. Model of a transversely isotropic solid.

### 4 THE COMPLEX VARIABLE EXPRESSION OF DISPLACEMENT COMPONENTS OF TRANSVERSE ISOTROPY

Zhang (2010) proved that when the stress boundary condition is only applied, the complex variable expression of stress function and stress components of transverse isotropy is the same as that of isotropy. However, the complex variable expression of displacement components is unequal because of the difference in physics equations. Furthermore, he also obtained the complex variable expression of displacement components of transverse isotropy under plane strain condition as follows:

$$u + iv = \left( \frac{3 - \mu}{E} - \frac{4\mu'^2}{E'} \right) \varphi_1(z) - \frac{1 + \mu}{E} [z \overline{\varphi_1'(z)} + \overline{\psi_1(z)}] \quad (3)$$

where  $\varphi_1(z)$  and  $\psi_1(z)$  are both analytic functions.

### 5 DISPLACEMENT ANALYTIC SOLUTION OF A DEEP ELLIPTICAL TUNNEL IN A TRANSVERSELY ISOTROPIC ROCK MASS

The conformal mapping method should be used in the solving process. Assuming that the mapping function that transforms the region exterior of a tunnel in the  $z$ -plane onto the exterior of a unit circle in the  $\zeta$ -plane is  $z = \omega(\zeta)$  (Fig. 3), all formulae with the independent variable  $z$  should be transformed into that with the independent variable  $\zeta$ . In order to establish the appropriate transformation relations, the following symbols should be adopted (Lv, 2007):

$$\left. \begin{aligned} \varphi(\zeta) &= \varphi_1(z) = \varphi_1[\omega(\zeta)] \\ \psi(\zeta) &= \psi_1(z) = \psi_1[\omega(\zeta)] \\ \Phi(\zeta) &= \varphi_1'(z) = \frac{\varphi'(\zeta)}{\omega'(\zeta)} \\ \Psi(\zeta) &= \psi_1'(z) = \frac{\psi'(\zeta)}{\omega'(\zeta)} \end{aligned} \right\} \quad (4)$$

Figure 3. Conformal mapping of a region exterior to a tunnel onto the exterior of a unit circle.

Based on Equation (3) and Equation (4), the displacement components in the  $\zeta$ -plane becomes

$$u + iv = \left( \frac{3 - \mu}{E} - \frac{4\mu'^2}{E'} \right) \varphi(\zeta) - \frac{1 + \mu}{E} \left[ \frac{\omega(\zeta)}{\omega'(\zeta)} \overline{\varphi'(\zeta)} + \overline{\psi(\zeta)} \right] \quad (5)$$

For the stress boundary condition shown in Figure 1,  $\varphi(\zeta)$  and  $\psi(\zeta)$  can be written as follows (Zhang, 2001):

$$\left. \begin{aligned} \varphi(\zeta) &= \frac{p+q}{4} \omega(\zeta) + \varphi_0(\zeta) \\ \psi(\zeta) &= \left( \frac{p-q}{2} - i\tau \right) \omega(\zeta) + \psi_0(\zeta) \end{aligned} \right\} \quad (6)$$

where  $\varphi_0(\zeta)$  and  $\psi_0(\zeta)$  are analytic in the exterior of the unit circle.

The displacement field consists of two parts (Cai, 2002). One is represented by the  $p + q/4 \omega(\zeta)$  and  $((p - q/2) - i\tau)\omega(\zeta)$ , which is caused by the initial stress field and takes place before tunnel excavation; the other is represented by  $\varphi_0(\zeta)$  and  $\psi_0(\zeta)$ , which is caused by tunnel excavation. The latter one is measurable and should be obtained. Eliminating  $p + q/4 \omega(\zeta)$  and  $((p - q/2) - i\tau)\omega(\zeta)$ , the displacement components caused by tunnel excavation can be written as follows:

$$u + iv = \left( \frac{3 - \mu}{E} - \frac{4\mu'^2}{E'} \right) \varphi_0(\zeta) - \frac{1 + \mu}{E} \left[ \frac{\omega(\zeta)}{\omega'(\zeta)} \overline{\varphi_0'(\zeta)} + \overline{\psi_0(\zeta)} \right] \quad (7)$$

The mapping function that transforms the region exterior of an elliptical tunnel in the  $z$ -plane onto the exterior of a unit circle in the  $\zeta$ -plane is as follows:

$$z = \omega(\zeta) = c \left( \zeta + \frac{m}{\zeta} \right) \quad (8)$$

$$\text{where } c = \frac{a+b}{2}, \quad m = \frac{a-b}{a+b}.$$

Based on Equation (8),  $\varphi_0(\zeta)$  and  $\psi_0(\zeta)$  can be expressed as follows:

$$\left. \begin{aligned} \varphi_0(\zeta) &= -\frac{c}{2\zeta} [m(p+q) + (p-q) + i \cdot 2\tau] \\ \psi_0(\zeta) &= -\frac{c}{2\zeta(\zeta^2 - m)} [(p+q)\zeta^2(m^2 + 1) + (p-q)(1 - m^2 + 2m\zeta^2) + i \cdot 2\tau(1 + m^2)] \end{aligned} \right\} \quad (9)$$

Substituting Equation (9) into Equation (7) yields

$$u + iv = \left( \frac{3 - \mu}{E} - \frac{4\mu'^2}{E'} \right) \left[ \frac{p+q}{2} f_1(\zeta) + \frac{p-q}{2} f_2(\zeta) - \tau f_3(\zeta) \right] + \frac{1 + \mu}{E} \left[ \frac{p+q}{2} f_4(\zeta) + \frac{p-q}{2} f_5(\zeta) - \tau f_6(\zeta) \right] \quad (10)$$

where

$$\left. \begin{aligned} f_1(\zeta) &= -\frac{mc}{\zeta}; \quad f_2(\zeta) = -\frac{c}{\zeta}; \quad f_3(\zeta) = \frac{ic}{\zeta} \\ f_4(\zeta) &= \frac{c\bar{\zeta}(1+m^2) - mc \left( \zeta + \frac{m}{\zeta} \right)}{\bar{\zeta}^2 - m} \\ f_5(\zeta) &= \frac{c(1-m^2 + 2m\bar{\zeta}^2)}{\bar{\zeta}(\bar{\zeta}^2 - m)} - \frac{c \left( \zeta + \frac{m}{\zeta} \right)}{\bar{\zeta}^2 - m} \\ f_6(\zeta) &= \frac{ic(1+m^2)}{\bar{\zeta}(\bar{\zeta}^2 - m)} - \frac{ic \left( \zeta + \frac{m}{\zeta} \right)}{\bar{\zeta}^2 - m} \end{aligned} \right\} \quad (11)$$

There are no physical parameters (e.g.  $E, \mu, E'$  and  $\mu'$ ) in  $f_k(\zeta)$ , but only the function of coordinates. It is assumed that the inverse function of  $f_k(\zeta)$  is  $F_k(Z)$ , which is also only the function of coordinates. The  $u$  and  $v$  in Equation (10) are displacement components in rectangular coordinates, but the radial displacement component  $u_r$  is easy to measure in practice, which can be expressed by  $u$  and  $v$  as follows:

$$u_r = u \cos \theta + v \sin \theta \quad (12)$$

Substituting  $u$  and  $v$  of Equation (10) into Equation (12), and replacing  $f_k(\zeta)$  with  $F_k(z)$ , yields the radial displacement component as follows:

$$\begin{aligned} u_r &= \left( \frac{3 - \mu}{E} - \frac{4\mu'^2}{E'} \right) \left[ \frac{p+q}{2} R_e[F_1(z)] + \frac{p-q}{2} R_e[F_2(z)] \right. \\ &\quad \left. - \tau R_e[F_3(z)] \right] \cos \theta + \frac{1 + \mu}{E} \left[ \frac{p+q}{2} R_e[F_4(z)] \right. \\ &\quad \left. + \frac{p-q}{2} R_e[F_5(z)] - \tau R_e[F_6(z)] \right] \cos \theta \\ &\quad + \left( \frac{3 - \mu}{E} - \frac{4\mu'^2}{E'} \right) \left[ \frac{p+q}{2} I_m[F_1(z)] + \frac{p-q}{2} I_m[F_2(z)] \right. \\ &\quad \left. - \tau I_m[F_3(z)] \right] \sin \theta + \frac{1 + \mu}{E} \left[ \frac{p+q}{2} I_m[F_4(z)] \right. \\ &\quad \left. + \frac{p-q}{2} I_m[F_5(z)] - \tau I_m[F_6(z)] \right] \sin \theta \end{aligned} \quad (13)$$

Equation (13) is the displacement analytic solution of a deep elliptical tunnel in a transversely isotropic rock mass considering the shear stress effect. When shear stress is not considered, namely  $\tau = 0$ , Equation (13) reduces to the displacement analytic solution with two unequal normal stresses (Zhang, 2012). In case of  $E' = E$  and  $\mu' = \mu$ , Equation (13) reduces to the displacement analytic solution in a transversely isotropic rock mass (Zhang, 2001). They verify the truth of the derivation.

Particularly, for a circle tunnel, in which  $a = b = r$  (where  $r$  is the radius),  $f_1(\zeta) \sim f_6(\zeta)$  can be expressed as follows:

$$\begin{aligned} f_1(\zeta) &= 0; f_2(\zeta) = -\frac{r}{\zeta}; f_3(\zeta) = \frac{ir}{\zeta}; f_4(\zeta) = \frac{r}{\zeta} \\ f_5(\zeta) &= \frac{r}{\zeta^3} - \frac{r\zeta'}{\zeta^2}; f_6(\zeta) = \frac{ir}{\zeta^3} - \frac{ir\zeta'}{\zeta^2} \end{aligned} \quad (14)$$

Accordingly,  $F_1(z) \sim F_6(z)$  should be expressed as follows:

$$\begin{aligned} F_1(z) &= 0; F_2(z) = -\frac{a^2}{z}; F_3(z) = \frac{ia^2}{z}; F_4(z) = \frac{a^2}{z} \\ F_5(z) &= -\frac{a^2z}{z^2} + \frac{a^4}{z^3}; F_6(z) = -\frac{ia^2z}{z^2} + \frac{ia^4}{z^3} \end{aligned} \quad (15)$$

Substituting Equation (15) into Equation (13) and noting that  $z = re^{i\theta}$ , we get the displacement analytic solution for a deep circle tunnel as follows:

$$\begin{aligned} u_r &= \frac{p+q}{2} \frac{a^2}{r} \frac{1+\mu}{E} + \frac{p-q}{2} \left[ \frac{a^4}{r^3} \frac{1+\mu}{E} \right. \\ &\quad \left. - \frac{4a^2}{r} \left( \frac{1}{E} - \frac{\mu'^2}{E'} \right) \right] \cos 2\theta + \tau \left[ \frac{a^4}{r^3} \frac{1+\mu}{E} \right. \\ &\quad \left. - \frac{4a^2}{r} \left( \frac{1}{E} - \frac{\mu'^2}{E'} \right) \right] \sin 2\theta \end{aligned} \quad (16)$$

## 6 CONCLUSIONS

1. In this paper, the radial displacement analytic solution for a deep elliptical tunnel in a

transversely isotropic rock mass considering the shear stress effect is obtained based on the complex variable expression of displacement components for transverse isotropy by using the conformal mapping method.

2. Although the cross-section is assumed to be parallel to the isotropic plane in the deduction, the displacement analytic solution indicates that the radial displacement of the surrounding rock is related not only to the elastic modulus and the Poisson ratio in the isotropic plane, but also to that in the direction normal to the isotropic plane.
3. The cross-section is assumed to be parallel to the isotropic plane in the deduction in this paper. Further research can be carried out on the problems that the cross-section intersects the isotropic plane.

# The effect analysis of subway tunnel construction accidents on adjacent buildings

X.W. Peng & D.C. Yuan

College of Basic Education, National University of Defense Technology, Changsha, Hunan, P.R. China

**ABSTRACT:** In order to obtain the effect rules of subway tunnel construction accidents on adjacent buildings, the material point method was employed to build a simplified model of subway tunnel construction accidents. The deformation and failure patterns of surrounding soils were studied. Furthermore, the mechanical properties and deformation characteristics of the adjacent masonry building under different locations, different embedded depths of tunnel and different degrees of damaged tunnel segment were discussed. As a result, the scope and intensity of the affected area are proposed.

**Keywords:** subway tunnel; material point method; masonry building; construction accidents; numerical simulation

## 1 INTRODUCTION

With the rapid process of urbanization, subway construction scale is expanding in China. During the construction process, subway projects (subway tunnel, foundation pit and connected aisle) in the high water-level soft soil area are exposed to high risks. Both in China and abroad, there are plenty of construction accidents, such as the tunnel collapsed accident of Guangzhou Metro Line 3, the foundation pit collapsed accident of Hangzhou, and the connected aisle collapsed accident of Germany subway tunnel. Accordingly, all of these accidents have a certain effect on adjacent buildings.

Due to the large deformation of soils occurring in the subway tunnel construction accidents, if the finite element method was applied to build the model, the mesh distortion would ultimately lead to the termination of the calculation. To overcome this problem, the material point method was employed in an innovative way, as it can avoid mesh distortion problems and suitably analyze large deformation of the subway tunnel.

In this study, a simplified model of subway tunnel construction accidents is built based on the material point method. Through controlling variables of location of adjacent building, the embedded depth of the tunnel and the damage degree of the segment, the effect rules of subway tunnel construction accidents on adjacent buildings are proposed.

## 2 NUMERICAL ANALYSIS OF SUBWAY TUNNEL DESTRUCTION

### 2.1 Computing model

In order to achieve the precise analysis of the deformation of adjacent buildings, a fine model of the building is shown in [Figure 1\(a\)](#). The building is a typical masonry structure, such as historical buildings. To simplify the calculation, the length in the y direction is 1 m, and the width and height of the building are 12 m and 8 m, respectively. The lengths of each layer and each truss are both 4 m, and the opening sizes of doors and windows are both 2.0 m × 2.0 m. In the model, the inside diameter of the shield tunnel is 2.7 m, and its outside diameter is 3 m. The lining structure of the shield tunnel is composed of three A-type segments, namely two B-type segments and one K-type segment, of which A, B, K are the standard block, adjacent block and capped block, respectively. As shown in [Figure 1\(b\)](#), the central angle of the capped block is 20°, and the central angle of the adjacent block and the standard block are both 68°.

For simplicity, the soil layer is assumed to be a single homogeneous soft clay in the model. Meanwhile, the segment, masonry building and soil are simulated based on the Drucker-Prager model. All of the parameters are listed in [Table 1](#).

The model simulated the practical construction process and then dynamically analyzed the effect

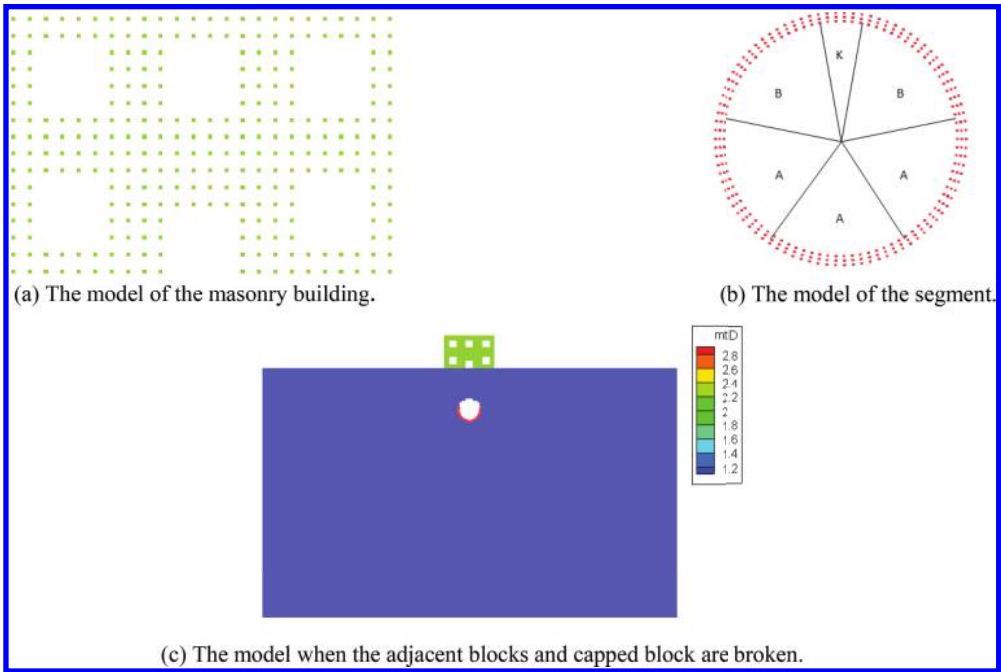

Figure 1. Network diagram of the model.

Table 1. Physical and mechanical parameters of materials.

Material type	Elastic modulus $E$ /(MPa)	Poisson's ratio $\mu$	Density (kg/m <sup>3</sup> )	Angle of internal friction $\Phi$ (°)	Cohesive force $C$ /(kPa)	Dilation angle (°)
Soft clay	7.5	0.49	1600	0	15	0
Tunnel segment	$3.55 \times 10^4$	0.2	2600	60	550	0
Masonry building	220	0.2	2000	30	100	0

of tunnel excavation on adjacent buildings, which are as follows:

- The number of material points and material types are counted.
- Background grid is divided, where the mesh size is  $x$  (0,100),  $y$  (0,1),  $z$  (0,100), and the unit is m.
- Boundary conditions are constrained.
- Physical mechanical parameters are assigned to segment, soil, and the building.
- Geometric models of the tunnel and adjacent building are built, and the parameters of the building location, embedded depth of tunnel, and degree of damaged tunnel segment are controlled to simulate different types of tunnel construction accidents. For example, the adjacent blocks and capped block are broken (segment partially broken), and the model is shown in Figure 1(c).
- Initial stress is balanced.

## 2.2 Failure patterns under different distances that the adjacent masonry building from the tunnel

In the model, equivalent plastic strain is calculated based on the distortion energy theory (the fourth strength theory). This theory considers that when the distortional energy density stored in unit body (vd) is approximated to the uniaxial tensile yield distortion energy density (vds), the material enters the plastic yield. As shown in Figure 2, when the segment is whole broken, the masonry building that is right above the tunnel will produce a plastic deformation zone toward the bottom along two sides of the corner. The plastic deformation region that is in two corners of the building and in the tunnel is integrated into a whole, forming a huge symmetric shear failure area. With the masonry building away from the

tunnel, the building inclines towards the side that is away from the tunnel, and the tilt increases and then decreases gradually.

### 2.3 Failure patterns under different embedded depths of the tunnel

Figure 3 shows the impact of tunnel destruction on surrounding soils that may be related to embedded depths of the tunnel, and the affected region is a semicircular area with a radius that is equal to the embedded depth of the tunnel. As shown in Figure 4, after the destruction of the tunnel, there is a plastic deformation zone around it. Influenced by the stress field, as the embedded depth of the tunnel decreases, the plastic deformation zone extends to the ground.

### 2.4 Failure patterns under different degrees of damaged tunnel segment

Subway tunnel accidents include failure of the un-supported section, failure of the tunnel heading, and failure of the both. To simplify the calculations, the simulation analysis is only for the case of un-supported section failure. As shown in Figure 5, the affected area of lateral displacement is small for segment whole broken, while it is large for the segment partially broken. It may be due to the soil right above the tunnel that partially collapses when the segment is partially broken, causing both sides of soil to be swarmed into the tunnel. In contrast, when the segment is whole broken, the soil beneath the tunnel rebounds, which reduces soil deformation on both sides.

Figure 2. Equivalent plastic strain cloud diagram under different distances from the tunnel.

Figure 3. Vertical settlement cloud diagram under different embedded depths of the tunnel.

Figure 4. Equivalent plastic strain cloud diagram under different embedded depths of the tunnel.

Figure 5. Lateral displacement cloud diagram under different degrees of damaged tunnel segment (left: segment whole broken; right: segment partially broken).

Figure 6. Vertical settlement scatter diagram under different distances from the tunnel (from the left to the right, the distance is 0 m, 10 m, 20 m, respectively).

### 3 ANALYSIS OF DEFORMATION OF THE ADJACENT MASONRY BUILDING

#### 3.1 Deformation of the adjacent masonry building at different distances from the tunnel

Assumed that the embedded depth of tunnel is 10 m and the segment is whole broken, the vertical settlement of the adjacent masonry building is obtained by recording the key points on the roof and floor ( $x = 0$  m, 4 m, 8 m, 12 m). As could be seen from Figure 6, when  $D = 0$  m ( $D$  represents the distance between the left side of the building and the point right above the tunnel), tension strain appears on the central of the building, while compression deformation exists on the both sides of it. With the  $D$  increasing, the whole settlement of the building decreases, indicating that the extent of damage to the building reduces. As the  $D$  increases from 0 to 20, an uneven sedimentation of the building emerges immediately and then decreases gradually.

#### 3.2 Deformation of the adjacent masonry building with different embedded depths of the tunnel

As could be seen from Figure 7, with the embedded depth of the damaged subway tunnel increasing, the

transverse compression value of the adjacent building within the affected area decreases, indicating that the degree of damage to the building reduces. The whole settlement of the building also reduces from 1.3 m to 0.7 m, which is in agreement with the expansion of the plastic deformation zone produced by the damaged tunnel shown in Figure 4.

#### 3.3 Deformation of the adjacent masonry building with different degrees of the damaged tunnel segment

By recording the key points on the left side and right sides of the wall ( $z = 0$  m, 4 m, 8 m), the lateral displacement ( $xdis$ ) of adjacent masonry building was investigated. As shown in Figure 8, when the segment is partially broken, a tensile failure appears on the first floor of the masonry building, while almost no lateral displacement appears on the second floor. When the segment is whole broken, monolithic translation to the right side (the side away from the tunnel) and tiny transverse compression appear on the first floor, while almost no lateral displacement appears on the second floor. In contrast, the segment partially broken evidently leads to a greater lateral displacement of the adjacent masonry building.

Figure 7. Vertical settlement scatter diagram under different embedded depths of the tunnel (left: 10 m; right: 20 m).

Figure 8. Lateral displacement scatter diagram under different degrees of damaged tunnel segment (left: segment partially broken; right: segment whole broken).

#### 4 CONCLUSIONS

In conclusion, as buildings get closer to the tunnel, the deformation caused by the damaged tunnel is larger. Correspondingly, the damage of buildings is greater. The obviously affected area may be a semicircular area with the radius of the embedded depth above the damaged tunnel, and with the embedded depth decreasing, the deformation of the building within the affected area increases. The segment partially broken leads to the partial collapse of the soil above the tunnel, which will enlarge the affected area of the lateral displacement. Whereas the segment whole broken mainly causes vertical settlement to the surrounding soils and buildings, and the affected area of the lateral displacement is smaller.

# Experimental study on properties of zeolite powder concrete under the hot and humid environment

ZhongTian Chen

*Southwest Jiaotong University, Chengdu, Sichuan, China*

**ABSTRACT:** With the tunnel construction gradually growing deep in direction, problems caused by high geothermal heat damage becomes increasingly prominent. High geothermal occurred mainly in two forms: dry heat and the hot and humid. Under these 2 conditions, the strength of concrete can be affected. Using zeolite powder as admixture is a viable way to improve the mechanical properties. But it remains unknown whether it performs better in hot and humid condition or dry heat. So we set 5 groups of experiments to determine the mechanical properties of zeolite powder concrete. Throughout the date we find that dry heat condition can cause a significant loss of zeolite powder concrete. But in hot and humid conditions, cement and zeolite powder can be fully hydrated, and calcium hydroxide active silica and zeolite powder contained in an alumina produced with cement hydration reaction to form secondary hydration, increasing the content of gelled material, thereby increasing the strength of the concrete. So that similar to the zeolite powder concrete and fly ash concrete, dry heat intensity decreases, and significantly increased strength under hot and humid conditions, it is more suitable for steam curing.

**Keywords:** zeolite powder concrete; hot and damp condition; mechanical properties; secondary hydration

## 1 INTRODUCTION

### 1.1 Background

The project comes from the topics of National Natural Science Foundation: <thermal properties of concrete harm Tunnels> (51008253).

When the tunnel construction gradually grows deeper in direction, problems caused by high geothermal heat damage becomes increasingly prominent. High geothermal occurred mainly in two forms: dry heat and the hot and humid.

Dry heat is the heat inside the geological strata in geological formations where there will be better spread through the rock tunnel surface. The hot and humid occurs in a high degree of development of rock crushing fracture zone, the underground water is easier to enrichment, which form hot springs. Injection concrete's performance differs in construction process parameters and physical mechanical properties contrast with normal temperature condition. High-temperature and high-temperature could lead sprayed concrete action to increased strength retraction system volume stability deteriorates and adhesion rock heavy losses and other issues. When the tunnel faced with thermal damage, it also faced erosion of sulfate and chloride. Coupling factors that could cause the ejection durability of concrete faced with great challenges,

whether it relates to the normal functioning of shotcrete tunnel lining role. [1]

The trial will focus on the mechanical properties of concrete zeolite powder at a relatively humid and dry heat harm environment.

Zeolite is a natural zeolite rock as raw material, crushing, grinding into powder materials. Zeolite powder contains large amounts of  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$ , silica fume after its pozzolanic activity. Its activity is better than fly ash and slag after volcanic ash silica fume. In addition to the active effect, Zeolite powder also has a special porous structure, pore zeolite adsorption of water can also be in the conservation of hydration to further promote the growth of strength. [2]

Therefore, this project tests these problems by simulating the thermal effects of different design than the preservation of the environment, mechanical testing, and other means of concrete mix, the mechanical properties of concrete with different contents of zeolite powder, thermal properties of concrete in hot condition to provide some guidance to improve the properties of concrete.

### 1.2 Zeolite powder

Zeolite is a natural zeolite rock from the ground. Zeolite rock is volcanic ash after an aluminosilicate mineral natural calcine, will have a certain amount

of active silica and alumina. The color is white (Fig. 1) Zeolite powder having a large internal surface area and an open structure, the fineness of 0.08 mm sieve <5%, an average particle diameter of 5.0 ~ 6.5 μm.

The chemical composition is shown in Table 1. [3]

It contains most of all the major elements and trace elements the aquatic animal growth needs, all these elements exist in ionic form easily used by aquatic animals. Therefore, aquaculture is the most commonly used zeolite powder. [4] Zeolite rock series has more than 30 varieties and ash zeolite and mordenite are commonly used as admixture of concrete. The micro structure is shown in Figure 2. [4]

Figure 1. Zeolite powder.

## 2 THE EXPERIMENT DESIGN

### 2.1 Dividing groups

In order to distinguish the performance of fly ash concrete and the zeolite powder concrete, we set 5 groups of experiments. Concrete blocks from each group will be cared in three different conditions: Hot water, dryer, and normal maintenance, and will be put into two kinds of mechanical test.

Every block is made into one unified size of 100 mm\*100 mm\*100 mm and will be cared for four weeks. The strength level of concrete is C30. [5]

To distinguish the blocks from three different conditions, we name the blocks cared in hot water with a word S in the end of its name. So as the ones from dryer with G, and normal condition with BZ.

After naming the groups, we determined the percentage of cement and other materials of each group. The detail is shown as follows.

### 2.2 The experimental group

- 2.2.1 Group 1 (100% cement) {1,2}
- 2.2.2 Group 2 (70% cement + 30% zeolite) {3,4}
- 2.2.3 Group 3 (70% cement + 30% fly ash) {5,6}
- 2.2.4 Group 4 (60% cement + 20% zeolite + 10% silicon ash) {7,8}
- 2.2.5 Group 5 (65% cement + 20% zeolite + 5% silicon ash) {9,10}

The number in these groups means whether the block will be tested in which way, the tensile splitting experiment or compressive experiment. Those with uneven number will be tested in compressive experiments, and others will be tested in tensile splitting experiment.

Each group has 3 blocks for the compressive experiment, and another 3 blocks for splitting the

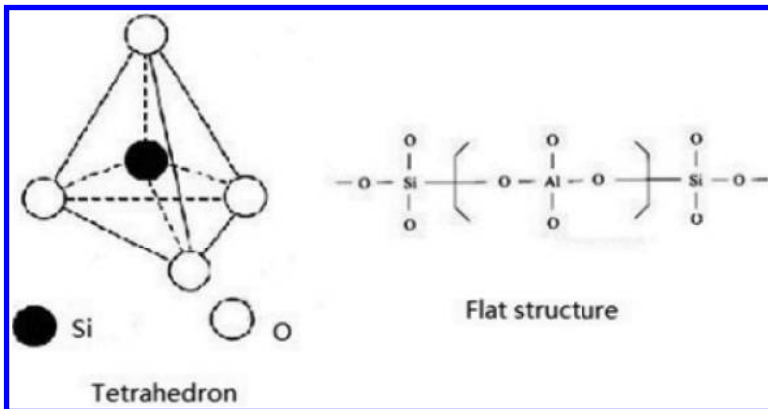

Figure 2. Micro structure.

compressive experiments. The actual data after the test are shown in Table 2.

The blocks just made and names are shown in Figure 3.

## 3 ANALYZE AND CONCLUSION

As we can see in Table 2, both the compressive properties and tensile splitting properties of concrete mixed with zeolite or fly ash cured in water tank is clearly higher than those cured under normal condition. But it comes to the same. Similarly, the zeolite powder concrete in hot and humid conditions exhibits mechanical properties of fly ash concrete, namely a significant reduction of breaking strength in dry heat conditions, and fracture strength under hot and humid conditions increase, which indicates that the dry and hot conditions on the zeolite powder concrete strength development is detrimental to the development and humid strip of concrete strength advantageous zeolite powder.

So we get the conclusion: Although the zeolite powder has a porous absorbent structure, but in the development of concrete strength under dry and hot conditions, the moisture in the concrete cement and zeolite powder is insufficient to support the completion of their hydration, that is, under these conditions, a portion of the water in the concrete cement hydration role, but zeolite powder lacks water and hydration cannot completely occur, resulting in incomplete gray concrete hydration which causes less gelled substance. In this case, early strength of concrete developed rapidly, due to lack of water, affects the development of late strength of concrete.

But in hot and humid conditions, water is abundant, cement and zeolite powder can be fully hydrated, and calcium hydroxide active silica and zeolite powder contained in an alumina produced with cement hydration reaction to form secondary hydration, increasing the content of gelled material, thereby increasing the strength of the concrete. So that, similar to the zeolite powder concrete and fly ash concrete, dry heat intensity decreases, and significantly its strength increases under hot and humid conditions; it is more suitable for steam curing.

**ABSTRACT:** Soil unloading caused by excavation will inevitably lead to the change of displacement and stress field, and this threatens the security of the subway at the bottom or side. Researches focus on vertical rebound deformation rules of existing tunnels under excavation and the reinforcement methods, and quantitative displacement calculation is also needed. Considering the soil plastic flow and groundwater buoyancy, the causes of foundation pit uplift are summarized. In addition, the study method of foundation pit excavation influence on existing tunnels can be summed up using theoretical calculation method, field measurement analysis method, numerical simulation, empirical formula method, and the centrifugal test. Finally, some problems which need to be further probed are presented.

**Keywords:** excavation of foundation pit; the existing tunnel; foundation pit uplift; study methods; deformation rules

## 1 INTRODUCTION

With the vigorous development of infrastructure, while the urban construction is growing on the ground, the underground construction is gradually expanding. The excavation of foundation pit will have an adverse impact on existing tunnels situated at the bottom or side, so this is related to the safe operation of subway tunnel. For the foundation pit located in the city center, the protection of surrounding pipelines and structures is becoming a controlling factor in the design and construction, so the impact of excavation on the tunnel should be controlled within the permissible range.

## 2 CAUSES OF FOUNDATION PIT UPLIFT

Foundation pit uplift is generally considered to be primarily caused by several factors: (1) rebound deformation produced by soil excavation; (2) due to soil pressure, the deformation of retaining wall below the basement is toward the center of the pit, and that shoves the soil in pit to uplift;

(3) irreversible soil deformation formed by plastic flow because of the existing weak layer in pit bottom; (4) uplift of soil caused by groundwater buoyancy and seepage flow; and (5) deformation due to the secondary release of cumulative stress from surrounding buildings during excavation. Moreover, the degree of resilience is also relevant to geological conditions, unloading volume, size of the pit, exposure time, sequence of excavation and equipment conditions, and so on. By analyzing these factors, the deformation mechanism of foundation pit uplift will be further understood.

## 3 RESEARCH STATUS

Issues related to this research focus on the following aspects domestically and abroad: (1) the variation of both the deformation and force of the existing tunnels during the construction of foundation works; (2) the influence factors and range of the tunnel deformation, and the prediction methods of the maximum tunnel uplift value; (3) the effect degree of different construction conditions on the

tunnel, and then to get the best design and construction scheme; and (4) the impact of foundation pit dewatering.

## 4 RESEARCH METHODS

Surrounding the influence of excavation on existing tunnels, many scholars have done a lot of works using a variety of methods, including theoretical calculation method, field measurement analysis method, numerical simulation, empirical formula method, and the centrifugal test.

### 4.1 Theoretical calculation method

Zhang Zhiguo proposed the two-stage method for analyzing effects on adjacent metro tunnels due to foundation pit excavation. Firstly, the additional stress due to adjacent foundation pit excavation is calculated. Secondly, the governing differential equation is built based on Winkler model. Then the differential equation is deduced to the finite element equation by the Galerkin method. Furthermore, the parametric analysis of existing tunnels is carried out, including the different depths and distance from the excavation site, the different geologic conditions, and the different outer diameters of the tunnel.

A simple two-stage method for estimating the longitudinal deformation of existing tunnels caused by adjacent excavation in soft soils is presented. In the first stage, the Loganathan and Poulos analytical solution is used to estimate the free-soil settlement induced by adjacent tunneling. The additional stress due to adjacent foundation pits excavation is calculated based on the Mindlin solutions. In the second stage, existing tunnels are considered as beams with infinite length based on the Winkler foundation model. The free-soil settlement or additional stress is then imposed on the existing tunnels. Displacements and internal forces of the existing tunnels are obtained.

Assuming that the tunnel deformation agrees with the soil displacement, the theory of residual stress and stress path method are used to build a predictive calculation model of tunnel deformation considered excavation, and it was applied to Shanghai square excavation under which the two existing tunnels lie. Meanwhile, using Boussinesq equation, soil resilience value  $s$  due to excavation can be calculated:

$$s = \frac{1 - \mu^2}{E} \omega b p_0$$

$b$  is the width of rectangular load or the diameter of circular load;  $\omega$  is the rebound influence coefficient of center point;  $E$  is the elastic modulus of

soil and usually replaced by deformation modulus;  $p_0$  is uniform load on foundation surface; and  $\mu$  is Poisson's ratio of soil.

Considering the equivalent stiffness of tunnel, excavation unloading and foundation reinforcement, deformation mechanisms are conducted on tunnel uplift due to mixing-piles driving above. Based on data from the East Road Underpass Project, a method to calculate the vertical displacement of tunnels using the Winkler model was derived, and the calculation is carried out. The result was compared with the measured data. It is indicated that effects of above foundation pit reinforcement on the vertical displacement of tunnels are considerable.

### 4.2 Field measurement analysis method

Through the arrangement of the measuring point, field monitoring is widely used in the study. The information of construction process can be acquired in time, and monitoring results can also be used to evaluate the security situation of the tunnel.

Combined with the field monitoring date from East Road Underpass Project in Shanghai, the influence of foundation pit excavation on adjacent tunnels is analyzed, and it shows that: with soil rebound the subway tunnel uplifts like a normal distribution curve, and the maximum point approaches the center of excavation; in quite a long period of time after the excavation, the soil in pit continues the trend of rebound, but rebound deformation is limited because of the upper load; some factors are remarkable to the displacement of the tunnel including the exposure time of excavation and the distance between tunnel axis and foundation pit, and the tunnel uplift presents a nonlinear increase with the increase of exposure time and excavation volume.

The horizontal and vertical displacement of the tunnel and the chordwise deformation of tunnel lining were measured in Shanghai Square excavation adjacent to tunnel. The results show the tunnel produces lateral displacement to foundation pit direction when deep excavation adjacent to tunnel, and the section of tunnel produces a lateral ellipse shaped deformation; the construction of concrete cushion timely can effectively control the further development of lateral tunnel displacement, and only after the completion of the foundation slab the displacement of the tunnel achieves stability; and grouting rectification in the outside of the tunnel can promptly correct the lateral displacement of subway tunnel, but the comprehensive effect is not very satisfactory.

Field measurement analysis can monitor the tunnel deformation in real time, and the data is reliable

and can provide guidance for the construction. However, most monitoring is for the vertical and horizontal displacement of the tunnel at present. Due to a limited number of measuring points there are less monitoring dates from convergence deformation of tunnel, soil pressure and pore water pressure.

#### 4.3 Numerical simulation

Compared with the field measurement analysis method, numerical simulation has the following advantages: (1) it can simulate the variation of tunnel deformation and stress state with pit reinforcement and excavation process; (2) through simulation to compare different effects of pit reinforcement measures on existing tunnel, and then to get the optimization scheme; and (3) by changing the parameters to study the influence extent of tunnel uplift by different factors. But some certain deviations are presented leading to the difference between calculated value and measured results, including parameter selection, mesh generation and unreasonable assumptions, and simplification.

#### 4.4 Empirical formula method

Based on measured dates from the Dongfang Road Underpass Project, the analysis shows that the maximum vertical uplift value of tunnel  $S$  increases with an increase in excavation width  $B$ , and their relation is a hyperbolic curve. The formula is:

$$S = A_1 \times e^{A_2/B}$$

$$A_1 = 12.614e^{-7.1246/t}$$

$$A_2 = 8.9151/t - 6.5242$$

$A_1$  is the extreme coefficient.  $A_2$  is the spatial sensitivity coefficient.  $t$  is the exposure time of excavation. The formula can simply estimate the maximum uplift value at any time of excavation and in any excavation width. The disadvantage is the formula is obtained only by the one project, so its reliability is difficult to guarantee, meanwhile the value of the exposure time of excavation is difficult to acquire.

#### 4.5 The centrifugal test

With a case of the excavation of Century Metropolis in Shanghai, centrifugal model tests are used to study the deformation of the retaining walls and tunnel structures. The studies show that test results conform to the actual project and can relatively reflect the practical situation. Excavating large

part of the pit firstly is more reasonable to control the deformation of the retaining walls and tunnel structures.

## 5 CONCLUSIONS

The protection of the underground environment is becoming the controlling factor in urban areas, and the design of foundation pit engineering has gradually changed from the stability control to deformation control. According to the research status, there are several shortage as follows: (1) There is only the qualitative explanation to the impact of the stiffness and insertion depth of retaining structure on foundation pit deformation, and shortage of a complete theoretical formula to quantitatively calculate; (2) During the construction the size of excavation area and the excavation depth of each step are ordinarily based on experience, so measures should be taken to optimize the parameters of foundation pit excavation; and (3) Studies on the influence of tunnel mainly concentrate on the period of excavation construction, however the long-term tracking studies are few, so subsequent related studies should be strengthened.

In general, the current study on this aspect isn't mature completely. Most researches are based on single project and lack of systems analysis; therefore, monitoring and analysis should be strengthened during foundation pit reinforcement and excavation to accumulate practical experiences for further theoretical analysis.

**ABSTRACT:** For the issue of foundation pit excavation on adjacent tunnels, numerical simulation software is applied to dynamically simulate the excavation and reinforcement process. The interaction of foundation pit and existing tunnels in four different relative positions is analyzed, including the tunnel under the foundation pit, the tunnel beside the foundation pit, the tunnel between the foundation pits and the foundation pit between the tunnels. Based on the simulation results, the effectiveness of soil reinforcement in passive zone, heap loading, and anti-floating pile is presented by comparative evaluation and the optimized excavation sequences are probed. Moreover, the superiorities and the deficiencies of numerical methods are introduced emphatically.

**Keywords:** numerical simulation; foundation pit excavation; existing tunnels; excavation sequences; deformation control

## 1 INTRODUCTION

In recent years, with the construction of the subway, the area along with the subway has been the flourishing region, and more and more construction projects are located on the subway tunnel or the side. Excavation will have an impact on the stability of the existing subway. The essential reason is the soil stress redistribution caused by surrounding excavation, which leads to a series of mechanical change. Therefore, it is essential to control the impact of the excavation pit on the subway tunnel within the allowable range.

Surrounding the influence of excavation on existing tunnels, many scholars have done a lot of works using numerical simulation methods. As a kind of mechanical state analysis tool, numerical simulation is a more effective means to solve the problem of geotechnical engineering and has been accepted by academia and engineering field widely. It is more and more applied in the stability analysis of rock and soil mass, geotechnical engineering design, and optimization of the construction process.

Numerical simulation method has the following advantages: (1) It can simulate the variation of

tunnel deformation and stress state with pit reinforcement and excavation process; (2) Through simulation to compare different effects of pit reinforcement measures on existing tunnel, and then to get the optimization scheme; (3) By changing the parameters to study the extent of different factors on tunnel uplift; and (4) The simulation is low-cost and can be repeatable.

## 2 NUMERICAL SIMULATION OF THE RELATIVE POSITIONS

### 2.1 *The tunnel under the foundation pit*

Based on the Xiqing Road Tunnel crossing over the existing tunnel boxes of the Tianjin Metro Line, the simulation models of the actual construction process and four other calculation conditions are built by using ABAQUS, as shown in [Table 1](#).

The effectiveness of the soil reinforcement alongside the existing tunnel is prominent by comparison especially to reduce the different deformations between the two adjacent boxes of deformation joint. The increase of the different reinforcement parameters can reduce the uplift of the track in the tunnel and the different deformations between the

Table 1. The calculation condition.

Model 3	N	Y	N
Model 4	N	Y	Y
Actual construction	Y	Y	Y

two adjacent boxes of deformation joint, but the reinforcement effect decreases with increase of the parameters, and it exists within a reasonable scope of the reinforcement.

To investigate the influence of the construction of the underground passage on the East Yan'an Road Tunnel in Shanghai and to evaluate the effectiveness of two protective measures, the numerical analysis of four different conditions is performed using the finite element code PLAXIS-GID, as shown in Table 2.

The results indicate that when excavating the bottom, the underlying tunnel uplifts in a range of about six times of the width of the pit. Each section of the tunnel produces a vertical egg-shaped plane deformation. The maximum of tunnel's curvature appears where the tunnel uplifts most. Unlike the above conclusion from the excavation of the Xiqing Road Tunnel in Tianjin, the result presents here that surcharge by heap loading is more effective to reduce the tunnel's curvature.

### 2.2 The tunnel beside the foundation pit

Based on the dates from the excavation of Daning Commercial Center in Shanghai, 3D FEM method is used to analyze the environmental effect due to excavation, and the modified Cambridge model was used to simulate soils. The results show that horizontal and vertical displacement of the tunnel gradually increases with the excavation of the basin edge in the side of subway, and then it reaches its maximum at the end of the excavation. The interval excavation in tunnel side can limit the deformation of retaining structures.

The numerical models of six different conditions are built to analyze the reinforcement effect of different widths and depths in foundation pit for the background of the excavation of the Pacific Plaza in Shanghai. The simulation results show that with the increase of the width and depth of the reinforced region, horizontal and vertical displacement of the tunnel decreases slightly, but some areas of which are flat or slightly uplifted. Passive zone reinforcement can slow down the tunnel settlement deformation, but simultaneously it shows that its

effect on horizontal displacement is greater than the vertical.

Pipeline protections are analyzed by numerical simulation to simulate three kinds of conditions, including passive zone reinforcement in pit, and reinforcement under and beside the pipelines. It turns out that the most effective method of controlling the displacement of underground pipelines is passive zone reinforcement. The closer the distance of the pit and the lateral reinforced structure is, generally the better the effect is. Grouting reinforcement under the pipelines can effectively control the vertical displacement of underground pipelines, but it has a lesser impact on the control of horizontal displacement. The bottom grouting reinforcement was not applied to prevent the deformation of the subway tunnel, and it needs further study to see if grouting reinforcement itself can cause the tunnel uplift.

### 2.3 The tunnel between the foundation pits

According to the practice of deep excavation adjacent to subway tunnel in Guangzhou, Midas/GTS is used to establish a 3D numerical model to analyze the interactive impact on the crossing tunnel caused by three kinds of different excavation sequences of the adjacent deep excavations on both sides of the tunnel. The calculation condition and the plane position are shown in Table 3 and Figure 1.

The result shows that the excavation and the support construction should be synchronous and symmetrical to control the horizontal displacement of the tunnel when excavating on both sides of the tunnel, but it is not suitable for controlling the vertical displacement of the tunnel. Partitioned excavation should be adopted to control the single unloading volume along the tunnel.

With a case in Lujiazui Financial District of Shanghai, a numerical simulation is conducted to analyze the influence of various factors, including the excavation sequence, installation of resistance piles, and relationship between tunnel and retaining wall of excavation. Plane position is as shown in Figure 2.

Table 2. The calculation condition.

Calculation condition name	Model 1	Model 2	Model 3	Model 4

Table 3. The calculation condition table.

Calculation condition name	Model 1	Model 2	Model 3
Excavation sequences	Symmetrical excavation of A1 pit and A2 pit	First excavation of A1 pit and then A2 pit	First excavation of A2 pit and then A1 pit

Figure 1. Plane position diagram.

Figure 3. Plane position diagram.

Figure 2. Plane position diagram.

It proves that when the excavation of foundation pit is divided into the small parts near the tunnel and the large parts in the distance, the method can isolate the impact on tunnels due to the excavation of the large parts. The displacement of tunnel

is mainly caused by the small excavation near the tunnel, and this method also can reduce tunnels uplift. The asymmetric excavation reduces the single unloading volume, but it can cause the lateral displacement of tunnels. Resistance piles connected with underground continuous wall of the tunnel in rigid connection can effectively control the vertical displacement of the tunnel.

#### 2.4 The foundation pit between the tunnels

Based on the excavation of Yajule International Plaza in Shanghai, the analysis of the deep foundation pit adjacent to tunnel on both sides is conducted. Plane position is as shown in Figure 3. With the support of multifarious construction technology including underground continuous wall, soil reinforcement with high-pressure rotary jet grouting pile in pit, well point dewatering, symmetrical excavation, and limited interval concrete

pouring, each step of construction completes successfully, so it is proved that the scheme is safe and economical.

### 3 CONCLUSIONS

For numerical simulation analysis: (1) Parameter selection and mesh generation have a great effect on calculation results; (2) Assumptions and simplification must be done for complex project, so it can not truly simulate completely; (3) The impact of construction technique on tunnel cannot reasonably simulate, such as trench construction of underground continuous wall and dynamic real-time tracing of grouting reinforcement. Therefore, some certain deviations are presented leading to the difference between calculated value and measured results.

Due to the complexity of the practical problems in geotechnical engineering, separately using a numerical method for the analysis of the engineering problems is not enough, therefore, the numerical analysis method of fluid-solid coupling analysis can be utilized fully in order to achieve the most effective analysis results. But in the meantime, geotechnical engineering materials is a complicated geological material with the feature of heterogeneity, anisotropy, and discontinuity, which presents the mechanical properties of nonlinear and inelastic. Therefore, the idea and method of numerical simulation should be improved to provide a high use value for practical engineering.

**ABSTRACT:** In order to limit the impact of the excavation on tunnels within the allowable range, the construction must be controlled strictly. The deformation rules of tunnels are summarized during the foundation pit reinforcement and excavation. In addition, the application of time–space effect, piling sequence, foundation pit dewatering, and passive zone reinforcement of foundation pit are analyzed in detail and also the combined application of temporary diaphragm wall and divisional excavation is introduced emphatically. Finally, the practice proved that all these measures can be successful to control the further deformation and have a reference value for the similar design and construction.

**Keywords:** foundation pit uplift; deformation control; time–space effect; passive zone reinforcement; temporary diaphragm wall

## 1 INTRODUCTION

Because of the importance of the subway tunnels, a strict requirement is needed for the deformation of their own and adjacent foundation pits. For Shanghai subway, the horizontal displacement of retaining wall of level-one foundation pit is required to be less than 0.14%H (H is the excavation depth). Moreover, it has the explicit requirements for construction projects in the protected areas of metro: The value of absolute settlement and horizontal displacement is not more than 20 mm; the radius of curvature of the tunnel deformation is more than 15000 m; relative bending is not more than 1/2500; vibration peak velocity caused by piling and explosion is not more than 2.5 cm/s.

## 2 DEFORMATION CONTROL MEASURES

### 2.1 Reducing exposure time of excavation

The pit bottom bounce capacity is affected by time factor. After excavation without support, the uplift value of the pit increases with an increase in exposure time, so it promotes the uplift deformation of tunnel under the foundation pit. Therefore, during excavation, the adverse effects of exposure time should be considered, and some measures should be taken including overbreak control, installation

of support, and pouring concrete bottom plate in time.

### 2.2 Reasonable excavation method

At present, there are a variety of excavation methods such as excavation in strips and section, excavation in layers, basin excavation, island excavation, and so on. The excavation of Shanghai Daning Commercial Center is divided into ten districts, where the each excavation performed step by step. First, slope excavating to the base and pouring the foundation slab, after the foundation slab reaches the design intensity, the next earthwork construction can conduct. The district in the range of 50 m around the tunnel is left for excavation finally, and set plain stage of slope with a certain width. The final excavation of surrounding slope in tunnel side is conducted in strips and the length of the strip limits within 20 m to control the deformation of retaining structure.

### 2.3 Concrete pouring timely and heap loading

Fully considering the space-time effect, for reducing the exposure time of soil in pit, concrete pouring of the underground structure timely and adding early strength agent to the concrete is effective. Using the prepared sand bag for heap loading on the foundation slab which has reached a certain intensity can

offset the lifting deformation, and the heap capacity should be dynamically adjusted to guarantee the structure safety based on the monitoring data.

#### 2.4 Increasing stiffness and insertion depth of retaining structure

The insertion depth of retaining structure and the load around foundation pit are the determinant for the stability coefficient of resisting upheaval, which affects the upheaval value of foundation pit. With the decrease of insertion depth of retaining structure and the increase of the load around foundation pit, the upheaval value of foundation pit becomes large, and it presents a non-linear relationship.

Soil mixing wall is adopted as the retaining structure of the foundation pit of new Jingqiao Square in Shanghai. It is  $\Phi 850 \text{ mm} @ 600 \text{ mm}$  soil-cement mixed piles by triaxial stirring machine and also the I-beam of  $H700 \times 300$  inserts the mixing piles. It forms the compound retaining structure and sealing structure. Moreover, the insertions of I-beam are more intensive in the critical parts to improve the fender piles lateral stiffness and reduce horizontal deformation of retaining structures.

Based on the construction technology of the two-time reinforcement outside the deep excavation adopted in the station of Shanghai metro line 7 Jing'an temple, underground obstacle as the barrier against the displacement transfer induced by deep excavation is presented for the first time. Before the construction of diaphragm wall, the reinforcement with SMW should be finished in outside row of the foundation pit for the first time, and when it reaches the intensity the construction of diaphragm wall can be conducted. After that, jet grouting pile is adopted to reinforce the soil between the diaphragm wall and the reinforcement of SMW for the second time, as shown in Figure 1.

Figure 1. The reinforcement scheme.

The practice has proved that compared with the surrounding natural soil, the underground reinforcement structure as the large-stiffness barrier has the effect of obstructing displacement.

#### 2.5 Foundation pit dewatering

Foundation pit dewatering is an effective and economical measure in foundation reinforcement. Based on the CheKung Temple interchange project of Shenzhen Metro, two-dimension finite element software Plaxis is used to establish the model of plane strain to analyze the impact of dewatering on tunnel uplift deformation. Analysis shows that the step of the greatest influence on existing tunnel deformation is foundation pit dewatering in the strong water permeability strata like Shenzhen region. Foundation pit dewatering can control the upheaval of underneath tunnel, but it is an adverse factor for controlling the horizontal deformation. Therefore, the displacement values of the underneath tunnel in different orientations should be considered to take the reasonable dewatering measures.

#### 2.6 Passive zone reinforcement

Mixing piles commonly are used to reduce the tunnel deformation within the scope of excavation. First of all, foundation reinforcement can increase internal friction angle  $\phi$ , cohesive force  $c$  and elastic modulus of soil, and as a consequence the coefficient of subgrade reaction increases. Second, reinforcement body forms a space plate system with great integrality, and under the soil compaction effect of piles the constraint on tunnels increases. The arrangement form of passive zone reinforcement in pit can take many forms, including grid type reinforcement and full pit reinforcement.

##### 2.6.1 Grid type reinforcement

High-pressure rotary jet grouting pile and deep mixing pile are employed in passive zone reinforcement of Shanghai Square as shown in Figure 2. Reinforcement thickness is 5 m, and the grille width is 1.2 m at 5.8 m intervals; the two gratings on both sides of the tunnel are 2.2 m in width and 11.5 m in thickness. In addition, to reduce the disturbance above the reinforced plane, high-pressure rotary jet grouting pile and deep mixing pile are continued grouting above the reinforced plane with the drill pipe lifting.

##### 2.6.2 Full pit reinforcement and anti-floating pile

Full pit reinforcement with cement-soil mixing piles are used in the project of Xiqing Road Tunnel crossing over the existing tunnel boxes of the Tianjin Metro Line 1, as shown in Figure 3.

Figure 2. The foundation pit soil reinforcement scheme.

Figure 3. Reinforcement along both sides of tunnel boxes.

Because the distance of the newly-built tunnel floor from the existing tunnel boxes is only 0.3 m, the pit reinforcement is only carried out on both side of the existing tunnel boxes with cement-soil mixing piles, meanwhile, anti-floating piles are also set on both sides. When the effective connection of anti-floating piles and the newly built tunnel floor is finished, a “protection hoop” is built around the existing tunnel boxes to limit the deformation.

### 2.7 Optimizing piling sequence

After the partial dissipation of pore water pressure, controlling the number of continuous piling is the effective method to control the tunnel uplift. For using barrier effect of pile driving itself, reasonable arrangement of piling sequence is a economical and practical method. Due to piling to one direction, the front soil will continue to accumulate the outward and upward displacement, piling sequence largely determines the direction of compaction. When piling away from or paralleled to the tunnel, the tunnel displacement is small, and it turns out just the opposite when piling towards the tunnel.

Based on the practice of the East Road Underpass Project in Shanghai, optimal piling sequence is firstly using cement–soil mixing piles to reinforce the soil above the tunnel, and then reinforce the soil near the tunnel as a barrier structure. After reaching the basic intensity, piling can gradually continue away from the tunnel for the dissipation of pore water pressure.

### 2.8 Reinforcement and rectification with two-shot grouting

Two-shot grouting reinforcement can be used to adjust the curvature and horizontal displacement of the tunnel if necessary. In the aforementioned project of Xiqing Road Tunnel in Tianjin, due to the small distance of the newly built tunnel floor from the existing tunnel boxes, the mixing pile reinforcement on the boxes is infeasible. Therefore, the two-shot grouting reinforcement is adopted to combine the existing tunnel boxes with the surrounding reinforced structure in the range of 0.5 m surrounding the tunnel, as shown in Figure 3.

Analogously, in the project of the East Road Underpass in Shanghai, before the construction of anti-floating pile on both sides of the tunnel, the two-shot grouting is used to reinforce the soil on upper half circle of the tunnel, and grouting thickness is 1 m, as shown in Figure 4.

### 2.9 Temporary diaphragm wall inside foundation pit

According to the practice of deep excavation of Shanghai Wheelock Square adjacent to Shanghai Metro Line 2, the simulation of the excavation method is conducted. A temporary diaphragm wall is located 7.5–12.5 m to the northern diaphragm wall, so the large foundation pit is divided into the north and south foundation pit, as cross-section of retaining structure is shown in Figure 5. First, the excavation of the south pit (the large foundation pit far from the subway) is executed and heaping

Figure 4. Cross-section of foundation reinforcement.

Figure 5. Cross-section of retaining structure.

loading on the foundation slab stabilizes the settlement deformation of tunnels, and then the north pit is excavated. Divisional construction can narrow the exposure range of excavation near the side of subway tunnel, and reduce the adverse effect of the whole excavation on subway tunnel.

### 2.10 Construction monitoring

The foundation pit excavation surrounding tunnels is a high-risk project, so the monitoring is very important for the operating metro tunnel and the surrounding environment. During excavation and reinforcement, based on the monitoring data the next deformation can be forecasted by using theoretical and numerical analysis tools. It is convenient to grasp the tunnel deformation, estimate the cause of the tunnel deformation and guide the construction.

## 3 CONCLUDING REMARKS

The protection of the underground environment is becoming the controlling factor in urban area, and the design of foundation pit engineering has also gradually changed from the stability control to deformation control. In summary, with the development of city construction in our country, the effects of foundation pit excavation and the related measures of controlling deformation will be paid much attention, and more effective and economic construction plan will be used to ensure the safety of the project.

# The study on safety evaluation method of metro construction based on SHEL—BP neural network

J.X. Zhao, K. Fan, J.H. Sun & M. Liu  
*Qingdao Technological University, Qingdao, China*

**ABSTRACT:** From the perspective of improving the safety construction control level, we are applying the SHEL model to evaluate safety of the subway construction project in order to establish evaluation index system. We are using the BP neural network to establish the subway construction safety evaluation model due to the nonlinear relationship between the elements in the system. By performing research on multiple projects, using MATLAB software to training and testing the model, the empirical study shows that the evaluation model of the safety of subway construction project can give a more accurate rating. This model provides a scientific and effective evaluation method for the safety subway construction.

**Keywords:** metro construction; safety evaluation; SHEL; BP neural network

## 1 INTRODUCTION

At present, the metro construction has entered a stage of rapid development, in view of the characteristics like large scale construction, complex technology and catastrophic accidents of the project, early intervention and evaluation of construction safety has become increasingly important. According to W.H. Heinrich survey found that the cause of the accidents 88% were due to people's unsafe behaviors, 10% attributed to the unsafe state of object, 2% due to force majeure factors. The focus of prevention should be put on the control of people's unsafe behavior in the engineering (Qian, 2012). To reduce the metro construction safety risk, we need to start from people that is the most active factor in the engineering evaluate safety control.

For the metro construction safety evaluation, many scholars both at home and abroad adopt the method that figure out reasons from the results to put forward safety control index evaluation system. But Elwyn Edwards (Wang, 2010) established a people-centered elements of security model that make the index system of metro construction safety be sorted out from the origin of risk. In view of the above reasons, this paper based on the SHEL model, according to system decomposition and data analysis of metro construction process and the nonlinear relationship of each factor in the metro project, introduced BP neural network to evaluate the metro construction safety risk. In hope to provide a reference for the safety evaluation of metro construction projects.

## 2 SAFETY RISK INDEX SYSTEM

Elwyn Edwards in 1972 first proposed the SHEL model (Zhou et al., 2014), in which, the “Liveware” in the security work is at the specific system interface. This interface including Liveware—Software, Liveware—Hardware, Liveware—Environment, and Liveware—Liveware four links. In this coupling model, the “Liveware” is in the key position, the connection of the zigzag reflects the fragile relationship between the four nodes. The model has a good simulation of the key link in the construction environment, and has a general guidance for the safety construction, the details are shown in [Figure 1](#).

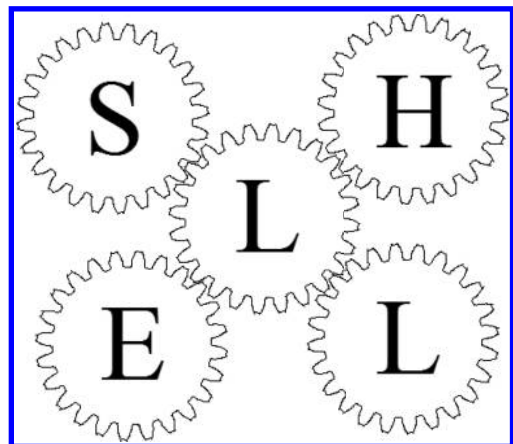

Figure 1. The SHEL model.

In the metro engineering construction:

1. L: It refers to all the factors that affect the construction safety in metro projects and have a direct contact with engineering personnel. As an organism who has subjective consciousness, people's behavior are limited by their own abilities and the objective project environment. Liveware generally includes the metro construction crew, material engineer, inspector, measurement engineer, technician, safety officer, mechanical operation team, design engineer, project manager and other related personnel in the system.
2. L-S: It refers to the degree of compliance with the work system, method in technical specifications and operation process for metro construction workers. If people free from the software interface or the interface is not scientific, it will increase the risk of accidents, and safety ratings downgrade.
3. L-H: It refers to the adaptive relationship between the metro construction personnel and physical factors. It would be a security risk during subsequent construction if operator can't correctly use system, material and advanced large equipment in the project.
4. L-E: It refers to the impact of the external environment on staff, including the construction environment, the meteorological environment, the company culture etc.
5. L-L: It refers to the collaborative relationship between underground engineering staff, is also the link that is most prone to errors in the system, reflecting in communication, technology level, cultural quality, etc.

The establishment of the metro construction safety evaluation index system based on the safety management's principles of integrity, unity and operability, considering the whole production safety activities process (Tian et al., 2011), combining with the literature (Ding et al., 2011) and the investigation of construction site workers and experts. The details are shown in Figure 2.

Figure 2. A typical structure of neural network.

### 3 METRO CONSTRUCTION SAFETY EVALUATION MODEL

#### 3.1 The BP neural network theory

BP neural network is an intelligent algorithm to mimic the human brain, it has a strong ability of imitation and association, due to a number of artificial neuron similar to natural nerve cells. Compared with the widely researched methods of fuzzy theory analysis, the BP neural network has a strong superiority between various factors about nonlinear causality in the evaluation of metro construction. It usually consists of three layers of neurons and its topology structure as shown in Figure 3.

#### 3.2 Establish the evaluation model

##### 1. index processing

In order to meet the requirements of the implementation of the BP neural network, we need

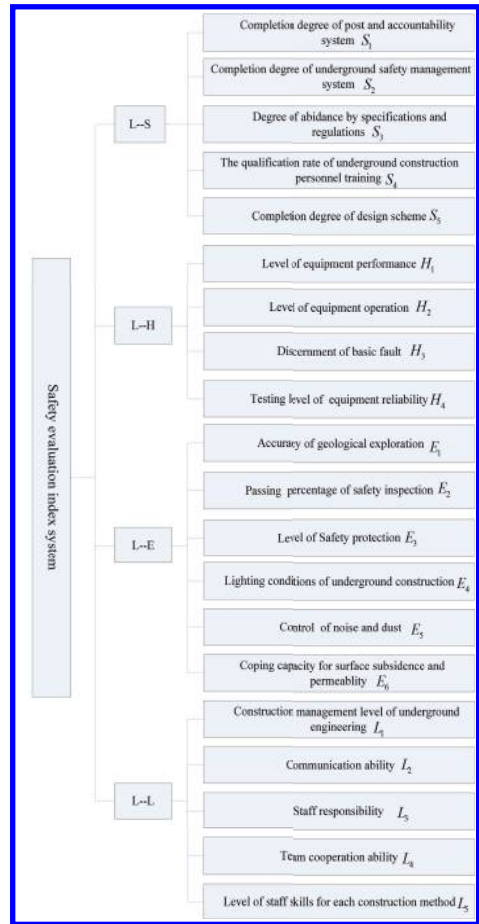

Figure 3. The evaluation index system.

to normalize index of different metrics datum, and convert it into a dimensionless index on [0, 1]. For qualitative indicators, we adopt expert scoring method and divide the indexes into five levels, that can be made of very poor, poor, general, good, excellent level. Specific definitions are shown in Table 1 (Li et al., 2014). We process the positive quantitative indicators with the formula (1) and process the negative quantitative indicators with the formula (2).

$$y = \frac{x - x_{\min}}{x_{\max} - x_{\min}} \quad (1)$$

$$y = \frac{x_{\max} - x}{x_{\max} - x_{\min}} \quad (2)$$

where  $y$  = processing after the index value and  $x$  = practical index value.

2. determine the output layer

The number of output layer neurons should be determined according to the system needs, the results of the model evaluation are the

safety of metro construction. Therefore, it can be described by a real number of continuous changes in [0, 1]. The output data can be converted into five qualitative index with very poor (0.1), poor (0.3), general (0.5), good (0.7) and excellent (0.9) level.

3. determine the hidden layer

There is not a definite theory to guide the hidden layer number, its selection is more flexible. If the node number is too little, network approximation effect is poor and it is not easy to convergence. Increasing the number of nodes can improve the approximation effect of existing discrete point sets, but the increased number of nodes inevitably leads to slow down the speed of training and make the calculated curve too flat (Chen et al., 2012). Generally, to best minimize the hidden layer number should follow that the output results should close to the simulation sample and meet the accuracy requirement. Therefore, many scholars use empirical formula (3) to determine the number of hidden layer.

$$n_y = \sqrt{n + m} + a \quad (3)$$

where  $n_y$  = the number of hidden layer neurons;  $n$  = the number of input layer neurons;  $m$  = the number of output layer neurons; and  $a$  is constant between 1 to 10.

Through experiment comparison, when the number of hidden layer neurons is 14, the speed

of training is fast, the fitting degree of the test sample is good, and the error is smaller.

#### 4. build neural network

NEWFF function is adopted to establish the feed forward network, the two layers of transfer function select the TANSIG that is a nonlinear hyperbolic tangent sigmoid function, training function selects the TRAINGD that the weights and threshold drop along the negative gradient direction of network performance function, the maximum number of training is 50000 epochs, learning step size is 0.1, the minimum mean square error is 0.00001, the layers of neural network is 3 and the rest of the parameters select system default values of the kit, in this paper.

### 4 EXAMPLE ANALYSIS

#### 4.1 Select Sample and network training

Chosen samples should follow the principle of typicality, authenticity and objectivity, we received 20 representative sets of data, and make surveys through Shanghai, Qingdao, Guangzhou and other metro construction projects, such as in Table 2. Through comprehensive assessments from multiple experts and third parties to obtain the expected output data, among which the previous 15 sets are used as training samples, the later 5 sets as the simulation test samples. The neural network whose mean squared error is not more than 0.00001 meet the requirements after 30274 times training. As shown in Figure 4.

#### 4.2 The simulation test

The simulation test tests trained neural network through the later 5 sets (16–20) datum as test sample. The error between the actual output and the expected output is small by comparison, among

Figure 4. The mean squared error curve.

Table 3. Contrast of expected and actual value.

	Actual output value	Expected output value	Error
16	0.7238	0.7 (good)	0.0238
17	0.5002	0.5 (general)	0.0002
18	0.3407	0.3 (poor)	0.0407
19	0.9125	0.9 (excellent)	0.0125
20	0.6771	0.7 (good)	0.0229

which the biggest error is 0.0407, the minimum error is 0.0002, all details are shown in Table 3. The above datum show that the results of the metro construction project safety evaluation conform to the practicality, and it is effect and feasibility, thus the model can be promoted for using.

### 5 CONCLUSIONS

1. This paper teases out the important factors from factors that affecting the safety of metro construction by using the idea of people-centered in SHEL model and build the index system of metro construction safety, quantitative processing method is given.
2. With the relationship of complex nonlinearity between the various influencing factors and final results taken into account, the paper establishes the metro construction safety evaluation model based on BP neural network. We found the model output can achieve the desired standard and the test results are in consistent with the actual situation by the training and simulation of samples. The process of evaluation is simple, feasible and the results are accurate after the model training.
3. The evaluation model need to collect a large number of datum as the training and testing samples during the initial period, after the completion of network training the corresponding security rating can be easily realized by input the relevant parameter values. Further, evaluation method has certain reference significance to relevant enterprises and institutions in metro construction safety control, with its simple process and strong feasibility. By further improvement it can be extended to other areas in safety control and evaluation.

# Influence of box culvert construction on running metro shield tunnel

Tianjun Liu, Guanfeng An & Hao Liang

*Guangzhou Municipal Engineering Group, Guangzhou, Guangdong, China*

**ABSTRACT:** This paper is based on a culvert construction method on the highway, above metro tunnels, and the loading and geological condition that sets up a three-dimensional numerical analysis modeled to analyze the influence of the culvert excavation construction. Studies show when it was digging or backfilling, the largest horizontal and vertical displacement appeared on the metro tunnel. The total maximum displacement was 1.84 mm, which was less than the subway protection requirements of the total displacement control values (8 mm). At the same time, the maximum displacement of tunnel rail was 1.37 mm, which was less than the value of the early warning system for metro rail deformation and control values (4 mm) that it would not affect the normal operation of the subway. That is to say, the construction measures, therefore, will not endanger the bottom of the box culvert construction of metro tunnel structure safety, the engineering experience can be provided as a reference for similar projects.

**Keywords:** box culvert; shield tunnel; MIDAS/GTS; displacement; bending moment

## 1 INTRODUCTION

With the speeding up of the national economy development and the increase of the urban traffic pressure, more and more metro are being constructed, the scale of operations and mileage raise rapidly. Most subway lines locate in the center of big city that much more construction projects will excavate near metro tunnels or stations. It will inevitably affect the subway structure so the protection of the subway tunnel and station is put forward severe challenges. From the situation of the current study, however, because of the complexity of the working condition, diversity of the construction methods, there is not a comparatively accurate theoretical analytical solution [1]. Most projects, before the construction, use numerical simulation methods to estimate the displacement of subway tunnel or station. How can better simulate the excavation influence on metro tunnel, there is a lot of research published for simulating the excavation influence on metro tunnel [2–4].

Box culvert can be defined as a long and narrow type of foundation pit. The excavation will influence the stability of the existing subway below. Its most essential reason is caused by box culvert of excavation unloading of surrounding rock stress state redistribution again, resulting in a series of mechanical behavior changes. Tunnel deformation of existing subway tunnel surrounding may be caused by the load changes that grasp the existing subway tunnel in the process of box

culvert excavation deformation characteristics and the internal force distribution is very important. Therefore, reasonable selection control is below the deformation of metro tunnel design and construction process, to ensure the normal use of the subway tunnel, which must be solved [5]. Due to foundation pit excavation boundary construction, such as box culvert, being complex, it is difficult go to through the analytical method to analyze the excavation impacts of metro tunnel. The numerical method provides a powerful tool for solving this problem [6].

Based on a box culvert construction in a highway above a certain operating metro tunnel, using the method of numerical simulation to analyze the whole process, evaluated the excavation unloading effect on both the deformation of metro tunnel and rail below. The results can be reference for similar projects.

## 2 PROJECT INTRODUCTION AND CONSTRUCTION SITUATION

### 2.1 *Project introduction*

The project locates in Liwan district of Guangzhou. It is an urban arterial road, which has a design speed of 60 km/h, planning for the urban expressway. This project main content for 7 new reinforce box culverts, 3 overpasses, an across river bridge. In this paper, the No. 3 box culvert construction and operating impacting the metro tunnels would be analyzed and the conclusions and suggestions

were proposed. The relationship between box culvert and tunnel is shown in Figure 1.

This box culvert excavation length was 80.6 m, height was 3.8 m, south end of it crosses above the north of metro tunnel, end in the bi-directional tunnel. Slope excavation was 1:1, considering on the bottom of the box culvert in fill when the excavation depth of 4.9 m. At the bottom of the box culvert with tunnel, the vertical net top edge distance is 6.1 m. Due to excavation at the bottom of the box culvert in filling, the excavation bottom distance at the top of the outer edge of vertical interval was only 5.0 m.

## 2.2 Construction condition

Due to the spatial location of the box culvert is near subway shield tunnel and the mechanics characteristic of narrow excavation. It accords section excavation, timely backfill, less digging above tunnel. Based on this principle, the whole box culvert construction is in accordance with the following steps.

Figure 1. Location relationship between No. 3 box culvert and metro tunnels.

Table 1. Construction condition of the culvert.

Construction condition	Characteristics
1	According to the steel sheet pile supporting structure, the excavation section of box culvert, layered with steel support excavation to the pit
2	Section of box culvert and backfill, the excavation section of box culvert, layered with steel support excavation to the pit
3	Section on the box culvert and backfill, the excavation section of box culvert, layered with steel support excavation to the pit
4	Section of box culvert and backfill, the demolition of the old southern box cover board for new box cover plate

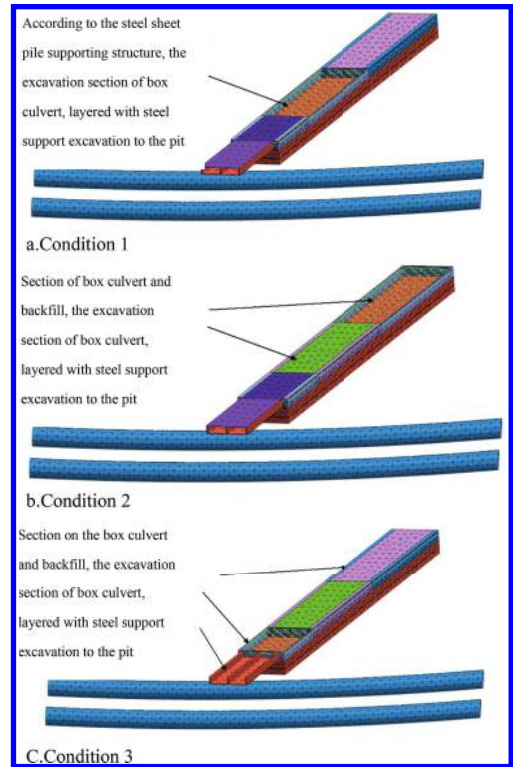

Figure 2. Construction condition.

## 3 THREE-DIMENSIONAL NUMERICAL ANALYSIS OF THE IMPACT BY NO. 3 BOX CULVERT CONSTRUCTION ON THE TUNNELS

### 3.1 Establish model

According to the geotechnical engineering investigation report, select the number 3 box culvert neighboring H3ZK1 drilling geological data as a basis for calculating model of soil. The soil parameters of the calculation model main bases on it, the missing part of the soil parameters refers to the "Foundation pit supporting technology regulations in Guangzhou area" and engineering experience. The specific parameters are shown in Table 2.

In addition, the calculation model mechanical parameters of tunnel, the culvert, and the original old box culvert structure are shown in Table 3. With considering the subway segment assembling results in the decrease of overall stiffness, combined with field investigation and related domestic subway engineering experience, the selected segment level corresponding to the elastic modulus of concrete on the basis of the original value may reduce to 80%.

Table 2. Soil mechanics parameters.

Soil layer	Weight (kN/m <sup>3</sup> )	Modulus of elasticity (MPa)	Poisson's ratio	Angle of internal friction (°)	Cohesion (kPa)
Grain filling 1-2	19	11	0.36	10	10
Muddy sand 2-3	19	18	0.35	22	5
Silty clay 3-1	20	22.5	0.34	10	20
Silty clay 4-2	19.9	30	0.32	20	20
Full-weathering silty mudstone 5-1	19.8	33.5	0.32	16	38
Moderately weathering silty mudstone 5-2s	23	1700	0.30	33	400
Intense weathering silty mudstone 5-2	23	300	0.30	32	4
Filling under the culvert	20	100	0.30	32	100

Table 3. Structural mechanics parameters.

Section	Material grade	Weight (kN/m <sup>3</sup> )	Modulus of elasticity (MPa)	Poisson's ratio	Notes
Tunnel segment	C50	25	$2.76 \times 10^4$	0.2	Reduce 80%
No. 3 new culvert	C35	25	$3.15 \times 10^4$	0.2	
Old culvert	C20	25	$2.55 \times 10^4$	0.2	
Pavement structure layer	C20	25	$2.55 \times 10^4$	0.2	

According to the spatial location relations and the construction characteristics, using numerical analysis software MIDAS GTS, to establish a three-dimensional finite element numerical calculation model is shown in Figure 3.

In terms of material model, soil model is the Moore—coulomb constitutive model and interval box culvert structure is the linear elastic model. In terms of load, it considers the weight and overloading during construction of the ground and road operation load. Z direction displacement is restrained, boundary conditions, forward and back of Y direction is restrained, left and right of X direction is restrained. Simulation for the real number three new box culvert construction and operation process of subway line below the influence of structure, calculation model fully considers the various working conditions during the construction period and operation period. Specific see Table 4.

### 3.2 Results analyze

Table 5 shows the box culvert in construction and operating period of different construction conditions and a horizontal displacement DXY, vertical displacement DZ and the maximum total displacement DXYZ. Figure 4 (1)—(4) respectively shows the box culvert in construction and operating period that the shield tunnel structure

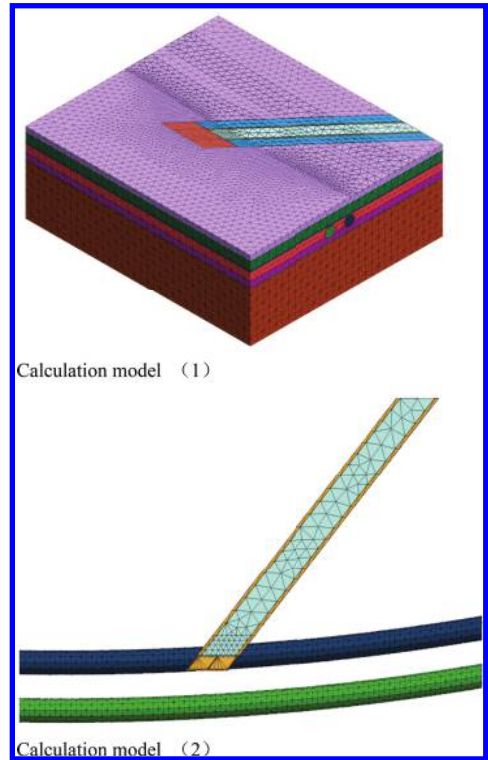

Figure 3. Calculation model.

Table 4. Construction condition of the model.

Construction condition	Characteristic
1	Establish strata, weight of in-situ stress analysis (excluding displacement)

7	The road into a permanent operation

Table 5. Maximum displacement values of different construction condition.

Construction condition	Horizontal displacement DXY (mm)	Vertical displacement DZ (mm)	Overall displacement DXYZ (mm)
1	1.03	+1.22	1.41
2	1.08	+1.04	1.44
3	1.13	+1.63	1.84
4	1.09	+1.05	1.46

Note: +/- means uplift/settlement of values DZ of vertical displacement.

in different working conditions of the overall displacement DXYZ distribution nephogram.

This section will analyze the deformation situation of the metro tunnel during the culvert construction and operating. On the new track location, set up a series of nodes to extract the deformation data of the orbit. Picture below is for the two-way operation line of the four tracks; the maximum total displacement of track and the total displacement curve when the steps in different conditions (because the first two conditions became zero, the working condition of the two data is not provided).

As the calculation results,

1. When No. 1 and 3 box culvert were during excavation construction and construction backfill,

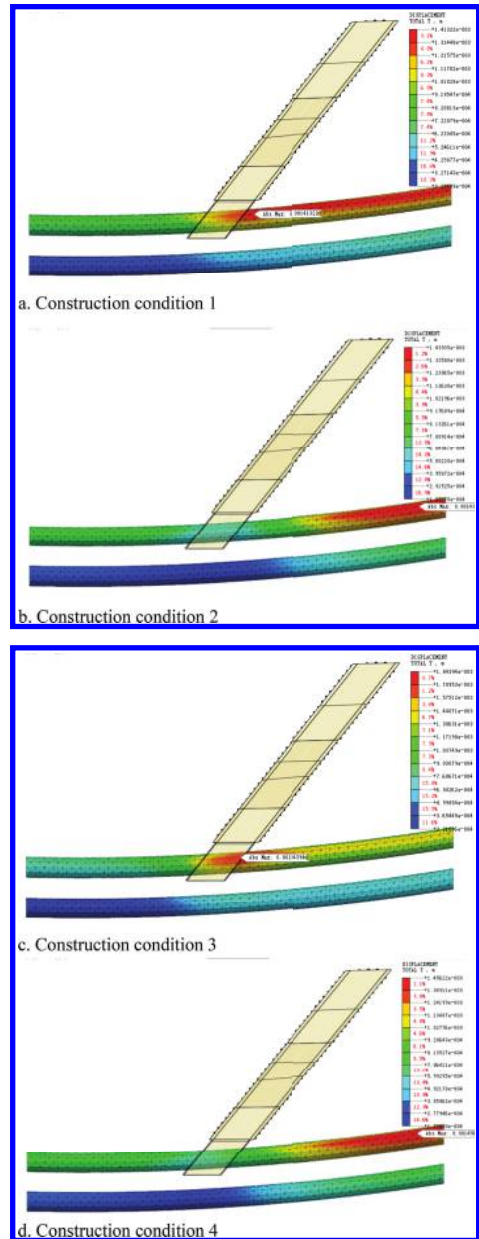

Figure 4. Total displacement DXYZ distribution of tunnels during culvert constructions.

the maximum horizontal value of a tunnel of metro line was 1.13 mm, maximum vertical displacement value was +1.63 mm (elevation), the overall displacement of a maximum was 1.84 mm, less than the total displacement control values (8 mm). That is to say the No. 3 box culvert in construction period impacted slightly

Figure 5. Tunnel displacement curve in different conditions.

on the tunnels, significantly less than the total displacement control values, less than a quarter of the control values.

2. In the condition of completing No. 3 box culvert construction and restoring the road after operation, the maximum horizontal value of tunnels was 0.26 mm, maximum vertical displacement was 0.42 mm (elevation), the overall displacement of a maximum was 0.44 mm that early stage of the box culvert construction caused by the uplift substantially reduce the settlement of become tiny. Therefore, there is also small effect.
3. When No. 3 box culvert construction and the avenue was put into operation, the maximum displacement value of the orbit was 1.37 mm, less than the value of early warning system for the deformation of metro rail and the control values that it may not affect the normal operation of the subway.

#### 4 CONCLUSION

This paper established a three-dimensional numerical analysis model of the project, specific analysis conclusion is as follows.

The influence causes by the project mainly includes: Old No. 3 box culvert would be dismantled, the steel sheet pile support or put at the bottom of the slope excavation to the bottom of the in filling culvert elevation and new on both sides of box culvert structure casting and backfilling effect on tunnel beneath the rapidness. The impact of

road on the tunnels during construction and road surface treatment.

The construction measures proposed in this paper, No. 3 box culvert construction and the construction of Guangfo metro tunnel excavation is less affected which significantly less than the total displacement control values, less than a quarter of the controlled variable; and track the maximum displacement value was 1.37 mm, less than the value of the early warning system for metro rail deformation and control values.

No. 3 box culvert construction will not endanger the Guangfo metro tunnel structure safety and normal operation of the subway.

# Quasi-static cyclic loading test and simulation of precast segmental bridge columns with a circular section

Zhan-Yu Bu & Wei-Ye Wu

*Faculty of Architectural, Civil Engineering and Environment, Ningbo University, Ningbo, China*

Jian Guo

*Ningbo Institute of Technology, Zhejiang University, Ningbo, China*

**ABSTRACT:** Precast segmental bridge column is an important part in accelerated bridge construction. Two unbonded prestressing segmental bridge columns and one monolithic reference column were fabricated and tested under a quasi-static cyclic loading. The first segmental column has only an unbonded prestressing tendon through segment joints. The second segmental column has an unbonded prestressing tendon as well as bonded energy dissipation bars to connect all segments together. The test results show that both segmental columns survived the cyclic loading at the end of the 7% drift level with no longitudinal reinforcement fracture, but only minor cracks were observed at column toes. Energy dissipation bars greatly enhanced the lateral strength and energy dissipation ability of the segmental column. Unbonded prestressing tendon plus energy dissipation bars reinforcement scheme was a good choice for moderate- to high-seismicity area segmented bridge column configurations.

**Keywords:** segmental column; cyclic loading; seismic response; unbonded prestressing tendon; energy dissipation

## 1 INTRODUCTION

As an important part of Accelerated Bridge Construction (ABC), precast segmental bridge construction can improve site constructability, total project delivery time, material quality and product durability, and work-zone safety for the traveling public and contractor personnel (Culmo 2011). Starting in 2008, Caltrans initiated a practice development and implementation for ABC. The main task of this project was to develop standards, guidelines, and key policies for implementing the structure design for Accelerated Bridge Construction (ABCAC 2008).

Precast Segmental Bridge Columns (PSBC) have bonded or unbonded post-tensioned strands, and/or bonded mild steel bars through segment joints. Many researchers have conducted model tests, finite simulation and analytical modeling of seismic behavior of PSBCs. Hewes and Priestley (2002) conducted a cyclic loading test of four PSBCs with steel jackets in the plastic end. A simple analytical model was proposed to predict the pushover curve of the test. Yamashita and Sanders (2002) carried out a shake table test of unbonded tendon PSBC with a hollow section. A two-dimensional finite element model was used for pushover parametric analyses. Chou and Chen (2006) tested two

unbonded Concrete-Filled Tube (CFT) PSBCs; among which, one contained energy-dissipating devices at the base to increase the hysteretic energy. Ou et al. (2010) investigated the seismic performance of PSBC with high-performance ED bars and conventional mild steel ED bars, and found that the unbonded length in the ED bar can reduce the stress concentration and increase its fatigue life. More recently, some innovative techniques started to be employed in PSBCs, such as external replaceable dissipaters (Marriott et al. 2009), concrete-filled fiber-reinforced polymer tubes (ElGawady et al. 2010), Shape Memory Alloy (SMA) bars (Roh and Reinhorn 2010), fiber-reinforced concrete/cement composite (Trono et al. 2004), embedded elastomeric pads (Motaref et al. 2014), and shear resistant connectors (Kim et al. 2010).

In this paper, the quasi-static cyclic loading test of two PSBCs and one monolithic column results were introduced, then fiber beam-column model was used to simulate the test results, and both the results were analyzed and compared.

## 2 SPECIMEN DESIGN

Two PSBCs and one monolithic reference column were cast for the cyclic loading test. [Figure 1](#) shows

Figure 1. Test specimens (a) MRC, (b) UPC and UPCE.

the configuration of three specimens. All three specimens have the same footing and loading block dimensions. The footing dimension is 1500 mm by 1000 mm by 600 mm. The loading block is 500 mm cube. The monolithic specimen, first segmental specimen with only an unbonded tendon, and the second segmental specimen with an unbonded tendon plus Energy Dissipation (ED) bars are abbreviated as MRC, UPC and UPCE, respectively. The columns of MRC, UPC and UPCE have the same diameter of 350 mm, and the total height of 1600 mm, with a cubic compressive strength of 44 MPa. The columns of UPC and UPCE are divided into four segments, each having a height of 400 mm. The nominal column height of three specimens is 1850 mm, measured from the column base to the center of the loading block. MRC uses 10 D12-mm deformed bars as longitudinal reinforcement with a yield stress of 491 MPa. UPC uses 3 D12.7-mm unbonded strands as longitudinal reinforcement with a yield stress of 1672 MPa. UPCE uses

3 D12.7-mm unbonded strands plus 6 D12-mm bonded ED bars as longitudinal reinforcement. The ED bar yield stress is 301 MPa. Segmental columns use 6 D12-mm deformed bars as longitudinal reinforcement inside the segments with a yield stress of 491 MPa to position spirals. The spiral stirrups used in three specimens are D7 mm deformed bar with a yield stress of 575 MPa. The spiral stirrups have a layer space of 50 mm and 80 mm for the base 400 mm in depth and other places of column, respectively. MRC has no axial force exerted. The axial forces of UPC and UPCE are provided by the prestressing load of tendons, which are 252 kN for both specimens, and the corresponding axial load ratio is 0.075.

### 3 LOADING PROTOCOL

The quasi-static cyclic loading is displacement controlled. The displacement levels of loading are: 0.1%, 0.2%, 0.3%, 0.5%, 0.75%, 1.0%, 1.5%, 2.0%, 2.5%, 3.0%, 3.5%, 4.0%, 4.5%, 5.0%, 6%, and 7%. Each displacement level repeated twice to observe the damage pattern and to incorporate the fatigue effect to reinforcement.

### 4 QUASI-STATIC CYCLIC LOADING TEST

The three specimens, shown in Figure 1, were loaded under the preceding cyclic displacement protocols, respectively. Force-displacement responses were monitored with an actuator data acquisition system. Reinforcement and concrete strain were monitored by strain gauges. The test results are discussed in the subsequent section.

### 5 CYCLIC LOADING SIMULATION USING FIBER MODEL

#### 5.1 Global response

The cyclic loading tests were modeled with OpenSees (OS) software (Mazzoni et al. 2007). The concrete column was modeled with a fiber beam-column element. Bonded ED bars were modeled with fibers inside the concrete section. Unbonded prestressing tendons were modeled with the truss element. The initial stress was considered in the tendon material model. Concrete was modeled with concrete01 material in OS. ED bar and tendon were modeled with steel02 material in OS. Reinforcement steel inside the segment was not explicitly modeled. The confinement or reinforcement was considered through enhancing the compressive strength of the core concrete.

Figure 2 (a), (b) and (c) shows the lateral force versus drift test results and fiber model simulation results. MRC experienced longitudinal reinforcement fracture during the first cycle of 7% drift. UPC and UPCE had no reinforcement fracture at the end of the 7% drift. The results were compared at the end of the 6% drift. The lateral forces of MRC, UPC and UPCE were 29.39 kN, 32.46 kN, and 51.57 kN, respectively. The asymmetric of lateral force response in UPC and UPCE was caused by the eccentric of prestressing tendon at the top of the loading block to the center of the column base section (Hewes and Priestley 2002). The fiber model gave a good prediction for lateral force responses of MRC and UPCE.

However, the unloading paths of UPC by the fiber model showed big discrepancies with the test results. This reveals the characteristics of OS software, which has a good precision in modeling mild steel reinforcement concrete cyclic responses, but has a bad precision in modeling unbonded prestressing reinforcement concrete cyclic responses. In the 6% drift cycle, the residual drifts of MRC, UPC, and UPE were 3.42%, 0.18% and 0.75%, respectively.

### 5.2 Stiffness, damping and energy

Figure 3 (a) shows the effective stiffness results from the test and simulation. The suffixes “T” and “M”

Figure 2. Lateral force-displacement comparison (a) MRC, (b) UPC, (c) UPCE.

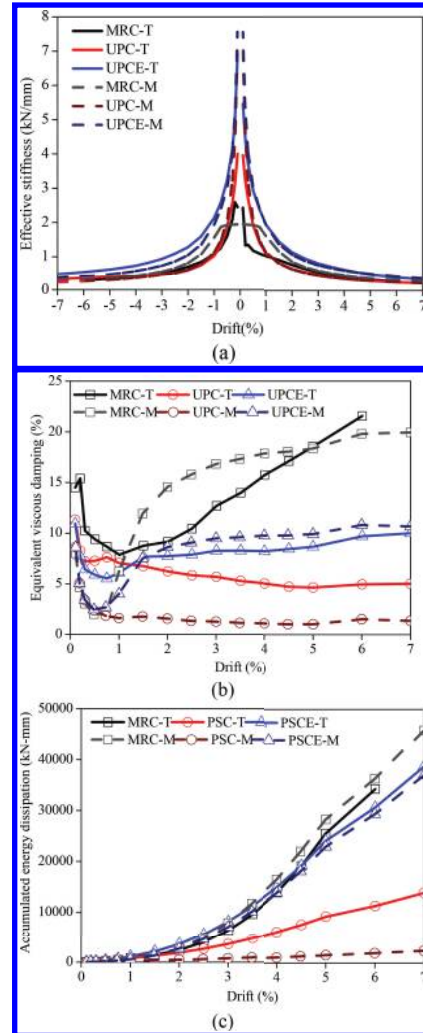

Figure 3. Stiffness, damping and energy comparison: (a) effective stiffness; (b) equivalent viscous damping; (c) accumulated energy dissipation.

mean test and model, respectively. MRC and UPC have a similar effective stiffness, while UPCE has a higher effective stiffness due to the added bonded ED bar compared with UPC. The fiber model gave a good approximation of effective stiffness for the three specimens. Figure 3 (b) shows the equivalent viscous damping of specimens as well as by fiber model simulations. MRC has a damping ratio between 10% and 20% for most of the drift levels. UPC and UPCE have damping ratios near 5% and 8%, respectively. The fiber model normally predicted the damping ratio of MRC and UPCE with a higher precision. Figure 3 (c) shows the accumulated energy dissipation of specimens. UPCE has approximately the same energy dissipation ability as MRC. UPC has the lowest energy dissipation as the column can only dissipate energy through prestressing tendon yielding and concrete minor cracking at critical joints. The fiber model gives a poor prediction for UPC for the reasons stated above.

## 6 CONCLUSIONS

Two segmental bridge columns and one monolithic column cyclic loading test and simulation are presented. The following conclusions can be derived on the basis of the results of the specimen test.

1. At the 6% drift, MRC and UPC have relatively lower lateral forces, and UPCE has the highest lateral force. The residual drifts of MRC, UPC, and UPCE are 3.42%, 0.18% and 0.75%, respectively.
2. MRC and UPC have a relatively lower effective stiffness, and UPCE has a highest effective stiffness.
3. MRC has a higher damping ratio ranging from 10% to 20%; UPCE has a moderate damping ratio of nearly 8%; UPC has a lower damping ratio about 5%.
4. MRC and UPCE have a similar energy dissipation ability; UPC has a lower energy dissipation ability.

From the test results conducted in this paper, UPCE is suggested to be used in moderate to high-seismicity areas; MRC and UPC are suggested to be used in low-seismicity areas.

**ABSTRACT:** A hysteretic model for Precast Segmental Bridge Column with unbonded posttensioned tendons was formed and validated through quasi-static cyclic specimen loading test. The model was capable of predicting the lateral force-displacement hysteretic response with high precision. The peak orienting assumption of post-yielding branches in hysteretic responses was more appropriate to the segmental columns with ED bars than those with only unbonded tendons. Earthquake history responses were also calculated using the proposed hysteretic model, and good correlation was found with quasi-static test results.

**Keywords:** hysteretic model; segmental column; unbonded tendon; cyclic test; earthquake response

## 1 INTRODUCTION

Self-centering unbonded Precast Segmental Bridge Columns (PSBC) are seismic resilient structures (Hewes & Priestley 2002), which can relieve the imparted earthquake loading through rocking of segment-segment joints, and keep the column with minor damage during the earthquake. As an important part of accelerated bridge construction scheme, PSBC provides several benefits to contractors and owners, including reduced traffic disruption, improved work zone safety, reduced environmental impact, improved constructability, increased quality and lower life cycle cost (Hieber et al. 2005). The lateral force-drift response of PSBC reveals flag-shape with essentially little residual drift at the end of earthquake excitation (Yamashita & Sanders 2009). Unlike the conventional steel reinforced concrete bridge columns, few shake table test results are available for PSBC, also simple and accurate hysteretic models are still lacking.

In previous studies by researchers, various self-centering systems have been developed, including unbonded posttensioned tendon (Yamashita & Sanders 2009, Ou et al. 2010), self-centering braces (Christopoulos et al. 2008), shape memory alloy (Roh & Reinhorn 2010) and elastomeric rubber pad (Motaref et al. 2014). Hewes (2002) used ideal flag shape hysteretic model to calculate the seismic response of unbonded posttensioned PSBCs.

Christopoulos et al. (2002) proposed a flag shape hysteretic model for posttensioned energy dissipating connections of precast frame structures. Ou et al. (2007) developed a peak oriented hysteretic model for PSBC based on experimental observation results.

In this contribution, a hysteretic model revised from literature (Ou et al. 2007) was developed and was used to model the PSBC quasi-static cyclic loading test, and history responses under ground motion excitation.

## 2 HYSTERETIC MODEL

The lateral force—displacement hysteretic model for Single Degree of Freedom System (SDOF) used in this contribution was shown in Figure 1. The first loading path was designated as path (1), which has fixed yielding point “A”. The elastic loading stiffness is  $k_e$ . The post-yielding stiffness is  $k_p$ . The unloading stiffness  $k_u$  is in relation with history peak displacement  $\Delta_m$  and yield displacement  $\Delta_y$ , as shown in Eq. (1).

$$k_u = k_e \left( \frac{\Delta_y}{\Delta_m} \right)^\gamma \quad (1)$$

where  $\gamma$  = coefficient, which is assumed to be constant for particular hysteretic model. The unloading

Figure 1. Hysteretic models for PSBC.

transition point is “C”, and the unloading path is ultimately directed to point “D” on elastic loading path.

The reloading path is directed to previous peak point “B” from elastic loading path point “E”. Then the loading path reloads with stiffness  $k_p$  till reaching peak point “F”. The unloading path has a transition “G” when intersects with the extending line of “D” and “C”. After that, the unloading is directed to “E”. In Figure 1, point “D” has a displacement of  $\Delta_0$  and point “E” has a displacement of  $\Delta_1$  on the elastic loading path.

The negative direction has same loading path definitions with those in positive direction, hence the critical points were not illustrated in Figure 1.

### 3 IMPLEMENTATION IN SDOF EQUATION OF MOTION

The equation of motion of damped SDOF system shown in Figure 2 can be written as,

$$m\ddot{x}(t) + c\dot{x}(t) + f(x(t), \dot{x}(t)) = -m\ddot{x}_g(t) \quad (2)$$

where  $m$  = mass;  $c$  = the damping coefficient;  $f$  = nonlinear spring force;  $x(t)$ ,  $\dot{x}(t)$ , and  $\ddot{x}(t)$  = relative displacement, relative velocity and relative acceleration of SDOF system to ground, respectively;  $\ddot{x}_g(t)$  = absolute acceleration of ground.  $f$  = loading history dependent (position and direction), so  $f$  is function of relative displacement and relative velocity. In Figure 2, wheels on the SDOF system has no friction force

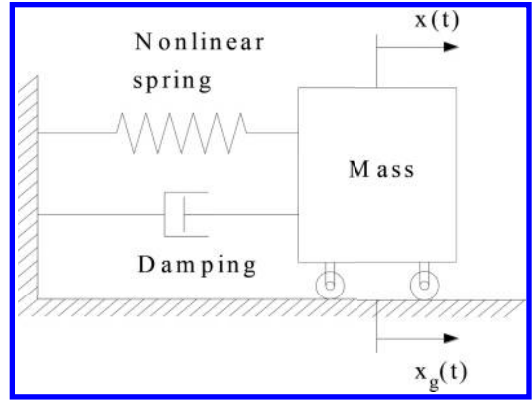

Figure 2. SDOF system.

with the boundary ground,  $x_g(t)$  is absolute displacement of ground.

Assume the damping force is small and effects can be eliminated in the reaction force, then  $f(x(t), \dot{x}(t))$  in Equation 1 can be looked as the reaction force shown in Figure 1. The relative displacement  $x(t)$  in Eq. (2) can be solved with average acceleration method with input ground motion acceleration  $\ddot{x}_g(t)$ , mass  $m$ , damping coefficient  $c$ , and nonlinear spring force  $f(x(t), \dot{x}(t))$  determined.

### 4 CYCLIC LOADING TEST MODELING

Two 1/4 scale segmental column specimens were fabricated and tested under cyclic reversal loading in laboratory. The columns had circular section with diameter of 350 mm. The column height was 1850 mm measured from column base to center of loading block. The column was composed with four 400 mm depth segments. Concrete cubic compressive strength was 44 MPa. First specimen PSC uses 3D12.7-mm unbonded strands as longitudinal reinforcement. Second specimen PSCE uses 3D12.7-mm unbonded strands plus 6 D12-mm bonded Energy Dissipation (ED) bars as longitudinal reinforcement. Prestressing strands had yield stress of 1672 MPa. ED bar had yield stress of 301 MPa. The effective prestressing force in PSC and PSCE are both 252 kN.

The parameters to define the hysteretic model in Figure 1 were identified from test lateral force-displacement curves as shown in Table 1. The comparison between the test results and hysteretic model modeling results were shown in Figure 3. The modeling had very high precision with test data, though some discrepancies existed in the post-yielding branches.

Table 1. Parameters identified from cyclic test.

Specimen	$k_c$ (kN/mm)	$k_p$ (kN/mm)	$\Delta_y$ (mm)	$\Delta_0$ (mm)	$\Delta_1$ (mm)	$\gamma$
SPC	2.22	0.063	9.45	7.37	2.90	0.235
SPCE	2.41	0.032	16.95	5.83	0.68	0.370

Figure 3. Quasi-static cyclic test modeling.

Figure 4. Selected ground motion input.

## 5 HISTORY RESPONSE MODELING

The design response spectra used for define the ground motion intensity was taken from AASHTO with a 7 percent exceedance in 75 years (1000 year return period) (AASHTO 2011). The acceleration response spectra was scaled with period scale factor of  $S_T = \sqrt{S_L} = 2.0$ , where  $S_L$  = the geometry scale factor. One typical history ground motion (Loma Prieta 1989 47125 Capitola 090 deg) was selected from PEER strong motion database. The ground motions were recorded on soil type C, and were generated

by the earthquake with a moment of magnitude of 6.9. The distance of the record stations to the nearest fault rupture was 14.5 km. Figure 4 (a) shows the scaled ground motion acceleration history. Figure 4 (b) shows the response spectra comparison between design and the scaled ground motion. Figure 5 shows the history responses of specimen SPC and SPCE under the selected ground motion excitation. The hysteretic model gave good prediction to envelope curve of specimens. The detailed hysteretic rules need more specimen tests validation under different loading protocols.

Figure 5. History response modeling.

## 6 CONCLUSIONS

A hysteretic model for unbonded posttensioned segmental columns was first validated through quasi-static cyclic loading tests, then was used for earthquake history response calculations. The following conclusions can be reached within the studies of this contribution.

1. The hysteretic model generally gave good prediction to quasi-static cyclic loading test lateral force-displacement cyclic responses. The hysteretic rules of peak orienting used in defining the model was more appropriate for segmental columns with ED bars than those only has unbonded prestressing tendons.
2. The envelope responses of specimens under ground motion were in accordance with cyclic loading test results, although the exact hysteretic rules need different loading path cyclic test validation in the future research work.

# The effect of convex friction distribution on the seismic performance of friction systems

B. Wei, T.H. Yang, X.D. Yu, P. Wang & L.Z. Jiang

*School of Civil Engineering, Central South University, Changsha, China*

*National Engineering Laboratory for High Speed Railway Construction, Changsha, China*

**ABSTRACT:** When the bearings were destroyed by the earthquake, a rough friction surface would be formed while the surrounding contact surface was smooth. The isolation condition of the damaged bearings, namely a convex friction distribution, was considered. By taking a friction-based isolation system as the study object, the effect of the convex distribution of friction coefficient on the structural isolation performance under different ground motions was analyzed by utilizing a compiled computer program. The results show that the convex distribution of friction coefficient almost always makes the structural maximum acceleration the largest and obviously increases the structural maximum relative displacement and the structural residual displacement. In general, it is unfavorable to the isolation system. Therefore, the convex distribution of friction coefficient should be avoided in the actual projects.

**Keywords:** bridge; isolation; friction; bearing; horizontal earthquake

## 1 INTRODUCTION

As to effectively isolate horizontal earthquake, several researchers have paid attention to the new isolation method based on friction. In order to avoid a five-floor RC frame structure building's earthquake damage subjected to soft soil earthquake in Mexico, Flores designed rolling ball devices. Ou et al. (2010) and Lee et al. (2010) designed a two-layer roller isolation device for use in highway bridges. Jangid (1998, 2000) first considered that elliptical rolling rods are more effective than rolling rods in reducing the seismic response of the structure, and then he considered that rolling rods with re-centering device also have an effective isolation performance. Guerreiro et al. (2007) invented a rolling-ball isolation system to protect light structures or other devices. Harvey & Gavin (2014) carried out a mathematical model and experimental validation for double rolling isolation systems, and the effects of the initial conditions, the mass of the isolated object, and the amplitude and period of the disturbance on the system's performance were assessed. As for some bridges, the bearings are often first destroyed by the earthquake. Although some designers considered that the destruction of bearings would protect other components of bridges from seismic damage, it lacks rigorous analysis. The stochastic damage of bearing will form a rough contact surface (Wei et al. 2015), i.e. a large friction coefficient exists. However, other contact surfaces are very smooth

with a less friction coefficient. Therefore, a natural isolation system with a convex distribution of friction coefficient is formed.

The objective of this paper is to investigate a friction isolation system and artificially interfere with the uneven distribution of friction coefficient to be convex, i.e. the friction coefficient in the center of the seismic isolation device is the largest one, and it gradually decreases along the surrounding path. Utilizing a numerical analysis method, we analyze the impact of the convex distribution of friction coefficient on the seismic performance under different ground motions.

## 2 CALCULATION PROCESS

### 2.1 Structure model

The study object of this paper, i.e. a friction isolation system, is shown in [Figure 1](#). In order to analyze the effect of the 'convex' distribution of friction coefficient on the seismic isolation performance in detail, this paper divides the friction coefficient and the earthquake input into several groups, and then obtains many combination cases.

As demonstrated in related studies, the isolated structure can be built as a rigid body since the stiffness of the isolation device is far less than that of the structure (Wei et al. 2014). So, in this paper, the superstructure is temporarily simplified to a rigid body. The superstructure mass is set to be 300 t.

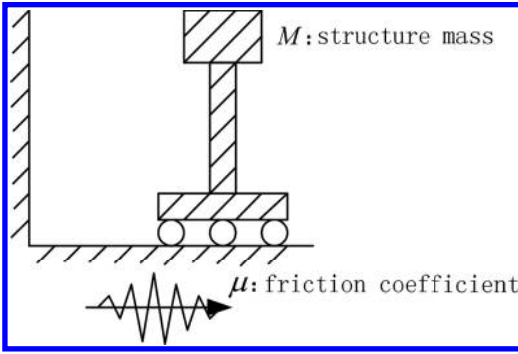

Figure 1. Structure model.

Figure 2. Four types of response spectrum.

For the convex friction distribution, the friction coefficient in the center of the isolation device is the largest one, which is assumed to be 0.03, and it gradually decreases along the surrounding path whose decrement ratios are assumed to be 0, 0.005, 0.010, 0.015, 0.020, 0.025 and 0.030, respectively.

### 2.2 Earthquake input

As shown in Figure 2, for each elastic response spectrum for the soil profiles I, II, III, and IV in Chinese criteria (JTJ 004-89), one accelerogram is generated by the Simqke procedure as the ground motion input of the structural model.

### 2.3 Calculation cases

For each case of the 6 friction distributions, each accelerogram in Section 2.2 is input as the ground motion, whose Peak Ground Accelerations (PGA) are adjusted to be 0.2, 0.4, 0.6 and 0.8 g, respectively. Hence, 112 cases are generated for further calculation utilizing a computer program (Wei et al. 2013).

In the following sections, only classical and common results are discussed in a detailed manner due to space limitations, while other results are considered but not listed.

## 3 STRUCTURAL ACCELERATION

Structural acceleration is considered for the isolated structure, as it directly indicates whether the earthquake will destroy the structure or not. Therefore, this section analyzes on the structural maximum acceleration.

Figure 3 shows the influence of the variability slopes of friction coefficient on the structural maximum acceleration for all cases in Section 2.3. As the slopes of friction coefficient variability increase, the maximum acceleration applied to the structure remains constant.

As for the isolation system based on friction, the acceleration that the ground motion transmits to the superstructure is  $\mu g$ . For the case of the “convex” friction distribution, although  $\mu$  varies regularly along with the position of friction surface, the maximum  $\mu$  appears at the original location of the structure. Thus, as soon as the structure starts moving under the earthquake, the acceleration reaches the peak point and gradually reduces as the structure moves away from the original location.

Therefore, for the case of the convex friction distribution, the maximum acceleration value depends on the friction coefficient value of the structural original location, and has no relation with the decrement ratio of the convex friction distribution or the earthquake situation.

The analysis results show that as the soil profiles and PGA of earthquake increase, the structural maximum acceleration remains constant, and the corresponding figures are omitted herein.

Figure 3. Effect of the decrement ratio of the convex friction distribution on the structural maximum acceleration.

## 4 STRUCTURAL RELATIVE DISPLACEMENT

### 4.1 The influence of the friction coefficient

For the isolation system, the structural relative displacement indicates whether the structure would leave away from its foundation, and whether the structure would collide with other things. This section and the following sections analyze the maximum relative displacement.

Figure 4 shows the influence of the decrement ratio of the convex friction distribution on the structural maximum relative displacement in the cases with soil profile III. On the whole, as the decrement ratio of the convex friction distribution increases, the structural maximum relative displacement increases gradually. The increasing trend is more significant when the PGA is larger.

In Figure 1, as for the cases of the convex friction distribution, when the ground velocity  $v_e$  is larger than the structural velocity  $v_s$ , the structural acceleration  $\mu g$  makes the structure have the tendency of moving forward, and there are two possibilities:

1. If the moving structure is on the left of its origin position, it means that the friction coefficient  $\mu g$  on the contact surface is decreasing, and the reduction of the structural acceleration  $\mu g$  is conducive to increasing the structural relative displacement.
2. If the moving structure is on the right of its origin position, it means that the friction coefficient  $\mu g$  on the contact surface is increasing, and the increment of the structural acceleration  $\mu g$  is conducive to increasing the structural relative displacement.

When the ground velocity  $v_e$  is smaller than the structural velocity  $v_s$ , the similar rules can be drawn.

Figure 4. Effect of the decrement ratio of the convex friction distribution on the structural maximum relative displacement with soil profile III.

In a word, the convex friction distribution is conducive to increasing the structural relative displacement.

### 4.2 The influence of earthquake

Figures 5 and 6 show the influence of the site type of soil profile and PGA on the structural maximum relative displacement in the cases with the decrement ratio 0.01 of the convex friction distribution.

In Figure 5, when the earthquake soil profile number increases, the structural maximum relative replacement also increases gradually. As for the larger PGA, this incremental trend is more evident.

In Figure 6, the structural maximum relative displacement increases with the PGA.

Figure 5. Effect of the site type of soil profile on the structural maximum relative displacement with the decrement ratio 0.01 of the convex friction distribution.

Figure 6. Effect of the PGA on the structural maximum relative displacement with the decrement ratio 0.01 of the convex friction distribution.

This incremental trend is more evident when the soil profile number increases.

A larger site type of soil profile or PGA means a larger absolute displacement of the ground motion, while the structural acceleration  $\mu g$  generated by the friction force  $\mu mg$  is a limited value. Thus, a larger site type of soil profile or PGA means a larger structural maximum relative displacement.

## 5 STRUCTURAL RESIDUAL DISPLACEMENT

### 5.1 The influence of the friction coefficient

The structural residual displacement should also be considered for the isolated structure, as it relates to the repair after the earthquake. Therefore, this section and the following sections analyze on the structural residual displacement.

Figure 7 shows the influence of the decrement ratio of the convex friction distribution on the structural residual displacement in the cases with soil profile III. The figure shows that the structural residual displacement is large.

As for the cases of the convex friction distribution in Figure 1, the structural motion direction after the ground motion just stops moving will influence the structural residual displacement:

1. If the structure moves away from the origin position, it indicates that the friction coefficient  $\mu$  on the contact surface decreases, which benefits on increasing the structural residual displacement.
2. Otherwise, it indicates that the friction coefficient  $\mu$  on the contact surface increases, which also benefits on increasing the structural residual displacement.

Figure 7. Effect of the decrement ratio of the convex friction distribution on the structural residual displacement with soil profile III.

Hence, the convex friction distribution outwardly increases the structural residual displacement.

However, as the structural residual displacement is just a special relative displacement when the structure stops moving, its value is naturally affected by that of the structural relative displacement. From the analysis in Sections 4.1 and 4.2, the influence factors on the structural relative displacement are so complicated that they have a sophisticated impact on the structural residual displacement.

Moreover, no matter in which direction the structure relatively moves to the original position, the existence of friction prevents the structure from moving. At this moment, the value of the friction coefficient is closely related to that of the structural relative displacement just as the ground stops moving. It may lead to the cases as follows:

1. If the structure moves away from the original position, and when the relative displacement is relatively large, the friction coefficient will be so small that it just faintly prevents the structure from moving away from the original position. However, as the relative displacement is relatively small, the friction coefficient will be large enough to effectively prevent the structure from moving away from the original position.
2. If the structure moves towards the original position, and when the relative displacement is relatively large, the friction coefficient will be large enough to effectively prevent the structure from moving towards the original position. However, as the relative displacement is relatively small, the friction coefficient will be so small that it just faintly prevents the structure from moving towards the original position.

Based on the comprehensive effect of the above-mentioned influence factors, the convex friction distribution may increase or decrease the structural residual displacement.

### 5.2 The influence of earthquake

Figures 8 and 9 show the influence of the site type of soil profile and PGA on the structural residual displacement in the cases with the decrement ratio 0.01 of the convex friction distribution.

In Figure 8, as the site type of soil profile becomes larger, the structural residual displacement first remains constant, and then increases.

In Figure 9, as the PGA increases, there is no obvious change rule. However, the structural residual displacement is large.

Figure 8. Effect of the site type of soil profile on the structural maximum relative displacement with the decrement ratio 0.01 of the convex friction distribution.

Figure 9. Effect of the PGA on the structural maximum relative displacement with the decrement ratio 0.01 of the convex friction distribution.

## 6 CONCLUSIONS

The convex distribution of friction coefficient almost always makes the structural maximum acceleration the largest and obviously increases the structural maximum relative displacement and the structural residual displacement. In general, it is unfavorable to the isolation system. Therefore, the convex distribution of friction coefficient should be avoided in the actual projects.

**ABSTRACT:** As for a bridge with damper, a friction and damper isolation system was formed after the fixed bearings were sheared off during an earthquake. And the spatial distribution of friction coefficient was convex due to the smooth surface around the roughly damaged bearings. By taking a friction and damper isolation system as the study object, this paper analyzes the impact of the convex distribution of friction coefficient on the structural isolation performance under different ground motions through a compiled computer program. The results show that the convex distribution of friction coefficient increases the structural maximum relative displacement and residual displacement. Although those responses can be weakened by the damper, the convex distribution of friction coefficient should be avoided in the actual projects.

*Keywords:* bridge; bearing; damper; friction; horizontal earthquake

### 1 INTRODUCTION

In 2014, many researchers have investigated the new friction-based isolation methods with the aim to get optimum seismic isolation performance. Harvey & Gavin (2014) carried out a mathematical model and experimental validation for double rolling isolation systems, and the effects of the initial conditions, the mass of the isolated object, and the amplitude and period of the disturbance on the system's performance were assessed. As for Harvey et al (2014), a simplified model presented in their paper was applicable to RISs with any potential energy function, was amenable to both lightly- and heavily-damped RISs, and was validated through the successful prediction of peak responses for a wide range of disturbance frequencies and intensities. Ismail & Casas (2014) investigated the Near-Fault (NF) seismic performance of a novel isolation system, referred to as the Roll-N-Cage (RNC) isolator, considering the cable-stayed Bill Emerson Memorial Bridge in Missouri, which showed that the RNC isolator was a convenient isolation system in protecting cable-stayed bridges against NF earthquakes. Wang et al (2014) studied the sloped multi-roller isolation devices for seismic protection of equipment and facilities and obtained an excellent in-plane seismic isolation performance.

And before 2014, these similar friction-based isolation devices were also paid attention by several famous researchers. In Japan, Kurita et al (2011) developed a new device for seismic response

reduction, and the peak acceleration amplitude was decreased by about 50–90%. Nanda et al (2012) in India considered that the base isolation in the form of Pure Friction (P-F), among all other isolation methods developed so far, was the simplest one, which could be easily applied to low cost brick masonry buildings. Furthermore, the P-F isolation is one of the best alternatives for reducing earthquake energy transmission to superstructure during strong earthquake.

Although the friction isolation device avoids seismic damages caused in structure, the induced displacement may be very large and difficult to control. Therefore, restoring devices, such as springs and dampers, are usually used to avoid excessive relative displacement and reduce the structural residual displacement. As for some bridges, the springs, such as the fixed bearings, are often firstly destroyed by the earthquake. Although some designers considered that the destruction of bearings would protect other components of bridges from seismic damage, it is lack of rigorous analysis. The stochastic damage of bearing will form a rough contact surface (Wei et al. 2015), namely a large friction coefficient exists. However, other contact surfaces are very smooth with a less friction coefficient. Therefore, a natural isolation system with a convex distribution of friction coefficient is formed. Combined with the damper, a convex-friction and damper system is obtained.

The objective of this paper is to investigate a friction and damper system and artificially interfere the uneven distribution of friction coefficient to

be convex, i.e. the friction coefficient in the center of the seismic isolation device is the largest one, and it gradually decreases along the around path. Utilizing a numerical analysis method analyzes the impact of the convex distribution of friction coefficient on the seismic performance under different ground motions.

## 2 CALCULATION PROCESS

### 2.1 Structure model

In order to analyze the effect of the ‘convex’ distribution of friction coefficient on the seismic isolation performance in detail, this paper divides the friction coefficient, the damping constant and the earthquake input into several groups, and then obtains many combination cases.

As demonstrated in the related studies, for the isolation structure, the structure is built as a rigid body since the stiffness of the isolation device is far less than that of the structure (Wei et al. 2014). So in the computer program, the superstructure is temporarily simplified to a rigid body. The superstructure mass is set to be 300t and the damping constants adopt 100, 200, 300, 400 and 500 kN·s/m, respectively.

For the ‘convex’ distribution of friction coefficient, the friction coefficient in the center of the seismic isolation device is the largest one which is assumed to be 0.030, and it decreases gradually along the around path whose decrement ratios are assumed to be 0, 0.005, 0.010, 0.015, 0.020, 0.025 and 0.030, respectively. They are the main analysis objects in this paper.

### 2.2 Earthquake input

As shown in Figure 2, for each elastic response spectrum for the soil profile I, II, III, and IV in Chinese criteria (JTJ 004-89), one accelerogram is generated by Simqke procedure to be the ground motion input of the structural model.

Figure 1. Structure model.

Figure 2. Four types of response spectrum.

### 2.3 Calculation cases

35 cases are obtained by combining 5 damping constants and 7 friction coefficients.

As for each case, each accelerogram in Section 2.2 is input as the ground motion, whose Peak Ground Accelerations (PGA) are adjusted to be 0.2, 0.4, 0.6 and 0.8 g, respectively. Thus, 560 cases are generated for the further calculation.

Then each case is calculated by the computer program (Wei et al. 2013).

## 3 STRUCTURAL ACCELERATION

### 3.1 The influence of friction coefficient

The structural acceleration is concerned for the isolated structure, as it directly indicates whether the earthquake will destroy the structure or not. Therefore, this section analyzes on the structural maximum acceleration.

Figure 3 shows the effect of the decrement ratio of convex friction distribution on the structural maximum acceleration. On the whole, as the decrement ratio of convex friction distribution increases, the structural maximum acceleration gradually decreases with some fluctuations. When the PGA is larger, the decreasing trend is more significant.

### 3.2 The influence of damping constant

Figure 4 shows the effect of the damping constant on the structural maximum acceleration. As the damping constant increases, the structural maximum acceleration gradually increases. When the PGA is larger, the increasing trend is more significant.

As demonstrated in the related researches, with regard to the general isolation structures, e.g. lead rubber bearing, as the structural period is close

Figure 3. Effect of the decrement ratio of convex friction distribution on the structural maximum acceleration with soil profile IV and damping constant 100 kN·s/m.

Figure 4. Effect of the damping constant on the structural maximum acceleration with soil profile IV and decrement ratio 0.03 of convex friction distribution.

to the seismic predominant period, increasing the damping constant of the isolation layer reduces the structural acceleration. As the structural period is much larger than the seismic predominant period, increasing the damping constant of isolation layer promotes a larger structural acceleration. The friction and damper isolation system doesn't have a fixed structural period, so it is approximately considered that the structural period is much larger than the seismic predominant period. And logically, just as illustrated in Figure 4, increasing the damping constant of the

isolation layer eventually increases the structural acceleration.

### 3.3 The influence of earthquake

Figures 5 and 6 show the effect of the site type of soil profile and the PGA on the structural maximum acceleration. As the site type of soil profile or the PGA is larger, the structural maximum acceleration gradually increases.

Figure 5. Effect of the soil profile on the structural maximum acceleration with damping constant 100 kN·s/m and decrement ratio 0.03 of convex friction distribution.

Figure 6. Effect of the PGA on the structural maximum acceleration with damping constant 100 kN·s/m and decrement ratio 0.03 of convex friction distribution.

## 4 STRUCTURAL RELATIVE DISPLACEMENT

### 4.1 The influence of friction coefficient

The structural relative displacement should be also concerned for the isolated structure, as it indicates if the superstructure will leave away from its foundation, and if the structure will collide with other things. Therefore, this section analyzes on the structural maximum relative displacement.

Figure 7 shows the effect of the decrement ratio of convex friction distribution on the structural maximum relative displacement. In general, as the decrement ratio of convex friction distribution increases, the structural maximum relative displacement gradually increases. When the PGA is larger, the increasing trend is more significant.

The convex friction distribution is conducive to increasing the structural relative displacement. Furthermore, as analyzed above, when the decrement ratio of convex friction distribution is larger, the structural maximum relative displacement increases as well.

### 4.2 The influence of damping constant

Figure 8 shows the effect of the damping constant on the structural maximum relative displacement. In general, as the damping constant increases, the structural maximum relative displacement gradually decreases. When the PGA is larger, the decreasing trend is more significant.

As the damper limits the structural relative velocity, it reduces the structural relative displacement. And as the damping constant is larger, this effect will be more significant.

Figure 7. Effect of the decrement ratio of convex friction distribution on the structural maximum relative displacement with soil profile IV and damping constant 100 kN·s/m.

Figure 8. Effect of the damping constant on the structural maximum relative displacement with soil profile IV and decrement ratio 0.03 of convex friction distribution.

Figure 9. Effect of the soil profile on the structural maximum relative displacement with damping constant 100 kN·s/m and decrement ratio 0.03 of convex friction distribution.

### 4.3 The influence of earthquake

Figures 9 and 10 show the effect of the site type of soil profile and the PGA on the structural maximum relative displacement. In general, as the site type of soil profile or the PGA is larger, the structural maximum relative displacement increases gradually.

A larger site type of soil profile or PGA means a larger absolute displacement of the ground motion while the structural acceleration  $\mu g$  generated by the friction force  $\mu mg$  is a limited value. Therefore, a larger site type of soil profile or PGA means a larger structural maximum relative displacement. As the damper is conducive to

Figure 10. Effect of the PGA on the structural maximum relative displacement with damping constant 100 kN·s/m and decrement ratio 0.03 of convex friction distribution.

reducing the structural relative displacement, the increment of the site type of soil profile or PGA will not significantly increase the structural relative displacement.

## 5 STRUCTURAL RESIDUAL DISPLACEMENT

The structural residual displacement is noted for the isolated structure, as it relates to the repair after earthquake. Therefore, this section analyzes on the structural residual displacement.

The results show that the convex friction distribution increases the structural residual displacement sometimes. The other three parameters, including the damping constant, the site type of soil profile and the PGA, have no obvious influence on the structural residual displacement. And the corresponding figures are not presented herein.

## 6 CONCLUSIONS

The convex distribution of friction coefficient increases the structural maximum relative displacement and residual displacement. Although those responses can be weakened by the damper, the convex distribution of friction coefficient should be avoided in the actual projects.

## Quasi-static finite element analysis of a precast concrete frame shear wall structure

Yue guo Zhang, Quan Zhong, Lian guang Jia & Wei jian Zhao  
Shenyang Jianzhu University, Shenyang, China

**ABSTRACT:** In order to research the overall seismic performance of a precast concrete frame shear wall structure, a three-floor three-span concrete frame shear wall is built as the calculation model. This paper, respectively, calculates the precast structure and cast-in-place structure under low cyclic loading using general finite element software ABAQUS, and makes comparison between the two structure models in hysteresis curves, deformation and energy dissipation performance. The analysis results show that the bearing capacity of the cast-in-place structure is more than that of the precast structure. In the stiffness degradation process, the lateral stiffness of the cast-in-place structure is greater than that of the precast structure. Compared with the cast-in-place structure, energy consumption of the precast structure is lower in late loading, while the ductility of the precast structure is better in the loading. Failure modes of the precast structure are different from the cast-in-place structure, some structural measures should be taken to guarantee safety in design.

**Keywords:** precast structure; frame shear wall; quasi static

### 1 INTRODUCTION

With the introduction of green, environmental-friendly, energy-saving building, the state vigorously promotes the “building industrialization, housing industry”. The study and application of prefabricated concrete structure has become a hot issue.

There have been numerous studies carried out abroad on the fabricated structure<sup>[1-3]</sup>. Research and practice of precast concrete structures at home mainly concentrated on the prefabricated shear wall structure<sup>[4,5]</sup>, mainly for residential construction. Prefabricated frame structure research<sup>[6-8]</sup> is aimed at the multi-layer structure. By using ABAQUS finite element software, this paper, respectively, analyzes the precast structure and the cast-in-place structure of a three-floor three-span concrete frame shear wall under low cyclic loading, and draws a difference between bearing capacity, stiffness, ductility and energy dissipation. So, we can give reference conclusions for further studies.

### 2 MODEL VALIDATION

ABAQUS is a powerful finite element software, which can analyze complex solid and structural mechanics problems, simulate a very large and complex numerical model, and deal with a highly

nonlinear problem<sup>[9]</sup>. However, it is necessary to choose the parameters for verification to establish the precast model and to ensure the accuracy and applicability of the parameters used.

The validation of the model proposed in this article is shown in [Figure 1](#). Model structure size, reinforcement conditions, boundary conditions and loading of the SW1 specimen have been reported in the literature<sup>[10]</sup>.

Concrete constitutive model for the selection of ABAQUS finite element software comes with the plastic damage model of concrete, concrete uniaxial compression, tensile stress-strain curve values, reported in appendix C in Design of Concrete

Figure 1. Validation of the finite element model.

Figure 2. Comparison between the curve of the finite element calculation and the curve of the experiment skeleton.

Structures (GB50010-2010). At the same time, we introduce damage factors and stiffness coefficient of restitution, which has been referred to in the papers of Nie Jianguo<sup>[11]</sup> and Zhang Jin<sup>[12]</sup>. Reinforcement constitutive selects the bilinear kinematic hardening model, considering the influence of the Bauschinger effect, and the strengthening modulus takes the value of  $0.01E_s$ .

The horizontal force-displacement skeleton curve of the finite element model under low cycle reciprocating loading and SW1 horizontal force-displacement skeleton curve were compared, as shown in Figure 2. The maximum error is less than 10%, indicating that the parameters of numerical simulation are selected accurately and can be applied to the analysis of the frame shear wall model in this paper.

### 3 OVERVIEW OF THE FRAME SHEAR WALL MODEL

#### 3.1 Specimen size and reinforcement

One structure is a three-floor three-span cast-in-place concrete frame shear wall structure (henceforth referred to as the cast-in-place structure), and the other is a three-floor three-span precast frame shear wall structure (henceforth referred to as the precast structure). Shear walls are decorated in the side span whose span is 2.1 m, and another two span is 3.3 m, each storey is 2.4 m high. Section dimensions of the column are  $400\text{ mm} \times 400\text{ mm}$ ,

while the beam is  $200\text{ mm} \times 400\text{ mm}$ , and the thickness of the shear wall is 200 mm. C30 concrete is used, steel bar of beams, columns, and walls adopt HRB400, stirrups using HPB300. Reinforcement of shear walls is the double two-way  $C10@200$ . Model structure layout and beams, columns sectional reinforcement are shown in Figure 3 and Figure 4.

#### 3.2 Split form of the precast model

Split form of the actual structure model is shown in Figure 5. Beams, columns and walls are precast, while the concrete of the joint core is cast. There is a latter pouring belt between walls and columns. In order to simplify the model, the contact surface is established between the precast components and cast nodes, so are shear walls and the beams on its upper part. The finite element analysis model is shown in Figure 6, where the dark solid line section is the position that defines the contact surface.

#### 3.3 The selection of the material constitutive relation

Cast-in-place structure and precast structure select the material constitutive relation whose validation has been verified in this paper, and which can be used in the finite element simulation analysis.

#### 3.4 Establishment of the finite element model

Both the analysis model of concrete and steel bar select measured values, reference [10], [13], [14]. Concrete unit adopts the C3D8R reduced integral unit and reinforced unit adopts the T3D2 truss unit, using the embedded relationship between the steel and concrete<sup>[15]</sup>. We consider mutual friction

Figure 3. Arrangement of the model structure.

Figure 4. Reinforcement of beams and columns.

Figure 5. Disassembling of the actual structure.

at the contact surface between the splices, obtaining a normal and tangential effect.

The axial compression ratio of the column is 0.4. Using the displacement load, the horizontal load applied displacement on three layers at the same time, and the loading points are located in

Figure 6. Disassembling of finite element analysis.

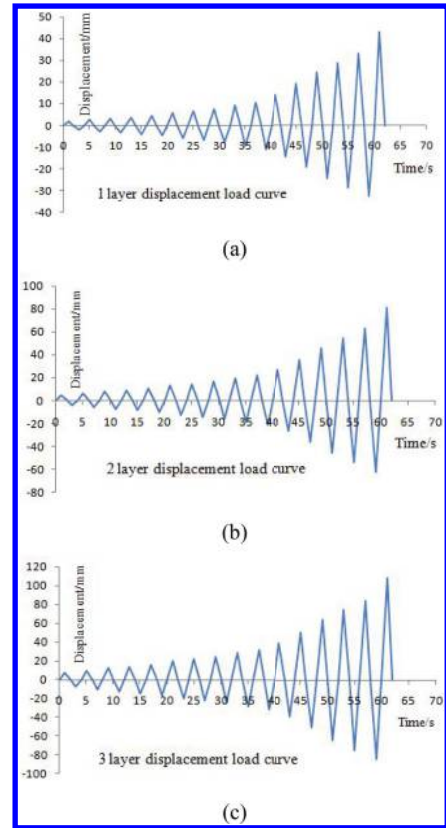

Figure 7. Curves of displacement loading.

the joints of the beams, columns on each shear wall side. Loading from the shear wall side to the side of the frame column is defined as the positive load, and vice versa for the negative load. Curves of displacement loading are shown in Figure 7.

## 4 FINITE ELEMENT ANALYSIS

### 4.1 ABAQUS stress analysis

For the precast structure, its yield first appeared in the longitudinal reinforcement in the shear wall, which assembled with beams together, and then the horizontal reinforcement of the shear wall yield. This is followed by the longitudinal reinforcement of the edge component of the shear wall yield, and the longitudinal reinforcement of each layer of the beam end yield. The last one is the longitudinal reinforcement of roots of the framework of the column yielding, stirrups yielding. There are differences between the precast structure and the cast-in-place structure observed from the failure mode. Necessary measures should be taken to ensure the safety for the failure mode of the precast structure in design.

von Mises stress at yield of concrete, and steel bar of the cast-in-place structure and the precast structure are shown in Figure 8 and Figure 9, respectively.

### 4.2 Hysteresis curve

The top load-displacement curves of the cast-in-place structure and the precast structure are shown in Figures 10 and 11. There are differences observed between the precast structure and the cast-in-place structure. The difference is that the surrounded area in the hysteretic curve of the precast structure is less than that of the cast structure, indicating that each hysteresis loop energy consumption of the precast structure is slightly lower than that of the cast structure. However, two hysteresis curves are relatively full, and there is no obvious “pinch shrinkage” phenomenon. This is because this article uses a separate modeling of ABAQUS, taking the embedded relationship between steel and concrete into account. The degree of freedom of embedded and embedding regions is fully constrained<sup>[6]</sup>, namely the bond and slip between steel and concrete are not consider completely. So, there is no obvious pinch effect, which is different from the actual structure hysteretic loading curve.

### 4.3 Analysis of capacity, ductility and deformation capacity

Displacement ductility coefficient, top limit displacement, yield displacement and corresponding yield and limit load of the precast structure and the cast-in-place structure of finite element analysis are listed in Table 1.

Displacement ductility coefficient of the specimens is the ratio of ultimate displacement to yield

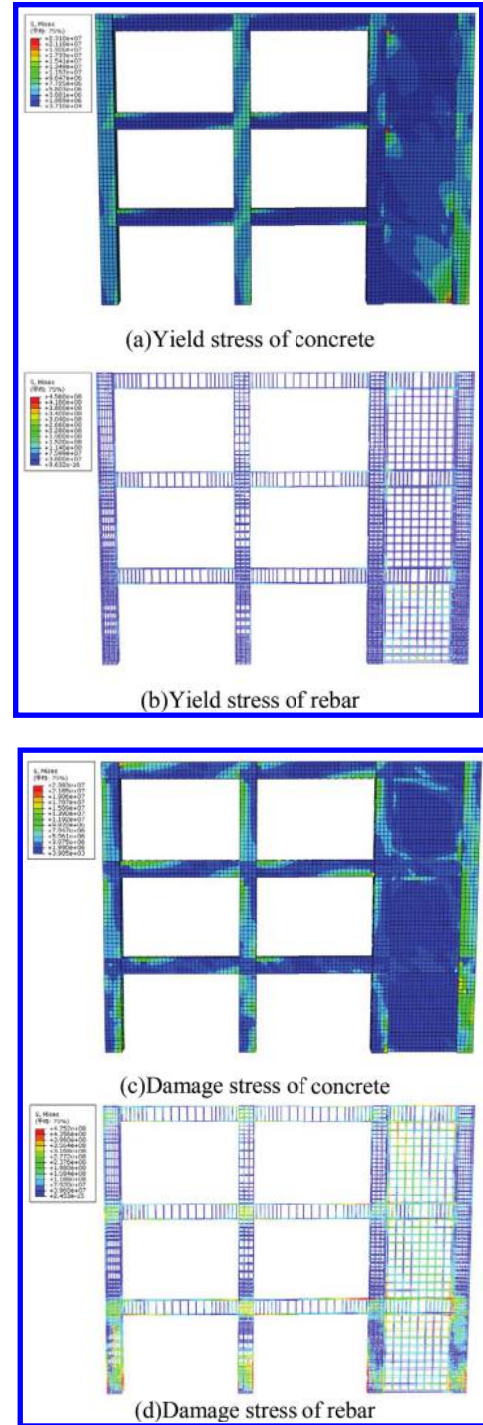

Figure 8. von Mises stress of concrete and rebar in the precast structure.

Figure 9. von Mises stress of concrete and rebar in the cast-in-place structure.

displacement, i.e.  $\mu = \Delta_u / \Delta_y$ . As can be seen from the table, the displacement ductility of the precast structure is superior to that of the cast structure. Yield load, peak load and ultimate load of the cast-in-place structure are higher than those of the precast structure.

#### 4.4 The stiffness degradation curve

To describe that the trends stiffness varies with displacement, the overall stiffness parameter is introduced. The overall stiffness of the specimen is the ratio of horizontal force to top displacement. Overall stiffness curves of the cast-in-place structure and the precast structure are shown in Figure 12.

By comparing the curve of overall stiffness degradation, we can see that the initial stiffness of the cast-in-place structure is greater than that of the precast structure, and in the process of loading, the stiffness

Figure 10. Top load-displacement curve of the cast-in-place structure.

Figure 11. Top load-displacement curve of the precast structure.

Table 1. Load and displacement of feature points and displacement ductility factor.

Structure	Direction of load	Yield load (kN)	$\Delta_y$ (mm)	Peak load (kN)	$\Delta_m$ (mm)	Ultimate load (kN)	$\Delta_u$ (mm)	$\mu$
Cast-in-place structure	Positive	954.074	14.134	1283.58	39.260	1091.043	79.384	5.62
	Negative	837.959	10.061	1199.07	39.588	1161.400	72.156	7.17
Precast structure	Positive	817.269	12.308	1134.87	50.923	964.640	77.030	6.26
	Negative	636.788	10.063	1086.54	51.064	1015.960	74.810	7.43

Figure 12. The overall stiffness contrast.

Figure 13. Comparison of energy consumption.

of the cast-in-place structure is always greater than that of the precast structure, which is caused by the characteristics of the precast structure. Whether it is the cast-in-place or the precast structure, the stiffness of the cast-in-place and the precast structure is reduced with loading, is close in late loading.

#### 4.5 Capacity of energy dissipation

In order to calculate energy consumption of the structure, we calculate the area of the hysteresis

loop with origin software. Energy consumption of the cast-in-place and the precast structure is shown in Figure 13.

We can see that in late loading, each loading cycle's energy consumption of the precast structure is lower than that of the cast-in-place structure. The reason is that the precast structure uses frictional contact at the junction, and there is mutual slip. Without considering the slip of steel in the process of simulation, the actual energy consumption is smaller, as shown in Figure 13.

## 5 CONCLUSION

1. Only considering the impact of the contact face, failure mode of the precast structure is different with the cast-in-place structure. Steel yielding of the precast structure first appeared in the longitudinal reinforcement of the shear wall, and then the horizontal reinforcement of the shear wall yield. This is followed by the longitudinal reinforcement of the edge component of the shear wall yield, and longitudinal reinforcement of each layer of the beam end yield. The last is the longitudinal reinforcement of roots of the framework of the column yielding, stirrups yielding.
2. The bearing capacity of the precast structure is lower than that of the cast-in-place structure. However, displacement ductility of the precast structure is better than that of the cast structure.
3. Lateral stiffness of the precast structure is smaller than that of the cast-in-place structure in early loading. Stiffness of the cast-in-place and precast structure is reduced with loading, but the stiffness of the cast-in-place structure is always greater than that of the precast structure.

X.X. Tao

Harbin Institute of Technology, Harbin, China

**ABSTRACT:** The time-averaged shear-wave velocity to a certain depth is an important parameter, which is used in seismic building codes and the Ground Motion Prediction Equation (GMPE). However, the main distinction is the different calculating depths. The relations between the shear-wave velocity to the depth less than 30 m  $V_{SZ}$  and that to the depth 30 m  $V_{S30}$ , developed by profiles in California and Japan, are verified by the data in China. The shear-wave velocity structures to shallow depths (<10 m) are found to be similar between California and Japan, through comparing the shear-wave velocity structure and the variation gradient of velocity. The velocity profiles obtained from the borehole measurements in California, Japan and China are adopted. The implication is that the sites in Japan are stiffer than the ones in California. The variation of the shear-wave velocity structure and the gradient variation of velocity are greater in the database of China. Surface sediments, soil physical properties and other factors are significantly different in these three regions. Therefore, it is not appropriate to estimate  $V_{S30}$  from  $V_{SZ}$  in China by the regression models from the databases of California and Japan.

### 1 INTRODUCTION

The time-averaged shear-wave velocity  $V_S$  is a crucial factor in classifying sites in seismic codes (e.g., Dbry et al., 2000; BSSC, 2001; Eurocode 8, 2004 et al.). There are various calculating depths of  $V_S$  in different seismic codes of different countries, caused by construction cost, engineering technology, built environment and other factors. The average shear-wave velocity to a depth of 30 m,  $V_{S30}$ , is used in the National Earthquake Hazards Reduction Program (NEHRP 2009). Seismic ground motion parameter zonation map of Japan (2009) states that the calculating depths of the average shear-wave velocity are to the soil layer with a shear wave velocity more than 400 m/s. In the code for seismic design of building of China (2010), a smaller value between the overlaying depth (the surface to the soil layer with the shear-wave velocity greater than 500 m/s) and 20 m is used. The calculating depth is usually less than 30 m. Even in the USA, the calculating depth does not extend to 30 m, restricted by site conditions in some cases. The average shear-wave velocity to

a depth  $Z < 30$  m  $V_{SZ}$  can be calculated by using Equation (1):

$$V_{SZ} = \frac{Z}{\sum_{i=1}^n \frac{Z_i}{V_{Si}}} \quad (1)$$

where  $Z_i$  is the thickness of the  $i$ th soil layer in the calculating depth  $Z$  (m);  $V_{Si}$  is the shear-wave velocity of the  $i$ th soil layer (m/s); and  $n$  is the number of soil layers.

The time-averaged shear-wave velocity to 30 m ( $V_{S30}$ ) has a number of applications in the field of engineering seismology. Some researchers have attempted to establish the relationship between  $V_{S30}$  and the average shear-wave velocity  $V_{SZ}$  to the depth  $Z$  ( $Z = 5$  m–29 m), especially in California and Japan with rich borehole data. Boore (2004b) established the log-linear model between  $V_{S30}$  and  $V_{SZ}$  using shear-wave velocities to the depths not less than 30 m, based on 135 California borehole data. Kanno et al. (2006) obtained a  $V_{S20}$ - $V_{S30}$  relation by KiK-net borehole data to the depth, and it can be used to extend  $V_{S20}$  in the K-NET stations

to  $V_{S30}$ . Cadet & Duval (2009) proposed the linear regressions of the logarithmic values of  $V_{SS}$ ,  $V_{S10}$  and  $V_{S20}$  with  $V_{S30}$ , which agree with those proposed by Boore (2004b), and applied to some European borehole data, whose standard deviation is smaller. Thus, Cadet & Duval (2009) concluded that the relations from the KiK-net database were adaptable to those from the non-Japanese data available for their study. Boore (2011) considered that the correlation for  $Z < 30$  m that was proposed by Boore (2004b) is unfit to Japanese data by comparing the shear-wave structure and the variation gradient of velocity from Japan, California, Turkey and Europe, and proposed the logarithmic quadratic polynomial model of  $V_{SZ}$  with  $V_{S30}$  by KiK-net data.

The 134 borehole data in California, 606 borehole data from KiK-net stations, used in this paper, are similar to those proposed by Cadet & Duval (2009) and Boore (2011). The 577 borehole data in China to a depth more than 30 m are used to discuss the suitability of empirical relations, developed by data from California and KiK-net stations.

## 2 THE COMPARISON OF THE REGIONAL DATABASE

The 134 borehole data in California, 606 borehole data from KiK-net stations and 577 borehole data in China to a depth more than 30 m are used and divided into 12 groups by the interval of 100 m/s, to compare the structures of these databases. The histogram of the proportion of each group is shown in Figure 1 to depths of 5 m, 10 m, 20 m and 30 m.

As shown in Figure 1, to a shallow depth (< 10 m), the shear-wave velocity structures of California and Japan are similar; to a deep depth (> 10 m), the shear-wave velocity structures are different. There is a great difference between the Chinese data and those from California and Japan.

The correlation coefficients of  $V_{SZ}$  with  $V_{S30}$  from 5 m to 29 m are calculated for these three sets, respectively, as listed in Table 1 and shown in Figure 2.

From Table 1 and Figure 2, we can see that the correlation coefficient increases with depth, the change in curve slopes from California is similar to that from Japan. However, the increase in the curve slope from Japan is faster than that from California, which indicates that the gradient change in the sites in Japan is greater than that in California, and that the near-surface soil layer of the former is stiffer than that of the latter. These curves are significantly different from the curve from China, which demonstrates that the statistical relations from the data of Japan and California are unfit to Chinese sites.

Cadet & Duval (2009) argued that the statistical relation from KiK-net data could be used for some non-Japanese sites. Both this model and the models

Figure 2. Correlation coefficient with depth.

of Boore (2004b) and Boore (2011) are employed to estimate  $V_{S30}$  by  $V_{SZ}$ , which are compared with the  $V_{S30}$  from borehole measurements. Mean values and standard deviations are shown in Figure 3.

From Figure 3, it can be seen that the standard deviations of Japan and California are similar, and their mean values are different obviously. The mean values and standard deviations of Chinese data are greater than those of Japan and California. The mean value from Europe is close to that from California; however, the difference in the standard deviations of Europe and California is great. It indicates

Figure 3(a). Mean values and standard deviations of the residuals between the estimated values (Boore model, 2004b) and the borehole measured values.

Figure 3(b). Mean values and standard deviations of the residuals between the estimated values (Cadet & Duval model, 2009) and the borehole measured values.

Figure 3(c). Mean values and standard deviations of the residuals between the estimated values (Boore model, 2011) and the borehole measured values.

that the statistical relation using the data of Japan and California is unfit to China, and that the statistical regression method has regional characteristics.

### 3 CONCLUSION

Three databases, including 134 borehole data in California, 606 borehole data from KiK-net stations from Cadet & Duval (2009) and Boore (2011), and 577 borehole data in China to a depth more than 30 m, are used to discuss the suitability of empirical relations, developed by data from California and KiK-net stations. The histogram of the proportion of each shear-wave velocity group to the depths of 5 m, 10 m, 20 m and 30 m and the correlation coefficients of  $V_{S30}$  with  $V_{SZ}$  ( $Z = 5\text{ m} \sim 29\text{ m}$ ) shows that the site conditions of Japan and California are similar, but the sites in Japan are stiffer than those in California, and that of China is obviously different from those of the other two countries. So, the statistical relation using the data of Japan and California is unsuitable for China.

Three statistical models are adopted to estimate  $V_{S30}$  from  $V_{SZ}$ . The mean values and standard deviations of the residuals between the estimated values and the borehole measured values show a great difference among these three databases. It can be inferred that the statistical regression results are regional, and it is not fit to the Chinese data.

### ACKNOWLEDGMENTS

The authors thank Associate Professor LIU Hongshuai for providing a part of Chinese borehole data. This work was financially supported by the National Nature Science Foundation of China (51178435 and 51478443).

# Structural dynamic anti-seismic performance analysis on the main machine hall in conventional island of Tianwan nuclear power station unit 5, 6

Yu-hao Jin, Jie Zhao & Gui-xuan Wang

*Dalian University R&D Center of the Civil Engineering Technology, Dalian, China*

**ABSTRACT:** Development of nuclear power has great significance to energy saving and optimizing energy structure in China and, therefore, much attention has been paid to the safety of nuclear power buildings. However, the research of the building's seismic performance is not enough at present. On the basis of the existing research, this paper used SAP2000 and ANSYS for elastic analysis and elastic-plastic deformation analysis of a severe earthquake on one main workshop in conventional island (pushover analysis), which analyzed the periods, modes and floor displacement angle among layers of main structure component, protracted capacity spectrum-demand spectrum curve and got a more complete dynamic response of structures from elasticity to elastic-plastic phase. Under a more severe earthquake, the response spectrum analysis and time—history analysis indicated that the structural seismic performance was good. Periods and vibration modes of the structure and the interlayer displacement angle of the elastic stage met the specification requirements. Under the strong seismic action, the static elastoplastic pushover analysis showed that the performance point that was obtained by the intersection of the demand spectrum curve and capacity spectrum curve appeared early, and was in the elastic range of the power spectrum, and structural seismic performance met the specification requirements. The analysis process for the anti-seismic performance analysis of main plant building in a normal island and other major construction projects has a certain reference and practical value.

**Keywords:** conventional island; anti-seismic performance; elastic analysis; elastic-plastic deformation analysis; pushover analysis

## 1 INTRODUCTION

Nuclear power has become an important energy for human use, and is an important part of the electric power industry. Its economic and social benefits are very significant. In recent years, safety accidents of nuclear power buildings have occurred many times (e.g., Chelo Bailey, Fukushima nuclear power plant), which not only caused serious economic losses, but also had a great influence on the society and the human mind. So, the safety of nuclear power building becomes the focus of attention. At present, the domestic and foreign research on the seismic performance of the conventional island nuclear power plant is not sufficient, and research still remains in the analysis of seismic performance of thermal power plant, which obtained some research results. For example, Liu zhiqing<sup>[1]</sup> studied on the seismic behavior of the frame bent hybrid structure of SRC columns—RC shear walls for the main building of thermal power plants. Shan liang<sup>[2]</sup> used the PKPM to research on the seismic performance of thermal power plant.

Wu tao<sup>[3]</sup> conducted an experimental study on the seismic behavior of RC bent structure of a large-scale power plant. These studies have to a certain degree demonstrated the seismic performance of this type of buildings and drew some conclusions, but lacked elastic-plastic deformation analysis<sup>[4]</sup>. Zhang qin<sup>[5]</sup> carried out a performance-based seismic design of nuclear plant, which is a trend for earthquake-resistant design. But this design has not been widely used because some problems still need to be studied and improved. The current specification<sup>[6][7]</sup> also lacks of relevant provisions of seismic design for the conventional island of nuclear power.

Therefore, using the structural analysis software SPA2000 and ANSYS, we carry out an analysis on the seismic performance of the conventional island of Tianwan Nuclear Power Station Unit 5, 6 to study on the deformation characteristics of the main plant system in the elastic stage and the plastic stage, and to discuss the stress of the conventional island under different earthquake scenarios. Thus, we provide the necessary basis to further

study on the seismic performance of the conventional island of nuclear power plant.

## 2 SEISMIC ANALYSIS METHODS OF STRUCTURE

Seismic analysis methods of structure include response spectrum analysis and time history analysis. The response spectrum analysis<sup>[8]</sup> is based on the modal decomposition response spectrum theory. This is only a common calculation method of structural dynamic response that is limited to the linear elastic structure under earthquake action. The first step is to use the reciprocal theorem (Betty theorem) to get the modal orthogonality so that we can break the vibration partial differential equations of multiple degrees of freedom into ordinary differential equations of the single degree of freedom system, which can achieve the displacement response of structure solution.

Time history analysis<sup>[9]</sup> is a kind of advanced analysis method in seismic analysis of structures, including linear elastic time history analysis and elastic-plastic time history analysis. The elastic-plastic time history analysis can be divided into static elastic-plastic time history analysis and elastic-plastic time history analysis. Dynamic elastic-plastic time history analysis inputs the earthquake acceleration data into the structure. According to the structural dynamic equations, we can solve the seismic response of structures by the numerical method. However, this method often needs more time and energy. The pushover method<sup>[10]</sup> is plastic static analysis under monotonic loading, which applies lateral force to the analysis model in some way of simulating seismic horizontal inertia force that gradually increases. If the structure fractures or yields, changing the stiffness parameters makes the structure reach a predetermined state. The horizontal load distribution form is as follows: bottom shear, first mode of structure, and modal decomposition of response spectrum<sup>[11]</sup>. Time history analysis is generally used only for important buildings and very complex buildings.

## 3 PROJECT OVERVIEW

In this paper, the conventional island of Tianwan Nuclear Power Station Unit 5,6 is taken as the research object. The workshop is 108 m long and the total span is 59 m. The structure of distribution is as follows. The cast-in-place reinforced concrete frame structure is composed of a steam room and an auxiliary room, the vertical axis (A,B,C) uses a frame structure;  $\pm 0.000$  m and 8.500 m platforms

of the steam room are the cast-in-place reinforced concrete structure, so the gable is less than 8 meters. The gable near the island sets the main steam pipe swinging proof structure, and the anti-rejection structure adopts the shear wall structure.

This structure is a semi-basement structure. Seismic grade is class one and the structure arrangement is very irregular. The load varies and the distribution of quality is very uneven. The effect of nuclear power equipment in the main building for structural seismic performance cannot be ignored<sup>[12]</sup>. In addition to the elastic analysis of the structure, plastic deformation analysis under the rare earthquake is also needed. According to the drawings and load data of the conventional island, SAP2000 and ANSYS are used for elastic analysis and elastic-plastic deformation analysis.

## 4 THE MAIN BUILDING MODEL

### 4.1 Input conditions

The design of load conditions of this project is as follows: (1) constant load, mainly the weight of the structure; (2) process load, including pipeline lifting, weight of equipment, maintenance of crane load; (3) crane load from four directions; (5) earthquake, considering torsional effect; (6) whipping loads of the main steam pipeline and main water supply pipeline; and (7) floor live loads and roof live load.

The seismic fortification intensity is 7 degrees and of the third earthquake group. The earthquake acceleration is 0.10 g and the site category is the second. The surface design ground motion parameters are listed in Table 1.

### 4.2 The main building model

During the establishment of the SAP2000 model, the beam-column element is imitated by the truss element. The node is rigid and the floor is the elastic shell element. Steel structure beams are all articulated and the concrete side wall around the main building is applied to the soil pressure; Eccentric setting is for all surface elements and beam elements, considering the actual elevation of the structure.

Table 1. The surface design ground motion parameters.

Earthquake level	Peak acceleration (cm/s <sup>2</sup> )	$\alpha_{max}$	T <sub>g</sub>	Damping ratio
Frequent	35	0.08	0.45	0.05
Rare	220	0.50	0.45	0.05

In the ANSYS analysis model of three-dimensional calculation, roof truss structure is simulated by link8. Beam189 is used to show the beam-column component. Shell99 is used to simulate all the surface shell elements. The three-dimensional model of the structure is shown in Figure 1 and Figure 2.

## 5 A SEISMIC ANALYSIS OF THE MAIN BUILDING STRUCTURE

### 5.1 Period and mode of vibration

In a given design ground motion, Table 2 lists the vibration period of the main plant structure. It can be seen that the first natural vibration period T1 and the second natural vibration period T2 of the structure calculated by using the SAP2000 and ANSYS models are dominated by translation. The natural vibration period T3 reverses, and

Table 2. Structure natural vibration periods of the main machine hall in the conventional island.

Item	Period	
	SAP2000	ANSYS
<i>Natural vibration period of structure</i>		
T1	1.082	1.091
T2	0.998	1.052
T3	0.891	0.905
T4	0.849	0.544
T5	0.464	0.492
T6	0.458	0.484
T7	0.419	0.458
T8	0.407	0.402
T9	0.396	0.389
T10	0.393	0.388
Torsional/translational	T3/T1 = 0.82	T3/T1 = 0.83

Table 3. Computing mode number and quality of modal participation factor.

Item	Period			
	SAP2000		ANSYS	
	Number of modes		Number of modes	
<i>Calculation of the number of modes and mode participation mass ratio</i>				
X	80	97%	80	99%
Y	80	98%	80	99%

T3/T1 is less than 0.9, meeting the “Technical specification for concrete structures of tall building” requirements.

The effect of higher modes of the seismic design of the building structure cannot be ignored. When the base shear and top displacement error is less than 5%, the cumulative mass participation ratio should be greater than 90% stipulated by the “Technical specification for concrete structures of tall building”. Table 3 gives the calculation of the number of modes and mode participation mass ratio. It can be seen from the table that up to 80 order vibration mode, the modal mass coefficient reaches 90%, meeting the requirements of the specification.

Vibration is the relative displacement of each particle when the free vibration occurs in the structure, which could be used to determine whether the structure system layout is reasonable or not. The first three modes of the structure are as follows: 1 translation, 2 translation, and 3 reverse. If the

torsional mode is premature, it is unfavorable to the seismic behavior of the building.

### 5.2 The elastic layer displacement angle under frequent earthquake

Under the influence of wind load and earthquake, the interlayer displacement angle of the main plant structure can meet the requirements of the specification (1/550). The interlayer displacement angle of the structure is given in Table 4.

### 5.3 The overall stability of structures in the elastic stage under frequent earthquake

The calculation results show that each layer frame ratio of stiffness to weight is greater than 10, which meets the standard requirements for the overall stability. When the ratio of stiffness to weight is greater than 20, it is unnecessary to consider the two-order effect. The ratio of stiffness to weight is given in Table 5.

### 5.4 The elastic-plastic deformation analysis under the rare earthquake

The seismic grade of the main building structure in this project is level 1, and the structure is irregular. The elastic-plastic deformation analysis

under the rare earthquake should be conducted after the elastic analysis. The pushover analysis in the structural model is built in SAP2000 (Pushover Analysis).

In the architecture of SAP2000, the specific reinforcement of beams and columns is made according to the reinforcement scheme to design the specific parameters of the plastic hinge. Moment rotation curve relationship of double section beams is worked out by the section size and reinforcement arrangement in the section designer, and then input the number to joint design parameters, the analysis results of which are as follows. From the spectrum-demand spectrum curve to capacity in the X axis and the spectrum-demand spectrum curve capacity in the Y axis<sup>[13]</sup>, it can be known that the performance point appears earlier and is in the elastic range capacity spectrum, which indicates that the structure has a good seismic performance of reserves and meets the standard requirements of fortification.

From the performance point of the structure, we can obtain vertex displacement corresponding to the structure according to formula (1), which can reflect the deformation structure under the rare earthquake:

$$S_d = \frac{\Delta_{top}}{\gamma_1 X_{top,1}} \quad (1)$$

According to the specification, we calculate the structure angle of floor displacement and test the structure to satisfy the deformation requirement of large earthquakes. The performance point of the interlayer displacement angle is given in Table 6.

It can be seen from Table 6 that the maximum drift angle is 1/242, which meets the specifications of the reinforced concrete frame structure elastic-plastic displacement angle limit of 1/50 requirements under the rare earthquake. At the same time, the calculated maximum displacement of the top layer is 0.112 m, which is far less than the  $1/50 \times 33 = 0.66$  m vertex lateral displacement limit, meeting the requirements of the specification.

After the determination of the structure that meets the earthquake deformation, the judgment

of weak structural layer can be made based on the distribution of the structural components of the plastic hinge. Observation of performance point hinge<sup>[4]</sup> is shown in Figures 3 and 4.

Figure 5 shows the hinge state graph. In the pushover analysis in X, framework beams and columns located in the performance of point are still in the A-B elastic stage, with no plastic hinge. In the pushover analysis in Y, the plastic hinge appeared in the end of the beam located in the performance of the main points, where the structure is in the elastic yielding stage, at the point B on the hinge state graph. Hinge is in beam ends that meet the seismic code “strong column and weak beam” seismic design concept in the structure. So, it satisfies the requirements of the local deformation component requirements.

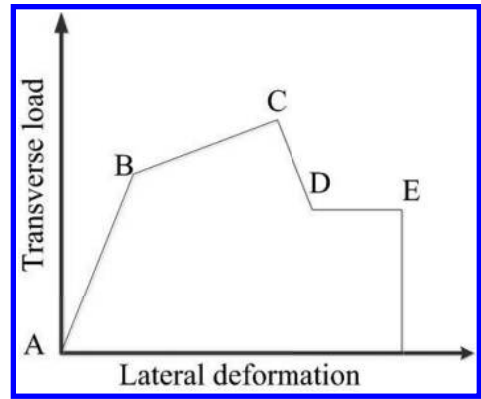

Figure 5. Hinge state curve.

## 6 CONCLUSION

Using the SAP2000 and ANSYS models, we carry out the analysis on the main building structure in Tianwan Nuclear Power Station Unit 5 and 6, obtaining the structural dynamic response under different effects of earthquake. We then compared the elastic response under frequent earthquake and time history analysis, and conducted plastic deformation analysis under severe earthquake. On this basis, the results showed that:

1. Under the frequent earthquake, response spectrum analysis and time history analysis show that the structural seismic performance is good. The cycle and vibration mode of the structure and the elastic layer displacement angle can meet the requirements of the specification.
2. The pushover analysis under the rare earthquake shows that the performance point that is from the intersection of the demand spectrum and the response spectrum appears earlier. The seismic performance of the structure can meet the requirements of the specification.
3. Hinge is in the beam ends, which meets the seismic code “strong column and weak beam” seismic design concept in the structure. So, it satisfies the requirements of the local deformation requirements.

# Behavior of steel double-channel built-up chords of special staggered truss steel frames structure under reversed cyclic bending

H.D. Ran & W.L. Liang

*School of Civil Engineering of Xi'an University of Architecture and Technology, Xi'an, China*

**ABSTRACT:** Finite element results from the tests of eight cantilever double-channel built-up members under reversed cyclic bending are presented. The main parameters investigated were stitch spacing, lateral bracing spacing, depth-thickness ratio of web and setting stiffeners. The moment-drift hysteretic loops, skeleton curves, the moment and drift values for different loading stages and seismic behavior index were obtained. According to these curves, the failure characteristic, ductility, and energy dissipation capacity of this type of structure were analyzed in this paper. The results indicate that the cantilever double-channel built-up members have good hysteretic behaviors. The reduction in stitch spacing can prevent lateral-torsional buckling of individual elements. A thicker web improves the bearing capacity. The stiffeners limit the buckling of web and flange, as well as improve hysteretic energy of the member.

**Keywords:** cantilever double-channel built-up members; reversed cyclic bending; hysteretic behavior; finite element

## 1 INTRODUCTION

As economic, efficient, the staggered truss frame system was a line with the development direction of Chinese steel buildings [1–2]. Because of the advantages, domestic and foreign scholars have done a lot of research. The results indicate that composite staggered truss frame steel structure under reversed cyclic bending, the developing sequence of plastic hinges was truss web members→truss chords→column [3], which was adverse to the seismic performance of structure. This paper proposed a method to promoted performance of the composite staggered truss frame, that is, chords were used as special segments to dissipate energy by yielding, and other members of structure remain elastic. This method improved the overall seismic performance of structures. With its rational use of material, high stiffness and well preventing lateral-torsional, steel built-up members were often used in earthquake-resistant structures or chord members in special truss girders. As the less study about double-channel built-up members' flexural performance, the research on double-channel built-up members under reversed cyclic bending has important practical significance in the hysteretic behavior.

## 2 MODEL OVERVIEW

A three-dimensional finite element model of the tested system has been developed via the Finite

Element Package ABAQUS to detect in detail the local and global behavior of the base connection. The finite elements used for the discretization are brick-type solids with 8 nodes (C3D8R). The channels, gussets and stitch plates were made of Q235, while modulus of elasticity  $E_s = 2.06 \times 10^5$  MPa, Poisson's ratio  $\nu = 0.3$ , and yielding strength  $\sigma_y = 235$  MPa. Material constitutive relation obeyed the ideal elastic-plastic material.

## 3 DESIGN OF SPECIMENS

The cantilever specimens would represent the chord member between the end of the special staggered truss steel frames structure (fixed end in test specimen) and midspan point of inflection of the special staggered truss steel frames structure (free end in test specimen) (Fig. 1). The load P in term of displacement acted on 200 mm below the free end. There were restraint about x, y and z direction on the ends of grade beam, as well as x direction on the loading point.

This paper consisted of testing of eight cantilever double-channel built-up members under reversed cyclic bending. Each specimen consisted of a gusset plate, and a double-channel built-up member made of either 2-C25a or 2-C25c sections. Figure 2 were the layout and geometrical sizes of specimens. There was no provisions about double-channel built-up members under bending on code for design of steel structures [4] (GB50017-2003).

Figure 1. Location of specimens and plastic hinge.

Figure 2. Layout and geometrical sizes of specimens.

Specimens 1–4 consisted of a 2-C25a built-up member, while the distance of stitch spacing was  $40i$ ,  $30i$ ,  $20i$ ,  $10i$ , respectively. Where  $i$  was the individuals' radius of gyration to weak axis. The four elements are designed such that buckling of the entire brace occurs prior to buckling of the

Figure 3. Displacement history.

individual members. Specimen 5 consisted of a 2-C25c built-up member, while the distance of stitch spacing was  $10i$ . It was setting stiffeners between the first stitch and 30 mm above the gusset plate. The distance of stiffeners was 50 mm. Specimen 6 was “identical” to Specimen 5, except for a reduced stiffener spacing of 40 mm, which could prevent local buckling of web and flange. Specimen 7 featured the same details as in Specimen 6, but was changed C25a. Based on specimen 6, specimen 8 set restraint about x direction on the first stitch. That could ensure the stable of members to study variations of depth-thickness ratio on member's behavior. The lateral bracing on specimen 8 met the chapter 8.5.5 on Code for seismic design of buildings [5] (GB50011-2010).

The method of cyclic displacement loading was based on specification of testing methods for earthquake resistant building [6] (JGJ 101-96) (Fig. 3).

#### 4 TEST RESULTS

The displacement was the horizontal displacement of loading direction. Conveniently, Rotation (rad) = displacement (mm)/1200 (mm).

Yielding of the channels in Specimen 1 was noticed at early stages of the test (about 4.25 mm) and spread over approximately 100 mm above the gusset plate during the later loading cycles. Lateral-torsional buckling of the individual channels was first noticed during the  $3\Delta_y$  cycles. This lateral-torsional buckling became severe during the cycles at  $10\Delta_y$  cycles, which ultimately led to the termination of the test. Specimen 2 showed a very similar response compared to Specimen 1 with a short stitch spacing of  $20i$ , but for yielding drift of 8.51 mm. Specimen 3 showed no deterioration of strength up to 8.72 mm. At  $4\Delta_y$  stage, slight local buckling in the channel web was observed, and failure due to lateral-torsional buckling of individuals occurred during the  $10\Delta_y$  (Fig. 4). A reduced center-to-center stitch spacing of 224 mm ( $10i$ ) was provided in Specimen 4. Yielding in the channels

Figure 4. Lateral-torsional buckling of individuals.

Figure 5. Local buckling of web.

of Specimen 4 was first noticed at approximately 8.75 mm and spread over 100 mm above the gusset plate during 17.5 mm cycles. It had higher bearing capacity and hysteric energy compared to Specimen 3. For the cycle to 96.25 mm ( $11\Delta_y$ ), the maximum moment of specimen 4 dropped to 86% of extreme moment. For the cycle to 100 mm, the maximum moment dropped to 85% of extreme moment, while flange and web severe buckling (Fig. 5). The reason for dropped bearing moment

Figure 6. Local buckling of flange.

was local buckling of flange and web. FEM and analysis indicated that the individuals could act as a member to bear load for the stitch spacing of 10i.

Yielding of the channels in Specimen 5 was noticed at early stages of the test (about 9.87 mm). Slightly buckling of flange was first noticed at  $7\Delta_y$ , while severely at  $9\Delta_y$  (Fig. 6). For the cycle to 100 mm, the maximum moment dropped to 97% of extreme moment, while reached the target rotation 0.08 rad, terminated. Yielding of the channels in Specimen 5 was 10.8 mm. The maximum moment dropped to 97% of extreme moment at 100 mm. That indicated that stiffeners spacing of 40 mm could ensure local stability. Yielding of the channels in Specimen 7 and Specimen 8 was 9.76 mm, 11.1 mm, respectively.

## 5 ANALYSIS OF TEST RESULTS

### 5.1 *Moment-drift hysteric loops*

The moment-drift hysteric loops of Specimens 1–4 were shown in Figure 7a–d. In the elastic stage, overall deformation was small in the early loading, with linear relationship of moment versus drift and a small residual deformation after unloading. The hysteresis loop was not obvious in this cyclic. In the elastic-plastic stage, with the increase of horizontal load, the area of hysteresis loop was increasing and the moment reached to maximum after yielding of the channels. The hysteresis loop was larger on the later loading. For the Specimens 1–3, carrying capacity dropped and hysteresis loop had rheostriction when rotation

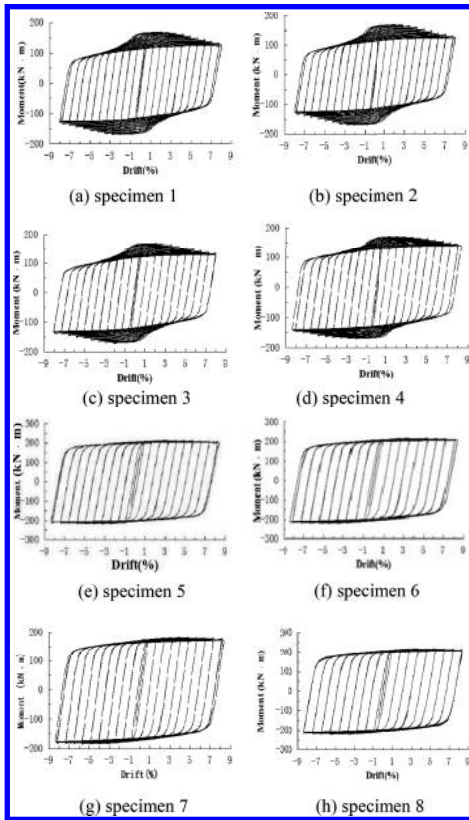

Figure 7. Moment-drift hysteretic loops.

exceeded 0.03 rad. The reason was lateral torsional buckling of individuals which resulted in losing carrying capacity, severely local buckling of flange and web. Specimen 4 enhanced the connection of individuals with the stitch spacing of 10i. Carrying capacity dropped when rotation exceeded 0.04 rad. The reason was local buckling of flange and web. Comparing to Specimen 1–3, Specimen 4 had a better plastic deformation and energy dissipation capacity and full hysteresis loop.

The moment-drift hysteretic loops of Specimens 5–8 were shown in Figure 7e–h. The hysteretic loops of four Specimens was similar in the elastic stage. The shape of hysteretic loops of four Specimens showed fusiform and was very full in later loading. When rotation exceeded 0.03 rad, the flange of Specimen 5 appeared slightly buckling. Compared to Specimen 5, the area of hysteresis loop of Specimen 6 slightly increased. Specimen 7 with fuller hysteresis loop to Specimen 4, which indicated set stiffeners prevented local buckling of flange and web. Compared to 7, the area of hysteresis loop of Specimen 8 slightly increased to 6. Until completion

of the loading, here was buckling of individuals and local buckling of web and flange.

### 5.2 Moment-drift skeleton curves, carrying capacity, ductility

The moment-drift skeleton curves of eight Specimens was shown Figure 8. From this figure, moment and drift in various loading stage can be calculated, as shown in Table 1. It was concluded the yielding point and extreme point shown ascendant trend. Compared to 3, the yielding moment of Specimen 4 improved to about 1.9% and yielding drift to 3.0%, while extreme point exhibited an almost identical. Which indicated Specimen 4 had a good ductility. The yielding and extreme moment of Specimen 7 was higher than Specimen 4. The yielding moment and drift improved to 2.8%, 11.5%, respectively. The extreme moment and drift improved to 6.9%, 178%, respectively. It was increased ductility of member by set stiffeners, which prevented local buckling of flange and web. The yielding and extreme moment of Specimen 6 was higher than Specimen 5. The yielding moment and drift improved to 1%, 9.4%, respectively. The extreme moment and drift improved to 1.4%, 9.4%, respectively. Which indicated the behavior of member slightly changed when reduced stiffeners spacing to 40 mm. The yielding and extreme moment of Specimen 8 approximately equaled to Specimen 6, but ductility increased. Specimen 8 with lateral bracing reduced effective length of out-of-plane improved behavior of member. Ductility factor also listed in the Table 1.

### 5.3 Energy-dissipating capacity

Figure 9 was the energy dissipation of eight specimens. As the big initial stiffness, specimens dissipated little energy and the loops of energy dissipation was gentle in the elastic stage.

Figure 8. Moment—drift skeleton curves.

Table 1. Characteristic moment and drift.

Specimen	My (kN·m)	$\theta_y$ (rad (%))	Mu (kN·m)	$\theta_u$ (rad (%))	$\mu$
1	159.87	0.703	68.03	1.4167	2
2	160.35	0.7092	168.67	2.1275	3
3	161.98	0.7267	169.27	1.4533	2
4	164.16	0.7292	169.32	1.4583	2
5	200.21	0.8225	212.47	3.2900	4
6	202.09	0.000	215.41	3.6000	4
7	168.71	0.8133	181.00	4.0667	5
8	202.88	0.9250	215.40	4.6250	5

Figure 9. Energy dissipation of specimens.

After yielding drift, the area of hysteretic loop of every specimens increased by yielding to dissipate. The equivalent viscous damping coefficient ( $h_e$ ) of eight specimens grow fast which indicated energy-dissipating capacity increased with development of plastic. At late load, every specimen showed good energy-dissipating capacity, with  $h_e$  to 0.522, 0.524, 0.527, 0.530, 0.565, 0.551, 0.547, 0.559, respectively. On the whole, a thicker web improved the carrying capacity, energy-dissipating capacity and  $h_e$ . The specimen with stiffeners, which prevented local buckling of flange and web, relied on yielding to dissipate energy. As no buckling of member, lateral bracing on plastic hinge slightly increased the behavior of dissipating energy. All the results indicated specimen 8 had the best hysteretic behavior.

## 6 SUMMARY AND CONCLUSIONS

1. The hysteretic loops of cantilever double-channel built-up members was full, whose shape was fusiform, indicated strong energy-dissipating capacity. It could be used as the chords of special staggered truss steel frames structure.

2. For the double-channel built-up members under reversed cyclic bending, the stitch spacing was advised  $10i$ .  $i$  was the individuals' radius of gyration to weak axis.
3. The specimen with stiffeners prevented local buckling of flange and web and increased carrying and energy-dissipating capacity. But the limit of stiffeners spacing was still a question.
4. Lateral bracing on plastic hinge slightly increased the behavior of member.

# Seismic influences on high-speed elevators in Super-High-Rise buildings

I. Torguet & W. Lu

*Research Institute of Structural Engineering and Disaster Reduction of Tongji University, Shanghai, China*

**ABSTRACT:** In the last few years, we have experienced an advent of Super-High Rise Buildings all around the globe, aiming to become iconic landmarks not only in height, but also in uniqueness and complexity of their structure. Along with the SHR buildings, new requirements have to be dealt to ensure their serviceability and safety, especially, when they are more vulnerable to get damaged: during an earthquake event. In essence, this study aims at first to provide guidelines for the analysis of the dynamic behavior of such structures, taking as example the Shanghai Tower and, furthermore, seeks to implement the behavior of the elevators in the overall response of the structures, to see how they interact between them. The research introduces the concept of the elevator's velocity in conjunction with the dynamic behavior analysis, implementing several configurations to determine the responses and relationships between the structure and the non-structural element.

**Keywords:** Super-High-Rise buildings; high-speed elevators; modal analysis; dynamic behavior; envelopes of excitation; acceleration spectrum; elevator velocity

## 1 INTRODUCTION

### 1.1 *Change of paradigm in Super-High-Rise Buildings*

Even though Super-High-Rise Buildings (SHR) have historically been located mainly in the US, in the past years there has been a shift of momentum, resulting in the Asian and Middle East countries being in the frontline of this kind of structure's development (Lu, 2011a).

Starting with the Petronas Twin Towers in Kuala Lumpur in 1998 and also with Taipei 101 in Taiwan in 2004 (Fan, 2009), this shift not only represents a geographically transition, but also a change in approach of SHR building's design. Now there is no further desire on an international style building, but rather a landmark to exhibit a design that avails itself of the country historical elements. The Jin Mao Tower in Shanghai, resembling an Asian Pagoda, or the Burj Khalifa in Dubai, currently the world's tallest building, which recalls some of the Islamic Art, are clear examples of such to reflect the culture of the country where they stand.

As a direct result of this change of paradigm, the SHR are becoming more and more complex structures, with upcoming requirements that cannot be assured by regular code complying techniques, and need further investigation and development (Jiang, 2011).

### 1.2 *Super-High-Rise Buildings in China*

China has experienced, in the last few decades, a rapid economic growth that continues up to date. As a consequence, China has seen a huge increase in the needs of urbanization and renewal of facilities, mainly focused on the big cities spread across the country.

Regarding the High-Rise Building field, Mainland China's boom in such kind of construction started in the 1990s, bearing in mind the fact that in places such as Hong Kong, some Super-Tall buildings were already constructed. Owing to the wide variety of social requirement for commercial or aesthetic purposes, the limited availability of land, and the preference for centralized services, the height of tall buildings had to grow taller, and the configuration as well as structural system, in consequence, has become more and more complex in recent years.

Nowadays, China has some of the tallest buildings in the world, and is aiming to construct even taller buildings than the ones already existing.

A key issue that must be fully understood in relation with SHR Buildings in China is their seismic safety, due to the fact that most of the buildings having been completed or being under construction are located in earthquake prone areas. Furthermore, a large amount of SHR buildings are located in the east coastal area of China, where the effects on structures by wind actions are significantly important.

Regarding all the possible threats, it is mandatory to attract researchers and investigation institutes in order to develop more reliable code provisions and design methods to deal with such threats. There is a need to undergo seismic dynamic analysis, such as the one aimed in this paper, to give further insight in such important matter.

## 2 SEISMIC BEHAVIOR OF SHANGHAI TOWER

### 2.1 Overview of the structure

As third tower in the trio of SuperTall buildings at the heart of Shanghai's Lujiazui Finance and Trade Zone, the Shanghai Tower is meant to represent a new way of thinking in SHR buildings (Xia, 2010). Placed in close proximity to Jin Mao Tower and Word Financial Center, the new tower rise high above the skyline and presumably become a symbol of the economic strength of China.

The Shanghai Tower will be a multi-functional office building, with a total height of 632 m and 121 storeys, filled with a unique mix of restaurants, shops, hotels, and offices spaced throughout the building. In addition, it will provide SHR buildings a new insight in how to improve the sustainability of such kind of structures, with the concept of vertical cities, wrapping the whole building in public spaces and sky gardens.

### 2.2 Shanghai Tower's model

The Shanghai Tower is a state-of-art structure, with some of the newest constructing techniques and element's performance. As a result, numerous studies are at the moment working on reliable and precise computational models to determine the responses of this structure (Lu, 2011b). The key insight that differs most of the models and the one that we are presenting relies on the approach. In some of the other researches, Finite Element Models have been conducted to simulate the Shanghai Tower, with more or less precision (Zhou, 2013). The problem is that these FE models consist on, as a piece of example, 19973 elements, 45418 shell elements, and 14376 solid elements, resulting in extremely complicated designs, only enabled by powerful software and great deal of computational process. Due to the complexity explained above, and aiming to find a simpler version, the structure model will be reduced into a set of lumped masses, which bundle the different elements' characteristics (Lu, 2014).

As a matter of fact, we know that the Shanghai's Tower program is organized into eight vertical zones, each with 12 to 15 floors, covering a different

Figure 1. Shanghai Tower Model. Approach of layout.

type of facility, but having a similar layout. Taking that into consideration, we have created our model lumping the elements in each zone, solving the need of an easy tool for understanding and properly collecting the responses of structures.

Once stated the approach for our model, several assumptions in terms of stiffness, mass, and damping have to be noted. In terms of the stiffness, the elements with the most contribution to the Shanghai Tower's stiffness are the core-tube, the super-columns and the outriggers with their belt truss. In this sense, it is assumed that the overall stiffness of the lumped mass is the sum of the stiffness of each structural element for a given zone (Carpinteri, 2013). Therefore, we will have stiffness for each floor separately. What's more, the stiffness depends on the direction along the axis desired, and for the purpose of our study we will select the one's from the X direction to undergo the dynamic analysis.

Regarding the mass of the structure, we will assume the same behavior as in the stiffness, having an overall lumped mass for each zone of the Shanghai Tower. Moreover, effective masses depending on the direction along the axis desired are taken into the analysis.

Finally, the damping will remain constant through all the building and, according to the latest regulation in Design Codes, precisely in the Section 5.3.4 of the Specification for the Design of Steel-Concrete Hybrid Structures in tall buildings (CECE230:2008), will have a value of 4%. If there is a need to vary that number in order to meet the requirements, it will be done during the computational process.

The data collected to model the Shanghai Tower is to be found in Table 1.

With the information collected, a modal analysis was carried out, in order to determine the

Table 1. Overall data for the zones in Shanghai Tower Model.

Zone	Mass (kN/g)	Kx (kN/mm)	Ky (kN/mm)
8	71656.3	172.09	177.47
7	59396.9	240.82	247.67
6	68695.8	372.62	374.90
5	82736.3	536.99	543.42
4	93246.8	877.36	878.11
3	108921.4	1295.76	1325.18
2	121295.4	2494.52	2658.71
1	68652.6	16215.13	17309.65

dynamic properties of the structure, such as the natural frequencies. It is crucial to know the frequencies and, therefore the periods, because they are the ones at which the structure will naturally resonate (Meera, 2013). In an event of an earthquake, it is imperative that the building's natural period does not match the period of the seismic action, or it will resonate and experience damage due to severe oscillations. The natural periods of our model, from the first to the eighth mode, are shown in Table 2.

Besides the values for the periods, the UX, UY, and RZ show the modal participation of each mode. As a matter of fact, modes 1, 3, and 6 are primarily the ones with greatest significance along the X direction. They will be the most contributors to the response of our model in the desired direction.

Hence, the mode shapes are generated. A mode shape of an oscillating system is the pattern of motion that will experience an object when all the parts of it move sinusoidally, with the same frequency and with a fixed phase relation. Using the commercial software ETABS, the modal shapes are drawn as shown in Figures 2 and 3.

### 2.3 Earthquake wave selection

According to the Chinese code "Code for Seismic Design of Buildings," the earthquakes, in terms of Peak Ground Acceleration (PGA), are categorized as: Minor or Frequently occurred, when their PGA is 0.035g, Basic or Moderate when the PGA is 0.1g, and Strong or Rare when the earthquake has a PGA of 0.25 or above.

In our analysis, we have chosen the Basic or Moderate earthquake type to be our ground motion input. The reason is that, even though it is a quite severe excitation, buildings have to deal with the deformations and remain operational once the event is over (Tenozhi, 2013). As a matter of fact, if we were to set our standards to the

Table 2. Modes of vibration of Shanghai Tower.

Mode	Period(s)	UX	UY	RZ
1	9.49	44.18	0.00	0.00
2	9.35	0.00	43.83	0.00
3	2.20	22.73	0.00	0.00
4	2.16	0.00	22.83	0.00
5	1.44	0.00	0.00	53.30
6	0.88	10.54	0.00	0.00
7	0.86	0.00	10.64	0.00
8	0.71	0.00	0.00	20.32

Figure 2. Mode shapes of vibration from 1-4.

Figure 3. Mode shapes of vibration from 5-8.

Strong or Rare earthquake, we could easily fall into over dimensioning our building. The requirements in terms of dynamic behavior are tougher, and the probability of such excitation happening is unlikely.

In addition to the categorization of type of earthquake, the Code also states that if a dynamic analysis is conducted, one must use at least seven different earthquake records. In that way, the Code enables us to find an average response of the structure throughout the comparison of the different responses achieved. Furthermore, as long as our model is set in the elastic range of deformation, the results with different earthquakes but with same peak ground motion can be compared directly. If it were a non-linear approach, such assumption would not be correct (Lee, 2002).

In our study, we have chosen as earthquake records the following: Mexx, L725, S790x, SHW3, El Centro NS, L604, and USx, having all of them a PGA of 0.1g. To show how the data from the earthquake records is treated we present Figure 4, extracted from Mexx earthquake, which displays the Time History of this ground motion.

#### 2.4 Seismic behavior: Elastic response

The study undertakes a behavioral analysis of the model, using as input the excitations events above, with the goal of obtaining the time domain history of the response, in terms of displacement, velocity, and acceleration. Furthermore, we have also extracted from the results the interstory drifts of the floors due to such excitations.

The displacement of our model due to the set of earthquakes is of vital importance. In essence, what we obtain is the history of the deformation from static position of our structure. With a quick look at the data, we are not only able to determine the absolute values of displacement, but also the shapes that the structure will take when excited. Knowing the possible shapes of a structure will enable us to determine the serviceability and safety of the structure in an event of excitation.

Figure 4. Mexx earthquake in time history.

Table 3. Average earthquake response. Overall maximums.

Floors	Displacement (m)	InterStory Drift (m)	Velocity (m/s)	Acceleration (m/s <sup>2</sup> )
8	0.938	0.312	0.924	2.366
7	0.658	0.255	0.573	2.386
6	0.464	0.183	0.603	2.272

The InterStory Drift gives us insight in the relative displacement between consecutive floors (Rofooei, 2012). In this sense, it is of great value because it helps us understand the actions and reactions that the floors have to manage due the motion of the others. In a particular way, to ensure the correct functioning of an elevator within the structure, there is a need to study the progression of the InterStory Drifts along the height of the structure. Any abrupt change in displacement between floors could damage the whole elevator machinery and represent a dramatic scenario (Yang, 2010). Therefore, we are keen on taking a closer look into the Drifts.

Acceleration is perhaps the most important factor when studying the behavioral dynamic analysis of a structure. This is due to the fact that it is closely related to the inertial effects of the structure due to the excitation, and it is an effective approach to deal with the frequencies that excite the structure (Miranda, 2005). When we examine the accelerations of a building, separately occurring in each floor, we are able to determine the frequencies that will contribute the most to the motion of that floor.

What's more, a study along the height of the structure showcases the relationships between floor's acceleration and, thus, the shape of the acceleration path. This aspect will be broadly used afterwards, in order to create the envelopes of excitation.

Once the dynamic analysis is done, the data is collected and compiled to further processing and treatment. With all the extracted data, an average response is developed. Taking into consideration that all the analysis is on the elastic range and that the values obtained are all dependent to a 0.1g of PGA earthquake, the comparison between them is feasible, computing the mean values.

As a result of that, the research obtains average maximum figures, again in terms of displacement, interstory drift, velocity, and acceleration.

That would be the expected values for a 0.1g earthquake. It is truly important for us because it gives an insight of what response would give our structure back in a random earthquake.

In this sense, we have knowledge of up to what value our structure has answer back due to the excitation. In other words, we are now capable to give a value of the threshold of response for each variable (displacement, interstory drift and so on), for any given floor.

Hence, we introduce the concept of Envelope of Excitation to our analysis. An envelope of excitation is the compilation, along the height of the structure, of the maximum values achieved in each floor. It gives us a frame, a restriction, to the response of the building, because it is composed of all the limits obtained. In a way, it is conceptual due to the fact that all maximum responses do not necessarily happen at the same time and, therefore, the response path is not likely to occur as we see it. However, it is of vital significance because, in a single graph, we can judge the possible deformation and reaction scenarios in our building.

Lastly, we are able to generate an average earthquake envelope, represented in Figure 5. The average earthquake envelope will represent the expected path and dynamic behavior for any given basic or moderate earthquake as stated in the Code for Seismic Design of Buildings.

With such envelopes, we are able to underline several important issues regarding the variables used. The displacement of the expected earthquake response follows with great similarity the first mode of vibration of the structure. In consequence, we are able to assume that the most contributors to the dynamic behavior of Shanghai Tower are the first mode of vibration, with a natural period of 9.49 s. The InterStory Drift also follows a similar path, stressing the assumption above.

The velocity of the Shanghai Tower under a 0.1g earthquake follows an approximately linear path, giving sense to an increase of the floors along the height. As we can see in the graph, at the seventh

floor there is a slight change in velocity, due to the way of motion of the structure itself.

The acceleration obtained follows a fairly straight line when deals with the upper floors, as expected. The lower floors, and specially the first floor, have a behavior that relates to the high frequencies of excitation.

Numerous studies undergone before in the Shanghai Tower (Lu, 2011) give a factor of  $k = 3$  as multiplication of the response in terms of acceleration. In our case, if we linearize our model envelope, we will get to a  $k = 2.5$ . Our results, pretty close to the ones from previous research, give strength to our analysis and ensure that our overall dynamic study is a good approach.

### 3 SEISMIC ACTIONS OF HIGH-SPEED ELEVATORS

#### 3.1 Overview. Analyzing the phenomenon

Since the invention of the safety elevator by Otis in 1852, there has been a need to ensure the serviceability and safety for the passengers in an elevator for any given circumstance. However, as long as the buildings where those elevators were implemented were not tall enough to fall into damage due to large oscillations in response, not much research was focused in that field.

In fact, the major shift in the elevator performance analysis would come after a series of damaging earthquakes in the United States. First in Alaska earthquake in 1964 and, after that, in San Fernando earthquake in 1971, the damage in the elevators was so significant that forced the competent organizations to look for better elevator seismic capacity (Anshell, 2008). From that moment on, people began to realize the seriousness of the matter and started to propose improvements and renewed techniques in order to overcome such undesired reactions in the non-structural elements.

Not with standing, research work was still scarce and much of it was mainly related to the counterweight dynamical behavior (Mirabdollah, 2012). From that time, many data was obtained by computer-based simulators that enable to see the behavior of the ropes and counterweight, but lacked accuracy. The problem was that the damage assessments, as their name indicated, were issued once the earthquake had already occurred, so it was unable to provide provisions for the maintenance and inspection, but rather to determine ways of dealing after such event.

In the experimental side, the most common practice is to work close to the elevator companies that have deployed the elevator mechanisms in the area of the earthquake event (Yao, 2007). In other

Figure 5. Average earthquake envelopes of excitation.

words, once an earthquake happens in a certain region, it is a must to convey a series of inspections to the damaged sites in order to get as much information about the performance as possible. As long as, presumably, there are more than one elevator companies in the area affected, the survey will have to be conducted by all of them at the same time. Hence, there will be a need to organize it via a government committee, who will unite the struggle of all parties affected in obtaining the response data.

In a way, there is still a long way to go in the seismic performance analysis of elevators. Nowadays, many new researchers are taking into closer examination the actions on elevators, aiming to develop techniques and computer-based models to guide the requirements these non-structural elements need to deal with in events of excitation (Arrassate, 2014).

### 3.2 Usage of the envelopes

In our previous dynamic analysis for the Shanghai Tower, we have ended up with a compilation of envelopes for an expected given earthquake of 0.1g, in terms of displacement, interstory drift, velocity and acceleration. At this stage appears the concept of envelope excitation. Used mainly in Nuclear Power Plants and other complex structures, the envelope excitation represents a quite intuitive restriction for the behavior of a structure. In its essence, its aims to show that, to model one structure to deal with a set of inputs, it needs to be able to deal with the most significant, and therefore, the most damaging of the responses due to that excitation.

As a matter of fact, the structure will experience the biggest response when subjected to an artificial sinusoidal wave with amplitude the maximum value of the variable in the response desired. But the problem now is that when we use a sinusoidal wave, we need to input amplitude and a frequency. In our case, we need as frequency the one that excites each floor, because it is the one that contributes to achieve the greatest response for a given zone. To do so, Fourier Transformations are carried out, deriving into a frequency domain analysis.

Therefore, we have undergone the envelope excitation analysis on the four variables (displacement, velocity, interstory drift and acceleration). The variables are differently treated due to the specific needs for each of them.

### 3.3 Overall Maximum Input

In this case, we have generated a single sinusoidal wave, with the information regarding the maximum response of the variable desired (in terms of

amplitude and frequency). As stated before, if our structure is able to deal with the inputs that excite its most significant response, then it is able to deal for the rest of inputs below that one. For the Overall Maximum Input, we have chosen the displacement and the velocity.

First, we proceed with the Displacement response. As we can see in the envelope in Figure 5, we experience the greatest deflection in the eighth floor, achieving a maximum value of 0.938 m. That is going to be our threshold, our envelope of excitation value. Hence, we run through all the earthquake records responses of displacement for the eighth floor. Meaning, we have chosen, for example, the Mexx earthquake, have taken the response in displacement of the eighth floor for that earthquake, and extracted the frequency. The same procedure will be carried out for each earthquake, finding in the end the frequencies that drive into that response for an expected earthquake.

The data collected is shown in Table 4.

Once we have the data, we are able to generate the sinusoidal wave. Using as amplitude the maximum displacement of the eighth floor, the outcome can be obtained by using the average frequency (as seen in Equation 1), or it can be an integral for the input, using as boundaries the maximum and minimum frequencies obtained (as in Equation 2).

$$d = 0.938\sin(2\pi \cdot 0,109t) \tag{1}$$

$$d = \int_{0,1038}^{0,1282} 0,938\sin(2\pi \cdot wt)dw \tag{2}$$

Regarding the velocity variable, we have undertaken in the same way that we have done with the displacement. In the velocity case, the maximum velocity is also located in the eighth floor, with an absolute value of 0.924 m/s.

Thus, the presentation of both the data collected and the waves generated is provided in the same format in Table 5, and Equations 3-4.

$$v = \int_{0.1038}^{0.4578} 0.924 \sin(2\pi \cdot wt) dw \tag{4}$$

### 3.4 Floor-by-floor Input

In this case we aimed to obtain a sinusoidal wave for each floor of the Shanghai Tower for a given variable. In this new scenario, we want to gather the frequencies for all the floors, throughout the seven earthquakes. This means that, in the end, we will have eight frequencies, one per each floor, times seven due to the earthquakes. What's more, we are able to find average values for each floor, so that we will know what frequencies make the largest responses per floor.

The InterStory Drift follows a similar path that the one from displacement. In a way, as long as the displacements go increasing along the height of the building, so it does the drift between them.

Once we have undergone the analysis for all floors and earthquakes, we are able to gather them in a single table, as presented in Table 6. The table also contains the data from the average values for each floor.

Furthermore, to present the data obtained in a prescriptive way, we have created a graph, where it is plotted together the path achieved with the average frequencies throughout the InterStory Drift values, and the tolerances for each floor drift, extracted from the maximum and minimum values in the seven earthquake records responses.

In essence, we have a tool that tells us in an easy visual way not only what are going to be the expected drifts for any given frequency, but also the boundary tolerances inherent to it due to the stochastic nature of an earthquake input.

Figure 6 is the figure explained above. In it, the thick horizontal lines represent the different floors InterStory Drift with the range of frequencies from maximum to minimum values. The thin continuous

USX	0.4578
Average	0.2053

Figure 6. InterStory Drift frequency spectrum.

line represents the path of the average InterStory Drift and their inherent mean frequency.

A graph of this kind is significantly helpful for elevator manufacturing companies, because when design and mount an elevator, can benefit from this graph, as it is an easily understood tool to determine for any given floor, what is the range in input that the elevator will have to deal with. In other words, for an elevator to properly function, it will need to be able to deal with all the frequencies expressed in the graph for that floor (Villaverde, 2004).

In terms of the acceleration, the research is conducted in the same way as in the InterStory Drift, collecting the frequencies for each floor throughout the seven earthquake records. The data of the mean values, extracted from the analysis, is shown in the Table 7.

Moreover, once again we have created the plot combining both mean frequencies and tolerance frequency ranges, which is presented in Figure 7, located in the next page.

Table 7. Frequencies to excite the acceleration.

Floor	Acceleration (m/s <sup>2</sup> )	Frequency for Drift (Hz)
8	2.366	0.455
7	2.386	0.699
6	2.272	0.790
5	2.010	0.895
4	1.910	0.669
3	1.909	0.884
2	1.685	1.537
1	0.764	10.015

Figure 7. Acceleration frequency spectrum.

This graph has the same explanation that the one about InterStory Drift, seen previously. It gives us information about the ranges in frequency that an element will experience in each floor. With this information, we can determine the restrictions that an elevator should abide in order to properly function during an average event of excitation.

From the data extracted, we can see that there are two differentiated parts in our graph. From 0.455 Hz up to 1.537 Hz, that represents the floors ranging from 2 to 8, the slope is really steep, having not much of a change in frequency. However, if we take a closer look into the floors 1 and 2, the frequencies have a much broader range, driving from 1.537 Hz to 10.015 Hz. In consequence, it can be stated that in the Shanghai Tower there are two differentiated areas, and the threshold is the second floor (at approximately 140 m from ground level). The range of frequencies being much bigger than the above floors is due to the significance in contribution of the higher frequencies in the acceleration at the lower parts. This lower parts excitation was

already noted when dealing with the envelope of acceleration in the SHR building section, where we noted a shifting inwards in the path. Therefore, it makes total sense the shape that this graph takes and, hence, it is a great tool for setting the requirements for the elevator's behavior.

### 3.5 Seismic actions of high-speed elevators: The velocity issue

All the information regarding the elevator analysis has been undergone with a static elevator, aiming to determine the reactions of it due to the excitation event. But we want to understand what impact will have to the elevator the fact that is moving, and, at last instance, how the velocity of the elevator itself will affect the response. Beforehand, we realize that there has to be a change in the behavior due to the speed at which the elevator moves along the tower. Therefore, what we aim is to stress is the variations in frequency range, due to the speed at which the elevator travels. In a way, the research is relying on the areas enclosed between the range of frequencies for a given floor and the graph of frequencies-accelerations.

In order to see the variations, 10 m/s and 20 m/s velocities have been selected. The reason is that 10 m/s is the current top speed for most of the SHR Buildings nowadays, whereas 20 m/s has been theorized as mechanically feasible, even though it hasn't actually been mounted on a SHR Building.

Nevertheless, as stated before, in our graphs there are two separated areas: below second floor and above second floor. Therefore, the study underlines these two cases and, afterwards, drives some conclusions.

#### 3.5.1 Case 1. Cabinet under the second floor

Prior to the analysis, an artificial earthquake scenario has been created, with PGA of 0.1g, a natural frequency of 5 Hz and time duration of 7 seconds. This earthquake is the one used to determine the reactions due to the speed.

The domain of the frequency-acceleration graph for the first two floors is quite large. As a matter of fact, an elevator that starts in the bottom will first experience a frequency input equivalent to the one from the ground motion, then achieve frequencies up to 12 Hz in the first floor, and finally get to the 1.5 Hz value. As a result of such disparity, the behavior of the elevator within that height will be highly affected by the rate of change of the frequency. Let's see what happens in the event of excitation explained above, taking as starting point the ground floor.

With a 10 m/s cabinet, during the seven seconds of the earthquake, the elevator will reach the first floor. Regarding the frequencies that the elevator

will have to deal with, those are going to be ranging from the initial frequency of 5 Hz, given by the earthquake, up to approximately 10 Hz. In other words, will suffer frequencies enclosed in the interval from 5 to 10 Hz.

Nevertheless, doubling the velocity, during the seven seconds that lasts the earthquake, the cabinet will reach the second floor (the threshold of 140 m). As a result of such increase in speed, the elevator will not only need to deal with the frequencies ranging from 5 to 12 Hz, but also with the frequencies from the first floor to the second. Those are ranging from 1,5 Hz to 12 Hz approximately.

As a consequence, if we were intending to design a suitable elevator to this scenario, we will have to bear in mind that in such event of ground motion, our elevator would have to be able to meet from 5 to 10 Hz in frequency requirements to be fully operational for a 10 m/s cabinet, while we would need to improve the requirements for the 20 m/s case. The improvement would provide a wider range of frequencies in order to deal with the overall response. Therefore, we are able to state that if the cabinet is located between ground floor and second floor, it will experience much different responses according to the velocity of the elevator itself.

To illustrate the range of frequencies affected by each case scenario, Figure 8 is presented below. In the graph, the enclosed area of horizontal lines is the one for 10 m/s cabinet, whereas the vertical lines represent the 20 m/s case.

### 3.5.2 Case 2. Cabinet above the second floor

The second case is when the elevator is moving along the height compressed between the second to the eighth floor. At this point, the graph of

Figure 8. Acceleration frequencies depending on the velocity of the cabinet under the second floor.

Figure 9. Acceleration frequencies depending the velocity of the cabinet above the second floor.

frequencies is much steeper, tending to a vertical shape.

As a result of that, there is not a big disparity among the frequencies, as long as they are all located in the range from 0.1038 Hz to 1.537 Hz. What's more, the new scenario contains more floors to be studied and, in consequence, we have treated it with a longer earthquake. In this case, the artificial earthquake has a PGA of 0.1g, a natural frequency of 5 Hz and time duration of 21 seconds.

With a 10 m/s cabinet, starting at the second floor, the elevator during the 21 seconds of earthquake will travel up to the fifth floor. During its journey, it will start getting as input 1,537 Hz, and by the time it gets to the top will be experiencing an average frequency of 0.895 Hz. From an engineering point of view, they behave similarly due to the fact that both of them are located in the low frequencies spectrum. As a matter of fact, even though the elevator travel during a quite long time, the change in frequency is not much significant. This will help greatly the manufacturers to design the elevators, as long as the requirements for the frequency do not vary much.

With a greater velocity, achieved by the 20 m/s cabinet, the elevator during the earthquake will travel from second floor to eighth floor. In this new scenario, the elevator will face a shift from 1.537 to 0.455 Hz, representing a similar range to the one obtained at 10 m/s. The key issue in that zone of the Shanghai Tower, the structure is mainly excited by the first three modes of vibration; the little discrepancies that might arise in the frequency range are not significant enough.

In consequence of the lack of remarkable disparity in the frequency, in this section of the building

an increase in velocity is not decisive enough for a drastic change in the requirements.

As a direct result of our analysis, we might state that the elevator company in charge of the designing of the elevator will be able to use mostly the same provisions as the ones used for the regular speed of 10 m/s after the second floor.

#### 4 CONCLUSIONS

This research, underlining the needs for this kind of study and according to the current situation in SHR Buildings, has provided the guidelines to determine not only the dynamic behavior, but also the implementation of non-structural elements to the analysis.

Using as example the iconic Shanghai Tower, the study has set the bases for a complete dynamic analysis of the structure, providing a computer-based model to compile the linear behavior of the building. We have been able to, in a simple and visual way, create a good approach to the actual response of the structure due to any given 0.1g of PGA earthquake.

One of the advantages of using our model is the simplicity inherent in it. The model is based in the mass-spring-damper system, having lumped masses that combine the different features of the structure. As a result, our model is no longer an over-complicated finite element method structure, with huge mesh and thousands of shells and elements involved, but rather an intuitive idea of the big picture that is the Shanghai Tower. Moreover, the analysis makes a step forward into the usual calculations in events of earthquake excitation, which are mainly based on post-earthquake damage control scenarios. Whereas, applying the rules from the Design Codes of China, we have obtained the average response for any given earthquake that abides certain characteristics. Therefore, it is a trustworthy data for the expected behavior to be used not only for future studies in the structure itself, but also in the construction of new structures. An average response path will further help researchers to know what are the thresholds and possible outcomes to expect in any earthquake.

In terms of the dynamic analysis, the results point out the following key issues:

1. The Displacement of the Shanghai Tower follows a similar path as the one from the first natural mode of vibration of the structure. In that sense, we are able to state that our model validates the idea that the most important contributor to Shanghai Tower's Displacement behavior is his first mode, with a 9.49s natural period.

The Acceleration of the Shanghai Tower, according to our model, is mainly affected by the second and third modes of vibration, with the frequencies of those as the most damaging to the structure. Such fact complies with most of the guidelines provided by the High-Rise building construction companies, where it is stated that such frequencies are the most significant in the dynamic behavior.

The course taken generates, thanks to the information of the dynamic behavior of the Shanghai Tower, a set of guidelines of what an elevator should be able to deal with in order to operate. So to speak, we have given the threshold of performance for elevators to cope if they want to remain in a serviceable state while an earthquake is happening.

Using the frequencies that excite our structure the most, both in the overall maximum input method and the floor-by-floor method, we have obtained an easy target for the performance of the elevator. As we have seen in the study, most of the times we are not only needing the average value obtained by the mean of the seven earthquakes, but we are rather interested in compiling all of them.

Another key issue of our study is the envelope excitation idea. In our perception, such method can be a genuinely new and plausible tool for implementing the frequencies obtained into the structural analysis of the whole structure.

Regarding the velocity issue, derived from the advent of High-Speed Elevators, we can conclude that, in terms of the Shanghai Tower behavior:

1. Elevator under the second floor. The range of frequencies that the elevator will have to deal with along the height is really wide, ranging from 1.5 Hz up to 12 Hz. As a result of that large range, the velocity becomes a crucial factor. This is because for a given earthquake with specific time duration, the velocity will determine the change in height and, therefore, the ranges will vary.
2. Elevator above the second floor. As long as the graph in this section of the structure gets more steep, the frequencies do not vary that much, staying mostly in the range of the first three modes of vibration. As a result, the velocity will not play a role as important as the one below the second floor. Despite the changes in velocity that will carry different frequency requirements, those will be minimized due to the vertical shape and, at last, will be treated almost indistinctively.

Despite the remarkable achievements carried out by this research, it faces the problem of experimental data. Real testing would definitely be

needed to validate the conclusions that arise from the theoretical treatment of the data. Without a testing part, the results lack of physical backing and can only be served as guidelines for posterior studies.

As a consequence of this, the next step in the study would be to build up a real model of an elevator installation in a Shaking Table Laboratory and put into test our theoretical model. In the laboratory, then, researchers would carry out sets of excitation events to the elevator specimen, and check out the responses. The outcomes of such testing experimentation would validate or not our model, and would definitely provide a deeper understanding of the behavior of this kind of elements.

To summarize, our study represents the first steps of a complex and lasting endeavor, which will seek to provide the direct correlation between the non-structural elements and the structures in which they are implemented. In essence, as the need of further research will become a high priority due to the current construction requirements, studies such as the one we have presented will serve as a pragmatic tool to help set the bases of them, as well as provide knowledge into many other future developments in dynamic behavior analysis.

# Comparison of deep soil deposit seismic response with three basement models

X.B. Peng & W.L. Yang

*Earthquake Administration of Jiangsu Province, Nanjing, China*

**ABSTRACT:** To the deep soil deposit, that the shear velocity is less 500 m/s while the burial depth is 100 m, the present methods in China dealing with the basement in seismic response estimation are discussed. Based on theoretical analysis and engineering case, 3 basement models (linear extrapolation, soft interlayer assumption and stiff basement) are created. The relative soil nonlinear parameters are provided by experiments and the models' dynamic response under different seismic intensity is calculated by 1D equivalent linearization routine. The PGA and response spectra in ground surface of those models are compared and the results show that the stiff basement model do not underestimate the seismic risk, while it is easy to build. The stiff model is recommended in engineering application.

**Keywords:** deep soil deposit; basement; seismic response; PGA; response spectra

## 1 INTRODUCTION

Special and systematic seismic risk evaluation is legally required for important engineering projects in China. The seismic response of engineering site is a key part in determining the final earthquake affecting coefficient, which is named design ground motion parameters. Previous researches have showed that the peak and spectrum are strongly affected by the site's soil characteristics (Hartzell, S. et al. 2004, Li, X. J. 2013). The soil characteristics are quantified by soil profiles, shear wave velocity, static and dynamic parameters, which are acquired by drilling, in situ tests and laboratory experiments. At present, the depth of drilling for seismic risk evaluation is not required to exceed 100m for most of engineering projects, according to the technical specification. However, in some areas with deep soft soil deposit, the shear wave velocity is apparently less than 500 m/s, which is the minimum requirement in the specification, in the depth range (Lu, S. D. 2005). In this situation, the basement for the site seismic response is required to special study.

Under the circumstances, there are 3 methods to determine the basement: (1) choosing the obvious velocity jumping interface, (2) using the soil comparison and empirical equation to estimate velocity, (3) linear or nonlinear extrapolating velocity (Hong, H.C. et al. 2013). The first method needs deeper drilling and testing. Although some velocity tomography technologies may reflect the inhomogeneity (Fan, X.P. et al. 2011, 2013), they do not have enough resolution and reliability to

employ in soil seismic response computation. The second method needs some typical reference data, which are not always existing or collectible. The tendency of velocity increasing along the depth is assumed to be same in third method. The assumption may be proper in some cases, but there are also some cases in which the velocity increase slowly or decrease in certain depth range.

The input basement can affect site seismic response in varying degrees for different soil velocity structures (Lou, M.L. et al. 2006, Shi, C.H. et al. 2009). In general, the soil characteristics in deep range have less significant effect to the ground surface seismic response of deep deposit site (Chen, G.X. & Chen, J.H. 2005) for the velocity is relatively high, such as greater than 400 m/s, and the nonlinearity is relatively weak. On the other hand, for the energy-dissipation of deep soil, the velocity extrapolation and small impedance ratio between the basement and the adjacent soil layer may underestimate the seismic response.

In this paper, based on a true engineering case, the seismic responses in the ground surface of a site under 3 basement model assumptions with 3 boreholes (zk1, zk2 and zk3), whose shear velocity are just about 450 m/s at 100m in depth, are studied.

## 2 DATA AND METHOD

The soil profile and in situ shear velocity of a true engineering site with 3 boreholes, whose depth is 100 m, are presented in [Figure 1](#). The figures show the

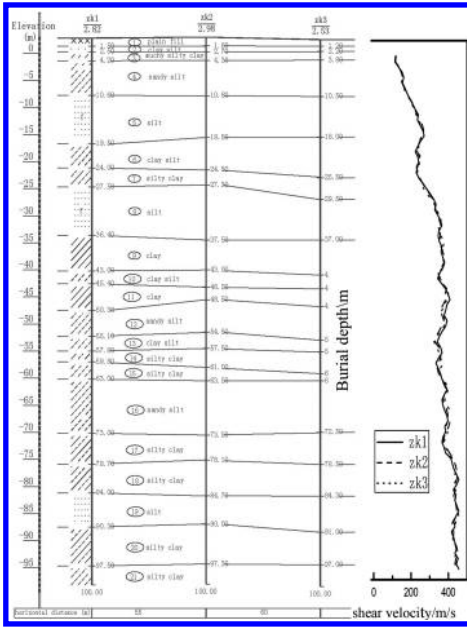

Figure 1. Profile and shear velocity of deep soil deposit.

soil is stratified and the velocity is very close at same depth of the 3 boreholes. The borehole is divided into 21 layers and each layer's depth is 10 m less. As the Figure 1 shows, it's difficult to predict what kind of soil will be in deeper zones. The characteristics of shear velocity are: (1) the tendency of the velocity along the depth is increasing, where the rate of increase is higher in 0–40m and gentler below 40 m, (2) controlled by the soil properties, there are relatively low velocity layers at different depth.

For the shear velocity of the boreholes is 500 m/s less, the choice of the basement needs to be considered when computing the seismic response. According to the geophysical prospecting and collecting information, we infer that the bed rock is about 300 m beneath the ground surface and there are not severe soft layers between 100m and 300m in depth. However, these data are not exact and complete enough to build a reliable model. So, for the sake of simplicity and engineering application, we propose 3 basement models to deal with the uncertainty of the deeper soil.

The soil seismic response is calculated by 1D equivalent linearization routine. The static and dynamic soil parameters are determined by experiments. For the degree of soil nonlinear strength reduction is different according to the earthquake intensity, we consider 3 levels of input strong motion, naming small earthquake, middle earthquake, and large earthquake, whose peak accelerations are 32.0 cm/s<sup>2</sup>, 144.0 cm/s<sup>2</sup> and 280.0 cm/s<sup>2</sup>. The response spectra

Figure 2. Response spectra of input strong motions.

Figure 3. Example of acceleration time series.

of the input are shown in Figure 2. The acceleration time series are artificially synthesized with the spectra, and one of it is shown in Figure 3. To eliminate the effect of input, 12 acceleration time series are employed for each calculation.

### 3 BASEMENT MODELS

#### 3.1 Linear extrapolation model

According to the rising tendency of shear velocity with depth, we employ the data during the depth range of 60–100 m to linear fit the equation between the shear velocity and the burial depth. The linearly dependent coefficient is 0.868. The fitting result is shown in Figure 4 and the equation is:

$$V_s = 2.4010 D + 216.9733 \quad (1)$$

where,  $V_s$  is shear velocity and  $D$  is burial depth.

Following the equation, we extrapolate the shear velocity to 500 m/s with  $D$  being 118 m. Then the deeper zone below 118 m is treated as the basement, which is stiff. This model is named M1.

### 3.2 Soft interlayer assumption model

Based on the M1, the velocity during 100–106m is replaced by a soft interlayer with velocity being 400 m/s, while the other part remains unchanged. This model is named M2.

### 3.3 Stiff basement model

For the lack of the wdeeper soil information and shear velocity data, a stiff basement with shear velocity being 500 m/s is assumed just beneath 100 m. This model is named M3.

## 4 RESULTS ANALYSIS

To eliminate the uncertainty, the mean of PGA and response spectra in ground surface excited by the 12 input motions is used in following analysis.

### 4.1 PGA

The mean PGA under 3 levels of input strong motion is listed in Table 1. There are several points we can infer from the table:

1. Controlled by the similar soil structure and shear velocity, the PGA of the 3 boreholes with same basement is close to each other. The maximum relative error is 1.5%, 1.9% and 7.5%

Figure 4. Linear fitting of wave velocity with burial depth.

Figure 5. Comparison of 3 models' response spectra in ground surface.

Table 1. Comparison of 3 models' PGA in ground surface.

Model	Small earthquake			Middle earthquake			Large earthquake		
	zk1	zk2	zk3	zk1	zk2	zk3	zk1	zk2	zk3
M1	47.1	46.8	47.5	161.4	163.3	163.8	296.6	309.8	319.2
M2	46.8	46.8	46.8	160.2	161.6	161.7	289.1	301.7	308.7
M3	47.2	47.4	47.2	164.9	167.5	168.0	304.5	317.3	327.8

under small earthquake, middle earthquake, and large earthquake, correspondingly. The more apparent error under large earthquake implies that PGA is more sensitive to soil properties, especially nonlinear parameters under strong input motion. It is consistent with the fact that it is more difficult to predict the PGA in near-fault area, where the bedrock motion is usually stronger.

2. Generally, the sort of the PGA among the 3-basement model is  $M2 \cong M1 \cong M3$ , which means the soft interlayer assumption reduces the response while the stiff basement enhances it. However, maximum relative error for different basement model is 1.5%, 3.5%, and 5.8% under small earthquake, middle earthquake, and large earthquake, correspondingly.

#### 4.2 Response spectra

For the response spectra of the 3 boreholes is very close, the mean response spectra of the 3 basement model under 3 levels of input strong motion is displayed in Figure 5. The figures show that the results from M3 are slightly larger in short period range, while all the curves are almost overlapping after about 1s. Although as assumed soft interlayer is put into M2, it does not lead to apparent lengthening of characteristic period, which is one of the important design ground motion parameters. So, it is confirmed that the variation of velocity in deep part have no significant effect on ground surface seismic response.

## 5 CONCLUSION

1. Based on the true engineering case, the different basement assumptions have no significant effect on ground surface seismic response for deep soil deposit. In general, the stiff basement does not underestimate the seismic effect.
2. For the sake of simplicity and safety, the stiff basement can be used for the situation where

the shear velocity is less than 500m/s for deep soil deposit. The optimized choice of basement shear velocity should be studied further.

**ABSTRACT:** A novel approach was proposed for determining the threshold Chloride Level (CTL) of rebar (HRB400). The  $Z_{1\text{ Hz}}$ , which is the resistance value when the frequency is 1 Hz, was extracted from the Electrochemical Impedance Spectroscopy (EIS) data. In a plot of the change in  $Z_{1\text{ Hz}}$  with  $[\text{Cl}^-]$ , the  $Z_{1\text{ Hz}}$  value was observed to shift sharply when the  $[\text{Cl}^-]$  was at the CTL. The EIS method has a wide application range and is highly sensitive compared with the potential method and current method. The Simulated concrete Pore Solutions (SPSs) were composed of 0.6 mol/L KOH, 0.2 mol/L NaOH and 0.001 mol/L  $\text{Ca}(\text{OH})_2$ . The carbonation process of concrete was simulated by adjusting the pH value using  $\text{NaHCO}_3$ . The penetration of chloride was simulated by adding NaCl. The influence of the pH on the CTL of HRB400 was significant and non-linear. The temperature had a relatively high impact on the CTL of HRB400.

**Keywords:** concrete reinforcement; Threshold Chloride Level (CTL); Open Circuit Potential (OCP); Electrochemical Impedance Spectroscopy (EIS); rebar (HRB400)

## 1 INTRODUCTION

Steel-reinforced concrete, a major engineering structural material, is widely used in civil engineering applications such as roads, bridges and harbors. However, the corrosion of steel bar inevitably results in severe damage to reinforced concrete structures in two ways<sup>[1]</sup>. Firstly, it reduces the cross-sectional area of the steel bar. Secondly, it produces more corrosion products than the steel itself. Such an increase causes tensile stress in the concrete, leading to cracking and, eventually, structural failure.

It is well known that the steel reinforcement in concrete is normally in a passive state against corrosion due to a thin iron oxide layer that is formed on the steel surface and remains stable in the highly alkaline environment of the concrete<sup>[2]</sup>. However, this passive state can be inhibited by the destruction of the passive film by aggressive ions (chlorides, sulfates) or by acidification of the environment near the rebar (carbonation). Corrosion of the reinforcing steel is the natural result of chloride penetration in reinforced concrete.

Tuutti<sup>[3]</sup> suggested that, from the point of view of reinforcement corrosion, the service life of a concrete structure could be subdivided into an incubation period ( $t_1$ ) and a propagation period ( $t_2$ ) (Fig. 1).

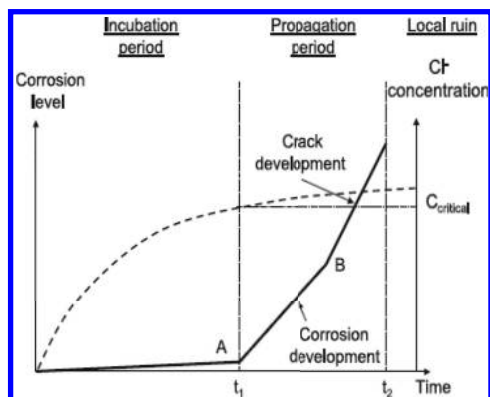

Figure 1. Schematic sketch of the steel corrosion sequence in concrete<sup>[3]</sup>.

- A. The incubation period ( $t_1$ ) corresponds to the chloride penetration within the porous materials and chloride ion accumulation in the vicinity of the rebar. The duration of this period depends on the concrete cover and the chloride concentration required to start the corrosion process.
- B. The propagation period ( $t_2$ ) corresponds to the stage when the chloride ions depassivate the reinforcing steel surface, leading to the development of corrosion and, at term, to the local ruin of the structure.

Chloride-induced corrosion of reinforced steel bar (rebar) is one of the major causes of premature degradation of reinforced concrete and consequent structure collapse<sup>[4]</sup>. The importance of chloride ions in the corrosion of steel in concrete has led to the concept of a Chloride Threshold Level (CTL). The CTL can be defined as the content of chloride at a given steel depth that is necessary to sustain local passive film breakdown and hence initiate the corrosion process<sup>[5]</sup>. Knowledge of the CTL for the corrosion of a steel reinforcement is essential for predicting the durability and service life of reinforced concrete contaminated with chloride ions. Consequently, numerous investigations<sup>[6-8]</sup> have been devoted to identifying the threshold value. Half-cell potential (Open Circuit Potential, OCP) measurements for determining rebar corrosion initiation have been standardized<sup>[9]</sup>. Another nondestructive technique, Linear Polarization Resistance (LPR), has also been used to characterize corrosion initiation and propagation according to a defined criterion value of the corrosion current density,  $i_{corr}$ , or the abrupt variation of  $i_{corr}$ <sup>[10]</sup>. Among the various electrochemical methods widely developed in the literature, Electrochemical Impedance Spectroscopy (EIS) seems to be the most reliable technique for monitoring the corrosion process in reinforced concrete<sup>[11-12]</sup>. This method, contrary to the stationary techniques (e.g., the anodic polarization method), allows the characterization, in a nondestructive way, of both the diffusion of aggressive species within the cement-based materials and the kinetics of the electrochemical reactions that occur on the steel electrode surface.

In this paper, we propose an EIS method to identify the CTL. The advantages of the EIS method

were compared with the OCP and LPR methods. The CTL, represented with  $[Cl^-]$ , for pre-rusted bars at four different pHs and three temperature SPSs was investigated using the EIS technique.

## 2 EXPERIMENT

### 2.1 Specimen preparation

Thread steel bar (HRB400) specimens were prepared for this study. The specimen types were cut into 30 mm lengths from black steel rebar of 12 mm nominal diameter. The unexposed faces were sealed with epoxy resin. Before exposure, the as-received surfaces were mechanically polished using 400, 800 and 1200 emery papers and lubricated using distilled water. The polished samples were cleaned with acetone, washed with distilled water, dried in air and stored over a desiccant. The average area of the exposed rebar surfaces was  $1.1 \pm 0.02 \text{ cm}^2$ .

### 2.2 Experimental setup

A 1 L glass container was used as a test cell in this study. Four types of Simulated concrete Pore Solutions (SPSs) were selected as pore water solutions. The chemical compositions of the SPSs are presented in Table 1<sup>[13]</sup>. The lower pH (SPS1) solution was intended to present pore water within a carbonated concrete environment. Approximately 0.8 L of SPS was used in each glass container, and the pH was monitored throughout the experiment. Because the deviation results were less than 0.1, the effects on the experimental results induced by pH fluctuations were ignored. The chloride concentrations in the SPSs were adjusted stepwise by adding reagent-grade NaCl crystals. For the chloride adjusting process, approximately 100 mL of solution was extracted with a syringe from the test cell. After the NaCl crystals completely dissolved, the extracted solution was poured back into the cell<sup>[10]</sup>. A magnetic stirring bar was placed at the bottom of each container and was set to rotate at the lowest rate to continuously and homogeneously mix the solution throughout the experiment, including

Table 1. Chemical compositions and nominal pH values of fresh simulated pore solutions.

Composition	pH	NaOH (mol/L)	KOH (mol/L)	Ca(OH) <sub>2</sub> (mol/L)	NaHCO <sub>3</sub>
SPSs1	9.6	0.6	0.2	0.001	Proper
SPSs2	10.6	0.6	0.2	0.001	Proper
SPSs3	11.6	0.6	0.2	0.001	Proper
SPSs4	12.6	0.6	0.2	0.001	Proper

the period when the electrochemical measurements (see below) were conducted. The ambient temperature was held at  $25 \pm 2$  °C,  $35 \pm 2$  °C and  $45 \pm 2$  °C. To reduce carbonation, all of the cells were covered except during the NaCl crystal addition and pH monitoring. At the beginning of the experiment, the specimens were immersed in the designated SPSs for 3 days for preconditioning. Subsequently, chloride was adjusted, and the interval for the stepwise chloride increment was approximately 2 days.

### 2.3 Electrochemical measurements

To assess the corrosion conditions of steel bars, electrochemical measurements were carried out. The rebar was used as the working electrode, a platinum net was used as the counter electrode, and a Saturated Calomel Electrode (SCE) was used as the reference electrode. During the course of the experiment, the rebar electrode was always immersed in the SPSs. For the open circuit potential measurement, the linear polarization measurement and the electrochemical impedance spectroscopy measurement, the Autolab Aut84458 Advanced Potentiostat/Galvanostat/FRA system was used. The linear polarization scan was carried out between  $-15$  mV and  $+15$  mV with respect to the rest potential ( $E_{\text{corr}}$ ). The potential was applied at a rate of  $0.0167$  mV/s. Electrochemical Impedance Spectroscopy (EIS) was measured with a sinusoidal potential excitation of  $15$  mV amplitude in the frequency range from  $100$  KHz to  $10$  mHz at the corrosion potential.

## 3 RESULTS AND DISCUSSION

### 3.1 Comparison of the methods for determining the CTL

#### 3.1.1 Determination of the CTL for the corrosion of rebar in the pH 9.6 spss at 25°C

Figure 2 shows the evolution of the OCP and corrosion potential ( $E_{\text{corr}}$ ) of HRB400 rebars with  $[\text{Cl}^-]$  increment in the pH 9.6 SPSs at 25°C. The solid shapes and the shaded area are the upper and lower boundaries of a dramatic shift in the OCP and  $E_{\text{corr}}$ , implying the initiation of corrosion of the rebar in the corresponding  $[\text{Cl}^-]$  range. To be conservative, the  $[\text{Cl}^-]$  value at the middle of the shaded area was considered the threshold value in this study. For the pH 9.6 SPSs at 25°C, prior to reaching the threshold value, the OCP and  $E_{\text{corr}}$  were more positive than  $-240$  mV vs. SCE, and the values remained in a relatively stable trend. After the  $[\text{Cl}^-]$  exceeded the threshold value, the OCP and  $E_{\text{corr}}$  shifted negatively by more than  $600$  mV.

Figure 2. The influence of the  $[\text{Cl}^-]$  on the OCP and  $E_{\text{corr}}$  of HRB400 in the pH 9.6 SPSs at 25°C.

The values for the corrosion potentials and corrosion current densities ( $i_{\text{corr}}$ ) were estimated from the intersection of the anodic and cathodic Tafel lines. Figure 3 presents the  $i_{\text{corr}}$  variation of the HRB400 bar as a function of the  $[\text{Cl}^-]$  stepwise increment variation in the pH 9.6 SPSs at 25°C. For all of the SPSs and all of the stepwise  $[\text{Cl}^-]$  additions, the  $i_{\text{corr}}$  fluctuations ranged from  $1 \times 10^{-4}$  to  $3 \times 10^{-2}$  mA/cm<sup>2</sup>. After the  $[\text{Cl}^-]$  reached the threshold value, sharp  $i_{\text{corr}}$  fluctuations were apparent.

EIS is a powerful technique for obtaining detailed knowledge of the conductive anode system. EIS provides information on a number of parameters, such as the presence of surface films, interfacial reactions and mass-transfer phenomena. Figure 4 shows the EIS data for the HRB400 bars, which were immersed in the pH 9.6 SPSs with different  $[\text{Cl}^-]$  at 25°C. The plots could be divided into two parts in the  $[-1, 1]$  range of  $\log f$ , and the CTL could be distinctly determined. The  $Z_0$ , which is the resistance value when  $\log f$  equals 0 (frequency is 1 Hz), was extracted from the EIS data. A plot of the change in  $Z_{1\text{Hz}}$  with  $[\text{Cl}^-]$  was drawn, as shown in Figure 5. The value of  $Z_{1\text{Hz}}$  sharply shifted, implying damage of the passive film by chloride ions. The  $[\text{Cl}^-]$  was at the CTL when the  $Z_{1\text{Hz}}$  value sharply shifted. The CTL could be easily determined using the potential, current and resistance methods; however, the resistance method is more sensitive than the others.

#### 3.1.2 Determination of the CTL for the corrosion of rebar in the pH 10.6 spss at 25°C

Figures 6–8 show the evolution of OCP,  $E_{\text{corr}}$ ,  $i_{\text{corr}}$  and  $Z_{1\text{Hz}}$  of the HRB400 rebars with  $[\text{Cl}^-]$  increment in the pH 10.6 SPSs at 25°C. The CTL could be easily determined using the current and

Figure 3. The influence of the  $[Cl^-]$  on the  $i_{corr}$  of HRB400 in the pH 9.6 SPSs at 25°C.

Figure 6. The influence of the  $[Cl^-]$  on the OCP and  $E_{corr}$  in the pH 10.6 SPSs at 25°C.

Figure 4. The EIS of HRB400 in the pH 9.6 SPSs with different  $[Cl^-]$  at 25°C.

Figure 7. The influence of the  $[Cl^-]$  on the  $i_{corr}$  of HRB400 in the pH 10.6 SPSs at 25°C.

Figure 5. The influence of the  $[Cl^-]$  on the  $Z_{1 Hz}$  of HRB400 in the pH 9.6 SPSs at 25°C.

Figure 8. The influence of the  $[Cl^-]$  on the  $Z_{1 Hz}$  of HRB400 in the pH 10.6 SPSs at 25°C.

resistance methods but not the potential method. Of the available methods for determining the CTL, the new resistance method was more sensitive and had a wider application range than the others. The resistance method allows the characterization,

in a nondestructive way, of both the diffusion of aggressive species within the cement-based materials and the kinetics of the electrochemical reactions that occur on the steel electrode surface. In this paper, the CTL was determined using the new resistance method.

### 3.2 The influence of temperature and pH on the CTL of HRB400 rebar in SPSs

Figure 9 shows the CTLs of HRB400 rebar in pH 9.6, 10.6, 11.6 and 12.6 SPSs at 25°C, 35°C and 45°C. Corrosion occurred on the HRB400 rebar without adding NaCl in the pH 9.6 SPSs at 45°C; therefore, the CTL was zero. Figure 10 shows the influence of the temperature and pH on the CTLs of HRB400 rebar in SPSs. The influence of the pH on the CTL of HRB400 was significant and non-linear. The carbonation of reinforced concrete was simulated by decreasing the pH, and carbonation had a very large and complicated influence on the CTL. The ambient temperature had a relatively high impact on the CTL of HRB400.

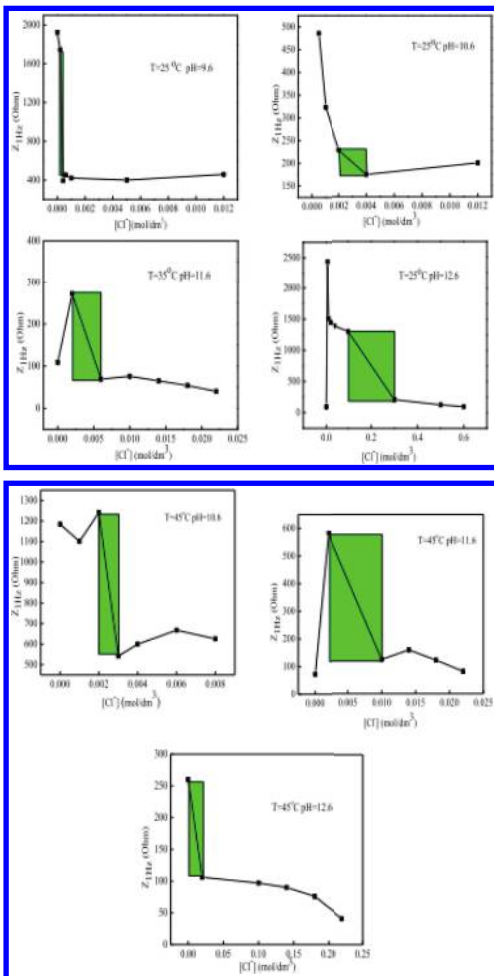

Figure 9. The CTLs of HRB400 rebars in SPSs with different temperatures and pH values.

Figure 10. The influence of temperature and pH on the CTLs of HRB400 rebars in SPSs.

## 4 CONCLUSIONS

According to the experimental results and discussion presented above, the following conclusions could be drawn:

1. The EIS method was proposed to identify the CTL: The  $Z_1$ , which is the resistance value when the frequency is 1 Hz, was extracted from the EIS data. In a plot of the change in  $Z_{1\text{Hz}}$  with  $[\text{Cl}^-]$ , a sharp shift in the  $Z_{1\text{Hz}}$  value was observed when the  $[\text{Cl}^-]$  was the CTL. The resistance method is more sensitive and has a wider application range than the other methods.
2. The carbonation of reinforced concrete was simulated by decreasing the pH. The influence of the pH on the CTL of HRB400 was significant and non-linear. Therefore, carbonation had a very large and complicated influence on the CTL. In addition, the ambient temperature had a relatively high impact on the CTL of HRB400.

**ABSTRACT:** The concentrations of dissolved oxygen, pH value and the other chemical factors, dramatically change in the thermocline of the tropical oceans. There is superior influence of the temperature and the dissolved oxygen concentration upon the corrosion of pipeline steel in the thermocline. With the decreasing of temperature and increasing of dissolved oxygen, the OCP of pipeline steel in the thermocline of tropical oceans rises. With the decreasing of temperature and dissolved oxygen, the Ecorr drops down and Icorr enlarges. If the pipeline steel is placed through the thermocline, the corrosion would occur that caused by the temperature difference and the oxygen concentration difference. The influence of the oxygen concentration on the corrosion was of significance.

**Keywords:** corrosion; thermocline; dissolved oxygen; temperature; tropical oceans

## 1 INTRODUCTION

The thermocline is a thin but distinct layer in a large body of fluid (e.g. water, such as an ocean or lake, or air, such as an atmosphere) in which temperature changes more rapidly with depth than it does in the layers above or below<sup>[1, 2]</sup>. In the ocean, the thermocline may be thought of as an invisible blanket which separates the upper mixed layer from the calm deep water below. The thermocline exists all year in the tropical oceans and subtropical oceans<sup>[3]</sup>. The concentrations

of dissolved oxygen, pH value and the other chemical factors, dramatically change in the thermocline<sup>[4]</sup>. The temperature, dissolved oxygen and pH value are important factors of metal corrosion. The corrosion behavior of metal material that subjected to a tropical marine atmosphere environment was investigated<sup>[5-7]</sup>. The corrosion behavior of metal material was studied in tropical seawater<sup>[8-10]</sup>. The effect of the sea mud on erosion-corrosion behaviors was studied<sup>[11, 12]</sup>. However, very few studies have been dedicated to the corrosion of metal material in the thermocline of ocean.

In this study, we use the sea water of the South China Sea as based electrolyte. By adjusting the temperature and dissolved oxygen, the upper and underlying water of thermocline were simulated. The corrosion of the pipeline steel was studied in the ocean thermocline. It is important for industrial and scientific research.

## 2 EXPERIMENTAL

### 2.1 Electrode and solutions

Test specimens were made of pipeline steel (X70), with a chemical composition (wt%) C 0.061%, Si 0.24%, Mn 1.53%, P 0.011%, S 0.009% and Fe balance. Specimens were cut into

Figure 1. Annual mean vertical ocean profile from 0–300 m along 160°E in the Western Tropical Pacific. Colors represent temperature (°C)<sup>[13]</sup>.

10 mm × 10 mm × 3 mm coupons. The unexposed faces were sealed with epoxy resin with an exposed area of 1.0 cm<sup>2</sup>. Before exposure, the samples were mechanically polished using 400, 800 and 1200 emery papers and lubricated using distilled water. The polished samples were cleaned with acetone, washed using distilled water, dried in air and stored over a desiccant.

The test solution used for the investigation was seawater collected from Zhanjiang Bay, Guangdong, China. The upper water of thermocline was prepared by adjusting the temperature of the basic test solution, the underlying water of thermocline was prepared by adjusting the temperature and adding Na<sub>2</sub>SO<sub>3</sub> (0.001 mol/dm<sup>3</sup> concentration) for controlling the dissolved oxygen of the basic test solution.

## 2.2 Electrochemical measurements

Electrochemical measurements were performed on a three electrode cell through an AUTOLAB (aut84458) electrochemical measurement system. Pipeline steel was used as working electrode, a platinum net as counter electrode, and a Saturated Calomel Electrode (SCE) as reference electrode. Prior to electrochemical measurements, the electrode was immersed in the test solution for at least 1 h until a steady-state corrosion potential was reached<sup>[14]</sup>.

The Linear Polarization (LP) was performed using a potentiostat/galvanostat (AUTOLAB aut84458). The linear polarization curve was measured by potential scanning from -800 to +500 mV vs. corrosion potential at a sweep rate of 1 mV/s.

The corrosion tests of pipeline steel caused by the difference of oxygen concentration and temperature were performed using the Electrochemical Noise (ECN) method. For this work we used an AUTOLAB potentiostat and the NOVA1.10, specific software for electrochemical noise studies.

Figure 2. Standard “Salt-Bridge” arrangement for electrochemical noise measurement.

The electrode assembly consisted of two working electrodes of pipeline steel and a Saturated Calomel Reference (SCE) electrode (VSCE = 0.244 V/NH). This disposition allows the simultaneous measurement of galvanic potential and galvanic current (Fig. 2)<sup>[15]</sup>.

## 3 RESULTS AND DISCUSSION

### 3.1 Open Circuit Potential (OCP) of pipeline steel in the thermocline

The OCPs of pipeline steel were measured for 1 hour in the four kinds of electrolyte (A 303 K seawater; B 303 K seawater + SO<sub>3</sub><sup>2-</sup>; C 288 K seawater; D 288 K seawater + SO<sub>3</sub><sup>2-</sup>) (Fig. 3). The 303 K seawater corresponds to the upper water of the tropical oceans thermocline which saturated with dissolved oxygen. The 288 K seawater + SO<sub>3</sub><sup>2-</sup> correspond to the underlying water which is low concentration of dissolved oxygen. The OCP raises in the cold seawater towards more positive value, on the contrary, the OCP drops down due to the low concentration of dissolved oxygen. The difference between the maximum value and minimum value of OCP was about 200 mV, which was a strong power to the corrosion of pipeline steel if it was placed in the upper and underlying seawater of thermocline.

### 3.2 The corrosion of the pipeline steel that is placed in the different areas of thermocline

The corrosion of the pipeline steel, which is placed in the thermocline, was measured by using LP measurements in the four kinds of electrolyte. Figure 4 represents the linear polarization curves of pipeline steel in the different layer of thermocline. From the figure, it can be

Figure 3. The OCPs were measured for pipeline steel in: (A: 303 K seawater; B: 303 K seawater+ SO<sub>3</sub><sup>2-</sup>; C: 288 K seawater; D: 288 K seawater+ SO<sub>3</sub><sup>2-</sup>).

Figure 4. Potentiodynamic polarization curves for pipeline steel in the four kinds of electrolyte: (A: 303 K seawater; B: 303 K seawater +  $\text{SO}_3^{2-}$ ; C: 288 K seawater; D: 288 K seawater +  $\text{SO}_3^{2-}$ ).

seen that the corrosion potential ( $E_{\text{corr}}$ ) values in the low-temperature seawater and in the presence of reductant are shifted to negative direction, the anodic current densities obtained in the low-temperature seawater and in the presence of reductant are higher than that of in the high-temperature seawater and the absence of reductant, the cathodic current densities obtained in the high-temperature seawater are higher than that of in the low-temperature seawater, no differences of the cathodic current densities were found in the absence or presence of reductant.

The values for the corrosion potentials and corrosion current densities were estimated from the intersection of the anodic and cathodic Tafel lines<sup>[8]</sup>. The corresponding corrosion potentials ( $E_{\text{corr}}$ ), corrosion current density ( $i_{\text{corr}}$ ), anodic Tafel slopes ( $b_a$ ) and cathodic Tafel slopes ( $b_c$ ) are listed in Table 1. From results obtained, it can be concluded that:

- The values of corrosion current density ( $i_{\text{corr}}$ ) increase with the decreasing of temperature and dissolved oxygen. The values of corrosion potentials ( $E_{\text{corr}}$ ) decreased with the decreasing of temperature and dissolved oxygen.
- The rate of anodic reaction controls the rate of the corrosion process in the high-temperature seawater. The rate of cathodic reaction controls the rate of the corrosion process in the low-temperature seawater.
- The corrosion current increases obviously after sodium sulfite is added in high-temperature seawater and low-temperature seawater. It is clear that the reducing of dissolved oxygen in seawater causes the markedly increase of in the corrosion rate.

Table 1. Electrochemical parameters: corrosion potential ( $E_{\text{corr}}$ ), corrosion current density ( $i_{\text{corr}}$ ), and Tafel slopes ( $b_a$  and  $b_c$ ) of pipeline steel in seawater.

Condition	Potentiodynamic polarization			
	$E_{\text{corr}}$ (mV)	$i_{\text{corr}}$ ( $\mu\text{Acm}^{-2}$ )	$b_a$ (mVdec <sup>-1</sup> )	$b_c$ (mVdec <sup>-1</sup> )
303 K	-800	3.304	234.64	98.93
303 K+ $\text{Na}_2\text{SO}_3$	-854	7.369	537.24	90.03
288 K	-912	16.14	109.40	667.5
288 K+ $\text{Na}_2\text{SO}_3$	-948	45.09	134.15	1050

Figure 5. ECN data in the time for pipeline steel that was placed through the thermocline: a potential around 0 V, b current.

### 3.3 The corrosion of the pipeline steel that is placed through the thermocline

The corrosion of the pipeline steel, which is placed through the thermocline, was measured by using the electrochemical noise method and using the experimental devices as Figure 2. Figure 5 shows the experimental ECN data for pipeline steel. The pipeline steel was placed in the high-temperature seawater (303 K) and in the low-temperature seawater (288 K), the potential difference between them is always negative and the current ( $I_{\text{High-DO}}$ ) caused by the temperature difference varies from 0 nA to 5 nA. The potential difference is the power of the corrosion caused by the temperature difference. The pipeline steel was placed in the high-temperature seawater (303 K) and in the low-temperature seawater added reductant (288 K +  $\text{SO}_3^{2-}$ ), the potential difference between them is always negative, but the absolute values of potential difference are decreased. The current ( $I_{\text{Low-DO}}$ ) caused by the temperature difference and the oxygen concentration difference varies from 0 nA to 50 nA. The mean of  $I_{\text{Low-DO}}$  enlarges about 10 times compared with the  $I_{\text{High-DO}}$ .

## 4 CONCLUSIONS

There is superior influence of the temperature and the dissolved oxygen concentration upon

the corrosion of pipeline steel in the thermocline of tropical oceans. With the decreasing of temperature and increasing of dissolved oxygen, the OCP of pipeline steel in the thermocline of tropical oceans rises. With the decreasing of temperature and dissolved oxygen, the Ecorr drops down and Icorr enlarges. If the pipeline steel is placed through the thermocline, the corrosion would occur that caused by the temperature difference and the oxygen concentration difference. The influence of the oxygen concentration on the corrosion was of significance.

# Numerical study of typhoon waves with the typhoon hindcasted model

Jia Dong, Jian-Feng Zhai, Zhi-Xia Zhu & Pei-Hua Dong

*Jiangsu Provincial Communications Planning and Design Institute Co. Ltd., Nanjing, China*

*Jiangsu Provincial Technology Research Center for Water Transport Engineering, Nanjing, China*

**ABSTRACT:** In this paper, the typhoon hindcasted model and third-generation wave model SWAN are coupled to simulate the typhoon wave. First, the gradient wind field of “KeLuoSha” was simulated with the Fujita-Takahashi Typhoon hindcasted model. Then, ambient wind and gradient wind are used to computed the typhoon field. In addition, three stations are chosen to validate the wind velocity of the model. Finally, typhoon wave is simulated with the SWAN model, and the wave parameters of the model are validated well with buoyed parameters. The result shows that the typhoon hindcasted model coupled with the wave model can simulate the typhoon wave precisely.

**Keywords:** typhoon simulation; typhoon wave; wave simulation

## 1 INTRODUCTION

Typhoon plays an important role in ocean and coastal engineering. It causes huge losses in China every year. In order to study the typhoon, a lot of work has been done by researchers<sup>[1-6]</sup>. Currently, there are two ways to simulate the typhoon field. One is through the weather model such as the WRF and MM5 model, another way is by using the typhoon parameters model. In this paper, the Fujita-Takahashi typhoon parameter model and the wave model SWAN are coupled to simulate the typhoon field and the wave field. First, the NECP-reanalyzed wind field data are interpolated to meet the accuracy of time and space. Then, the Fujita-Takahashi parameter model is used to calculate the gradient wind field of the typhoon. Then, the typhoon field is composed and validated well with measured parameters. Finally, the third-generation wave model SWAN is used to simulate the wave field induced by the typhoon. The result shows that the typhoon parameters model coupled with the SWAN model can simulate the typhoon wave accurately.

## 2 MODEL THEORY AND PARAMETER SETTING

### 2.1 Typhoon parameters model of Fujita-Takahashi

The typhoon field can be decomposed into the gradient wind field and the ambient wind field. The Fujita-Takahashi Typhoon model are used to

simulate the gradient wind field, which is described below<sup>[5]</sup>.

As  $0 \leq r < 2R$ , the wind velocity can be computed as follows:

$$W_z = C_1 V_{dz} \exp\left(-\frac{\pi}{4} \cdot \frac{|r-R|}{R}\right) - C_2 \left\{ -\frac{f}{2} + \sqrt{\frac{f^2}{4} + \frac{2\Delta P}{\rho_a R^2} \left[1 + 2\left(\frac{r}{R}\right)^2\right]^{\frac{3}{2}}}\right\} \cdot [(x-x_0)\sin\theta + (y-y_0)\cos\theta] \quad (1)$$

$$W_y = C_1 V_{\theta j} \exp\left(-\frac{\pi}{4} \cdot \frac{|r-R|}{R}\right) - C_2 \left\{ -\frac{f}{2} + \sqrt{\frac{f^2}{4} + \frac{2\Delta P}{\rho_a R^2} \left[1 + 2\left(\frac{r}{R}\right)^2\right]^{\frac{3}{2}}}\right\} \cdot [(x-x_0)\cos\theta + (y-y_0)\sin\theta] \quad (2)$$

As  $2R \leq r < \infty$ , the typhoon velocity in the x and y direction can be described as follows:

$$W_z = C_1 V_{dz} \exp\left(-\frac{\pi}{4} \cdot \frac{|r-R|}{R}\right) - C_2 \left\{ -\frac{f}{2} + \sqrt{\frac{f^2}{4} + \frac{\Delta P}{\rho_a R r} \left[1 + \frac{r}{R}\right]^2}\right\} \cdot [(x-x_0)\sin\theta + (y-y_0)\cos\theta] \quad (3)$$

$$W_y = C_1 V_{dy} \exp\left(-\frac{\pi}{4} \cdot \frac{|r-R|}{R}\right) + C_2 \left\{ -\frac{f}{2} + \sqrt{\frac{f^2}{4} + \frac{\Delta P}{\rho_a R r} \left[1 + \frac{r}{R}\right]^{-2}} \right\} \cdot [(x-x_0)\cos\theta - (y-y_0)\sin\theta] \quad (4)$$

$$f = 2 * 7.292 * 10^{-5} * \sin\phi \quad (5)$$

where  $C_1$  and  $C_2$  are the empirical coefficient;  $r$  is the distance from the center of typhoon to the calculated point;  $f$  is the Coriolis coefficient; and  $W_x$ ,  $W_y$  are the wind velocity in the x and y direction, respectively.

## 2.2 Wave model of SWAN

The third-generation wave model SWAN is based on the balance of energy spectrum, in the coordinate of Cartesian, which can be described as follows<sup>[6]</sup>:

$$\frac{\partial}{\partial t} N + \frac{\partial}{\partial x} c_x N + \frac{\partial}{\partial y} c_y N + \frac{\partial}{\partial \sigma} c_\sigma N + \frac{\partial}{\partial \theta} c_\theta N = \frac{S_{\cos}}{\sigma} \quad (6)$$

where  $N$  is the action density;  $c_x$ ,  $c_y$  are the speed of the wave group in the x and y direction, respectively; and  $c_\sigma$ ,  $c_\theta$  are the frequency and direction of the speed, respectively.

## 2.3 Parameter setting

In the typhoon wind field gradient field of the model, the typhoon center movement speed and the typhoon center typhoon related data, such as maximum wind speed and air pressure can be obtained from the typhoon yearbook. The typhoon wind field space step length is  $0.05^\circ * 0.05^\circ$ , time step of 1 hour, the time span for September 29, 2007 to October 16, 2007. The north and south direction space spans  $14.5^\circ \text{N} - 41.5^\circ \text{N}$ , east-west  $118.5^\circ \text{E} - 138.5^\circ \text{E}$ . The typhoon field environment wind field is mainly adopted to analyze the NECP wind field. Its space and time step is longer, in order to meet the accuracy requirement of the typhoon wind field, on the linear interpolation. For obtaining the typhoon wind field, the proportion of weight, and with the longer the distance the distances from the center of the typhoon, the gradient wind place much proportion of the smaller.

In the wind and waves in the process of simulation, the calculation of the wave model range is shown in Figure 1: the northwest boundary of Yantai to Dalian, the northeast border for South Korea to Japan, and south near the boundary for the Philippines. In order to better fit the complex

Figure 1. The depth of computational domain in the wave model.

coastline, the model adopted in an unstructured grid. Calculation, initial conditions with the method of the cold start, driving stress for the typhoon wind field, considering the nonlinear interaction between waves in the process of simulation, white hat losses, the bottom friction and physical phenomena such as wave breaking wave spectrum using Jonswap spectrum, strengthen the spectral peak factor of 3.3, spectrum for 0.05 1 Hz, which is divided into 30, the direction will be divided into the 36, computing time step for 5 min, output time step for 30 min.

## 3 MODEL VERIFICATION AND ANALYSIS

### 3.1 Verification of the typhoon wind field

Typhoon wind field can be obtained by the gradient wind farm and environmental wind farm. Currently, the parameter model of typhoon gradient wind farm is developed. This paper selects the internationally popular Fujita-Takahashi formula to calculate the typhoon gradient wind farm. Since the model belongs to the theoretical pressure model, the calculated wind field is circular. The characteristics of wind speed distribution are as follows: the speed of the typhoon wind field center is 0m/s, with the distance from the center of typhoon being much far, the wind speed shows an increased trend and then a decreased one. The wind speed reaches the maximum in the vicinity of typhoon maximum radius. Figure 2 shows the

distribution of the typhoon wind speed field at some point. The red circles represent the location of typhoon. We can see that relative to the whole computational domain, the influence of typhoon is relatively small, in five times the radius maximum wind speed, the typhoon influence is relatively large, while beyond five times, the radius of the maximum wind speed influencing the typhoon is very small.

Whether the typhoon wind speed simulation is accurate or not has an important influence on the accuracy of the simulation of the wave. In order to verify the accuracy of typhoon wind speed, this paper selects three stations near the typhoon path to validate the wind speed. These three stations are Hualian buoy (121.63°E, 24.03°N), Kueishan Island buoy (121.93°E, 25.85°N) and Suao buoy (121.88°E, 24.63°N). The simulation of the wind speed value is compared with the observation value, and the results are shown in Figure 2–Figure 5.

Figure 2. The distribution of wind velocity of the typhoon.

Figure 3. The comparison of wind velocity of the model measured in HuaLian.

Figure 4. The comparison of wind velocity of the model measured in Guishan.

Figure 5. The comparison of wind velocity of the model measured in Suao.

We can see that the simulation value and the observation value of wind speed fit very well for these three stations. Not only the change in the trend is consistent, but also the size is similar. It shows that the typhoon parameter model can simulate the typhoon process very well, and the precision is higher, so it provides a reliable basis for the later period to simulate wave field accurately.

### 3.2 Verification and analysis of typhoon waves

Typhoon waves can cause great harm to engineering every year. Many engineering problems are directly or indirectly related to typhoon waves, such as the design wave elements problems in engineering, sudden siltion problem caused by typhoon, security issues caused by the effect of waves on building structures and the local scour problem of the bottom of buildings under the waves, so it has an important engineering significance for the accurate simulation of typhoon waves. Whether the typhoon wave simulation is accurate or not mainly depends on the accuracy of bathymetric and precision of the driving wind field. After the previous wind speed verification, we can see that the wind speed has reached a high accuracy. Typhoon is generally formed in deep sea, so water depth has a relatively small effect on it. In order to verify the reliability of the simulation results of the model, this paper compares the simulation results with the observed value of three wave floating stations, and the results of the comparison are shown in Figure 6–Figure 8. Figure 6 shows the results of the comparison of the simulated and observed values of Hualian floating station height and period.

Figure 6. The comparison of wave parameters of the model measured in Hualian.

Figure 7. The comparison of wave parameters of the model measured in Guishan.

Figure 8. The comparison of wave parameters of the model measured in Suao.

During the typhoon process, the maximum wave height for Hualian station reached 11m, and the maximum average period reached 13s. The wave heights and periods have a similar change in trend, both of them first become larger and then gradually decrease. Figure 7 shows the results of the comparison of the simulated and observed values of height and period for Kameyama station, with the maximum wave height reaching 15m and the maximum average period reaching 12s. Figure 8 shows the results of the comparison of the simulated and observed values of height and period for SuAo station. As can be seen from the graph, only the wave heights and periods have a similar

change in trend but the size is similar. When the typhoon passed, the maximum wave height of this station reached 12m, the maximum average period reached 12s. On the whole, the typhoon wave model has a high precision simulation result. The simulation accuracy of the Kameyama station is lower than that of the Hualian station and SuAo station. Generally, the simulation accuracy of the wave period is higher than the wave height at these three stations. Although the wave simulation has

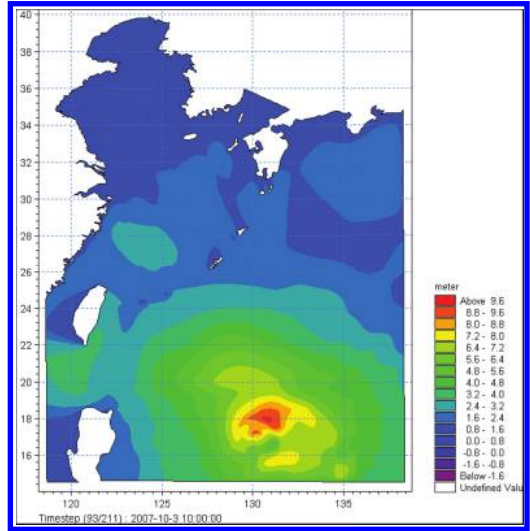

Figure 9. The distribution of wave height as typhoon develops.

Figure 10. The distribution of wave height as typhoon grows up.

a high precision, there are also some error. This is mainly due to the accuracy of the wind field data and depth data.

In order to study the distribution of the wave field at different times, Figure 9 and Figure 10 show the distribution of typhoon waves at two different times. Figure 9 shows the distribution of the wave field in the typhoon development process, with the maximum wave height reaching about 9m. Figure 10 shows the distribution of the wave field after the typhoon has grown, with the maximum wave height reaching about 15m. From the two graphs, we can see that the overall trend of the distribution of wave height is that the wind speed is relatively large when close to the center of typhoon, and the wave height decreases when the distance from the center of the typhoon is much far.

#### 4 CONCLUSION

Through the above research, we can find that using the Fujita-Takahashi model of typhoon parameters coupled with the third-generation wave model SWAN is a good solution to solve the simulation problem. The overall trend of the distribution of typhoon waves is that the wind speed is relatively large when close to the center of typhoon, and the wave height decreases when the distance from the center of the typhoon is much far. The coupled model can simulate the typhoon waves relatively

accurately, so it has a practical significance in engineering.

# Model study on the sediment dynamics in the Bohai Sea

H. Liu & H.X. Kang

College of Marine Sciences, Shanghai Ocean University, Shanghai, China

B.S. Yin & D.Z. Yang

Institute of Oceanology, Chinese Academy of Sciences, Qingdao, China

**ABSTRACT:** A surface wave and 3-dimensional current interaction model is coupled to a Suspended Particulate Matter (SPM) transport model to reproduce the sediment dynamics in the Bohai Sea (BS). Both simulations and observations show that the highest SPM concentration appears in the mouth of the Yellow River. In addition, both the Laizhou and Bohai bays are characterized by the high level of riverine sediments due to the evolution of the river plume under the predominant southeasterly wind in the flood season, and the high level of SPM in the Laidong Bay can be ascribed to the joint effects of the riverine inputs from the Liaohe River and the strong tidal currents that erode the bottom sediments into the water column. The least SPM concentration appears in the central basin. Since the central basin is characterized by strong wave-induced mixing and weak tidal mixing, it can be suggested that wind waves may play a minor role in the local sediment dynamics in summer.

**Keywords:** numerical model; water mixing; SPM transport; Bohai Sea

## 1 INTRODUCTION

The transport of Suspended Particulate Matter (SPM) in coastal seas plays an important role in many oceanic processes, not only in marine geology but also in marine ecology. Therefore, this topic attracts more attention of oceanographers with different disciplines. For example, the SPM transport is tightly correlated with light intensity in the water column, and the latter is one of the dominating parameters in ecological modeling. Thus, it can be suggested that to develop a robust SPM transport model that reflects the local sediment dynamics is imperative to reproduce a better marine ecosystem.

The SPM transport in the Bohai Sea (BS) is mainly governed by the tidal currents and wind waves. In previous studies, the wave or current simulations were carried out independently, that is, wave features were reproduced using the wave models, and the currents were simulated using the ocean circulation model (Yang et al., 2005; Liu et al., 2005; Liu, 2011). More often than not, the wave-current interaction is seldom put together in a single numerical model. In this paper, a surface wave and three-dimensional current interaction model was developed to simulate the key hydrodynamics in the BS, and further coupled to a sediment transport model to examine how these physical processes govern the sediment dynamics in the BS.

## 2 MODEL DESCRIPTION

### 2.1 Equation of the sediment dynamics

The feature and application of the surface wave and three-dimensional current interaction model has been introduced elsewhere (Liu et al., 2013). Using the same model design as the hydrodynamic model, the three-dimensional equation of the sediment dynamics can be written as follows:

$$\begin{aligned} \frac{\partial C}{\partial t} + \frac{\partial UC}{\partial x} + \frac{\partial VC}{\partial y} + \frac{1}{D} \frac{\partial (w - w_s)C}{\partial \sigma} = \frac{\partial}{\partial x} \left( A_H \frac{\partial C}{\partial x} \right) \\ + \frac{\partial}{\partial y} \left( A_H \frac{\partial C}{\partial y} \right) + \frac{1}{D} \frac{\partial}{\partial \sigma} \left( \frac{K_H}{D} \frac{\partial C}{\partial \sigma} \right) + S_C \end{aligned} \quad (1)$$

where  $C$  is the SPM concentration;  $A_H$  and  $K_H$  are the horizontal and vertical diffusivities, which are calculated from the Smagorinski scheme and the MY turbulence closure model, respectively;  $S_C$  is the riverine load of SPM ( $\text{gs}^{-1}$ ).

In this study, the sediment flux via atmospheric deposition is assumed to be null. The sediment erosion and deposition are highlighted since the vertical mass exchange between the sea bed and the bottom layer of seawater is important. As a consequence, the vertical boundary conditions on the sea surface and bottom can be expressed as follows:

$$\begin{cases} \frac{K_H}{D} \frac{\partial C}{\partial \sigma} = 0 & \sigma \rightarrow 0 \\ \frac{K_H}{D} \frac{\partial C}{\partial \sigma} = F_{ero} - F_{dep} & \sigma \rightarrow -1 \end{cases} \quad (2)$$

where  $F_{ero}$  and  $F_{dep}$  represent the flux of sediment resuspension and deposition, respectively. Following Einstein and Krone (Arndt et al., 2007), these terms can be, respectively, expressed as follows:

$$\begin{cases} F_{ero} = p_{ero} \cdot e_c \cdot C_{kb} \\ F_{dep} = p_{dep} \cdot w_s \cdot C_{kbm1} \end{cases} \quad (3)$$

where  $C_{kbm1}$  is the SPM concentration in the bottom layer of seawater; and  $C_{kb} = \rho_b(1 - \phi)$  is the concentration of total solids in the sediment, in which  $\rho_b = 2650 \text{ kgm}^{-3}$  is the sediment density and the sediment porosity is assumed to be  $\phi = 0.7$ ;  $e_c = 5.5 \times 10^{-4}$  is the erosion constant; and  $w_s$  is the SPM settling velocity. In addition, according to the Stokes' law that assumes a spherical particle shape, the following formula can be used:

$$w_s = \frac{1}{18} \frac{(\rho_s - \rho)gd^2}{\rho\nu} \quad (4)$$

where  $\rho_s$  and  $\rho$  are the densities of SPM and seawaters, and their values are assumed to be 1760 and  $1025 \text{ kg m}^{-3}$ , respectively; the fluid kinetic viscosity is assumed to be  $\nu = 5.5 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$ ; and  $d$  is the averaged grain diameter.

From Figure 1, we can see that the BS sediment consists of a heterogeneous mix of the river-derived mud and the fine-to-coarse marine sand. Therefore, the simulation of the SPM transport processes must account for these heterogeneities. In the model design, Arndt's method is adopted. It means that the SPM size class  $C_i$  ( $i$  indicates clay mud, silt mud, coarse silt, fine sand, respectively) is characterized by a specific flux change due to the erosion and deposition, so a unique particle diameter

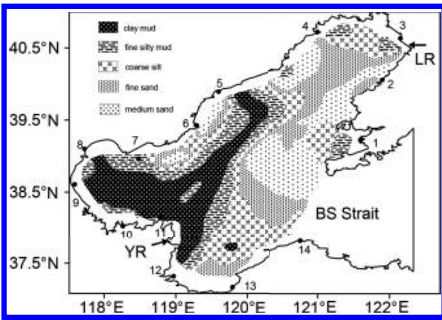

Figure 1. Sediment type distribution in the BS and two major rivers: Yellow River and Liaohe River.

and a continuous Gaussian grain size distribution are used. This distribution is totally characterized by the averaged grain diameter  $d$  and its standard deviation  $\delta d^2$ , which are given as follows:

$$\begin{cases} d = \sum_i d_i \frac{C_i}{C} \\ \delta d^2 = d^2 - \sum_i d_i^2 \frac{C_i}{C} \end{cases} \quad (5)$$

where  $d_i$  indicates the representative particle diameter in the individual size classes  $C_i$ .

Due to the erosion and deposition processes,  $d$  experiences the temporal evolution as a response to the variation in the composition of SPM. For instance, the resuspension of the coarse sediments leads to an increase in  $d$ , while the higher settling velocity of the coarser grains and their preferential deposition results in a decrease of the averaged grain size.

Equation (3) shows that the mass exchange between seawater and sea floor mainly depends on the solid concentration in the bottom layer of the water column as well as that in the bottom sediments. Therefore, by adapting the depth-mean formula of Wirtz and Eckhardt (1996) to the present three-dimensional sediment dynamic model, the time-dependent variance in the average grain diameter of suspended sediment  $d$  and bottom sediment  $d_b$  due to erosion and deposition processes can be approximated as follows:

$$\begin{cases} \frac{d}{dt}(d)|_{ero} = e_c \cdot p_{ero} \cdot \frac{C_{kb}}{C_{kbm1}}(d_b - d) \\ \frac{d}{dt}(d)|_{dep} = \delta d^2 \cdot p_{dep} \cdot \frac{(\rho_s - \rho)g}{9\mu} \cdot d \\ \frac{d}{dt}(d_b)|_{dep} = w_s \cdot p_{dep} \cdot \frac{C_{kbm1}}{C_{kb}}(d - d_b) \\ \frac{d}{dt}(d_b)|_{ero} = 0 \end{cases} \quad (6)$$

where  $p_{ero}$  and  $p_{dep}$  represent the possibilities for sediment erosion and deposition, respectively, and can be formulated as follows:

$$\begin{cases} p_{ero} = \begin{cases} \frac{\tau_b}{\tau_{crd}} - 1 & \tau_{crd} \leq \tau_b \\ 0 & \tau_{crd} > \tau_b \end{cases} \\ p_{dep} = \begin{cases} 1 - \frac{\tau_b}{\tau_{crd}} & \tau_{crd} \geq \tau_b \\ 0 & \tau_{crd} < \tau_b \end{cases} \end{cases} \quad (7)$$

where the bottom shear stress  $\tau_b = \rho u_b |u_b|$ , in which  $u_b$  is the bottom friction velocity; and  $\tau_{crd}$  is the critical shear stress for erosion and deposition, which can be given as follows:

$$\tau_{crd} = (\rho_b - \rho)g \cdot d_b \cdot \theta_{crd} \quad (8)$$

where  $\theta_{crd}$  is the critical mobility parameter, and is given by the following empirical formulations:

$$\begin{cases} \theta_{crd} = 0.24d_*^{-1} & d_* \leq 4 \\ \theta_{crd} = 0.14d_*^{-0.64} & 4 < d_* \leq 10 \\ \theta_{crd} = 0.04d_*^{-0.10} & 10 < d_* \leq 20 \\ \theta_{crd} = 0.013d_*^{-0.29} & 20 < d_* \leq 150 \\ \theta_{crd} = 0.055 & d_* > 150 \end{cases} \quad (9)$$

where  $d_*$  is a non-dimensional particle parameter, and can be written as follows:

$$d_* = \left[ \frac{(\rho_b - \rho)g}{\rho v^2} \right]^{1/3} d_b \quad (10)$$

## 2.2 External forcings and data sources

The model is driven by true forcings, considering tides, wind currents and waves, as well as the river discharges. Eight major tides, namely  $M_2$ ,  $S_2$ ,  $N_2$ ,  $K_2$ ,  $K_1$ ,  $O_1$ ,  $P_1$  and  $Q_1$ , are superimposed on the southeastern open lateral boundary to simulate tidal wave propagations. The wind field is derived from 14 coastal meteorological stations around the BS by means of interpolation and extrapolation. The monthly mean river runoff and riverine sediment load data have been provided by Zhang et al. (2004). Because the input of freshwater and river-borne sediments mainly concentrates in the flood season, we would like to focus our interests on this situation.

## 3 SIMULATIONS

### 3.1 Key physical process

The key hydrodynamics is investigated using a surface wave and three-dimensional current interaction model. It is found that the semi-diurnal tides are dominant in the BS, and the wind-induced surface currents are conducive to the offshore transport of the riverine materials. The significant wind wave height is also reproduced, which shows the large value in the central basin and the wave heights reduce towards the shallow bays. Such knowledge is crucial for better understanding the sediment dynamics in the BS. Detailed descriptions of simulated tides, wind currents and waves have been provided by Liu et al. (2013).

### 3.2 SPM transport characters

Figure 2 shows the simulated and observed depth-mean sediment distribution in the BS. Observations show that the highest level of SPM appears in the mouth of the Yellow River, and the Bohai bay is

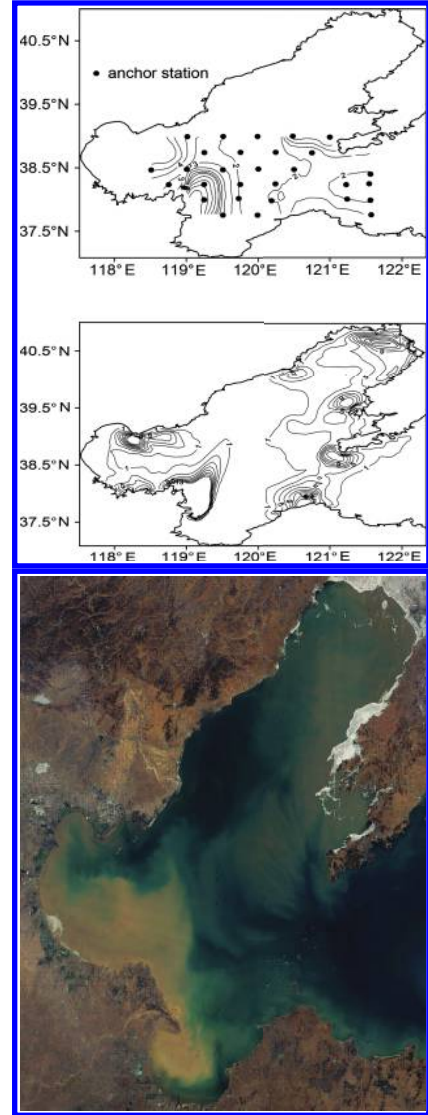

Figure 2. (a) Observed, (b) simulated SPM concentrations ( $\text{gm}^{-3}$ ), and (c) SPM distribution from the Terra-MODIS image on June 4, 2004.

also characterized by the high concentration of SPM. Comparatively, the SPM concentration in the central basin is small. Compared with the observation, the simulation also reflects the same situation. According to the model results, the highest level of SPM in the YR estuary is induced by the riverine sediments from the YR. Driven by the southeasterly winds, the river plume of the YR extends northeastwards and enters the central basin. Since the large amounts of riverine sediments have settled down around the mouth of the YR due to gravity, the concentrations of riverine SPM in the mouth of the YR

plume decrease significantly. It is one of the reasons why the central basin seems to be clearer than three bays. The alongshore currents may be responsible to carry the riverine sediments into the Bohai Bay.

Although the *in situ* investigations for the Liaodong Bay are not available for us to check the model results, a satellite image taken on June 4, 2004 can be used as an alternative. Driven by the south-easterly wind, the river plume of the Liaohe River (LR) is confined to the end of the Liaodong Bay, so the riverine sediments from the LR concentrate there and form a patch of SPM. Besides the river-induced SPM patch, the regions around the headland of Liaodong Peninsula and Changxing Isle are also characterized by the high level of SPM. These regions are relatively far from the river mouth, hence there must be different mechanisms responsible for the high sediment concentrations. In order to investigate what is the governing mechanism, two numerical experiments are carried out: in experiment one, we run the coupled model with all specified external forcings, except the mean wind field; in experiment two, we rebuild the model design but omit the tidal impact purposely. The model results show that the SPM patches far from the estuaries are more probably induced by strong tidal currents. As indicated by Lin et al. (2011), the wave-induced mixing mainly functions in the upper layer of the water column; if the wind field is not strong enough or the water is relatively deep, the wind wave-induced mixing is hard to reach the sea floor to disturb the sediments. The long-term averaged wind field in summer is generally no more than  $5 \text{ ms}^{-1}$ , so it can be suggested that wind waves may play a subordinate role in sediment dynamics in the BS. Both observations and simulations show that the central basin is characterized by strong wind-wave forces and the least SPM concentration, which also suggests the minor role that wind waves play in the local sediment dynamics. Comparing the simulations with the satellite image, it can be found that the fundamental distribution features of SPM are reproduced by the coupled model, though some discrepancies also exist in the meantime. For instance, the observation shows an evident patch of SPM with high concentration in the southern part of Laizhou, but it is not captured by our model. Since only the mean wind field is used in this study, implying that some extreme climate or intermittent northerly and westerly winds are smoothed out, the simulated clear waters in the southern part of the Laizhou Bay can be imagined. Of course, there are still other causes responsible for the differences between simulations and observations, among which the relatively coarse description of the erosion and deposition processes may be a key one, due to the fact that the involved parameters are either taken from literature or from very rough estimations. Overall, the model results

show a general structure that is similar to that visualized in the satellite image.

## 4 CONCLUSIONS

A coupled physical and sediment dynamic model is used to reproduce the SPM transport in the BS. It is found that the tidal current plays the major role, especially in eroding sediments, whereas the effect of the wind wave is relatively small due to the weak mean wind field in summer months (flood season). It should be pointed out that the SPM transport in a shelf sea is determined by a large number of complicated processes, and at present, the dynamics concerning the SPM transport are far from fully understood. In this sense, there are many efforts that should be done to improve the present research. In the near future, the key processes such as beach erosion, bio-turbulence or bio-stabilization function in the local sediment dynamics need to be investigated, and the quantification of these processes should be highlighted.

# Three-dimensional numerical simulation of the tidal flat and channel during flood tide

Zengxiang Jiao, Xinzhou Zhang, Xiping Dou, Yun Pan & Lei Ding

Nanjing Hydraulic Research Institute Key Laboratory of Port, Waterway and Sedimentation Engineering of the Ministry of Transport, Nanjing, China

**ABSTRACT:** In this paper, the flow pattern between the channel and tidal flat with free surface flow was simulated using a numerical model analyzed by Fluent. The cross-section is divided into the main channel, the tidal-flat adjacent channel, and the tidal flat and bank. It obtained the distribution of transverse velocity during the flood tide. The water surface profile was obtained by using the Volume Function Method (VOF) method. During the flood, the velocity of the main channel landward decreased and transverse velocity increased. The velocity of the main channel seaward increased during the ebb by the influence of runoff and tidal. The transverse velocity decreased from the area of the near wall to the zone of tidal-flat adjacent channel.

**Keywords:** numerical simulation; cross section; volume function method

## 1 INTRODUCTION

More recent work has addressed the hydrodynamic between the tidal flat and channel in an estuary<sup>[1]</sup>. During the flood, water diverges from the deep channel to the tidal flat and ebbs converge to from the tidal-flat to the channel<sup>[2]</sup>. Chanyan Li<sup>[3]</sup> identified that the lateral velocity was influenced by the following parameters: the ratio of depth about the tidal and channel; the ratio of tidal level and the average of depth; the ratio of the length wave and estuary. The VOF method has an advantage to treat the free surface. Wang Xuejun<sup>[4]</sup> analyzed the problem of wave flume by using this method. Li Zhiqin<sup>[5]</sup> obtained the distribution of flow velocity around the groyne field with this method.

## 2 NUMERICAL MODEL AND METHODS

### 2.1 Numerical model

This experiment was conducted in a flume with dimensions of 16 m wide, 10 m deep and about 20 m long. While the channel was 6 m wide and 10 m deep, the tidal flat was 5 m wide, 2 m deep at one side. In order to simulate the free surface level, there must be 3 m depth air on the free surface.

### 2.2 VOF model

To represent the sharp interface between the air and water, the VOF method was used. In this

approach, the interface is tracked by introducing the volume fraction for the  $i$  phase.

Water phase:

$$\frac{\partial \alpha_w}{\partial t} + \nabla \cdot (\mathbf{v} \cdot \alpha_w) = 0 \quad (1)$$

where  $\alpha_w$  is the volume fraction of water. Only such transport equation needs to be solved since the volume fraction of the other phase can be inferred from the constraint  $\alpha_a = 1 - \alpha_w$ , where  $\alpha_a$  is the volume fraction of air. The FVM is used to solve the above equation and relies on the flow domain being divided into a grid consisting of a large number of cells. In each cell, if it contains only water, then  $\alpha_w = 1$ , if none,  $\alpha_w = 0$  for each cell that spans the interface between the air and water, with  $0 < \alpha_w < 1$ . Thus, it can be assumed that the surface is on the volume fraction of 0.5.

### 2.3 Equations and calculation methods

Fluent computation fluid dynamic code was used for 3D numerical modeling. Numerical modeling involves the solution of the Navier-Stokes equations, which are based on the assumption of conservation of mass and momentum within a moving fluid. The conservation of mass is described by the differential equation:

$$\frac{\partial}{\partial t}(\rho) + \nabla \cdot (\rho \vec{v}) = 0 \quad (2)$$

where  $\bar{v}$  is the flow rate and  $\rho$  is the fluid density.

The momentum equation can be described as follows:

$$\frac{\partial}{\partial t}(\rho\bar{v}) + \nabla \cdot (\rho\bar{v}\bar{v}) = -\nabla p - \nabla \cdot [\mu(\nabla\bar{v} + \nabla\bar{v}^T)] + \rho\bar{g} + \bar{F} \quad (3)$$

here,  $P$  is the pressure;  $\bar{v}$  is the velocity;  $g$  is the gravity;  $\mu = \mu_0 + \mu_t$ , where  $\mu_0$  is the viscosity of the fluid and  $\mu_t$  is the turbulent viscosity; and  $\bar{F}$  is the body force.

Turbulence model can be obtained using the standard model. The  $k - \varepsilon$  model, which was proposed by Launer in 1972, is used widely as follows:

$$\mu_t = \rho C_\mu \frac{k^2}{\varepsilon} \quad (4)$$

$$\begin{aligned} & \frac{\partial(k\rho)}{\partial t} + \frac{\partial(\bar{u}_i k \rho)}{\partial x_i} \\ &= \frac{\partial}{\partial x_i} \left( \frac{\mu_t}{\sigma_k} \frac{\partial k}{\partial x_i} \right) + \mu_t \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \frac{\partial \bar{u}_i}{\partial x_j} - \rho \varepsilon \end{aligned} \quad (5)$$

$$\begin{aligned} & \frac{\partial(\varepsilon\rho)}{\partial t} + \frac{\partial(\bar{u}_i \varepsilon \rho)}{\partial x_i} \\ &= \frac{\partial}{\partial x_i} \left( \frac{\mu_t}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial x_i} \right) + C_{\varepsilon 1} \frac{\varepsilon}{k} \mu_t \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \frac{\partial \bar{u}_i}{\partial x_j} - C_{\varepsilon 2} \rho \frac{\varepsilon^2}{k} \end{aligned} \quad (6)$$

where  $k$  is the turbulent kinetic energy;  $\varepsilon$  is the turbulent dissipation rate;  $C_\mu$ ,  $\sigma_k$ ,  $\sigma_\varepsilon$ ,  $C_{\varepsilon 1}$ ,  $C_{\varepsilon 2}$  are constant in this study, taking the value of 0.09, 1.00, 1.30, 1.45, and 1.92.

Boundary conditions are shown in Figure 1. The river discharge is 28 L/s upstream, and at 20 m, the wave boundary, where wavelength is 2 m, the

Figure 1. Initial velocity of flume.

Figure 2. Initial surface level.

amplitude was 0.4 m high. To estimate the effect of the wall on the flow, the empirical wall function, known as the standard wall function, was used.

### 3 CALCULATION RESULTS

In  $X = 10$  section, we choose four lines, namely 1# ( $y = 0$ ), 2# ( $y = 3$ ), 3# ( $y = 5$ ), and 4# ( $y = 7.5$ ), to find the velocity distribution from the bottom to the surface.

Transverse circulation with the interaction of river discharge and tide will occur during the flood. Velocity along the axial direction in the channel reaches to 0.56 m/s at the depth of  $-4$  m, and the surface flow to the seawards, and the bottom flow to the landwards. The velocity along the axial direction on the tidal-flat adjacent channel varied from 0.2 to 0.2 m/s, and on the tidal and bank water flow to the landwards, and the channel velocity is greater than the tidal flat, as shown in Figure 3.

As shown in Figure 4, the channel transverse velocity is near 0 m/s during the flood. It reached 0.5 m/s on the surface at the tidal-flat adjacent channel as with the tidal flat. And it decreased from the tidal flat to the bank along the cross-section. Water flows from the channel to the tidal flat.

As shown in Figure 5, the surface water in the channel flows to the seawards, and the bottom flows to the landwards. The maximum velocity is at 10 m along the channel. The channel velocity increases compared with the tidal flat velocity during the flood, and the gradient on the tidal-flat adjacent channel is greatest. This means that momentum exchanges from the channel to the tidal flat.

Velocity along the axial direction in the channel reaches to 0.65 m/s at the depth of  $-0$  m, and the surface flows towards the landwards. The velocity along the axial direction on the tidal-flat adjacent channel decreases, and on the tidal and bank water flows to the seawards, the channel velocity

Figure 3. Velocity along the axial direction.

Figure 6. Distribution of velocity on the horizontal coordinate.

Figure 4. Transverse velocity.

Figure 7. Velocity along the axial direction.

Figure 5. Distribution of velocity on the vertical coordinate.

Figure 8. Transverse velocity.

is greater than the tidal-flat velocity, as shown in Figure 7.

As shown in Figure 8, the transverse velocity from the tidal to the channel decreases across the section. On the tidal flat, the surface velocity

reaches to 0.16 m/s, with 0.12 m/s at bottom. On the tidal-flat adjacent the channel, it varies from 0.08 to 0.02 m/s to the channel.

As shown in Figure 9, the surface water in channel flows to the seaward, and the bottom flows to the landward. The maximum velocity occurs at 10 m

Figure 9. Velocity on the vertical coordinate.

Figure 10. Velocity on the horizontal coordinate.

along the channel. The channel velocity increases compared with the tidal-flat velocity during the flood, and the gradient on the tidal-flat adjacent channel is greatest. This means that momentum exchanges from the channel to the tidal flat.

#### 4 CONCLUSIONS

In this paper, the flow pattern between the channel and tidal flat during flood was studied using a 3-D

numerical hydraulic model. The  $k - \varepsilon$  turbulence model with the VOF method was used to simulate a fully three-dimensional flow. In the channel and tidal flat during the initial flood tide, the velocity along the channel increased compared with that along the tidal flat. The transverse velocity reached the peak on the tidal-flat adjacent the channel, and decreased from the tidal-flat to the bank. At the end of the flood tide, the velocity decreased along the channel flow to the landward, the transverse velocity decreased from the tidal flat to the channel, and the flow from the tidal to the channel.

# Numerical modeling of regional hydrodynamic and seabed morphological effects from the construction of artificial islands in Danzhou, Hainan

S.H. Zuo, B. Li & Z. Zhang

Key Laboratory of Engineering Sediment of Ministry of Communications, Tianjin Research Institute of Water Transport Engineering, Tianjin, China

**ABSTRACT:** Haihua Island is a large artificial island in Danzhou, Hainan. The construction of Haihua Island changes the hydrodynamic environment of Yangpu's sea area, and further affects its morphological change. A 2-D numerical model combining the effects of tides and waves was set up to study the regional hydrodynamic and seabed morphological effects from the construction of Haihua Island in the Yangpu's sea area of Hainan. Verification and validation were carried out against the measured data. Details were given about the variations of nearshore hydrodynamic characteristics of the Yangpu Bay with the construction of artificial island engineering. In addition, the influence on the seabed, with the transportation of sediment considered, was computed. The outcomes of this study lay a foundation for the feasibility analysis of Haihua Island's exploitation.

**Keywords:** Haihua Island; tidal currents; sediment; mathematical model; Yangpu Bay

## 1 INTRODUCTION

The artificial island project of Haihua Island is located in the Yangpu waters in Danzhou of Hainan Province, China (Fig. 1). The project intends to adopt the form of an offshore artificial island with planning five artificial islands, and bridges among the islands and between the island on both sides and the land. The area of artificial islands is 7.53 km<sup>2</sup> and the coastline is 39.44 km.

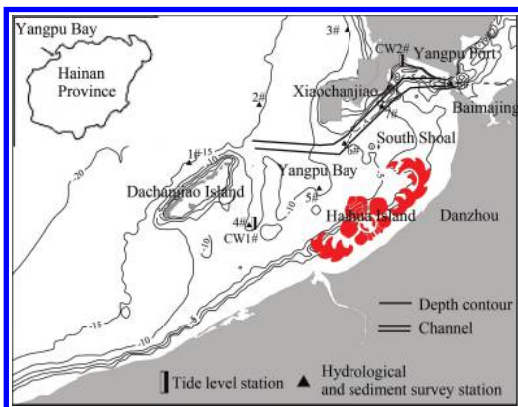

Figure 1. Location of Haihua Island in Hainan, the depth of Yangpu waters and hydrological stations.

The minimum area of the five artificial islands is about 0.146 km<sup>2</sup>, and the maximum area is about 3.811 km<sup>2</sup>, and the distance among the islands is about 48 m–196 m. Haihua Island is mainly located in Yangpu shallows (Fig. 1) with the depth less than 2 m.

Haihua Island belongs to a large-scale reclamation project, and the project implementation causes hydrodynamic environment changes in Yangpu waters and adjacent area, and further affects the seabed morphological change. With the development of theories about numerical simulation and the improvement of computational facilities, two-dimensional (2D) mathematical models have been widely used in the solution of many real-life engineering problems involving hydrodynamic and sediment transport by tidal currents and waves (Li, 2006a, 2006b; Zuo, 2009). A 2-D numerical model is used to simulate the effects of hydrodynamic and seabed morphological change caused by the project in this paper.

## 2 GENERAL SITUATION OF THE STUDY REGION

The tide is irregular diurnal with the mean tidal range 1.91 m in Yangpu waters, and the tidal flow has a reciprocating flow with a slight rotation.

The measured surface flow velocity is about 0.82 m/s, and the maximum current velocity is 0.3–0.5 m/s with reversing directions of SW-NE near the project area. The annual average wave height is 0.8 m in the Dongfang Station located near the project. The Suspended Sediment Concentration (SSC) is low with the average value of 0.02–0.03 kg/m<sup>3</sup>. The tidal passage of the Yangpu Bay is a curved deep channel with the length of 8.2 km, the width of 600 m and the depth of 10 m–20 m. The deepest depth is above 24 m, and the shallowest depth is about 5 m in the sandbar area, and the length of the depth less than 8.5 m is about 3.5 km. The seabed around the Yangpu Bay is mainly silty clay, and the sea bed nearby the Haihua Island is relatively coarse, and the median size is from 0.05 m to 0.9 mm (Wang, 2006; Zuo, 2010).

### 3 NUMERICAL MODEL

#### 3.1 2D tidal current model under the function of waves

The continuity equation is as follows:

$$\frac{\partial z}{\partial t} + \frac{\partial(hu)}{\partial x} + \frac{\partial(hv)}{\partial y} = 0 \quad (1)$$

The momentum equation is given as follows:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -g \frac{\partial z}{\partial x} + \frac{\tau_{sx}}{h\rho} + \frac{\tau_{bx}}{h\rho} + f v + R_x + \lambda \Delta u \quad (2)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = -g \frac{\partial z}{\partial y} + \frac{\tau_{sy}}{h\rho} + \frac{\tau_{by}}{h\rho} - f u + R_y + \lambda \Delta v \quad (3)$$

where  $z$  = water level, the distance between the free surface and the base level;  $h$  = water depth, the distance between the free surface and the seabed,  $h = z + z_0$ ;  $z_0$  = seabed surface elevation, the distance between the base level and the seabed surface;  $u, v$  are the horizontal velocity components in the  $x$  and  $y$  directions, respectively;  $f$  = Coriolis parameter;  $g$  = gravity acceleration,  $g = 9.81$  m/s<sup>2</sup>;  $\rho$  = water density;  $\tau_{sx}, \tau_{sy}$  are components of wind stress  $\tau_s$  in the  $x$  and  $y$  directions, respectively;  $\tau_{bx}, \tau_{by}$  are components of bottom shear stress  $\tau_b$  with interactions of wave and tidal current in the  $x$  and  $y$  directions, respectively;  $\lambda$  = horizontal eddy viscosity coefficient;  $\Delta = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$ ;  $T_x = -\frac{1}{\rho h} \left( \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} \right)$ ;  $T_y = -\frac{1}{\rho h} \left( \frac{\partial S_{yx}}{\partial x} + \frac{\partial S_{yy}}{\partial y} \right)$ ;  $S = \begin{pmatrix} S_{xx} & S_{xy} \\ S_{yx} & S_{yy} \end{pmatrix}$  is radiation stress.

#### 3.2 2D model of suspended sediment transport under the function of waves and currents

##### 3.2.1 General equation

Because sediment transport produced by tidal current velocity is larger than natural diffusion of the sediment, sediment yield of suspending can be ignored, and the two-dimensional suspended sediment transport equation under the function of waves and currents can be written as follows:

$$\frac{\partial(hC)}{\partial t} + u \frac{\partial(hC)}{\partial x} + v \frac{\partial(hC)}{\partial y} = \alpha \omega_s (C - C^*) \quad (4)$$

where  $\alpha$  can be expressed in the following form:

$$\alpha = \begin{cases} \alpha_1 & (C < C^*) \\ -\alpha_2 & (C \geq C^*) \end{cases} \quad (5)$$

##### 3.2.2 Seabed deformation equations due to suspended sediment

$$\frac{\partial(hS)}{\partial t} + u \frac{\partial(hS)}{\partial x} + v \frac{\partial(hS)}{\partial y} = -\gamma_s \frac{\partial z_0}{\partial t} \quad (6)$$

where  $\gamma_s$  is the dry unit volume weight of bed bottom sediment particles; and  $z_0$  is the depth from the undisturbed sea level to the sea floor.

### 3.3 Solution conditions

#### 3.3.1 Initial conditions

Initial conditions are related to the initial distributions of surface elevation, velocity and sediment concentration. As shown in Equation (14),  $\zeta_0(x, y, t_0)$  is the tidal level when  $t = t_0$ ;  $u_0(x, y, t_0)$  and  $v_0(x, y, t_0)$  are the tidal velocity along the  $x$  and  $y$  directions, respectively, when  $t = t_0$ ; and  $S_0(x, y, t_0)$  is the sediment concentration when  $t = t_0$ :

$$\left. \begin{aligned} \zeta(x, y, t) \Big|_{t=t_0} &= \zeta_0(x, y, t_0) \\ u(x, y, t) \Big|_{t=t_0} &= u_0(x, y, t_0) \\ v(x, y, t) \Big|_{t=t_0} &= v_0(x, y, t_0) \\ S(x, y, t) \Big|_{t=t_0} &= S_0(x, y, t_0) \end{aligned} \right\} \quad (7)$$

In this paper, the initial tidal level is taken as the mean tidal level and the initial tidal velocity is taken as zero on the computational boundary. The initial sediment concentration can be obtained from interpolation of the measured values.

#### 3.3.2 Boundary conditions

There are four open sea boundaries in the model. The tidal levels control them. The sediment

concentrations at the open boundaries are obtained from the nearest survey point.

### 3.3.3 Computational area and the grids

According to the characteristic of the study area, unstructured grids are applied to fit the boundaries of the estuary and the harbor project because the grids can be used in irregular geometries and the elements may have arbitrary sizes in regions of interest. The simulated study area is about 1848 km<sup>2</sup>. The east-west length of the simulated study area is 56 km and the north-south width is 33 km. Overall, 45869 nodes are included in the model. The spatial steps are between 30 and 600 m, and the smaller grids are used in the harbor project region.

Using the project boundary and topography data of 2011, the actions of tidal currents and wind waves are simulated in the model. The movement of both tidal currents and suspended sediment is simulated. The results of calibration of velocity, direction, sediment concentration, and variation of the seabed are given.

### 3.3.4 Selection of parameters

The Manning roughness coefficient,  $n$ , is estimated to range from 0.010 to 0.025. According to the model calibration, the coefficient is adjusted to the landform change. According to the characteristics of the bed sediment, the Yangpu waterway sea area belongs to the class of a muddy coast. The dry unit volume weight of seabed sediment particles,  $\gamma_s$ , is 750 kg/m<sup>3</sup>; the specific weight of water,  $\gamma$ , is 1000 kg/m<sup>3</sup>. The settling velocity,  $\omega_s$ , is related to many factors, such as sediment particle size, sediment concentration, salinity, and temperature.

## 4 MODEL CALIBRATION

Using the data of July 2011, the computational results for the water-surface elevation, velocity, flow direction and suspended sediment concentration are found to be in good agreement with the field data. Owing to space limitations, only parts of the results are shown in this paper (Fig. 2–Fig. 4).

Figure 2. Calibration results for the tidal level.

Figure 3. Calibration of current velocity and direction.

Figure 4. Calibration of suspended sediment concentration.

According to the seabed deposition and erosion in the Yangpu Bay measured from 2006 to 2007, the seabed deformation is calibrated in detail. So, the model would be combined with the simulations of flow motion, sediment transportation and bed-form reworking.

## 5 HYDRODYNAMIC AND SEABED MORPHOLOGICAL IMPACT ANALYSIS

### 5.1 Change of tidal currents after the project

After the implementation of the project, the overall trend of tidal current in the whole sea area is

Figure 5. The change of tidal current velocity (+ increase; - decrease).

Figure 6. Seabed change during different weather conditions. (a: three years after the project in normal weather conditions; b: strong wind weather conditions).

not change, the current is still reversing current with the direction of NE-SW in the deep channel of Yangpu Bay. The local current is forced to the waterway.

Figure 5 shows the change of tidal current velocity. The artificial islands project makes the local flow velocity increase by 10% or 0.02 m/s. The maximum velocity has increased by about 0.05 m/s in the Yangpu Port Channel.

## 5.2 Seabed evolution after the project

It can be seen from Figure 6 that the seabed change is from  $-0.12$  m to  $0.48$  m during 3 years after the implementation of the project in normal weather conditions. As can be seen in Figure 5, the flow velocity increases with about  $0.02$ – $0.05$  m/s in the south of Xiaochantan. Therefore, the seabed erodes in both the south of Xiaochantan and the Haihua Island. The seabed around the Haihua Island is mainly deposited due to the reduction of the flow velocity.

According to the calculations, the seabed change is from  $-0.03$  m to  $0.15$  m for 24 hours during the strong wind weather condition.

## 6 CONCLUSIONS

Haihua Island belongs to a large-scale reclamation project. The construction of Haihua Island changes the hydrodynamic environment of Yangpu's sea area, and further affects its morphological change. A 2-D numerical model combining the effects of tides and waves was set up to study the regional hydrodynamic and seabed morphological effects from the construction of Haihua Island in the Yangpu's sea area of Hainan.

The validity of the model is verified by the observation data obtained in July 2011 including the tidal flow and suspended sediment concentration in the vicinity of the sea area. The verification of the calculation shows that the calculated values are in good agreement with the measured data. The field of tidal currents, suspended sediment concentration and the deformation of seabed can be successfully simulated. Using the numerical model, a case study was applied to research the effects from the construction of Haihua Island.

The results show that: (1) the construction of Haihua Island makes the local flow velocity increase; (2) within 3 years, the waters between Haihua Island and Xiaochanjiao are eroded with the value from  $0.03$  m to  $0.12$  m due to the velocity increase in the area; the bed level deposits with the value from  $0.06$  m to  $0.18$  m in the south area of the Yangpu channel (i.e. the South Shoal); the waterways between the islands are deposited with

the value from 0.06 m to 0.30 m; (3) the seabed are deposited in the surrounding sea area of the Haihua Island by the SW wave of 50-year return period, and the deposited rate is 0.05–0.15 m/d.

## 3D numerical simulation of local scour around regulating structures in tidal reaches

Xinzhou Zhang & Xiping Dou

*Nanjing Hydraulic Research Institute, Key Laboratory of Port, Waterway and Sedimentation Engineering, Ministry of Transport, Nanjing, China*

Zengxiang Jiao

*Nanjing Hydraulic Research Institute, Nanjing, China*

**ABSTRACT:** The flow and sediment transport, and local scour characteristics around the regulating structures in tidal reach were analyzed. Tidal reach regulating structures near the three-dimensional characteristics of water and sediment movement and local scour analyses were two-dimensional and three-dimensional turbulent sediment mathematical models developed for the next tide heights near velocity distribution role, local erosion processes, erosion and scour depth morphology that were simulated. It was pointed out that although the two-dimensional mathematical model of sediment can obtain a more accurate scour hole depth, it cannot obtain the right shape and scour erosion position.

**Keywords:** regulating structures; local scour; 3D characteristics; numerical simulation

### 1 INTRODUCTION

With the accelerated development along the coast and the river, the tidal channel and coastal estuary have been vigorously trained. In the regulations, a groin is a commonly used hydraulic structure. When the groin is used for river regulation, the best embedding depth should be first designed so as to ensure the safety of the groin. This is because a larger scour pit is always formed at the groin head, endangering its own safety and restricting the effectiveness of groin works. The flow and sediment movement near the groin are the typical three-dimensional problem. Especially at the tidal river reaches, the tidal movement is characterized as tidal unsteady reciprocating flow at estuaries, and the hydrodynamic conditions and sediment movement show periodical changes, so that this problem becomes more complex. Therefore, it is of far-reaching importance for the construction and protection of navigation channels to conduct research on the local water flow and the law of sediment movement near hydraulic structures like groins at the tidal reaches and to predict the formation of the maximum scour depth of local scour. In this paper, a three-dimensional numerical model is established to simulate the local scour of groins at the tidal reaches.

### 2 3D CHARACTERISTICS OF LOCAL SCOUR AROUND REGULATING STRUCTURES

Local scour renovation process nearby a regulating structure is a very complex three-dimensional phenomenon, including the strong three-dimensional nature of the flow movement and sediment transport. It is generally believed that after setting piers, groins and other hydraulic structures in the river, artificially increasing the flow resistance will form the upstream backwater, which will change the original velocity field and pressure field in front of structure formation pressure gradient, accompanied by the increase in the rate of water flow to generate a three-dimensional separation that occurs on the side of the boundary layer structure, resulting in a series of swirls. Horseshoe vortex formation including the scour edge flow downstream side of the vertical vortex structures generated as a result of the separation boundary velocity gradient formation, as well as the downstream movement of wake vortices. Many scholars have used the prototype observation, model test and numerical simulation, different methods and means of local scour to conduct a comprehensive study of the phenomenon, widely believed by local scour spur dike whirlpool, dive flow, increasing the flow rate per unit width of spur dike and other factors

resulting from the combined effects. In summary, the formation of the scour hole is mainly caused by changes in the local water flow and sediment conditions.

### 3 2D AND 3D NUMERICAL SIMULATION OF LOCAL SCOUR AROUND REGULATING STRUCTURES

#### 3.1 Simulation reach

The reach to simulate is generalized from the North Passage at the Yangtze River Estuary (Fig. 1). The generalized reach is about 10 km long, and its longitudinal gradient is designed with reference to 0.027% of the actual longitudinal gradient of the North Passage at the Yangtze River estuary. Two guide levees not crossing water are arranged on the southern and northern sides respectively. The reach between guide levees is about 6 km long and about 2 km wide, and the outlet is a widened section, which is 3 km at its widest point. The bottom elevation of the channel between the guide levees is  $-10$  m and the bottom width is 160 m, while the side slope of the channel is 150 km. The bottom centerline of the channel is about 1.3 km away from the north guide levee and about 0.7 km away from the south one. The bottom elevation of both sides of the channel is generalized as  $-6$  m (Fig. 2). A pair of groins is arranged in the guide levees (Fig. 3). The long groin is about 660 m long, while the short

Figure 1. Arrangement diagram of guide levees and groins under the deep water channel regulation works at the Yangtze River Estuary.

Figure 2. Cross-section drawing of the generalized reach.

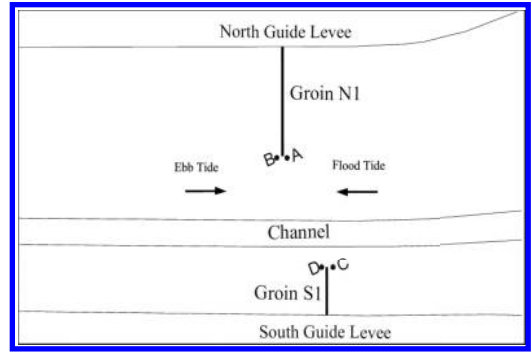

Figure 3. Arrangement of groins Deepwater Channel Regulation Project and observation points.

groin is about 270 m long. Both types of groin are non-submerged and vertical to the guide levee.

Under the action of tidal flow and unidirectional flow, the local scour processes of a pair of groins (only the south groin S1 and the north groin N1) at the generalized river reaches are separately studied through the numerical model, and four points A–D are set at the head of the groin to specifically observe the changes of scour depth at four points (Fig. 3).

#### 3.2 Model establishment

The turbulent movement of incompressible viscous fluid can generally be described by the Reynolds Equation:

$$\frac{\partial u_i}{\partial x_i} = 0 \quad (1)$$

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = X_i - \frac{1}{\rho} \frac{\partial p}{\partial x_i} + \nu \frac{\partial^2 u_i}{\partial x_j \partial x_j} + \frac{1}{\rho} \frac{\partial(-\rho u'_i u'_j)}{\partial x_j} \quad (2)$$

where  $u_i$  is the component of time average velocity in the direction  $i$ ;  $X_i$  is the mass force;  $\nu$  is the coefficient of kinematic viscosity;  $\rho$  is the fluid density;  $-\rho u'_i u'_j$  is the Reynolds stress; and  $p$  is the pressure.

As an unclosed equation, the Reynolds equation contains the Reynolds stress. It needs to be closed by a turbulent model. Currently, the most widely used equations are  $k$  and  $\varepsilon$  equations raised by Launder and Spalding (1974):

$$\frac{\partial k}{\partial t} + u_i \frac{\partial k}{\partial x_i} = \frac{\partial}{\partial x_i} \left( C_k \frac{k^2}{\varepsilon} \frac{\partial k}{\partial x_i} + \nu \frac{\partial k}{\partial x_i} \right) - \overline{u'_i u'_j} \frac{\partial u_i}{\partial x_j} - \varepsilon \quad (3)$$

$$\frac{\partial \varepsilon}{\partial t} + u_i \frac{\partial \varepsilon}{\partial x_i} = \frac{\partial}{\partial x_i} \left( C_{\varepsilon} \frac{k^2}{\varepsilon} \frac{\partial \varepsilon}{\partial x_i} + \nu \frac{\partial \varepsilon}{\partial x_i} \right) - C_{\varepsilon 1} \frac{\varepsilon}{k} \overline{u'_i u'_j} \frac{\partial u_i}{\partial x_j} - C_{\varepsilon 2} \frac{\varepsilon^2}{k} \quad (4)$$

The three-dimensional suspended sediment transport equation can be expressed as follows:

$$\frac{\partial S}{\partial t} + u \frac{\partial S}{\partial x} + v \frac{\partial S}{\partial y} + w \frac{\partial S}{\partial z} = \frac{\partial}{\partial x} \left( \varepsilon_{sx} \frac{\partial S}{\partial x} \right) + \frac{\partial}{\partial y} \left( \varepsilon_{sy} \frac{\partial S}{\partial y} \right) + \frac{\partial}{\partial z} \left( \varepsilon_{sz} \frac{\partial S}{\partial z} \right) + \frac{\partial \omega_s S}{\partial z} \quad (5)$$

where  $S$  is the sediment concentration;  $\omega_s$  is the settling velocity of sediment grains;  $\varepsilon_s$  is the sediment diffusion coefficient; and  $\sigma_s$  is the Schmidt number with a value range of 0.5~1.0. Based on the suspended sediment transport equation, the bottom boundary condition for the suspended sediment movement is given by

$$\omega_s s + \frac{\nu_t}{\sigma_s} \frac{\partial s}{\partial z} = D_b - E_b \quad (6)$$

where  $D_b$  is the deposition flux on the riverbed interface and  $E_b$  is the uptrend flux of the sediment on this interface. According to the conservative flux, the equation for the riverbed deformation caused by the suspended sediment is as follows:

$$-\gamma'_s \frac{\partial \eta_s}{\partial t} = -D_b + E_b \quad (7)$$

where  $\gamma'_s$  is the dry density of the sediment;  $\eta_s$  is the thickness of silt or scour caused by the suspended sediment; and  $E_b - D_b$  is the net flux on the sediment interface.

The bottom sediment transport equation is as follows:

$$\frac{\partial N_b}{\partial t} + \frac{\partial u_b N_b}{\partial x} + \frac{\partial v_b N_b}{\partial y} = \beta_s w_s (N_b - N_b^*) \quad (8)$$

where  $N_b$  is the amount of the bed load sediment in a unit volume; and  $u_b$  and  $v_b$  are the flow velocity at the calculation points near the bottom grid. The riverbed deformation caused by the bed load can be expressed as follows:

$$\gamma_0 \frac{\partial \eta_b}{\partial t} = \beta_s w_b (N_b - N_b^*) \quad (9)$$

There is a great difference between local scour and general scour. Through the study of local scour,

many scholars have discovered that local scour is produced when the velocity of approach does not reach the incipient velocity of general scour. Dou Xibing (1997) gained a new formula for the critical incipient velocity of local scour by taking into consideration the action of vertical water flow during the local scour. This new equation is as follows:

$$\frac{U_{b,cr}^2}{(\rho_s/\rho-1)gd} = 3.61(\tan \phi \cos \alpha - \sin \alpha) + \left[ -B \frac{|w|^2}{(\rho_s/\rho-1)gd} \right] \quad (10)$$

where  $B$  is an undetermined coefficient. This equation takes into consideration the action of vertical flow velocity in addition to the impact of the slope and repose angle, which can be used to calculate the critical incipient velocity of the sediment at the time of the occurrence of local scour.

### 3.3 Local scour process

Figure 4 and Figure 5 show the simulation results of the local scour processes of the N1 and S1 groin heads.

Figure 4. Local scour processes around groin N1.

Figure 5. Local scour processes around groin S1.

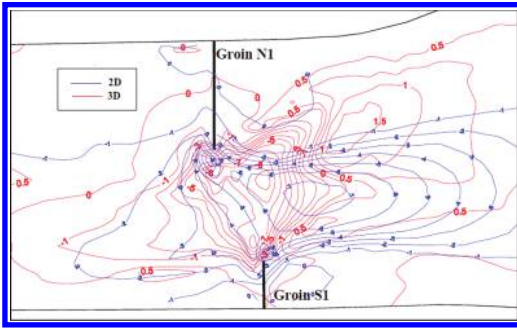

Figure 6. Local scour shape comparison of 2D and 3D.

According to the calculated results, the scour depth increasing trend of the groin heads under the action of tide is consistent with the measured results. The local scour depth of 3D is slightly deeper than that of 2D. The main reason is that the vertical velocity of flow around regulating structures takes a key role in the three-dimensional calculation for the critical starting velocity of the sediment.

### 3.4 Local scour shape

Figure 6 shows the numerical simulation results of the local scour shape of 2D and 3D. The maximum local scour positions of 2D and 3D are located at the groin head similarly, but the position of the three-dimensional calculation of the maximum scour is farther from the mainstream area and close to the main water area. The distribution of sediment erosion and deposition zone is also significantly different from the two-dimensional calculation results.

## 4 COMPARATIVE ANALYSIS OF TWO-DIMENSIONAL AND THREE-DIMENSIONAL CALCULATION RESULTS

The flow line around the groin near the bed bottom of 2D and 3D is shown in Figure 7. The flow becomes a kind of jet-flow and deviates to the transverse direction before the upstream face of the groin in 3D lowest level flow, and then bypasses the groins and joins back in the recirculation zone quickly.

Figure 8 shows the velocity distribution of the YZ plane before the upstream face of the groin calculated by the 3D model. As can be seen in the figure, the transverse velocity suddenly increases before the upstream cross-section of the groin, where the transverse velocity is much closer to the

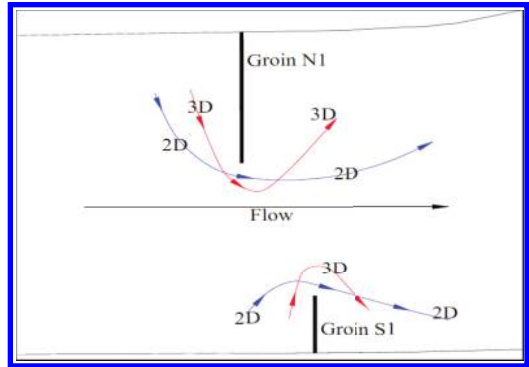

Figure 7. The flow line around the groin near the bed bottom.

Figure 8. The velocity distribution before the upstream face of the groin calculated by the 3D model (Y-Z profile).

bottom. This is the reason that the flow deviates to the transverse direction before the upstream face of the groin in the 3D model.

## 5 CONCLUSION

1. The erosion around the groin is different because the flow structure is different from the 2D and 3D simulation results. Three-dimensional model simulates the groins area near the bottom of the velocity distribution more accurately. Although the two-dimensional mathematical model for the sediment can obtain a more accurate scour hole depth, it cannot obtain the right shape and scour erosion position.
2. The velocity distribution between the surface and bottom is different from each other. The sediment erosion and deposition are determined by the velocity and the concentration of the sediment near the bottom. Theoretically, a more realistic calculation not only results in the size of the largest scour depth with the measured data

agreeing well, but also provides a more reasonable results with respect to the form of erosion than the two-dimensional mathematical model.

3. The results illustrate that groins local scour problem is a typical three-dimensional problem, so we must adopt a three-dimensional model that can be more accurate and provide a reasonable size and scope of erosion simulation.

**ABSTRACT:** Siltation in the rivers downstream of floodgates has become a serious problem in China, making the discharge capacity of rivers to decrease obviously and threatening the flood control in upper rivers. Tidal wave deformation is one conclusive dynamic factor leading to siltation downstream of floodgates in estuaries. The hydrodynamic characteristics of tidal wave deformation are different with different river lengths downstream of floodgates, so the fluvial processes and morphology characteristics are also different. A 2D numerical model is established to simulate the tidal wave deformation and sediment deposition with river of different lengths downstream the floodgate. The length of the river downstream of floodgates influences sediment deposition obviously. On this basis, several conclusions are obtained in this paper, which can provide some theoretical basis for the prediction and analysis of the siltation characteristics in the lower reach caused by floodgates with different lengths in estuaries.

**Keywords:** sedimentation downstream tidal gates; length of irrigation channel; physical model; numerical model

## 1 INTRODUCTION

In order to defend against tides for the development of agricultural production, lots of sluices have been built in the coastal areas of China since 1950s, with the number of about 300 at present. Siltation in the rivers downstream of floodgates is a very serious problem in China. According to statistics, among the 58 sluices with the drainage flow of over 100 m<sup>3</sup>/s in Jiangsu Province, 5 are almost silted up, 15 are in severe siltation and the other 38 are relatively less silted. Besides, in the 35 estuaries with sluice constructed in the Haihe River basin, 22 are in serious siltation, where the upper and lower reaches are universally silted, causing the river drainage capacity to reduce by 60%. Siltation in the rivers downstream of floodgates makes the discharge capacity of rivers to decrease obviously and threatens the flood control in upper rivers, and influences the agricultural production. Therefore, it is vital to perform research on siltation downstream of floodgates.

Study on siltation downstream of floodgates in China began with the research on the Sheyang estuary by G.R. Dou, showing that tidal wave deformation was the main factor leading to sedimentation

downstream sluice. Then, many scholars have studied the silting mechanism and basically agreed with the conclusion that tidal wave deformation is one conclusive dynamic factor causing siltation downstream of floodgates. Tidal wave deformation and reflection usually occur under the influence of river morphologic resistance when it comes into the estuary, which will be more evident in the estuaries where floodgates have been built. Tidal wave will be reflected fully by the floodgate, and tidal wave properties change from a progressive wave to a standing wave, with a significant phase difference between the hydrographs of flow velocity and tidal level. Besides, the high tidal level rises while the low tidal level goes down, and the duration of flood tide is shortened and the mean depth of flood tide decreases, while that of ebb tide goes opposite. Therefore, the flow velocity of flood tide increases and that of ebb tide decreases, respectively. Sediment transport capacity of flood tide is enhanced relative to that of ebb tide due to the change in hydrodynamic characteristics, so that the sediment, which is carried into the river by flood tide, cannot be taken back to the estuary by ebb tide, and then deposited in the lower reach downstream the floodgate.

## 2 NUMERICAL MODEL AND VERIFICATION

### 2.1 Simulation schemes

To study how the length of the approach channel at the downstream of the floodgate influences the sediment deposition, a 2D numerical tidal current and sediment transport model is built based on the prototype of the floodgate in the estuary of the Sheyang River. The actual morphology of the estuary of the Sheyang River is simplified and applied as the open sea condition of the model. The open boundary of the model is about 6.5 km from the estuary, near the  $-7$  m contour. In addition, the area covered by the model between its south and north boundaries is about 7.2 km wide (Fig. 1). In the model, the approach channel was simplified into a 77 km-long and 660 m-wide compound channel. The bottom of the inner passage of the approach channel is about 220 m wide, with its elevation at  $-4.0$  m. The side slope of the passage is 1:8, and the bottom elevation of the point bar is about 3.0 m.

The hydrodynamic boundary condition of the model is designed on the basis of the actual condition in the estuary of the Sheyang River. The high tidal level is at 4.05 m and the low tidal level is at 1.8 m (Fig. 2). The hydrodynamic boundary condition of the open sea remains unchanged in the study; however, we hypothesize various lock sites of the floodgates and different lengths of the approach channel so as to study how the sediment deposition at the downstream of the floodgate is influenced accordingly.

### 2.2 Numerical model establishment

The continuity equation, momentum equation of tidal current and sediment transport equation in the numerical model are discretized using FVM (Finite Volume Method) as follows:

Figure 1. Domain of the model boundary.

Figure 2. Design curve of the tide on the outer boundary.

$$\frac{\partial \zeta}{\partial t} + \frac{\partial Hu}{\partial x} + \frac{\partial Hv}{\partial y} = 0 \quad (1)$$

$$\begin{aligned} \frac{\partial Hu}{\partial t} + \frac{\partial Huu}{\partial x} + \frac{\partial Huv}{\partial y} = & -gH \frac{\partial \zeta}{\partial x} - \frac{\partial Hu'u'}{\partial x} - \frac{\partial Hu'v'}{\partial y} \\ & + \frac{\tau_{sx} - \tau_{bx}}{\rho} + fHv \end{aligned} \quad (2)$$

$$\begin{aligned} \frac{\partial Hv}{\partial t} + \frac{\partial Huv}{\partial x} + \frac{\partial Hvv}{\partial y} = & -gH \frac{\partial \zeta}{\partial y} - \frac{\partial Hv'u'}{\partial x} - \frac{\partial Hv'v'}{\partial y} \\ & + \frac{\tau_{sy} - \tau_{by}}{\rho} - fHu \end{aligned} \quad (3)$$

$$\begin{aligned} \frac{\partial HS}{\partial t} + \frac{\partial HuS}{\partial x} + \frac{\partial HvS}{\partial y} = & \frac{\partial}{\partial x} \left( H \varepsilon_x \frac{\partial S}{\partial x} \right) \\ & + \frac{\partial}{\partial y} \left( H \varepsilon_y \frac{\partial S}{\partial y} \right) + \alpha \omega (S_* - S) \end{aligned} \quad (4)$$

River bed evolution can be calculated by the following formula:

$$\gamma_0 \frac{\partial \eta_s}{\partial t} = \alpha \omega (S - S_*) \quad (5)$$

Incipient motion estimate formula of cohesive sediment and sediment transport capacity of tidal currents and waves are key parameters in the numerical model of tide and sediment transport. Dou (1999) analyzes the group characteristics and the movement characteristics of cohesive sediment, and deduced a calculation formula for starting velocity including the bulk density effect, according to the effect of cohesive force between fine particles, water depth and bulk density:

$$u_c = k' \left( \ln 11 \frac{h}{\Delta} \right) \times \left( \frac{\Delta}{\Delta_*} \right)^{1/6} \sqrt{3.6 \frac{\rho_s - \rho}{\rho} g d + \left( \frac{\gamma_0}{\gamma_0^*} \right)^{2.5} \frac{\varepsilon_0 + g h \delta (\delta/d)^{1/2}}{d}} \quad (6)$$

where  $k'$  is the coefficient ( $k' = 0.26$  for impending motion,  $k' = 0.32$  for little motion,  $k' = 0.41$  for general motion);  $\Delta$  is the roughness height of the bed surface ( $\Delta = 1 \text{ mm}$  for  $d \leq 0.5 \text{ mm}$ ,  $\Delta = 2d$  for  $d > 0.5 \text{ mm}$ ),  $\Delta_* = 20 \text{ mm}$ ; and  $\rho_s$  and  $\rho$  are the density of sediment particles and that of water, respectively,  $\gamma_0$  and  $\gamma_0^*$  are the dry volume weight and the stable dry volume weight of the sediment on the bed surface;  $\varepsilon_0$  is the synthetic parameter of cohesive force whose value is related to the physical and chemical properties of the particle materials, and also to the organic content and siltation environment for cohesive soil, with  $\varepsilon_0 = 1.75 \text{ cm}^3/\text{s}^2$  for natural sediment; and  $\delta$  is the parameter of water film thickness, with  $\delta = 2.31 \times 10^{-5} \text{ cm}$ .

Luo (1997) deduced a calculation formula for sediment transport and carrying capacity for different wet densities of fluid mud, with an overall verification of the calculation formula being made, and satisfactory results were obtained, showing that the calculation formula can be used as the practical formula for the study of engineering-related sediment problems:

$$S^* = 0.296 \gamma_s \left( \frac{\gamma}{\gamma_w} \right)^{12.8} \frac{V^2}{gD} \quad (7)$$

where  $\gamma_w$  is the wet density of fluid mud;  $\gamma$  is the density of water;  $\gamma_s$  is the density of sediment;  $V$  is the water velocity under the common action of tidal currents and waves; and  $D$  is the water depth.

### 2.3 Numerical model verification

The corresponding boundary conditions of the model are controlled by tidal levels. The upstream of the model is the floodgate, and it is treated as the closing boundary. In addition, the moving boundary method is used to discriminate the land area from the water area. The orthogonal curved grid is used in the model with the grid size ranging between 50 m and 200 m, and the time step is 2 seconds.

The numerical model was verified by the data of the physical model, for which the tidal level is shown in Figure 2, and the length of the irrigation channel is 12.5 km. The verification of the tidal level (Z1) and the current velocity (V1) in the estuary are shown in Figure 3 and Figure 4, respectively, and deposition depth along the

Figure 3. Verification of tidal level.

Figure 4. Verification of flow velocity.

Figure 5. Deposition depth along the distance.

distance is shown in Figure 5. The results indicate that the model can simulate the process of deposition and accord with the physical model, and that the accuracy of the numerical model is satisfactory.

## 3 EFFECT OF IRRIGATION CHANNEL LENGTH ON DEPOSITION DOWNSTREAM THE TIDE GATE

The distribution of the average deposition depth downstream tide gate along the irrigation channel with different lengths under the action of spring tidal condition is shown in Figure 6, where the simulation time is about 180 days.

Figure 6. Deposition depth distribution along the irrigation channel with different lengths.

The result shows that the deposition is affected by length of irrigation seriously in the same hydrodynamic boundary condition. All the three conditions showed that the depth of silting decreases from the tide gate to the estuary. The velocity of the short irrigation is greater than that of the long one, so the silting increases greatly. In the long irrigation channel, the sediment transport a long time to the tide gate, the silting increases slowly. The depth profile appears triangle to the estuary.

The rate of deposition is decreased linearly with time under three irrigation channel conditions. The more the length of the irrigation, the smaller the ratio of silting, and the slower the decay of the ratio. Total river silting is the longest irrigation channel.

#### 4 CONCLUSION

This paper proposed a 2D tidal current and sediment numerical model to simulate the process of deposition downstream the tide gate, and analyzed

the different irrigation channels that affected the silting, and the results showed that:

1. The deposition was affected by the length of irrigation seriously in the same hydrodynamic boundary condition. All the three conditions showed that the depth of silting decreased from the tide gate to the estuary.
2. The velocity of the short irrigation was greater than that of the long one, so the silting increased greatly. This would shorten the irrigation channel to reduce the total river siltation and was propitious to maintain the depth of the channel.

# Application of ecological revetment in Lianshen waterway regulation project

Jie Chen, Jian Zhang, Yun-peng Zhou & Li-Yuan Xu

*Jiangsu Provincial Communications Planning and Design Institute Co. Ltd., Nanjing, China*

**ABSTRACT:** As a new revetment technique, ecological revetment has become a trend of waterway regulation. On the basis of ecological revetment classification, the schemes of LianShen waterway regulation project are analyzed according to local natural conditions, and then used for ecological revetment. It may serve as a reference for other waterway regulation projects.

**Keywords:** waterway regulation; ecological revetment; application

## 1 INTRODUCTION

With the development of society and economy, people have started paying more attention to waterway ecology. Therefore the concept of ecological revetment for reinforcement was proposed. Because land limitation restricted the waterway, a reasonable structure and other measures should be adopted to reduce land acquisition. Lianshen waterway is located in the Yangtze river region, which flows through most of the developed regions and play a positive role in promoting economy of Jiangsu province.

## 2 TYPES OF ECOLOGICAL REVETMENT

According to practical situation of Jiangsu province, ecological revetment has been promoted in Grand Canal, Yanhe waterway regulation etc. and obtained better results. Summarizing the application of ecological revetment in Jiangsu province can be divided into three categories: whole-ecological revetment, half-of ecological revetment and part-ecological revetment.

There are two types of complete ecological revetment: the first is to keep original ecosystem which means repairing or reinforce only a part of slope; the second is using less hard cover and more vegetation on slope. Complete ecological revetments are mainly applied in waterways that have wide sections or more bottomland. Common types of whole-ecological revetment are vegetation revetment, reed revetment, timber pile revetment etc.

Half-ecological revetment uses part of hard cover, keeping the rest of the ecosystem on

original slope. Half-ecological revetments are mainly applied in waterways, which have narrow sections and large construction areas. The ecosystem of half-ecological revetment reflects in secondary revetment, which is above normal water level. Common types of half-ecological are ecological bag revetment, self-embedded revetment, box-type revetment etc.

## 3 ECOLOGICAL REVETMENT SCHEMES OF LIANSHEN WATERWAY

Lianshen waterway flows through two different sections between the town and village. According to using conditions and geological environment, different types of ecological revetments are used in Lianshen waterway regulation.

### 3.1 Town section

Vertical-type revetments occupy less area, which is suitable for the waterway. It does not easily expand or demolish and is also economical. Most of the towns that Lianshen waterway flows through are advanced regions. Therefore, vertical-type revetments are adopted for saving land, reducing demolition and costs. Town section schemes for ecological revetment of Lianshen waterway adopt ecological bag revetment, box-type revetment, and self-embedded revetment.

#### 1. Ecological bag revetment

Ecological bags have filter function, which not only prevent loss of filler, but also realize normal moisture communication in the soil. Ecological bag can provide plenty of moisture and let the plant grow through the bag body. The roots

Figure 1. Ecological bag revetment.

Figure 3. Self-embedded revetment.

Figure 2. Box-type revetment.

Figure 4. Vegetation revetment.

pass into soil of the engineering foundation, like countless anchors which stable bag bodies. Further, the permanent stability slope is achieved and greatly reduces the maintenance cost.

## 2. Box-type revetment

The advantage of box-type structure lies in saving loss of concrete material, and the cavity reserved along length direction could fill with non-fine concrete, stone etc. This kind of revetment has an effective to waste soil, and a low project cost. In addition, structure of box-type revetment is simple and the stress condition is good, and overturning resistance moment improves because of friction force between concrete and wall.

## 3. Self-embedded revetment

In this method, blocks between lumps of self-embedded revetment without mortar and other consolidation measures are used, which have characteristics of good stability, fast construction, low cost, adaption to soft ground etc. By optimizing self-embedded structure, self-embedded green revetment is generated. This kind of structure consists of embedded block, plastic stick, filter, and soil, where wall surface and body could be planted. When applied in water environment, underwater structure could have aquatic plants and provide survival space for fish, giving a better interpretation of ecological revetment.

## 3.2 Rural section

Relative to sloping ecological revetment, vertical ecological revetments are slight deficiency in water permeability and hydrophilic. Then sloping ecological revetments could be used in widely section or of waterway.

Vegetation revetment technology includes planting submerged plants, floating-leaved plants, emerging plant and hygrophyte from the foot to the top of slope, which shapes into multi-level ecological protection. The principles of vegetation revetment stabiling slope are vegetation water culvert and soil conservation; both take ecological function and landscape function into account.

## 4 APPLICABILITY OF ECOLOGICAL REVETMENT

Because of resistance and durability is weakness under the influence of water flow and ship wave, so vegetation revetment is mainly applied to waterway which river is wide or original condition is better. Ecological bag revetment has advantages as economic price and high plant coverage, which is applicable to land shortage and poor soil conditions. Box-type revetment has advantages as saving materials and low cost, which is applicable to land shortage and poor soil conditions. Self-embedded revetment has advantages as quick construction and high durability, which is applicable to land shortage and poor soil conditions.

## 5 CONCLUSIONS

1. Ecological revetment is the development trend of revetment construction because of scour prevention and beautifying the environment. Attention should be paid to popularizing it and applying ecology revetment if the desired engineering effects are achieved and conditions are permissible.
2. The application of ecology revetment should follow the requirement of hydrodynamic and surround environment, selection of a reasonable ecological revetment type, and paying attention to the joint using with hard revetment engineering.

# Numerical simulation analysis of the pressure-dispersed anchor cantilever retaining wall's effect mechanism

C. Wang

*School of Mechanical Engineering, USTB, Beijing, China*

C. Li, X.G. Song, H.B. Zhang & Q.Y. Meng

*School of Civil Engineering, Shandong University, Jinan, China*

**ABSTRACT:** Based on practical engineering, the pressure-dispersed anchor cantilever retaining wall's effect mechanism was calculated by the FLAC3D program. Through the simulation test, the soil stress, anchor axial force, stress and horizontal displacement of this new type of retaining wall were analyzed, and conclusions were obtained as follows. (1) The upper and lower soil of the anchor plate was in the state of shear and compression, the influence scope was about 1.5 times the anchor plate width on both sides of the plane of the anchor plate, and the shear stress of soil on both sides of the anchor plate was in the opposite direction. (2) The longer the length of the anchor cable, the smaller the horizontal displacements in the operation period and the greater the axial force. (3) When the horizontal displacement of the crown was smallest in the operating period, the horizontal displacement of the bottom slab was the largest. The displacement changed linearly along the wall height, and the horizontal displacement of the whole wall decreased after being prestressed. (4) The horizontal stress of the upper wall was comparatively less, the horizontal stress of the bottom slab was largest, and the stress concentration appeared in the position of the anchor, which became more distinct after being prestressed.

**Keywords:** pressure-dispersed; retaining wall; FLAC3D; effect mechanism

## 1 INTRODUCTION

Pressure-dispersed anchored cantilever retaining wall consists of the cantilever retaining wall, the pressure dispersed anchor rod (rope) and the anchor plate. This type of retaining wall combines the advantages of cantilever, anchor plate and anchor rod retaining wall, and the pressure-dispersion characteristic of pressure-dispersed anchor rope. It is a new type of retaining wall developed in recent years, which improves the overall stability by inflicting prestress to the anchor and has a remarkable effect on high filled embankment slope reinforcement. Currently, studies of this type of retaining wall are few. Xue (2013) analyzed the mechanical characteristic of pressure-dispersed anchor retaining wall consolidated high filled embankment during the construction process. Song (2014) studied the earth pressure distribution regularity of pressure-dispersed anchor retaining wall. Wu (2014) analyzed the earth pressure distribution regularity, mechanical characteristic during the construction period and the operation period of a pressure-dispersed anchor retaining wall, and the major controlling factors that influenced the

bearing capacity of a pressure-dispersed anchored cantilever retaining wall. Wang (2011) carried out the design and calculation of the structural theory of a pressure-dispersed anchor retaining wall, and through some methods such as field monitoring and finite element analysis, the mechanical properties of this type of retaining wall were analyzed under the situation of construction, operation and earthquake, which has deepened the understanding of this new type retaining wall.

Based on the above research and the substantial project of the pressure-dispersed anchor cantilever retaining wall on QingLin expressway, this paper established a finite difference numerical model by FLAC3D, and conducted the simulation analysis of this new type of retaining wall.

## 2 NUMERICAL CALCULATION MODEL

### 2.1 *Fundamental assumption of the model*

To truly reflect the mechanical and deformation characteristics of the retaining wall in the engineering and to study the effect mechanism of the retaining wall conveniently, the following

assumptions were made to the numerical calculation model:

1. There is no longitudinal deformation that occurs along the way of the model;
2. The surface and base materials of the road are elastic, between which the deformation is successive and no slippage or separation will occur;
3. The material of the retaining wall is elastic and there may be slippage or separation among the retaining wall, filling earth behind and foundation soil.
4. Subgrade filling construction is completed in one time, and equal prestress is inflicted to each bundle of the anchor cable.

## 2.2 Model building

In the actual project, a cluster of pressure-dispersed anchors were installed on the retaining wall longitudinally at the interval of 4 m, so the longitudinal size of the model along the road is 3 m. Because the subgrade filler soil is laminar and isotropic, and the model is a typical axisymmetric problem whose axis of symmetry is the center line of the road, half of the actual engineering were taken to analyze when modeling, setting the upper surface of the model free and the others fixedly constrained. Model groups include the subgrade, the foundation, the cantilever retaining wall, and the gravel replacement cushion rubber, and the model size is 30 m \* 4 m \* 19 m (length \* width \* height), the grid size is 0.3–0.5 m, the total number of units is 24224, and the calculation ignores the influence of groundwater. The grid division of the calculation model is shown in Figure 1.

FLAC3D contains multiple structural elements to simulate the beam, anchor cable, pile, shell, geogrid, and lining; among which, shell as the finite

element with identical thickness can be regarded as an isotropic linear elastic material without a failure limit, and cable as the linear element with a uniform section composed of 2 node yields in the tensile and compressive sides, and fails in the resistance of bending moment. According to the basic assumption and the related research of this paper, the shell element was adopted to simulate the subgrade surface, base and anchor plate, and the cable element was employed to simulate the pressure-dispersed anchor. The model structure unit (marked red) is shown in Figure 2.

The size of the anchor plate in the model is 1 m \* 0.6 m \* 0.3 m (length \* width \* height), and the length of the anchor cable is 8 m, 11 m, 14 m and 17 m, with one end of the anchor cable being connected to the anchor plate and the other end connected to the cantilever retaining wall.

In the numerical calculation, there are two main methods to inflict prestress to the anchor cable, namely the command “Sel node apply force” and the command “Sel cable pretension”. Command one is used to inflict prestress load directly to the element node, equivalent to exerting the concentrated load, which is usually used to simulate the influencing process of inflicting prestress to the cable on the working condition and reinforcement mechanism; Command two is used to inflict prestress to each anchor cable, of which each micro portion has the equal stress, before the numerical calculation. This command suits for the situation that the outside anchor head is locked after inflicting prestress to the anchor cable.

Based on the assumption of this article, this passage adopts command two to inflict prestress to the anchor cable, the stress value inflicted to each bundle of the anchor cable is 80 kN.

Because of the significant stiffness difference among the cantilever retaining wall, gravel replacement cushion rubber and soil layer, slippage and

Figure 1. The grid division of the calculation model.

Table 1. Computational mechanics parameter.

Material	Density ( $\text{kg}\cdot\text{m}^{-3}$ )	Bulk modulus (K/MPa)	Shear modulus (G/MPa)	Cohesion (c/kPa)	Angle ( $\phi/^\circ$ )
Subgrade	1950	8.46e1	3.91e1	41	37
Foundation	1800	3.33e1	1.54e1	15	13
Retaining wall	2550	2.17e4	1e4	**	**
Cushion rubber	1840	3.33e2	1.54e2	0	40
Pavement	2550	**	**	**	**
Anchor plate	2550	**	**	**	**

separation may occur on the actual contact surface. For this purpose, this paper established FLAC3D contact area, to better simulate the slippage and separation on the contact surface.

In order to compare with the influence of prestress on the pressure-dispersed anchor cantilever retaining wall, this paper additionally established the anchor cable calculation model without prestress. The only difference is the anchor cable prestress value before the unprestressed anchor cable model calculation, which can be null or not, while the rest of the parameters, boundary conditions and calculation methods are all the same.

### 2.3 Model parameters

Mohr-Coulomb is chosen as the constitutive model, while for the calculations of soil and gravel replacement cushion rubber, the constitutive model of the cantilever retaining wall is considered as the elastic model. Model parameters can be obtained according to the field survey and indoor experiment. Computational mechanics parameter summary is given in Table 1.

## 3 CALCULATION RESULTS AND ANALYSIS

Calculation process was carried out in accordance with the actual construction, namely establishing the model of the cantilever retaining wall on the weight self-balancing foundation. 80 kN prestress was inflicted to each anchor cable and subgrade filling construction should be completed in one time, and then the numerical calculation of the retaining wall during operation periods can be conducted.

### 3.1 Stress analysis of soil mass

Anchor cable is unbonded type, and anchoring force is mainly provided by the soil around the anchor plate. To analyze the stress state of soils surrounding the anchor plate, shear stress nephogram (Fig. 3) and its local amplification figure

Figure 3. Sxy shear stress nephogram.

Figure 4. Sxy shear stress nephogram local amplification figure.

(Fig. 4), the principal stress nephogram of soil (Fig. 5) and its local amplification figure (Fig. 6) were extracted.

Figure 3 and Figure 4 shows that the soil around the anchor plate is affected by the shearing action, and the sheared soil is mainly distributed in the upper and lower anchor plate, and 1.5 m to both sides of the plane of the anchor plate, i.e. the main shear influence scope was about 1.5 times the anchor plate width on both sides of the plane of the anchor plate. Besides, the shear stress of the soil on both sides of the anchor plate was in the opposite direction.

Figure 5 and Figure 6 show that the soil around the anchor plate is in the state of compression, the areas of which mainly locate in the upper anchor

Figure 5. Sxx principal stress nephogram of the soil.

Figure 6. Sxx principal stress nephogram local amplification figure.

plate, while less in the lower soil. The soil under pressure distributes on both sides of the anchor plate, about a 1.5 m range, roughly equal to the distribution of the sheared soil.

Figure 3 and Figure 5 show that the soil around the anchor plates is influenced by shear stress and compressive stress, the values of which are approximately constant in the soil, showing that the distribution of the pressure subjected to the anchor plate is approximately identical; in other words, the pressure is dispersed evenly.

### 3.2 Axial force analysis of the anchor cable

After being inflicted prestress, the anchor cable will be affected by the tension from the cantilever retaining wall in the operation period, which is similar to the process of all-tension after each bundle of the anchor cable is tensioned. So, the axial force is bound to increase. To analyze the change rule of the anchor axial force, each computed result of the anchor axial force in the operating period was extracted, as shown in Table 2.

From Table 2, it can be seen that the shorter the anchor cable, the smaller the axial force in the operating period, which is different from the previous axial force distribution law of unit under equal stress tension<sup>[9]</sup>. Therefore, this paper extracts the displacement vector graph of each anchor plate

Table 2. Axial force of the anchor cable during the operating period.

Anchor plate	Axial force/kN			
Interval	8 m	11 m	14 m	17 m
3 m	80.44	82.03	83.54	85.05

Figure 7. The displacement vector graph of structure units.

element and anchor cable element, as shown in Figure 7. As shown in Figure 7, the displacement vector of the shorter anchor is in the ramp below direction and its horizontal displacement component is bigger; nevertheless, the displacement vector of the longer anchor is approximately in the downward direction and its horizontal displacement component is smaller. Consequently, when the cantilever retaining wall is in integral tension, the elongation per unit length of the longer anchor cable is bigger and the elongation per unit length of the shorter anchor cable is smaller, which manifests that the longer the anchor cable, the larger the axial force increment of anchor cable in the operating period, accordingly the larger the axial force.

### 3.3 Horizontal displacement and stress analysis of the anchor cantilever retaining wall

Through the establishment of the unprestressed anchor cable calculation model, the influence of prestress on stress and horizontal displacement of the cantilever retaining wall was obtained in this paper, as shown in Figure 8 and Figure 9.

As shown in Figure 8, the horizontal displacement on the top of the cantilever retaining wall is the smallest and the horizontal displacement of the bottom slab is the largest, and the displacement changes linearly along the wall height and reaches the maximum on the bottom slab. Compared with the retaining wall anchor cable without prestress, the horizontal displacement of the whole wall decreases after inflicting prestress to the anchor cable, and the maximum horizontal displacement reduced from 17.78 mm to 17.1 mm. Thus, we can clearly draw the conclusion that the infliction of prestress can restrict the lateral sliding of the retaining wall to a certain extent.

As shown in Figure 9, the horizontal stress of the upper wall is smaller and the bottom slab is the largest. This explains the reason why the horizontal

Figure 8. Horizontal displacement of the cantilever retaining wall.

Figure 9. Horizontal stress of the cantilever retaining wall.

displacement distribution is larger at the upper part, while less at the bottom slab. These two sets of curves show the stress concentration phenomenon at the 2.4 m height, which is exactly the position of pressure-dispersed anchor cable layouts. Pressure-dispersed anchor cable make the stress concentration phenomenon emerge at this position and after inflicting prestress, the stress concentration phenomenon is more obvious, in which the peak value increases from 35.02 kPa to 383.8 kPa. While the excessive stress concentration is harmful to the wall mechanic characteristic; therefore, reinforcement treatment should be applied to this area of the retaining wall when designing and construction.

#### 4 CONCLUSIONS

1. Upper and lower soil around the anchor plate of the pressure-dispersed anchor cantilever retaining wall was in the state of shear and compression, the influential area of which is 1.5 m to both sides in the plane of the anchor plate,

i.e. the influential scope was about 1.5 times the anchor plate width on both sides of the plane of the anchor plate, and the shear stresses of the soil on both sides of the anchor plate are in the opposite direction.

2. The longer the length of the anchor cable, the smaller the horizontal displacements in the operation period, and thus the greater the axial force.
3. When the horizontal displacement of the wall crown is smallest in the operating period, the horizontal displacement of the bottom slab is the largest. The displacement increased linearly along the wall height and the horizontal displacement of the whole wall decreased after being prestressed.
4. The horizontal stress of the upper wall is comparatively less and the horizontal stress of the bottom slab is the largest. The stress concentration appears in the position of the anchor, which is more severe after being prestressed. Such excessive stress concentration is harmful to the wall mechanic characteristic. Therefore, reinforcement treatment should be applied to this area of the retaining wall during designing and construction.

## Simulations of transit priority under multi-flow conditions

J. Ding, Y.Y. Ma, M. Yang & W. Wang

School of Transportation, Southeast University, Sipailou, Nanjing, P.R. China

**ABSTRACT:** Transit priority is a fundamental support for improving buses' level of service. The most common way to ensure the buses to run fluently is to equip roads with bus lines. Besides, buses can get signal priority in some cases. To evaluate the effects of transit priority on the entire intersection under different traffic flows, the Shuanglong-Jiyin Intersection was taken as a case. According to the simulations results, hybrid transit priority together with bus line and signal priority can cut down 60% of intersection delay, but transit priority should be considered when the intersection is under heavy traffic pressure.

**Keywords:** transit priority; bus line; signal control; microscopic simulation; traffic flow sensitivity

### 1 INTRODUCTION

The transit priority has numerous intensions since the development of nearly six decades (Yagar, S. 1993, Ji, Y.J. et al. 2005, Arasan, V.T. & Vedagiri, P. 2010). The most direct and operable to help the transit system operate efficiently is to give more right-of-way to buses. Generally, two main parts of transit priority in the right-of-way are exclusive bus lines in the space level and the signal priority in time level (Sunkari, S.R. et al. 1995). More and more cities are establishing their bus lines, and signal priority has been applied in some cases, although it's not as popular as the former strategy. Thus, it may be interesting to explore the effects of different kinds of transit priority strategies under different conditions.

According to early researches, the exclusive bus lines can improve the safety and pollution of transit system, as well as increasing the travel speed of buses by more than 10% (Zargari, S.A. & Khan, A.M. 1998). Signal priority can promote the buses to operate more smoothly in the intersection (Li, J. et al. 2012, Shen, F. & Yang, X.G. 2009). Ma and Yang (Ma, W.J. & Yang, X.G. 2006) tried three signal strategies by simulation, consequently, the delay of buses might drop sharply and meanwhile, it could interrupt automobiles to different extents.

However, few early studies can combine the spatial and temporal transit priority together and most the simulations focused on the original traffic flow rate, therefore, the effects of transit priority can't be evaluate in a relevant wide range, and the references for building up transit priority might be unscientific owing to the lack of experiments.

To explore the performances of buses and automobiles under different priority strategies and traffic flow rates. Shuanglong-Jiyin Intersection

was simulated in the microscopic simulation tool, VISSIM. Three scenarios was designed, which are the current scenario, the bue line only scenario and the bus line with signal priority scenario. Each scenario has 10 flow rates reformed from the observed data.

### 2 DATA

The study is based on the case of the Shuanglong Road—Jiyin Road Intersection. The Shuanglong Road is an arterial road which stretches from south to north. It has all together 8 lanes, with the bus going straight through the road. The Jiyin Road is a secondary main road in Nanjing, China, and

Figure 1. The canalization of Shuanglong-Jiyin Intersection.

Figure 2. The canalization with bus lines.

Table 1. Traffic flows of Shuanglong-Jiyin Intersection (pcu/h).

Entrance	South	North	East	West
Left	188	178	136	135
Straight	1654	1637	812	831
Right	180	199	90	96

it crosses with the Shuanglong Road vertically. To verify the effectiveness of the priority for buses, the study puts a bus line on the outer side of the intersection. The intersection's original and reformed canalizations are showed in Figure 1 and Figure 2. The traffic volumes of the intersection are acquired through video tapes on the morning peak period in a work day. The statistics are shown in Table 1.

### 3 SIMULATIONS

#### 3.1 Building the simulation scenarios

The microscopic simulation software VISSIM is used in the study. To verify the influence on the intersection if giving the priority to buses, the study researches on three different simulation scenarios: the original one, the one with the bus line only and the one that applies the bus line and the signal priority at the same time.

**Scenario 1:** The original scenario, which is completely the same with the real conditions.

**Scenario 2:** The road with the bus lane. The bus lane is placed at the sides of Shunanglong road,

Figure 3. Extend the green time for buses.

Figure 4. Compress the green time for the former phase.

as shown in Figure 2. The signal timing, however, is still in accordance with the field statistics.

**Scenario 3:** Use the bus line and the signal priority at the same time. Add a bus arrival detection which uses the “green time starting early and cutting off late” method to give buses the priority in the signal timing. The detailed method is explained as follows.

#### 3.2 Signal priority for buses

The bus arrival detection is placed about 80 meters before the stop line. Once the detector is activated, it immediately judges whether the phase for buses is green light or not. If the signal is green, then nothing has to be changed, otherwise, the time difference between the activated time to the beginning and end of the pass phase for buses should be compared. If the time difference to the phase beginning is shorter, then the pass phase for buses will start 10 seconds earlier. Contrarily, the phase end will extend for extra 10 seconds. The process is illustrated in Figures 3 and 4.

In order to find out the influence that bus priority will bring to the intersection on different scenarios, the study uses 10 different volumes for each scenario. New volumes are acquired by multiplying the original volume with 60%–105%, and the interval is 5%.

### 4 ANALYSIS AND DISCUSSIONS

Delay is often used as an index in evaluating the efficiency of travelling. The study tests on 10 different volumes through 3 scenarios. The results are shown in Figure 5.

From the figures above, we can draw the conclusion that the delay of buses is relatively stable

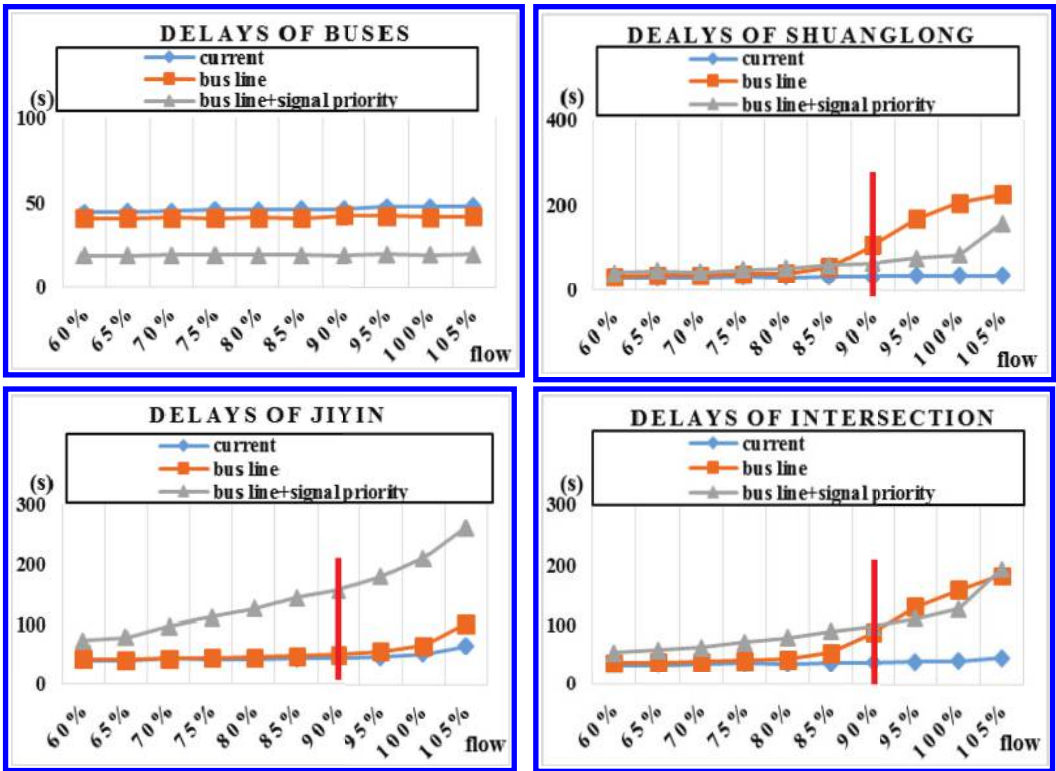

Figure 5. Delays of simulation results.

no matter what the scenario is. The bus line could decrease delay for about 10%. Together with signal priority, the delay could drop significantly for more than 50%. Thus, the priority for buses, especially the integrated one involves time and space, will bring huge augment in the efficiency of travelling of buses.

However, as an arterial road, the Shuanglong Road doesn't get benefits. The priority for buses means less road resources for social vehicles, and thus the delay of social vehicles increases, especially when the volume grows bigger than 90% of the original one. Under that circumstance, there will be severe congestions at the intersection, and thus this condition is inappropriate for the priority for buses. What's more, it's noticeable that some social vehicles which share the same phase with buses also get benefits if the buses have signal priority. That can explain why the delay of social vehicles in Scenario 3 is much smaller than that in Scenario 2.

Bus priority has some negative influences on the traffic capacity of secondary main road. Because when the signal controllers accept the priority applications of buses, more green time will be provided for the phase for buses and social

traffic sharing the same phase with them, which also results in lower probability and higher delay for vehicles travelling on the secondary road to pass the intersection. The signal priority increases its delay further. Even though the volume is 90% of the original one, bus priority will still trigger the collapse of social vehicle system. The last diagram in Figure 5 illustrates that when the volume in intersection is close to its saturation point, the bus priority affects the passage of social vehicles greatly.

## 5 CONCLUSION

The bus priority is an unavoidable trend for the development of the public transit. The hybrid temporal and spatial priority for buses can boost buses' efficiency of travelling remarkably, but its application should be considered carefully according to the real conditions, as what we want to achieve is that we can operate the whole transportation system with as few congestions as possible, the bus priority shouldn't ignore the social traffic who run on the road recently. Also, the most efficient bus priority happens under the condition that

local automobiles don't have the ability to fulfill the roads.

This passage is based on the case study of the Shuanglong Road and Jiyin Road Intersection, tested the sensitivity under different volume conditions by the microscopic simulation software on three different scenarios: the original one, the bus line only one and the bus line plus signal priority one. The study shows that, in this case, the hybrid temporal and spatial priority for buses can decrease the delay of buses for more than 60%, but it affects the efficiency of social vehicles. So when the volume of intersection is close to its saturation point, the application of bus priority should be further considered. Besides this, finding out a priority method that can handle the contradiction between buses and social vehicles, and generalizing it into all traffic webs, is definitely a key point in future studies.

# Diseases of long span steel bridge pavement and their solutions

Shanshan Ji, Yaxun Yang & Gao Gong

*Highway Institute in Chang'an University, Xian'an, Shanxi, China*

**ABSTRACT:** This paper mainly focuses on the analysis of the stress state of long span steel orthotropic plate and highlights the influence of the structure of bridge deck on the mechanical characteristics of the bridge pavement. Also, it uses Ansys to simulate that condition. At the same time, aiming to solve the diseases, we could try to find answers from the structure of the bridge deck and materials.

**Keywords:** orthotropic plate diseases; materials; bridge pavement

## 1 INTRODUCTION

With the development of road transport, rapid development has been made in bridge construction technology. Bridges of sleek and innovative structure at medium-size continue to emerge across the country. Deck as an important component of the overall structure of the bridge, its quality and durability directly affect safety, comfort of driving, durability, and investment benefits during operation. But over the years many of China's new long-span bridges (e.g. the Jiangyin Yangtze River Bridge, the Runyang Yangtze River Bridge) in deck paving of steel bridge, they have suffered various degrees of damage, seriously affecting the driving comfort and durability of steel girder. And these long-span bridges as a transportation hub, repairing them would bring a great deal of disturbance to the community, and costing a large sum of money. So, the study of the causes of large-span bridge deck pavement damage has a great value, also guiding us to find a solution to this problem.

## 2 ANALYSIS OF CAUSES FOR DEFECTS

Bridge deck gets damaged for many reasons, including all aspects of design, construction, the environment of operations, and conservation. The design of deck pavement is unreasonable, or construction technology and construction organization are not comprehensive, over-weight vehicle traffic overload, untimely conservation, which are the main causes of such diseases. With complicated geometry and large flexibility, the stress state of orthotropic steel panel pavement is more complex

than the ordinary cement concrete pavement. Thus, under the external force, they will produce a lot of shear stress between layers, and corresponding higher interlayer adhesion requirements. From the whole of the structure, the steel box girder is an excellent main beam structure. However, due to the special quality of its structure, steel deck pavement has often some diseases occurring on it. Similarly, the destruction of the adhesive layer between the pavement and the steel greatly reduces the composite action, and even may accelerate the destruction of pavement. The reasons for the rut include heavy traffic, channelization of traffic and the nature of pavement materials. But at the same time, we should also take into account the effect of the orthotropic bridge deck structure on force of the bridge deck pavement.

## 3 SOLUTIONS

In view of the above analysis of the causes of disease, we can solve this problem from two aspects. First, orthotropic deck plate is an excellent form of bridge structure; however, it is not researched deeply at the present stage and the stress state lacks clarity, which may lead to some unforeseen problems when designing. Therefore, strengthening the research to find a reasonable form, or giving a reasonable reference range of design parameters, has a great significance in guiding the designer. At the same time, asphalt concrete has been used for a long period, and has the advantage such as comfortable driving. But it also has its own shortcomings. And asphalt concrete may be not the best combination with steel bridge, so we can try to find a new alternative material.

### 3.1 The impact of performance of the orthotropic steel bridge deck on bridge deck pavement

To investigate this question, we use a finite element software, Ansys, to simulate a long-span steel bridge deck in China. The simulation uses a simplified model. The basic model of structure is shown in Figure 3. By simplifying the structure, we can save a large amount of calculation, which is very convenient for the designer to simulate the deck of the bridge. During FEA simulation, we use shell181 element to mesh the structure and control the size of element at 10 mm. Due to stress concentration of wheel load, it is necessary to refine the grid, whose Young's modulus is equal to 210000 MPa and Poisson's ratio is equal to 0.25. Model sizes involved in the argument are listed in Table 1.

At the same time, we need to simplify the wheel load. The wheel load is distributed on double rectangles, as shown in Figure 1. There are two load rectangular areas, with the width set to 200 mm and the length converted according to the load size. When the length is translated into approximately 250 mm, the weight of the rear axle is about 14 ton. A square load is used to adapt the shape of the element. The distributed load size is 0.7 Mpa, as shown in Figure 2.

In order to find the most unfavorable load position, we need to create the FEA model, and put the load on the designated place and then get the most unfavorable position. First, we need to select some position, as shown in Figure 4.

Table 1. Parameters of the structure.

Thickness of the roof	12	U-shaped rib height	280
Diaphragm distance	3200	U-shaped rib width	300
U-shaped rib spacing	600	U-shaped rib thickness	6

Note: Unit in mm.

Figure 1. Diagram of the basic model structure size.

Figure 2. Wheel load diagram (Unit: mm).

Figure 3. Simplified model of orthotropic bridge deck in Ansys.

Figure 4. Lateral position of vehicle load.

We need to check the lateral loads on different locations and find the maximum value. Also, we need to arrange the position of the vehicle load in the longitudinal direction.

In the process of loading to the model, by comparing, we can find out the most unfavorable load position, observing the distribution regularity of stress and strain under the double-deck wheel load.

As can be seen from the figure, the force of orthotropic bridge deck is very complex, and under the wheel load, the maximum tensile strain occurs in combination of ribs with the bridge deck, reaching its maximum value of 549  $\mu\epsilon$ .

This can easily lead to fatigue cracking of the deck pavement under repeated loads and vehicles that cause pavement slip off due to insufficient

Figure 5. Transverse strain.

capacity shear of the adhesive layer. This is also the main reason for the destruction of the bridge deck early. The main reason of crack is the complex of bridge deck and severe traffic environment, which are prone to make pavement produce fatigue cracking, such as steel bridge, asphalt pavement deck supported by steel deck acted by the vehicle load will produce deformation leading to longitudinal stiffeners, transverse bulkhead or transverse stiffeners, clapboard, stiffening girder webs and other components and welded steel deck at a high-stress area. Moreover, it would produce a greater negative moment in the pavement at the position that tensile stress or tensile strain concentration area of at the surface of the pavement at these locations. Crack appeared first on the surface of the pavement, and then gradually developed to the underside. In the longitudinal stiffeners, the surface of deck pavement the main beam web will appear longitudinal cracks, transverse cracks at the surface of the deck pavement, transverse bulkhead or transverse stiffeners and at the intersection of the transverse bulkhead and stiffeners, pavement surface prone to develop into a network of cracks. With pavement cracking and slip, some steel panels will be further damaged. Since this disease is caused by the characteristics of orthotropic plate structural, we can adjust some parameters structure to control the maximum value of positive strain reasonably. With foreign scholars having used the finite element method, by 8-node isoparametric element analysis of space with a roof deck stiffener, obtaining the position of the vehicle loading on the deck pavement surface where transverse tensile stress achieved maximum, we can, from the viewpoint of tensile failure, get the suggested values, such as spacing between stiffeners, beams and thickness of steel plate. For example, the width of the U-shaped rib should be not more than 350 mm. The recommended parameters have better guidance for design.

### 3.1.1 Effect of opening width of U-shaped rib on orthotropic plate

We still use the same FEA model, just changing the opening width of U-shape and watch the change of transverse tensile strain values. As shown in Figure 6, it is the result of the situation where the width is equal to 0.5. From the picture, we can get the maximum value of transverse tensile strain (i.e. 1020  $\mu\epsilon$ ). We can build other model in the same way, and list the result on Table 2.

From the table and Figure 7, we can get the conclusion that with the increasing opening width of U-shaped ribs, the maximum value gets larger. So, when we design the size of the ribs, we should control the size during the suitable range. Last but not least, we also can research the effect of the thickness of deck and space of the diaphragm.

### 3.2 Finding a new bridge deck replacement material

Asphalt is certainly not the best material for long-span steel bridge deck. Temperature properties of bituminous materials are poor, and prone to cracking in winter, to soften in summer and higher thermal efficiency of steel structures and combined with the complex mechanical characteristics of orthotropic, so it is easy for bridge pavement made of asphalt concrete deck to catch crack. Asphalt concrete is difficult to overcome the shortcomings of its own.

Ultra High Toughness Cementitious Composite (UHTCC) is a good choice. UHTCC came out not

Figure 6. Maximum value of transverse tensile strain.

Table 2. Regular of changing opening width.

Opening width (mm)	Max value of transverse tensile strain ( $\mu\epsilon$ )
300	549
400	706
500	1020

Figure 7. The effect of the opening width of the rib.

long ago, but researchers carried out many studies, and research results also show us the strengths of the material. It is sure that all the RC members inevitably crack, and cracks conventionally from concrete structures usually are above one millimeter. It can also be seen from these advantages that UHTCC is more suitable to work with orthotropic plate than asphalt concrete. First, UHTCC in direct tension and strain can best be stabilized at 3%, and sometimes as high as 6%, hundreds of times that of ordinary concrete, 10–20 times that of yield strain of the steel bar. At the same time, when it reaches the ultimate tensile strain, crack corresponds to no more than 100 μm, which are difficult to detect with the naked eye. Self-heal refers that the material has ability to repair cracks without any outside intervention. Crack self-healing can reduce the width of the fractures, so that the durability and mechanical properties of materials can be improved, which is important to the security of structure and extending the useful life of infrastructure. Meanwhile, UTCC is a new kind of material with a high-performance fiber-reinforced cementitious composites. Because it has performance of multiple cracking and excellent controllability of the crack width, it has a more excellent self-healing properties. At the same time, we can find the strength of the UHTCC by comparing the experiment with normal concrete. The result is shown in Figure 8.

It is clear that UHTCC has higher carrying capacity and better deformability than normal concrete, which is important for the material used as pavement, especially suffering largely repeated vehicle load. Obviously, if we use this material, we need not worry about cracks due to exceeding the maximum tensile strain, and even at the ultimate tensile strain, its protective effect on the bridge deck still exists. Furthermore, the temperature linear expansion coefficient of UHTCC and steel is closer, so the two can work better.

Figure 8. Bending test of high strength concrete.

### 3.3 Conclusions

From the above analysis, we can get that there are two main reasons of the damage of the bridge pavement especially for a long span bridge. First, the special structure of the orthotropic plate can produce complex stress and strain state, being prone to crack. Second, we notice the inherent weakness of the asphalt. According to these main reasons, we find different methods to overcome the diseases of the pavement. Controlling the size of the U-shaped ribs, thickness of plate and finding new alternative materials is a good way. Thus, UHTCC is a good choice.

# The research on the internal force effect of different vertical curves on a curved box girder bridge

Yu-xiao Liao & Jing-hong Gao

Department of Mechanics and Civil Engineering, Jinan University, Guangzhou, China

Key Laboratory of Disaster Forecast and Control in Engineering, Ministry of Education of China, Guangzhou, China

**ABSTRACT:** Using the stimulated structure MIDAS Civil to conduct the calculation with REM modeling, this paper analyzes the internal force of the curved girder bridge whose radius of curvature is  $R = 200$  m. Under the condition of the unaltered span and radius of curvature, this paper investigates the effect of the internal force variation of the continuous curved box girder bridge that is influenced by permanent load and moving load with different vertical curves.

**Keywords:** curved girder bridge; vertical curves; internal force variation

## 1 INTRODUCTION

With the rapid development of scientific technology and economy, nowadays, the quality of the construction of highway bridges has become critical increasingly. Compared with the traditional bridges that suffer the impact of terrain, surface features and floor space, curved bridges are widely applied to the modern highways as well as urban overpasses, with their numbers also increasing every year. The requirements for the highways and their bridges are not only to ensure the rationality and the networked characteristic, but also to enhance the line grade for accelerating the speed, improving security and comfort. In recent years, curved bridges have attracted much attention from China's national engineering, and are increasingly applied to the highways and urban overpasses.

The operating function of curved bridges mainly depends on the curvature. When vertical load works on the bridge, the bending moment and torque of the curved bridge will come into contact simultaneously and interact with each other, complicating the mechanical analysis of curved bridges. When the centrifugal force of the live load works on the curved bridge, the lateral bending moment and torque of the curved bridge will appear, complicating the stress of the curved bridge as well. Therefore, it is very useful and necessary to determine the principles of designing and the methods of calculating.

## 2 PROJECT OVERVIEW

In this section, a straight girder bridge with a span of  $36\text{ m} + 60\text{ m} + 36\text{ m}$  is considered. Many nodes

are set in the top and bottom of supports. In the bottom of each support, a general support constraint (constrain of D-all) via elastic connection (general) is simulated (which means the strength of supports). Finally, the top of the support and girder are connected in a rigid manner.

A curved of the box girder bridge is modeled with Midas. Here, its radius of curvature is 200 m, and longitudinal gradient varies from 0 degrees to 6 degrees (where the alpha is changed from 0 degrees to 6 degrees). Then, they are analyzed and contrasted between several box girder bridges with the same span but different longitudinal gradients.

## 3 FINITE ELEMENT MODEL

The main girder is modeled by 3-Dimension. A fixed boundary condition is set in the bottom of the bridge pier. Its longitudinal gradient varies from 0 degrees to 6 degrees gradually. In this model of continuous bridge piers, the whole bridge is divided into 149 nodes and 76 unites, and the main girder nodes occupy from 1 to 77 and unite to take 1 to 76 around them. The X, Y, Z axes are created

Figure 1. Curved continuous box girder bridge.

Figure 2. Finite element model.

across the centerline in one side of the girder and extended to the other side, as shown in Figure 2.

#### 4 ANALYSIS RESULT OF THE FINITE ELEMENT MODEL

For the curved girder is a symmetrical structure, the analysis result is worked out in the force of permanent loads and pre-stressing strain force. Units 2, 21, 39, 57, and 76 are considered for analysis.

##### 4.1 In the work of permanent load

At different longitudinal gradients, the axial force, torque, bending moment Y, and bending moment Z are shown in Figures 3 to 6.

In the force of self-gravity, the curved girder with 0 degrees of longitudinal gradient operates with little axial force and bending moment in the Z axis, which can be ignored. When the longitudinal gradient grows with gradient per degree, the axial force, torque, and bending moment of the Z axis of the girder increase gradually. The maximum axial force in the middle of the span is 1911 KN, which is close to the theoretical force. The torque and bending moment that developed by self-gravity are steady with the change in the longitudinal gradient. And the anti-banding moment of the girder around the support is in a large force, and the maximum anti-banding moment is 122591 KN·m, which is also is close to the theoretical result.

Comparing between axial force, torque, and bending moment created by self-gravity, it can be seen around the sheet. With the increasing longitudinal gradient, axial force increases at a rate of 32%, torque decreases at a rate of 8.7%, the bending moment in the Y axis has no change, the bending moment in the Z axis increases obviously at a rate of 370%, which has a maximum bending moment of 3133 KN·m when the longitudinal gradient is 6 degrees.

##### 4.2 In the work of moving load

At different longitudinal gradients, the axial force, torque, bending moment Y, and bending moment Z are showed in Figures 7 to 10.

Under the moving load, the radius of the 200 m curved bridge's axial force increases gradually as the

Figure 3. Permanent load-axial force.

Figure 7. Moving load-axial force.

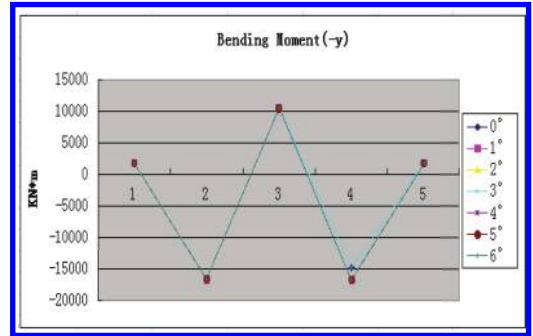

Figure 9. Moving load-bending moment (-y).

Figure 8. Moving load-torque.

Figure 10. Moving load-bending moment (-z).

slope increases and the change is obvious, but their values are not within reasonable limits. The slope of the zero curved bridge in the z-direction bending moment is small, which can be approximated to zero. As the slope increases, the corresponding torque, axial force, and bending moment in the z direction increase gradually. The middle span axial force is maximum 2036 kN, which does not differ significantly with theoretical result. The torque and bending moment developed by self-gravity are steady with the change in the longitudinal gradient.

And the anti-bending moment of the girder around the support is in a large force, and the maximum anti-bending moment is 120752 KN·m, which is also close to the theoretical result.

Under the moving load, as the slope increases, the axial force increases by 20%. However, the torque is reduced relevantly, but its values differ little. In the Y and Z directions, bending moment increases by 10%, but it is still in the same order of magnitude, which can be ignored in actual projects.

Table 2. Moving load.

## 5 CONCLUSION

Base on the internal force data by varying the longitudinal gradient in a symmetric curved girder, conclusion can be drawn. Designing a main curved girder spanning less than 60 meters can be followed by that. In self-gravity, there is a steady bending moment in the Y axis, so the method of strengthening could be done in the same was as the normal horizontal girder. However, an obviously increasing bending moment in the Z axis must be taken care when the longitudinal gradient is changed. The torque decreases by 8.7% at the lift longitudinal gradient, which is due to the complex interaction between the bending moment and torsion, so this should not be ignored while designing.

# A study on the stretch tensor of the beam end in a curved girder bridge caused by environmental temperature change

Jie-shan Liu

College of Science and Engineering, Jinan University, Guangzhou, China

Jing-hong Gao

Key Laboratory of Disaster Forecast and Control in Engineering, Ministry of Education of China, Guangzhou, China

**ABSTRACT:** With day turning to night and summer to winter, the girder in the bridge would be lengthened or shortened. This is a normal phenomenon in every object. However, the curved girder bridge has a dissymmetric structure, supported shearing force, bending moment and torsion in the same node, which would stretch in an abnormal way when the temperature is changed. In this paper, using Midas Civil app after the theoretical analysis of thermodynamics, the displacement of the beam end is simulated in this finite element analysis software with the altering radius of the road centerline. By comparing these data of displacement with central angle in the equal radius of the girder, which work at the same temperature condition, the result shows that the connection between the displacement and central angle becomes approximate when considering in a small angle at the center. In addition, it would be a useful reference when installing the expansion joint.

**Keywords:** curved girder bridge; displacement of beam end

## 1 INTRODUCTION

### 1.1 Current circumstance

With a growing pace of economic increasing, the requirements of traffic are gradually rigorous when the ground area is limited. Overpass has been the new design method in these several decades. On the one hand, bridge is built in a limited space. On the other hand, curved girder bridge is a significant element in the crossroad design. Nowadays, curved girder bridge takes an enlarged part in crossroads in order to satisfy the smooth line for an easy driving condition.

### 1.2 Research in this paper

Each bridge works in a normal environment, in which the temperature alters throughout day and night, and season cycle. Thermal expansion and contraction is easy to grasp in straight line girders, but it is uncertain in curved girder bridges. Because of the dissymmetry in the curved girder bridge, its deformation is complicated, including the impact of supported shearing force, bending moment and torsion, when the temperature changes around the girder. In this research, displacement of the beam end caused by temperature stress in the curved

girder bridge is taken into consideration. Within Midas Civil app and building several curved girder bridges, the displacement of the beam end is collected and analyzed, and then the results are discussed, which can be a reference to the installation of the expansion joint.

## 2 BASE OF THE MODEL

### 2.1 Origin of the analysis model

In this paper, a model is sampled from a city's overpass curved girder bridge, whose radius of circular curve is 400 meters. It is a continuous curved box girder bridge, whose cross span combination is 36 meters in side span and 60 meters in main span, adding up to 132 meters. The schematic diagram of this curved girder bridge is shown in [Figure 1](#).

The cross-section of this curved girder bridge is a variable cross-section with a concrete single box beam. Its cross-section of two typical sections and the longitudinal section is shown in [Figure 2](#).

The body of the prestressed box girder is made of C55 concrete in JTG D62-2004, which could support 55Mpa in axial compressive experiments. The prestressed steel strand is arranged in the same direction with a center line of the curved girder

Figure 1. A schematic diagram of the origin curved girder bridge.

Figure 2. A longitudinal section and two typical cross-sections.

Figure 3. A planar graph about the curved girder.

bridge. It can endure 1860 Mpa in the tensile test, and is settled at a low relaxation level. A basin rubber support is installed between the curved girder and the bridge pier.

## 2.2 Model simplification

In this research, the curved girder bridge is made of C55 concrete, and linked with other beams through the expansion joint. Then, one pier connects the box girder with two fixed basin rubber supports; in the other pier, there are two movable basin rubber supports that connect with the box girder. So, it can be suggested that the whole concrete box girder bridge acts as an unconstrained body and free to deformation in the direction of the central line.

From Figure 3, it can be seen that two vectors  $\vec{a}$  and  $\vec{b}$  are the displacement of the beam end. The  $\vec{a}$

side is near to the fixed supports, and  $\vec{b}$  side is near to the movable supports.

## 3 CONCEPT OF THERMODYNAMICS

### 3.1 Linear expansion coefficient

Based on the above discussion, the factor that should be taken into consideration is deformation of the whole concrete box girder, especially the displacement of the beam ends. Also, the discussion ignores the influence of deformation of prestressed steel strand because of its ratio of reinforcement that takes a low-section occupation and can be negligible.

We then take the linear expansion coefficient into consideration. The concrete is so complicated and disordered that its exact parameters cannot be located. It is known that the linear expansion coefficient of concrete is  $\alpha_c = 1 \times 10^{-5}/^\circ\text{C}$  at the temperature between  $0^\circ\text{C}$  and  $100^\circ\text{C}$ .

This means that when the temperature of the concrete is increased or decreased per  $1^\circ\text{C}$ , the rate of the dilatation-magnification ratio is  $1 \times 10^{-5}$  square the whole length of the concrete body. The calculating formula is as follows:

$$\alpha_c = \frac{l_t - l_0}{l_0 \Delta t} \quad (1)$$

where  $l_0$  is the length of the original structure;  $l_t$  is the length of the structure after deformation; and  $\Delta t$  is the temperature difference between the original structure and after deformation.

So, the calculating formula (1) can be transposed to be other formulation as follows:

$$l_t = l_0 (1 + \alpha_c \Delta t) \quad (2)$$

### 3.2 Temperature setting

On the basis of statistical data, a typical value of temperature is set at  $40^\circ\text{C}$  at fluctuating temperature in total. It is means that an original box girder works in a normal environment in which the temperature increases or decreases less than  $20^\circ\text{C}$ .

### 3.3 Extension in the linear model

According to formulation (2), the length of expansion can be calculated. The original engineering model can be modified into a theoretical straight box girder bridge, and the cross span of the whole box girder bridge is 132 meters, which is 36 meters in two side spans and 60 meters in main span. By substituting 132 meters into  $l_0$ ,  $20^\circ\text{C}$  into  $\Delta t$  in formulation (2),  $\alpha_c$  will be equal to  $1 \times 10^{-5}/^\circ\text{C}$ .

Then, the main girder extension can be calculated as follows:

$$l_t = 132m \times (1 + 1 \times 10^{-5} \times 20^\circ C) = 132.0264m$$

The difference in length compared with the original one is 0.0264 meters, which is 26.4 millimeters in total.

## 4 MODEL ESTABLISHMENT

### 4.1 Circle curve of the girder bridge

This research analyzes the beam end displacement between different curve radii of box girders. In the real engineering practice, the radius of the circular curved girder bridge is 400 meters and cross-section is 132 meters in length.

Thus, by comparison, there are 7 different curve radii of the box girder to be established and simulated. The radii of the circle curve of each girder are 200 meters, 250 meters, 300 meters, 350 meters, 400 meters, 450 meters and 500 meters.

The main girder beam is simulated by a three-dimensional model. In the setting of the section material characteristic value, the material characteristic of the concrete is C55 in accordance with the JTG04 (RC) standard, and prestressed reinforcement is Strand1860 in accordance with the JTG04 (S) standard.

### 4.2 Support between the girder and the pier

This box girder bridge is a structure that consists of two piers with three spans. Each pier has two supports that connect with the main girder. In these finite element models, only two supports in a same pier are fixed support, another two supports in the other pier is a movable support along the central line. The schematic diagram is shown in Figure 3.

Thus, we establish nodes in the top and bottom of supports in each pier to simulate the actual box girder bridge. Under the bottom of the girder that is located above one pier is a rigid connection. And on the top of the pier and under the support is a general support with constraint.

### 4.3 Central angle of the girder bridge

The above-discussed model differs only in curve radius, which is set as 200 meters, 250 meters, 300 meters, 350 meters, 400 meters, 450 meters and 500 meters. Thus, the central angle can be calculated according to the following formula:

$$\beta = \frac{l_0}{R} \quad (3)$$

Table 1. Central angle of the girder at each radius.

Radius (meters)	200	250	300	350
Central angle (rad)	0.660	0.528	0.440	0.377
Radius (meters)	400	450	500	
Central angle (rad)	0.330	0.293	0.264	

where  $\beta$  is the central angle of the curved girder bridge (unit: rad);  $l_0$  is the total span of the curved girder bridge, with  $l_0/L$  equal to 132 meters; and  $R$  is the curve radius of the curved girder bridge.

Table 1 summarizes the calculating result for each girder bridge.

## 5 OPERATION AND DATA

After the setting of all bridges, we start to operate the analysis. Each model is operated independently. When the operation analysis is finished, we click the beam ending node, and check the displacement of the two ends of the girder. The below table presents the displacement of each beam end of each girder bridge model. According to the formula for the calculation of displacement angle,

$$\cos \gamma = \frac{\vec{a} \cdot \vec{b}}{|\vec{a}| |\vec{b}|} \quad (4)$$

where  $\vec{a}$  is the displacement of one side of the beam end that is near the fixed support; the  $\vec{b}$  is the displacement of the beam end that is far from the fixed support; and  $\gamma$  is the angle between the displacement directions of  $\vec{a}$  and  $\vec{b}$ .

According to the Midas Civil app,  $D_x$  is the displacement component in the  $X$  axis, and  $D_y$  is the displacement component in the  $Y$  axis,  $D_x D_y$  is the modules of vectors  $\vec{a}$  and  $\vec{b}$ . The angle part is the angle between the vectors, which is  $\vec{a}$  or  $\vec{b}$ , and  $Y$  axis. The relative angle is the angle between  $\vec{a}$  and  $\vec{b}$ , which, in these tables, is an acute angle. After running and analysis in the Midas Civil app, we search the result of the displacement of the side node. Then the angle between the two displacement directions of each beam end can be calculated, as given in Tables 2-8.

## 6 ANALYSIS AND CONCLUSION

### 6.1 Analysis

The whole extension length of the curved girder bridge is added up with  $\vec{a}$  and  $\vec{b}$ , which is the digital of  $D_x D_y$  in the table on the 5 sections, and the

$\vec{a}$	7.326	1.547	7.488	0.208	

Table 6. The displacement and angle data of the 400-meter curved girder bridge.

	$D_x$	$D_y$	$D_x D_y$	Angle	Relative angle
$\vec{b}$	19.035	1.428	19.088	0.075	0.234
$\vec{a}$	7.228	1.149	7.249	0.159	

method is added  $D_x D_y$  of  $\vec{a}$  and  $D_x D_y$  of  $\vec{b}$ , as listed in Table 9.

Mathematically, the central angle is equal to the angle between the normal directions of the two beam ends. Thus, we take the simulation results and the theoretical result of the central angle, as given in Table 10.

By comparing the result of the data, some conclusion can be drawn.

In the model of the short radius, which is a large central angle, the angle between the extension

Table 7. The displacement and angle data of the 450-meter curved girder bridge.

	$D_x$	$D_y$	$D_x D_y$	Angle	Relative angle
$\vec{b}$	19.384	0.908	19.405	0.047	0.174
$\vec{a}$	7.280	0.931	7.339	0.127	

Table 8. The displacement and angle data of the 500-meter curved girder bridge.

	$D_x$	$D_y$	$D_x D_y$	Angle	Relative angle
$\vec{b}$	19.360	0.729	19.374	0.038	0.140
$\vec{a}$	7.267	0.747	7.305	0.102	

Table 9. The comparison of total extension length.

Radius (m)	200	250	300	350
Practical result (mm)	26.934	27.947	27.318	27.013
Radius (m)	400	450	500	Theoretical result
Practical result (mm)	26.337	26.744	26.679	26.4

Table 10. The comparison between the relative angle and the central angle.

Radius (m)	200	250	300	350
Relative angle (rad)	0.662	0.541	0.384	0.385
Central angle (rad)	0.660	0.528	0.440	0.377
Radius	400	450	500	
Relative angle	0.234	0.174	0.140	
Central angle	0.330	0.293	0.264	

displacements of the two side beam ends is larger than that of the long radius. As the radius increased, and the central angle decreased, the angle between the two beam ends also decreased.

Except the two curved girder bridges with the shortest radius in this discussion, others are not approximated to its own central angle, also with a tendency that the angle increasing between the two side beam ends becomes more deviated from its own central angle.

The direction of displacement of the beam end that is near the fixed support is larger than that of the other side that is near the movable supports.

By calculating the extension of each side beam end in one curved girder bridge, the theoretical displacement can be expressed as follows:

$$|\vec{a}| = 36m \times (1 \times 10^{-5} \times 20^\circ C) = 0.0072m = 7.2mm$$

$$|\vec{b}| = (36 + 60)m \times (1 \times 10^{-5} \times 20^\circ C) \\ = 0.0192m = 19.2mm$$

By comparing with the data given in [Table 9](#), it is clear that the practical displacement is very close to the theoretical result.

Also, the data given in the table that represent the whole extension displacement of each curved girder bridge show that the result is close to the theoretical calculation.

## 6.2 Conclusion

From the analysis of the results, some conclusion can be drawn as follows:

In the curved girder bridge with a short radius, the extension displacement could be considered to be along the same line of the road line.

When installing the expansion joint, it can use a one-way expansion joint, which is more costly than the other type. And the allowance displacement of the expansion joint could be decided by the length of the whole girder bridge.

## Shear-lag effect in a prestressed continuous rigid frame bridge

Xun Wu, Hui Li & Xin Yuan

Department of Bridge Engineering, Tongji University, Shanghai, China

**ABSTRACT:** Continuous rigid frame bridge is one of the main forms of long-span bridges. The shear-lag effect of the box girder should be taken into consideration when designing a continuous rigid frame bridge. In this paper, a three-span prestressed concrete continuous rigid frame bridge is taken as the example. The finite element method is used to analyze the shear-lag effect of each critical section under the action of structure weight and the interaction of structure weight and prestressing action. The results show that under the action of structure weight, the shear-lag coefficient is small. The shear-lag effect varies under the interaction of structure weight and prestressing action.

**Keywords:** continuous rigid frame bridge; shear-lag effect; finite element method; prestressing action

### 1 INTRODUCTION

Since the continuous rigid frame bridge has many advantages, it has become one of the main form of long-span bridges. Existence of the shear-lag effect of the box girder makes stress obtained through theory to be smaller. Shear-lag coefficient is commonly used to estimate the value of the shear-lag effect. In this paper, a three-span continuous rigid frame bridge (65 + 110 + 65 m) is analyzed. The finite element method is used to analyze the shear-lag effect of each critical section under the action of structure weight and prestressing force, respectively. The conclusion can be applied in the design and review of other similar bridges.

Shear-lag coefficient is commonly used to estimate the value of the shear-lag effect. In this paper, the shear-lag coefficient is defined as follows:

$$\lambda = \frac{\sigma_{\max}}{\bar{\sigma}_s}$$

$\sigma_{\max}$ —the maximum normal stress;

Figure 1. Finite element model of the bridge.

$\bar{\sigma}_s$ —the average normal stress obtained by the integration of normal stress along the transverse floor of the box girder.

For a large bridge, dead load plays a main role. Therefore, the study of the shear-lag effect under dead load makes great significance. The action of structure weight and the interaction of structure weight and prestressing action are analyzed.

### 2 SHEAR-LAG EFFECT UNDER THE ACTION OF STRUCTURE WEIGHT

Shear-lag coefficient defined in this paper is applied to analyze the shear-lag effect in the top and bottom flange of the main section. The main sections are section of closure segment of side spans, 1/4 side span, consolidation

Figure 2. Finite element model of the section.

Figure 3. Shear-lag coefficient of the top slab.

Figure 6. Shear-lag coefficient of the bottom slab.

Figure 4. Shear-lag coefficient of the bottom slab.

Figure 7. Shear-lag coefficient of the top slab.

Figure 5. Shear-lag coefficient of the top slab.

Figure 8. Shear-lag coefficient of the bottom slab.

segment of pier and beam and closure segment of middle span.

### 2.1 Shear-lag effect on the section of closure segment of side spans

For the closure segment of side spans, the shear-lag effect is not obvious. The maximum shear-lag

coefficient of the top slab is 1.025, while the minimum is 0.966. For the bottom slab, the maximum shear-lag coefficient is 1.024, and the minimum is 0.992.

### 2.2 Shear-lag effect on the section of 1/4 side span

The shear-lag effect is not obvious at 1/4 L. The maximum shear-lag coefficient of the top slab is

1.011, while the minimum is 0.984. For the bottom slab, the maximum shear-lag coefficient is 1.005 and the minimum is 0.996.

2.3 *Shear-lag effect on the section of consolidation segment of the pier and the beam*

The shear-lag effect is obvious, especially the maximum shear-lag coefficient of the bottom slab is 1.167. In actual engineering, attention should be paid to such region. The maximum shear-lag coefficient of the top slab is 1.023, while the minimum is 0.984. For the bottom slab, the maximum shear-lag coefficient is 1.167 and the minimum is 0.902. Compared with the top slab, the shear-lag effect of the bottom slab is more obvious, due to the existence of the thin-wall piers and cross beam.

2.4 *Shear-lag effect on the section of closure segment of the middle span*

The maximum shear-lag coefficient of the top slab is 1.025, while the minimum is 0.971. For the bottom slab, the maximum coefficient is 1.055 and the minimum is 0.973.

Figure 9. Shear-lag coefficient of the top slab.

Figure 10. Shear-lag coefficient of the bottom slab.

It is concluded that for a large span continuous rigid frame bridge, under the action of structure weight, the shear-lag effect is not obvious. Due to the external force, the shear-lag effect of the region in piers is apparent. More accurate research should be done to ensure safety.

3 SHEAR-LAG EFFECT UNDER THE INTERACTION OF STRUCTURE WEIGHT AND PRESTRESSING ACTION

Considering the interaction of structure weight and prestressing action, the shear-lag coefficients are obtained, which are compared with those under the action of only structure weight.

For the top slab near the closure segment of side spans, since the internal force distribution of the structure changes due to prestressing steels, a negative shear-lag effect occurs. For the bottom slab, the shear-lag coefficient does not change very much.

Figure 11. Shear-lag coefficient of the top slab in the closure segment of side spans.

Figure 12. Shear-lag coefficient of the top slab in the 1/4 side span.

Figure 13. Shear-lag coefficient of the top slab in the pier center.

Figure 14. Shear-lag coefficient of the top slab in the closure segment of the middle span.

For the top slab of the other three sections, the shear-lag coefficient reaches its peak over the web, because the prestressing steels are mainly concentrated in the region over the web. Besides, due to the effect of prestressing, the original tensile stress

region with an obvious shear-lag effect becomes compressive, which is good for the safety of the structure.

#### 4 CONCLUSION

1. For the prestressed concrete continuous rigid frame bridge, under the action of structure weight, the shear-lag effect is not obvious. Due to the external force, the shear-lag effect of the region in piers is apparent.
2. When under the interaction of structure weight and prestressing action, the shear-lag coefficients vary to some extent, compared with those under the action of only structure weight. The effect of prestressing makes the original tensile stress region with an obvious shear-lag effect to become compressive, which can make a contribution to the safety of the structure.

**ABSTRACT:** Large-scale planning of tram has begun in many cities of China. While the design and construction technology lacks of profound study. In this paper, 3D finite element model was built to simulate the practice condition. Then the temperature field distribution was calculated. On this basis, the most unfavorable condition of load and temperature coupling effect, load in the center of the slab at 1.5 to 2 pm, was selected. Different values of roadbed slab thickness, support layer thickness, contact condition of roadbed slab and support layer, roadbed slab modulus, modulus of support layer and resilient modulus of subgrade were selected to calculate the stress and deflection of roadbed, which provides the design and construction with very important reference values.

**Keywords:** monolithic roadbed; coupling effect; load and temperature; 3D finite element

## 1 INTRODUCTION

Temperature has a great influence on tram monolithic roadbed. Rheda, Züblin and Bögl calculated the warping stress and buckling stability of monolithic roadbed under the action of deadweight and temperature gradient<sup>[1] [2] [3]</sup>. In Japan, many researchers analyze the hydration heat, daily and seasonal temperature difference and thermal stress using 2D finite element model<sup>[4]</sup>. And several post-graduates in South West Jiaotong University tested the effect of slab temperature stress on structure design<sup>[5] [6] [7]</sup>, then built the calculation method of bottom slab temperature stress<sup>[8] [9]</sup>.

In the field of temperature stress calculation of highway cement concrete pavement, a lot of research and tests were explored and implemented<sup>[10] [11]</sup>, from 1920s to now, until AASHO proposed the pavement design method by observation data of test road.

While, whether the monolithic roadbed or highway, the relation between temperature and load was established on the foundation of Winkler ground. And the contact condition of concrete

and steel bar, mechanic behavior under the load and temperature coupling effect and wheel-rail contact were not taken into consideration.

In this paper, monolithic roadbed slabs thickness, support layer thickness, contact condition of pavement and base, and the strength of monolithic roadbed, support layer and subgrade were analyzed in different conditions of temperature and load. 3D finite element model was used to calculate the effect of those factors on mechanic behavior of monolithic roadbed slabs.

## 2 TEMPERATURE EFFECT THEORY AND PARAMETER SETTING

### 2.1 Structure surface radiation effect parameter

Boundary conditions of tram monolithic roadbed were limited by the two methods blow:

#### 1. The third boundary condition

The relation of heat flow via the cement surface, surface temperature ( $T$ ), air temperature ( $T_a$ ) and daily radiation is:

Table 1. Materials parameters of calculation model.

Parameters	Conductivity [W/(m·°C)]	Specific heat [J/(kg·°C)]	Density [kg/m³]	Emissivity	Film coefficient [W/(m²·K)]
Monolithic roadbed	2.54	988	2500	0.94	13
Support layer	1.0	817	2000	/	/
Subgrade	1.2	879	1870	/	/
Steel	34.9	520	7800	/	/

Figure 1. Temperature time history curve of roadbed slab.

$$-\lambda \frac{\partial T}{\partial n} = \beta(T - T_a) - \alpha_s S \quad (1)$$

where  $\beta$  is the total heat release coefficient of structure surface, considering heat exchange of convection and radiation;  $T_a$  is the air temperature in the place without illumination;  $\alpha_s$  is the daily radiation heat absorption coefficient of structure surface; and  $S$  is the radiation intensity.

2. The fourth boundary condition

When two kinds of solid have a good contact, the temperature and heat flow on the interface are continuous. Then the boundary condition is:

$$T_1 = T_2, \lambda_1 \frac{\partial T_1}{\partial n} = \lambda_2 \frac{\partial T_2}{\partial n} \quad (2)$$

If the contact is not good, the temperature is discontinuous. Then, the concept of thermal resistance is introduced. A hypothesis of ignorance of heat in the contact gap is built, and heat flow balance is maintained. Then, the boundary condition is:

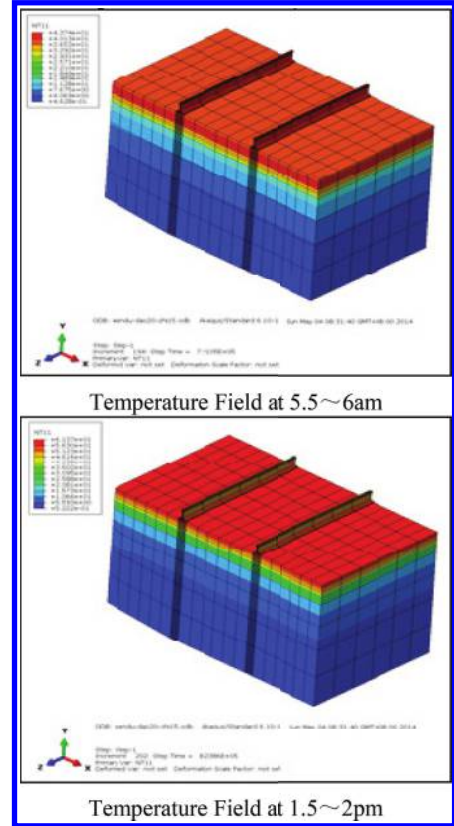

Figure 2. Calculation results of temperature field of monolithic roadbed slab.

$$\begin{cases} \lambda_1 \frac{\partial T_1}{\partial n} = \frac{1}{R_c} (T_2 - T_1) \\ \lambda_1 \frac{\partial T_1}{\partial n} = \lambda_2 \frac{\partial T_2}{\partial n} \end{cases} \quad (3)$$

where  $R_c$  is the thermal resistance caused by bad contact.

The contact of monolithic roadbed slabs is related to the fourth boundary condition.

## 2.2 Radiation intensity

Solar energy is transferred to earth in the form of electromagnetic waves. Solar constant is the energy per unit area and time from sun when the distance between the sun and earth is the average value, which can be expressed by “ $J_0$ ”. The latest observing value of  $J_0$  is  $1367 W/m^2$ . While the distance is changing every day, the daily correction coefficient ( $\xi$ ) is introduced. The equation of  $J$  can be corrected to:

$$J = \xi J_0 = \left[ 1.0 + 0.034 \cos\left(\frac{2\pi}{365} n\right) \right] J_0 \quad (4)$$

where  $n$  is the data number in a year. January 1 is the first day;  $\xi$  is the correction coefficient considering the elliptic orbit of earth revolving around the sun.

## 2.3 Material thermodynamic parameters

The material thermodynamic parameters used in the calculation of finite element model are given in Table 1.

Stefan-Boltzmann constant is  $5.775 \times 10^{-4} W \cdot m^{-2} \cdot K^4$ , absolute zero temperature is  $-273^\circ C$ .

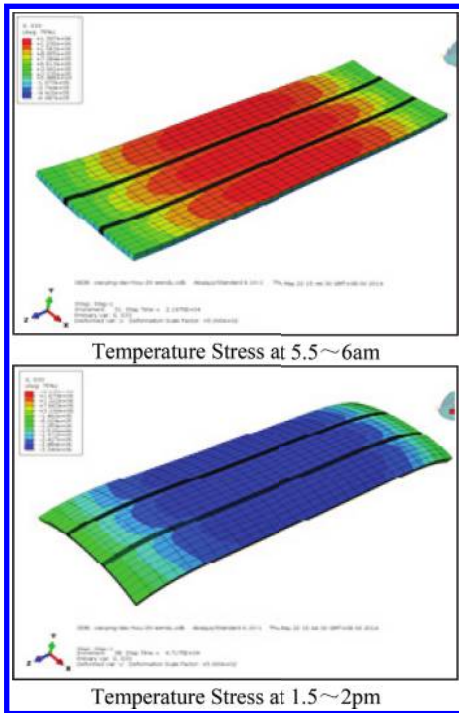

Figure 3. Calculation results of temperature stress of roadbed slab.

## 2.4 Temperature field and stress calculation

First, setting up the thermal resistance in the interlayer of roadbed slab, steel rail, support layer, and subgrade to simulate the effect of heat conduction. Then setting heat flux and heat transfer coefficient for the top of roadbed slab to calculate the transient heat conduction under the solar radiation.

As it is shown in Figure 2, the highest temperature can reach to  $62^\circ C$ , the largest difference value in temperature is  $18^\circ C$ . Importing the results to the calculation model of temperature effect to get the temperature stress relatively.

From Figure 3, we can see the highest temperature stress to be  $2.135 MPa$ . So the most unfavorable conditions of load and temperature coupling effect are load in slab end at 5.5 to 6 am and load in the middle of the slab at 1.5 to 2 pm.

## 3 CALCULATION AND ANALYSIS OF MECHANICAL BEHAVIOR OF LOAD IN THE MIDDLE WITH THE TEMPERATURE EFFECT ON ROADBED

### 3.1 Influence of structure combination

#### 3.1.1 Roadbed slab thickness

5 kinds of thickness were selected to analyze with the values of 20, 22, 24, 26, and 28 cm. Then, assuming the value of interlayer contact is 0.9. Calculating 5 times with different thickness and remaining other parameter settings the same.

The results are shown in Table 2. And variation of horizontal tensile stress on the slab bottom

Table 2. Results of mechanical response of the monolithic roadbed slabs in different slab thickness.

Slab thickness/cm	Extreme value of mechanical response			
	Cross-section			
	$\sigma_{dy}/MPa$	$D_d/mm$	$\sigma_{sz}/kPa$	$D_{ss}/mm$
20	2.174	0.929	50.363	1.524
22	1.967	0.948	49.418	1.505
24	1.746	0.964	48.328	1.484
26	1.527	0.960	47.161	1.458
28	1.313	0.941	45.901	1.435
	Vertical section			
	$\sigma_{dy}/MPa$	$D_d/mm$	$\sigma_{sz}/kPa$	$D_{ss}/mm$
20	3.422	0.414	46.788	1.490
22	3.463	0.469	45.807	1.466
24	3.475	0.548	44.449	1.440
26	3.460	0.627	43.308	1.413
28	3.422	0.704	41.019	1.391

( $\sigma_{dy}$ ), deflections on the top surface of slab ( $D_d$ ) and pressure stress ( $\sigma_{sz}$ ) and deflections on the subgrade top ( $D_{ss}$ ) with changing depths were shown in it.

As shown in these tables and figures:

1. In the cross-section, the stress distribution shapes as “M” and the concentration appear in wheelpath. The largest stress is in the bottom of wheel when thickness is 20cm with the value of 2.174MPa. It decreases to 1.313MPa with the increase in thickness. And the deflection changes a little in the same slab thickness.
2. In the cross-section, stress on the top of subgrade presents the shape of “M” with the same slab thickness. The difference in cross-section is significant, and the smallest value only accounted for 41% of the largest one, which reached 50.363kPa with the deflection of 1.524mm when thickness is 20cm.
3. In the vertical section, the stress concentration appears in the bottom of rail load. The maximum value is 3.422MPa when the thickness is 20cm, which means vertical effect is more obvious. Besides, increasing thickness leading to a larger temperature difference in vertical section makes a larger temperature deformation.
4. In axial direction of slabs, stress on the top of subgrade present the shape of “M” with the same slab thickness. The stress value decreased to 12% of former one when the thickness increases from 20cm to 28cm.

### 3.1.2 Support layer thickness

5 kinds of thickness were selected to analyze with the values of 12, 14, 16, 18 and 20cm. Then assuming the value of interlayer contact is 0.9. Calculating 5 times with different thickness and remaining other parameter settings the same.

The results were shown in Table 3.

1. In the cross-section, the stress concentration appears in wheelpath. The largest stress is in the bottom of the wheel when thickness is 12cm with the value of 1.63MPa. It decreases to 1.584MPa with the increase in thickness. And the deflection changes a little in the same slab thickness.
2. In the cross-section, stress on the top of subgrade presents the shape of “M” with the same support layer thickness. The difference in cross-section is significant, and the smallest value only accounts for 33% of the largest one. The deflection of subgrade changes a little with a shape of inverted “V”.
3. In the vertical section, the stress concentration appears in the bottom of rail load. The maximum value is 3.515MPa when the thickness is 12cm, which means vertical effect is more obvious. Besides, deflection distributed as a

Table 3. Results of mechanical response of the monolithic roadbed slabs in different support layer thickness.

Support layer thickness/cm	Extreme value of mechanical response			
	Cross-section			
	$\sigma_{dy}$ /MPa	$D_d$ /mm	$\sigma_{sz}$ /kPa	$D_{ss}$ /mm
12	1.630	0.732	46.603	1.442
14	1.645	0.783	47.642	1.466
16	1.612	0.785	46.719	1.474
18	1.606	0.787	45.796	1.482
20	1.584	0.786	44.799	1.483
Vertical section				
	$\sigma_{dy}$ /MPa	$D_d$ /mm	$\sigma_{sz}$ /kPa	$D_{ss}$ /mm
12	3.515	0.600	44.901	1.393
14	3.483	0.579	44.251	1.420
16	3.462	0.596	43.265	1.431
18	3.431	0.613	42.278	1.442
20	3.399	0.635	41.227	1.446

“W”. The maximum values in the load center is 0.258mm and that of in the end is 0.6mm. when thickness increased to 20cm, the values changed to 0.255mm and 0.635mm respectively.

4. In axial direction of slabs, stress on the top of subgrade present the shape of “M” with the same slab thickness. The stress value decreased 8% of the former one and the subgrade deflection increases 4% when the thickness increased from 12cm to 20cm.

### 3.1.3 Contact condition of roadbed slab and support layer

5 kinds of friction coefficient were selected to analyze with the values of 0.2, 0.6, 0.9, 1.2 and 1.5. Calculating 5 times with different friction coefficient and remaining other parameter settings the same. The results were shown in Table 4.

1. In the cross-section, when friction coefficient increases, tensile stress increases appreciably, while  $D_d$  and  $D_s$  decrease a little.
2. In the vertical section, when friction coefficient increases,  $\sigma_{dy}$  and  $\sigma_{sz}$  decrease a little, while  $D_d$  and  $D_s$  increase appreciably.

## 3.2 Influence of material parameters

### 3.2.1 Roadbed slab modulus

5 kinds of modulus were selected to analyze with the values of 30, 35, 40, 45 and 50GPa. Then assuming the value of interlayer contact is 0.9. Calculating 5 times with different modulus and

1.2	3.461	0.596	43.949	1.426
1.5	3.453	0.604	43.891	1.427

remaining other parameter settings the same. The results were shown in Table 5.

1. In the cross-section, the stress concentration of tensile appears in wheelpath. The largest stress is in the bottom of wheel when modulus is 50GPa with the value of 2.049MPa. It decreases to 1.728MPa with the decrease in modulus. And the deflection changes a little in the same modulus.

2. In the cross-section, stress on the top of subgrade present the shape of “M” with the same modulus. The difference in cross-section was significant, and the smallest value only accounted for 40% of the largest one. The deflection of subgrade changed a little with a shape of inverted “V”.
3. In the vertical section, the stress concentration appears in the bottom of rail load. The maximum value is 4.102MPa when the modulus is 50GPa. And it decreases to 2.798MPa when modulus decreases to 30GPa. Besides, the maximum value in the load center is 0.349mm and that of it in the end is 1.457mm. When thickness increases to 50GPa, the values change to 0.18mm and 1.404mm respectively.
4. In axial direction of slabs, stress on the top of subgrade presents the shape of “M” with the same modulus. The stress value decreases 9% of former one and the subgrade deflection increases 4% when the modulus increases from 30GPa to 50GPa.

### 3.2.2 Modulus of support layer

5 kinds of modulus were selected to analyze with the values of 6, 9, 12, 15 and 18GPa. Then assuming the value of interlayer contact is 0.9. Calculating 5 times with different modulus and remaining other parameter settings the same. The results were shown in Table 6.

1. In the cross-section, the stress concentration of tensile appears in wheelpath. The largest stress is in the bottom of wheel when modulus is 6GPa

Table 6. Results of mechanical response of the monolithic roadbed slabs in different modulus of support layer.

Modulus of support layer/GPa	Extreme value of mechanical response			
	Cross-section			
	$\sigma_{dy}/\text{MPa}$	$D_d/\text{mm}$	$\sigma_{sz}/\text{kPa}$	$D_{ss}/\text{mm}$
6	1.674	0.969	47.745	1.478
9	1.654	0.966	47.720	1.476
12	1.636	0.964	47.714	1.471
15	1.619	0.961	47.695	1.467
18	1.602	0.959	47.675	1.462
Vertical section				
	$\sigma_{dy}/\text{MPa}$	$D_d/\text{mm}$	$\sigma_{sz}/\text{kPa}$	$D_{ss}/\text{mm}$
6	3.512	0.579	44.192	1.431
9	3.491	0.583	43.888	1.429
12	3.471	0.588	43.796	1.426
15	3.452	0.591	43.709	1.424
18	3.433	0.595	43.709	1.420

with the value of 1.674MPa. It decreases with the increase in modulus. And the deflection changes a little in the same support layer modulus.

2. In the cross-section, stress on the top of subgrade presents the shape of “M” with the same modulus. The difference in cross-section is significant, and the smallest value only accounts for 33% of the largest one. The deflection of subgrade changes a little with the shape of inverted “V”.
3. In the vertical section, the stress concentration appears in the bottom of rail load. The maximum value is 3.512MPa when the modulus is 6GPa. And it decreases to 3.433MPa when modulus increases to 18GPa. Besides, the maximum value in the load center is 0.268mm and that of it in the end is 1.431mm. When thickness increases to 18GPa, the values change to 0.25mm and 1.420mm respectively.
4. In axial direction of slabs, stress on top of subgrade presents the shape of “M” with the same modulus. The stress value decreased 1% of former one and the subgrade deflection decreases 1% when the modulus increases from 6GPa to 18GPa.

### 3.2.3 Resilient modulus of subgrade

5 kinds of resilient modulus of subgrade were selected to analyze with the values of 30, 45, 60, 75 and 90MPa. Then assuming the value of interlayer contact is 0.9. Calculating 5 times with different modulus and remaining other parameter settings the same. The results were shown in Table 7.

1. In the cross-section, the stress concentration of tensile appears in wheelpath. The largest stress is in the bottom of wheel when modulus is 30MPa with the value of 1.33MPa. It increases with the increase in modulus. And the deflection changes a little in the same resilient modulus of subgrade.
2. In the cross-section, stress on the top of subgrade present the shape of “M” with the same modulus. The difference in cross-section is significant, and the smallest value only accounts for 48% of the largest one. When subgrade modulus is 90MPa, the stress reaches to the maximum value of 65.747kPa and the deflection is 0.878mm.
3. In the vertical section, the stress concentration appears in the bottom of rail load. The maximum value is 3.638MPa when the modulus is 30MPa. And it decreases to 3.364MPa when modulus increases to 90MPa. Besides, the maximum value in the load center is 1.033mm and that of it in the end is 1.457mm. When thickness increased to 90MPa, the values change to 0.25mm and -0.014mm respectively.

Table 7. Results of mechanical response of the monolithic roadbed slabs in different resilient modulus of subgrade.

Resilient modulus of subgrade/ GPa	Extreme value of mechanical response			
	Cross-section			
	$\sigma_{dy}$ /MPa	$D_d$ /mm	$\sigma_{sz}$ /kPa	$D_{ss}$ /mm
30	1.330	1.884	28.448	3.112
45	1.500	1.293	38.378	2.036
60	1.636	0.964	47.714	1.471
75	1.751	0.747	56.822	1.119
90	1.849	0.591	65.747	0.878
Vertical section				
	$\sigma_{dy}$ /MPa	$D_d$ /mm	$\sigma_{sz}$ /kPa	$D_{ss}$ /mm
30	3.638	1.457	25.889	3.058
45	3.546	0.886	34.477	1.986
60	3.471	0.588	43.796	1.426
75	3.411	0.401	52.737	1.079
90	3.364	0.272	61.762	0.842

4. In axial direction of slabs, stress on the top of subgrade present the shape of “M” with the same modulus. The stress value increases 139% of former one and the subgrade deflection decreased 73% when the modulus increases from 30MPa to 90MPa.

## 4 CONCLUSION

3D finite element model was found to calculate the temperature field distribution of roadbed slab. Then different loads were imposed to slab center in the condition of largest positive temperature difference and to slab end in largest negative temperature difference. According to the calculation results, many influencing factors were analyzed contrastingly. Several conclusions are as follows:

1. The largest positive temperature difference reaches at 1.5 to 2 pm. And the largest negative temperature difference reaches at 5.5 to 6 am. The highest temperature is 62°C, and the largest temperature difference of slab is 18°C. The highest temperature stress of roadbed slab is 2.135MPa.
2. In the coupling effect of central load and temperature, slab thickness has a limited influence on the mechanical response. And the effect of support layer thickness is similar to slab. Interlayer contact condition has a great effect on stress and deflection. Subgrade modulus is important for improving the deflection of slab. The stress value increases by 139% of former

one and the subgrade deflection decreases by 73% when the modulus increases from 30MPa to 90MPa.

3. Warping stress is larger in condition of load in center than that of load in the end. When subgrade modulus is 90MPa, the stress can reach 101.216kPa. And warping stress is affected directly by joint width, which is the key of roadbed slab design.

**ABSTRACT:** Shear strength of some subgrade soils in seasonal frozen area was tested using the quick direct test method. To process the test data, multistage grouping variance analysis was utilized. It is shown that the significance of influence factors of subgrade shear strength is in attenuation sequence: water content, normal stress, and degree of compaction. Based on the field observation of subgrade humidity during spring-thawing period, analysis of subgrade stress and the regression relation between water content, cohesion and friction angle, the maximum value of safety for each layer was calculated. The calculation indicates that the most dangerous part of subgrade is the last-thawing layer, and overload can extend the boundary of shear failure region. The research reveals the shear failure mechanism of highway subgrade in seasonal frozen area during spring-thawing period.

**Keywords:** spring-thawing period; seasonal frozen area; highway subgrade; shear failure

## 1 INTRODUCTION

Frost heaving accompanied with frost boiling and thawing settlements are the main diseases of seasonal frozen area. Usually, frost heaving occurs in winter while the latter two diseases come out in the following spring. Since former studies<sup>[1][2][3]</sup> showed that during the circulation above, the resilient module of subgrade reaches two extreme points, including the maximum value in frost heaving and minimum value in thawing settlement, with the changing of moisture, it is chosen to be the evaluating indicator of treatment on freeze-thaw diseases.

According to field researches, it can be found that shear failure of subgrade during spring-thawing period, usually resulting in the overall lateral slippage of subgrade together with subsidence of pavement (shown in Fig. 1), is closely connected with shear strength of subgrade. Therefore, it is necessary to make deep analysis on shear strength

Figure 1. Pavement settlement and crack.

and failure mechanism on subgrade soils in seasonal frozen area in order to provide sufficient support to diseases treatment.

Considering that the subgrade in the northeast part of our country mainly consists of clayey soil and this paper focuses on the shear failure due

Table 1. Error control results of water contents.

Compactness	92%					96%				
	Target water content (%)	11.2	14.2	17.5	20.6	22.7	11.2	14.2	17.5	18.4
Tested water content (%)	11.12	14.28	17.62	20.47	22.54	11.28	14.3	17.62	18.53	20.44
Error (%)	0.71	0.56	0.69	0.63	0.70	0.71	0.70	0.69	0.71	0.69

to drainage barrier in short term during spring-thawing period, quick direct shear test is chosen.

As shear strength of subgrade is mainly affected by water content, compactness and normal stress of soil, different ways including indoor tests on shear strength of soil specimens under different working conditions, field investigations of moisture on typical roads in Jilin Province and theoretical calculations of stress level in each layer of the road structures are taken to collect enough information. Based on the results, this paper gives the detailed function of the three factors above and explains the shear failure mechanism of subgrade.

## 2 INDOOR QUICK DIRECT SHEAR TEST

### 2.1 Test material

1. Sample. According to the investigations on freeze-thaw diseases in Jilin, Road S106 (Provincial Road) is chosen to study for its bad situation. Typical soil samples are taken on the location of K108+60, right side of Changling-Changchun section. After grain size test and compaction test, these samples are defined as low liquid limit clay, with secondary freeze-thaw sensitivity, and the optimum water content ( $w_{op}$ ), saturated water content ( $w_{sat}$ ) under two compactness (92%, 96%) are 14.2%, 20.6%, and 18.4%.
2. Test Design. Considering the effect of both compactness ( $w$ , %) and normal stress ( $p$ , kPa) on shear strength, water contents are chosen as  $w_{op}-3\%$ ,  $w_{op}$ ,  $0.85w_{sat}$ ,  $w_{sat}$ ,  $1.15w_{sat}$  and compactness levels are 92% and 96% (a range of 92~98% is suggested in 《Highway engineering design and construction technology for antifreeze》 but the final value is determined for the consideration of operability). Since normal stress in actual working area of subgrade ranges from 10 kpa to 50 kpa, gradient values of 12.5 kPa, 25 kPa, 37.5 kPa, 50 kPa, 62.5 kPa are chosen.

### 2.2 Test method

After taking both the current specification on direct shear test and actual state of soils in seasonal frozen area into consideration, quick shear test is carried out with the help of test instrument (Model SDJ-II)

manufactured by Ningxi soil instrument co., LTD in Nanjing.

1. Sample Preparing. Prepare Standard specimen with size of 10 cm × 20 cm, then Cut each specimen into 5 cylinders and modify them to proper height (the upper edge of sampler) with ring sampler coated by Vaseline.
2. Data Collection. Different rules are applied to record the data according to the condition: take the reading of dial gage when the failure happen in the early stage while write down the reading at the relative displacement of 6 mm in shear container if no failure occurred at last. Figure out the shear strength of specimen according to the calculation method in the specification.

### 2.3 Error control

A total of 50 working conditions, each containing 3 parallel specimens, are simulated with different water content, compactness and normal stress. The error between target water content and tested water content is within 1% as shown in Table 1. The error between target compactness and tested compactness is also within 1%, while error of parallel specimens is within 5%.

## 3 RESULT ANALYSIS

### 3.1 Water content

Plot the results in a figure, with the horizontal and vertical coordinates representing the water content and shear strength, and fit the trend lines (Seen in Fig. 2).

From Figure 2 conclusions can be drawn as follows: (1) At the same level of normal stress and compactness, the shear strength decreases significantly with water content increasing. (2) At the compactness of 92%, these trend lines show an inverted “S” shape (shown in Fig. 2. a) with inflection points appear near  $w = 17\%$ . The declining rate of shear strength goes down with water content decreasing where  $w < 17\%$  while it rises with water content decreasing where  $w > 17\%$ , which indicates that the sensitivity of shear strength reaches a highest value at  $w < 17\%$ . (3) At the compactness of 96%, these trend lines are similar to

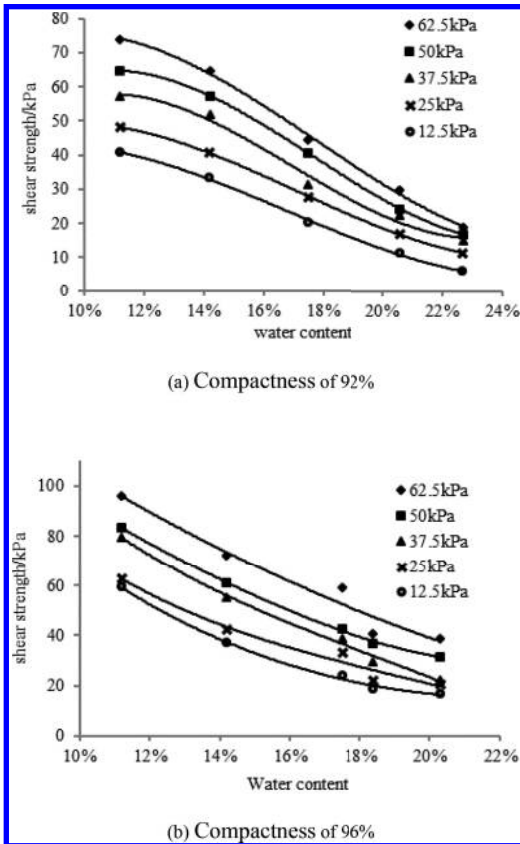

Figure 2. Shear strength vs water content at different compaction degree.

exponential function lines. The sensitivity of shear strength goes down with water content increasing and it tends to be a stable figure near  $w_{sat}$ .

### 3.2 Compactness

Compare the shear strength at different compactness while keeping the rest factors the same. The results illustrated in Figure 3 at compactness of 92% and 96%.

It can be concluded that as the shear strength rises with compactness increasing under the water content of 5. The sensitivity of shear strength towards compactness is analyzed through the way of difference comparison. The results show that: at  $w_{op}$  and  $0.85 w_{sat}$ , the shear strength is slightly affected by compactness with changes from 3~5 kPa; while at the other three water content it is obviously affected by compactness, which means the sensitivity of shear strength reach the minimum value at  $w_{op}$  and heavily increases away from  $w_{op}$ .

### 3.3 Significance analysis

Orthogonal design and variance analysis are taken in this paper to verify the significance of the following three factors: water content (A), normal stress (B) and compactness (C). The results of variance analysis are listed in Table 2.

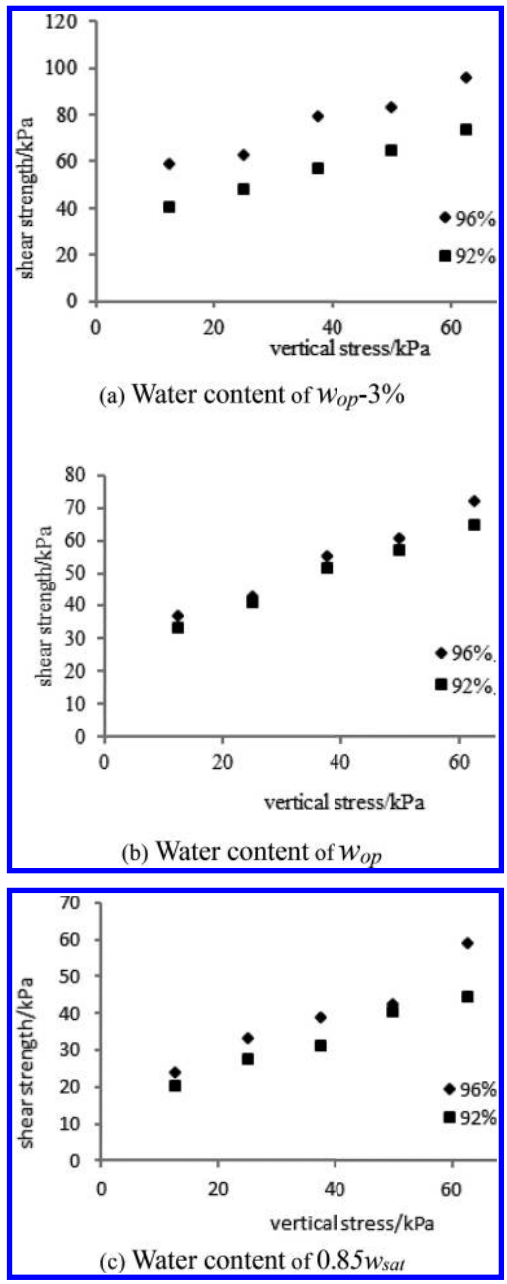

Figure 3. (Continued).

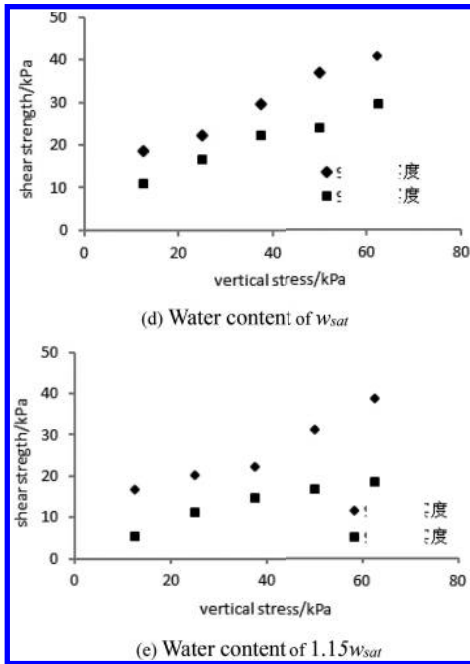

Figure 3. Shear strength vs compaction degree at different water content.

Table 2. Result of variance analysis water content see of 96%e y subgrade subgrade shear strength.

	Square	Mean			
Variance	sum	Freedom	square	F	Significance
A	1291.33	1	1291.33	672.71	**
B	410.23	1	410.23	213.71	**
A × B	20.91	1	20.91	10.89	
C	72.14	1	72.14	37.58	*
C × A	20.91	1	20.91	10.89	
Errors	3.83	2	1.92		
Sum	1830.05	7			

Seen from Table 2,  $F_{0.99}(1,2) = 98.5$ ,  $F_{0.95}(1,2) = 18.5$ . To compare with F in Table 2, when  $\alpha = 0.05$ , all of the three factor A, B, C have a significant effect on the shear strength, and the degree of influence can be ranked as below:  $A > B > C$ . However, the interaction of every two factors has no significant influence on the shear strength.

## 4 ANALYSIS ON SHEAR FAILURE

### 4.1 Humidity during spring-thawing period

The spring season frozen area of subgrade thawing period in general every year 3, April, Accord-

ing to the researches on S106 in Jilin province in April 2012, the distribution of subgrade humidity in the vertical direction is illustrated in Figure 9. Serious pavement diseases are found in positions 1 and 2.

Viewing the changes as a whole, moisture in these two points reflect the characteristics of the subgrade humidity distribution in seasonal frozen spring-thawing period: the humidity of soil is relatively high and it has even been saturated in the depth of 1.5 m~2 m due to the complex inner and outer water migration in freezing process<sup>[8]</sup>. The reasoning is also proved by the core sampling which shows that with the melt of frozen layer, water in upper and lower layers will migrate to this layer. Combining with the gravity, the subgrade humidity will remain at a high level within a period of time in the depth of 1.5 m~2 m in result to cause shear failure.

### 4.2 Stress analysis during spring-thawing period

BISAR is used to calculate the theoretical value of shear stress. Table 3 gives the parameters.

Considering about the overload in actual traffic condition and taking the standard axle load and overload (2 times the standard axle load) into account, the maximum ( $\sigma_1$ ) and minimum ( $\sigma_3$ ) principal stress can be calculated and shown in Figure 5.

Friction angle and cohesive force are obtained by direct shear test of subgrade soil under different moisture contents. Take the most unfavorable

Figure 4. Subgrade humidity distribution during Spring-thawing Period.

Table 3. Parameters for pavement structure analyses of S106.

Name	Thickness/ mm	Modulus/ MPa	Poisson ratio
Pavement	18	1200	0.3
Base	32	1600	0.3
Subgrade		30	0.35

Figure 5. Calculated value of stresses in different layers of subgrade.

situation into consideration and make regression analysis at compactness at 92%, the cohesion and friction angle of the regression equation towards the water content are obtained (1) (2):

$$c = 317.91e^{-0.186W}, R^2 = 0.9622 \quad (1)$$

$$\varphi = -1.7545W + 55.405, R^2 = 0.9562 \quad (2)$$

Take measured moisture content into these two equations to obtain  $c$ ,  $\varphi$ . Calculate the minimum principal stress by using maximum principal stress under equilibrium condition:

$$\sigma_3 = \sigma_1 \tan^2(45^\circ - \varphi/2) - 2c \tan(45^\circ - \varphi/2) \quad (3)$$

According to the formula (3), compare the calculated minimum principal stress  $\sigma_3$  and theoretical value of minimum principal stress  $\sigma_1$ , shown in Figure 6.

The shear failure only happens when the calculated value of minimum principal stress is larger than the theoretical value. The potential failure in the subgrade can then be figured out by the

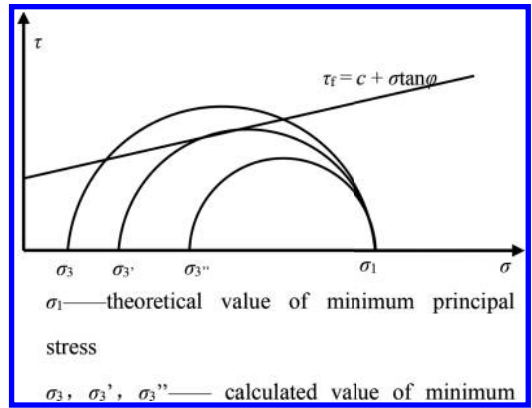

Figure 6. Checking of the limit equilibrium method.

Figure 7. Calculation of subgrade stress in different traffic loads.

checking calculation for each layer, shown in Figure 7.

From Figure 7 it can be known that: (1) under the condition of standard axle loads, the minimum principal stress value of these two points are both less than the theoretical value, which means shear

failure will not occur in all of the layer in subgrade. However, there is still a potential shear failure in the depth of 2 m–2.5 m with the melt of frozen layer. (2) under the condition of overloads, the minimum principal stress value at point 1 is larger than the theoretical value and will lead to shear failure. Besides, with the melt of frozen layer in the depth of 1.5 m–2 m, the value of  $c$  and  $\phi$  may continue to decrease with the increasing water content and broken layer will move toward the final melting layers.

## 5 CONCLUSION

1. The three main factors affecting the shear strength of subgrade are water content, compactness and normal stress of soil. Besides, the water content has a maximum influence while compactness has a minimum one.
2. Based on the analysis of shear stress in the subgrade, the most unfavorable layer for shear failure is near the melted layer and has a close connection with frozen depth during frost heaving period. The checking calculations also show that there is a possible shear failure in a large range under overload situation.

# The study progress of performance reliability of rolling bearings for urban rail

X.T. Xia, S.J. Dong, W.H. Zhu & Y.Y. Meng

*Henan University of Science and Technology, Luoyang, P.R. China*

**ABSTRACT:** With the rapid development of urban rail and traffic engineering, growing attention has been paid to the study of the performance and reliability of rolling bearings to ensure safe and reliable operation of urban rail. In most cases, the reliability distribution functions are usually a puzzle or the parameters in a known distribution function are unknown. Therefore, the performance reliability prediction and evaluation have become a key problem urgently to be solved for urban vehicles. For this end, the grey bootstrap forecasting method for the reliability of zero-failure data with poor information, the bootstrap chaotic forecasting method for the lifetime and reliability, the bootstrap weighted-norm method and dynamic bayesian significant test method of rolling bearings are summarized in this paper.

*Keywords:* subway vehicles; rolling bearing; poor information; reliability

## 1 INTRODUCTION

In order to predict different kinds of rolling bearing faults of subway vehicles, methods of fault prediction methodology based on poor information are put forward. The fault prediction method has high application value in the subway operation process. As the key component of high speed subway vehicles, the performance and reliability of rolling bearing is well worth studying for the regular running and safety [1–2]. Therefore, it is very significant for urban rail and traffic engineering to study on the performance reliability of rolling bearings.

Poor information means incomplete information, such as in system analysis, a known probability distribution with a small sample, an unknown probability distribution with only a few data, trends without any priori information, etc. The introduction of information-poor system theory to the assessment of performance and reliability of modern bearings will greatly prompt the development of the design theory of rolling bearings and relevant subjects [3–5].

So far, researches on the prediction and evaluation of the performance and reliability of rolling bearings along with poor information have made some progress. This paper mainly reviewed the prediction of the reliability of zero-failure data and that of the reliability variation process along with performance data, and the reliability evaluation with failure data under a given distribution.

## 2 RESEARCHES ON PERFORMANCE RELIABILITY OF ROLLING BEARING BASED ON POOR INFORMATION

### 2.1 *Forecasting methods for lifetime and reliability of rolling bearings along with the performance data*

A forecasting method for lifetime and reliability of bearing products along with the performance data, viz. bootstrap chaotic forecasting method is proposed by Xia [6], which fuses the principle of bootstrap method and five chaotic predicting methods. And the five chaotic methods are the adding-weight zero-rank local-region method, the adding-weight one-rank local-region method, the one-rank local-region method, the improved adding-weight one-rank local-region method and the maximum Lyapunov exponent method. It only depends on current operational information of the obtained product performances, without any prior information of performance variation over time and any prior information of the performance life probability distribution function.

The predicting procedures of the method are summarized as follows:

1. Set an evaluating indicator of the rolling bearing performance during the bearing running or testing.
2. Obtain a time series of the product performance through a measurement system, thus the time series of the current operation information are formed.

3. Apply phase space reconstruction to the time series of the current operation information, then many space points are acquired.
4. Five time series of the future operation information of the rolling bearing are predicted by the five chaotic forecasting methods.
5. Work out the five runtime data which reach the evaluating indicators by use of the five time series of the future operation information.
6. Obtain a large amount of generated data by an equiprobable resampling with replacement from the five runtime data.
7. Deduce the runtime probability density function, and then establish the estimated runtime reliability function with the performance data, finally finish the prediction of the reliability of the rolling bearing performance variation process with poor information.

### 2.2 Reliability evaluation of zero-failure data with poor information

Fusing the advantages of the bootstrap method [7] and the grey prediction GM(1,1) [8], along with an empirical failure probability function, Xia has proposed the grey bootstrap forecasting method for the reliability of zero-failure data, which is not only suitable for rolling bearings but also applicable to the reliability analysis of other products.

The specific steps of the method are described as follows: During the lifetime experiment or the service period of a product, detect the zero-failure time of individuals and the number of these data, thus obtaining the zero-failure data of product individuals; Obtain a large amount of generated data by an equiprobable resampling with replacement from the zero-failure data collected; Predict a mass of zero-failure data of the population with the generated data, thus obtaining the distribution function of the zero-failure data of the population; Construct the failure probability function of the population via the number of the zero-failure data of individuals and the distribution function of the zero-failure data of the population; Get the reliability function of the population with the population failure probability function, thus completing the evaluation of the product lifetime and reliability with zero-failure data.

A new calculation model of reliability with zero-failure data is proposed by Xia. Let the reliability coefficient be  $c$ , and then construct  $P$ , the failure probability function of the population, in the light of  $m$ , the number of the zero-failure data of product individuals, and  $F$ , the distribution function of the zero-failure data of the population.

$$P = P(x) = \frac{c}{m(1-F) + 1} \quad (1)$$

$R$ , the reliability function of the population is obtained by the failure probability function of the population as follows:

$$R = R(x) = 1 - p \quad (2)$$

In this method, it is worth noticing that the selections of parameters  $m$  and  $c$  in Eq. (1) are vital to the calculated result of reliability  $R$  in Eq. (2). The grey prediction GM(1,1) in the grey system theory and the bootstrap method require the minimum value of  $m$  to be 4, which can help to improve the reliability of the prediction.  $c$  is an empirical reliability coefficient, which has an impact on the calculated results of  $R$ . An example is taken to illustrate the effect of  $c$ , and the results are as shown in Figure 1. It can be seen that reliability  $R$  decreases as coefficient  $c$  increases. Therefore, we have to select the values of  $m$  and  $c$  reasonably according to the engineering practices.

### 2.3 The reliability calculation of given distribution

The bootstrap weighted-norm method is proposed by Xia [9], which Fusing the principle of the bootstrap method and the norm criterions, to evaluate of the optimal confidential interval of the reliability with three-parameter Weibull distribution.

The specific steps of the method are described as follows:

1. Based on the difference between empirical value and theoretical value of reliability, and six norm criterions, the optimal parameters information vector of Weibull distribution are constructed.
2. The generated parameters information vector is obtained by the bootstrap resampling from the optimal parameters information vector.
3. The probability density function of parameters is simulated by the generated parameters information vector.

Figure 1. Relation of reliability  $R$  with empirical reliability coefficient  $c$ .

- Under the given confidence level, the estimated true value of parameters and their confidence intervals are figured out, and thus the estimated true value function of reliability and its optimal confidence interval function are established.

In the method the reason why six different norm criterions (minimum 1-norm criterion, minimum 2-norm criterion, the minimum—norm criterion, minimum weighted 1-norm criterion, minimum weighted 2-norm criterion and minimum weighted—norm criterion) are employed to estimate the parameters is that the useful information of different sides can be revealed by different criterions. Different side information can reflect different properties of parameters, therefore, the more the criterions are, the more comprehensive the parameters properties gained can be, which is conducive to the establishment of the parameter probability density function and the accurate estimation of reliability parameters, and finally to achieving the accurate evaluation of reliability.

### 3 STUDIES ON HYPOTHESIS TESTING AND IDENTIFICATION METHOD OF POOR INFORMATION PROCESS OF ROLLING BEARING PERFORMANCE

#### 3.1 *Dynamic bayesian significant test method for performance variation information of rolling bearing*

Based on maximum entropy principle and self-help method, dynamic bayesian significance test method is put forward, which can be used to solve the problem of performance variation information of rolling bearing under the condition of unknown priori information of probability distribution and trend priori knowledge. Period of time series of rolling bearing performances is obtained by regular sampling. The time origin moments can be obtained by bootstrap method and the time probability density function can be established through principle of maximum entropy. Based on the reference time series, the posteriori probability density function is established and coincidence degree is defined. Under a given significance level, the dynamic Bayesian significance test of the performance variation information of rolling bearing is carried out with the aid of coincidence degree. The experimental results show that the dynamic Bayesian significance test method can effectively test the performance variation information of rolling bearing under unknown probability distribution and trend of prior information.

#### 3.2 *Case study and discussions*

Taking vibration variation of rolling bearing caused by wear as an example. The experimental data of

vibration acceleration (unit:  $m/s^2$ ) are studied to test the wear process of bearing. Every five days for one times to get the data and a total of 10 days of data is obtained. The daily first 4000 data are selected as the research object, so each bearing has 40000 original vibration data during the whole experiment process (a total of 10 time units, each time unit has 4000 data). As shown in [Figure 2](#) and [Figure 3](#).

From [Figure 2](#) and [Figure 3](#), it can be seen that in the dynamic measurement of rolling bearing vibration, some fluctuation and variation is very complex and the probability distribution and trend are unascertained.

Bootstrap method is used for 10 data segment in the first time unit, that is to say each segment of 400 data and 500000 times bootstrap samplings are conducted respectively. Then in combination with bayesian statistics, the posterior probability density function of the prior sample is constructed and mathematical expectation and variance can be calculated, which decides to choose in which period of prior information as the prior sample. The results as shown in [Table 1](#).

From [Table 1](#), the fourth segment data in the first time unit is selected as reference time series, because of its minimal variance. 500000 times bootstrap samplings proceed by using bootstrap method on other 9 time units (a total of 90 data segment). Through bayesian statistics, the posterior probability density function is constructed and mathematical expectation, variance ratio and coincidence degree can be calculated. As shown in [Figure 4–6](#).

It can be seen the wear process and vibration performance variation process as follows. The initial

Figure 2. Vibration experimental data of rolling bearing (the first 5 days).

Figure 3. Vibration experimental data of rolling bearing (the last 5 days).

wear increases gradually and the vibration performance variation is progressively significant; vibration performance variation of the transition from initial wear to normal wear is not significant; vibration performance variation is not significant from the normal wear. The above analysis shows that the proposed method can accurately test the significance in the process of rolling bearing performance variation.

Table 1. Selection of reference time series.

## 4 CONCLUSIONS

The bootstrap chaotic forecasting method for the reliability along with performance data, the grey bootstrap forecasting method for the reliability of zero-failure data and the bootstrap weighted-norm method for the reliability of rolling bearing performance lifetime with failure data summarized in this paper are able to well forecast and evaluate the performance reliability of rolling bearings with poor information. Bayesian significant test method will help us detect early the hidden danger of degradation and failure of the product performance. During the rolling bearing performance experiment or its operating period, these methods can help to achieve the real-time prediction and evaluation for information of lifetime and reliability of rolling bearing performances, and detect the performance degradation and failure risks in time, thus avoiding the occurrences of serious accidents for urban vehicles.

## Aircraft taxiing trajectories partly update approach for A-SMGCS

Xinping Zhu, Zhixing Tang & Zhenghong Xia

College of Air Traffic Management, Civil Aviation Flight University of China, Guanghan, China

**ABSTRACT:** For airport surface operation under the control of A-SMGCS (Advanced Surface Movement Guidance and Control System), an approach on aircraft taxiing trajectories update is proposed to tackle the efficiency and safety degrades caused by surface uncertain events. Firstly, partly taxiing trajectories update strategy is adopted and Time Window Constrained Petri Net (TWCPN) is used to model local surface operation process affected by uncertain events. Secondly, time window computation rules for TWCPN model are provided to get the simplified local sub-model, also aircrafts taxi conflict conditions are derived from the sub-model. Thirdly, aircrafts taxiing trajectories update is fulfilled with the purpose of minimizing taxi cost. Finally, the proposed taxi trajectories update approach is validated through case study.

**Keywords:** air traffic control; airport; taxiing trajectories; A-SMGCS

### 1 INTRODUCTION

Advanced Surface Movement Guidance and Control System (A-SMGCS) is the most advanced airport surface control system in the world<sup>[1]</sup>. 4-Dimensional aircraft trajectory based operation is one of basic concepts in A-SMGCS, which incorporates algorithms to generate aircraft taxiing trajectories, including a series of well-spaced target points and the required time of arrival. However, surface uncertain events could bring disturbance for aircraft taxiing and lead to conformance error<sup>[2]</sup>.

Traditionally, taxi conformance and trajectories update mainly depends on air traffic controller's eye inspection and VHF talk, which can not handle large traffic volume. Past research provide taxiing trajectories at every designed period of time<sup>[3-6]</sup>. It is possible for updating taxiing trajectories in real time with information from A-SMGCS surveillance module<sup>[7-10]</sup>. Wang proposed taxiing trajectories update for airport surface operation, however, the conformance monitor and taxiing trajectories update are not integrated in a proper mechanism. TANG provided a three-stage aircraft taxiing trajectories scheduling strategy, including initial taxiing trajectories planning, taxiing trajectories assignment and update<sup>[11]</sup>. In stage of initial taxiing trajectories planning, trajectories are provided for arrival and departure flight once flight plans are transmitted to A-SMGCS. In stage of taxiing trajectories assignment, trajectories are provided before aircrafts taxi. In stage of taxiing trajectories update, trajectories are provided once conformance errors are detected. Past research is mainly

focus on the first two stages<sup>[12]</sup>. In this paper, we mainly report our research on the third stage about taxiing trajectories update.

### 2 PROBLEM DESCRIPTION

The transportation system of airport surface is divided into typical operation units, such as taxiway intersection units and line segment units. According to 4-Dimensional aircraft trajectory based operation concept, aircraft occupy units in a specified time window deriving from taxiing trajectories. However, the disturbance introducing by

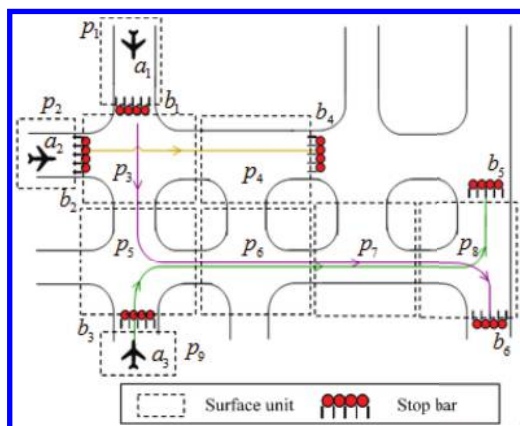

Figure 1. Aircraft taxiing process on part of airport surface.

surface uncertain events from pilots manipulation or taxiway condition could lead to conformance error or even surface conflict.

For surface demonstrated in Figure 1, assume aircraft  $a_1, a_2, a_3$  taxi through unit  $(p_3, p_5, p_6, p_7, p_8), (p_3, p_4), (p_5, p_6, p_7, p_8)$ , respectively. For taxiing process of  $a_1$  on taxiing trajectories segment, which include  $p_3, p_5, p_6, p_7$  and  $p_8$ , can not be stopped by stop bar lights (the segment is called continuous taxiing segment in this paper). Thus, when  $a_1$  has to be postponed to occupy unit  $p_1$  caused by some reasons, it will lead to conflict among flights occupy the same unit in future, such as  $a_1$  and  $a_2$  in  $p_1$ , or  $a_1$  and  $a_3$  in one of the unit  $p_5, p_6, p_7$ , and  $p_8$ . Considering surface operation safety and efficiency, aircraft taxiing process needs to be monitored and taxiing trajectories update need to be conducted in real time. Usually, A-SMGCS is implemented in large and busy airport, it is impossible to fulfill aircraft taxiing trajectories update without precise mathematical mode and algorithm. We provide approach for it.

### 3 AIRCRAFT TAXIING TRAJECTORIES UPDATE MECHANISM DESIGN

In past, aircraft taxiing trajectories update is investigated through Operational Research (OR) model of airport surface in an up-down methodology. However, this kind of model can not be resolved in real time for its complexity. We propose taxiing trajectories update mechanism, in which the optimization and feed-back are integrated. And also, the monitored surface uncertain events are the main driver of aircrafts taxiing trajectories update.

Basically, two kinds of events will bring to the update of aircraft taxiing trajectories. One is the ending of aircraft occupy taxiway unit. The other is the disturbance occurring as a result of uncertain events. The update process caused by the

former is called routine taxiing trajectories update and the latter is called non-routine taxiing trajectories update. A-SMGCS taxiing trajectories update mechanism is provided as described in Figure 2, which include aircraft taxiing process module needed to be guided and controlled by pilots and navigation aids on surface, affected by outer conditions and aircraft performance; aircraft taxiing state monitor module and the local surface operation modeling module which depict the surface operation process in a mathematical method; algorithms for the routine and non-routine taxiing trajectories update. The new taxiing trajectories are transmitted to aircrafts on surface, until the next update event occurring.

### 4 LOCAL SURFACE OPERATION PROCESS MODELLING

Definition 1 Time window constrained Petri net (TWCPN) model for surface operation is a structure

$$TWCPN = \{P, T, I, O, M_0, \delta\}$$

$P = \{p_1, p_2, \dots, p_n\}$  is finite set of place;

$T = T_1 \cup T_2$  is finite set of transition;  $T_1$  represents block transitions “|” which describe aircraft movements that can be stopped by stop bar;  $T_2$  represents line transitions “|” which describe aircraft movements that can not be stopped by stop bar;

$I(O)$  is the input (output) function of TWCPN;

$M_0$  is the initial discrete marking of TWCPN;

$\delta: P \rightarrow W$  specifies the time window associated to places, which is derived from aircraft taxiing trajectories, representing aircraft taxiing plan on surface.

For taxiing process of aircraft  $a$ , current continuous taxiing segment is denoted by  $r_a$ , the remaining taxiing segment of aircraft  $a$  is denoted by  $l_a$ , and the next continuous taxiing segment is denoted by  $r_a^*$ .

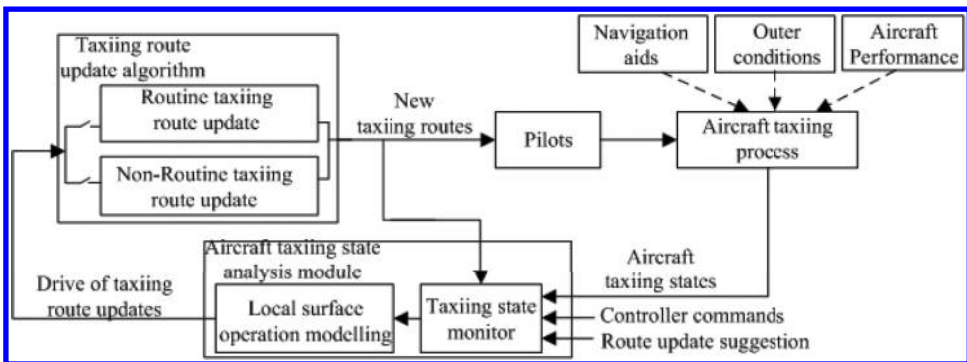

Figure 2. Aircraft taxiing trajectories update mechanism for A-SMGCS.

If there exist same unit in continuous taxiing segment of different aircrafts, the segment is called correlated segment. The generation rules of a local surface sub-model from TWCPN are as follows:

Rule 1:

$$P' = P'_a \cup P''_a \cup P'''_a,$$

$$P'_a = P(l_a) \cup P(r_a^*); P''_a = P(l_j),$$

$$l_j \in F(l_a) \cup F(r_a^*);$$

$$P'''_a = P(l_i), l_i \in F^*(l_j);$$

$$\forall p \in P', M'(p) = M(p);$$

Rule 2:

$$T' = \{t \mid t \in p^{(l)} \cap T, p \in P'_a\},$$

$$T = T_1 \cup T_2;$$

Rule 3:  $I'(p,t) = I(p,t)$ ,  $O'(p,t) = O(p,t)$

Rule 4:  $\Psi'(p) = \Psi(p)$

According to Rule 1, places of the remaining taxiing segment, of the next taxiing segment, of the correlated segment, ones in the last taxiing segment are constituted into places in local surface sub-model, and the markings of sub-model are the same as TWCPN; According to Rule 2, the output transitions of places determined by Rule 1 are constituted into transitions in local sub-model; According to Rule 3, the input and output function of local sub-model is the same as the origin function of TWCPN; According to Rule 4, current taxiing trajectories of aircraft remaining as before in TWCPN.

Example 1: The operation scenario for part of taxiway system is demonstrated in Figure 1. Assume taxiing trajectories of aircraft  $a_1$  is  $r_1(1,6) = t_1^1 t_2^1 t_3^1 t_4^1 t_5^1 t_6^1 \dots$ , and it is postponed to occupy current unit, thus the local sub-model of aircraft  $a_1$  can be established by rules proposed above.

Firstly, for current taxiing segment ( $r_1$ ) of aircraft  $a_1$ , unit represented by Place  $p_1$  is one of the units in its remaining taxiing segment  $l_1$  in  $r_1$ ; Place  $p_3, p_5, p_6, p_7, p_8$  are units of the next continuous taxiing segment  $l_1^*$  of aircraft  $a_1$ ; According to Rule 1, we get  $P'_1 = P(l_1) \cup P(l_1^*) = \{p_1, p_3, p_5, p_6, p_7, p_8\}$ . Secondly, for  $l_1$  and correlated segments of  $l_1^*$  which is denoted by  $F(l_1^*) = \{l_2, l_3\}$ , units represented by Place  $p_3$  and  $p_5$  are of the units in segment of  $l_2$ , units represented by Place  $p_5, p_6, p_7, p_8$  are of the units in segment of  $l_3$ . Thus, we get  $P''_1 = P(l_2) \cup P(l_3) = \{p_3, p_4, p_5, p_6, p_7, p_8\}$ . Thirdly, Place  $p_2$  (or  $p_5$ ) is one of units for previous continuous taxiing segment of aircraft  $a_2$  (or  $a_3$ ). Finally, transitions, time window for place can be determined by Rule 2~4. The local sub-model for aircraft  $a_1$  is demonstrated in Figure 3.

Figure 3. Sub-model of aircraft  $a_1$  in Figure 1.

## 5 AIRCRAFT TAXI CONFLICT PREDICTION ON LOCAL PART OF SURFACE

Definition 2 Currently Correlated Areas ( $CCA$ ) is segment which is related to the current continuous taxiing segment of one aircraft, and places in the corresponding local sub-model are denoted by

$$CCA = \{p \mid p \in P(l_a) \cup P(l_i), l_i \in F(l_a)\};$$

Next Correlated Area ( $NCA$ ) is segment which is related to the next continuous taxiing segment, and places in the corresponding sub-model can be denoted by

$$NCA = \{p \mid p \in P(r_a^*) \cup P(l_j), l_j \in F(r_a^*)\}.$$

Definition 3 Transition  $t \in T_1$  which meets condition  $t^{(p)} \subseteq CCA$  (or  $t^{(p)} \subseteq NCA$ ) is defined as the input transition of current correlated area (or the next correlated area).

Definition 4 Time window for aircraft occupying taxiing unit is represented as  $w_a^p = \{p, [t_a^i, t_a^o]\}$ . Of which,  $t_a^i$  is the time for aircraft  $a$  entering unit  $p$  (taxiway intersection or line segment);  $t_a^o$  is the time for aircraft  $a$  leaving unit  $p$ .

If units corresponding to place  $p_i, p_j \in CCA$  (or  $p_i, p_j \in NCA$ ) will be occupied by aircrafts at the same time, there exists taxi conflict among aircrafts. In order to analyze the conflict, we propose computation rule denoted by ad.

For time window  $w_1 = \{p_1, [\tau_1, \tau_2]\}$ ,  $w_2 = \{p_2, [\tau_3, \tau_4]\}$ , the ad computation can be fulfilled in following rules:

Rule 1:  $ad(w_1, w_2) = \{H, [\tau_1, \tau_4]\}$ , of which,  $H = \{p_1, p_2\}$ ,  $\tau_1 \leq \tau_3 \leq \tau_2$ ;

Rule 2:  $ad(w_1, w_2) = \{H, [\tau_1, \tau_2] \cup [\tau_3, \tau_4]\}$ , of which,  $H = \{p_1, p_2\}$ ,  $\tau_2 < \tau_3$ .

## 6 AIRCRAFT TAXIING TRAJECTORIES UPDATE

The local sub-model for aircraft  $a$  can be simplified using above rules, and the derived simplified model is demonstrated in Figure 4.

For continuous taxiing segments of aircraft  $a$  in local sub-model, Place sets in the resulted simplified model in Figure 4 is denoted by  $H_a$  and  $H'_a$ . For clearly, we call it model  $a$ . Similarly, for aircrafts  $a_1, a_2, \dots, a_m$  ( $a_n, \dots, a_k$ ), their continuous taxiing segments in local sub-model can be simplified, and we call them model  $a_1, a_2, \dots, a_m$  ( $a_n, \dots, a_k$ ), respectively.

Surface units corresponding to Place sets  $H_a, H_i$  ( $i=1,2,\dots,m$ ) are formed into current correlated area. Surface units corresponding to Place sets  $H'_a, H_j$  ( $j=n, n+1, \dots, k$ ), are formed into next correlated area. If aircraft  $a$  entering the taxiing segment is delayed  $\Delta\tau$  by some reasons, the conflict judgment conditions for local part of surface operation are as following:

Condition 1: condition for conflict in CCA

If aircraft  $a$  entering taxi segment corresponding to model  $H_a$  at  $\tau_0$ , aircraft  $a_1, a_2, \dots, a_m$  entering taxi segment corresponding to  $H_i$  at  $\tau_i$ , there exists conflict in CCA between aircraft  $a$  and  $a_i$  using following conditions:

- ①  $H_i \cap H_a \neq \Phi$ ;
- ②  $[\tau_0, \tau_0 + |w_a| + \Delta\tau] \cap [\tau_i, \tau_i + |w_i|] \neq \Phi$ , of which,  $|w_i|$  represents duration of time window  $w_i, i=1, 2, \dots, m$ .

Condition 2: condition for conflict in NCA

If aircraft  $a$  entering taxi segment corresponding to model  $H'_a$  at  $\tau'_0 = \tau_0 + |w_a| + \Delta\tau$ , aircraft  $a_n, \dots, a_k$  entering segment corresponding to  $H_j$  at  $\tau_j$ , there exists conflict in local correlated area for aircraft  $a$  and  $a_i$  using following conditions:

- ①  $H_j \cap H'_a \neq \Phi$ ;
- ②  $[\tau'_0, \tau'_0 + |w'_a|] \cap [\tau_j, \tau_j + |w_j|] \neq \Phi$ , of which,  $|w_j|$  represents the duration of time window  $w_j, j=n, n+1, \dots, k$ .

Figure 4. Simplified model for local sub-model of aircraft  $a$ .

In local sub-model corresponding to part of surface, the taxiing trajectories set is denoted by  $W_o$ . For correlated areas where exists taxi conflict, the input transition of its sub-model can be used to generate sequence  $\varepsilon$  and formed into set  $X$ .

The generation rules of sequence  $\varepsilon$  are as follows: ① transition enabled by token represented VIP flight shall be arranged in priority; ② transition enabled by token represented arrival flight shall be arranged in priority.

The taxiing cost for flights which will occupy the correlated are is set as optimization target:

$$\min_{\varepsilon \in X} f(\varepsilon, \Delta\tau, W_o)$$

The computation method is as follows:

Firstly, for transition sequence  $\varepsilon = t_1 t_2 \dots t_n$ , the firing time  $\beta_i$  ( $i=1, 2, \dots, n$ ) can be determined according to taxiing trajectories  $W_o$  in this local area; If the flight denoted by token which enabling the transition  $t_1$  meet some uncertain events, the firing time  $\beta_1$  can be adjusted by adding  $\Delta\tau$ .

And then, time for aircrafts occupy correlated areas can be computed by following steps:

- ① Time for aircraft leave the correlated area can be determined by  $\tau_i = \beta_i + \mu_i$ , of which,  $\beta_i$  is the time for transition firing,  $\mu_i$  is the duration aircraft occupying the area.
- ② For transition  $t_i$  ( $i=2, 3, \dots, n$ ) in sequence  $\varepsilon$ , we can determine its firing time by  $\beta'_i = \max\{\tau_{i-1}, \beta_i\}$  and duration  $\mu_i$  for aircraft occupy this correlated area. And also, time of aircraft leaving this correlated area can be determined by  $\tau_i = \beta'_i + \mu_i$

Finally, the taxiing cost for aircrafts can be determined by

$$f(\varepsilon, \Delta\tau, W_o) = f_1 + f_2$$

In which, taxiing cost of aircraft taxiing through the correlated area is

$$f_1 = \sum_i \mu_i \times c_i$$

$c_i$  is aircraft taxi cost in unit time.

Taxiing delayed cost of aircraft before entering this correlated area

$$f_2 = \sum_i p_d \times \max\{\tau_i - \beta_{i+1}, 0\}$$

$p_d$  is aircraft taxi delay cost in unit time.

## 7 CASE STUDY

Aircraft taxiing trajectories update in Figure 1 is analyzed, considering one of aircrafts is delayed. The assigned taxiing trajectories for aircraft  $a_1, a_2, a_3$  are listed in Table 1, and the taxiing priority of  $a_1$  is higher than  $a_2$  and  $a_3$ .

Take the operation data of A320 as an example, the taxi cost of unit time  $c_t = 84$  Yuan/min, and delayed cost of unit time  $p_d = 178$  Yuan/min. If aircraft  $a_1$  is postponed to occupy unit  $p_1$  by 50 seconds detected from surveillance module in A-SMGCS, the time occupying next segment will also be delayed 50 seconds. The local surface area affected by delay of aircraft  $a_1$  is analyzed and taxiing trajectories of aircraft through this area can be updated in the following steps:

Firstly, the local surface operation sub-model when aircraft  $a_1$  is delayed can be represented in Figure 3.

Then, the sub-model can be fatherly simplified by analyzing aircrafts in this local surface, and the resulted model is demonstrated in Figure 5.

$$w'_{a1} = \{H'_{a1}, [\tau'_1, \tau''_1]\},$$

$$H'_{a1} = \{p_3, p_5, p_6, p_7, p_8\},$$

$$\tau'_1 = 9:37:50, \tau''_1 = 9:38:50;$$

$$w_{a2} = \{H_{a2}, [\tau'_2, \tau''_2]\},$$

$$H_{a2} = \{p_3, p_4\}, \tau'_2 = 9:38:12,$$

$$\tau''_2 = 9:38:32;$$

$$w_{a3} = \{H_{a3}, [\tau'_3, \tau''_3]\},$$

$$H_{a3} = \{p_5, p_6, p_7, p_8\},$$

$$\tau'_3 = 9:38:40, \tau''_3 = 9:39:30.$$

Operation units corresponding to Place sets  $H'_{a1}, H_{a2}, H_{a3}$  are formed into the next correlated area. According to conflict judgment conditions  $H'_{a1} \cap H_{a2} \neq \Phi$  and  $[\tau'_1, \tau''_1] \cap [\tau'_2, \tau''_2] \neq \Phi$ , there exists conflict in this area between aircraft  $a_1$  and  $a_2$ . Similarly, there exists conflict between aircraft  $a_1$  and  $a_3$  in this area.

Finally, taxiing trajectories can be updated for aircrafts in this area using method proposed in

Table 1. Time window for aircrafts taxiing trajectories in Figure 1.

Aircraft	Time window for each unit of taxiing route
$a_1$	$\rightarrow \{p1, [9:36:50,9:37:00]\} \rightarrow \{p3, [9:37:00,9:37:10]\} \rightarrow \{p5, [9:37:10,9:37:25]\} \rightarrow$ $\{p6, [9:37:25,9:37:35]\} \rightarrow \{p7, [9:37:35,9:37:45]\} \rightarrow \{p8, [9:37:45,9:38:00]\} \rightarrow$
$a_2$	$\rightarrow \{p2, [9:38:02,9:38:12]\} \rightarrow \{p3, [9:38:12,9:38:22]\} \rightarrow \{p4, [9:38:22,9:38:32]\} \rightarrow$
$a_3$	$\rightarrow \{p9, [9:38:30,9:38:40]\} \rightarrow \{p5, [9:38:40,9:38:55]\} \rightarrow \{p6, [9:38:55,9:39:05]\} \rightarrow$ $\{p7, [9:39:05,9:39:15]\} \rightarrow \{p8, [9:39:15,9:39:30]\} \rightarrow$

Figure 5. Taxiing model for aircrafts in Figure 3 and its simplified model.

Table 2. Updated time window of taxiing trajectories for aircrafts.

Aircraft	Updated time window for each unit of taxiing route
$a_1$	$\rightarrow \{p1, [9:37:40,9:37:50]\} \rightarrow \{p3, [9:37:50,9:38:00]\} \rightarrow \{p5, [9:38:00,9:38:15]\} \rightarrow$ $\{p6, [9:38:15,9:38:25]\} \rightarrow \{p7, [9:38:25,9:38:35]\} \rightarrow \{p8, [9:38:35,9:38:50]\} \rightarrow$
$a_2$	$\rightarrow \{p2, [9:38:02,9:38:50]\} \rightarrow \{p3, [9:38:50,9:39:00]\} \rightarrow \{p4, [9:39:00,9:39:10]\} \rightarrow$
$a_3$	$\rightarrow \{p9, [9:38:30,9:39:10]\} \rightarrow \{p5, [9:39:10,9:39:25]\} \rightarrow \{p6, [9:39:25,9:39:35]\} \rightarrow$ $\{p7, [9:39:35,9:39:45]\} \rightarrow \{p8, [9:39:45,9:40:00]\} \rightarrow$

this paper. The firing sequence for input transition of next correlated area can be determined as  $X = \{< t_1^1, t_2^1, t_3^1 >, < t_1^1, t_3^1, t_2^1 >\}$  according to taxiing priority relation among aircrafts. For transition sequence  $< t_1^1, t_2^1, t_3^1 >$ , when aircraft taxi through the correlated area, the following results can be reached: taxiing time for aircraft  $a_1$  is 60 s ( $u_1 = 60$  s), and the delayed time is 0 second; taxiing time for aircraft  $a_2$  is 20 s ( $u_2 = 20$  s), and the delayed time is 38 s; taxiing time for aircraft  $a_3$  is 50 s ( $u_3 = 50$  s), and the delayed time is 30 s; Taxiing cost for aircrafts through this local surface  $f_1 = 182$  yuan, while taxiing delay cost for aircrafts through this local surface  $f_2 = 201$  yuan; and the overall taxiing cost is 383 yuan.

Similarly, for sequence  $< t_1^1, t_3^1, t_2^1 >$ , the overall taxiing cost is 472 yuan.

Thus, by comparison, aircraft  $a_1, a_2, a_3$  should taxiing through the area according to the arrangement corresponding to sequence  $< t_1^1, t_2^1, t_3^1 >$ , updated taxiing trajectories are demonstrated in Table 2.

## 8 CONCLUSION

Aircraft taxiing trajectories update approach is proposed for surface operation under the control of A-SMGCS. The trajectories update is driven by real time information from surveillance module of A-SMGCS, combining optimization and feedback mechanism; Rules generating local sub-model from TWCPN model are provided, and conflict judgment conditions are proposed for aircrafts on surface corresponding to the sub-model. Taxiing trajectories update is fulfilled with the minimization of overall taxiing cost of aircrafts on the corresponding local surface.

For 4D trajectory based surface operation under the control of A-SMGCS, the taxiing conformance monitor and taxiing trajectories update method for aircrafts on entire surface need to be investigated in future.

# Performance analysis of prestressed concrete T-beam structure after fire

Qi-feng Wang

Research Institute of Highway Ministry of Transport, Haidian District, Beijing, China

**ABSTRACT:** Combined with an engineering example of prestressed concrete T-beam, and based on the parameters investigated, such as appearance characteristics of the T-beam, compressive strength of concrete and fire temperature, structure section loss, reduction parameters of concrete and reinforcement mechanics performance are presumed. Moreover, through current state structural analysis, the structural performance of this prestressed concrete T-beam bridge is evaluated. Then some maintenance suggestions and construction methods are presented, which could provide important reference for rapid evaluation of mechanical behavior and maintenance and strengthening of the same type of bridges after fire.

**Keywords:** after fire; prestressed concrete; T-beam; mechanical performance

## 1 INTRODUCTION

In recent years, the bridges damaged due to the fire happened frequently in China. The mechanical properties of the structure were damaged under different degrees; at the same time, it caused huge economic loss. Usually, the mechanical properties of prestressed concrete structure material will change due to the physical and chemical changes in concrete and reinforcement caused by fire. As a result, significant change will happen in the mechanical behavior of structure [1]. After the fire, fire sprinklers are often used. However, the high temperature of concrete and reinforcement suffer from fire cooled sharply by the water which will result in large areas of concrete stripping, spalling, and bare bar phenomenon [2]. There may even be cracks distributed along the reinforcement. According to the relevant research results, the methods used in evaluation of the performance of prestressed concrete structure after fire can be load test [3], theoretical calculation analysis [4], or calculation, and an analysis can be adopted based on detection and load test [5]. Combined with an engineering example of prestressed concrete T-beam, an effective way of rapid evaluation through calculation and analysis is provided in this paper, which is based on the investigation of section loss, the test of compressive strength test, the presumption of fire temperature, and the calculation of reduction parameters.

## 2 PROJECT OVERVIEW

A combination of bridge span is 27.3 m + 10 × 33.0 m + 33.0 m, total length is 390.4 m, full width

is 16.8 m, the upper structure is prestressed concrete T-beam, and the clearance is about 4 m. The T-beam suffered from fire for about 2 hours due to the flammable construction (wood) materials piled under side span; therefore, the end of T-beam was badly damaged. In order to evaluate the effect of fire on the structure mechanics performance and determine maintenance method rapidly and accurately, the investigation of section loss, the test of concrete compressive strength, and presumption of fire temperature were carried out, and the analysis of structure performance was provided based on the reduction parameters.

## 3 FIRE SITUATION INTRODUCTION

The fire lasted about 110 minutes due to the wooden building materials temporarily stacked under the bridge. To get the fire under control, fire hoses sprayed water on the surface of T-beam. The strip and flake of concrete appeared immediately after spraying water on the surface area of T-beam.

## 4 INVESTIGATIONS OF APPEARANCE CHARACTERISTICS

The fire covered 22 pieces of T-beam, including 17 pieces of which local area color changed obviously and the rest were all blackened, moreover, 15 pieces of which web and flange plate local area concrete presented serious phenomenon of stripping and bare bar. The typical damage situation of T-beam suffered from is shown in the [Figure 1](#).

Figure 1. The typical damage situation of T-beam.

Table 1. The compressive strength.

Core sample	Compressive strength /MPa		Design strength
	1#	2#	
1	18.6	39.4	45
2	24.2	31.1	45
3	40.1	37.9	45
4	34.7	22.0	45
5	18.0	25.0	45
6	43.7	43.6	45
7	17.0	18.6	45

## 5 CONCRETE COMPRESSIVE STRENGTH

The compressive strength of the regions in T-beam which were damaged obviously was tested, and the specimens were obtained by core drilling method. The measured concrete compressive strength of T-beam are between 17.0 and 40.1 MPa, the compressive strength of concrete in the surface of T-beam decreased significantly, the compressive strength test results are shown in Table 1.

## 6 FIRE TEMPERATURE AND THE PRESUMPTION OF SECTION LOSS

According to requirements of Assessment standard of existing build structures after fire (CECS 252:2009) [6], combined with appearance investigation, color change, concrete stripping condition and hand hammer knock test: the surface temperature of the region that color changes obviously was 700°C~ 800°C, the depth that was influenced by the high temperature is about 4 cm in the side of the web, and 6 cm at the bottom of the web. Despite of surface layer, the internal temperature of concrete did not exceed 300°C. The surface burning temperature at bottom of T-beam flange plate was greater than 500°C, the temperature of other parts of flange plate was below 200°C.

## 7 STRUCTURE CALCULATION AND ANALYSIS

### 7.1 Calculation model

1. According to the original design data and presumption results of section loss, the reduction

Figure 2. T-beam calculation models for different stages.

of geometric cross section is carried out for the calculation model, therefore, considering 6 cm of the concrete at the bottom of T-beam and 4 cm of web are failure. Calculation models are shown in Figure 2.

2. The compressive strength, elastic modulus, prestressed reinforced concrete bond strength are selected according to the concrete compressive strength test results and Assessment standard of existing build structures after fire (CECS 252:2009). And the reduction factors are determined based on that the concrete internal fire temperature is 300°C, so the reduction factor of concrete elastic modulus is 0.75, bond strength between prestressed reinforcement and concrete is 0.90, concrete compressive strength is 0.70. The key calculation parameter values are shown in Table 2.
3. The reduction range of the cross section and calculating parameters mentioned above is 0~12 m from the end of the beam, and cross section and calculation parameters of other beam segments used are in accordance with the original design values.

### 7.2 Strength checking of normal section

The calculation analysis results show that normal section strength of 12~13 units of T-beam after fire cannot meet the application requirements, while the rest of the section satisfy the requirements, the calculation results of the key section before and after fire are shown in Table 3.

### 7.3 Strength checking of oblique section

The calculation analysis results show that the section size of 0.7~6.7 m of T-beam after fire cannot meet the shear strength requirements, while others all satisfy the requirements. The strength calculation results of key oblique section before fire under typical load combination are shown in Table 4; moreover, the strength calculation results of key oblique section before fire under typical load combination are shown in Table 5.

Table 2. The key calculation parameter values.

Items	The original values	Reduction factors	Values after reduction
Elastic modulus(MPa)	34200	0.75	25650
Shear elastic modulus(MPa)	14706	0.75	11029.5
Linear expansion coefficient (/°C)	1.00E-05	1.00	1.00E-05
Poisson ratio	0.1666	1.00	0.1666
Volume weight (kN/m <sup>3</sup> )	25.0	1.00	25.0
Concrete mark	45.0	0.70	31.5
Axial compressive strength standard value (MPa)	32.2	0.70	22.54
Axial tensile strength standard value (MPa)	2.84	0.70	1.99
Axial compressive strength design value (MPa)	26.3	0.70	18.41
Axial tensile strength design value (MPa)	2.33	0.70	1.63

#### 7.4 Analysis of normal service condition

The stress state calculation and analysis results of T-beam which is constructed without live load (closed traffic) show that due to the section damage reduction, the compressive stress at the edge of T-beam 8–13 units can meet the requirements

Table 6. The accumulated stress state of normal section without live load (closed traffic).

Units	Left upper flange/MPa	Left lower flange/MPa	Right upper flange/MPa	Right lower flange/MPa	Axial compressive strength design value/MPa	Ultimate strength after fire/MPa	Strength of construction stage/MPa	Estimation
8	4.780	12.600	4.720	13.500	25.75	18.025	13.068	unsatisfied
9	4.720	13.500	4.820	14.000	25.75	18.025	13.068	unsatisfied
10	4.820	14.000	4.780	15.600	25.75	18.025	13.068	unsatisfied
11	4.780	15.600	4.740	15.400	25.75	18.025	13.068	unsatisfied
12	4.740	15.400	4.650	14.800	25.75	18.025	13.068	unsatisfied
13	4.650	14.800	4.420	16.600	25.75	18.025	13.068	unsatisfied

without live load, but cannot satisfy the requirements of the construction stage. It indicates that the structure is safe under the closed traffic condition; however, it will be unsafe in the later maintenance construction, the calculation results of key cross section are shown in Table 6.

## 8 CONCLUSIONS

By analyzing the structure performance, the following comments about mechanics properties of the T-beam can be made:

1. The normal section strength, oblique section strength, and the stress of normal service condition of the T-beam before fire all satisfy the design requirements.
2. When the T-beam after fire is under the live load, the normal section strength of prestressed concrete T-beam around mid-span cannot meet the application requirements, and the oblique section shear capacity from the end of the beam to L/4 cannot meet the application requirements.
3. When the T-beam after fire is without the effect of live load, the cross section stress state from the end of the beam to L/2 cannot satisfy the requirements of construction stage.

The following proposals for repairs and maintenance are provided according to the analysis of structure mechanics performance:

1. The normal section bending resistance and oblique section shear capability can be restored by means of enhancing the section, however, the stress state cannot be restored, and the compressive stress of effective section of T-beam after fire will always remain larger.
2. There might be some security risks to do the construction maintenance work on the bridge, while it is safer when using under bridge construction methods.
3. The mechanical properties of concrete and reinforced will be significantly reduced after fire, therefore, the regular observation of key position of the T-beam after the maintenance should be strengthened.

Zheng-ran Lu

School of Management, Shenyang Jianzhu University, Shenyang, China

**ABSTRACT:** The composite pavements associated with up Cross Tensioned Concrete (CTC) slabs and lower Reinforced Concrete (RC) slabs, isolated by Asphaltic Sand Mixture (ASM) layer, were proposed to suit the heavy traffic, based on Xiu-Shui line traffic surveys. The up CTC slabs could bear part axle load and total temperature stress, and ensure the pavements continuous. The lower RC slabs only could bear part over axle load and no temperature gradient stress. The up CTC slabs stress elements fatigue strength is higher than the plain concrete as without lateral compression, or the RC with passive lateral compression, for the up CTC slab elements in triaxial compression state by the cross tension. The axle load is beard by lower RC slabs and up CTC slabs according to their section bending stiffness ratio.

**Keywords:** heavy traffic; cross tensioned pre-stress concrete pavements; concrete fatigue; temperature gradient stress

## 1 INTRODUCTION

Cross Tensioned Concrete Pavements (CTCP) could eliminate joints and cracks, by applying an external force with the Retard-Bonded Tendons (RBPT) (ACI325.7R-88). CTCP had better drive quality too, for the absence of transverse joints (Mustaque Hossain, et al. 2003), it was developed in china, during the past five years (Dong-sheng Zhang and Na Li, 2011). Cross Tensioned and Reinforced Concrete Pavements (CTRCP) also increased the load capacity of the pavements as shown in Figure 1. This double-slabs design technique can bear more traffic loading stress, but less temperature gradient stress than equivalent thick PCCP, CRCP and CTCP. The RBPT is applied through an un-bonded strand to a bearing plate attached to the end of the strand at first, then changed to bonded as the epoxy adhesives solidified. This paper discusses only RBPT procedures (I. Tsiafis et al. 2012).

## 2 FUNDAMENTAL DESIGN CONCEPTS

CTCP design uses the flexural-tensile strength of concrete as the strength parameter of concrete

and does not directly take advantage of the high compressive strength of concrete. The RBPT increases the flexural-tensile strength by introducing cross tension in the concrete slabs. The fundamental formula for the design of CTCP is:

$$\sigma_t + \sigma_p \geq \sigma_{\Delta t} + \sigma_F + \sigma_L \quad (1)$$

where  $\sigma_t$  = concrete allowable flexural-tensile stress;  $\sigma_p$  = RBPT compressive stress in concrete;  $\sigma_{\Delta t}$  = temperature gradient curling stress;  $\sigma_F$  = ASM friction stress; and  $\sigma_L$  = traffic loading stress in the CTC slabs. As the ASM isolated layer, there is only part axle loading fatigue stress, no temperature gradient stress in lower RC slabs.

$$\gamma_r \cdot \sigma_{bpr} \leq f_r \quad (2)$$

$$\gamma_r \cdot \sigma_{bp,m} \leq f_r \quad (3)$$

where  $\gamma_r$  = reliability coefficient;  $\sigma_{bpr}$  = axle loading fatigue stress of lower RC slabs;  $f_r$  = concrete flexural strength standard values;  $\sigma_{bp,m}$  = max axle loading stress of lower RC slabs.

Figure 1. CTRCP structures and stresses.

### 3 AXLE LOADING STRESS ANALYSIS

Axle loading stresses of CTRCP slabs were calculated by double-elastic-deck theory (JTG D40-2011):

$$\sigma_{pr} = k_r k_f k_c \sigma_{ps} \quad (4)$$

where  $\sigma_{pr}$  = axle loading fatigue stress at the most adverse position of up CTC slabs;  $k_r$  = stress reduction factor of considering joint load transfer;  $k_f$  = fatigue stress coefficient considering cumulative fatigue load stress in design reference period;  $k_c$  = composite coefficient considering difference between theory of computation and engineering practice as well as dynamic load;  $\sigma_{ps}$  = max loading stress on up CTC slabs at the most adverse position, by standard axle load.

$$\sigma_{bpr} = k_f k_c \sigma_{bps} \quad (5)$$

where  $\sigma_{bpr}$  = axle loading fatigue stress at the most adverse position of lower RC slabs;  $\sigma_{bps}$  = max loading stress on lower RC slabs at the most adverse position.

The up CTC and lower RC slabs nearly each share half heavy traffic load stress; this is the CTRCP key advantage in over axle loading traffic.

### 4 TEMPERATURE STRESS OF UP CTC SLABS

Temperature gradient stress of up CTC slabs were calculated by gradient stress theory (JTG D40-2011):

$$\sigma_{\Delta t} = k_t \cdot \sigma_{\Delta t, m} \quad (6)$$

where  $\sigma_{\Delta t}$  = temperature gradient fatigue stress of up CTC slabs;  $\sigma_{\Delta t, m}$  = max temperature gradient stress along the longitude of up CTC slabs.  $k_t$  = temperature fatigue coefficient of up CTC slabs.

### 5 FRICTION OF UP CTC SLABS WITH ASM

The up CTC slabs would move on the ASM isolation layers for the principle of expand on heating

and contract on cooling. There were frictions between the slabs and ASM layers, the maximum at the middle of up CTC slabs.

$$\sigma_F = \frac{\mu\gamma L}{2} \quad (7)$$

where  $\mu$  = friction coefficient of up CTC slabs with ASM layers;  $\gamma$  = density of concrete.

## 6 PRESTRESS OF UP CTC SLABS

Assume that the compress by the tension in the up CTC slabs was uniform distribution; the compress of concrete stress element could be calculated from:

$$\sigma_{2p} = \frac{(\sigma_{con} - \sigma_{loss})A_p}{h_c \cdot s \cdot \sin \alpha} \quad (8)$$

$$\sigma_{3p} = \frac{(\sigma_{con} - \sigma_{loss})A_p}{h_c \cdot s \cdot \cos \alpha} \quad (9)$$

where  $\sigma_{2p}$ ,  $\sigma_{3p}$  = pre-compressive stress on the CTC elements by the cross tension along the 2 and 3 directions;  $\sigma_{con}$  = control tension stress value of tendon;  $\sigma_{loss}$  = loss of prestress during construction stage;  $A_p$  = section area of prestress;  $\alpha$  = intersection angle of tendon and road longitudinal direction;  $s$  = tendon spacing along road longitudinal direction.

Table 1. Pavement structure.

$L$ (m)	$b$ (m)	$h_c$ (m)	$h_a$ (m)	$h_b$ (m)	$h_1$ (m)	$h_2$ (m)	$h_3$ (m)	$s$ (m)	$\alpha$ (°)

-0.94	-3.05	-2.67	-0.89	-2.89	-2.9	1.64	1.64	-0.73	-1.63	-0.625	2	4.47

## 7 GROUND CONTACT PRESS

Ground contact presses were the vertical main stress of up CTC slabs element; it could be calculated from (Meng 2007):

$$A = 200p_s + 15200 \pm 7000 \quad (10)$$

$$p = \frac{P_s}{2A} \quad (11)$$

where  $A$  = ground contract area;  $\pm 7000$  = deviation range for 95% guarantee rate, “-” was recommended considering overload in Chinese;  $p$  = ground contact press.

## 8 CASE

The pavements structures, materials parameters, and stress calculated results of Xiu-Shui heavy traffic line were list in Table 1, 2 and 3. The concrete triaxial compression experimental investigation (Cao 2005) concluded as:

$$S_{max} = 2.305 - 0.1056 \log N \quad (R = 0.10) \quad (12)$$

While:  $N = 20$  Million  $S_{max} = 1.53$ . It could be concluded that the concrete fatigue strength was increased to 1.05 times max static strength by the  $0.07 f_c$  lateral pressures, which equal to 1.6 times plain concrete as without lateral compression, under the same fatigue life.

## 9 CONCLUSIONS

On the theory of concrete fatigue strength significantly enhanced by cross tension and laboratory fatigue test data, the CTRCP were introduced into the heavy traffic. By the double-elastic-deck theory, the temperature gradient stress, part axle loading stress, friction, ground contract press, lateral prestress of up CTC slabs element, and part axle loading stress of lower RC slabs were deeply analyzed.

On the up analysis, the CTRCP could bear 20 million times standard axle load (100 KN), and over axle load (350 KN) combine with max temperature stress of 50 years recurrence interval simultaneously. The most advantage of this CTRCP could keep 100 m continuous without transverse joints.

The up CTC slabs stress elements fatigue strength is higher than the plain concrete as without lateral compression, or the RC with passive lateral compression, for the up CTC slabs elements in triaxial compression state by the distribute cross tension. The over axle load is beard by lower RC slabs and up CTPC slabs according to their section bending stiffness ratio.

# Study on reinforcement effect of modified epoxy resins by repeated loading

Li Zhao

Highway Administration of Lanzhou, China

Dingbang Wei

Highway Maintenance Technology Research Institute of Gansu, China

**ABSTRACT:** Hollow bridge hinge joint is one of the main damage forms of Gansu, China. Modified epoxy resin was used to reinforce hinge joints under traffic. A pulse load on reinforced composite trabecular was adopted and the stress and strain characteristics were analyzed. It was found that the composite trabecular after reinforcement has a good overall performance, and the performance was more excellent when reinforcement by high-strength mortar.

**Keywords:** bridge hinge joints; modified epoxy resin; reinforced under traffic; repeated loading

## 1 INTRODUCTION

### 1.1 Bridge disease

Concrete hollow plank has been widely used in highway bridge engineering because of light weight, good structural performance and can be prefabricated. Since 1970s, many hollow plank bridges were constructed. However, a large proportion of these bridges' hinge joint were damaged due to environmental factors, increased road traffic or unreasonable design and construction, which leads to weakening of the overall carrying capacity of bridges and culverts, and in extreme cases, hollow plate may also rupture and causing safety problems, as shown in [Figure 1](#).

Figure 1. Hollow hinge joint of one bridge in China.

### 1.2 How to repair

The conventional reinforcement method of hollow hinge joint required to clear the entire bridge deck. Although it is a good solution to solve the damage, but because of the bridge clearance process requires up to one month or even more, so a great deal of traffic pressure was faced. Therefore, a new reinforcement method without disrupting traffic was needed.

Grouting at the bottom of the hinge joint, and spraying polymer modified mortar the reinforcement can be achieved without traffic break off. A modified epoxy resin, which has a fast-curing characteristics, was used to bond a composite trabecular, simulating the vehicle load by using of pulse load. Stress and strain data was collected to evaluate the effect of the technique.

## 2 EXPERIMENT

### 2.1 Material

1. Modified epoxy resin  
Prepared in laboratory and the performance parameters were shown in [Table 1](#).
2. Polymer modified mortar  
Prepared in laboratory and the performance parameters were shown in [Table 2](#).

### 2.2 Sample preparation

To be reinforced mortar specimens with dimensions of  $20 \times 25 \times 280$  mm, which cured in room

Table 1. Performance of modified epoxy resin.

Test	Condition	Standard	Result
Application time (min)	25°C		70
Initial viscosity (mPa·s)	25°C		142
Unconstrained linear shrinkage (%)	23 ± 2°C (7 days)		0.14
Flexural strength (MPa)	23 ± 2°C (7 days)		72
Compressive strength (MPa)	23 ± 2°C (7 days)		61
Steel-concrete tensile bonding strength (MPa)	23 ± 2°C (7 days)		5.5

Table 2. Performance of polymer modified mortar.

Test	Standard	Result
Setting time/min	Initial	40
	Final	50
Flow (%)	0 mins	0
	30 mins	0
Compressive strength (MPa)	2 hour	23.3
	24 hour	45.8
	3 day	55.8
	28 day	81.6
Flexural strength (MPa)	2 hour	6.8
	24 hour	10.6
	3 day	11.7
	28 day	13.6
Bond strength/MPa	24 hour	2.5
	28 day	3.5
Expansion/%	28 day	-0.05

regimen for seven days, get a compressive strength of 52 MPa. 1 mm gap was surrounded by two mortar blocks, in which modified epoxy resin was poured. Then the prepared samples were cured in laboratory and to be tested.

### 2.3 Repeated loading test

1. The shear rheometer controlled by strain was adopted to study on the curing process of modified epoxy resin, the control strain levels were 1%, 5%, 7.5%, 10%, 20%.
2. The repeated load test was carried out by IPC Company UTM-100 universal testing machine to evaluate the reinforcement effect. 20 KPa stress was used, loading 0.1 s, unloading 0.9 s, 10,000 times. Test apparatus shown in Figure 2.

Modified epoxy resin curing rapidly with time, during the curing process, certain frequency load on the composite trabecular to simulated the traffic.

Figure 2. Experiment instruments: (a) shear rheometer; (b) universal testing machine.

## 3 RESULT AND ANALYSIS

### 3.1 Effects of different loads on modified epoxy curing effect

The modified epoxy resin used to reinforcement under traffic should have a good workability and rapid curing characteristics. Viscosity of the resin was tested during the curing process by Brookfield rotational viscometer using a Brookfield rotational viscometer as shown in Figure 3.

Figure 3 shows that, the viscosity of epoxy A and B are almost no change within 90 minutes. However, after 120 minutes, the viscosity rise quickly and generate heat significantly, indicating that fast curing occurs during this time. Compared to the sample A, B shows a more obvious mutation point.

Different strain (1%, 5%, 7.5%, 10%, 20%) was loaded to test the curing process of modified epoxy resin, for exploring the effect of load.

The complex viscosity of the modified epoxy resin, rise up with curing time. From the characteristic of these five curves, we can see that the curing process was affected by continuous strain. When the loaded strain rise from 1% to 5%, the final complex viscosity decrease from  $1 \times 10^6$  Pa·s to  $0.2 \times 10^6$  Pa·s; when the loaded strain rise from 5% to 20%, the final complex viscosity decrease from  $0.2 \times 10^6$  Pa·s to  $0.2 \times 10^5$  Pa·s.

### 3.2 Resin reinforced experimental results

Using single trabecular simulate undamaged bridge, unbonded double trabeculars simulate damaged bridge which is reinforced by modified epoxy resin A or B. Flexural strength and deformation were measured as shown in Figure 5.

From Figure 5 it can be seen that, the flexure strength of single trabecular is 7.8 MPa compared to 3.0 MPa of unbonded double trabeculars,

Figure 3. Viscosity of two types of epoxy during the curing process.

Figure 4. Complex viscosity with time of modified epoxy resin under different level strain.

Figure 5. Test results of 4 kinds of samples.

whereas flexure elasticity modulus 10GPa to 2GPa.

Modified epoxy resin A and B was used to reinforce the double trabecular, it was found that the mechanical properties of the specimen got a improved largely after 24 hours. Resin B had a better performance than A.

Compared to “damaged” bridge, the flexure strength of specimen reinforced by resin A increased from 3.0 MPa to 4.7 MPa, resin B increased from 3.0 MPa to 8.0 MPa; The deformation/cycle of specimen reinforced by resin A decreased from 1.1 mm to 0.7 mm, resin B decreased from 1.1 mm to 0.45 mm; The flexure elasticity modulus of specimen reinforced by resin A increased from 2.0GPa to 2.5GPa, resin B increased from 2.0GPa to 6.5GPa; since it is safe to say that modified epoxy resin B have a good reinforcement effect.

### 3.3 The impact of interference on the effect of resin reinforcing process

To simulate the effect on the reinforcement under continuous load, a 20 KPa, 1 Hz stress applied on the specimen for 1 hour and 2.5 hours, another comparative specimen was set up without load. Flexible strength and deformation of all the specimens were collected after 24 hours. The results were shown in Figure 6.

As seen in Figure 6, the flexible strength of the three specimen under 1 hour loading, 2.5 hour loading and without loading were 4.42 MPa, 4.15 MPa and 4.75 MPa respectively, with a decrease of 6% and 12% after loading. Meanwhile, the deformation increase 9% and 15.6%, deformation/cycle increase 1% and 6.8% respectively.

### 3.4 Micro-analysis of bonding interface

Specimens after fracture were observed and it was found that the fracture surface of specimen reinforced by resin B is relatively smooth as shown in Figure 7.

The fracture surface of specimen reinforced by resin B was observed by SEM, and the picture was shown in Figure 8. It was found that there was a good bond of modified epoxy resin and mortar,

Figure 6. Impact on reinforcement under different loading time.

Figure 7. Fracture surface of the specimen (a): specimen reinforced by resin A; (b): specimen reinforced by resin B.

Figure 8. SEM picture of the fracture surface.

without obvious gap; because of better permeability, the resin penetrate deeper in mortar, and form a good mechanical interlocking and chemical bonds, improving bond strength.

#### 4 CONCLUSION

1. Viscosity test result by Brookfield viscometer indicates that there is a mutation point in the

curing process of the modified epoxy resin. And the dynamic shear rheometer test result shows that there is some effect on the curing process with the load strain over 5%.

2. Resin B has a better mechanical performance on trabecular reinforcement.
3. The continuous load during the curing process makes the strength of the trabecular specimen decrease 6~12%, deformation increase 9~15.6%, compared to the specimen without load; the result was acceptable.
4. A good bond was found by SEM between modified epoxy resin and mortar.

# Safety evaluation of long and steep slope based on BP neural network

Juan Zhang, Jun Chen & Xiaowei Li

*Xi'an University of Architecture and Technology, Xi'an, China*

**ABSTRACT:** Evaluating the safety of long and steep slope is essential in identifying the potential road safety hazard, which could result in casualties and property losses. In this paper, a BP neural network was built by using neural network toolkit in “Matlab,” 11 long and steep slopes are used in calibrating and validating the network. The high level of predictability provided that the application of BP neural network model to road safety evaluation of long and steep slope is feasible, and evaluation results coincide with the actual situation.

**Keywords:** long and steep slope; safety evaluation; BP neural network

## 1 INTRODUCTION

Compared to other slope, long and steep slope has the characteristics of long slope, steep gradient, and bad horizontal alignment. Traffic accident statistics show that long and steep slopes appear a series of segments where accidents are facile to happen; even a lot of accidents are serious accident, causing serious casualties and economic losses. The safety of long and steep slope becomes the focus of the whole society, many university and scientific research units begin to study the safety of long and steep slope. Road safety evaluation of a specific road traffic system is the use of qualitative or quantitative way to objectively describe system's security features<sup>[1]</sup>. The core is to obtain an objective description about existing road safety status and conclude factors that may affect traffic safety, evaluate how much the factors constraint, and provide opinions for the improvement of road safety. In this paper, BP neural network was used to evaluate the safety of long and steep slope with alignment Parameters as input layer and accident data as output layer.

## 2 BP NEURAL NETWORK

### 2.1 Features of BP neural network

Back-Propagation Network (BP network) is a nonlinear differentiable function weight training multi-layer network. Its strong nonlinear mapping ability automate the correlation of known data and, hence, obtain the underlying logic in a supervised learning neural network; attributes of input samples and the desired output value were first input into the network for interaction. The outputting connection weights of neurons are knowledge,

experienced and this evaluation experience then become the criterion for solving future problems with similar situations. Further, analysis would only require input of corresponding attribute values. System will automatically assign weights of the evaluation index according to the sample training using the validated model, and adjust weight automatically within the network's iteration, which can ensure an objectives' evaluation<sup>[2]</sup>. Thus, the data of the road that selected as learning sample is reliable; the BP neural network is a good and feasible method of road safety evaluation.

### 2.2 BP algorithm

The principle of BP algorithm's is that suppose the number of learning sample is  $n$ , the sample input is  $X_1, X_2, \dots, X_n$ , the corresponding output is  $T_1, T_2, \dots, T_n$ ; The training algorithm will adjust the connection value and the threshold value according to the error between network outputs  $Y_1, Y_2, \dots, Y_n$  and the  $T_1, T_2, \dots, T_n$ , until the error between  $Y_i$  and  $T_i$  achieves the stipulated precision.

There are twice runs in the learning process. One is forward pass calculation where information of samples is passed into input-layer, through hidden-layer, output-layer, the error between the ideal output  $T_i$  and the algorithm output signal  $Y_i$  were then calculated; the other is the reverse pass calculation, information is passed from the output-layer to input-layer, modify the value iteratively according to the error between  $T_i$  and  $Y_i$ . Figure 1 shows the neural network construction. Neural network toolbox of “Matlab” has a practical package based on the algorithm; the calculation for road safety evaluation in this paper is carried out based on the package<sup>[2]</sup>.

Figure 1. BP neural network construction.

### 2.3 Evaluation steps

Matlab based on neural network toolkit of “Matlab” for assessment includes the following steps:

- I. Determine evaluation objects
- II. Establish evaluation index system  
The status of the evaluation objects can be indicated by a series of evaluation index, each index reflects the status of the evaluation object from different side, which determines the nodes of input-layer, hidden-layer, and output-layer, and formed the BP neural network.
- III. Select learning samples with the evaluation index, provide them for BP neural network to train and learn, in order to get a well-trained BP neural network model.
- IV. Determine the validity of the BP neural network evaluation model using another set of actual data.
- V. Use the model to evaluate objects.

## 3 BP TRAINING MODEL FOR ROAD SAFETY EVALUATION

### 3.1 Selection of evaluation indexes

Long and steep slope, mostly in mountain area, has the characteristics of long slope, steep gradient and bad horizontal alignment, based on the above characteristics and the research results of relevant research literature<sup>[3]</sup>, this paper choose curve radius, easement curve length, curve length, difference in gradients, slope length, vertical curve radius, and vertical curve length as evaluation indexes.

### 3.2 Training model

The performance of the neural network is closely related to the selected samples; a good training sample set should not only pay attention to the sample size, but also pay attention to the quality of the sample. That means the sample should be representative. The training results can response to

its inherent law better with larger sample size. But when the sample size reaches a certain degree, with the increase of sample size, the precision of the network becomes very hard to improve, and the information capacity of network will surge. In this paper, on the basis of collecting data of road alignment and accident data, the number of input and output layer neurons, the training samples is determined for 11. The 11 training samples should be representative as for as possible, so that the training results can better response the relationship of geometric parameters, accident number and the accident consequences. Table 1 is the geometric parameters of the samples, namely, the input layer for safety evaluation indexes; Table 2 is the corresponding accident indicators of the samples, namely the output layer for target value.

### 3.3 Sample data normalization processing

To improve the learning speed of the network normalized processing of input signal, can make the means of all the samples' input signal close to 0 or relative to their mean square error is small. In addition, the incentive function of BP neural network is sigmoid function, the values the function of are between 0 and 1, the last node output of the network is also between 0 and 1, for this reason the output of the sample also need normalized. Usually, normalized processing adopt premmnx statements; its specific syntax format is: [Pn, minp maxp, Tn, mint, maxt] = premmnx (P, T); P is the original input and T is the output data; Minp is the minimum value of P and maxp is the maximum value of P; mint is the minimum value of T and maxt is the maximum value of P.

Normalized processing the geometric parameters and accident data of samples, the code is as follows:

```

P = [650 600 135 128 117 106 98.9 95.2 80.6 73.3
62.3;
0 0 104.54 99.586 46.5 84.724 79.77 77.293
67.385 62.431 55;

Difference in gradients (%)	2.2	0.3	3.412	3	1.8	2.709	3.1	2.8	0.7	0	3.5
Slope length (m)	640	500	340	180	230	460	300	330	230	650	230
Vertical curve radius (m)	929.22	912.72	855.94	850.94	827.68	815.48	781.12	770.1	735.96	0	632.86
Vertical curve length (m)	140	150	154	206	226	186	178	202	200	0	150

Table 2. Accident indicators of the samples.

	Extra serious accident	Major accident	Ordinary accident	Minor accident
1	0	1	2	1
2	1	4	5	0
3	0	1	7	0
4	1	4	16	1
5	0	15	15	0
6	1	8	15	1
7	1	6	16	0
8	0	7	3	0
9	1	8	7	3
10	3	9	5	2
11	0	5	10	1

```

end;
for i = 1:4;
T(i,:) = (0.8*t(i,:)-min(t(i,:)))/(max(t(i,:))-min(t(i,:))+0.1);
end;

```

After the normalization processing, sample data can be normalized to the interval between [0.1, 0.9].

### 3.4 Determine the number of hidden layer neurons

The neurons number of hidden-layer has a direct relationship, the neurons number of input-layer and output-layer. In this training model, input-layer has 7 neurons, Output-layer with 4 neurons, the neurons number of hidden-layer can be determined step by step based on the number of neurons of input-layer and output-layer. There is few neurons number of hidden-layer, the error will be relatively large; contrary, over conservative number of neurons selected will result in long learning time while the error is not necessarily the best. It might cause tolerance, and the sample, which not happened previously, can not be recognized.

The following formula is the reference formula which is used to determine the optimal neurons number of hidden layer.

$$n_1 = \sqrt{n+m} + a$$

where,  $n_1$  is neurons number of hidden-layer,  $n$  is neurons number of input-layer,  $m$  is neurons number of output-layer,  $a$  is constant  $\in [1, 10]$ .

From the above formula, the approximate neurons number of hidden-layer is about 14. Hence the neurons number of hidden-layer is set to be between 10 and 20, in order to determine when the network is more efficient and the output error is relatively small. Comparison of the training error and results, a reasonable neurons number of hidden-layer will be determined.

### 3.5 BP network of the MATLAB program

BP network in MATLAB software mainly call the corresponding function. The main algorithm procedure of training samples is as follows:

```

P = [650 600 135 128 117 106 98.9 95.2 80.6 73.3 62.3;
0 0 104.54 99.586 46.5 84.724 79.77 77.293 67.385 62.431 55;
194 130 32.5 39.5 92.155 60.5 67.6 71.1 85.1 92.1 103;
2.2 0.3 3.412 3 1.8 2.709 3.1 2.8 0.7 0 3.5;
640 500 340 180 230 460 300 330 230 650 230;
929.22 912.72 855.94 850.94 817.68 815.48 781.12 770.1 735.96 0 632.86;
140 150 154 206 226 186 178 202 200 0 150]
T = [0 1 0 1 0 0 1 1 0 1 3 0;
1 4 1 4 15 8 6 7 8 9 5;
2 5 7 16 15 15 16 3 7 5 10;
1 0 0 1 0 1 0 0 3 2 1]
for i = 1:7;
P(i,:) = (0.8*p(i,:)-min(p(i,:)))/(max(p(i,:))-min(p(i,:))+0.1);
end
for i = 1:4;
T(i,:) = (0.8*t(i,:)-min(t(i,:)))/(max(t(i,:))-min(t(i,:))+0.1);
end
res = 1:11

```

Table 3. Number of hidden layer neurons and training error.

Neuronal number	11	12	13	14	15
Training error	0.366	0.346	0.354	0.341	0.048
Neuronal number	16	17	18	19	20
Training error	0.364	0.371	0.378	0.386	0.392

```

S1 = 10:20
for i = 1:11
net = newff([S1(i) 2], {'tansig','logsig'}, 'traingdx');
net.trainParam.epochs = 1000;
net.trainParam.goal = 0.001;
net = train(net,P,T);
y = sim(net, P);
error = y-T;
res(i) = norm(error);
end

```

Table 3 is the training error with the number of hidden layer neurons for 11–20.

Table 3 shows that function approximation effect is best with the hidden layer neurons for 15; its training error is minimum. So, the number of hidden layer neurons was set to 15. Thus, the neural network was determined, and the training result with training error of 0.048 is quite good.

#### 4 MODEL VALIDATION

In order to determine the effectiveness of the proposed neural network model, a section of a long and steep slope was selected as a validated sample. Table 4 is the geometric parameters of the section.

The code for normalized processing of the geometric parameters, are as follows:

```

P = [340 100 336 0.3 505.6 912.72 150]
for i = 1:7;
P(i,:) = (0.8*p(i,:)-min(p(i,:)))/(max(p(i,:))-min(p(i,:))+0.1);
end

```

The trained BP neural network was used to evaluate the validated sample. The evaluation result was anti-normalized and rounded to the nearest integer, the following data was the evaluation accident number of the validated sample.

$$Y = [0 \ 0 \ 2 \ 1]$$

The above result show that the number of accidents of validated sample by model evaluation is: 0

Table 4. Parameters of validated sample.

Curve radius (m)	340
Easement curve length (m)	100
Curve length (m)	336
Difference in gradients (%)	0.3
Slope length (m)	505.9
Vertical curve radius (m)	912.72
Vertical curve length (m)	150

extra serious accident, 0 major accidents, 2 general accidents, and 1 minor accident. The result is fully consistent with the actual accident numbers. The evaluation accident number and the actual accident numbers also show that the validated sample should belong to safer roads.

#### 5 CONCLUSION

Using the established BP neural network model for safety evaluation of long and steep slope is feasible with curve radius, easement curve length, curve length, difference in gradients, slope length, vertical curve radius, and vertical curve length as evaluation indexes. Evaluation results have a good coincide with the actual data. The evaluation provides valuable insight on potential road's safety condition in the planning stage of an infrastructure project. Necessary counter measures can be incorporated into actual roadway construction to ensure high level of safety.

# Safety audit of continuous downhill in Ma-Chao expressway

S.H. Chen

*Yunnan Highway Research Institute of Science and Technology, Yunnan, China*

J.H. Liao & X. Wang

*Research Institute of Highway Ministry of Transport, Beijing, China*

**ABSTRACT:** Based on Ma Chao highway, safety audit methods of Continuous downhill are summarized in this paper. Continuous long downhill of Ma Chao highway are analyzed and evaluated comprehensively from the aspects including the truck brake temperature, linear combination of horizontal and vertical design, and structure angle settings. Security countermeasures and recommendations are proposed to improve the traffic engineering designing and guarantee the operational safety.

**Keywords:** highway; traffic safety; continuous downhill; safety audit

## 1 INTRODUCTION

Restricted by topography conditions, geological conditions and other investment factors, highways in mountain area usually use continuous downhill to overcome dispersion which leads to a higher risk of operational safety, especially for heavy-duty trucks under the condition of overloading. Domestic road industry applications show that traffic safety audit is important to eliminate security risks and improve highway safety level. “Highway Engineering Technical Standards” (JTG B01-2014), which was implemented at January 1, 2015 has the requirements that highway and class I road should use reasonable average longitudinal gradient with a demonstration. Domestic scholars have researched more about continuous downhill safety audit. For example Truck Escape Ramp (TER) position research based on brake temperature analysis by Dong Ou (2014), mountain highway safety audit criteria research based on the average longitudinal by Huang Lin (2014), safety audit indicators and assessment System research by Weiyuan Peng (2013), Xin Guo (2014) establishes a Truck Escape Ramp (TER) evaluation Index System of continuous downhill considering braking bed length, aggregate depth, line of sight conditions, the brake bed slope, aggregate type, tip protection, angle and other factors. This paper summarizes research findings of continuous downhill, proposes safety methods, evaluates safety of continuous downhill on Ma Zhao highway and tells security countermeasures and recommendations.

## 2 SAFETY AUDIT METHODS OF CONTINUOUS DOWNHILL

### 2.1 *Safety audit methods based on brake temperature of heavy-duty trucks*

The truck has potential energy when it starts going downhill, and in the process of going down some part of potential energy is absorbed by the engine, while some part is dissipated by resistance acting, or converts into kinetic energy. Because of performance degradation, the brake system can not absorb all of the energy which is converted by potential energy. The excess will convert to kinetic energy increment, and truck running speed will continue to increase. In this case, the brake system component temperature will continue to rise which lead that speed can not be controlled. The above is basic theory of truck brake temperature prediction model (Wu 2008, Liao 2007).

Considering that a unified and recognized truck brake temperature model does not exist in the country, this paper use GSRS model to evaluate continuous downhill safety which is established based on theoretical analysis and experiments in the United States at 1980s. Safety audit techniques are based on truck brake temperature, which are further used as the key technical indicators. Research shows that: under normal circumstances, when the brake temperature does not exceed 200°C, the braking force of the vehicle will not attenuate significantly; When the brake temperature reaches 400–600°C, the braking force decreases, which can only reach 25% of normal temperature (100°C or less); When the

brake reaches 600°C, the braking force may drop to zero approximately. Generally, when the brake pads temperature rises to 200°C, the truck braking performance begin to be affected; when the temperature exceeds 260°C, the truck may have a brake failure. Therefore, 260°C is defined as critical temperature of the brake pads performance. Truck Escape Ramp (TER) is considered to set when the brake pads temperature exceeds to 260°C.

### 2.2 Truck safety audit technology based on downhill risk index

SETRA (research institute in French) determines risk deciding conditions of longitudinal sections by two methods: performance analysis of heavy vehicles on the longitudinal section; vehicle accidents Statistical Analysis occurred on longitudinal sections.

SETRA counted representative sections on 22 highways. The results [7] show that it is very suitable to use the average longitudinal gradient and slope length as a variable for researching the risk of driving the vehicle. When  $d \cdot p < 130$  ( $d$ : the total longitudinal gradient length;  $m$ : average slope, %), excessive risk will not occur; When  $d \cdot p \geq 130$  and  $p \geq 3\%$ , the accident rate on longitudinal gradient sections will begin to increase with  $d \cdot p$  increasing. When  $p < 3\%$ , there is no risk.

According to the research results, the risk of the truck on the downhill section can be evaluated. The risk index model has two parameters including the average longitudinal gradient and slope length. First, calculate the average longitudinal gradient, if the average longitudinal gradient is less than 3%, without next calculation. If more than 3%, calculated risk index. Second, determine the risk index values, if more than 130, it is necessary to focus on security facility design of continuous downhill section.

Considering the different performance and other aspects of domestic and foreign vehicles, the evaluation results is as a reference but not risk decision basis of the truck on the downhill section.

### 2.3 Safety audit technology based on operating speed

According to the observation results of the operating speed on the typical continuous downhill section, considering the factors such as the average longitudinal gradient, cumulative slope length, radius of curvature, operating speed prediction model (Liao 2012) of the continuous downhill section is as follows:

$$V_{truck} = EXP \left( \begin{array}{l} 4.1491 + 0.1880 \ln(\text{grade}) \\ + 0.0366 \ln(\text{grade})^2 \\ + 0.1241 \ln(\text{len}) - 0.1129 \ln(\text{len}) \\ \cdot \ln(\text{grade}) \end{array} \right) \quad (1)$$

Table 1. Safety audit standard based on operating speed on continuous downhill section.

Safety level	Index	Description
Well	$ \Delta v_{85}  < 10 \text{ km/h}$	Operating speed coordination is well.
Medium	$ \Delta v_{85}  \in [10, 20]$	Operating speed coordination is acceptable. The technical indicators should be adjusted if conditions permit, which makes
Poor	$ \Delta v_{85}  > 20 \text{ km/h}$	Operating speed coordination is bad. Adjust the level and the vertical design.

$$V_{car} = EXP \left( \begin{array}{l} 4.4897 + 0.0911 \ln(\text{len}) \\ + 0.1830 \ln(\text{grade}) \\ + 0.0477 (\ln(\text{grade}))^2 \\ - 0.03 \text{grade} \cdot \text{len} - 0.0052 \text{len} \cdot \text{radi} \end{array} \right) \quad (2)$$

where  $V_{car}$ —operating speed of cars (V85%, km/h);  $V_{truck}$ —operating speed of trucks (V85%, km/h);  $\text{grade}$ —average longitudinal gradient to the top of the hill (%), with the absolute value of longitudinal gradient);  $\text{len}$ —cumulative slope length to the top of the hill (km);  $\text{radi}$ —Reciprocal of curvature radius (1/km), the value of the straight line is 0.

The safety audit method of continuous downhill section based on operating speed is mainly referring to “Guidelines for Safety Audit of Highway”. Evaluating operating speed coordination is based on calculating the difference between the predicted operating speeds on adjacent section. Evaluating the coordination of design speed and operating speed is based on calculating the difference between them on the same section of the road. The evaluation standard is shown in Table 1.

## 3 CONTINUOUS DOWNHILL SAFETY AUDIT OF MA CHAO HIGHWAY AND COUNTERMEASURE

According to the design files, Ma Chao highway continuous long downhill information is as shown in Table 2.

### 3.1 Downhill risk assessment

According to downhill risk assessment method proposed by SETRA, all average longitudinal gradient of continuous downhill on Ma Chao highway are no more than -3%. So the operating risk of the 4 continuous downhill sections is low. The average

Table 2. Ma Chao expressway continuous long downhill information.

Section	Gradient (%)	Slope length (m)	Relative altitude (m)
ZK68 + 260~ZK57 + 470	-1.95	10790	210.09
ZK55 + 760~ZK51 + 300	-1.75	4460	78.17
ZK47 + 860~ZK23 + 600	-2.57	24260	623.045
ZK22 + 270~ZK0 + 200	-2.6	22470	584.825

longitudinal gradient of ZK47 + 860~ZK23 + 600 and ZK22 + 270~ZK0 + 200 exceed  $-2.5\%$ , and the cumulative slope length exceed 20 km, so it is necessary to analyze the brake temperature and geometric design further.

### 3.2 Truck brake temperature evaluation

The evaluated vehicle is a 55 tons truck, and the default of speed on downhill is 60 km/h. Brake failure temperature is  $290^{\circ}\text{C}$ . The result of the brake temperature analysis is as shown in Figure 1.

The truck has a brake temperature close to  $290^{\circ}\text{C}$  when running on the downhill. It is reasonable that Truck Escape Ramp (TER) is arranged at K22+40 in the design files.

### 3.3 Combination of horizontal and vertical design evaluation g

Through the analysis of horizontal and vertical alignment, the alignment of ZK47 + 860~ZK23 + 600 is not well. For example the S curves of composed of horizontal curves with radius as 820 m, 851.6 m, and 804 m, and the longitudinal gradients are  $-2.7\%$ ,  $-3.9\%$ ,  $-2.0\%$ , and  $-2.8\%$ . From this, we can see that the radiuses are low, and the longitudinal gradients are high, which causes that driving safety risk is relatively high.

So we suggest: 1, enhancing sight guidance of S curve; 2, ensuring roadside and central horizon; 3, setting the speed-down markings and proposed speed sign; 4, setting speed capture facility, etc.

### 3.4 Structure setting evaluation

The structures of ZK47 + 860~ZK23 + 600 continuous downhill are intensive, and there are less roadbed, more bridges and tunnels. Such as K30 + 531~K24 + 067, are "bridge + tunnel + bridge", and the longitudinal gradients are mostly above  $2.5\%$ , even the maximum longitudinal gradient is  $-3.9\%$ . This slope section is located close to the bottom of S curve, which is not conducive to driving safety.

Bridge and tunnel sections do not have conditions to set Truck Escape Ramp (TER), so

Figure 1. The result of the brake temperature analysis.

Figure 2. Infrared temperature measurement of truck wheels.

we suggest: 1, taking compulsory deceleration measures; 2, enhancing sight guidance of bridge and tunnel sections; 3, ensuring a smooth transition of light between inside and outside the tunnel entrance; 4, improving traffic signs; 5, improving the anti collision degree of bridge barrier, etc.

### 3.5 Other suggestions

According to the analysis results of typical accident case on continuous downhill, the reasons of the accidents are mainly human factors. Some truck drivers are illegal, speeding, overloading, or fatigue driving for economic benefits. Therefore, in addition to take passive protection measures, it is more important to strengthen traffic control and raise the level of law enforcement after opening and operation, especially, overloading.

We suggest: 1, prohibiting vehicles with a total weight of more than 55 tons going into a continuous downhill; 2, strengthening the control of dangerous goods transport vehicles; 3, improving the drivers' safety awareness; 4, playing the role of safety facilities; 5, checking the truck to ensure

the brake performance before continuous downhill section; 6, forbidding the vehicle to exceed the speed limit and monitoring speed by detection system; 7, installing weather monitoring station and early warning ice, and other bad weather; 8, installing brake safety warning system for trucks, such as infrared imaging sensor, as shown in [Figure 2](#).

#### 4 CONCLUSIONS

On the basis of Ma Chao highway, the safety audit methods for the continuous downhill section are summarized, and the continuous downhill section of the Ma Chao highway is evaluated. For the characteristics of the project, the safety improvement suggestions are proposed to improve the traffic engineering design, and ensure the safety level of continuous downhill section after operation. Meanwhile, it also provides a reference for the safety improvement and safety audit of the continuous downhill section of the highway.

# Reynolds-number effects on static force coefficients of $\Pi$ -shape bridge deck section with wind fairing

Qingliang Zhan, Zhiyong Zhou & Yaojun Ge

Bridge Engineering Department, Tongji University, Shanghai, China

**ABSTRACT:** To study the Reynolds-number effects on static force coefficients of a typical  $\Pi$ -Shape bridge section with wind fairing, both wind tunnel tests and computational fluid dynamics method are performed. Three different types of deck sections are studied to evaluate the influence of handrails and wind curtain on Reynolds-number effects. 2D CFD simulations are carried out respectively to visualize the flow pattern around deck sections and reveal the mechanism on static coefficient Reynolds-number effects. The conclusions are: (i) Drag coefficient and lift coefficient of  $\Pi$ -Shape bridge with fairing and moderate height handrails are sensitive to Re number (ii) The results of  $\Pi$ -Shape bridge with tall wind curtain are not affected by Re number significantly (iii) Drag and lift coefficient obtained from low Re is conservative.

**Keywords:**  $\Pi$ -Shape deck section, wind fairing, wind curtain, bluff body, lift coefficients, drag coefficients, moment coefficients

## 1 INTRODUCTION

A common assumption in wind engineering is that flow around bluff body with sharp corners is independent of Reynolds number, so that drag coefficients, lift coefficients and moment coefficients conducted in wind tunnel tests can be directly applied to prototype structure calculation. This is applicable for some truly bluff bodies in some specific Reynolds-number ranges. In general, flow around bluff bodies is independent of Reynolds-number, but for streamlined structures, flow pattern is quite sensitive with Reynolds-number. In this paper, we provide the results of research on Reynolds-number effects on steady force coefficients of typical  $\Pi$ -shape bridge section with wind fairings.  $\Pi$ -Shape bridge section can be viewed as bluff body but for long span bridges, this kind of shape section usually suffers from serious aerodynamic problems such as flutter and vortex induced vibration. Therefore, it is likely to add wind fairing on both side of  $\Pi$ -Shape section to improve aerodynamic stability. This kind of section can not be viewed as streamlined body any longer, and it is different from  $\Pi$ -Shape section.

Many research projects into Reynolds number effects and aerodynamic stability have been carried out recently, but they mostly involved streamlined sections with no handrails or wind curtain. Schewe [1] conducted wind tunnel testing of Great Belt East Bridge in a pressurized wind tunnel. Strouhal number at high and low Re for bridge

girder cross section is different. Flow visualization is used to analyze different flow field at different Re region. Schewe [2] also reviewed several experiments results in different Re numbers, the author concluded that 2-D sections that behaved as a bluff or streamlined body depended on Re number and slender bodies with sharp-edged cross-sections may also suffer from pronounced Reynolds-number effects. Matsuda [3] measured steady and unsteady aerodynamic force coefficients in Reynolds number region from  $1.1 \times 10^4$  to  $1.5 \times 10^6$  of central-slotted bridge deck. The author concluded that conventional wind tunnel test results in the low Reynolds number region are conservative for wind resistant-design of bridge decks. Liu [4] and Li [5] studied streamlined and bluff bridge deck Reynolds-number effects using wind tunnel test, but with out handrails and air-curtain. Li [6] studied Re number effects of two different bridge decks, however, the numerical results did not agree with experimental results.

In the present research, to study the Reynolds-number effects on static force coefficients of a typical  $\Pi$ -Shape bridge section with wind fairing, both wind tunnel tests and computational fluid dynamics method are performed. Three different types of cross sections are studied to evaluate the influence of handrails and wind curtain on Reynolds-number effects. 2D CFD simulations are carried out respectively to visualize the flow pattern around deck section and reveal the mechanism on static force coefficient Reynolds-number effects.

## 2 STUDY METHODS AND MODALS

### 2.1 Description of deck sections

$\Pi$ -Shape bridge section is widely used in bridge engineering recently especially for long span bridge. Compared with closed deck section, this kind of opening section is economic and reasonable for sustainable force. Three kinds of  $\Pi$ -Shape bridge sections are studied in this paper as shown in Figure 1. All the three sections include wind fairing as a countermeasure in order to reduce VIV and flutter problems.

### 2.2 Section model test in wind tunnel

A scaled sectional model bridge was built and tested in TJ-1 boundary layer wind tunnel of Tongji University. The rigid model, 1.47 m long, 0.58 m wide, and 0.058 m deep, is made of two steel cores, providing the stiffness, and a plywood skin to reproduce girder's aerodynamic shapes.

The model is mounted fixedly in the tunnel floor (see Fig. 2), with a force balance installed in the bottom of model. The output from the balance can be used to measure the lift and drag forces acting on the model when incoming air flows past it.

An air velocity range is set from 2.3 m/s to 8.6 m/s, to obtain a series of Reynolds number. By measuring the lift and drag forces under each air velocity, we can check the Reynolds number effects on the aerodynamic characteristics of the model.

### 2.3 CFD calculation setup

The 2D computational domain is a circle with the bridge girder placed in the center (see Fig. 3). The size of sectional model in the wind tunnel is applied in the size of bridge girder in the numerical simulation. A coarse mesh is adopted to deal with the area far field from the central wall, with a fine mesh to deal with the near-wall district (see Fig. 4). The overall grids can be added up to 420,000.

Figure 1. Three deck sections.

Figure 2. Experimental setup in the wind tunnel.

Figure 3. Overall mesh of computational domain.

Figure 4. Near-wall mesh.

The left side of the outer boundary is set as velocity inlet, and the right side is set as pressure outlet. The velocity magnitude of inlet is set the same with experimental values, from 2 to 8 m/s. Thus the Reynolds number varies from  $0.9 \times 10^4 \sim 3.5 \times 10^4$

RANS approach is undertaken to provide steady-state solutions of the flow field and SST k- $\omega$  modal is used to consider the turbulence model.

### 3 RESULTS

#### 3.1 Drag coefficients of wind tunnel test

The definitions of the steady aerodynamic force coefficients in this research are listed as follows:

$$\begin{aligned} C_D &= \frac{F_D}{(1/2)\rho U^2 H} \\ C_L &= \frac{F_L}{(1/2)\rho U^2 B} \\ C_M &= \frac{M}{(1/2)\rho U^2 B^2} \end{aligned} \quad (1)$$

where  $C_D$ ,  $C_L$ ,  $C_M$  are the drag, lift and pitching moment coefficients, respectively.  $\rho$  is the air density,  $U$  is the wind speed,  $B$  is the deck width,  $H$  is the deck height.

Figure 5 shows the results of drag coefficients in case of different Reynolds number for three deck sections. The results of Section B are greatly affected by the Reynolds number. As Reynolds number increases, drag coefficient of Section B decreases from 2.2 to 1.15, and stay constant when Re number is greater than  $3E4$ . On the contrast,

Figure 5. Drag coefficients as a function of Re number.

drag coefficients of Section A and Section C are independent of Re number.

#### 3.2 Flow characteristic of CFD calculation

In Figure 6, X-velocity contour is presented of three sections at the  $Re = 9 \times 10^3$ . Flow separation occurs at the downside opening part of Section A (Fig. 6a). And on the upside surface, there exists a thin boundary layer due to lack of handrails. So in this situation, flow always separates at some constant regions and Re number effects are not that significant for the flow pattern. For section C (Fig. 6c), wind curtain disturbed upside flow and the turbulent boundary layer of upper deck is quite thick, therefore this kind of section behave like a quasi-bluff body. For Section B (Fig. 6b), compared with Figure 6d which shows the same section under  $Re = 3.5 \times 10^4$ , it shows that in the near wake region, velocity of higher Re number is smaller than that of lower Re number, thus the pressure of wake is bigger, leading to smaller drag coefficient.

Figure 6. X-velocity counter map.

### 3.3 Lift and moment coefficient characteristic

Figure 7 shows lift coefficients as a function of Re number for three deck sections. It can be concluded that with barriers placed on the upside surface, the lift coefficient decreases. The reason is that the existence of barriers on the upside surface makes air velocity lower, so the local pressure is relatively bigger on the upside, thus the total vertical force is stronger downward.

Again, lift coefficients of Section B are greatly affected by Re number, due to the same reason as drag coefficient.

Because the downside surface of three deck sections tend to be almost the same, difference between upside surfaces cause different results of Re number effects. Figure 8 shows the detailed flow velocity contour behind upwind handrails. Boundary layer thickness of lower Re flow field is thicker and flow is much smoother under the higher Re number. It shows that, the existence of

Figure 7. Lift coefficients as a function of Re number.

Figure 8. Local X-velocity counter map.

Figure 9. Moment coefficients as a function of Re number.

Figure 10. Frequency analysis of lift time-history.

handrails causes the Re number effects, because it causes flow disturbance on the upside surface.

From Figure 9, it can be concluded that moment coefficients of all three sections are not sensitive to Re number.

Frequency analysis of lift time-history for Section B and C is also done. And it shows that the main frequency of flow movement is independent of Re number.

## 4 CONCLUSIONS

- i. Drag coefficient and lift coefficient of  $\Pi$ -Shape bridge with faring and moderate height handrails are sensitive to Re number.
- ii. The results of  $\Pi$ -shape bridge with tall wind curtain are not affected by Re number significantly.
- iii. Drag and lift coefficients obtained from low Re is conservative.

The authors gratefully acknowledge the support of National Key Basic Research Program of China (2013CB036300) and the National Natural Science Foundation of China (91215302).

# Study on performance of cold recycling mixture with emulsified asphalt or foamed asphalt

Menghui Hao

School of Highway, Chang'an University, Xi'an, China  
Henan Transport Investment Group Co. Ltd., Zhengzhou, China

**ABSTRACT:** The technology of asphalt pavement cold recycling, which can reuse the old asphalt mixture, raise resource utilization ratio and protect ecological environment, accords with the strategic policy of developing recycle economy and realizing sustainable development in our country. This paper investigates two typical cold recycling mixtures and contrastive studies pavement performance by high temperature stability, water stability, low temperature anti-cracking and water permeability performance between emulsified asphalt and foamed asphalt. The research shows that two types of cold recycling mixtures all satisfy the standard of hot-mix asphalt mixture except low temperature anti-cracking ability. And the cold recycling mixture can be used in the road engineering as the asphalt under layer.

**Keywords:** cold recycling mixture; emulsified asphalt; foamed asphalt; pavement performance

## 1 INTRODUCTION

The asphalt pavement constructed in the 1980s in our country early is entering into rehabilitation period, which produces a large amount of reclaimed asphalt mixture. The technology of asphalt pavement rehabilitation, which can reuse the old asphalt mixture, raise resource utilization ratio and protect ecological environment, accords with the strategic policy of developing recycle economy and realizing sustainable development in our country. So the study of the cold recycling technology has important practical significance.

Studies of cold recycling mixture mainly focus on the material mixture design and conventional strength currently. Less comparative study is conducted between emulsified asphalt and foam asphalt of cold-recycling mixture. The only comparative study is conducted in the 1980s, whose emulsified asphalt and foam asphalt material had a big difference from today's material, which has little applicability.

Through a lot of laboratory experiments, the paper aims to systematically study high temperature stability, water stability, and low temperature anti-cracking of the cold recycling mixture with emulsified asphalt and also compared with foamed asphalt.

## 2 RAW MATERIAL AND GRADUATION

### 2.1 Raw material

As needed, the raw material in this article includes aggregate, RAP, cement, asphalt

(for foamed asphalt) and emulsified asphalt. The test results of the raw material as follows.

#### 1. RAP

Conduct water content and sieve test on the Recycle Asphalt Pavement (RAP) material, conduct tests on the former asphalt material extracted from RAP. The test results of the raw material in Table 1.

#### 2. Asphalt

The foamed asphalt in the project adopts 70# A-class asphalt. The test results of the raw material in Table 2.

The basic process of foaming asphalt is as follows. When cold water (environment temperature) contacts with high temperature asphalt (above 140°C), it will set off a chain reaction here. The heated asphalt and water drop exchanges their energy. The water drop is heated to 100°C. The asphalt cools down at the

Table 1. Test results of RAP.

Material	Subject	Unit	Results
RAP	Water content	%	1.2
	Asphalt content	%	4.8
Asphalt in RAP	Penetration (25°C, 5 s, 100 g)	0.1 mm	48
	Ductility (15°C)	cm	14.8
	Softening point (ring and ball method)	°C	51.8

same time. The transferred heat exceeds the steam latent heat, which leads to volume expansion and steam generation. When the steam in expansion chamber pushes in asphalt continuous phase, a large number of vesical steams shoot up from the nozzle. The compressed steam expands which makes the cooled-off asphalt forms thin film. It relies on the thin film's surface tension wraps the bubble entirely. During expansion process, the asphalt film generates surface tension to resist steam pressure until reaching an equilibrium state. Because of the low thermal conductivity of asphalt and water, the equilibrium state can last only a few numbers of seconds. A large number of bubbles from the foaming process exist at certain metas Table levels, which is easily fall through.

Test the matrix asphalt through foaming experiment, the test results of the raw material in Table 3.

Table 2. Test results of asphalt.

Subject	Unit	Results	Specifications
Penetration (25°C, 5 s, 100 g)	0.1 mm	77	60~80
Ductility (15°C)	cm	>150	>100
Softening point (ring and ball method)	°C	55	>46

Figure 1. Asphalt foaming principle.

Table 3. Test results of asphalt foaming performance.

Foaming temperature	Subject	Mixing moisture content		
		1.0%	1.5%	2.0%
150°C	Expansion (multiple)	12	16	18
	Half-life (s)	9.4	8.2	7.6
160°C	Expansion (multiple)	18	22	24
	Half-life (s)	12	10	8
170°C	Expansion (multiple)	17	20	24
	Half-life (s)	9	8.6	7.4

From the foaming experiment, the foaming temperature is 160°C, and 1% of the foaming water consumption is satisfied.

### 3. Emulsified asphalt

The project adopts slowly splitting emulsified asphalt with smaller needle penetration. The test results of the raw material in Table 4.

### 4. Cement

Join a small number of cement in the cold-recycling to enhance its early strength. Adopt Portland cement in the cement. The test results of the raw material in Table 5.

## 2.2 Gradation design

Design the granular composition to satisfy the scope of emulsified asphalt's and foamed asphalt's granular composition. The test results of the raw material in Table 6.

## 2.3 Mix proportion design

According to the normal method, conduct a moisture-density test with compound mineral aggregate, to ensure the best moisture content. Though the Marshall's test to make sure the optimal asphalt content of mixture. The test results of the raw material in Table 7.

Table 4. Test results of emulsified asphalt.

Subject	Unit	Emulsified asphalt	Specifications

### 3 PAVEMENT PERFORMANCE ANALYSES

#### 3.1 High temperature stability performance

The high temperature stability performance of asphalt pavement mainly reflects by rutting resistance. Because of the heavy traffic, heavy loading, and track disease are more and more serious, it is very important to study the high temperature stability performance of cold recycling mixture. The test results are in Table 8.

According to the test results.

Two types of cold recycling mixtures all satisfy the standard of hot-mix asphalt mixture greater than 1000 dynamic stability.

The high-temperature stability of emulsified asphalt mixture is stronger than foamed asphalt. Dynamic stability of emulsified asphalt mixture is 1.09 times of those with foamed asphalt.

Looking from the data analysis of track deepness, the deformation rate of emulsified asphalt mixture is much lower than foamed asphalt.

Table 8. Results of cold recycling mixture high temperature performance test.

Mixture type	Emulsified asphalt	Foamed asphalt
<i>The depth of wheel rut after 60 mins (mm)</i>		
1	3.257	4.504
2	3.164	3.754
3	3.354	4.324
Average	3.258	4.194
<i>Dynamic stability, DS (time/mm)</i>		
1	1527	1201
2	1341	1546
3	2012	1728
Average	1627	1492

Track deepness of emulsified mixture is 0.94 mm less than those with foamed asphalt.

#### 3.2 Water stability performance

In order to examine the water stability performance of cold recycling mixture, using Marshall's vestigial stability and cycle of freezing and thawing separation experiment to test water stability performance of the mixture.

According to the test results.

Two types of cold recycling mixtures all satisfy the standard of hot-mix asphalt mixture greater than 80% immersion residual stability and 75% TSR.

The immersion residual stability of two types of cold recycling mixtures has little difference with each other.

The freeze thawing and splitting strength ratio of emulsified asphalt mixture is stronger than foamed asphalt.

#### 3.3 Low temperature anti-cracking ability

Conducting an experiment of flexural strength and breaking strain to check out the low temperature anti-cracking ability of cold recycling mixture. The test temperature is -10°C and loading rate is 50 mm/min.

According to the test results.

Two types of cold recycling mixtures all unsatisfied the standard of hot-mix asphalt mixture greater than 2000 failure strain.

The low temperature failure strain of two types of mixtures has little difference with each other.

The reason is, compared with hot-mix asphalt mixture, the freeze thawing's mechanical property is lower and asphalt content is lesser. The cohesiveness of aggregate cannot reach the hot stirring's result, which speeds the producing of low temperature crack and minify the destructed deflection. All this has an influence on bituminous mixture's breaking strain.

Table 9. Results of cold recycling mixture water stability performance test.

Mixture type	Emulsified asphalt	Foamed asphalt
Marshall stability, MS (KN)	9.48	8.69
Immerses the 48 h stability, MS1 (KN)	7.81	7.03
Immersion residual stability, MS0 (%)	82.4	80.9
Has not carried on the thaw-freeze cycle, RT1 (MPa)	0.538	0.503
Carried on the thaw-freeze cycle, RT2 (MPa)	0.435	0.381
TSR (%)	80.9	75.7

Table 10. Results of cold recycling mixture low temperature performance test.

Mixture type	Emulsified asphalt	Foamed asphalt
Maximum load (N)	1025	868
Cross amount of deflection (mm)	0.289	0.307
Intensity of anti-pulls curved (MPa)	4.4	3.7
Breaking strain ( $\mu\epsilon$ )	1778	1890
Bending stiffness modulus (MPa)	2475	1958

Table 11. Results of cold recycling mixture water permeability coefficient test.

Mixture type	Emulsified asphalt	Foamed asphalt
Water permeability coefficient (mL/min)	26	35

### 3.4 Water permeability

Conduct the water permeability coefficient experiment to check out cold recycling mixture.

According to the test results.

Two types of cold recycling mixtures all satisfy the standard of hot-mix asphalt mixture water permeability coefficient less than 120 mL/min.

## 4 CONCLUSIONS

Emulsified asphalt and foamed asphalt cold recycling mixture have well high temperature stability, which meets the standard of hot-mix asphalt. The high temperature stability of emulsified asphalt is better than foamed asphalt. Its dynamic stability is 1.60 times of foamed asphalt.

Emulsified asphalt and foamed asphalt cold recycling mixture have well water stability, which meets the standard of hot-mix asphalt mixture. The reducing range of the mixture's splitting strength becomes lesser after cycle of freezing and thawing.

The low temperature anti-cracking ability of emulsified asphalt and foamed asphalt is worse than hot-mix asphalt mixture. From the low temperature trabecula bending test, there is a little difference of two types of mixture's failure strain, which doesn't meet the standard of hot-mix asphalt mixture.

Emulsified asphalt and foamed asphalt cold recycling mixture have well closely knit. From water penetration test, the water-seepage of two kinds of recycle mixture meets the standard of hot-mix asphalt.

Emulsified asphalt and foamed asphalt cold recycling mixture meets the design base requirements of the asphalt pavement. At the same time, it satisfied the performance requirement of the asphalt under layer, which applies to the construction of highway.

# Analysis of safety criterion on track irregularities of heavy haul railway under 30t axle load

H.F. Zhang & S.L. Lian

Key Laboratory of Road and Traffic Engineering of the Ministry of Education, Tongji University, Shanghai, China

**ABSTRACT:** Track geometry irregularity is an important excitation source for the train vibration and dynamic response between wheel and rail, which is directly related to the train safety and stability. When the axle load is up to 30t, track irregularity has a significant effect on the train safety and dynamic force between wheel and rail. The paper establishes the 30t axle load vehicle-track coupling model with Simpack multi-body dynamic simulation software to analyze the dynamic response of the vehicle and dynamic response between wheel and rail. The simulation sample of track irregularity in a time domain is achieved through track irregularity spectrum, and taking the coexistence of detrimental wavelengths into account. The estimated safety limits of vertical, alignment, longitudinal, and gauge track irregularity are compared with the limits calculated under the excitation of single harmonic wave. The results show that the estimated method in this paper can take into account the irregularity containing a wide range of wavelength compared with the single harmonic waves as an input, and the estimated limits value are higher than the limits calculated by single harmonic waves.

**Keywords:** heavy haul railway; track irregularity; dynamic response; safety limits

## 1 INTRODUCTION

Track geometry irregularity is an important excitation source for the train vibration and dynamic response between wheel and rail, and also directly related to the train safety and stability. Since the 21st, in order to improve the single transport volume, the axle load of haul railway has improved to 30t. And the track regularity is deterioration with the increased axle load. To ensure the train safety and stability, it is necessary to limit the irregularity within a certain range. Countries like America, Japan, Germany, etc., have safe limit standard of track irregularity. Chinese academy of railway sciences obtain the track irregularity safety criterion of existing railway by field text, setting the 10 m wavelength single harmonic wave in the test line. Cai Chengbiao et al. (1995) estimated the limits based on the theory of vehicle-track coupling dynamics and simulate various types of track irregularity.

All above research regard detrimental wavelengths as an ideal single sine or cosine function, which calculating the corresponding system dynamic response by controlling its amplitude, and then estimate the limits of irregularity. But the actual railway contains many kinds of wavelength irregularity, which have different influences on vehicle-track system, only consider a single

wavelength is not comprehensive. So, when calculating the limits of irregularity, it needs to consider the influence of various wavelengths. This paper regards the time domain waveform calculated by track irregularity spectrum as excitation to simulate the relation between system dynamic response and amplitude of detrimental wavelengths, and then estimate the safety limits of track irregularity.

## 2 TRACK IRREGULARITY ESTIMATED METHOD

### 2.1 Track irregularity simulation

The simulation sample of track irregularity in time domain is achieved through track irregularity Power Spectrum Density (PSD), based on the Blackman-Turkey period gram method. According to the theory, the equation of PSD and frequency spectrum is shown in Eq. (1).

$$\begin{aligned} X(k) &= \xi_k |X(k)| = N_r \xi_k \sqrt{S_k(k)} \\ &= N_r \xi_k \sqrt{S_x(f = k\Delta f)\Delta f} \end{aligned} \quad (1)$$

where  $N_r$  is the sampling number,  $\xi_k$  is a sequence with independent phase,  $X(k)$  is the frequency

spectrum of track irregularity,  $S_k(k)$  is the track irregularity Power Spectrum Density (PSD), and  $\Delta f$  is the sampling interval in frequency domain.

The track irregularity sample in time domain is described in Eq. (2), which is achieved by the inverse Fourier transform of  $X(k)$ .

$$x(n) = \frac{1}{N} \sum_{k=1}^N X(k) \exp\left(\frac{2j\pi kn}{N}\right) \quad (2)$$

To control the amplitude of detrimental wavelengths, introduce a variable  $x(t)$  as shown in Eq. (3) which is a sine function with stochastic primary phase. The  $x(t)$  is the track irregularity with the wavelength of  $\lambda_0$ .

$$x(t) = A \sin\left(2\pi \frac{v}{\lambda_0} t + \phi\right) \quad (3)$$

where  $A$  is the half maximum and  $\phi$  is the random variables uniformly distributed on  $[0, 2\pi]$ .

Since  $x(t)$  is a second-order stationary process, its power spectral density estimation can use the Blackman-Turkey period gram method. The  $x(t)$ 's power spectral density function is shown in Eq. (4).

$$\begin{aligned} S_x(\omega) &= \int_{-\infty}^{+\infty} \frac{A^2}{2} \cos(\omega_0 \tau) \cos(\omega \tau) d\tau \\ &= \frac{A^2}{2} \pi \left\{ \delta(\omega - \omega_0) + \delta(\omega + \omega_0) \right\} \end{aligned} \quad (4)$$

As the fact that, the track irregularity spectrum is one side, so convert Eq. (4) to the one-side form as shown in Eq. (5).

$$S_x(\omega) = A^2 \pi \delta(\omega - \omega_0) \quad (5)$$

where  $\omega = 2\pi v/\lambda$ ,  $\omega_0 = 2\pi v/\lambda_0$ ,  $S_x(\omega)$  is the Power Spectral Density (PSD).

The PSD of detrimental wavelengths is described in Eq. (5). With Eq. (5), the track irregularity spectrum can be described by a piecewise function. When the  $\omega = \omega_0 = 2\pi v/\lambda$ , the spectrum use Eq. (5) and the other frequency is still calculated by the track irregularity spectrum as shown in Eq. (6). By the  $A$  in the piecewise function, the amplitude can be controlled to simulating the dynamic response excited by the detrimental wavelengths, so the safety limits can be obtained.

$$S_x(\omega) = \begin{cases} A^2 \pi \delta(\omega - \omega_0) \\ \frac{k A_v \omega_c^2}{(\omega^2 + \omega_c^2) \omega^2} \end{cases} \quad (6)$$

Figure 1. Track irregularity in time-domain.

As a result in the vehicle-rail coupling dynamic (Zhai Wanming 2007), 10 m wavelength is the detrimental wavelengths of the freight car and the heavy haul railway maintenance departments also use the 10 m wavelength method of chord measuring for track irregularity maintenance. So 10 m wavelength vertical, alignment, longitudinal, and gauge track irregularity are used to estimating the safety limits. In case of Chinese heavy haul railways track irregularity and field test taken by Xu Lei et al. (2013), the amplitude is not more than 20 mm, so choosing the US 5-grade spectrum for track irregularity time-domain simulation. Figure 1 shows the simulation results by the method above, which detrimental wavelengths is 10 m and amplitude is 10 mm.

## 2.2 Vehicle-rail model and calculation parameters

Based on the theory and parameters of freight car, the analysis model is established by Simpack multi-body dynamic simulation software. Rail material is U75 in China's railway, and the simulation speeds are 80,100,120 km/h.

## 2.3 Assessment criteria

To assess the safety and stability, six criteria indexes can be used: derailment coefficient ( $Q/P$ ), wheel unloading rate ( $\Delta P/\bar{P}$ ), vertical ( $P$ ) and lateral wheel-rail force ( $Q$ ), vertical ( $a_z$ ) and lateral ( $a_y$ ) vehicle acceleration, and the value of them are shown as followed defined by GB/T 5599-1985 Railway Vehicle-Specification for Evaluation of the Dynamic Performance and Accreditation Test.

$Q/P \leq 0.8$ ,  $\Delta P/\bar{P} \leq 0.65$ ,  $P \leq 250$ ,  $Q \leq 0.4P_w$  ( $P_w$  Static wheel load),  $a_z \leq 0.7 g$ ,  $a_y \leq 0.5 g$ .

## 3 RESULTS AND DISCUSSIONS

Figures 2–4 show the dynamic responses excited by the track irregularity. Since the irregularity has an effect on different types of vehicle-rail dynamic response, the figures only show the main response

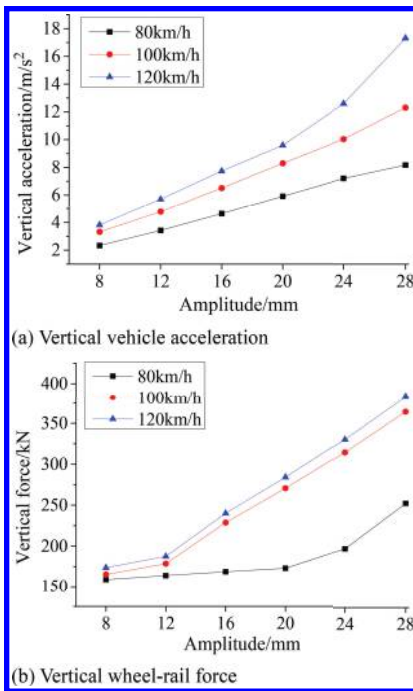

Figure 2. Dynamic responses excited by vertical irregularity.

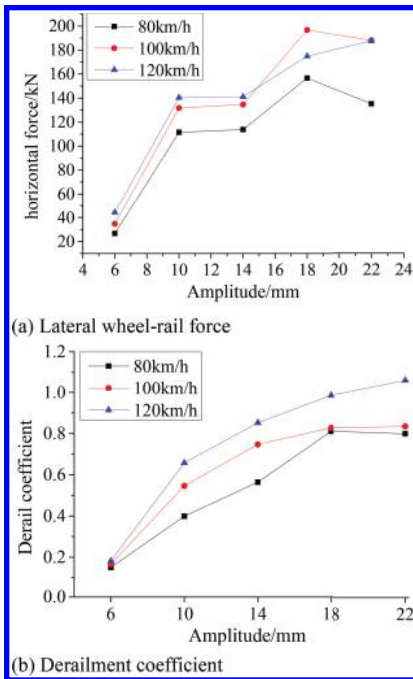

Figure 3. Dynamic responses excited by alignment irregularity.

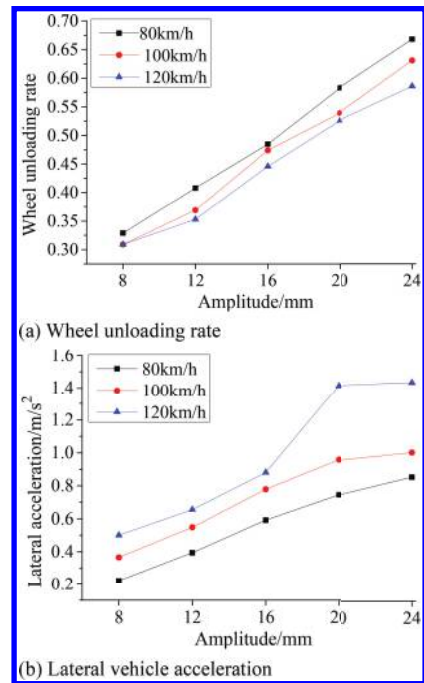

Figure 4. Dynamic responses excited by longitudinal irregularity.

Table 1. Track irregularity limit.

Irregularity	Assessment criteria	Amplitude/mm
Vertical	Vehicle acceleration	22
Alignment	Derailment coefficient and Lateral wheel-rail force	7
Longitudinal	Wheel unloading rate	20
Gauge	Geometrical dimensions	+24/-12

controlling the vehicle running safety and stability. And according to Luo Lin (1990), since gauge irregularity has a smaller influence on dynamic response, the limit of gauge irregularity is controlled by geometrical dimensions. The dynamic response results are less than the assessment criteria by the maximum and minimum gauge irregularity +24 mm/-12 mm as an input.

It can be seen from Figure 2. to Figure 4. that dynamic responses increase linearly as the amplitude of track irregularity increase. It has a higher requirement as the vehicle speed increase from 80 to 120 km/h. According to practical speed of the heavy haul railway, choose the dynamic responses under 80 km/h to estimate the safety criterion. Track irregularity limit under 80 km/h are shown in the Table 1.

Figure 5. Track irregularity limit (single harmonic results and calculation by the method of this paper).

Figure 5 shows that the limits results calculated by the method of this paper and under the excitation of single harmonic waves. It can be seen that the limit by this paper are more than the single harmonic waves method. The effect is caused by failing to consider other wavelengths of track irregularity, when use the single harmonic waves for estimation. The method of this paper controls the amplitude of the detrimental wavelengths during the simulation of the track irregularity PSD, which contain a wide range of wavelengths.

#### 4 CONCLUSION

Track geometry irregularity has an effect on the dynamic response of vehicles and rail and also directly related to the train safety and stability. This paper based on the vehicle-rail coupling dynamics, estimate safety limits of vertical, alignment, longitudinal, and gauge track irregularity and taking the coexistence of detrimental wavelengths into account. Compared with the limits calculated by single harmonic waves, the estimated

track irregularity limits are generally more than them. This method provides a new approach for the acquisition of the theoretical track irregularity limits through dynamic simulation. But this paper is aimed at 30 t axle load vehicles, the vehicle type is unitary, the speed also to have certain restriction, and for different vehicle types, its irregularity safety limits still need according to the actual situation.

## Analysis of rail thermal effect due to wheel-rail rolling contact in heavy-haul railway

S.J. Gu, X.W. Yang & S.L. Lian

*Key Laboratory of Road and Traffic Engineering of the Ministry of Education, Tongji University, Shanghai, China*

**ABSTRACT:** Thermal damage caused by wheel-rail contact is one of the main failure modes of wheel-rail system in heavy-haul railway. When a heavy haul train is running, the adhesion and slip of wheel-rail contact will lead to wheel-rail temperature rise which can reduce the adhesion between the wheel-rail and also can lead to the cracks, scratches, and stripping damage on the surface of the wheel-rail. First, a wheel set axial slice projection method is used to calculate wheel-rail rigid contact point; then, a virtual penetration method and Kalker's FASTSIM Program are used to calculate wheel/rail contact stress, which can better reflect the real wheel-rail contact status; and then, a moving heat source is used to simulate the movement of the wheel on the rail; finally, the rail thermal effect is calculated. A wheel-rail contact thermal effects analysis program is compiled using Matlab software. The temperature field was analyzed on the basis of wheel-set lateral displacement, wheel speed, and the creepage of wheel-rail. The results show that the temperature of rail surface is high on the condition of wheel-rail rolling contact, and the material parameters changes along with the temperature changes should be considered when calculating wheel-rail thermal contact coupling.

**Keywords:** heavy haul railway; wheel-rail contact; thermal effect; temperature rise

### 1 INTRODUCTION

In railway transport industry, there are many problems urgently needed to be solved, such as, thermal damage caused by wheel-rail contact is one of the main failure mode of wheel-rail system in heavy-haul railway. When a heavy haul train is running, the adhesion and slip of wheel-rail contact will lead to wheel-rail temperature rise which can reduce the adhesion between the wheel-rail (Pei Youfu et al. 1996), and also can lead to the cracks, scratches, and stripping damage on the surface of the wheel-rail contact.

Many scholars have done lots of research on the wheel-rail friction temperature rise and thermal stress. Blok (1937) and Jaeger (1942) have made initiative research on sliding body heat conduction. Researching on the wheel-rail friction temperature rise, many scholars have done much mainly based on Laplace transform method and Green function method (K. Knothe & S. Liebelt 1995, F.D. Fiseher et al. 2003, Gu Shaojie et al. 2015). In those research, moving heat source method to simulate the slip and the distribution of contact pressure between the wheel-rail is Hertz contact ellipse and the heat source is transient static heat source. Generally, the wheel-rail contact is not elliptical contact. With the development of computer,

finite element method has been used to solve the wheel-rail temperature rise to increase the credibility of the engineering (Johan Ahistrom & Birger Karlsson 2002, Ji Huai-zhong et al. 2005, T.C. Kennedy et al. 2006, Qi Wanming et al. 2010, Li Wei et al. 2010, Wang Wei et al. 2012, Xiao Qian et al. 2013).

For the wheel-rail contact thermal problems caused by rolling contact, the current study is rare. In this paper, a wheelset axial slice projection method (Yan Juanmao 1983) is used to calculate wheel-rail rigid contact point; and then, a virtual penetration method (Piotrowski, J. & Kik, W. 2008) and Kalker's FASTSIM Program (Kalker, J.J. 1982) is used to calculate wheel/rail contact stress and distribution of adhesion and slip zone; finally, the rail thermal effect is calculated.

### 2 THERMAL ANALYSIS

#### 2.1 *Wheel-rail relative slip velocity*

According to virtual penetration method and Kalker's FASTSIM Program, the contact normal and creep stress can be calculated. When the creep force less than the limit, consider this element is in adhesion zone, otherwise in slip zone, and all the

process need to be modified by Cullen theorem. Based on the above, the distribution of adhesion and slip zone can be calculated, as shown in Figure 1.

The relative velocity (slip velocity) for steady-state rolling and linear elasticity is defined according to Eq. (1) (Kalker, J.J. 1990)

$$\vec{v}_{slip} = \begin{bmatrix} v_x \\ v_y \end{bmatrix} = V_{vehicle} \left[ \begin{bmatrix} \xi_1 - \xi_3 y \\ \xi_2 + \xi_3 x \end{bmatrix} - \frac{\partial \bar{u}(x, y)}{\partial x} \right] \quad (1)$$

where  $V_{vehicle}$  is the vehicle speed (m/s),  $\xi_1$  the longitudinal creepage,  $\xi_2$  the lateral creepage,  $\xi_3$  the spin creepage,  $u$  the elastic displacement, and  $x, y$  the cartesian coordinates of the contact ellipse.

However, the “elastic slip” term in Eq. (1) is not possible to calculate with FASTSIM and is thus neglected in this simulation. Since the rigid slip term is usually much larger, it is not a severe limitation to neglect the elastic part.

### 2.2 Thermal conduction analysis

When the relative slip between the wheel/rail, the surface of wheel/rail will generate a lot of friction heat, the expressions of heat flow density is as follows:

$$q(x, y) = \mu p(x, y) |\vec{v}_{slip}| \quad (2)$$

where  $q(x, y)$  is heat flow density  $q(J/m^2 \cdot s)$ ,  $\mu$  the coefficient of friction,  $p(x, y)$  contact stress and  $v_{slip}$  the slip velocity.

The classic thermal conduction equation is as follow (Caralaw, H.S & Jaeger, J.C. 1980)

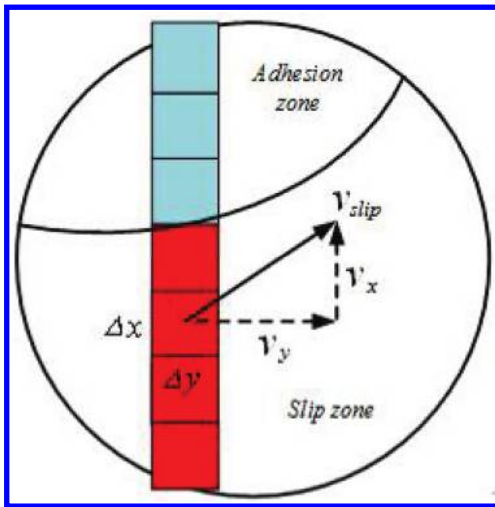

Figure 1. The distribution of adhesion and slip zone.

$$\frac{\partial^2 \theta}{\partial x^2} + \frac{\partial^2 \theta}{\partial y^2} + \frac{\partial^2 \theta}{\partial z^2} = \frac{1}{\kappa} \frac{\partial \theta}{\partial t} \quad (3)$$

where  $\theta$  is temperature rise ( $^{\circ}C$ ) and  $\kappa$  thermal diffusivity ( $m^2/s$ ).

$$\kappa = \frac{k}{\rho c_p} \quad (4)$$

where  $k$  thermal conductivity [ $W/(m \cdot K)$ ],  $\rho$  density and  $c_p$  thermal capacities [ $J/(g \cdot K)$ ].

### 3 TEXT CASE

In the present analysis, the CHN 75 kg/m rails and LM-type wheel-set profiles of China freight car (as shown in Fig. 2) are selected to calculate wheel-rail contact stress under different wheel-set lateral displacement ( $Y_w$ ), and applied to the elastic half-space model, to calculate rail surface thermal effect on the basis of wheel speed ( $V_{vehicle}$ ) and the creepage of wheel-rail ( $\xi$ ). The wheel velocity respectively take 1 km/h, 2 km/h, 5 km/h, 10 km/h, 20 km/h, 30 km/h, 40 km/h, 50 km/h, 60 km/h, 80 km/h, 100 km/h, and 120 km/h; and the creepage respectively take 0.001, 0.002, 0.003, 0.004, and 0.005 (the lateral, longitudinal and spin creepage are the same). The material parameters of rail are in Table 1.

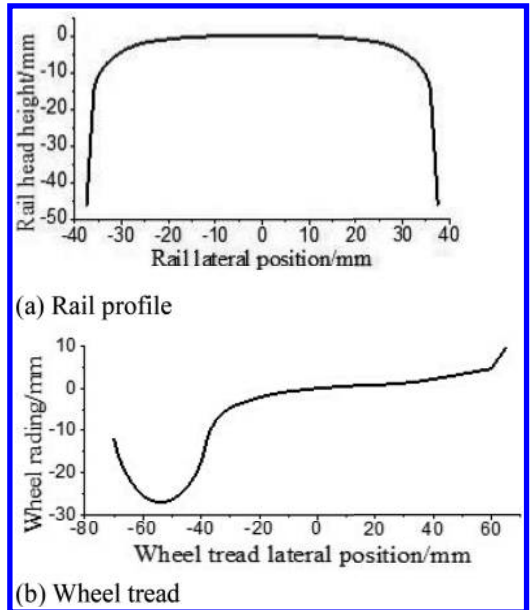

Figure 2. The profiles of wheel and rail.

Table 1. Material parameters.

Parameters	Value
Specific heat capacity $c/(J \cdot kg^{-1} \cdot K^{-1})$	470
Thermal conductivity $k/(W \cdot m^{-1} \cdot K^{-1})$	41
Density $\rho/(kg \cdot m^{-3})$	7790
Poisson's ratio $\nu$	0.3
Young's modulus $E/(N \cdot m^{-2})$	$2.07 \times 10^{11}$
Environmental temperature $T_d/^\circ C$	20

#### 4 RESULTS

Figure 3 shows that, under the condition of  $\xi$  is 0.005, the rail surface temperature change rule with the change of  $V_{vehicle}$  and  $Y_w$ . In the Figure, for the accumulation of heat at a low  $V_{vehicle}$ , the rail temperature is increased. With the increased of wheel-set lateral displacement, the rail surface temperature has a process of first decreasing and then increasing. When  $Y_w$  is 3 mm, the rail surface temperature is relatively small, for the wheel-rail is matched, so the contact stress and heat flow density is small. And when  $Y_w$  is 9.18 mm, the wheel-rail occur two-points contact, the contact stress and heat flow density is large, so the rail surface temperature is relatively large.

Figure 4a, 4b respectively show that, under the condition of  $Y_w$  is 0 mm and 9.18 mm, the rail surface temperature change rule with the change of  $V_{vehicle}$  and  $\xi$ . We can see from the figure, with the increased of  $\xi$ , the rail surface temperature is increased, this is due to the area of slip zone and relative slip velocity is increased with the increased of  $\xi$ , in this case, the heat flow density is increased, so the rail surface temperature correspondingly increased.

Figure 5 shows that the distribution of adhesion and slip status, heat flow density and rail surface temperature rise, on the conditions of  $Y_w = 0$  mm  $\xi = 0.003$ ,  $V_{vehicle} = 5$  km/h. Figure 5a shows the contact patch adhesion and slip status, the red zone represent the slip zone, the blue is adhesion zone which don't produce heat flow. Figure 5b shows the contact patch heat flow density, we can get from this figure is that all the heat come from slip zone. Figure 5c shows the rail surface temperature rise, the maximum temperature rise is  $51^\circ C$ .

Figure 6 shows that the distribution of adhesion and slip status, heat flow density and rail surface temperature rise, on the conditions of  $Y_w = 9.18$  mm  $\xi = 0.003$ ,  $V_{vehicle} = 5$  km/h. The value of this condition is larger than the condition of above (as shown in Fig. 5.), due to the condition occur two-point contact, the contact stress and relative slip velocity is more large, so the rail surface temperature is large, the maximum temperature rise is  $211^\circ C$ .

Figure 3. The rail surface temperature change rule with the change of  $V_{vehicle}$  and  $Y_w$ .

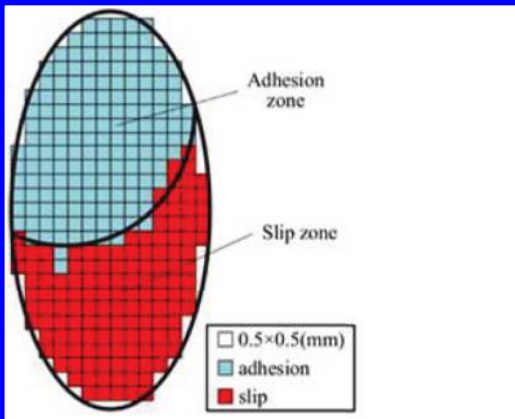

(a)  $Y_w = 0$  mm

## 5 CONCLUSION

The temperature of rail surface is high on the condition of wheel-rail rolling contact, and the material parameters changed along with the temperature changes should be considered when calculated wheel-rail thermal contact coupling. The influence of  $V_{vehicle}$  and  $\xi$  on rail surface temperature rise is obvious. With the increased of  $\xi$  and the decreased of  $V_{vehicle}$ , the rail surface temperature is increased. When wheel-rail occur two-point contact, the rail surface temperature rise is larger than one-point contact. The results can provide a support for the further research on cracks, scratches, and stripping damage on the surface of the wheel-rail.

# Research of computation methods on self-anchored cable-stayed suspension bridge

Jin-ling Chai & Jun Shi

*Henan Vocational and Technical College of Communications, Zhengzhou, China*

**ABSTRACT:** In order to find out a reasonable finished bridge state of triple pylon self-anchored cable-stayed suspension bridge, a neoteric bridge style, the method to determine the finished bridge state of composed system bridge with unsymmetrical spans was studied, and the iteration method of geometric shapes and internal forces of spatial cables, hangers and stayed-cable was presented. The geometric nonlinear finite element model was set up. The unstrained lengths and stiffness matrix were revised continually until the nodes. Displacements met the precision requirement in the processing of nonlinear iteration calculation. Then the finished bridge state of the whole bridge was determined. With this method, the finished bridge state that meets the design requirement of self-anchored suspension bridge and the geometric shapes and internal forces of cables, hangers, and stayed-cable. An example proves that the method is valid and feasible for engineering requirement and determining the finished bridge state of spatial cable-stayed self-anchored suspension continuous composed system bridge.

**Keywords:** bridge engineering; cable-stayed self-anchored suspension continuous composed system bridge; main cable shape; segmental catenary method

## 1 INTRODUCTION

Suspension bridge and cable-stayed bridge is the first choice for large-span bridge form. Most of the suspension bridge is given priority to with anchor block, which needs to be huge and expensive anchorage to resist the powerful tension of main cable. Self-anchored suspension bridge main cable anchorage on the stiffening girder avoid building anchorage, and can also provide stiffening girder with pretested [1]. For cable-stayed bridges, suspension bridges show their shortcomings and the insufficiency, which already cannot completely meet their requirements. So self-anchored cable-stayed suspension bridge rises at the historic moment [2]. It embodies the advantages of both, and is made up for the inadequacy. In the process of the design of the bridge, the tower and form of beam section size is determined, its load is made up of main girder, a bridge tower, and the share of the stay cables, reasonably determine the ratio of each component to share is very important. So the design of the bridge cable system is to determine the reasonable first into the bridge state, namely the reasonable state of linear and internal force, and suspension—suspension cooperative system bridge is a kind of new bridge, its bridge state research is less. This paper is conducted through calculation of the segmental catenary theory stress free cable

long, through the influence matrix method, and the theory of geometric nonlinear iteration, which determine it into a state of the bridge. Using the method of a suspension—suspension cooperative system bridge is calculated, linear and completed in accordance with the actual requirements.

## 2 THE BRIDGE DESIGN CONDITION

### 2.1 *Self-anchored suspension bridge completion state*

The method of linear suspension bridge main cable into a bridge mainly adopts parabolic method, based on the catenary clues yuan of recursive method, virtual beam method, etc. Parabolic method is simple, but the precision is not high, suitable for preliminary design of suspension bridge, the Catenary method with high precision. Back cable force calculation of main basis of stiffening girder section of gravity and the second phase of constant load, Point by vice tower back the moment balance between the centroid can conclude main cable tower of the vice of horizontal force  $H$  and vertical force  $V$ . Set up the structure of the whole bridge along horizontal uniform weight and the sum total of live load for  $q$ :

The side span of main cable horizontal component  $H$  is:

$$H = \frac{qL^2}{8f} = \frac{qL}{8\lambda} \quad (1)$$

Among them:  $\lambda = \frac{f}{L}$ —rise-span ratio of the side span;  $L$ —Side span;  $f$ —Side span rise.

Rise-span ratio  $\lambda$  is calculated by type (1). Considering the actual situation, into the bridge main cable by load for main cable arc length uniformly distributed along the main cable gravity and delivering the sling concentration (unit weight of stiffening girder and the second phase of dead load). So the suspension bridge main cable force schema can be simplified as along the arc length under uniformly distributed load with concentrated force of the flexible cable, The lifting point between the main cable shape of acceptor line weight of catenary [3–5]. The main cable can be seen as more paragraphs that differentiate by the lifting point the combination of catenary, as shown in Figure 1.

For any period  $i$  of suspension cable, the equation for:

$$c = -\frac{q}{H},$$

$$a_i = sh^{-1} \frac{h_i c}{2sh\left(\frac{cl_i}{2}\right)} - \frac{cl_i}{2}, \quad (2)$$

$$b_i = -\frac{1}{c} cha_i$$

$$y_i = \frac{1}{c} [ch(cx + a_i)] + b_i \quad (3)$$

Main cable overall balance equation:

$$\begin{cases} H_1 = H_2 \\ V_1 = q \sum_{i=1}^n s_i + \sum_{i=1}^n P_i + H_2 \tan \theta_2 - H_1 \tan \theta_1 \end{cases} \quad (4)$$

Figure 1. Main cable force analysis.

And satisfy the compatibility conditions:  $\sum_{i=1}^n h_i = f$ .

Type:  $s_i$ —The  $i$  section of long,  $s_i = \int_0^{l_i} ds = \int_0^{l_i} \sqrt{1 + (y')^2} dx$ .

And in the concentrated load point between paragraphs satisfy the force equilibrium condition:

$$\begin{cases} Hy' \big|_{x_i=l_i} - Hy' \big|_{x_i=0} = P_i, \\ H[sh(cl_i + a_i) - sha_{i+1}] = P_i, \end{cases} \quad (5)$$

Among them,  $P_i$  as the focus;  $L$  and  $h$ , respectively, as the main line at the ends of the horizontal distance and elevation difference, Computing needs to give certain initial value, iteration to get precise linear.

## 2.2 Cable-stayed bridge finished bridge state

Bridges at home and abroad experts put forward a lot of dead load cable force of cable-stayed bridge calculation method, which has rigid support continuous beam method, zero displacement method, the method of internal force balance, specify stress method, and other methods [6]. The cable force optimization method has limitations, it is difficult to obtain satisfactory results; this paper presents a method of comprehensive:

1. Deciding initial dead state using minimum bending energy method  
The cable and the axial stiffness of beam and column is increased to large enough, so to get in the main girder and the tower bending moment are relatively small, the target is basically uniform state into a bridge. This state into a bridge, one of the few to cable force may be very unreasonable, main girder and the tower bending moment small also is not reasonable. Therefore, this state is not the ultimate goal as a bridge, but is adjusted into a state of bridge foundation.
2. By adjusting cable force influence matrix method was obtained by minimum bending energy method and tower into the state of the bridge girder bending moment and rationalization [8–9]

$$[A]\{\Delta T\} = \{\Delta R\} \quad (6)$$

Type:  $[A]$ —Influence matrix;  $\{\Delta T\}$ —Cable force adjustment quantity;  $\{\Delta R\}$ —The amount of control target to adjust.

Using least squares solution [7], work out, you can get the adjusted control target:

$$\{R\} = \{R_0\} + [A]\{\Delta T\} \quad (7)$$

Type:  $\{R\}$ —After the adjustment control target;  
 $\{R_0\}$ —Before the adjustment of control target;  $\{A\}$ ,  
 $\{\Delta T\}$ —Same as above.

### 3 ACCURATE EQUILIBRIUM ANALYSIS

Cable-stayed suspension bridge width 555 m, its a composite system of tower bridge. Including the main tower system segment and the anchor cable suspension system. Combination of main span is:  $25\text{ m} + 90\text{ m} + 2 \times 25\text{ m} = 162.5\text{ m} + 90\text{ m} + 90\text{ m}$ . Based on the special finite element program MIDAS/Civil to tower suspension—since the anchor cable cooperation system bridge for 3 d modeling.

Due to the bridge tower of vice about asymmetric structure, main cable tension and back sola force will produce unbalanced moment to Kentucky vice tower under the action of dead load. So, its must control the bending moment in a certain range to ensure the safety of the tower of vice. According to this principle, to determine main cable tension stiffening girder and derrick undertake weight ratio. Nonlinear finite element equilibrium iteration calculation, determine the reasonable state into a bridge. stiffening girder maximum bending moment for  $-159137\text{ KN.M}$ , the maximum axial force  $-115519\text{ KN}$ , stiffening girder maximum bending moment for  $-159137\text{ KN.M}$ , and the maximum axial force  $-323872\text{ KN}$ . In the bridge condition, the stiffening girder internal force as shown in Figures 2–3, inclined boom internal forces are shown in Table 1.

Back into the bridge condition cable force are shown in Table 2.

From Table 2 shows, back into the bridge condition basic cable force between 6200 KN and 6600 KN, cable force was homogeneous. Into a state of suspension bridge cable force are shown in Table 3.

From Table 3, into a state of suspension bridge cable force is divided into two parts, the unit

#### 4 CONCLUSION

1. This paper uses the three towers self-anchored cable-stayed suspension bridge cooperation system bridge stress analysis. First segmental catenary method is used to iterative calculation, its reasonable linear, recycling limited displacement theory of derrick and stiffening girder internal force calculation, a further iteration, the geometric main cable stress free cable long, finally, got into a reasonable bridge state.
2. The research proposed for vice towers on both sides of the asymmetric into the bridge linear and internal force of the iterative calculation method, by this method can quickly find the bridge balance. Into the state of the bridge finite element model is established for the nonlinear iterative calculation to determine the whole bridge structure into a state of the bridge.

**ABSTRACT:** In this paper, mesoscale convective systems and lightning phenomenon surrounding the Poyang Lake region were analyzed with mesoscale convective systems and lightning monitoring data in 2006–2008, to reveal the law of the influence of the Poyang Lake on the mesoscale convective system and its concomitant phenomena of lightning. The results showed (1) the characteristics of the temporal distribution of lightning activities in the Poyang Lake region: lightning activities were mainly in the late spring to early autumn, mostly in summer, while the frequency of lightning activities was mainly at 12:00–22:00, in particular, focusing at 13:00–19:00. Lightning incidence trend around the Poyang Lake area was in accordance with that in Jiangxi Province. The difference was that the Jiangxi lightning frequency changed greatly in the afternoon, and the lightning frequency around the Poyang Lake area distributed symmetrically, with obvious change. The reasons may be attributed to the difference in the underlying surface, as a result of which the land surface-underlying surface was very different (such as forests, mountains or hills), while the water surface-underlying surface was relatively homogeneous. (2) The spatial distribution characteristics of lightning activities around the Poyang Lake region: within 12:00–14:00, lightning occurred mainly in the West Bank region of the lake, followed by the central area of the Eastern bank region, within 14:00–20:00, occurred mainly in the southern area of the Lake. Such distribution patterns may be related to the topography distribution of the Poyang Lake and the local circulation of lake-land wind. In addition, they may be closely related to the moving path of mesoscale convective weather systems. (3) When the mesoscale convective system moved to the Poyang Lake, the moving speed slowed down. This was due to the surface heating by solar radiation during the day, with terrestrial heating up being much faster than that of the lake surface. Compared with land, the Poyang Lake was a cold source. Because of heat expansion, the land-based air group went up and converged, under the action of the horizontal pressure gradient force, the air flew over the lake from the sky over land, then sank to the lake, and finally, flew over the land from the lake surface, forming a local thermal circulation. (4) There was a good positive correlation between lightning frequency in the Poyang Lake area and the lake monthly evaporation. The vigorous times during which the latent heat of the lake releases was also the frequent times of convective clouds and their adjoint lightning activities. This was due to the release of the lake latent heat, which affected the energy balance of convective clouds transited and water vapor balance, by the exchange between energy and water vapor, to promote the development of strong convective clouds, the intensity and frequency of lightning activities exacerbated indirectly. (5) The vertical perturbation of the Poyang Lake area on the mesoscale convective weather systems transited led to instability of its energy and produced severe weather, such as thunder and strong convection.

## 1 INTRODUCTION

### 1.1 Study area

The studied area in this paper was the Poyang Lake (28°22′~29°45′N, 115°47′~116°45′E). Poyang Lake

is located in the northern part of Jiangxi Province (the southern bank of the Yangtze River). The terrain is shown in [Figure 1](#), where the north region is the entrance of the Yangtze Rive, which is narrow. The south region is the lake's main body, which is

Figure 1. Geography location of the Poyang Lake by satellite remote sensing.

Figure 2. Monthly distribution of the lightning frequency in 2006–2008.

broad. According to the satellite remote sensing measurement, the largest area of the lake in a large water period was 5100 km<sup>2</sup>.

### 1.2 Data source

The data used in this paper were provided by the Jiangxi Provincial Institute of Meteorological Science from 2006 to 2008 on lightning location system data and image data from the observation data of Poyang Lake meteorological satellite Fengyun Fy2-c. The heat flux data used were calculated by Min Qian (2006) through the water surface evaporation climatology model of experimental data.

Figure 3. Daily variation of the lightning frequency in 2006–2008.

## 2 SEASONAL AND TIME OF ANNULUS POYANG LAKE CONVECTIVE CLOUDS AND LIGHTNING OCCURRENCE

The monthly distribution of Jiangxi ground lightning (Fig. 2 Y-label used the logarithmic coordinate) showed that the Jiangxi Province was a thunderstorm area. Thunderstorms occurred mainly from July to August. The second was from April to May and September. In January and December, lightning appeared rarely. The thunderstorm activity frequently occurring time (Fig. 3 Y-label used the logarithmic coordinate) was mainly concentrated from 12:00 to 22:00, especially from 13:00 to 19:00, there appeared more thunderstorms. Ring thunder occurred in the Poyang Lake region, which was in line with the trend of Jiangxi. The difference was that Jiangxi lightning frequency changed greatly in the afternoon, and the lightning frequency around the Poyang Lake area distributed symmetrically, with no obvious change. The reason for this can be attributed to the difference in the underlying surface, as a result of which the land surface-underlying surface was very different (e.g. forests, mountains or

hills), while the water surface-underlying surface is relatively homogeneous.

## 3 SPATIAL DISTRIBUTION OF THE RING POYANG LAKE

Through analyzing the data on the average number of lightning (2006–2008), it showed that around the Poyang Lake during the afternoon (12:00–14:00) lightning mainly occurred in the west coast region of the lake (Figs. 4a and 4b shading). The second occurred in the central region of the area. While during 14:00–20:00, it occurred mainly in the south region (Figs. 5a, 5b, 6a and 6b shading).

Such distribution patterns may be related to the topography distribution of the Poyang Lake and the local circulation of lake-land wind. In addition, they may be closely related to the moving path of mesoscale convective weather systems. For example,

Figure 4a. Lightning distribution at 12:00–13:00.  
Figure 4b. Lightning distribution at 13:00–14:00.

Figure 5a. Lightning distribution at 14:00–15:00.  
Figure 5b. Lightning distribution at 15:00–16:00.

Figure 6a. Lightning distribution at 16:00–17:00.  
Figure 6b. Lightning distribution at 17:00–18:00.

Figure 7a. Lightning distribution in June 24–27, 2006.  
Figure 7b. Lightning distribution in June 24, 2007.

in June 24–27, 2006 and in June 24–25, 2007, the strong convective weather occurred with a strong thunder process (Fig. 7a and Fig. 7b shaded part).

#### 4 THE LATENT HEAT RELEASE OF THE POYANG LAKE INFLUENCE NEAR CONVECTIVE CLOUD AND LIGHTNING

The method used herein was that of Qian Min (2006): through the water evaporation, the climatology model can be calculated as follows:

Figure 8. Mean monthly evaporation at the Poyang Lake in 1955–2004.

$$E = 2.33 B \times (1 - f \times r) \exp(0.06782T) \quad (1)$$

where  $E$  is the monthly average water evaporation (MM);  $B$  is the number of days per month (28, 29, 30, 31);  $R$  is the monthly average relative humidity; and  $T$  is the monthly average temperature ( $^{\circ}\text{C}$ ).

Based on the calculation, the result is shown in Figure 8 (the unit in the Y-label is mm). Compared with Figure 3, we can see that there is a positive correlation between the average monthly number of lightning ring at the Poyang Lake and the monthly average evaporation. From July to September, it was the most large evaporation, especially in August. Correspondingly, it was also the most frequent lightning activity period. In other words, the latent heat release active period of the lake was also the activity period of lightning and the convective cloud. This was because the release of latent heat for the lake water body affected the transit energy balance of the convective cloud and moisture. Through the exchange of energy and water vapor, it prompted strong convective cloud development. This indirectly contributed to the intensity and frequency of lightning activity.

#### 5 CONCLUSIONS

From the above discussion, the following conclusions can be made:

(1) The characteristics of the temporal distribution of lightning activities in the Poyang Lake region: lightning activities were mainly in the late spring to early autumn, mostly in summer, while the frequency of lightning activities was mainly at 12:00–22:00, in particular, focusing at 13:00–19:00. Lightning incidence trend around the Poyang Lake area was in accordance with that in Jiangxi Province. The difference was that the Jiangxi lightning

frequency changed greatly in the afternoon, and the lightning frequency around the Poyang Lake area distributed symmetrically, with no obvious change. The reason for this can be attributed to the difference in the underlying surface, as a result of which the land surface-underlying surface was very different (e.g. forests, mountains or hills), while the water surface-underlying surface was relatively homogeneous. (2) The spatial distribution characteristics of lightning activities around the Poyang Lake region: within 12:00–14:00, lightning occurred mainly in the West Bank region of the lake, followed by the central area of the Eastern bank region, within 14:00–20:00, occurred mainly in the southern area of the lake. Such distribution patterns may be related to the topography distribution of the Poyang Lake and the local circulation of lake-land wind. In addition, they may be closely related to the moving path of mesoscale convective weather systems. (3) When mesoscale convective system moved to the Poyang Lake, the moving speed slowed down. This was due to the surface heating by solar radiation during the day, with terrestrial heating up being much faster than that of the lake surface. Compared with land, the Poyang Lake was a cold source. Because of heat expansion, the land-based air group went up and converged, under the action of the horizontal pressure gradient force, the air flew over the lake from the sky over land, then sank to the lake, and finally it flew over the land from the lake surface, forming a local thermal circulation. (4) There was a good positive correlation between lightning frequency in the Poyang Lake area and the lake monthly evaporation. The vigorous times during which the latent heat of the lake releases were also the frequent times of convective clouds and their adjoint lightning activities. This was due to the release of the lake latent heat, which affected the energy balance of convective clouds transited and water vapor

balance, by the exchange between energy and water vapor, to promote the development of strong convective clouds, the intensity and frequency of lightning activities exacerbated indirectly. (5) The vertical perturbation of the Poyang Lake area on the mesoscale convective weather systems transited led to instability of its energy and produced severe weather such as thunder and strong convection.
