Mild cases of piriform aperture stenosis can be successfully managed with careful observation, nasal steroids, and the suctioning of secretions with a bulb syringe. Babies who have the mildest cases of stenosis should be followed expectantly for growth of the piriform aperture.

Children who have considerable respiratory distress will usually benefit from surgical enlargement of the piriform aperture with removal of the obstructing bone. This is accomplished via a sublabial degloving approach with elevation of the piriform

aperture periosteum and careful drilling of the bone. The nasal opening is then stented to reapproximate the periosteum to the bone.

Prognosis

The prognosis is favorable for children who have mild piriform stenosis treated with conservative measures of saline lavage and frequent suctioning. In those babies undergoing surgical enlargement of the piriform aperture for severe symptoms, the prognosis depends upon the degree to which the stenosis can be enlarged. Children should be followed for growth and the maintained relief of nasal obstruction for at least 1 to 2 years.

67.3.3 Rare Congenital Nasal Anomalies

Derangements in embryologic formation of the nose can result in various abnormalities of the nasal structure. These conditions are rare and infrequently reported in the medical literature, but they can be highly alarming to the baby's parents.

Proboscis lateralis is a rare condition in which a tubelike formation either replaces the entire nasal structure (often in association with cyclopia, or single midline eye) or is located to the side of the nose. If the proboscis is on the side, the ipsilateral nostril is often absent or markedly smaller than the contralateral normal nostril (□ Fig. 67.6). The ipsilateral nasal cavity may be smaller than normal, and the attachment point of

Fig. 67.5 Computed tomographic scan demonstrating piriform aperture stenosis (arrows).

Fig. 67.6 (a) Proboscis lateralis with ipsilateral stenotic nostril. (b) After removal of the proboscis and left-sided reconstruction of the nostril with a portion of the proboscis.

Fig. 67.7 Arrhinia with anophthalmia. Note the lack of a nasal opening.

the proboscis may indicate derangement of the tear duct system. Surgical management includes excision of the proboscis, evaluation of the continuity of the tear duct system, and reconstruction of the hypoplastic or absent nostril. These children have an excellent prognosis for appearance and nasal and tear duct function when the nostril and nasal cavity are less severely affected.

Supernumerary nostrils are duplication anomalies of the nose. Although rare, they are easily identified by their characteristic appearance at birth. The extra nostril is often superior to the true nostril and may, but not always, exist in continuity with the true nasal cavity. The treatment is surgical excision of the duplicate nostril; local flaps may be needed to restore normal contour to the perinasal crease.

Arrhinia is an extremely rare congenital condition in which the nose is absent. In this case, there is no nostril or nasal opening, and the nasal cavity is not present or patent. This condition results when the nasal placode fails to canalize during embryologic development. Treatment is aimed at maintaining an adequate airway, and early mouth breathing is mandatory. Surgical construction of an exterior nose is performed in multiple stages, and nasal passages are difficult to construct (□ Fig. 67.7).

67.3.4 Congenital Midline Nasal Masses: Dermoids, Gliomas, and Encephaloceles

Etiology, Pathophysiology, and Pathogenesis

Congenital midline nasal masses are uncommon and comprise a spectrum ranging from dermoid cysts through gliomas to encephaloceles; nasal dermoids are the most common. These masses are caused by errors in the development of the nasal space and are found in 1 per 20,000 to 1 per 40,000 live births. A child with a dermoid, glioma, or encephalocele may present with an external or internal nasal mass. Before nasal development, the foramen caecum of the developing neuropore normally closes by the third week of embryologic development, with ultimate separation of the intracranial and extracranial structures. When the foramen caecum fails to close, a tongue of prolapsing dura may extend into this space and extracranially into the developing nose and septum. If brain tissue is contained within the protruding dura and remains attached to the fully developed brain by a tubelike stalk, an encephalocele is present. When the dura or brain tissue inside the mass is isolated from the brain (85 to 90%) or attached only by a fibrous stalk (10 to 15%) in the region of the foramen caecum, the mass is defined as a glioma (□ Fig. 67.8). Gliomas are most commonly extranasal (up to 60%) and affect males three times as frequently as females. Nasal dermoid cysts are considered to form similarly to gliomas and encephaloceles because the dura is closely approximated to the nasal skin around the time of neuropore closure and foramen caecum closure. It is felt that the proximity of the nasal skin to the dura at this time (approximately the third or fourth week of development) results in some of the skin cells being drawn up into the developing nasal cavity, with resultant formation of the dermoid cyst. Dermoid cysts consist of ectodermal and mesodermal embryonal germ layers, in contrast to teratomas, which also have an endodermal layer and are lined by skin with hair and sebaceous glands. Encephaloceles are often associated with other congenital abnormalities and are seen evenly in males and females.

Nasal Dermoid Cyst

Presenting Symptoms

Dermoid cysts are slowly growing, smooth masses that are firm and do not transilluminate in or around the nasal area. Often, a pore (with or without a tuft of hair) is present on the external skin, which is characteristic of dermoid cysts only. Dermoids are not compressible, nor do they enlarge with crying or Valsalva maneuvers. They are found anywhere from the glabella to the nasal tip, as well as intranasally or within the septum. Because of the unique embryologic development of dermoid cysts, there can be a fibrous connection intracranially through a patent foramen caecum. There may be deformation and lateral splaying of the nasal bones, depending upon the location of the cystic portion of the dermoid (□ Fig. 67.9a and □ Table 67.2). Intra-nasal dermoids may present with nasal congestion and/or nasal obstruction. There may be widening of the nasal septum if the cyst is within the septal cartilage. When the mass is relatively small, the lesion may not be identified until the patient is older.

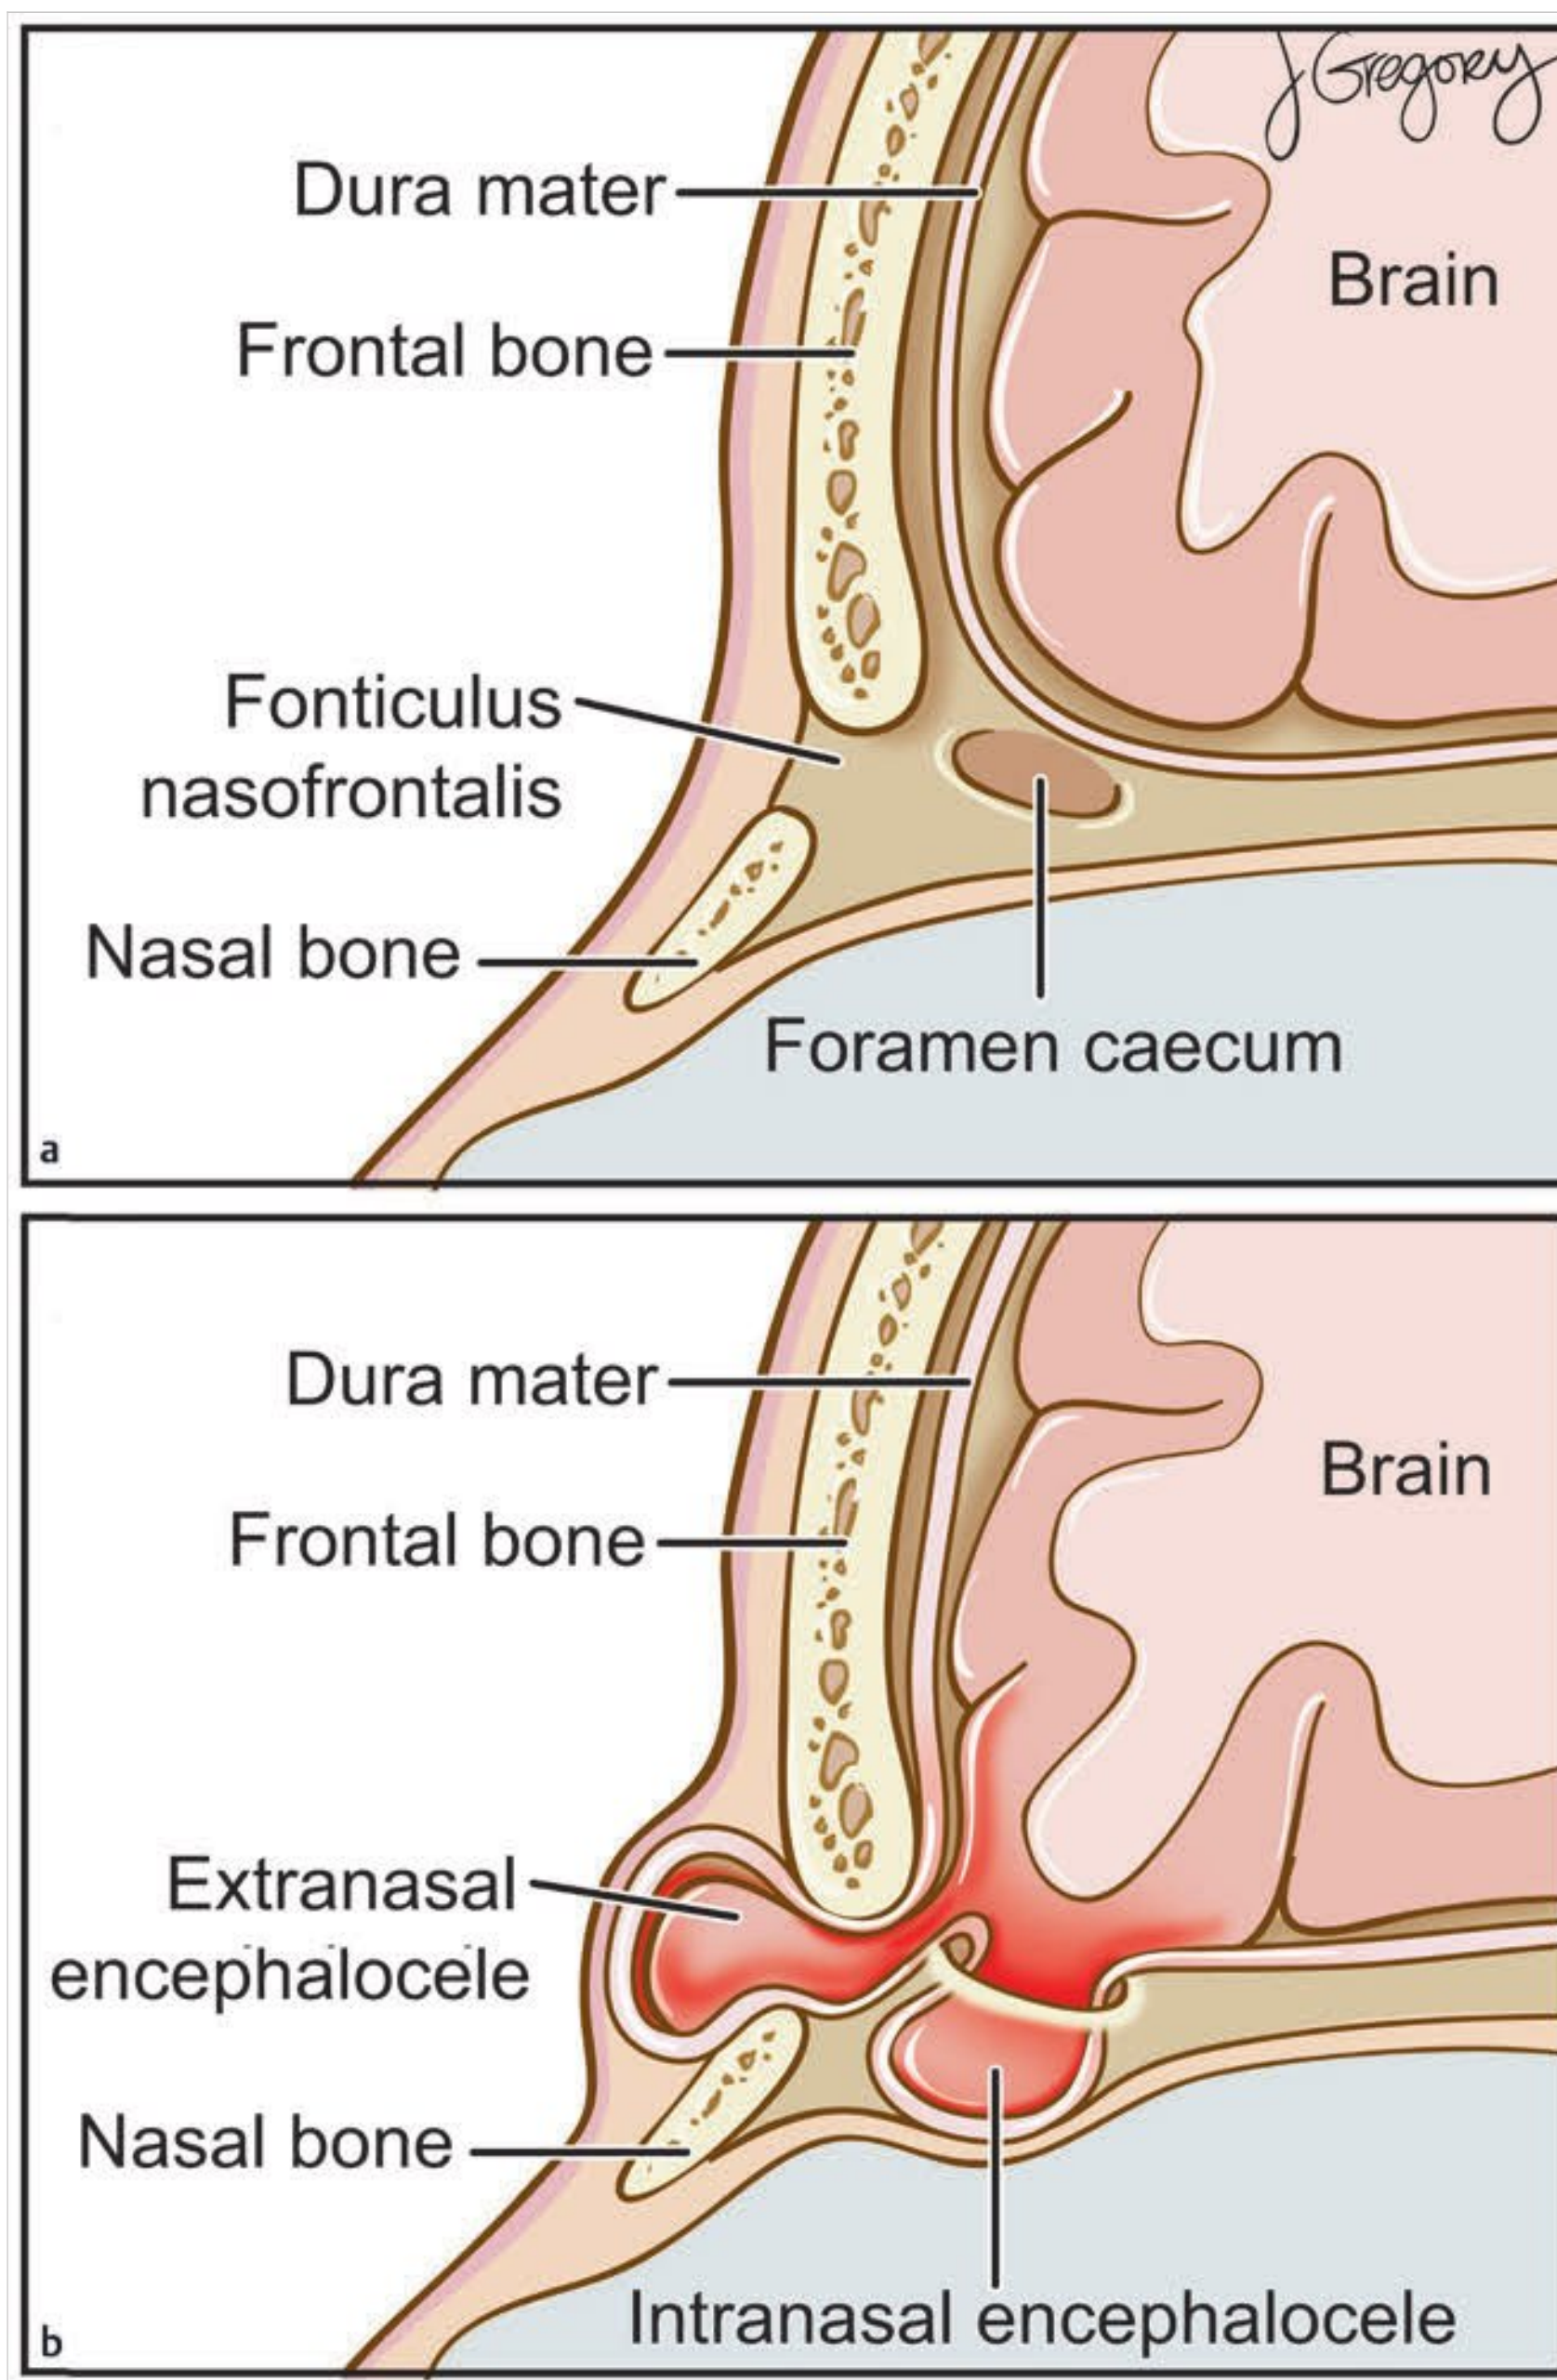

Fig. 67.8 (a) Normal anterior skull base. (b) Anterior skull base and foramen caecum location with encephalocele.

Medical Evaluation and Testing

After the mass is identified, radiographic imaging is obtained. CT in the axial and sagittal planes will not only demonstrate the mass but also delineate the bony confines and surrounding structures. There may be a bifid crista galli or widening of the foramen caecum in the anterior cranial fossa with the suggestion of a possible intracranial communication. Magnetic resonance (MR) imaging is very helpful in determining if a suspected intracranial communication is present and is felt to be more sensitive and specific for this component of the diagnosis; the T1-weighted MR image is hyperintense in dermoid cysts.

Treatment

The treatment for dermoid cysts is complete surgical excision when the lesion is diagnosed. There is a risk for infection in

dermoid cysts, and if infection occurs with rupture of the cyst, complete excision is difficult. Incompletely excised dermoid cysts generally recur, with revision surgery even more complex than primary excision. Usually, an external approach (e.g., direct incision, external rhinoplasty, lateral rhinotomy) is used for lesions external to the nasal bones (□ Fig. 67.9b). Intranasal cysts may require midfacial degloving or endoscopic approaches. Neurosurgical consultation is required for dermoids with intracranial extension, and craniotomy may be necessary for safe, complete removal.

Complications and Prognosis

Dermoid cysts may become infected, making definitive excision more difficult. Spread of infection to the paranasal tissues may occur. A cerebrospinal fluid (CSF) leak may occur in lesions with

Fig. 67.9 (a) Nasal dermoid with hair protruding at midline. (b) Excision of a nasal dermal sinus cyst with the sinus tract passing through the nasal bones.

intracranial communication. Late complications include scars from external approaches, loss of septal cartilage integrity with saddle nose deformity, and cosmetic complications when the nasal bones are affected. The prognosis is excellent when the dermoid is completely excised.

Glioma

Presenting Symptoms

Gliomas present as external masses in the glabella region (about 60% of all gliomas) but may occur anywhere within or around the nasal region. When they are external, they are firm, nontender, and noncompressible masses. They do not transilluminate, and if close to the skin surface, they may have a purplish discoloration. Gliomas are usually diagnosed at birth when external, but the diagnosis of intranasal gliomas may be delayed. Symptoms of intranasal gliomas include nasal congestion, nasal obstruction, and stertorous snoring. Hypertelorism and splaying of the nasal bones occur with larger lesions.

Intranasal examination may reveal a mass high in the nasal cavity by the septum or emanating from the lateral nasal wall. The mucosa-covered mass usually will be smooth and firm to palpation.

Diagnostic Testing

The presence of an intranasal mass requires radiologic evaluation. MR imaging is the most specific and sensitive study. MR imaging can determine whether there is an intracranial stalk communication and helps to differentiate glioma from encephalocele. Gliomas are hyperintense on T2-weighted images; on T1-weighted images, they are variable in intensity. CT is complementary to MR imaging. Gliomas are isodense on CT. CT reveals important relationships to the intranasal anatomy and is useful for surgical planning (□ Fig. 67.10).

Treatment

Once a glioma is diagnosed, consultation with a pediatric neurosurgeon is recommended because of the risk for intracranial

Table 67.2 Comparison of findings in congenital midline nasal masses

	Dermoid	Glioma	Encephalocele
Age at diagnosis	Infants and children	Infants and children	Infants and children
Location of mass	Intranasal+extranasal	Intranasal+extranasal	Intranasal+extranasal
Cranial defect	Rare	Up to 15%	All
Pulsation	No	No	Yes
Transillumination	No	No	Yes
Appearance	Firm ± pore or hair	Purplish, firm, smooth	Purplish, soft
Compressibility	No	No	Yes
Cerebrospinal fluid connection	Rare	Rarely	Yes
Possible infection	Local infection	Possible meningitis	Meningitis

Fig. 67.10 Intranasal glioma on T2-weighted magnetic resonance image.

communication. Biopsy for diagnosis is not advised because of the risk for infection and the creation of a CSF leak if there is an intracranial communication. Surgical treatment is recommended with complete excision. External lesions may be removed in a manner similar to that used for nasal dermoids. Intranasal gliomas without intracranial extension may be removed endoscopically with or without a combined neurosurgical craniotomy for total resection. This may be accomplished in a single stage or in two procedures. Endoscopic techniques have evolved recently, and the use of intraoperative stereotactic image guidance systems increases the likelihood of complete excision (including gliomas with intracranial communication) and repair of the anterior cranial fossa defect.

Complications and Prognosis

Excision of a glioma carries a specific risk for CSF leak, particularly when an intracranial communication has not been anticipated. Endoscopic removal of the glioma increases the risk for CSF leak and fistula, which must be repaired as soon as it is discovered.

The prognosis is excellent with complete removal of the glioma, regardless of the resection technique. Recurrence rates are very low (<10%), even if the lesion is incompletely removed.

Encephaloceles

Presenting Symptoms

Most encephaloceles, like gliomas, are diagnosed at or soon after birth, particularly when they are extranasal. Because encephaloceles contain brain tissue and CSF, they are compressible masses that readily transilluminate. They are smooth, slightly firm masses within or around the region of the nose. When intranasal, they tend to cause symptoms of nasal congestion, nasal obstruction, or stertor. Other physical findings may include hypertelorism and splaying of the nasal bones, similar to that seen in gliomas.

Diagnostic Testing

MR imaging and CT are recommended for reasons similar to those for gliomas. The foramen caecum is patent with a variably sized defect in the anterior skull base on CT scans. The MR image may show brain, meninges, or dura within the mass and intracranial communication. The MR image will demonstrate CSF within the mass and connecting stalk, which can help to distinguish an encephalocele from a glioma (□ Fig. 67.11).

Fig. 67.11 Magnetic resonance image demonstrating brain tissue in a nasal encephalocele.

Treatment

The treatment options are similar to those for glioma. Biopsy for diagnosis is not performed on encephaloceles, for reasons similar to those for glioma. The need for neurosurgical consultation and collaboration is increased in cases of larger encephaloceles. Endoscopic management is possible for smaller masses, with the expectation of performing CSF and anterior cranial floor repairs.

Complications and Prognosis

The prognosis is excellent when a careful resection is planned and performed. The correction of associated deformities, such

as hypertelorism, is often planned concurrently with the resection or as a later, staged procedure.

67.4 Epistaxis

67.4.1 Anatomy

The nose and nasal area have a rich blood supply from both the external and internal carotid arteries. The main arterial supply to the nose and septum comes from branches of the anterior and posterior ethmoidal arteries (superior), sphenopalatine artery (posterior), and greater palatine and superior labial arteries

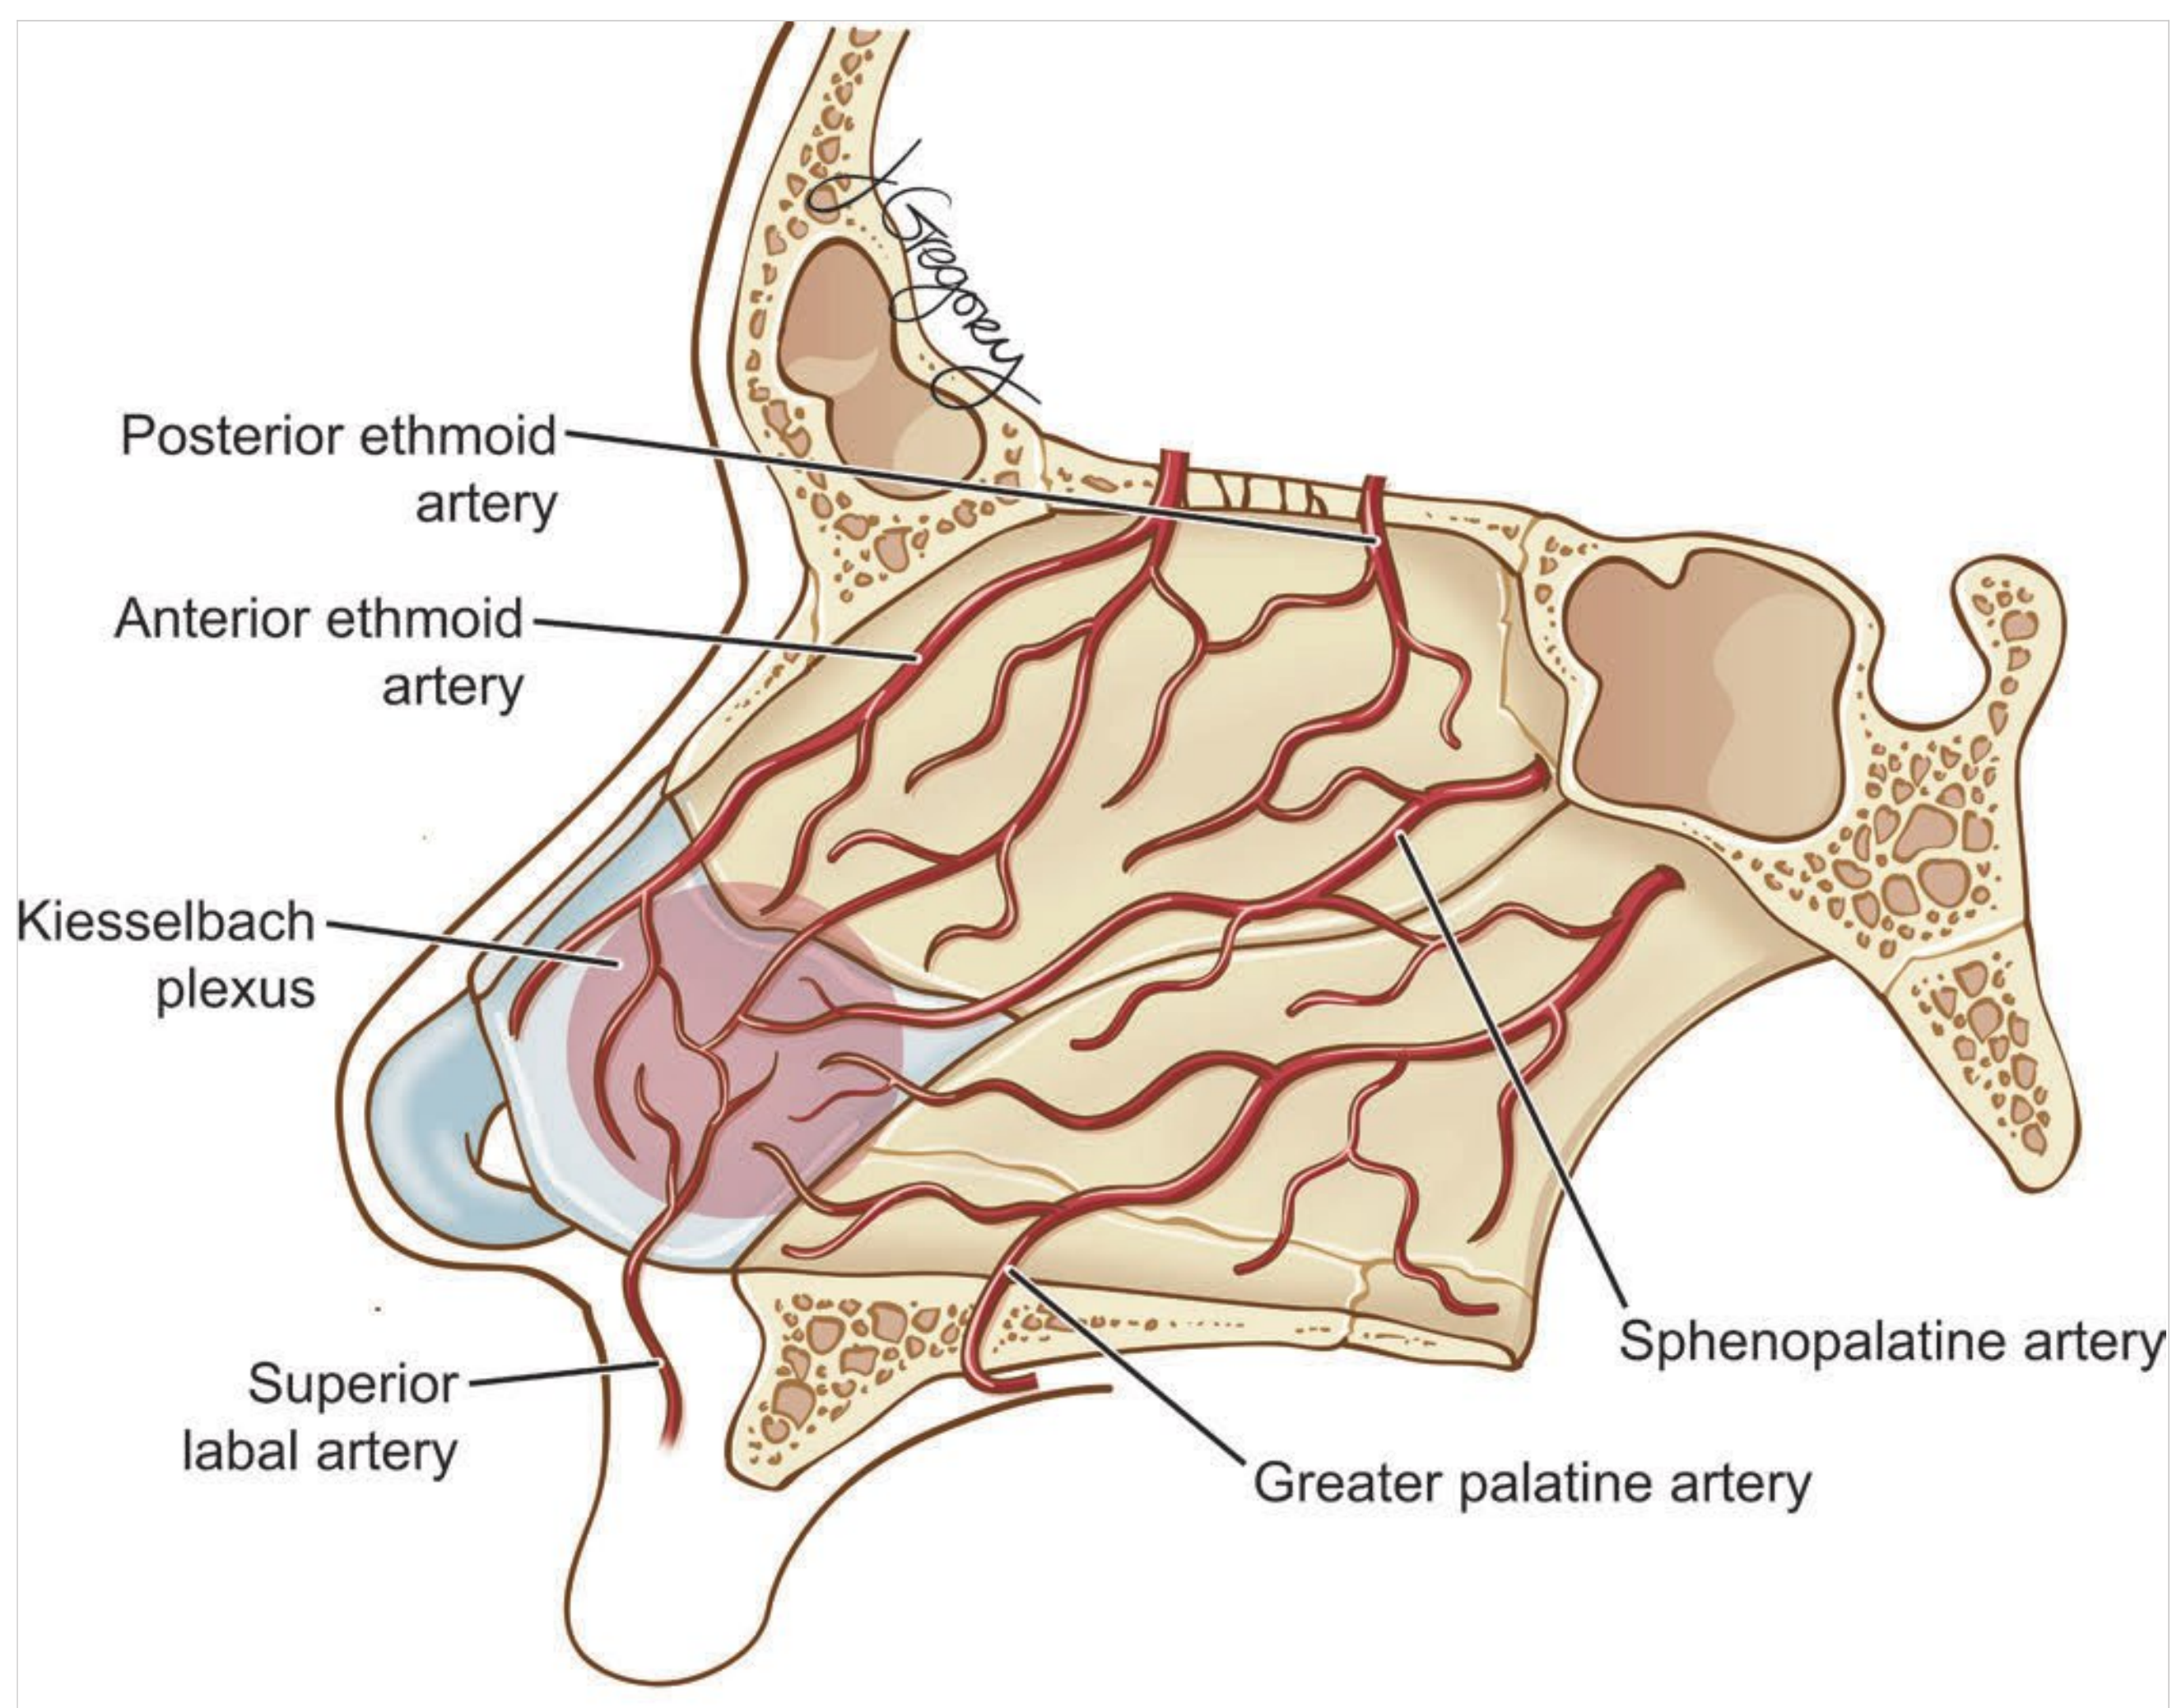

Fig. 67.12 Nasal septal vessels forming the Kiesselbach plexus.

(inferior). The anterior and posterior ethmoidal arteries are branches of the ophthalmic artery, an intracranial branch of the internal carotid artery. The sphenopalatine artery and the greater palatine artery are end branches of the internal maxillary artery, one of the main branches of the external carotid artery. The internal maxillary artery and its branches also supply the sinuses and lateral nasal wall. The greater palatine artery is a sub-branch of the internal maxillary artery and supplies the inferior septum and nasal floor. The superior labial artery is a sub-branch of the facial artery and supplies the anterior nasal floor and anterior septum. A rich vascular plexus, the Kiesselbach plexus, is formed from contributions of these arteries, particularly in the anterior septum (□ Fig. 67.12). The Kiesselbach plexus is the most common location for epistaxis in young children because of its location in the anterior septal region and highly vascular nature.

67.4.2 Etiology and Pathogenesis

There are myriad causes of epistaxis in children. Common causes of epistaxis include trauma, abnormal airflow through the nose, dry air, and inflammation. Trauma to the delicate anterior nasal septal mucosa, especially if it is already inflamed, is

the most common cause. Trauma to the nasal mucosa can be digital trauma (“nose picking”), direct blunt trauma (nasal fracture), or innocent rubbing of the nose. Injury to the mucosal integrity leads to excoriation and thinning of the mucosal surface over the blood vessels.

Inflammation plays a significant role in epistaxis in children. Children are predisposed to viral upper respiratory infections with associated nasal secretions. They are more likely to develop secondary bacterial infections of the nostril skin and nasal mucosa, which may increase the vascularity of the nasal tissues. The risk for epistaxis increases when infection is accompanied by drying of the mucus and crusting at the anterior septum and nares, compounded by digital trauma.

Abnormalities of airflow through the nose, often due to various types of nasal obstruction, may cause inflammatory changes to the mucosa of the nasal cavity, with increased vascularity. In addition, the nose serves to humidify the ambient air during respiration. When the humidity of the air is excessively low (in certain geographic regions, during the winter, or in heated environments), the mucosa will dry (especially in the anterior septal area), increasing the risk for microfissures and cracks, which result in epistaxis.

Children with tumors or systemic conditions may be at increased risk for epistaxis. Any medical condition resulting in a coagulation abnormality (e.g., hemophilia, von Willebrand disease) or thrombocytopenia (e.g., idiopathic thrombocytopenia, complications of chemotherapy, initial presentation of certain leukemias), as well as certain medications (e.g., aspirin, nonsteroidal anti-inflammatory drugs), can result in epistaxis that may be difficult to control.

67.4.3 Presenting Symptoms and Examination

Although epistaxis can be a life-threatening condition in children, most cases are mild episodes of bleeding from one or both nostrils. Most children seen in a medical office will present with a history of repetitive episodes of nose bleeding. The duration and frequency of the episodes should be determined. In girls and prepubescent boys, the most common finding on anterior rhinoscopy is multiple visible blood vessels on the anterior septum and nasal floor or shallow excoriations in this area. Care must be taken to evaluate the entire nasal cavity to exclude intranasal masses, especially in postpubescent boys, because juvenile angiofibroma may be a cause in this group.

67.4.4 Treatment

The treatment of epistaxis in children depends upon whether the child is actively bleeding at the time of evaluation. When the child is actively bleeding, the situation is more urgent, and the severity of bleeding and degree of blood loss must be rapidly determined and measures taken to halt the epistaxis. Maintaining a calm composure while dealing with the child and parents is essential to control a nosebleed, and if a child is unable to cooperate, restraints may be required.

If the nose contains blood and clots on first inspection, either having the child blow the nose or applying gentle suction is necessary. The nose is then inspected, either with an otoscope or with a nasal speculum and headlight. The nasal cavity is sprayed with a decongestant (either oxymetazoline or phenylephrine) and a topical anesthetic (usually 4% lidocaine). Often, the decongestant will stop the nosebleed. The nasal and septal mucosa is inspected for the bleeding site, and if it is identified, it may be cauterized (with silver nitrate or electrocautery), or a gelatin hemostatic sponge may be placed at the intranasal site. Antibiotic ointment should be placed on the site and may be used as the only treatment in mild epistaxis with efficacy similar to that of cautery.

More severe nosebleeds may require intranasal packing. Common materials include hemostatic balloons (although they are often too large for most young children), nasal packing with hemostatic agents (such as gelatin collagen sponges or other, similar dissolvable materials), or standard strip gauze packing. In some cases, general anesthesia may be required to evaluate and control severe epistaxis in children. The use of dissolvable agents is preferred in children whenever possible. A search for the cause of the epistaxis must be made, with correction of those underlying factors to reduce future episodes of epistaxis. Any clotting disorder (hemophilia, von Willebrand disease) or thrombocytopenia must be corrected in severe epistaxis for the maintenance of hemostasis.

67.4.5 Complications of Treatment

Complications from the management of epistaxis are uncommon when certain precautions are taken. Nasal packing, particularly with strip gauze, is a known risk factor for the development of toxic shock syndrome. Toxic shock syndrome is a severe, life-threatening condition resulting from toxin produced by *Staphylococcus aureus* or *Streptococcus pyogenes* superinfection in the nasal packing material. Toxic shock syndrome consists of high fever (over 39°C), hypotension, a diffuse erythematous rash with desquamation, and severe organ system involvement. Although the risk for toxic shock syndrome cannot be eliminated, it is substantially reduced by the use of systemic antibiotics while nasal packing is in place.

Nasal septal perforation is a complication of extensive bilateral septal mucosal cauterization. This complication is reduced by limiting cauterization to one side of the septum with interval treatment of the opposite side. In many cases of bilateral bleeding from nasal septal vessels, treatment of the worse side may result in improvement in the opposite side, decreasing the need for treatment of the second side.

67.4.6 Prognosis

Children with epistaxis have an excellent prognosis, especially those with mild cases. Recurrent epistaxis can usually be substantially decreased with a reduction of the conditions resulting in digital trauma, an increase in humidification, and the use of daily topical antibiotic ointments. Patients whose epistaxis does not improve should undergo hematologic evaluation for a bleeding or clotting disorder. The control of underlying conditions is essential to reduce the impact of epistaxis in this group of patients.

67.5 Foreign Bodies in the Nose

67.5.1 Etiology and Pathogenesis

Children are prone to explore their bodies and will often place foreign objects into their nose or ears. The most common pathway children use to introduce foreign objects into their nose is via the nares, although foreign bodies may enter the nasal cavity via the nasopharynx and choanae. After the foreign body is placed into the nasal passage, it is unusual for children to complain about the discomfort the foreign body causes. Most foreign body insertions are not witnessed by caregivers.

67.5.2 Presenting Symptoms and Examination

Unless someone has seen the child place a foreign body into the nose or the child admits the act to a caregiver, the child will present with symptoms or complications caused by the presence of a foreign body in the nose. The nasal complaint will usually be unilateral (more rarely bilateral) chronic nasal discharge lasting days to weeks or longer. The nasal discharge is a direct effect of the foreign body on the nasal mucosa and possible obstruction of the nasal cavity by the foreign body.

The nasal examination will usually show thick mucus or mucopurulent discharge in the affected side of the nose, which may prevent the foreign body from being initially visualized. The unaffected side is usually normal in appearance. After the mucus has been suctioned, the foreign body is usually seen lodged between the septum and turbinates in the anterior or middle region of the nasal cavity. The mucous membrane may exhibit marked inflammation and irritation, with easy bleeding in the area of the object. Disc batteries are readily available in toys and common household objects that are accessible to children, and special attention and intervention are required if these are suspected as foreign bodies. When moistened with nasal secretions (electrolyte-containing fluids), the disc battery will begin to leak and cause a severe chemical burn to the nasal mucosa. The child will complain of severe pain, and nasal discharge will begin much sooner than with other foreign bodies. Disc batteries placed in the nose should be treated as an urgent matter.

67.5.3 Diagnostic Testing

Clinical examination is usually all that is needed to detect the vast majority of foreign bodies found in children's noses. If a foreign body is seen on a radiograph, it is usually an incidental finding on sinus series films or lateral neck films, such as those obtained for the evaluation of sinusitis or adenoid size.

67.5.4 Treatment

Most foreign bodies found in a child's nose can be removed safely in the office with the proper equipment and restraint of the child. Although older children may tolerate removal of a foreign body from the nose under topical anesthesia, younger children rarely are willing to cooperate. Proper restraint of the child is essential to safe removal. Often, a papoose board is needed to control the child during the treatment. The first attempt to remove a nasal foreign body is the one most likely to succeed, and the otolaryngologist is the health provider most likely to succeed.

After topical anesthesia and decongestion of the nasal cavity, a headlight or the microscope can be used to illuminate the nasal cavity. Using a nasal speculum and an appropriate tool, such as a Hartmann or bayonet forceps, right angle hook, or curved wire loop, the physician grasps the object or places the instrument behind the object. The object is then pulled forward and out of the nostril. The nasal mucosa is reinspected following the extraction. Care is taken to note any injuries to the mucosa caused by the foreign body or the removal, and care should be taken to ensure that only one foreign body was in the nose. Minor injuries to the mucosa can be expected to heal completely.

If the foreign body is a disc battery, it is most likely to have already leaked, causing a chemical burn of the nasal mucosa. Disc batteries can cause a direct septal perforation. If septal perforation has occurred, it is recommended to flush the area with saline to dilute the battery alkaline contents and cleanse the mucosa. Following foreign body removal, care of the nose includes the use of saline sprays and rinses.

67.5.5 Complications and Prognosis

Foreign body removal is usually successful as an office procedure; however, some children have been so traumatized by

prior attempts that it is impossible to remove the foreign body without general anesthesia. Arrangements should be made to remove the foreign body as soon as possible, with NPO (nil per os) status and type of foreign body in mind. The removal of chronic foreign bodies, except for disc batteries, can wait until appropriate NPO status is possible.

Children, after successful removal of an intranasal foreign body, have an excellent prognosis. Although most foreign bodies do not cause sequelae, some foreign bodies can result in stenosis, synechiae, or perforation of the nasal septum. Saddle nose deformity may result if the septal cartilage has been damaged.

67.6 Nasal Trauma in Children

67.6.1 Etiology

Accidental nasal trauma frequently occurs in active young children during play and sports. Most commonly, there is minimal to mild swelling of the nasal soft tissues with possible self-limited epistaxis. When there is significant impact to the nose, nasal bones, or midface, the pediatric skeleton is unable to absorb the impact, and fracture of the affected area may occur.

67.6.2 Pathogenesis

The pediatric facial skeleton is capable of absorbing minor impacts because of the flexibility and somewhat elastic nature of the developing bones. The central facial area is prone to impact, especially the nasal area. The thin nasal bones are particularly at risk for injury from trauma, especially the inferior and lateral aspects of the nasal bones. Direct impact can result in fracture of the bone or cartilage of the nasal septum, as in the adult. However, in the younger child, the cartilage and bone are more pliable and elastic, and so are more likely to flex than to fracture. As children age into their teens, the nasal structures lose these elastic properties and become more prone to fracture, as in the adult.

67.6.3 Presenting Symptoms

Children with facial trauma present soon after the injury. The history must include the details of the incident and the mechanism of injury, as well as the presence of epistaxis or new nasal obstruction. An examination performed immediately after the injury may reveal the presence or absence of a deformation of the nasal bones; however, most patients present with moderate to severe facial soft-tissue edema, precluding an assessment of nasal bone displacement. Intranasal examination is very important, with particular attention to the septum. Complaints of nasal obstruction, combined with swelling of the septal mucosa (unilateral or bilateral) that is soft and compressible, are compatible with a septal hematoma, a relative emergency. The patient must be evaluated for possible associated ocular or orbital injuries, and ophthalmic consultation should be promptly obtained if indicated.

The examination should be repeated about 5 or 6 days after the injury if there is a question of nasal bone fracture. The delayed examination allows time for a reduction of perinasal edema and an easier assessment of displacement of the nasal

bones. Periorbital ecchymosis may be seen days after the injury when a nasal fracture has occurred.

67.6.4 Diagnostic Testing

Clinical examination is usually all that is needed to make a diagnosis of nasal bone fracture and/or septal hematoma. Nasal bone radiographs are unlikely to provide information beyond what a careful evaluation of the position, symmetry, and contour of the nasal region will yield. In older children with prior episodes of nasal trauma, it may be difficult to differentiate current findings from prior injuries. When adjacent trauma is present, CT is recommended to evaluate the orbit or maxilla for associated fracture or trauma.

67.6.5 Treatment

Nasal fractures are usually treated with closed nasal bone reduction under local or general anesthesia. The optimal time for reduction of a nasal fracture in children is between 5 and 8 days. Children heal much more quickly than adults, and a fixation of the malpositioned fracture will develop in just a few days, so that the timing of treatment is more urgent in children. Septal hematoma requires urgent treatment with either aspiration or incision and drainage with packing as soon as the diagnosis is made to prevent the formation of a septal abscess or the late complications of septal cartilage loss and saddle nose deformity.

Closed nasal bone reduction in children is commonly performed with general anesthesia because of patient anxiety. The nasal cavity is prepared with the application of a topical decongestant (oxymetazoline) on cottonoid pledgets. The Goldman elevator is typically used to disimpact, elevate, and mobilize the displaced nasal bone. First, pressure is applied in the direction of the displaced bone, and the elevator is then used to elevate and replace the bone into the proper position. Finger pressure is applied to assist in the use of the elevator. When the procedure is successfully performed, the surgeon can often feel the displaced bone “pop” into its normal position. The symmetry of the nose should be evaluated from the frontal and bird’s-eye position. A splint is applied for 5 to 7 days; in children, intranasal packing is rarely needed.

67.6.6 Complications

The main risk of nasal fracture and its treatment is unsuccessful reduction. If the displaced bone cannot be reduced, too much time may have elapsed between the injury and fracture reduction. Often, this is due to patient delay in seeking treatment. Inadequate fracture reduction may be the result of a greenstick type of fracture, with slow relapse of the bone to its pretreatment position. In addition to the nasal bone, the septum may sustain a fracture or become deviated, with resultant nasal obstruction.

When closed nasal reduction is unsuccessful, formal rhinoplasty can be considered once the child has achieved facial maturity. This is generally around the age of 15 to 16 years in girls, and 16 to 17 years in boys. Extensive nasal surgery, especially septal surgery, in younger children risks injury to the nasoseptal growth center, and midfacial and nasal growth

deficiencies may result. As previously mentioned, untreated septal hematoma may progress to septal abscess. The organisms most commonly encountered are *Staphylococcus* species. Septal hematoma or abscess may result in septal cartilage destruction and ultimate saddle nose deformity.

67.6.7 Prognosis

Most children who sustain a nasal fracture will have an excellent prognosis after prompt medical treatment. Successful closed nasal reduction is expected to restore the patient’s preinjury cosmetic appearance. However, unrecognized and untreated septal trauma, when present, may become noticeable only as the child matures and a deviated cartilaginous dorsum becomes apparent. When treatment is delayed or unsuccessful, later rhinoplasty in the late teen years has an excellent outcome.

67.7 Nasal Obstruction

Nasal obstruction can be difficult to diagnose in children. Children do not usually reliably complain of an inability to breathe through the nose, and therefore other associated symptoms and signs must be considered to make the diagnosis of nasal obstruction. Nasal obstruction itself is a symptom of other conditions that may originate within the nose or in the nasopharynx. Symptoms of chronic mouth breathing, snoring, chronic runny nose, and a decreased sense of smell all indicate possible nasal obstruction and are important components of the medical history.

67.8 Rhinorrhea

67.8.1 Etiology

Rhinorrhea is frequent in childhood. It is a nonspecific state caused by many conditions affecting the nose, including foreign bodies and allergic, infectious, inflammatory, and obstructing conditions. The nose responds to various insults by increasing its output of nasal secretions. When the volume of the nasal secretions is increased over basal rates, rhinorrhea is seen. Rhinorrhea may occur as a unilateral or bilateral problem, be episodic or constant, and have an acute or a gradual onset.

67.8.2 Infectious Rhinitis

Viral Infection

Viral upper respiratory infections occur frequently in children and are the most common reason for health care visits in children. Until the age of 6 years, children have between six and 10 viral upper respiratory infections per year on average, with each lasting between 10 and 14 days. Although the upper respiratory infection may have resolved, some of the symptoms, such as cough, may persist for several more weeks. The viruses frequently implicated include rhinovirus, adenovirus, coxsackieviruses A and B, respiratory syncytial virus, and influenza viruses. Respiratory syncytial virus is an important cause of severe respiratory illness in children, especially children younger than 12 months of age, and premature children. Children in day

care environments are known to be at increased risk for acquiring viral infections and have more upper respiratory infections. Rhinorrhea is seen in the prodromal stage in many viral infections, including measles, mumps, rubella, and roseola.

67.9 Treatment of Viral Infections

The treatment of viral nasal infections is symptomatic and aimed at reducing the impact of congestion and nasal obstruction. Nasal decongestants may be carefully used in the most severe cases. Nasal saline sprays and irrigations with frequent suctioning (with bulb syringe) are helpful in the youngest children and may reduce the possibility of bacterial superinfection.

67.9.1 Bacterial Infection

Bacterial infections of the nose are frequently seen in children and may result as a secondary infection after an upper respiratory infection. They are noted when discolored nasal discharge persists longer than 10 to 14 days or is associated with high fever or worsening symptoms of the upper respiratory infection. Purulent nasal discharge frequently may be caused by *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pneumoniae*, and other species of *Streptococcus* and *Staphylococcus*. Bacterial infection in the nose causes mucosal edema (particularly in the turbinates), a foul smell, halitosis, postnasal drip, and nasal obstruction.

Persistent nasal discharge lingering past the time when the symptoms of an upper respiratory infection should have resolved should be considered a bacterial suprainfection. It is recommended that cultures be obtained for long-standing nasal discharge and antibiotic therapy selected based upon the organism or proven sensitivities. Pending the culture results, antibiotic treatment with a β -lactamase-resistant or augmented penicillin, macrolide, or (usually second-generation) cephalosporin may be initiated; this can be adjusted, if necessary, based on the culture reports.

Rhinitis neonatorum is a bacterial nasal infection of infants. This condition deserves special mention because infants are still usually within the phase of obligate nasal breathing, and this nasal infection may cause considerable respiratory distress. The child usually presents with chronic watery or purulent rhinorrhea of some weeks' duration, nasal congestion, partial or complete nasal obstruction, and snorting or snoring. Some babies will demonstrate retractions, indicating more severe nasal obstruction. Infants are particularly susceptible to bacterial infections of the nose. Although they receive transplacental maternal antiviral antibodies during fetal life, their natural resistance against bacterial pathogens is weaker. Bacteria usually found on culture include *H. influenzae*, *Staphylococcus* species, and *Streptococcus* species, among others. Because of increased antibiotic resistance patterns, the administration of a culture-driven antibiotic for 7 to 14 days is recommended. Symptomatic care, including saline and suctioning, is recommended adjunct treatment.

67.9.2 Complications and Prognosis

Although rhinitis and rhinorrhea are common conditions in childhood, most children are only mildly affected and recover

well from these illnesses. Complications of rhinitis are rare, but untreated and persistent rhinitis may develop into rhinosinusitis with its potential complications.

Allergic Rhinitis

Etiology

Allergic rhinitis is the response of the nasal organ to antigen exposure in a sensitized individual. As in adults, allergic rhinitis in children is usually due to sensitization to an environmental agent or allergen that is present either seasonally (e.g., pollens and grasses) or year-round (e.g., human dust mites, molds, cockroaches, dander).

The allergic individual is not born with an allergic response to an allergen; rather, an allergic reaction develops following one or multiple exposures to the allergen. The nose is frequently affected because of the airborne nature of many potential allergens.

The development of an allergy requires an individual tendency (often familial) to develop the allergy and exposure to the actual allergen. Allergen-sensitized individuals will exhibit allergic symptoms after exposure to that specific allergen. Individuals may be sensitized to a single or multiple unrelated allergens. The most common allergens are pollen from trees, grasses, and other flowering plants; house dust; dander (cat and dog); mold spores; and peanut dust. Children who exhibit atopy, with eczema and asthma, are at the highest risk for allergic rhinitis.

Pathophysiology and Pathogenesis

Allergic rhinitis is a type of immediate hypersensitivity reaction to an allergen and is typically mediated by immunoglobulin E (IgE) antibodies to the allergen. Upon previous exposure to an allergen, the allergic individual produces IgE antibodies to that specific allergen. When the sensitized individual is again exposed to the specific allergen, the allergen combines with IgE antibodies on the cell membranes of mast cells in the submucosa of the nasal mucous membranes. A cascade is initiated that results in degranulation of the mast cells, with a mediator-regulated reaction and histamine release. This immune reaction results in tissue edema due to increased vascular permeability, increased nasal secretions rich with eosinophils, and concomitant congestion and nasal obstruction. Associated symptoms of itching, sneezing, and tearing frequently occur.

Presenting Symptoms, Medical Evaluation, and Testing

The diagnosis of allergic rhinitis is suggested by the symptoms of nasal congestion and obstruction; thin, clear, watery rhinorrhea; itchy nose; and increased sneezing after exposure to specific environmental agents. In some cases (particularly in perennially occurring allergies), the symptoms have been present so consistently and for so long that the patient is unable to identify specific environmental agents.

Examination of the nose will often reveal congestion of the mucosa; clear, watery rhinorrhea; and pale, boggy, bluish turbinates obstructing the nasal cavity. In long-standing cases, the physical examination findings may be less obvious: general

congestion and typical rhinorrhea without significant turbinate pathology.

Collection of the nasal discharge may demonstrate a marked increase in the number of eosinophils on histologic smear. Although helpful by indicating the presence of allergy, eosinophil counts do not assist with identifying the allergen. More commonly used studies to determine specific allergens are serum IgE titers or skin prick (intradermal) testing. RAST (radioallergosorbent testing) is frequently used to identify specific titers, and the results are compared with norms. RAST is often used because it may test for many allergens in one serum sample, provides quantitative data, and carries no risk for the patient. On the other hand, skin prick testing is also an excellent test for allergens, albeit with an increased risk to the patient of an acute reaction. Skin tests are less expensive, available for a large number of potential allergens, and allow the detection of allergic reactions that are not IgE-mediated. The results of skin prick testing are nearly immediately available. Both RAST and intradermal skin testing should be performed after antihistamine drugs have been discontinued for 72 hours.

Treatment

Successful treatment for allergic rhinitis includes (1) elimination of environmental exposure when possible; (2) symptom control with medications (including antihistamines, topical steroids, and nasal decongestants); and (3) immunotherapy. For children afflicted with mild seasonal allergies, control of environmental exposures and pharmacologic therapy are most likely to succeed.

Control of environmental exposures is a critical component of the management of allergic rhinitis. Items likely to initiate allergic attacks, such as carpets, rugs, and stuffed toys in the case of dust mite allergy, must be removed from the environment. The use of HEPA (high-efficiency particulate air) filters on forced central air vents is helpful to reduce the circulation of dust in the home.

The pharmacologic control of allergic rhinitis has been revolutionized in the last 25 years by the development of nonsedating antihistamines (which do not cross the blood–brain barrier) and intranasal topical steroids. Diphenhydramine, a widely used antihistamine, is an excellent allergy medication, but its use is limited by its sedative side effect, as is the use of hydroxyzine. Although it is still used in the treatment of severe allergic reactions, diphenhydramine is not desirable for the treatment of allergy in children because they may be adversely affected by drowsiness.

Newer antihistamines commonly given to children include loratadine, cetirizine, and fexofenadine. These medications have the benefit of being administered once daily for 24-hour control, and they do not have sedating side effects because they are unable to cross the blood–brain barrier. They are preferred for school-age children and have excellent efficacy.

In addition to systemic antihistamines, the newer topical antihistamine sprays are useful when patients have only nasal or ocular symptoms. Topical antihistamine nasal sprays include Astelin (azelastine, Meda Pharmaceuticals), Omnaris (ciclesonide, Sunovion Pharmaceuticals), and Patanase (olopatadine, Alcon Laboratories). Astelin and Omnaris are approved for use in children 5 to 6 years of age and older, and Patanase is approved for children 12 years of age and older.

Topical intranasal corticosteroid sprays are highly effective for treating and inhibiting the symptoms of allergic rhinitis. The intranasal sprays typically contain steroids that are inactivated at pH levels typically found in gastric secretions and thus are minimally absorbed systemically. The sprays stabilize inflammatory cells and cell membrane permeability.

Topical nasal corticosteroid sprays are typically well tolerated by children as young as 2 years of age. Growth inhibition from the long-term use of intranasal corticosteroids is not seen, even after years of use.

Patients with long-standing allergies and incomplete symptom control with antihistamines and topical nasal steroids frequently experience symptom relief with the leukotriene receptor antagonist montelukast (Singulair; Merck). This agent also effectively treats asthma and perennial allergic rhinitis by modulating leukotrienes in the immune response. Excellent control of allergies may be seen with this once-daily agent.

Decongestants may be added to the regimen periodically to treat exacerbations of allergies, or at the onset of therapy with other agents. Oral pseudoephedrine is an excellent nasal decongestant without rebound, whereas topical oxymetazoline and phenylephrine both exhibit rebound effects following continuous use for 3 days or longer. These agents are recommended when symptoms are severe and intolerable. All three agents have the potential side effect of systemic hypertension.

Immunotherapy is used when symptoms cannot be controlled with the above pharmacologic measures. It involves the preparation of weak mixtures of the specific allergens that cause the patient's most significant symptoms and attempts to induce the formation of IgG blocking antibodies to the allergens, resulting in competition between IgG and IgE for the allergen receptors. Immunotherapy can provide excellent results in carefully selected patients with high levels of IgE antibodies to specific allergens.

Complications

The most common complication of allergic rhinitis is the impact of undiagnosed or undertreated allergic rhinitis on the patient's quality of life. Allergic rhinitis can affect sleep quality and efficiency. The effect of sleep disturbance in combination with the use of sedating antihistamines can have a profound impact on school performance in young children. Rarely, allergic rhinitis may progress to allergic nasal/sinus polyposis, which is a generalized swelling of the sinus mucous membranes with protrusion from their sinus confines into the nasal cavity through the sinus ostia. Allergic rhinitis is the underlying etiology of nasal polyposis, and medical management is mandatory.

67.10 Roundsmanship

- Newborn children have very small maxillary and ethmoid sinuses. The frontal and sphenoid sinuses begin to develop at about 4 to 6 years of age.
- Choanal atresia may be bilateral or unilateral. When it is bilateral, babies may present with cyanosis because newborns are obligate nasal breathers. In cases of bilateral choanal atresia, surgery must be performed after the baby is stabilized and the cardiology evaluation completed.

- Choanal atresia is found in about 1 in 35,000 live births. It is frequently seen in children with the CHARGE (coloboma, congenital heart malformations, choanal atresia, retardation of growth, genitourinary tract malformations, and ear malformations and hearing loss) association.
- Choanal atresia may be corrected via a transnasal endoscopic approach or via a transpalatal approach. The endoscopic transnasal approach is less invasive but carries a higher risk for revision surgery for choanal stenosis.
- An intranasal mass in a young child may be a dermoid cyst, glioma, or encephalocele. Biopsy of any midline or superiorly located intranasal mass is not recommended until imaging studies are performed to evaluate for these congenital lesions.
- Epistaxis is a common ailment in children. Most frequently, nosebleeds occur from the disruption of superficial blood vessels in the anterior septum. Treatment with topical silver nitrate helps to substantially reduce most nosebleeds from this region.
- Severe nosebleeds may be from a juvenile nasal angiofibroma in teenage boys. A complete nasal examination is necessary to exclude this disease in pubescent males.
- Unilateral purulent nasal discharge is the most common presenting sign of intranasal foreign body.
- Nasal bone fractures heal much faster in children than in adults. Closed nasal reduction is most successful if performed within 10 days of the injury.
- The management of septal deviations in children is problematic. Facial growth centers are found in the septal/vomer region; disruption from septal surgery risks damage with possible resultant midface growth disturbances. Septoplasty for

nasal obstruction is usually postponed until children are past the pubertal growth period.

- Allergic rhinitis is a common problem in children. The common treatments include topical steroid nasal sprays, antihistamines, leukotriene receptor antagonists, and immunotherapy. The prognosis is good when the specific allergen is identified.

68 Pediatric Sinus Disorders

Robin A. Dyleski

68.1 Acute Sinusitis

68.1.1 Etiology

Inflammatory infections of the nose in young children may progress to sinusitis. It is difficult to distinguish between purulent rhinitis and sinusitis in children, and the term rhinosinusitis is frequently used to describe an inflammatory condition affecting both the nose and paranasal sinuses.

Young children have approximately six to 10 viral upper respiratory infections per year, and up to 5% of these are complicated by bacterial rhinosinusitis. The otolaryngologist faces the dilemma of determining which child requires increased medical treatment for bacterial sinusitis as opposed to symptomatic care of an upper respiratory infection.

68.1.2 Pathophysiology and Pathogenesis

In order to maintain a healthy state in the paranasal sinuses, patent ostia, normal mucociliary function and flow, and secretions of normal composition are required. Derangements in any of these basic requirements impact the sinuses and result in various disease states.

The inflammatory effects of viral and bacterial pathogens on the nasal and sinus mucosa cause edema and congestion. The mucosal linings of the sinus ostia are similarly affected, resulting in obstruction of the sinus outflow tract. With obstruction, the sinus mucous secretions are prevented from exiting the

sinus ostia, resulting in fluid buildup in the sinus; similarly, the flow of fresh air into the sinus is blocked, resulting in a hypoxic state within the sinus. The presence of stagnant secretions in a hypoxic sinus establish conditions favorable for bacterial supra-infection and the development of sinusitis (□ Fig. 68.1).

In very young children, the ethmoid sinuses are the most developed and the most commonly affected. The ethmoid sinuses have tiny communicating ostia between the air cells and therefore are the most prone to mucosal inflammatory swelling during viral or bacterial infections. The maxillary sinuses are also frequently affected by sinusitis, but because of their location, they are less often sources of the complications of sinusitis.

68.1.3 Presenting Symptoms

Upper respiratory infection is the most common condition resulting in sinusitis. Acute sinusitis is usually diagnosed in children with purulent rhinorrhea persisting longer than 10 to 14 days after the onset of an upper respiratory infection (□ Table 68.1). In most cases of acute sinusitis, the symptoms of an upper respiratory infection will persist without improvement past the usual 7 to 10 days; these include postnasal drip, daytime cough, purulent nasal discharge with nasal congestion, and continued (usually low-grade) fever with generalized irritability. When a high fever ($>38.5^{\circ}\text{C}$), facial swelling, or pain is present, the child must be monitored closely for potential development of the complications of sinusitis. The symptoms of acute sinusitis resolve spontaneously in 60% of patients in about 3 to 4 weeks.

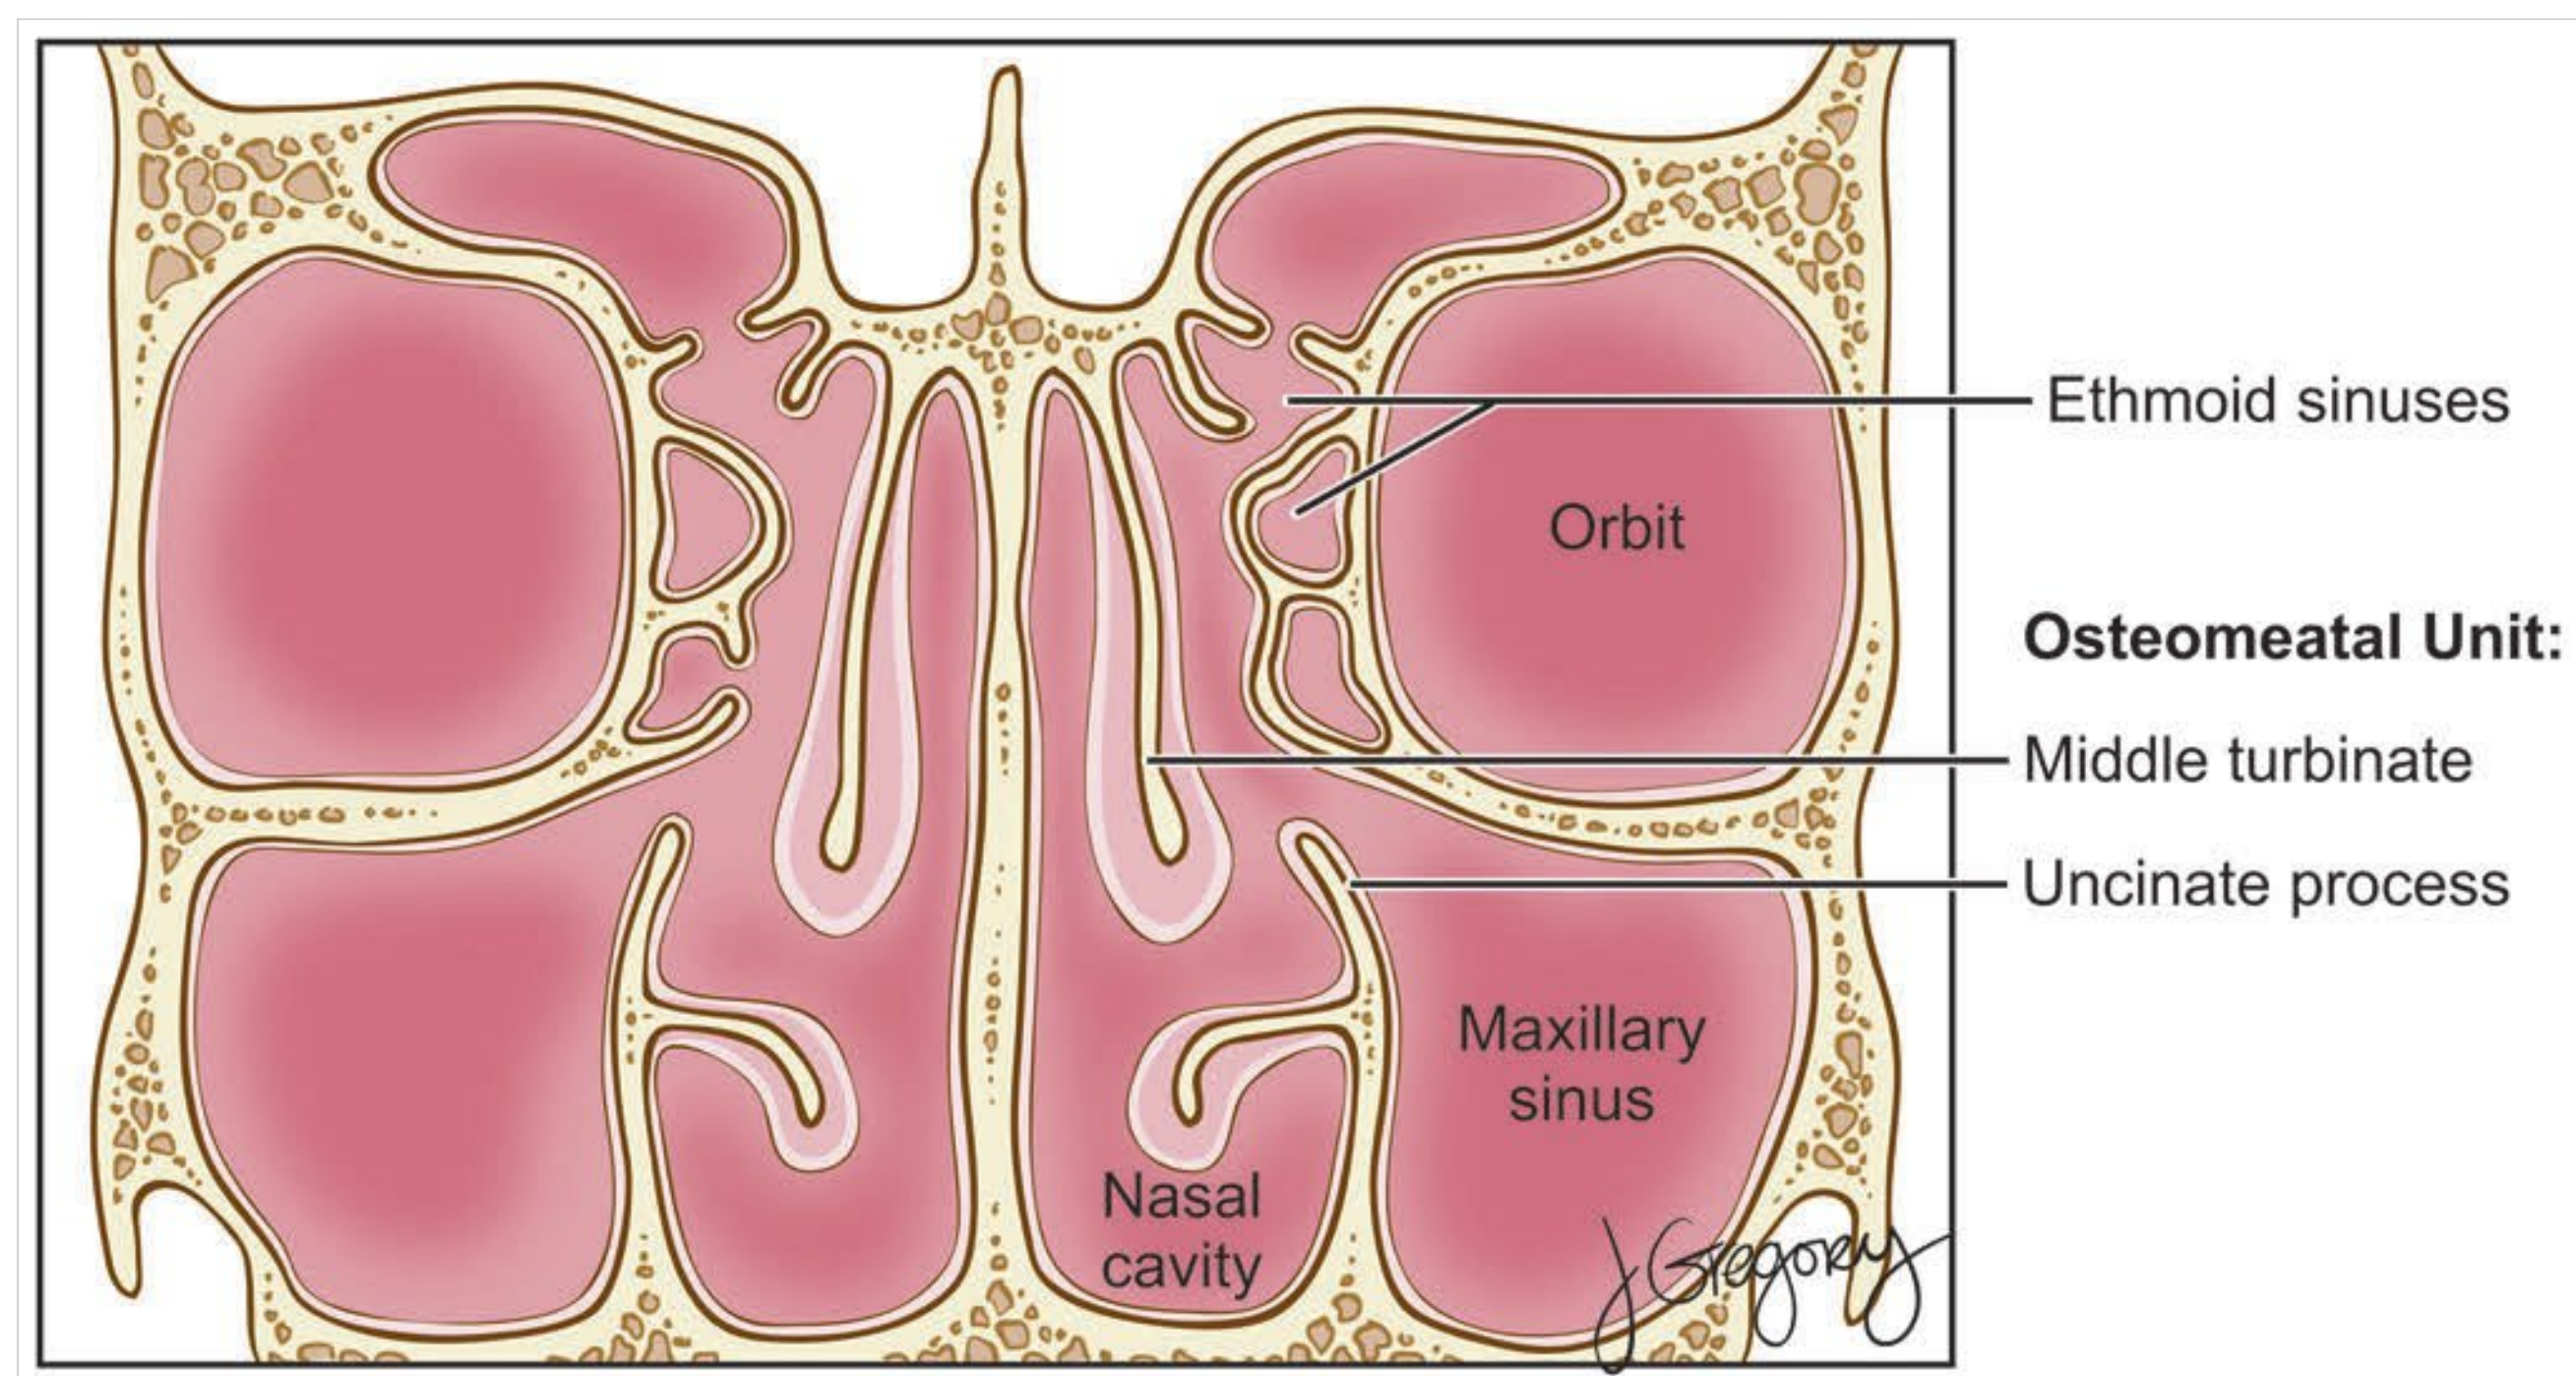

Fig. 68.1 Relationship of the osteomeatal unit to the turbinate and nasal structures.

Table 68.1 Major and minor features of acute sinusitis

Major features	Minor features
Purulent nasal discharge or postnasal drip	Fever (chronic)
Intranasal purulent discharge	Headache
Facial pain or pressure	Halitosis
Fever (acute)	Dental pain
Nasal obstruction or blockage	Cough
Hyposmia or anosmia	Ear pain or pressure
Facial congestion or fullness	Fatigue

Table 68.2 Common bacterial pathogens in acute sinusitis

Bacteria	Incidence (%)
Streptococcus pneumoniae	25–30
Haemophilus influenzae	15–25
Moraxella catarrhalis	15–25
Streptococcus pyogenes	<5
Anaerobes	<5
Sterile culture (no growth)	~ 20

Fig. 68.2 (a) Coronal computed tomographic (CT) scan of normal sinuses. (b) Coronal CT scan of acute sinusitis with mucosal thickening.

Recurrent acute sinusitis, defined as repetitive episodes of acute sinusitis with full and complete resolution of symptoms between episodes, may occur in children.

68.1.4 Medical Evaluation and Testing

The examination will confirm the presence of nasal discharge or a purulent postnasal drip. Purulence in the middle meatus is a strong indicator of sinusitis. The nasal tissues often will be congested, and in compliant patients, the intranasal application of decongestants will permit a more thorough evaluation of the middle meatus. Facial or periorbital swelling is a sign of a potential complication of sinusitis. Purulent secretions should be cultured, especially if the patient has already received antibiotics and shows no improvement.

A clinical diagnosis is made in uncomplicated cases of acute sinusitis and treatment provided. In patients with altered mental status, severe headache (rare in young children), facial or orbital swelling, or severe facial pain, computed tomography (CT) is mandatory. CT (with contrast for suspected complications of sinusitis) is the preferred study for evaluating the bony confines of the sinuses, as well as inflammatory processes when sinusitis extends past the sinuses (□ Fig. 68.2). Plain X-ray films, magnetic resonance (MR) imaging, and ultrasound are radiographic modalities of

limited value in diagnosing and planning the treatment of sinusitis.

68.1.5 Treatment

The most common bacterial pathogens in acute sinusitis are the same bacteria that cause acute otitis media. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* are the most commonly cultured bacteria in pediatric acute sinusitis (□ Table 68.2). Although antibiotic selection for these pathogens may seem straightforward, antibiotic resistance is increasing in these bacteria. In most cases, a 10- to 14-day course of an augmented penicillin, second-generation cephalosporin, or macrolide is used, but it is important to consider specific antibiotic resistance patterns within the patient's community.

Adjuvant therapy is aimed at diminishing symptoms. In addition to the use of systemic or topical nasal decongestants, nasal saline lavage is highly effective in relieving the symptoms of nasal congestion and improving the clearance of nasal secretions.

68.1.6 Complications

Sinus infection and inflammation that extend beyond the boundaries of the sinus into adjacent regions are serious complications of acute sinusitis and mandate immediate medical evaluation.

Fig. 68.3 (a) Patient with periorbital swelling from subperiosteal abscess. (b) Coronal computed tomographic (CT) scan of subperiosteal abscess, an orbital complication of acute sinusitis. (c) Axial CT scan of subperiosteal abscess with rim enhancement.

Orbital Complications

The most common complication of acute sinusitis is the spread of infection and inflammation to the orbit through the lamina papyracea of the ethmoid bone, either directly or hematogenously. The lamina papyracea is an eggshell-thin bone defining the lateral extent of the ethmoid complex. When an acute ethmoiditis erodes this bone or travels through preformed pathways, or if infection spreads hematogenously, the infection may spread into the orbit. There are defined stages in the development and severity of the orbital complications of acute ethmoiditis, each carrying an increasingly worse prognosis: preseptal cellulitis, orbital cellulitis, subperiosteal abscess (□ Fig. 68.3), orbital abscess, and cavernous sinus thrombosis (□ Table 68.3).

Intracranial Complications

Intracranial complications of acute sinusitis in young children may occur by direct extension of the infection through a dehiscence of the bone of the sinus or preformed pathways, or by hematogenous spread of the infection (particularly the venous system). Spread may lead to the development of a subperiosteal abscess (either extracranial or intracranial), meningitis, or a subdural or parenchymal brain abscess. The incidence of intra-

cranial complications increases as patients approach puberty and the facial skeleton matures, with growth and development of the frontal sinus. Patients with a history of nondisplaced frontal sinus fracture managed conservatively are at increased risk for a complication of frontal sinusitis.

The management of these infections requires the administration of intravenous (IV) antibiotics, neurosurgical and infectious disease consultations, and appropriate treatment of the underlying sinus disease after patient stabilization.

Potts Puffy Tumor

Frontal sinus infection that spreads to the surrounding bone may result in osteomyelitis of the frontal bone, known as a Potts puffy tumor; this infection may spread intracranially or externally and result in abscess formation (□ Fig. 68.4). Surgical drainage of the sinus and associated infection is necessary, with the administration of appropriate IV antibiotics to treat the osteomyelitis.

Prognosis

Most patients with sinusitis have an excellent prognosis, and infections resolve without the development of complications.

Table 68.3 Orbital complications of acute ethmoiditis

	Location	Cellulitis versus abscess	Proptosis	Vision	Extraocular muscle status	Mental status
Preseptal cellulitis	Edema anterior to eyelid septum	Cellulitis	No	Normal	Normal	Normal
Orbital cellulitis	Orbital space posterior to septum	Cellulitis	Yes	Normal	Impaired	Normal
Subperiosteal abscess	Under periosteum of the lamina papyracea	Abscess	Yes	Normal to mildly impaired	Impaired	Normal
Orbital abscess	Orbital soft-tissue abscess	Abscess	Yes	Severely impaired	Severely impaired	Normal
Cavernous sinus thrombosis	Abscess in cavernous sinus	Abscess	Yes	Severely impaired (bilateral)	Severely impaired (bilateral)	Impaired, meningeal signs

Fig. 68.4 Axial computed tomographic scan of frontal sinusitis with dehiscence of the anterior table and soft-tissue abscess.

Some children may have frequent episodes of acute sinusitis with their upper respiratory infections. As the children get older, they have fewer upper respiratory infections and fewer episodes of acute sinusitis.

68.2 Chronic Sinusitis

68.2.1 Etiology

Chronic sinusitis is defined by the presence of low-grade symptoms and findings of sinusitis lasting for longer than 3 months without improvement, the occurrence of six or more episodes of recurrent acute sinusitis in a 12-month period, or the persistence of some sinusitis symptoms with acute exacerbations for longer than 3 months. Children in whom these diagnostic criteria are met often have abnormal sinus anatomy—particularly a lack of osteomeatal unit patency, chronically inflamed mucous membranes, polyps, abnormalities of ciliary transport, or alterations in immunity. In some cases, children with chronic sinusitis simply have such frequent and severe upper respiratory

infections that they are unable to recover fully between infections, increasing the likelihood of rapid progression to sinusitis.

68.2.2 Presenting Symptoms

Symptoms will vary depending upon which criteria for the diagnosis of chronic sinusitis the patient has met. In patients in whom chronic sinusitis is diagnosed because of the persistence of sinusitis symptoms for 3 months or longer, the main complaints are chronic nasal obstruction, nasal discharge, and nasal congestion. Older children may also have facial pain, pressure, or headache; these symptoms are infrequent in younger children, even when all sinuses are affected.

Most pediatric patients are significantly affected by their chronic sinusitis and often report a poor quality of life as measured on validated scales. They experience sleep disruption caused by nasal congestion and obstruction, and they frequently have persistent nighttime cough. They often snore and are mouth breathers. Examination reveals intranasal findings similar to those previously described, and the patients may have large, congested turbinates and visible nasal or postnasal discharge.

68.2.3 Treatment and Diagnostic Testing

Children suspected by history and examination to have chronic sinusitis are usually treated in a specific, systematic manner. Children with chronic sinusitis are divided into two general treatment categories, based on age younger than or older than 6 years.

Children Younger Than 6 Years of Age

The initial management of children younger than 6 years of age with symptoms of chronic sinusitis who fail medical management with antibiotics and other symptomatic care is adenoidectomy. The rationale behind adenoidectomy is twofold: (1) The adenoids may be enlarged in children younger than 6 years and physically obstruct the nasopharynx and the normal drainage pathway of nasal secretions, thus increasing stasis within the nasal cavity. (2) Bacterial biofilms have been discovered on the surface of the adenoids. Bacterial biofilms are aggregations of bacteria and accretions that adhere to biological or nonbio-

logical surfaces (e.g., indwelling catheters and tracheotomy tubes) without specifically causing an invasive infection of the biological surface. The presence of such biofilms on otherwise normal tissue creates a reservoir of bacteria; the bacteria are not usually eradicated with standard antibiotic treatment, and their presence in a biofilm may increase the antibiotic concentration necessary for eradication by a factor of 1 million. The presence of biofilm on the adenoids has no relationship to adenoid size or to whether the patient has recently been treated with antibiotics.

Many children with chronic sinusitis who undergo adenoidectomy experience improvement of their nasal symptoms and sinusitis. Complete cures are not usually obtained because the children are still predisposed to the initiating event, the upper respiratory infection, of their sinusitis. Generally, the children are free of symptoms for longer periods and have less severe symptoms during later upper respiratory infections.

Children Older Than 6 Years of Age

In patients who have chronic sinusitis without polyps, the initial treatment of chronic sinusitis is carried out with maximization of medical therapy before imaging studies are obtained. This involves total medical treatment with an appropriate antibiotic effective against the typical sinus bacteria (for up to 3 weeks) with topical nasal steroids, decongestants, and antihistamines (only if the patient has allergies) for a total of 4 to 6 weeks. After treatment, CT of the sinus is obtained, the patient is reevaluated, and the resolution of any symptom or finding is noted. Abnormalities on the CT scan, such as sinus mucosal thickening, opacification, and osteomeatal unit obstruction, are also noted (see □ Fig. 68.2b). These abnormalities represent sinus disease resistant to maximum medical therapy. Depending upon the degree of persistent sinus disease, either surgical management or observation may be considered.

68.3 Polyposis

In patients with visible nasal polyps, either in the nasal cavity or in the middle meatus (□ Fig. 68.5), optimization of treatment of the underlying allergies is important. The spontaneous regression of polyposis in children is unusual, and most children will require surgical removal of the polyps in addition to ongoing medical management of the underlying allergies causing the polyposis. CT of the paranasal sinuses is obtained in axial and coronal planes for surgical planning at the time of diagnosis.

68.4 Special Surgical Considerations in Pediatric Sinus Surgery

Surgery for the management of pediatric sinus disease is generally similar to sinus surgery in adults, albeit with some differences. Pediatric sinus disease may be surgically managed with endoscopic intranasal techniques or via traditional external direct approaches with trephination or Lynch incisions. More often in children, traditional external approaches are used after failure of endoscopic sinus management. Under endoscopic magnification, the nasal structures are accessed similarly, after

Fig. 68.5 Endoscopic image of a sinonasal polyp in the middle meatus.

decongestion of the mucosa. Although cocaine is popularly used in adult sinus surgery, it is not advised for use in children because of its dramatic effects on the cardiovascular system. Pediatric telescopes and small surgical forceps, scissors, and punches are available that allow access into even the smallest noses and sinus spaces.

Technically, pediatric endoscopic sinus surgery is challenging because of the much smaller intranasal space and limited options for the use of surgical forceps and powered instrumentation. In general, it is more important to improve and widen the affected sinus ostia than to remove all diseased mucosa within the sinus. The goal of pediatric sinus surgery is to improve affected sinus ostia patency and to remove tissue obstructing the middle meatus and ostia.

Intraoperative stereotactic image guidance is more important for sinus surgery in children, particularly when the frontal, ethmoid, and sphenoid sinuses are accessed (□ Fig. 68.6). Although there is no substitute for technical familiarity with the paranasal sinus anatomy, intraoperative image guidance is particularly beneficial in pediatric patients with anatomical bony anomalies. In general, image guidance improves the likelihood of accessing all affected (especially the frontal and sphenoid) sinuses and increases safety by preventing intracranial and orbital penetration.

Absorbable sinus packing may be used, instead of packing that requires removal, in children younger than 10 to 12 years of age. In addition, postoperative débridement is often impossible without general anesthesia, and a “second-look” débridement may be needed 1 to 2 weeks following initial sinus surgery in some children.

68.4.1 Complications of Medical or Surgical Management

Complications of the disease process, when untreated, have been described in the preceding section. Complications of the surgical management of sinusitis involve traversing the bony confines of the sinuses into the orbit or cranium. Immediate detection of the penetration, prompt consultation with neuro-

Fig. 68.6 (a) Stereotactic navigation image guidance system in use during pediatric endoscopic sinus surgery. (b) Image guidance provides three-dimensional localization of the surgical probe relative to the preoperative computed tomographic scans. (c) Stereotactic navigation image guidance localization is viewed alongside the endoscopic image during surgery.

surgery and ophthalmology, and repair of the dura and cerebrospinal fluid leak are necessary.

Children are at greater risk than adults for postoperative synechiae and scarring in the middle meatus because postoperative care is often difficult in children without general anesthesia.

68.5 Special Sinus Conditions

68.5.1 Cystic Fibrosis (Mucoviscidosis)

Etiology and Pathophysiology

Cystic fibrosis (CF) is a chronic multisystem genetic disease that primarily affects the respiratory and gastrointestinal systems. CF is caused by several mutations of the gene encoding the exocrine gland chloride channel receptor, transmembrane conductance regulator glycoprotein (CFTR gene, located on the long arm of chromosome 7). CF is transmitted in an autosomal-recessive pattern and is seen in approximately 1 in 3,500 Caucasian live births in the United States. Caucasians have the highest incidence, as noted; the incidence in Hispanics is 1 in 9,500 births, and the condition is very uncommon in Asian or African groups. Males and females are affected evenly. CF is usually diagnosed in infancy because of manifestations of pancreatic gland and pulmonary dysfunction. The diagnosis of CF is confirmed with a sweat chloride skin test; a sweat chloride concentration above 60 mEq/L is diagnostic.

The target of the CF DNA mutation is the cyclic adenosine monophosphate (cAMP)-mediated chloride channel on the apical surface of the epithelial lining of exocrine glands, which results in the secretion of abnormally viscid mucus. CF primarily affects the lungs and pancreas, with the production of thick mucus and the development of chronic lung disease, bronchiectasis, exocrine pancreatic insufficiency, rhinorrhea, nasal obstruction, and sinusitis.

Nasal secretions are noted to be very thick and difficult to clear from the nose, resulting in stasis and secondary bacterial colonization/infection of the nose and sinuses with *Staphylococcus aureus*, *Pseudomonas*, *Proteus*, and the other usual nasal bacterial pathogens. Nasal polyposis is commonly found in patients with cystic fibrosis. The frequent symptom of nasal obstruction is produced in these children by the combination of chronic nasal mucosal inflammation, thick viscid secretions, and the presence of nasal polyps.

The lifespan of patients with CF has increased recently, with patients living into their forties because of advances in the management of their lung disease.

Presenting Symptoms

Most children with CF have previously received medical attention when they are referred for the management of nasal symptoms of obstruction, secretions, and polyps. The specific aim is to reduce the nasal symptoms, particularly postnasal drip and obstruction, and improve the patient's quality of life.

Medical Evaluation and Testing

Typically, patients have thick, purulent (often greenish) nasal secretions that are difficult to suction and clear from the nasal

Fig. 68.7 Coronal computed tomographic scan of sinusitis with polyposis in a patient with cystic fibrosis.

cavity. The mucosa is hyperplastic, and polyps may be visualized in the middle meatus on rhinoscopy.

If not already performed by the patient's other medical caregivers, CT should proceed without the usual prior medical treatment of chronic sinusitis. CT scans usually demonstrate complete opacification of the sinuses, and possible hypoplasia of the frontal sinus in older children (□ Fig. 68.7).

Treatment

Treatment is offered to patients with symptoms. The goal of the management of sinusitis in CF is to relieve nasal obstructive symptoms, reduce and thin nasal secretions, and improve quality of life. The initial use of tobramycin-saline nasal irrigations may thin and clear viscid nasal and sinus secretions and help control bacterial suprainfection. Endoscopic surgery is aimed at removing obstructive polyps and enlarging the sinus ostia to the greatest extent possible. Most patients with CF require increased treatment of their pulmonary problems, with a "tune-up" to improve their pulmonary status, before a general anesthetic is administered. Postoperatively, the tobramycin-saline nasal irrigations are resumed as soon as possible and are continued daily as maintenance treatment for the nasal manifestations of CF.

Prognosis

Because of the underlying genetic etiology of CF, it is not possible to cure sinusitis in patients with CF. However, it is possible to

control symptoms in a substantial number of children. Repeated hospitalizations and sinus procedures are not uncommon as the patients age.

68.5.2 Primary Ciliary Dyskinesia (Kartagener Syndrome)

Etiology

Primary ciliary dyskinesia, also known as immotile ciliary syndrome or Kartagener syndrome, is a rare, inherited autosomal-recessive disease in which abnormal cilia are present in the respiratory tract (including the nasal cavity and sinuses), ear, and genital organs.

Mutations on two genes are responsible for structural defects in the outer dynein arms, resulting in immotile cilia with abnormal function. Structural defects of the dynein arms, identified with electron microscopy, are diagnostic of this disorder.

Embryologic development is affected by the defective ciliary movement, resulting in situs inversus (reversed laterality of the internal organs) in children with primary ciliary dyskinesia. Situs inversus occurs randomly and is seen in about 50% of cases. It can occur with or without dextrocardia (right-sided heart).

Pathophysiology and Pathogenesis

The abnormal cilia in the respiratory epithelium result in the impaired clearance and stasis of lung, nasal, and sinus mucus. The result is chronic and recurrent episodes of pneumonia, bronchiectasis, and sinusitis.

Presenting Symptoms

Although primary ciliary dyskinesia is a rare condition, it may be suspected in children who present with a history of recurrent pneumonia in addition to the typical symptoms of recurrent sinusitis. Chronic nasal discharge, obstruction, and congestion are typical in these patients. Prolonged antibiotic therapy may have previously been unsuccessfully attempted.

Medical Evaluation and Testing

A high index of suspicion is required to make a diagnosis of primary ciliary dyskinesia because specialized testing is needed. Chest X-ray may demonstrate dextrocardia, which, although it raises suspicion for primary ciliary dyskinesia, is in itself not diagnostic. The diagnostic test for primary ciliary dyskinesia is biopsy of ciliated epithelium and the observation of dynein arm abnormality on electron microscopy. The most common sites for biopsy of the mucosa are the nose, bronchial tubes, and trachea. The nose and lungs may have areas of mucosa with a deficient quantity of cilia as a result of chronic bacterial infection. An alternative, and preferred, method of obtaining an adequate cilia sample is to use a bronchial brush in the nasal cavity. This method has a higher likelihood of obtaining a sufficient sample for electron microscopic analysis and may be performed in the office without the need for general anesthesia. Electron microscopy demonstrates typical dynein arm abnormalities and establishes the diagnosis, along with a history of recurrent pneumonia and chronic sinus infections.

Treatment

Treatment is aimed at the medical control of symptoms and surgical enlargement of the sinus ostia to permit postural drainage of the sinuses.

68.5.3 Tumor of the Sinonasal Tract: Juvenile Nasopharyngeal Angiofibroma

Etiology

Juvenile nasopharyngeal angiofibroma (JNA) is a rare benign tumor of the posterior nasal cavity and nasopharynx. It is seen only in boys at the onset of or during puberty. It initially occurs at the junction of the middle turbinate with the sphenopalatine foramen. Its exact etiology is uncertain, but growth of the tumor is influenced by androgen and estrogen hormones. JNAs account for fewer than 0.05% of all head and neck tumors and are more common in Middle Eastern and Indian boys.

Pathophysiology and Pathogenesis

JNAs originate in the area of the posterior nose at the sphenopalatine foramen. The tumors then slowly grow to occupy the ipsilateral nasal cavity with extension into the nasopharynx. Large tumors frequently extend into the pterygopalatine fossa, as well, and develop a “dumbbell” shape. The tumors enlarge by expanding the surrounding tissues, with erosion of the bony constraints into the maxilla, sphenoid, and skull base seen with very large tumors. In some cases, the JNA will have extended to the orbit. The blood supply to a JNA is usually based on the internal maxillary artery and its branches.

JNA is a benign vascular tumor composed of thin-walled blood vessels that have absent or incomplete smooth muscle within their walls. This accounts for the difficulty encountered in controlling epistaxis originating from a JNA.

Presenting Symptoms

Prepubescent and teenage boys present with a history of nasal obstruction (unilateral or bilateral, depending upon the size and location of the tumor) and epistaxis, sometimes reported as extreme with significant blood loss. Alteration of the speech resonance and bulging of the soft palate may be seen as the tumor grows.

Medical Evaluation and Testing

The tumor appears on physical examination as a reddish, smooth, mucosa-covered mass in the nasal cavity. It may cause septal deflection into the opposite nasal cavity, and if it is located in the nasopharynx, it may cause obstruction. This intranasal mass should not be biopsied because of the risk for significant epistaxis.

CT with contrast is often the initial radiographic study, showing excellent detail of the bony anatomy. MR imaging is complementary to CT and provides excellent detail of the soft-tissue extent of the tumor. The diagnosis is usually made through a combination of the clinical history, examination, and imaging studies (□ Fig. 68.8).

Fig. 68.8 (a) Endoscopic appearance of juvenile nasopharyngeal angiofibroma (JNA) in the nasal cavity. (b) Computed tomographic scan of JNA. (c) Magnetic resonance image of JNA.

Treatment

JNA is staged by its extent, particularly its orbital and intracranial extent; this information is useful in determining the techniques required for tumor removal.

Preoperative embolization allows complete removal of a JNA with reduced blood loss. The approach to complete tumor resection varies depending upon the stage and extent of the specific tumor, but many are resected endoscopically, with good a success rate for complete tumor removal. Other approaches include transpalatal lateral rhinotomy and combined otolaryngologic–neurosurgical procedures.

Radiation therapy is another option that is usually reserved for severe cases in which there is tumor recurrence or a tumor that cannot be entirely removed.

Complications

JNA is a benign tumor that can cause pressure-related damage to adjacent organs, such as the eyes. The vascular nature of a JNA can result in life-threatening epistaxis, and blood transfusion is not uncommonly required. Surgical complications are specifically related to the structures in the region.

Prognosis

The cure rate for JNA approaches 100% with complete resection of the tumor. This is reduced in cases of large, lobulated lesions, particularly with intracranial extension. There have been rare reports of malignant transformation of a JNA, but most of them had previously been treated with radiation therapy.

68.6 Conclusion

Children have numerous sinonasal conditions that can easily be confused, but the patient's history will soon point toward the diagnosis. Concern and a consideration of the patient's age and the impact of the condition on his or her quality of life will assist in the management of the pediatric patient.

68.7 Roundsmanship

- Most children have between six and 10 upper respiratory infections annually, but acute rhinosinusitis develops in only 5%

- *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis* are the most commonly cultured bacteria in pediatric cases of acute sinusitis.
- In most children, acute rhinosinusitis can be diagnosed by the observation of worsening symptoms of an upper respiratory infection or purulent discharge in the middle meatus. CT may be needed in special cases.
- Acute ethmoiditis and acute frontal sinusitis may present with intraorbital or intracranial complications. Treatment is a combination of appropriate antibiotic therapy and often surgical drainage.
- Adenoidectomy is often recommended as first-line surgical treatment for uncomplicated recurrent or chronic sinusitis in young children to reduce symptoms.
- Endoscopic sinus surgery, often with intraoperative stereotactic navigation guidance, is used in refractory cases, with improved outflow drainage from the sinus ostia as the goal of the procedure.
- “Second-look” endoscopic examinations with the patient under general anesthesia is sometimes needed following endoscopic sinus surgery.
- Children with special medical conditions, such as cystic fibrosis and primary ciliary dyskinesia, often require endoscopic sinus surgery to improve outflow drainage from the sinuses. These patients also require special management for their pulmonary problems.
- Juvenile nasopharyngeal angiofibroma is a serious, potentially life-threatening tumor seen only in peripubescent boys. The

tumor should not be biopsied in the office setting because of the risk for severe hemorrhage. Imaging studies with a clinical history are diagnostic. Complete excision is recommended.

69 Pharyngeal and Esophageal Disorders in Children

Joshua R. Bedwell and Robin A. Dyleski

69.1 Introduction

Problems concerning the oral cavity and throat are among the most common reasons why children visit an otolaryngologist. These conditions vary in cause, severity, and length of illness, and they may have a large impact on the well-being of a child. This chapter addresses the most common conditions affecting the oral cavity and throat in children.

69.2 Mucosal Conditions

69.2.1 History

A variety of infectious and inflammatory disorders may lead to mucosal changes in the oral cavity. Important historical points to elicit include age at onset, history of trauma to the region or exposure to chemicals, vaccination history, recently started medications, presence or absence of pain, and any systemic symptoms, such as fever. An immune-compromised state widens the differential diagnosis to include opportunistic pathogens not seen in otherwise healthy children. Any associated symptoms should be noted in a complete review of systems.

69.2.2 Physical Examination

A detailed oral and oropharyngeal examination should be performed, and the appearance of any lesions described in detail. Palpation will demonstrate any induration and/or tenderness. Exudates should be tested for adherence to the underlying mucosa and sent for culture. Any regional adenopathy should be noted.

69.2.3 Infectious Disorders

Several viral agents can cause oral mucosal lesions. Herpes simplex virus (most commonly type 1) can cause a stomatitis in which small, painful vesicles are typically seen on the gingivae, palate, lips, or tongue. The lesions rupture and leave ulcerations in which a gray exudate covers an erythematous base. Systemic symptoms such as fever and malaise may also be present. Treatment consists of oral acyclovir. Herpangina, caused by coxsackievirus A, manifests as an intensely painful pharyngitis associated with small vesicles in the posterior oral cavity and pharynx. Hand-foot-and-mouth disease, also due to coxsackievirus A, is similar to herpangina, with the addition of a papular rash on the palms and soles. The treatment of these infections is supportive. Koplik spots are red lesions with a light bluish center that are seen on the buccal mucosa in measles (rubella); they typically appear 24 to 48 hours before the generalized maculopapular rash, fever, and coriza generally observed in this infection.

There are a few rare but notable bacterial causes of oral lesions. Acute necrotizing ulcerative gingivitis (also known as Vincent gingivitis, or trench mouth) is an infection caused by multiple organisms, including the spirochete *Borrelia vincentii*.

Patients present with widespread inflammation and necrosis of the gingivae, with gray exudate and hemorrhage. This condition is most often seen in malnourished, immunocompromised, or otherwise debilitated patients. Treatment consists of oral hygiene and antibiotics, typically a penicillin. Primary syphilis, caused by *Treponema pallidum*, presents as a painless ulcer, or chancre, with surrounding induration; it is treated with penicillin.

The most commonly encountered fungal infection in the oral cavity is candidiasis, or thrush, caused by *Candida albicans*. Candidiasis presents with white plaques that when scraped off reveal a friable, erythematous mucosa that bleeds. Although thrush is often seen as a benign infection in infants and patients on antibiotics, it should serve as an alert for a possible underlying immune-compromised condition (e.g., diabetes, HIV infection). Treatment typically consists of topical antifungal agents (nystatin, clotrimazole lozenges), although systemic fluconazole can be used for more severe cases.

69.2.4 Inflammatory and Idiopathic Disorders

Aphthous stomatitis accounts for the most common oral ulcers. Patients present with a painful, white ulceration of the mucosa and surrounding erythema. Ulcers are categorized as minor (<1 cm), major (>1 cm), or herpetiform (multiple small ulcers). Major and herpetiform ulcers carry a risk for scar formation. Treatment is supportive, although topical steroids such as Kenalog in Orabase (triamcinolone oropharyngeal, Bristol-Myers Squibb) may bring some relief. Recurrent or chronically nonhealing ulcers should be biopsied to rule out carcinoma. Behçet disease is an autoimmune disorder in which patients present with painful oral and genital aphthous ulcerations, ocular inflammation (e.g., uveitis, iritis), and a host of other symptoms. Immunosuppressive therapy is the standard treatment.

Oral mucosal lesions may accompany the classic target-shaped cutaneous lesions of erythema multiforme. Erythema multiforme is an acute vasculitis that may occur spontaneously or as part of a hypersensitivity reaction. Patients will present with an abrupt onset of symptoms, along with fever. Stevens-Johnson syndrome is a serious form of erythema multiforme. The treatment of both is with corticosteroids and supportive care.

There are a number of autoimmune disorders in which antibodies are directed against various aspects of the attachments of epithelial cells to the underlying basement membrane. These disorders present as painful ulcerations that form with minor trauma. Pemphigus vulgaris is caused by the formation of autoantibodies to intracellular bridges and is the bullous disease most frequently presenting with oral mucosal lesions. The diagnosis hinges on skin biopsy showing intraepithelial deposits of immunoglobulin G. Corticosteroids are the mainstay of treatment.

69.2.5 Neoplastic Disorders

Oral neoplasms are rare in children, and the majority are of vascular or salivary origin. Rhabdomyosarcoma is a malignant tumor of skeletal muscle origin that can present in the oral cavity (most frequently on the tongue, palate, or cheek) as a nontender, firm, enlarging intramuscular mass. The diagnosis is made by biopsy of the mass with complete excision at the biopsy procedure if possible. Rhabdomyosarcoma is staged following pathologic diagnosis on the basis of the disease remaining in the patient, and thus a complete excision may affect staging of the disease. Chemotherapy with or without radiation is the mainstay of treatment, with surgical excision or debulking performed when it is possible to do so without creating a large cosmetic or functional defect.

69.3 Salivary Disorders

Most salivary disorders in children are acute, infectious, and self-limited. There are, however, a number of other important causes of salivary gland pathology that must be considered.

69.3.1 History

Patients will most often present with enlargement of one or more salivary glands. One should delineate the onset of symptoms (acute, insidious), the presence of pain, and any fluctuations in symptomatology (e.g., exacerbation with eating). A history of trauma, animal bites or scratches, recent dental procedures, and any recent illnesses should be elicited. Systemic complaints such as fever, chills, and malaise should be noted. A complete review of systems is important, as is an understanding of any coexistent medical conditions (especially immunodeficiency).

69.3.2 Physical Examination

The examination should focus on the degree and nature of glandular enlargement. Any overlying skin erythema or discoloration should be noted. Bimanual palpation of the affected gland can aid in differentiating between a diffusely enlarged gland, a discrete intraparenchymal mass, and a mass separate from the salivary gland (e.g., enlarged lymph node, branchial cleft cyst). Any discrete mass should be carefully characterized (firm or fluctuant, mobile or fixed, tender or nontender). An intraoral examination should note the amount, consistency, and appearance of saliva expressed from the duct orifice (scant, clear, purulent). Any palpable stones along the course of the duct should be noted.

69.3.3 Diagnostic Evaluation

In cases with a suspected infectious etiology, a leukocyte count and differential may be helpful. Other markers of systemic inflammation, such as the C-reactive protein level and erythrocyte sedimentation rate, may also be of value. Specific bacterial tests (*Bartonella henselae* titers, purified protein derivative [PPD] test) and viral titers (Epstein-Barr virus, HIV, mumps virus) can be obtained when appropriate. Salivary fluid should be sent for aerobic and anaerobic culture.

Imaging tests commonly employed to evaluate the salivary glands include ultrasound, plain X-ray, computed tomography (CT), and magnetic resonance (MR) imaging. More invasive studies, such as sialography, in which the salivary ducts are directly injected with contrast, are infrequently used. Ultrasound is useful in differentiating between solid and cystic lesions and between intrinsic and extrinsic salivary masses, and in directing fine-needle aspiration (FNA) biopsy. Advantages of ultrasonography include lack of a need for sedation and avoidance of radiation exposure. Plain films are primarily useful for identifying radiopaque salivary calculi (up to 80% of parotid stones and 20% of submandibular stones are radiolucent). CT and MR imaging are both useful for providing anatomical context to a mass. MR imaging is superior for providing soft-tissue detail, although the longer scan time often requires using sedation or even general anesthesia in young children and infants.

FNA biopsy of salivary gland lesions is controversial but can be of help in differentiating benign from malignant processes up to 93% of the time. Furthermore, FNA can aid in differentiating masses arising in salivary gland tissue from adjacent or intraglandular lymphoid tissue. FNA may need to be performed under sedation or general anesthesia in young children.

69.3.4 Infectious Sialadenitis

Acute Bacterial Sialadenitis

The majority of cases of infectious sialadenitis are bacterial in nature. Patients present with an acutely enlarged, painful gland and systemic signs of infection. Massage of the gland often expresses purulent discharge from the duct orifice. The parotid gland is more commonly involved than the submandibular gland. It is believed that the more mucinous saliva produced by the submandibular gland has more antibacterial activity than the serous saliva of the parotid gland. In either gland, infection is thought to arise because of salivary stasis due to obstruction by a stone or an extrinsic mass or to dehydration. Saliva from the affected gland should be expressed and sent for Gram stain and culture. The bacteria most commonly identified in acute bacterial sialadenitis are *Staphylococcus aureus* and *Streptococcus viridans*. Antibiotic treatment with a penicillinase-resistant penicillin (e.g., amoxicillin with clavulanate) is combined with glandular massage, warm compresses, hydration, and sialogogues (e.g., sour candy, lemon juice). The persistence or progression of fever and pain despite antibiotic therapy should raise concern for an intraglandular abscess, which can be evaluated with CT or ultrasound. An abscess requires incision and drainage under general anesthesia.

Chronic Bacterial Sialadenitis

Several bacterial agents forming granulomas can affect the lymph nodes adjacent to and within the salivary glands. Tuberculous mycobacterial infections are often associated with hilar and mediastinal lymphadenopathy and can be diagnosed with a positive PPD test. Treatment consists of systemic antituberculous drugs. Atypical mycobacterial infections are most commonly seen in children and frequently manifest in the head and neck. Violaceous discoloration of the overlying skin can be a clue to such infections. *Mycobacterium avium-intracellulare* is

the most common causative agent. The PPD test may be weakly positive and cultures may be positive, but a long incubation is required. As a result, the diagnosis is often based on clinical suspicion or pathologic analysis. Because systemic antibiotic therapy is rarely successful, treatment consists of surgical excision of the lesion.

Cat-scratch disease, caused by *Bartonella henselae*, may result in chronic enlargement of the periparotid or intraparotid lymph nodes, mimicking a salivary neoplasm. A remote history of an animal scratch or bite may be elicited. FNA biopsy may show the non-acid-fast, gram-negative bacillus on a Warthin-Starry stain. Treatment is symptomatic, and macrolide antibiotics may be required to hasten resolution of the mass.

Viral Sialadenitis

Although extremely uncommon since the introduction of mandatory vaccination, mumps (caused by a paramyxovirus) may be a cause of sialadenitis. Patients who have mumps present with painful, diffuse swelling of the major salivary glands following a prodromal period of systemic complaints of fever, malaise, and symptoms of an upper respiratory infection. Associated findings include painful inflammation of the meninges, testicles or ovaries, and pancreas. The diagnosis can be made by the measurement of acute viral titers. The treatment is supportive in nature. Complications include sensorineural hearing loss and infertility due to orchitis/oophoritis.

HIV infection may cause chronic enlargement of the salivary glands, most often presenting as lymphoepithelial cysts within the parotid parenchyma. Diffuse enlargement due to lymphoid hyperplasia is also seen frequently, often as an initial presentation of the disease. Cysts should be managed conservatively, with needle aspiration employed for cosmetic deformity or discomfort. Parotidectomy is not advised because of the risk for injury to the facial nerve.

Sialadenitis may be seen as part of infectious mononucleosis (caused by the Epstein-Barr virus). Additional findings will include sore throat, posterior cervical lymphadenopathy, and possibly hepatosplenomegaly.

69.3.5 Obstructive Salivary Conditions

Salivary stones, or sialoliths, form from the deposition of calcium salts around an organic matrix. The submandibular gland is involved in 90% of cases and the parotid in 10%. The increased incidence in the submandibular gland is attributed to the more alkaline and viscous saliva produced, as well as the course of the Wharton duct, through which saliva travels against gravity. The calculi obstruct salivary flow, causing pain and intermittent salivary gland enlargement that is exacerbated with eating. Sialadenitis often results from salivary stasis. Palpation often reveals calculi near the Wharton duct orifice or along its intraoral course. Parotid calculi may be more difficult to palpate. Plain radiographs or noncontrast CT scans will show radiopaque calculi. Eighty percent of submandibular stones are radiopaque, as opposed to only 20% of those arising in the parotid. If the calculus is found near the ductal orifice, it may be either milked out or removed with a small incision intraorally. Patients who have stones within the glandular parenchyma require either submandibular gland excision or superficial parotidectomy.

Recurrent bouts of acute sialadenitis can lead to chronic glandular inflammation and distortion of the ductal architecture. Strictures can form, obstructing salivary outflow. Over time, the proximal duct can dilate (sialectasis), causing persistent glandular enlargement.

Obstruction of minor salivary glands can lead to two related but distinct entities. Mucous retention cysts are true, epithelium-lined cysts. A ranula is a mucous retention cyst that forms in the floor of the mouth as a consequence of obstruction of the sublingual gland. Ranulas can become quite large and extend into the neck deep to the mylohyoid muscle, a condition known as a “plunging” ranula. Mucoceles, in contrast, are not true cysts in that they represent the extravasation of mucus into surrounding tissue and lack an epithelial lining. Both mucous retention cysts and mucoceles are managed by marsupialization or complete excision. This can typically be accomplished via an intraoral approach, although a plunging ranula may require an external excision.

69.3.6 Congenital Masses of the Salivary Glands

A variety of congenital cysts may present in the salivary glands. Dermoid cysts most often present within the parotid gland, and complete excision is required to prevent recurrence. First branchial cleft anomalies can be found in the parotid region. Work type I anomalies are simple duplications of the membranous external auditory canal. Work type II anomalies involve duplication of the membranous and cartilaginous external canal. These are typically found posteroinferior to the angle of the mandible and can be closely related to the facial nerve. Congenital retention cysts may be seen in infants. These will typically regress spontaneously, and observation is appropriate.

69.3.7 Salivary Neoplasms

Salivary neoplasms are rare in children; however, a neoplasm in a child is more likely to be malignant than a neoplasm in an adult. In fact, if the vascular tumors are set aside, up to 50% of salivary gland masses in children will prove malignant. As in the adult population, the parotid is the most frequently involved gland.

Vascular Tumors

Unlike in adults, the most common neoplasms in children are vascular tumors; of these, hemangiomas are the most common. Hemangiomas appear shortly after birth, and their course is one of proliferation and growth over several months to a year, followed by a period of involution of variable duration. Because the majority of lesions will involute, observation is appropriate, barring complications. Complications include ulceration and hemorrhage, functional impairment, infection, incomplete involution with cosmetic deformity, and rapid growth with Kasabach-Merritt syndrome (platelet trapping within the tumor leading to a consumptive coagulopathy). Treatments range from medical therapy with propranolol or corticosteroids to more invasive techniques such as laser ablation and surgical excision.

Lymphatic malformations, also called lymphangiomas, present as compressible masses that consist of dilated, mal-

formed lymphatic channels. They are classified as microcystic, macrocystic, or mixed based on the size of the cystic areas. These malformations can become quite large and may compromise the airway. Treatment is by complete resection when possible, although the use of sclerosing agents such as OK-432 has been gaining in popularity, especially for macrocystic lesions.

Finally, vascular malformations may present in the salivary glands. In contrast to hemangiomas, these malformations are present at birth and grow as the child grows, with no involution.

Benign Tumors

Pleomorphic adenoma is the most common benign epithelial neoplasm found in the salivary glands of children. As in adults, a pleomorphic adenoma presents as a slowly growing, firm nodule. FNA is often sufficient for diagnosis, and excision with a superficial parotidectomy is the treatment of choice.

Malignant Tumors

Mucoepidermoid carcinoma is the most common malignant salivary gland neoplasm in children. These tumors are designated as low- or high-grade based on their histologic characteristics, and staging is similar to that in adults. Low-grade lesions are treated very successfully by surgical excision with adequate margins of normal parotid. High-grade lesions require total parotidectomy, neck dissection, and possibly adjuvant radiotherapy. In either case, as long as it is not involved with tumor, the facial nerve should be preserved.

Acinic cell carcinoma is the next most common malignant salivary tumor. These tumors are most often low-grade, and the treatment is similar to that for low-grade mucoepidermoid carcinoma, with complete surgical excision and attempted preservation of the facial nerve.

69.3.8 Sialorrhea

Sialorrhea, or excessive saliva production, should be distinguished from ptyalism, or drooling. Ptyalism is often multifactorial, with components of excessive production and impaired clearance of secretions due to dysphagia. Conservative management with speech and swallowing therapy should be the initial step. Medical therapy includes an antihistamine such as scopolamine or glycopyrrolate. Surgical management should be used only in cases of medical failure. Various options include injection of botulinum A toxin into the salivary gland parenchyma under ultrasound guidance, submandibular gland excision, Wharton duct rerouting, intraoral duct ligation, and chorda tympani/tympanic neurectomy.

69.4 Tonsils and Adenoids

69.4.1 Anatomy and Physiology

The palatine tonsils, adenoids (pharyngeal tonsils), and lingual tonsils make up a ring of lymphoid tissue known as the Waldeyer ring. The lymphoid component consists primarily of B cells and T cells, with a small percentage of plasma cells. The tonsils are involved in secretory immunity (immunoglobulin

production and regulation) and are situated in a prime location for sampling inhaled and ingested antigens. The tonsils and adenoids increase in size and immunologic activity in early childhood and involute after puberty.

The palatine tonsils are situated in fossae along the lateral oropharyngeal wall between anterior and posterior muscular pillars. The palatoglossus forms the anterior pillar, and the palatopharyngeus is present within the posterior pillar. The lymphoid tissue of the tonsil is tightly adherent to a fibrous capsule that lies adjacent to the pillars and the underlying pharyngeal constrictor muscle. The surface of the tonsil is marked by numerous invaginations or crypts lined with stratified squamous epithelium. The main arterial supply enters at the inferior pole, with contributions from the facial (tonsillar branch of the ascending palatine) and lingual (tonsillar branch of the dorsal lingual) arteries. The ascending pharyngeal and lesser palatine arteries enter at the superior pole. The venous drainage feeds into lingual and pharyngeal veins, which drain eventually into the internal jugular vein. Lymphatic drainage is to the jugulodigastric and superior deep cervical nodes.

The adenoids lie on the superior and posterior nasopharyngeal walls and project into the nasopharynx. This lymphoid tissue is covered by a pseudostratified ciliated columnar epithelium. The ascending pharyngeal branches from the internal maxillary and facial arteries supply the adenoids. As with the tonsils, pharyngeal veins drain into the internal jugular vein.

69.4.2 Infectious Disorders

History

Patients who have a tonsillar/pharyngeal infection most commonly present with a sore throat and odynophagia. Dysphagia can result from hypertrophy of the lymphoid tissue of the tonsils during acute infection. Otalgia may be present, caused by concomitant otitis as part of an upper respiratory tract infection; alternatively, the otalgia may be “referred pain,” due to innervation of both the pharynx and the middle ear by the glossopharyngeal nerve. Fever and other systemic signs of infection are often part of the clinical picture.

One should evaluate the patient’s ability to tolerate oral intake, and intravenous hydration and admission should be considered for patients who have signs of dehydration or are unable to maintain adequate oral intake. Any history of similar infections and the frequency of episodes of tonsillitis are important to know in counseling patients on the need for eventual surgical management. Finally, any history of immune suppression is important to know because opportunistic pathogens not seen in normal hosts may be encountered.

Physical Examination

The patient’s general appearance, with special attention paid to signs of airway compromise, sepsis, and dehydration, must be noted. Examination of the pharynx will demonstrate enlarged, erythematous tonsils that may be covered in purulent exudate. The tonsil size should be rated on a scale of 0 to 4+ based on the degree of projection into the oropharyngeal airway. A designation of 0 is used to describe prior tonsillectomy. Grade 1+ tonsils are within the fossa and project into the airway,

reaching less than 25% of the distance to midline; grade 2+ tonsils extend 25 to 50%, grade 3+ tonsils up to 75%, and grade 4+ tonsils more than 75% and often meet in the midline, nearly completely obstructing the oropharynx. The tonsils should be symmetric. Asymmetry should prompt concern for malignancy. Cervical lymphadenopathy is typically present. Unilateral bulging of the soft palate and/or medial displacement of a tonsil is seen in peritonsillar abscess. Severe odynophagia (as evidenced by refusal of oral intake and drooling), high spiking fevers, and a stiff neck raise suspicion of a retropharyngeal abscess.

Patients with acute adenoiditis will demonstrate purulent rhinorrhea and postnasal drip. Fiber-optic examination will reveal enlarged, erythematous adenoids covered in purulent exudate. Like the size of the tonsils, the size of the adenoids is rated based on the degree of obstruction of the choanae. Grade 1+ indicates 25% obstruction, grade 2+ indicates 50%, grade 3+ indicates 75%, and grade 4+ indicates complete obstruction.

Diagnostic Evaluation

Typically, the diagnosis can be made on clinical examination, often paired with a rapid strep test and throat culture to direct antimicrobial therapy. A monospot test may be useful in differentiating between infectious mononucleosis and bacterial pharyngitis. CT is helpful if a retropharyngeal or parapharyngeal abscess is suspected.

Viral Infections

Viral tonsillitis is often present along with other symptoms of an upper respiratory tract infection (cough, rhinorrhea, sneezing). Viruses responsible include rhinovirus, adenovirus (often with associated conjunctivitis), respiratory syncytial virus, influenza viruses, and parainfluenza viruses. Herpes simplex virus infection may demonstrate painful vesicular lesions, as will herpangina (coxsackievirus).

Pharyngitis caused by Epstein-Barr virus can be part of a complex of symptoms known as infectious mononucleosis. The tonsils may be greatly enlarged and are often covered with a fibrinous gray exudate. In addition, palatal petechiae may be noted. Associated findings include posterior triangle cervical lymphadenopathy, hepatosplenomegaly, fever, malaise, and rash. The diagnosis can be made based on a positive monospot test, the presence of heterophil antibodies, and a lymphocytosis with more than 10% atypical lymphocytes on a complete blood cell count, or EBV antibody titers.

Viral pharyngitis is most often self-limited, and supportive management is all that is required. Failure to improve or a worsening of symptoms should raise suspicion of a bacterial superinfection. The marked tonsillar enlargement seen in mononucleosis may lead to airway compromise requiring systemic steroids, a nasal airway trumpet, or in extreme cases endotracheal intubation.

Bacterial Infections

The most common culprits in acute bacterial tonsillitis are group A β -hemolytic streptococci. In comparison with viral infections, streptococcal pharyngitis tends to present with a more abrupt onset and higher fevers. Aside from erythematous ton-

Fig. 69.1 Strawberry tongue.

Table 69.1 Jones criteria for the diagnosis of rheumatic fever

Major criteria	Minor criteria
Carditis	Fever
Aschoff bodies (subcutaneous nodules)	Elevated erythrocyte sedimentation rate or C-reactive protein level
Migratory polyarthritits	Elevated streptococcal titer
Chorea	Prolonged PR interval on electrocardiogram
Erythema marginatum	

sils and pharyngeal walls, one may find purulent exudates, tender lymphadenopathy, and palatal petechiae. Infection of the adenoids presents with similar symptoms and signs, as well as purulent rhinorrhea and postnasal drip. Group A β -hemolytic streptococci produce an endotoxin that may cause a complex of secondary effects known as scarlet fever, including rash, strawberry tongue (□ Fig. 69.1), and perioral erythema and desquamation. The diagnosis is aided by rapid antigen tests and throat culture.

Treatment is aimed at preventing potential sequelae. Acute post-streptococcal glomerulonephritis presents 1 to 3 weeks after the pharyngitis with gross hematuria, fever, generalized edema, and hypertension. The nephritis is thought to arise from the deposition of antigen-antibody complexes and is typically self-limited. Rheumatic fever is a potentially more severe complication of group A β -hemolytic streptococcal infection that may have lasting consequences. Rheumatic fever arises because of the formation of antibodies against bacterial M-protein that cross-react with antigens in connective tissue of the heart, joints, and central nervous system. The diagnosis is based on the presence of two major or of one major and two minor Jones criteria following a group A β -hemolytic streptococcal infection (□ Table 69.1).

Penicillin and amoxicillin are appropriate antibiotics for uncomplicated cases and should be continued for 10 days. Clindamycin is a good alternative in penicillin-allergic patients. Failure

to respond within 48 to 72 hours should prompt escalation to amoxicillin with clavulanate.

A variety of other bacteria can cause pharyngeal and tonsillar infection, including *Moraxella*, *Haemophilus influenzae*, *S. aureus*, and *Escherichia coli*. Cases of diphtheria caused by *Corynebacterium diphtheriae* are rare and present with gray, adherent pharyngeal exudate. Laryngeal involvement can lead to airway compromise and exotoxin-induced shock. Treatment includes antitoxin and penicillin. The sexually transmitted infections syphilis and gonorrhea can cause pharyngitis. Syphilis, caused by the spirochete *T. pallidum*, can cause oral chancres in the primary phase or exudative pharyngitis in the secondary phase. As with the other manifestations of syphilis, treatment is with penicillin, tetracycline, or erythromycin. Infection with *Neisseria gonorrhoeae* may present as exudative pharyngitis and is treated with doxycycline or ceftriaxone, or a quinolone in older patients.

Fungal Infections

Candida albicans is the most frequent fungal pathogen in pharyngeal infections. Oropharyngeal candidiasis, or “thrush,” is often seen in patients who are immunocompromised or undergoing antibiotic therapy. Physical examination will show white, cottage cheese–like plaques adherent to the underlying mucosa, which bleeds upon removal of the exudate. Depending on the severity, treatment can be topical (clotrimazole lozenges, nystatin swish and swallow) or systemic (fluconazole).

Chronic Infection

In contrast to acute bacterial tonsillitis, chronic infection is often polymicrobial, including both aerobic and anaerobic bacteria. Chronic adenoiditis and tonsillitis are treated with extended antibiotic therapy with β -lactamase–stable antibiotics and/or adenotonsillectomy. Chronic tonsillitis or adenoiditis may be a cause of halitosis, an otherwise rare complaint in children. Tonsiliths, or beige-colored granules, may be seen in the tonsil crypts. Tonsiliths are foul-smelling concretions of *Actinomyces* bacteria and are difficult to treat medically. Prolonged penicillin therapy or tonsillectomy is advised for this cause of chronic tonsillitis.

Complications

A peritonsillar abscess occurs when infection extends beyond the tonsillar capsule, with pus collecting in the potential space between the capsule and the surrounding pharyngeal musculature. Patients present with fever, severe odynophagia, trismus, and a muffled “hot potato” voice. They are often dehydrated and unable to tolerate oral intake because of pain. Examination will reveal a bulging soft palate and medially displaced tonsil on the affected side. Trismus may make the examination difficult. The diagnosis is confirmed with needle aspiration, and the abscess is treated definitively with incision and drainage and 10 to 14 days of antibiotics. In some cases, tonsillectomy is performed to drain the abscess and prevent recurrence. Interval tonsillectomy is recommended by many otolaryngologists and also prevents recurrence of peritonsillar abscess.

In severe cases, the abscess may extend beyond the immediate peritonsillar space or into the parapharyngeal space. Fiberoptic examination reveals lateral pharyngeal swelling extending inferiorly to the hypopharynx and potentially causing significant airway obstruction. Contrast CT should be obtained to determine the extent of the abscess. Management should begin with airway control and continue with drainage of the abscess in the operating room and a course of intravenous antibiotics. Spread into the retropharyngeal space is also possible and is managed like a parapharyngeal abscess, with localizing imaging and surgical drainage. Parapharyngeal or retropharyngeal space abscesses may be drained either transorally or through an external neck incision, depending upon the location of the abscess in relation to the carotid artery and jugular vein and the proximity of the abscess to the pharynx.

69.4.3 Tonsil and Adenoid Hypertrophy

The adenoids and tonsils are lymphoid tissue and can enlarge in response both to bacterial colonization with normal flora and to chronic or recurrent infections. Significant hypertrophy can cause pharyngeal airway obstruction, presenting as hyponasal speech, nasal obstruction, rhinorrhea, snoring, chronic mouth breathing, poor feeding, and obstructive sleep apnea (OSA). Enlarged, chronically inflamed adenoids may interfere with the normal function of the eustachian tubes, leading to recurrent otitis media. Patients may exhibit a characteristic “adenoid facies,” consisting of an elongated face, flattened midface, high arched palate, short upper lip, and open-mouth breathing. Adenoid hypertrophy can be identified with either fiber-optic examination or lateral neck X-ray. Medical management with nasal steroid sprays may be attempted. Adenotonsillectomy is the definitive treatment for refractory or severe obstructive symptoms.

69.4.4 Neoplastic Disorders

Lymphoma and squamous cell carcinoma are the most common malignancies encountered in the tonsil. Unilateral tonsillar enlargement should raise suspicion for a neoplastic process, and tonsillectomy is performed for biopsy. The likelihood of malignancy increases with the presence of constitutional symptoms (weight loss, night sweats), cervical lymphadenopathy, and a rapidly progressive course. Nasopharyngeal carcinoma is a rare malignancy that may present in the nasopharynx in children. It often presents as a painless neck mass or enlarging neck lymph node in the posterior triangle (level V). The staging of these malignancies is similar to that in the adult and should prompt an oncologic consultation for treatment.

69.4.5 Indications for Tonsillectomy and Adenoidectomy

Indications for tonsillectomy include OSA; suspected malignancy; recurrent tonsillitis (more than five to six episodes in 1 year, four episodes per year for 2 years, or three episodes per year for 3 years); tonsillitis with febrile seizures; chronic tonsillitis unresponsive to antibiotic therapy; and peritonsillar abscess with a history of frequent tonsillar infection. Tonsillectomy may

Table 69.2 Indications for tonsillectomy and adenoidectomy

Indications for tonsillectomy	Indications for adenoidectomy
Recurrent acute tonsillitis	Recurrent adenoiditis
Tonsillitis with febrile seizures	Chronic sinusitis
Chronic tonsillitis	Recurrent acute otitis media
Peritonsillar abscess	Chronic middle ear effusion
Suspected malignancy	Suspected malignancy
Obstructive sleep apnea	Obstructive sleep apnea
Sleep-disordered breathing	Sleep-disordered breathing
Dysphagia	

also be considered if significant hypertrophy is seen in association with significant dysphagia that has no other apparent cause or with speech abnormalities.

Indications for adenoidectomy include OSA, suspected malignancy (as a biopsy procedure), recurrent infection, chronic or recurrent sinusitis, and recurrent acute otitis media (□ Table 69.2).

The risks of adenotonsillectomy should be well understood by the patient and family. They include bleeding (1 to 2% of children, typically 5 to 7 days postoperatively),odynophagia with poor oral intake and dehydration, and infection. Adenoidectomy may lead to velopharyngeal insufficiency (manifesting as hypernasal speech and nasal regurgitation of food and liquid), especially in the setting of a submucous cleft palate. Such situations are avoided by routinely examining the palate for evidence of a bifid uvula or diastasis of the palatal musculature. Patients with Down syndrome present a special case. These children are prone to atlantoaxial subluxation and should be evaluated with flexion–extension neck radiographs before surgery. Children who have velocardiofacial syndrome may have aberrant carotid arteries with an abnormally medial location, placing them at risk during routine tonsillectomy and adenoidectomy. Preoperative CT angiography will demonstrate such vascular anomalies.

69.5 Sleep-Disordered Breathing and Obstructive Sleep Apnea

69.5.1 History

Pediatric patients may present with nighttime symptoms that include snoring, witnessed episodes of apnea, gasping for breath, sweating, restless sleep, and enuresis. The frequency of the episodes of gasping or apnea should be elicited, as should the length of the apnea episodes. Unlike adults, who exhibit daytime somnolence, children with OSA are often hyperactive and inattentive, and they may have behavioral problems and a learning disability (□ Table 69.3). Various medical conditions put children at greater risk for OSA, including craniofacial abnormalities (e.g., Treacher Collins syndrome or Pierre Robin syndrome) and neuromuscular disorders leading to decreased tone in the pharyngeal musculature (especially cerebral palsy and Down syndrome).

Table 69.3 Differences in the presentation of obstructive sleep apnea in adults and children

Adults	Children
Daytime somnolence	Hyperactivity/behavioral disturbances
Frequent obesity	Underweight/failure to thrive

69.5.2 Physical Examination

The patient's height and weight should be plotted and compared with established norms. Any craniofacial abnormalities (retrognathia or micrognathia, cleft lip and/or cleft palate, macroglossia) should be noted. The size of the tonsils should be rated, as previously described. A fiber-optic examination should be performed to evaluate for nasal obstruction, adenoid hypertrophy, or other airway anomalies (e.g., laryngomalacia). The appearance and length of the soft palate are important to note, especially in children whose tonsils and adenoids are somewhat small.

69.5.3 Diagnostic Evaluation

A lateral neck film may be helpful in evaluating adenoid size in the uncooperative child. Polysomnography is discussed below.

69.5.4 Sleep-Disordered Breathing

Sleep disorders in children encompass a continuum, ranging from relatively benign primary snoring to potentially life-threatening OSA. The diagnosis and treatment of sleep disordered-breathing differ significantly between children and adults. Although apnea in adults is generally defined as the cessation of breathing for 10 seconds, the duration in children is shortened to two or more consecutive breaths. Hypopnea is variably described as a 50% reduction in airflow or respiratory effort, or an increased end-tidal CO₂ level (normally ~ 40 mm Hg).

Up to 10% of children snore during sleep. Those whose snoring is not accompanied by obstructive symptoms are given the diagnosis of primary snoring and require no further treatment. Children who snore and display evidence of partial airway obstruction, including frequent arousals due to increased respiratory effort, but who do not experience true apnea or hypopnea as defined above are classified as having upper airway resistance syndrome. Because of their frequent arousals, they may present with many of the daytime symptoms of children with OSA.

69.5.5 Obstructive Sleep Apnea

OSA is seen in 1 to 3% of children and is defined as airway obstruction (apnea and/or hypopnea) leading to hypoxemia and/or hypercarbia. As in adults, severe OSA can lead to pulmonary hypertension and cor pulmonale. Although it is true that obese children are at a greater risk for developing OSA, most children with OSA are not overweight, and they may, in fact, present with poor growth or failure to thrive.

The diagnosis of OSA is typically made by obtaining an appropriate history of sleep disturbance and obstructive symptoms.

Polysomnography provides information on a variety of parameters measured while the child sleeps. The accepted standard polysomnography includes electroencephalography to measure sleep stage, electromyography to measure limb movements and arousals, electrocardiography, measures of chest wall and abdominal movements with respiration, pulse oximetry, end-tidal CO₂, and oronasal airflow. Polysomnography will give information about the number of apnea and hypopnea episodes per hour (the respiratory disturbance index, or RDI); the degree of hypoxia (defined as arterial oxygen saturation [SaO₂] <92%) and hypercarbia (peak end-tidal CO₂ >50 mm Hg); and sleep architecture (non-rapid eye movement [NREM] vs rapid eye movement [REM] sleep). Although there are no widely accepted standards for stratifying the severity of OSA in children, an RDI above 1.5 is considered abnormal.

Although polysomnography is the gold standard for diagnosing OSA, it is not practical for every patient. Polysomnography should be used for high-risk patients (those with craniofacial abnormalities, neuromuscular disorders, or significant comorbidities that could complicate surgical management) and for patients whose history and physical examination findings are inconsistent.

The treatment of OSA in children typically consists of adenotonsillectomy to relieve pharyngeal airway obstruction when it is caused by large tonsils and adenoids. In patients with mild OSA, one can expect a resolution of obstructive symptoms after surgery, although patients with severe apnea may have persistent problems. Aside from the resolution of airway complaints, numerous studies have shown improvements in quality of life and in behavior and school performance.

More complex treatment may be required in children with craniofacial anomalies. In patients with severe OSA that is refractory to standard management, tracheotomy is indicated. Patients who have significant nasal obstruction related to allergy may benefit from medical therapy with nasal steroid sprays. Finally, patients who are poor surgical candidates or have persistent issues postoperatively can be managed with continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) as an alternative to tracheotomy.

69.6 Dysphagia and Gastroesophageal Reflux

Pediatric dysphagia encompasses an immense range of eating and/or swallowing disorders. An in-depth discussion of each of the possible causes of dysphagia in children is beyond the scope of this chapter; rather, the aim here is to present a framework for evaluating a patient, based on an understanding of the normal swallow mechanism, knowledge of the salient historical clues and physical examination findings, and an awareness of the broad categories in which the majority of diagnoses can be placed.

The normal swallowing mechanism can be separated into three phases: oral, pharyngeal, and esophageal. The oral phase involves the ingestion of food, mastication, and then posterior propulsion of the food into the oropharynx. The pharyngeal phase is reflexive and requires the coordination of multiple cranial nerves (including cranial nerves V, IX, X, and XII) to close the nasopharynx, elevate the larynx while closing the airway,

and propel the food into the hypopharynx. The esophageal phase begins with relaxation of the cricopharyngeus, which allows the food bolus to enter the esophagus, where peristaltic contraction propels it to the stomach.

69.6.1 History

In the newborn, the prenatal and birth history take on extreme importance. A history of polyhydramnios may point toward esophageal malformation or neurologic compromise. Perinatal respiratory compromise requiring intubation should prompt concern for traumatic injury to the pharynx and/or larynx, or it can indicate a period of significant hypoxia leading to central nervous system damage. Prior surgical procedures should be noted, especially those that put cranial nerves at risk (ventriculoperitoneal shunt, patent ductus arteriosus ligation). A detailed family history is important in ruling out genetic, neurologic, and neuromuscular disorders.

In older children, the onset of the dysphagia (abrupt vs progressive) and the time course of the symptoms (constant vs episodic) deserve special attention. One should determine whether the patient has dysphagia to solids, liquids, or both. A history of the sudden onset of dysphagia in an otherwise normal child is concerning for foreign body ingestion, whereas a worsening dysphagia progressing from solids only to liquids points toward esophageal obstruction. Odynophagia points toward an infectious/inflammatory etiology, a foreign body, or caustic ingestion. Vomiting is an important associated symptom and should be characterized by timing with regard to feeding (during, immediately after) and by the nature of the food regurgitated (digested or undigested). Airway symptoms such as stridor and cyanosis with feeding may indicate airway obstruction as a cause of dysphagia; alternatively, they may result from aspiration.

A detailed review of systems is important in ruling out systemic issues such as autoimmune, endocrine, and neurologic disorders, as well as immunocompromised states and infection.

69.6.2 Physical Examination

The patient's height and weight should be noted and plotted over time to document adequate growth and development. Weight loss and failure to thrive (as indicated by weight below the third percentile) indicate a serious problem requiring immediate attention. In the case of infants, one should observe the infant feed, noting whether the child exhibits appropriate rooting and suck reflexes. The absence of these important reflexes may indicate neurologic deficiencies.

A complete head and neck examination should be performed. Craniofacial anomalies (e.g., cleft lip and/or cleft palate, retrognathia, macroglossia, and glossoptosis) should be noted, and the physician should maintain a high index of suspicion for genetic disorders and syndromes with characteristic facies.

Fiber-optic examination of the upper aerodigestive tract is an important tool in the evaluation of patients with dysphagia and is often the main reason for referral to an otolaryngologist. Examination should rule out nasal obstruction due to rhinitis, deviated nasal septum, choanal atresia, or adenoid hypertrophy. Evaluation of the hypopharynx may demonstrate the pooling of secretions or gross aspiration. Laryngeal abnormalities, both

anatomical (e.g., laryngeal cleft, laryngomalacia) and functional (vocal fold paralysis), should be noted.

Finally, a neurologic examination should be performed. Obviously, special attention should be paid to the cranial nerves, although a peripheral examination is also important, and any abnormalities (e.g., hypotonia) documented.

69.6.3 Diagnostic Testing

Various radiologic studies are available to aid in the diagnosis. A chest X-ray can assess cardiac, tracheobronchial, and mediastinal abnormalities. Further evaluation with CT or MR imaging should be directed by the history and physical findings of a neck mass. Modified barium swallow uses fluoroscopy to visualize swallow function during the oral and pharyngeal phases. Information regarding aspiration can be obtained, and different consistencies of food used to determine the safety of oral feeding. Modified barium swallow is often combined with a barium esophagram to rule out structural or motility problems.

Functional endoscopic evaluation of swallowing can provide information on laryngopharyngeal sensation, laryngeal mobility, and aspiration. As with modified barium swallow, different consistencies of food can be used.

Twenty-four-hour pH probe studies are the gold standard for the diagnosis of reflux. Probes are positioned at the proximal and distal ends of the esophagus as well as the pharynx (in the case of a three-probe study). Esophageal manometry allows an assessment of esophageal motility. Endoscopy allows direct visualization of the esophagus and is indicated for both diagnosis and treatment (e.g., removal of a foreign body, dilation of a stricture).

69.6.4 Differential Diagnosis

In the evaluation of a patient with dysphagia, it is best to break down the myriad etiologies into a number of broad categories. It is important to recognize that multiple factors may be contributing to a patient's dysphagia.

69.6.5 Developmental Issues

Premature infants often require both ventilatory and feeding support. Such patients may have a weak suck reflex and difficulty coordinating feeding and respiration. They are maintained on alternate methods of feeding (gavage, gastrostomy). Fortunately, in the absence of neurologic injury, the majority of these patients will progress to normal oral intake.

69.6.6 Congenital Anatomical Defects

Defects involving the aerodigestive tract at any level from the nasal passage to the distal trachea and esophagus can interfere with normal swallowing. Obstruction of the nasal airway, as in piriform aperture stenosis, choanal atresia, or even severe septal deflections (as from birth trauma), can affect an infant's ability to coordinate feeding and respiration.

Craniofacial abnormalities can impair the feeding and swallowing mechanism in a number of ways. Children with cleft lip and palate are unable to generate an effective seal and must be fed with a special bottles and nipples. Patients with a cleft

palate will also regurgitate feeds into the nasal cavity through direct communication via the cleft and defective velopharyngeal closure. Syndromes that include abnormalities in the growth, position, and proportions of the mandible and other facial bones can lead to feeding issues. Notable examples include Crouzon, Apert, Goldenhar, and Treacher Collins syndromes. When craniofacial disproportion is combined with a cleft palate and/or lip, the dysfunction becomes increasingly pronounced. Macroglossia, as seen in Down (trisomy 21) and Beckwith-Wiedemann syndromes, can interfere with the sucking mechanism, food bolus propulsion, and laryngeal protection. Finally, malposition of the tongue, due to macroglossia or retrognathia (as in Pierre Robin sequence), can cause airway obstruction and subsequent feeding problems.

Congenital laryngeal malformations such as laryngomalacia, laryngeal webs and clefts, and cysts cause dysphagia secondary to airway obstruction, aspiration, or both. Stridor and/or hoarseness should raise suspicion for a laryngeal cause of dysphagia.

Numerous tracheal and esophageal issues lead to dysphagia. Esophageal pathologies include atresia, duplication, tracheoesophageal fistula, webs, and strictures. Tracheoesophageal fistulas are often accompanied by other congenital defects, commonly involving the cardiac and genitourinary systems. Tracheoesophageal fistulas are seen in four typical configurations in association with esophageal atresia. Respiratory symptoms of choking, aspiration, and respiratory distress may be associated with the various types of tracheoesophageal fistula. The treatment of tracheoesophageal fistula involves surgical correction of the esophageal and tracheal abnormalities, typically soon after the condition is diagnosed in the infant.

Vascular rings can involve both the esophagus and the trachea, leading to stridor that worsens with feeding. Alternatively, dysphagia arising from such rings may not become apparent until the child begins eating solid food.

69.6.7 Acquired Anatomical Defects

Within this category, esophageal foreign body ingestion is likely the most common etiology encountered. The ingestion of caustic substances can cause dysphagia in the acute setting as well as later as a result of stricture of the esophagus. A good medical and surgical history should elucidate an iatrogenic cause of the patient's symptoms (intubation trauma, prior aerodigestive tract surgery). A history of tracheal or esophageal surgery, as well as any cardiac procedures, should raise suspicion for recurrent laryngeal nerve injury with vocal fold paralysis or superior laryngeal nerve injury resulting in alterations of laryngeal sensation.

69.6.8 Infectious and Inflammatory Disorders

Infections of the upper aerodigestive tract are common causes of odynophagia and dysphagia in children. Bacterial or viral pharyngitis is frequently seen in children and should be obvious on physical examination. Deep neck space infections (e.g., retropharyngeal and parapharyngeal abscesses) should be suspected in children with systemic signs of infection and complaints of odynophagia or refusal to eat. In immunocompromised patients, one should be alert to opportunistic infections

of the esophagus with bacteria, *Candida* and other fungal agents, *Mycobacterium tuberculosis*, or viral pathogens such as cytomegalovirus and herpesvirus. Chagas disease, caused by the parasite *Trypanosoma cruzi*, is seen in Central and South America and leads to esophageal atonia (and ultimately megaesophagus).

Like adults, children may be affected by various connective tissue disorders that lead to dysphagia. Scleroderma affects smooth muscle and can limit esophageal motility, as well as lead to strictures due to severe reflux. Sjögren syndrome produces xerostomia. Juvenile rheumatoid arthritis (Still disease) can cause an arthritis of the cricoarytenoid joint, with pain on phonation and swallowing, as well as respiratory distress from fixation of the cricoarytenoid joint.

69.6.9 Neoplastic Conditions

Obviously, neoplasms within the upper aerodigestive tract can obstruct the passage of food, leading to the complaint of dysphagia. In addition, mediastinal tumors may extrinsically obstruct the esophagus. A history of progressive dysphagia, moving from problems with solids only to problems with both liquids and solids, is highly suggestive of obstruction due to neoplasm.

69.6.10 Neurologic Disorders

A neurologic cause of dysphagia should be considered when no other anatomical or functional cause can be found. Infants with central nervous system dysfunction may not demonstrate robust rooting and suck reflexes. They may have difficulty managing their secretions, with drooling and aspiration. Additional signs of neurologic impairment, including generalized hypotonia, may be present. Etiologies of the neurologic insult include hypoxia, trauma, infection, congenital defects (Chiari malformation), and genetic disorders (myasthenia gravis, muscular dystrophy).

69.6.11 Psychological/Behavioral Issues

Only after all organic causes of dysphagia have been ruled out should psychological reasons be considered. Clues in the history that may lead one to suspect the symptoms are behaviorally based are normal weight gain despite complaints and normal swallowing at meals, with symptoms occurring only between meals.

69.6.12 Other Gastrointestinal Disorders Affecting the Esophagus

Primary disorders of the gastrointestinal tract are relevant in the evaluation of dysphagia. Cricopharyngeal achalasia, or failure of the upper esophageal sphincter to relax with swallowing, causes the symptoms of gagging, regurgitation, and aspiration. Diffuse esophageal spasm, or “nutcracker esophagus,” presents with odynophagia and chest pain and can be diagnosed via barium esophagram and esophageal manometry. Reflux of the gastric contents can cause symptoms of dysphagia and will be discussed in further detail in the following section.

69.6.13 Gastroesophageal Reflux

Gastroesophageal reflux occurs when relaxation of the lower esophageal sphincter allows reflux of the gastric contents into the esophagus. Gastroesophageal reflux disease (GERD) is the clinical manifestation of mucosal damage secondary to prolonged exposure to refluxed materials. Pathologic reflux is most often due to inappropriate so-called transient lower esophageal relaxations, but it may also be related to delayed gastric emptying and/or defective esophageal clearance.

History

Reflux in children may present with a variety of symptoms and signs but may be generally divided into two large categories: esophageal and extra-esophageal manifestations. Furthermore, within those groups, GERD presents differently in children of different age groups.

Esophageal Manifestations

Sporadic postprandial reflux, often accompanied by effortless regurgitation, is a normal occurrence in infants but typically disappears by 1 year of age. Infants with GERD may have more frequent regurgitation, choking, food avoidance, and back arching due to odynophagia and esophageal irritation; in the most serious cases, they may exhibit failure to thrive. Older children often complain of heartburn, dysphagia, and globus sensation.

Extra-esophageal Manifestations

GERD has been implicated in disorders involving the upper and lower airway, sinonasal system, and ears. Airway complaints in infants include stridor, cyanotic spells, and recurrent croup. In older children, one may see chronic cough, asthma, and recurrent pneumonia. Reflux has been implicated in the development of subglottic stenosis and must be a primary concern in any patient undergoing airway reconstruction. Reflux should be considered a contributing factor in patients with recurrent, chronic rhinosinusitis and otitis media.

Physical Examination

If the child has reflux beyond the upper esophageal sphincter into the pharynx, fiber-optic examination will reveal characteristic changes. Lymphoid hyperplasia secondary to chronic irritation can give the posterior pharyngeal wall a knobby, “cobblestone” appearance. Examination of the larynx may show erythema and edema of the postcricoid area and arytenoids. Other laryngeal findings include ulcerations, granulomas, and subglottic stenosis. Esophagoscopy may demonstrate mucosal erythema or ulceration.

Diagnostic Evaluation

In children with suggestive symptomatology and findings consistent with reflux on fiber-optic or rigid endoscopic examination, empiric antireflux therapy may be started with no further work-up. Indeed, studies have demonstrated similar sensitivities and specificities for endoscopic findings and other testing modalities. However, when the diagnosis is in doubt or

the patient fails to respond to empiric therapy, additional testing may be required.

The 24-hour dual pH probe has long been considered the gold standard for the diagnosis of GERD. Two pH probes, one at the distal end of the esophagus and one at the proximal end of the esophagus or the pharynx, are used to record episodes of acid reflux. The standard criterion for GERD is a recorded esophageal pH of less than 4 for more than 5% of the recording time. This measure is inadequate for the diagnosis of extra-esophageal reflux disease. The pharynx and larynx lack the robust mucosal defenses of the esophagus and may be damaged by exposure to a much smaller amount of refluxate. Furthermore, there is strong evidence that much of the damage associated with reflux is caused not by acid but by pepsin, which has been shown to maintain some proteolytic activity at pH values up to 6.5.

Barium swallow and upper gastrointestinal series may show reflux but are unreliable; they are more useful for ruling out anatomical defects such as pyloric stenosis, which leads to feeding difficulties. Scintigraphy may demonstrate delayed gastric emptying or the aspiration of refluxed materials but is not sensitive for GERD. Esophageal biopsy may be indicated in recalcitrant cases to distinguish between GERD-related esophagitis and other entities, such as eosinophilic esophagitis. Findings at esophagoscopy that favor eosinophilic esophagitis include circular rings (“trachealization”) of the esophagus, vertical linear furrows, and exudates. These disorders are differentiated via histologic examination.

Management

In less severe cases, management may begin simply with lifestyle changes, including upright feeding for infants, weight loss, avoidance of foods and drinks that induce reflux (spicy, acidic, or fatty foods; caffeine), and avoidance of meals 1 hour before sleep or exercise.

Medical therapy is indicated for patients with more severe symptoms, including airway involvement, and for those who do not respond to conservative management. Proton pump inhibitors (PPIs) are the mainstay of therapy. PPIs have been found to be metabolized faster in children than in adults, and as a result, higher doses and twice-daily administration are often necessary. Histamine₂ blockers may also be useful, either alone or in conjunction with PPIs. Prokinetic agents (metoclopramide, erythromycin, baclofen) may be of use in selected cases, especially if delayed gastric emptying is a concern.

Finally, in patients in whom severe symptoms remain despite maximal medical therapy, or in whom lifetime problems are

anticipated (e.g. neurologic disorders), surgical therapy such as gastric fundoplication may be warranted.

69.7 Conclusion

The anatomy and physiology of the oral cavity and pharynx are complex, leading to a wide variety of disorders. Timely diagnosis and treatment are important because diseases in this region can have far-ranging effects on the growth and overall health of a child.

69.8 Roundsmanship

- Most disorders of the salivary glands in children are infectious or obstructive in nature; however, neoplasms are more likely to be malignant in children than in adults.
- Obstructive sleep apnea and recurrent tonsillitis or adenoiditis are common indications for adenotonsillectomy. Symptoms of obstructive sleep apnea in children differ significantly from those in adults.
- Obstructive sleep apnea can often be diagnosed based on the patient history. Polysomnography is the gold standard diagnostic tool for obstructive sleep apnea and may be helpful in children with comorbid conditions, or when the history is unclear.
- Gastroesophageal reflux disease has a wide array of extraesophageal manifestations in children. A definitive diagnosis is more difficult to obtain in children, and empiric trials of medication are often appropriate.

70 Pediatric Obstructive Sleep Apnea

Miguel Krishnan and Robin A Dyleski

70.1 Introduction

Of the basic human needs, water, food, and sleep are essential for well-being. Sleep provides nourishment for both mind and body. It is a time of rest, recuperation, and regeneration from the day's demanding tasks. Pediatric obstructive sleep apnea (OSA) is one of the most commonly diagnosed ailments that may interfere with a child's ability to obtain good-quality sleep.

A child's struggle to breathe during sleep may manifest as a spectrum ranging from turbulent airflow that produces snoring to the extreme situation of complete airway obstruction and apnea. As apnea leads to hypoxia, the child is likely to change position, with a resultant fragmentation of sleep in order to maintain respiration. The outcome is that the child suffers more than just a loss of sleep; there are consequences that affect daytime development, as well.

Sir William Osler first described pediatric OSA in 1892. "Chronic enlargement of the tonsillar tissues is an affectation of great importance and may influence in an extraordinary way the mental and bodily development of children." At night, the child's sleep is greatly disturbed; the respirations are loud and snorting, and there are sometimes prolonged pauses, followed by deep, noisy respirations. The child may wake up in a paroxysm of shortness of breath.

Only in the past 20 years has the differentiation between adult and pediatric OSA become recognized as a topic of great importance. The prevalence, incidence, presentation, sequelae, and treatment of pediatric OSA vary greatly from those for the adult counterpart. Information about the differences between adult and pediatric OSA and new knowledge of pediatric OSA continue to be unveiled. Pediatric OSA has become a subject of great interest, especially with respect to its effect on children's behavior, psyche, and overall health.

70.2 Incidence

Pediatric OSA occurs in children between the neonatal period and adolescence. In neonates, it is usually due to craniofacial abnormalities, such as those associated with Down syndrome, Pierre Robin sequence, and choanal stenosis or atresia, as well as any chronic condition resulting in nasal obstruction or stenosis. In older children, OSA may be due to a multitude of factors.

The prevalence of pediatric OSA is 1 to 3% with nearly 500,000 children affected in the United States. The cost to the health care system of children with OSA is increased by 226% compared with the cost of controls. After adenotonsillectomy is performed, this cost is noted to decrease by one-third.

Pediatric OSA shows no sex predilection in comparison with adult OSA. However, toward late adolescence, a slight male predominance is noted, as in adults. The incidence seems to be higher in African-Americans, which is felt to be due to their craniofacial structure. Although obesity does have some impact, most children who display symptoms of OSA are found to be underweight rather than overweight. However, as obesity

continues to increase in the pediatric population, so does the incidence of pediatric OSA.

Snoring is nearly universally seen in pediatric OSA. Although snoring does not always suggest OSA, it is considered a hallmark of sleep-disordered breathing. Six to 27% of children snore on a regular basis, and 3% of children may have abnormalities of reduced gas exchange.

The incidence of pediatric OSA usually peaks in children between 2 and 8 years of age. This is the period during which the lymphoid tissue is largest in relation to the size of a child's pharyngeal airway space and head. The incidence of pediatric OSA is higher in children who have narrow pharyngeal airways, as well as in children who have craniofacial anomalies and syndromes associated with midface hypoplasia and pharyngeal disturbances.

70.3 Terminology and Classification

According to the American Thoracic Society, OSA of childhood is defined as a disorder of breathing during sleep characterized by prolonged partial upper airway obstruction and/or intermittent complete obstruction that disrupts normal ventilation during sleep and normal sleep patterns.

We have realized over the years that sleep disturbance can be attributed to a disturbance in breathing patterns during sleep. As in the classification of other ailments, categories of mild, moderate, and severe only scratch the surface of the true classification of cases of pediatric OSA.

Pediatric OSA is better defined as a point along a spectrum of sleep-disordered breathing. This spectrum commences with snoring, and as the condition intensifies in severity, it becomes sleep disordered breathing and finally frank pediatric OSA.

Primary snoring is snoring that is not associated with hypoxemia, hypercarbia, or apnea. Snoring is the first step toward the sleep apnea syndrome. It may occur every night or on an intermittent basis. It may be associated with a temporary condition of decreased nasal patency, such as that caused by allergic rhinitis, recurrent sinusitis, or chronic rhinorrhea.

The next entity along the spectrum is upper airway resistance syndrome. This is a combination of snoring with partial airway collapse during sleep. It is associated with restless sleep patterns and a reduction in airflow without hypoxemia, hypercarbia, or apnea.

Finally, the point on the spectrum at which the problem is most severe is OSA. This is characterized by snoring, upper airway resistance syndrome, hypercarbia, hypoxemia, hypoventilation, and frank apnea (□ Fig. 70.1).

70.4 Etiology

The most common cause of pediatric OSA is chronic enlargement of the lymphoid tissues within the pharynx: in the nasopharynx, the nasopharyngeal tonsils (adenoids) and the

Fig. 70.1 Starling resistor model of the upper airway. R_{US} , upstream resistance; R_{DS} , downstream resistance; P_{US} , upstream intraluminal pressure; P_{DS} , downstream intraluminal pressure; P_{crit} , extraluminal pressure in collapsible segment. Airway obstruction occurs when P_{crit} exceeds intraluminal pressure in the collapsible segment.

Primary snoring	Upper airway resistance syndrome	Obstructive hypopnea syndrome	Obstructive sleep apnea
Increase airway resistance without other symptoms	Sleep disturbance with normal blood gas profile	Hypopnea, sleep disturbance without desaturation	Apnea, hypopnea, sleep disturbance with desaturation

Fig. 70.2 The continuum of obstructive sleep-disordered breathing.

nearby tubal (Gerlach) tonsils; in the oropharynx, the pharyngeal tonsils; and at the base of tongue and vallecula, the lingual tonsils.

Although these four sets of tonsils are the most frequent culprits in the origin of pediatric OSA, pediatric OSA can realistically be caused by any of the structures that limit the size of the nasal and oral cavities, all the way to the glottis.

Other conditions within the nasal cavity that can cause OSA include nasal polyposis, nasal septal deviation, turbinate hypertrophy, allergic rhinitis, choanal stenosis/atresia, anterior piriform aperture, and midnasal stenosis.

The nasopharynx and the oropharynx contain more than 30 paired muscles, which maintain the intricate balance between airway patency and airway narrowing. According to the Starling resistor model and Bernoulli's principle, airway resistance is increased not only by relaxation but also by the dynamics of airflow (□ Fig. 70.2).

These laws apply to the small airways associated with craniofacial syndromes and to the low level of muscle tonicity occurring in congenital neurologic conditions, further contributing to obstruction. Still, the most common areas involved in pediatric upper airway obstruction are the tonsils and adenoids, located in the nasopharynx and oropharynx (□ Fig. 70.3 and □ Fig. 70.4).

A high incidence of OSA may associated with obesity, although OSA is more commonly noted in thin children. Obese children are more likely to present with snoring and sleep-dis-

ordered breathing than with frank OSA; however, it should be noted that some extremely obese children may have very severe OSA.

70.5 Sequelae

The consequences of pediatric OSA are diverse and can have lifelong, permanent effects upon a child's growth and development. As a child continues to mature anatomically, physiologically, and immunologically, his or her progress must be monitored with these effects kept in mind. The onset, duration, severity, and progression of OSA may increase a child's risk for developing long-term sequelae.

OSA can be difficult to diagnose in children (□ Table 70.1). Their signs and symptoms do not always accurately reflect the severity of OSA disease, and not enough normative data are available to predict those who will have adverse outcomes.

Children may present with a variety of sequelae affecting multiple body systems, such as failure to thrive, neurocognitive deficits, and cardiopulmonary compromise. Somatic development can be affected; poor growth velocity despite adequate caloric intake and the absence of other chronic illness is a frequent pattern. Not only can adenotonsillar hypertrophy lead to decreased olfactory sensation and decreased taste, it also can cause dysphagia due to the direct impairment of oral and oropharyngeal swallowing.

The caloric expenditure of children who struggle to breathe during sleep may be increased by the effort needed to maintain adequate ventilation; the resultant hypercarbia can impair the physiologic release of insulin-like growth factor and lead to decreased linear growth. After adenotonsillectomy for obstructive apnea, children often exhibit significant weight gain and catch-up growth spurts.

The neurocognitive effects can lead to irritable behavior, lack of attention, and poor school performance. Contrary to popular

belief, lack of sleep in the pediatric population leads to hyperactivity and an increase in aggressive behavior. Frequent snoring has also been associated with poor academic performance.

The cardiovascular sequelae can range from structural abnormalities to autonomic dysfunction. The consequences can include ventricular hypertrophy, pulmonary hypertension, systemic hypertension, cor pulmonale (right-sided heart failure),

Fig. 70.3 Surgical view of tonsillar enlargement with limitation of the oropharyngeal airway.

Fig. 70.4 Surgical view of adenoids with impairment of the posterior choanae and nasopharyngeal airway patency. The red rubber catheters at the top of image pass through the nasal cavity and are retracting the soft palate. The posterior ends of inferior turbinates are seen intranasally beyond the posterior choanae.

Table 70.1 Childhood versus adult obstructive sleep apnea syndrome

	Child	Adult
Presentation		
Underweight/failure to thrive	Frequent	Rare
Daytime mouth breathing	Frequent	Rare
Adenotonsillar enlargement	Frequent	Rare
Daytime drowsiness	Rare	Frequent
Obesity	Common	Uncommon
Male-to-female ratio	1:1	2:1
Sleep pattern		
Obstructive	Obstructive apnea or hypoventilation	Obstructive apnea
Arousal with obstruction	Uncommon	Common
Disrupted	Uncommon	Common
Management		
Surgical	Definitive treatment in most patients	Minority of patients
Medical	Only in Selected Patients	Majority of Patients

and congestive heart failure. It is impossible to predict which children are more likely to develop these serious sequelae, and all children with long-standing untreated obstructive sleep apnea are at risk for serious morbidity and mortality.

The pathophysiology of the cardiopulmonary problems is multifactorial. OSA results in increased levels of catecholamines, which may elevate the diastolic blood pressure; this process begins during sleep and persists into the awakening hours. Recurrent hypercapnia and hypoxia can elicit vasomotor recruitment of the pulmonary circulation, resulting in pulmonary hypertension. It is uncertain whether these sequelae reverse after the treatment of OSA.

70.6 Presentation

OSA may present in several different ways in children. These include loud snoring and restless sleep patterns, behavior problems in school, and cardiovascular manifestations leading to early mortality. The variety of possible presentations may lead to management by several independent specialists. Children may be brought to a developmental pediatrician because of failure to thrive; they may be referred to a neurologist for narcoleptic hypersomnolence or hyperactivity; they may be under the care of a psychologist for behavior issues or a pulmonologist for respiratory insufficiency; they may present to an otolaryngologist for snoring, mouth breathing, and enlarged tonsils. The presentation is complex, demonstrating that OSA may be the etiology of a variety of other problems. In many cases, the parents themselves may not even be aware that their child's snoring is abnormal.

Respiratory Disturbance Index (RDI) Formula

$$\text{RDI} = (\# \text{ obstructive [apnea/hypopnea] events} + \# \text{ Central [apnea/hypopnea] events} + \# \text{ mixed [apnea/hypopnea]}) \times 60 / (\# \text{ minutes of observed sleep})$$

The parental history and physical examination are ineffective for discerning the true severity of the disease. Although a child may present with snoring, it is difficult to distinguish primary snoring from frank OSA. Upon additional questioning, the parents may describe their child as a restless sleeper who moves all over the bed. The child may sleep in odd positions and use the accessory muscles of respiration (manifested as tracheal or sternal retractions) to relieve upper airway obstruction. The parents may observe choking or gagging respirations with periods of apnea, or they may describe “gasping” resuscitative breaths after apneic pauses. The parents often state that their child has very “frightening breathing.”

70.7 Testing

During the history and physical screening process, the physician can determine if further testing is necessary. Family audio and video recordings can be reviewed for more information. These are useful when obtained during deep sleep, several hours after the child has gone to bed. The intensity of the noisy respirations and restlessness is often a better indi-

cator of OSA than are the apneic episodes seen during sleep disturbance.

The physical finding of hypertrophic tonsils and adenoids does not always indicate the severity of OSA. It is the combination of enlarged lymphoid tissues and hypotonia during sleep that indicates the severity. However, if the findings on physical examination do not correlate with the history, further testing may be necessary.

A multitude of tests are available to ascertain the severity of sleep-disordered breathing. These vary from basic pulse oximetry to comprehensive polysomnography. Basic pulse oximetry is a good screening tool to identify patients with significant desaturations due to OSA; however, its negative predictive value is very poor, and further testing is required for clarification.

The 2-hour nap study, which is cost-effective, is performed during the daytime. Because of its brevity, it does not allow rapid eye movement (REM) sleep to be sustained. Therefore, a negative study may not rule out OSA.

Overnight polysomnography is the current gold standard for diagnosing and grading the severity of OSA. There are specific indications for polysomnography (see Box Indications for Polysomnography (p.559)). In addition to situations in which the history and physical examination are neither mutually suggestive nor exclusive, polysomnography is helpful in children who have craniofacial abnormalities, are obese or younger than 2 years of age, or have conditions such as mucopolysaccharidosis, neuromuscular disease, and sickle cell anemia.

Apnea–Hypopnea Index (AHI) Formula

$$\text{AHI} = (\# \text{ obstructive [apnea/hypopnea] events}) \times 60 / (\# \text{ minutes of observed sleep})$$

Polysomnography is a 6-hour overnight examination with multiple components for evaluating sleep disturbance, including electrocardiogram, electro-oculogram, electromyogram, electroencephalogram, pulse oximeter, end-tidal CO₂ monitor, snoring microphone, thoracic/abdominal piezo crystal, nasal thermistor, and videogram.

The following definitions are important in making the diagnosis of pediatric OSA.

1. Central apnea is the absence of chest wall motion with absence of airflow at the nose and mouth for at least 10 seconds.
2. Obstructive apnea is the presence of chest wall motion with absence of airflow at the nose and mouth for at least two respiratory cycles (a breath cycle defined as a cycle of inhalation and exhalation).
3. Hypopnea is a reduction in airflow of at least 50% or a 3 to 4% drop in oxygen saturation and/or arousal.
4. Mixed apnea is the combination of an obstructive component of any duration and a central component of at least 4 seconds' duration or twice the length of the respiratory cycle for that age group.

These components are used in calculating the indices for determining the severity of pediatric OSA. The respiratory disturbance index (RDI) is the sum of the obstructive apneas,

Table 70.2 Classification of pediatric obstructive sleep apnea based on the apnea index

Normal	AHI < 1.5
Mild OSA	1.5 < AHI < 5
Moderate OSA	5 < AHI < 15
Severe OSA	AHI > 15

Abbreviations: AHI, apnea–hypopnea index; OSA, obstructive sleep apnea.

hypopneas, central apneas, and mixed apneas per hour of sleep (see Box Respiratory Disturbance Index (RDI) Formula (p.558)). The apnea–hypopnea index (AHI) is the sum of all obstructive apneas and hypopneas per hour of sleep. The AHI is seen as a more sensitive indicator in pediatric OSA than in adult OSA (see Box Apnea–Hypopnea Index (AHI) Formula (p.558)). An AHI value below 1.5 (events per hour) is considered to be normal in pediatric patients (□ Table 70.2). It is important to take into consideration the presence or absence of oxygen desaturation in conjunction with the AHI.

Indications for Polysomnography

- Differentiate between OSA and primary snoring
- Evaluate symptoms of excessive daytime sleepiness, growth delay, or failure to thrive
- Evaluate patients older than 6 years of age with enuresis refractory to treatment
- Evaluate patients with behavioral or attention disorders, especially when associated with intermittent hyperactivity
- Evaluate patients with unexplained cor pulmonale, pulmonary hypertension
- Confirm the diagnosis and assess the severity of OSA
- Assess the efficacy of adenotonsillectomy in a patient with documented severe OSA
- Determine the CPAP parameters to be used in treating OSA
- When performed with pH monitoring, provide information on the relationship of gastroesophageal reflux disease to respiratory events such as nocturnal asthma, nonproductive cough, and apnea or hypoxemia

Abbreviations: CPAP, continuous positive airway pressure; OSA, obstructive sleep apnea.

Source: Adapted with permission from Alkhalil M, Lockey R. Pediatric obstructive sleep apnea syndrome (OSAS) for the allergist: update on the assessment and management. *Ann Allergy Asthma Immunol* 2011;107(2):104–109.

An intermittent decrease in oxygenation below 90% or a sustained desaturation below 92% is considered hypoxemia. End-tidal CO₂ above 45 mm Hg for more than 60% of the total sleep time or end-tidal CO₂ above 53 mm Hg is considered hypercarbia.

Airway events that result in hypercarbia cause blood gas chemistry changes that alert the body's homeostatic protective mechanisms to sustain adequate ventilation and oxygenation in distant tissues. This protective mechanism is known as an arousal. Arousals occur as a consequence of hypoxemia, hypercarbia, and upper airway resistance and are scored as

respiratory events resulting in arousal (RERAs). Arousals cause significant fragmentation in sleep and should be taken into consideration when the neurocognitive behavior of a child is being evaluated.

70.8 Treatment

Treatment protocols can be medical, nonsurgical, or surgical, depending on the symptoms, their severity, and parental preference. The site of obstruction is a key factor in determining which type of treatment may be used successfully in the management of pediatric OSA.

70.8.1 Medical Treatment Options

If the sleep apnea is mild and the nasal obstruction is caused by turbinate hypertrophy or enlarged adenoids, a trial of intranasal corticosteroids is a viable nonsurgical option. The use of a leukotriene inhibitor or intranasal corticosteroid has been shown to lessen the severity of pediatric OSA by relieving the nasal obstructive component. The effects are known to last for as long as 6 months after the termination of therapy.

Leukotrienes and their receptors are increased in adenotonsillar tissue, suggesting that topical intranasal corticosteroids may have additional beneficial effects in mild to moderate OSA.

In children with allergic rhinitis, montelukast in combination with an intranasal corticosteroid can result in adequate reduction of inflammation. This therapy has also been useful in the treatment of residual sleep-disordered breathing after adenotonsillectomy.

Some studies have shown that after the withdrawal of these medications, long-term effects continue. It is important to remember that a child's immunologic and anatomical status continually matures. Medical management can be used as a temporary treatment to help alleviate sleep apnea during the interim period of growth and development.

70.8.2 Nonsurgical Therapeutic Options

As the anatomical features of a child continue to grow, natural resolution is likely in many cases, given enough time. In mild to moderate OSA, short-term therapy may be all that is needed. In this situation, nonsurgical measures may be the best therapy.

A commonly used form of nonsurgical management is continuous positive airway pressure (CPAP). CPAP splints the airway open. Patient compliance, however, is usually very poor because of the inability to tolerate discomfort. The direct use of supplemental oxygen is not recommended for the treatment of pediatric OSA because it compromises the central respiratory oxygen drive mechanism and leads to further hypercarbia.

The association of OSA with morbid obesity is still unclear. Besides the direct adverse effect of obesity on the cardiovascular system, there is a direct effect of excess lipid deposits in the pharyngeal oral and neck tissues. Studies have not shown that morbid obesity has a direct correlation with the severity of pediatric OSA; however, weight loss is still a frequently recommended method to reduce the severity of pediatric OSA.

Other conservative measures that may resolve intermittent snoring due to inflammatory conditions include the avoidance of environmental allergens and irritants, such as tobacco

smoke. Households with exposure to tobacco smoke have been shown to be strongly associated with snoring in children. Measures to reduce common allergens, such as dust and animal dander, are recommended. Avoidance of any food allergens is also helpful to increase nasal patency.

70.8.3 Surgical Options for Pediatric Obstructive Sleep Apnea

Adenoid, tonsil, and lymphoid hypertrophy is the primary source of upper airway obstruction in most children with OSA. Whether a child has complex medical problems or is otherwise normal, adenotonsillectomy is the initial treatment for alleviating pediatric OSA in the vast majority of patients.

Approximately 80% of children will require only an adenotonsillectomy to relieve their OSA. The remaining 20% will show improvement but may still need additional treatment.

Other recommendations may include the medical management of allergic rhinitis and allergen avoidance. The child with obstruction at other levels may need adjunctive surgeries. Relief of anatomical nasal obstruction may require septoplasty or inferior turbinate reduction. Uvulopharyngopalatoplasty, tongue base suspension, lingual tonsillectomy, or orthognathic surgery may be necessary in selected cases. The atypical child with complex medical problems, hypotonia, or uncorrectable obstruction may require tracheostomy for airway management.

Perioperative management must be individualized to each child's needs. The vast majority of children with mild OSA may successfully undergo adenotonsillectomy as an ambulatory surgery procedure. Children who have craniofacial anomalies, are younger than 3 years of age, have neuromuscular disorders, or have severe OSA should be admitted for postoperative monitoring for airway events and oral intake following surgery.

Contrary to the theoretical belief that edema may develop in the upper airway after surgery, objective polysomnographic measures have shown that surgical treatment for OSA in otherwise normal children significantly reduces obstruction as early as the first postoperative day. Although the airway is nearly always immediately improved, there may be residual abnormalities in the respiratory drive centers in children with severe OSA; these may take 24 to 48 hours to adjust to normal levels of carbon dioxide in the bloodstream. However, it is recommended to wait a minimum of 6 weeks before considering reevaluation with postoperative polysomnography.

70.9 Summary

Pediatric OSA is one of the most commonly diagnosed ailments and has multisystem effects on the development of a child. Previously grouped with adult OSA, pediatric OSA is now considered a separate entity, and its effects on behavior, cognition, and learning in children are well recognized. Accurate diagnosis

and early intervention in cases of pediatric OSA are important in preventing long-term sequelae in growing children. Pediatric OSA comprises a broad spectrum ranging from snoring to sleep-disordered breathing to frank OSA. Although other areas may be involved, OSA is most commonly associated with adenotonsillar hypertrophy in children, and adenotonsillectomy is usually the recommended therapeutic intervention.

70.10 Roundsmanship

- Snoring and disturbed sleep patterns can be the harbinger of other long-term consequences, such as behavior problems, neurologic sequelae, and cardiovascular and pulmonary effects.
- Early diagnosis and treatment are necessary to promote the healthy development of a child.
- Adenotonsillectomy is generally the initial treatment and will cure or alleviate pediatric OSA in most healthy children.
- Postoperative monitoring should be performed on an individual basis for children who may have other risk factors.

71 Cleft Lip and Palate

Robin A. Dyleski and Kenneth M. Rosenstein

71.1 Introduction

Cleft lip and cleft palate are the most common birth defects seen in the head and neck in children. A cleft lip occurs when incomplete fusion of the maxillary and median nasal processes results in an opening of the upper lip. A cleft palate is an opening in the palate caused by failure of fusion of the lateral palatal shelves (□ Fig. 71.1). Cleft lip and cleft palate occur together or individually, with or without other physical defects in the face or organs. Cleft lip and palate are immediately observed at birth, and in addition to the obvious deformity affecting the lip and palate, they may cause difficulties with respiration and feeding immediately following birth. In the emotional moments following a birth, the discovery of a cleft lip can be difficult for the parents. This chapter discusses the anatomical abnormality, genetics, and treatment of cleft lip and palate. Issues related to speech are also discussed, as well as management options. This chapter is not intended to supplant more comprehensive texts on this topic, but to provide an overview of the general care and management of children with cleft lip and palate.

71.2 Epidemiology and Genetics

Second in frequency only to clubfoot (talipes equinovarus), cleft lip and/or palate is the most commonly observed congenital malformation of the head and neck. In general, cleft lip with or without cleft palate is considered to be a distinct and separate condition from cleft palate without a cleft lip. The combined risk for cleft lip with or without cleft palate and cleft palate in the United States is about 1 in 600 live births. The risk for cleft lip with or without cleft palate is about 1 in 940 live births, whereas the risk for cleft palate without cleft lip is 1 in 1,500 live births, based upon the latest data (2006) from the National Institutes of Health Center for Dental and Craniofacial Research (□ Table 71.1). Additionally, gender affects the prevalence of cleft lip with or without cleft palate, with boys twice as likely to be affected as girls. In the case of isolated cleft palate without cleft lip, girls are affected twice as frequently as boys. In the United States, ethnicity affects the rates of clefts; Native Americans have the highest rate of clefting, at 3.6 per 1,000 births, followed by persons of Asian descent, Caucasians, and African-Americans (□ Table 71.2).

Both cleft lip with or without cleft palate and cleft palate may present as part of a syndrome or without any other identifiable malformations (nonsyndromic). Genetic counseling is highly recommended because of the high risk that the obvious cleft lip and palate are part of a recognized syndrome.

Specific genetic syndromes are inherited via single-gene transmission (autosomal-dominant, autosomal-recessive, X-linked) and via various chromosomal deletions, translocations, and additions, including trisomy. Many factors (both genetic and nongenetic) influence the development of cleft lip or palate. Well-known maternal risk factors include diabetes and gestational diabetes, folate deficiency, drug exposures (e.g., ethanol, phenytoin, thalidomide), and environmental exposures (e.g., to-

bacco smoke). The gene for transforming growth factor- α (TGF- α) has specifically been found to influence nonsyndromic cleft formation and is the focus of much research in cleft causation.

Syndromes that frequently include cleft lip with or without cleft palate are listed in □ Table 71.3. Increasingly, syndromes have become more often located to abnormalities at specific genetic loci. Knowledge of the presence of a syndrome benefits the child by allowing early access to programs that can assist parents in dealing with associated developmental problems the child may manifest.

71.3 Embryology

Cleft lip with or without cleft palate and isolated cleft palate are considered separate conditions not only because they seem to differ in epidemiologic expression but also because they occur at different times during embryologic development. Embryologic development of the lips and palate occurs very early in the fetus, in the first trimester. There are two related phases. The first begins in the fourth to fifth week of embryogenesis and involves formation of the lips, nose, and primary palate (the premaxilla, which is the bony palate consisting of the alveolus with the central four incisors anterior to the incisive foramen). The second phase, which begins around the eighth to ninth week, is closure of the secondary palate (the two lateral palatal shelves containing all the remaining teeth and the soft palate).

71.3.1 Embryology of the Cleft Lip

Around the fourth to fifth week, the ectoderm and mesoderm of the frontonasal and two lateral labial maxillary processes proliferate. The frontonasal process is destined to become three structures: (1) the philtrum (anterior labial segment), (2) the central alveolus containing the four upper incisors (anterior palatal segment), and (3) the hard palate anterior to the incisive foramen (posterior palatal segment). This process occurs and is completed by the end of the sixth week of development when the two lateral labial maxillary processes fuse with the central frontonasal process (□ Fig. 71.2).

The frontonasal process forms with differentiation of the olfactory placode epithelium. Differential growth of the placode forms the curl of the nasal ala at the same time that the frontonasal process develops. Fusion begins at the nasal sill, forming the ovoid nostril shape, and continues down the upper lip to the free edge of the vermilion on the lip, while simultaneously the lateral palatal shelves fuse with the central premaxilla, closing the alveolus bilaterally. The current theory of labial and palatal formation involves epithelial contact of the edges of the processes with differential resorption of the surface epithelial cells, modulation and fusion of the mesodermal layer, and further differentiation of the germ layers into the bone, muscle, mucosa, and skin. The direction of the fusion of the three processes explains the great degree of variation in the severity of cleft lip and primary (alveolus) palate defects. Cleft lip can be unilateral or bilateral, complete (open all the way to the nose)

Fig. 71.1 (a) Child with unilateral cleft lip before repair. (b) Same child immediately after repair of cleft lip. (c) Same child, age 2 years. (d) Child with bilateral cleft lip before repair. (e) Same child immediately after repair of bilateral cleft lip. (f) Same child, age 3 years. (g) Unrepaired cleft palate.

Table 71.1 Average prevalence of cleft lip and palate and number of births affected by these defects each year in the United States, 2004 to 2006

	Prevalence ^a	Annual number of cases
Cleft palate only	6.35	2,651
Cleft lip with or without cleft palate	10.63	4,437

Source: Data from the U.S. Centers for Disease Control and Prevention (CDC) National Birth Defects Prevention Network (NBDPN). Cleft lip and palate data for 2004 to 2006 collected from 13 states (Arkansas, Arizona, California [eight-county Central Valley], Colorado, Georgia [five-county metropolitan Atlanta], Illinois, Iowa, Kentucky, Massachusetts, North Carolina, Oklahoma, Texas, and Utah) and Puerto Rico, representing 4,038,506 live births and adjusted for race-specific distribution.

^aPrevalence per 10,000 live births.

Table 71.2 Rates of cleft lip with or without cleft palate within different ethnic groups in the United States

Ethnic group	Rate of cleft lip ± cleft palate (per 1,000 births)
Native Americans	3.6
Asians	2.1
Caucasians	1
African-Americans	0.5

or incomplete (extending partially from the free vermilion edge up to the nose). Also, the alveolus may be uninvolved (normal) or completely or incompletely cleft (□ Fig. 71.3).

The second, or palatal, phase is complete by the 10th week. The lateral palatal shelves grow and protrude medially. Because the primary palate has fused (along with the lip) by the end of the sixth week, the secondary palate (the palate posterior and immediately lateral to the incisive foramen) is in position

Table 71.3 Common syndromes associated with cleft lip and palate

Syndrome	Cleft type	Inheritance Mode
Velocardiofacial	Cleft palate	Autosomal-dominant
Stickler	Cleft palate	Autosomal-dominant

to begin the process of making epithelial contact and undergoing epithelial resorption and mesodermal merging, with fusion at the midline. At the onset of this process, the forming tongue is located in the space between the lateral palatal shelves, causing a sloping cant to the lateral shelves. As the palate fuses from the incisive foramen anteriorly to the uvula posteriorly, the tongue position drops away. The process and direction of fusion explain the variety of cleft palates seen in our patients, with many degrees of incomplete closure ranging from cleft uvula to a complete cleft of the secondary palate (cleft extending to the incisive foramen; □ Fig. 71.4).

71.4 Classification of Cleft Lip and Palate

Understanding the embryology of cleft lip and palate has made it possible to devise a classification of cleft lip and palate for documentation and comparison. As mentioned earlier, clefts can be complete (failure of the entire fusion process) or incomplete (partial fusion of the lip or palate). Complete cleft lip is more commonly associated with complete cleft palate because the failure of closure of the lip and alveolus sets the secondary palate edges far enough apart to reduce the likelihood of contact and initiation of the fusion process.

In general, the most commonly used classification of clefts follows the scheme devised at the University of Iowa Department of Otolaryngology-Head and Neck Surgery (□ Fig. 71.5). This classification divides clefts into four groups: group I, lip; group II, palate only; group III, alveolus and palate; and group IV, alveolus only. Group I (clefts of the lip) is subdivided into unilateral (right or left) and bilateral and further into complete and incomplete. Complete cleft lip (either unilateral or bilateral) extends completely into the nasal sill. An incomplete cleft lip extends a variable distance from the vermilion free edge.

In group II (palate-only clefts), the cleft is classified according to whether the cleft affects only the uvula or extends into the soft palate, and according to the degree of distance and shape of the hard palate component of the cleft. The cleft deformity seen in Pierre Robin sequence (an association of retrognathia/micrognathia, airway obstruction, and U-shaped cleft palate) is an example of group II-4, the U-shaped complete cleft palate.

Group III comprises the commonly seen variations of cleft lip with cleft palate, unilateral and bilateral. The alveolar (primary palate) clefts included in group IV are clefts of the alveolus that are associated with cleft lip. These alveolar clefts are not associated with a cleft of the secondary palate. The classification does not include the classic submucous cleft palate (diastasis of the soft palatal musculature, bifid uvula, and posterior V-shaped notching of the posterior midline hard palate), which is

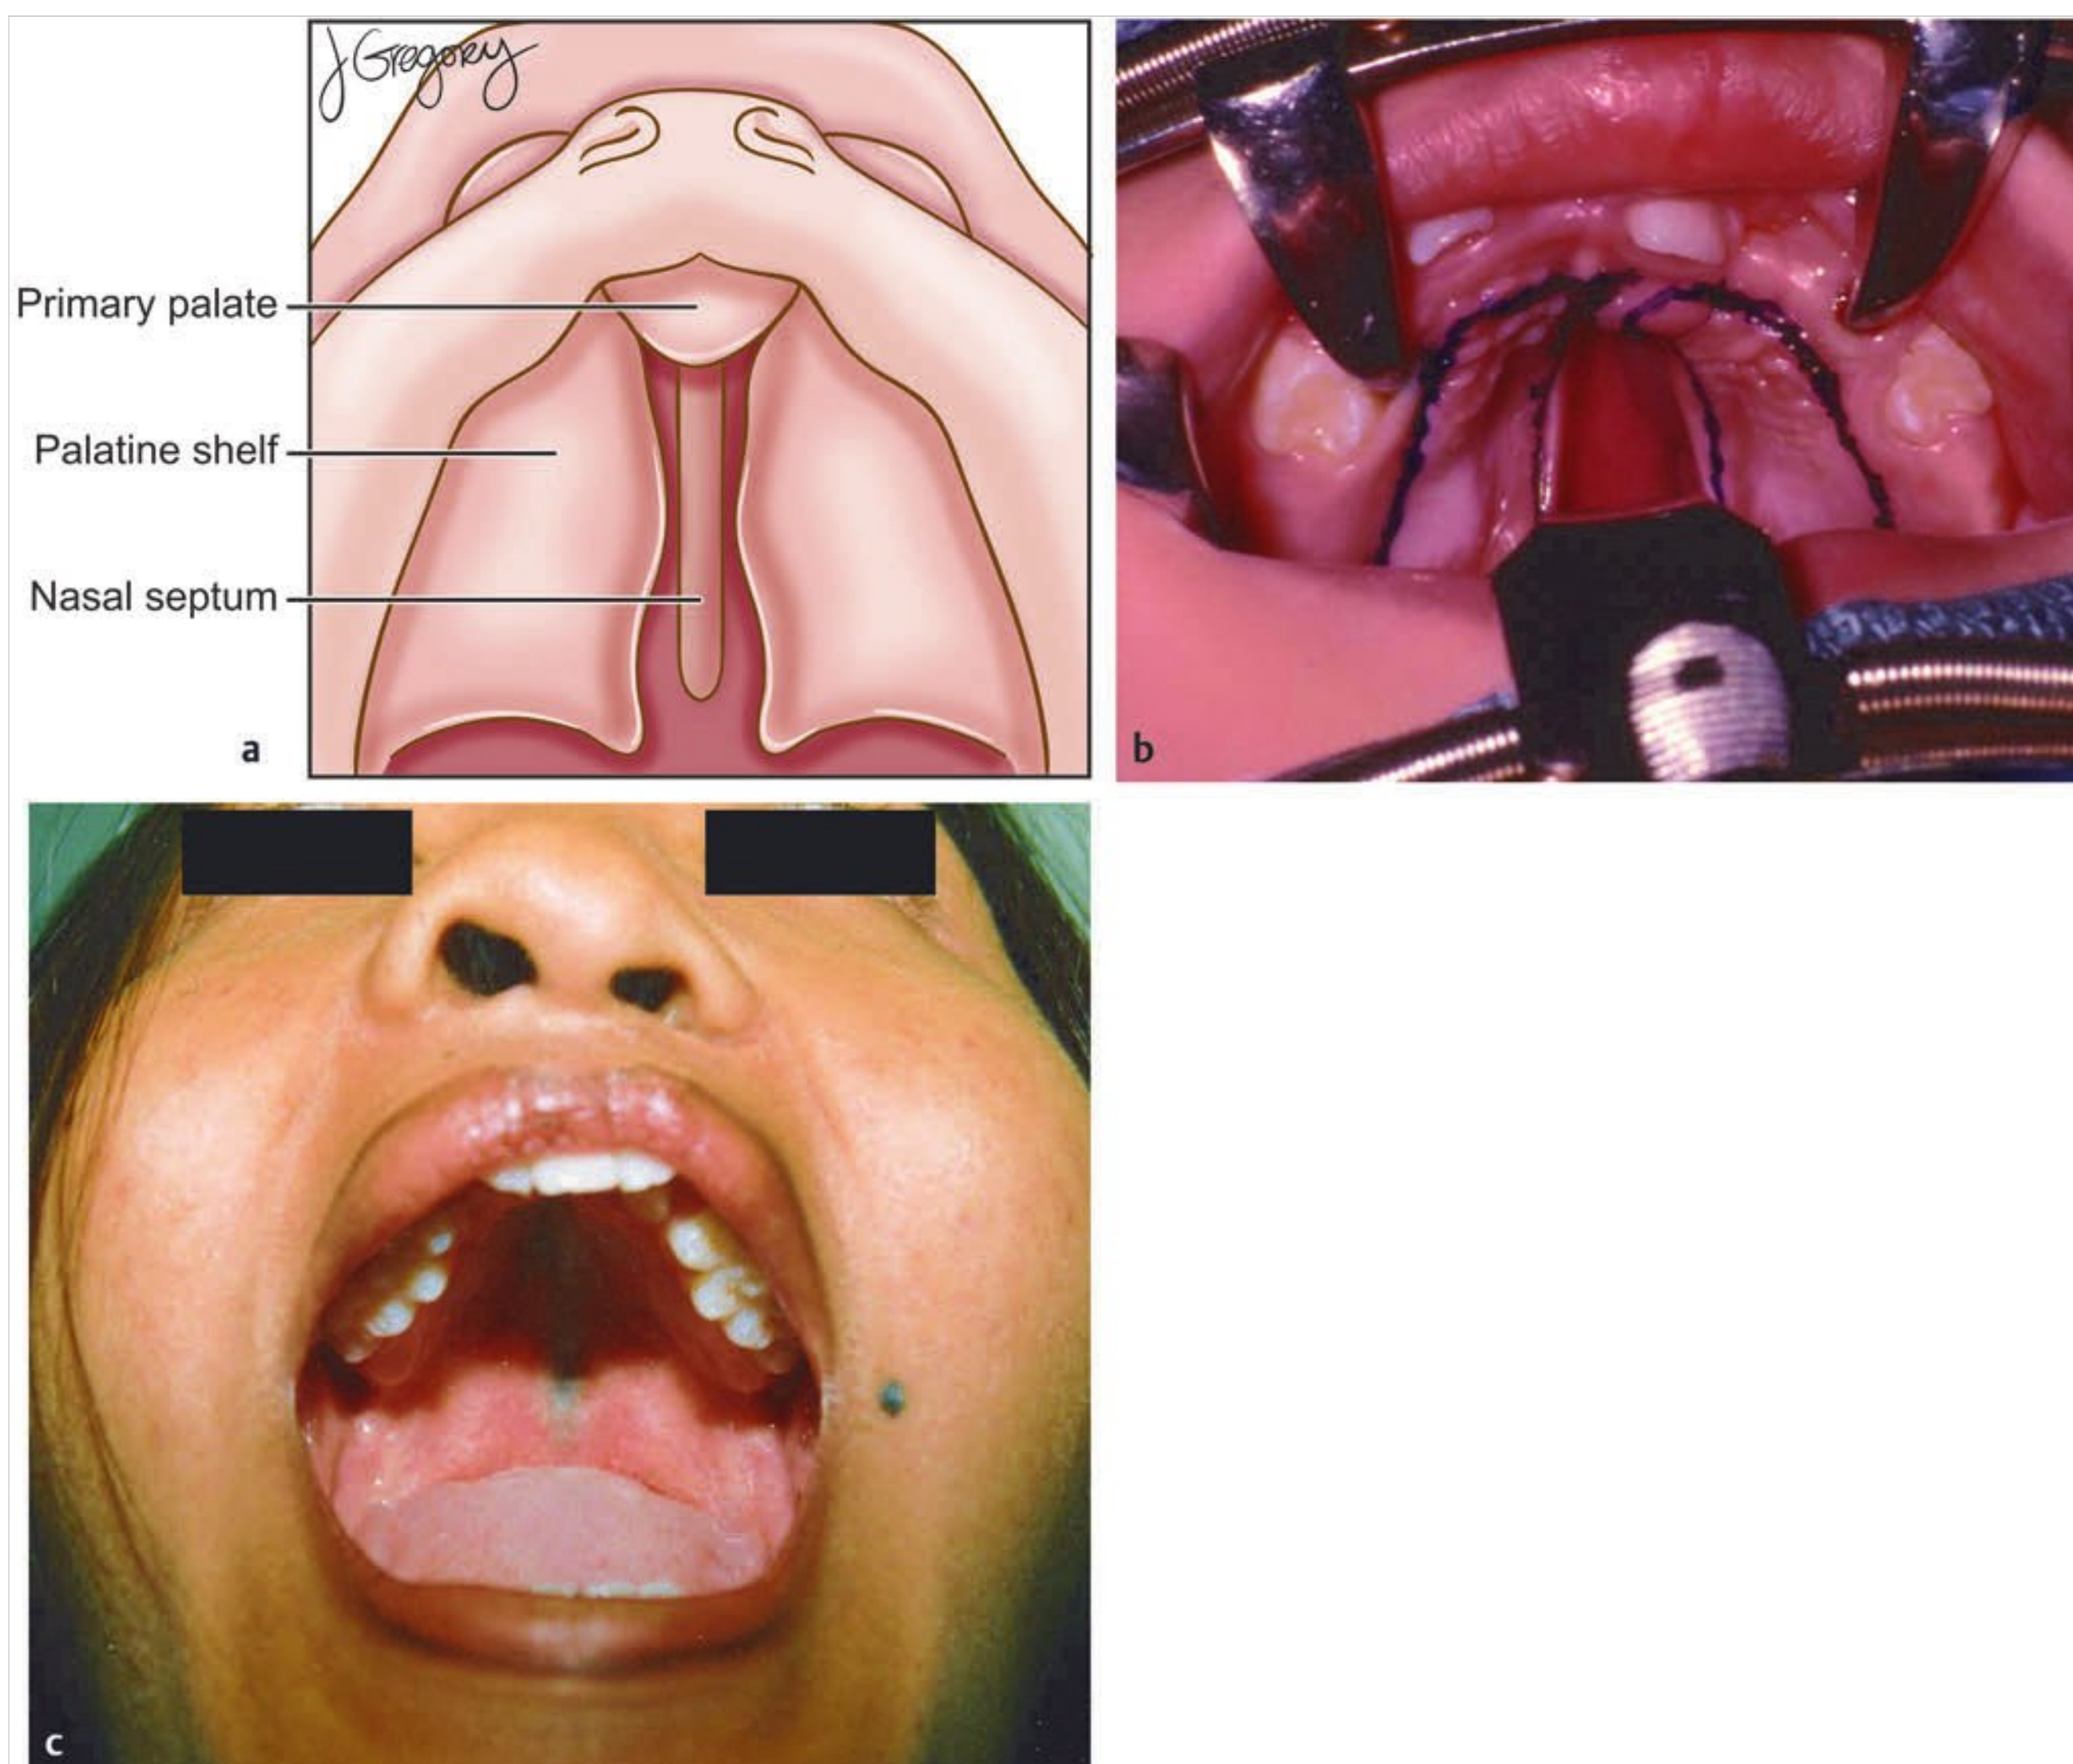

Fig. 71.4 (a) Palatal closure at 6.5 weeks. (b) Unrepaired complete cleft palate. (c) Submucous cleft palate.

a microform cleft palate. Submucous cleft palate is considered an incomplete cleft of the secondary palate.

71.5 Initial Evaluation and Care of the Infant with Cleft Lip or Cleft Lip and Palate

Babies born with cleft lip with or without cleft palate or cleft palate can have considerable difficulties in the newborn period. The first challenge these children face is respiration. The alteration in oral anatomy and the relationship of the tongue base to the pharynx and palate may result in airway obstruction requiring intervention. Most babies with cleft palate soon adapt to breathing with their cleft palate; however, various maneuvers can assist the child in accommodating, such as lateral positioning, placement of nasogastric tube (which moves the tongue

away from the posterior pharynx), and continuous positive airway pressure devices.

Feeding the baby with a cleft lip and palate can be difficult. After airway stability is established, maintaining oral feeding is essential. Children with cleft lip alone or with alveolar clefting only are usually able to use a standard nipple or be breastfed, but they may have some difficulty creating a seal around the nipple because of the lip defect. Babies with cleft palate have more special feeding needs. Because a cleft palate (except for incomplete alveolar clefts) prevents the infant from establishing oral suction, a child with a cleft palate usually needs a nipple that does not require sucking. Special nipples are available to facilitate feeding babies with cleft palate, such as the Pigeon and Haberman cleft palate nipples. These nipples contain one-way valves that allow milk to flow in only one direction: from the bottle into the nipple. The baby applies pressure from the alveolus to express the milk from the nipple. Most babies with cleft palate are able to feed and grow with these nipple systems.

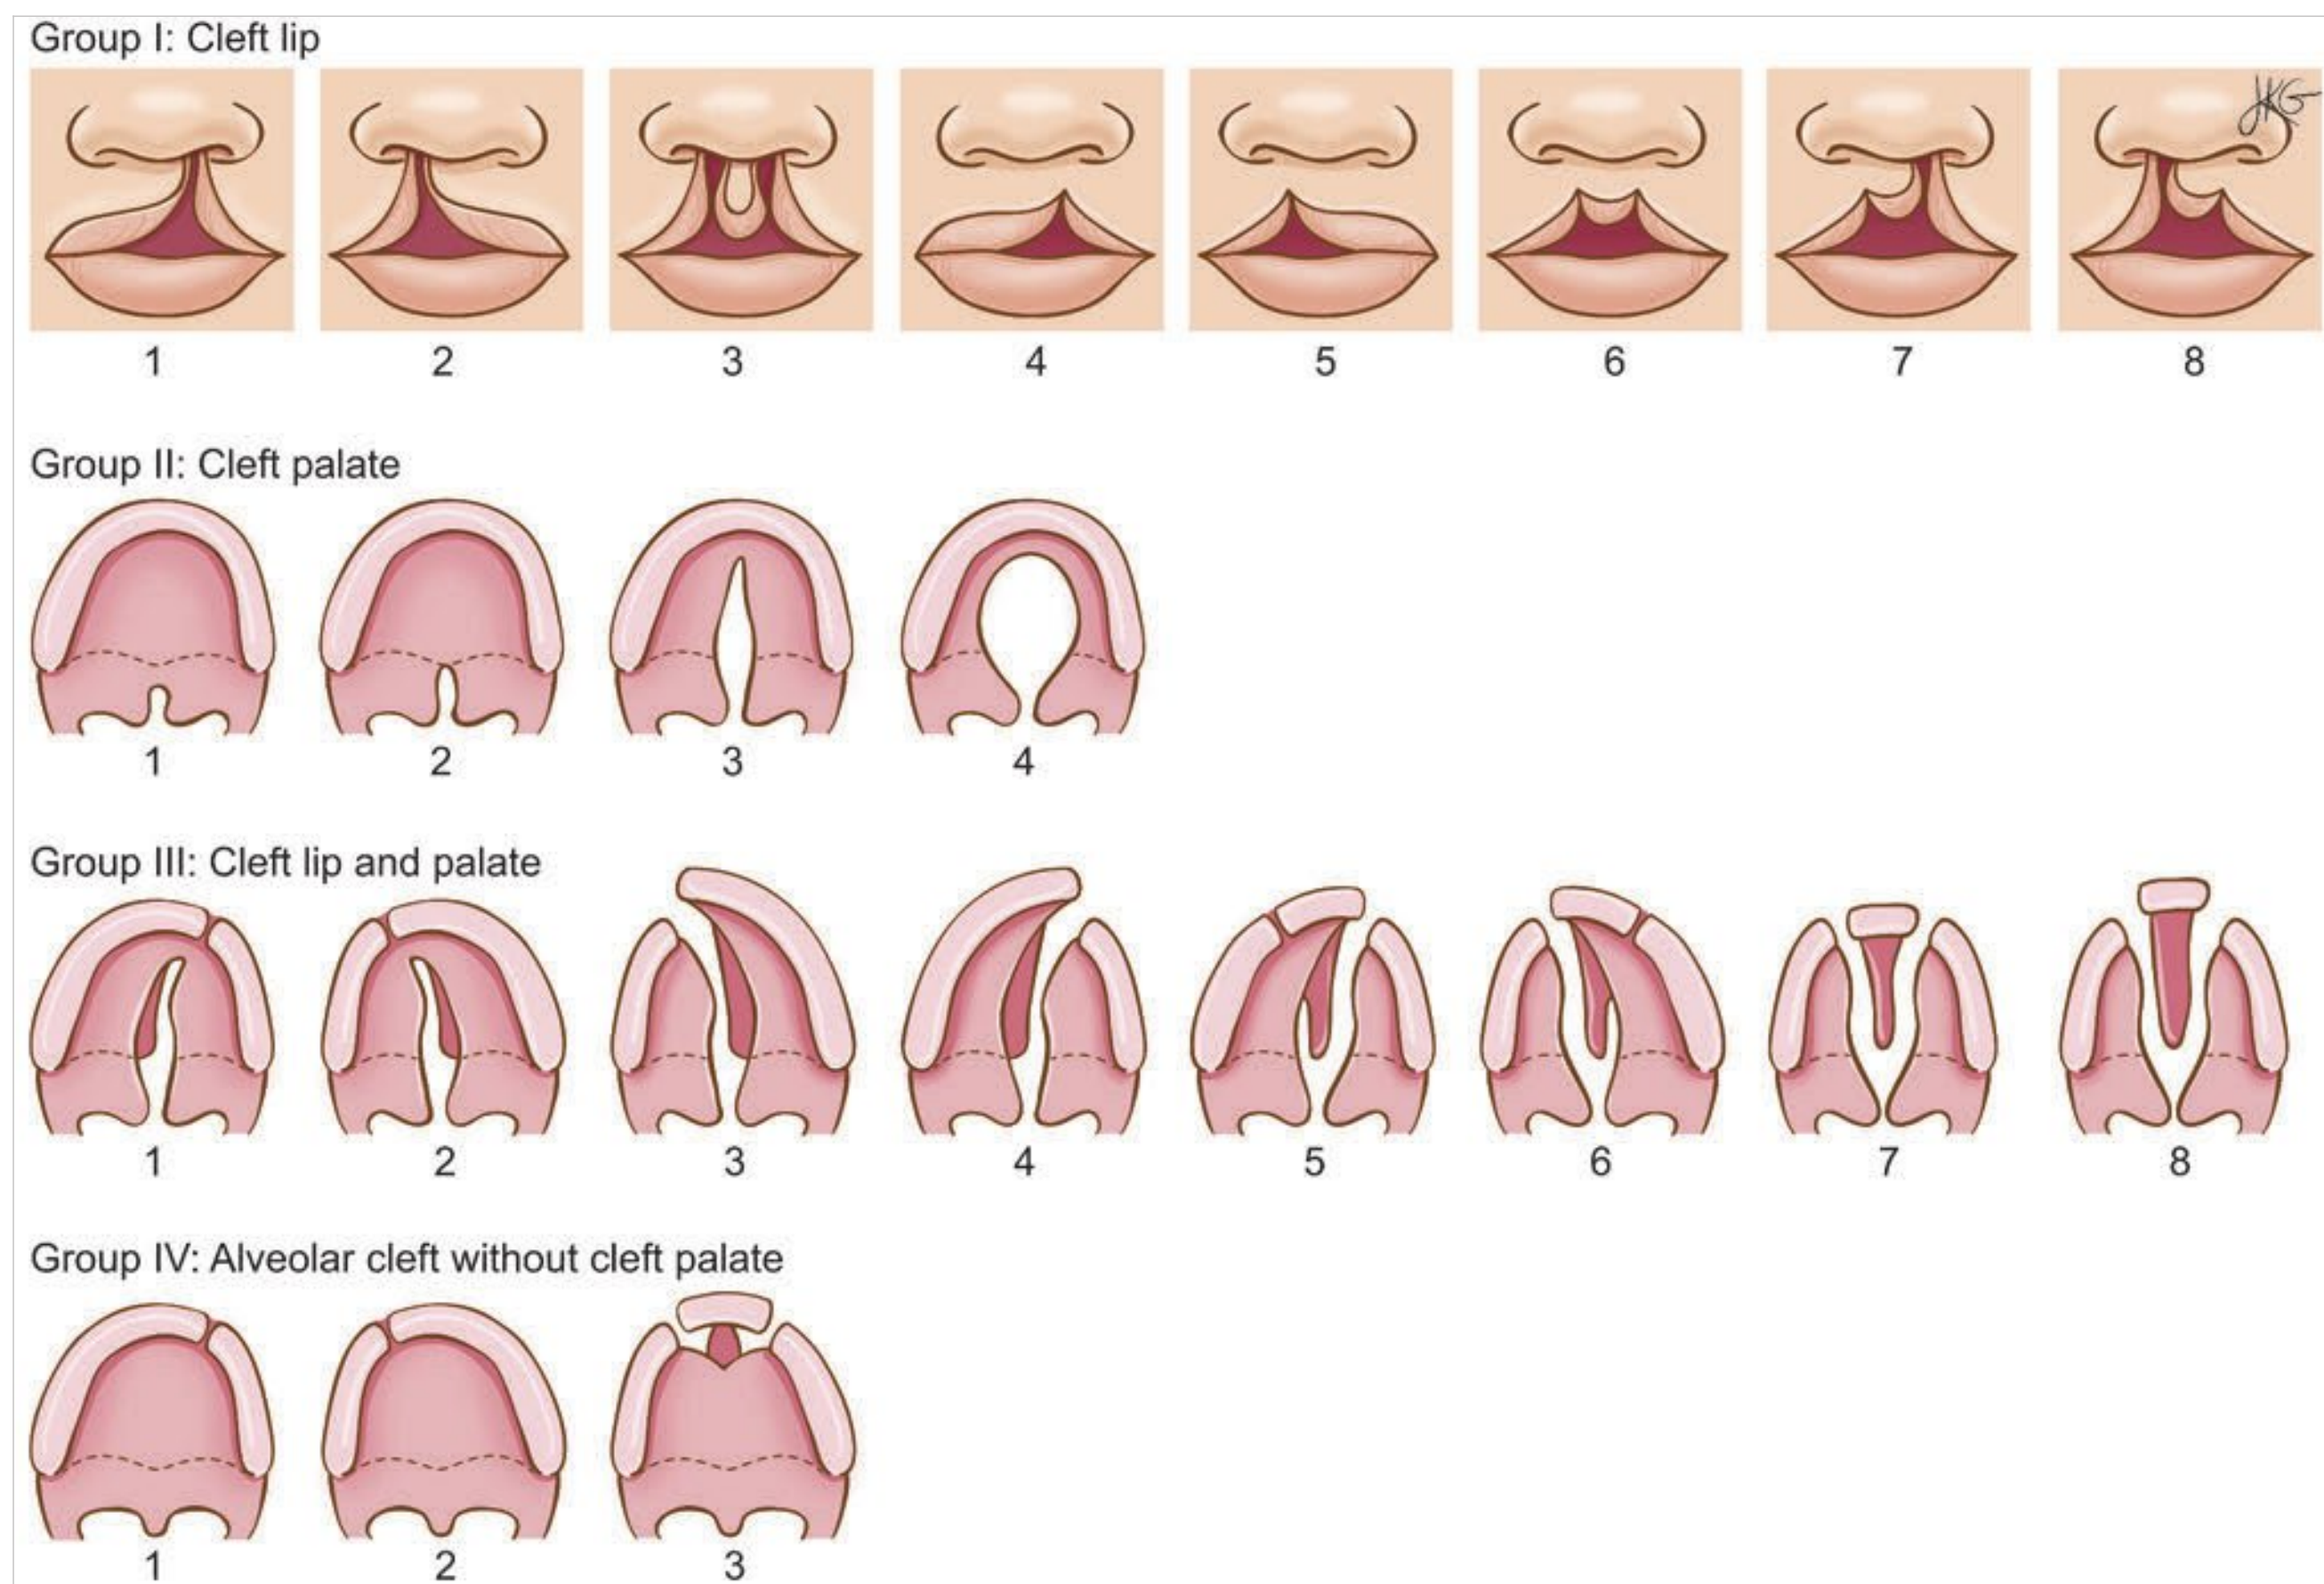

Fig. 71.5 Cleft classification used by the University of Iowa Department of Otolaryngology-Head and Neck Surgery.

71.6 Surgical Management of Cleft Lip and Palate

Cleft lip and palate repair is usually performed in the first year of life. In a child who is growing and gaining weight well, cleft lip and palate repair can proceed according to a general schedule used by most cleft surgeons.

71.6.1 Cleft Lip

Cleft lip repair helps the baby feed by improving its ability to seal its lips around the nipple. Most healthy children have gained sufficient weight by 8 to 12 weeks of age to undergo a safe cleft lip repair. In general, the “rule of tens” can be followed: cleft lip repair when the infant is about 10 weeks of age, weighs 10 lbs., and has a hemoglobin level of 10 g/dL. There are advantages to performing the cleft lip repair in the first few months of life in a child who is growing and thriving. The repaired cleft lip has a positive orthopedic effect on the width of the alveolar cleft in the patient with a complete cleft lip and palate, resulting in a significant narrowing of the alveolar and palatal cleft.

71.6.2 Cleft Palate

In the United States, repair of cleft palate is performed around 10 to 14 months of age in healthy children. Another “rule of

tens” is generally used: age of 10 months, weight of 10 kg, and hemoglobin level of 10 g/dL. Other factors are considered in the timing of cleft palate repair, such as the width of the cleft palate (distance between the palatal shelves), degree of airway obstruction anticipated after repair (particular in babies with Robin sequence), and other medical comorbidities. The most commonly observed postoperative concern is airway obstruction resulting from the change in the baby’s reconstructed oropharyngeal airway. This must be anticipated and monitored postoperatively. It is sometimes necessary to delay a palate repair for several months to allow the baby to grow and so avoid airway obstruction after repair.

71.6.3 Surgical Technique of Cleft Lip Repair

Many techniques for cleft lip repair have been developed, but the most commonly used repair follows the general design described by Dr. Ralph Millard in the 1950s: the rotation–advancement repair. This technique has been adapted over the years, but the general tenets remain constant: restoration of the natural Cupid’s bow, camouflage of the scars in the philtral ridges, reconstruction of the orbicularis oris musculature, and correction of the nasal deformity seen in cleft lip. Bilateral cleft lip repair follows similar principles, but the surgeon must proceed without a “normal” side as a guide.

Unilateral Cleft Lip Repair

Although there are many techniques available for unilateral cleft lip repair, the Millard rotation–advancement technique will be described here. This technique is versatile and can be used in any unilateral cleft lip regardless of whether it is a microform cleft lip or a wide complete cleft. It is based upon the identification of key surgical landmarks (□ Fig. 71.6a). The noncleft side is the rotation flap, and the cleft side–lateral lip is the advancement flap. An advantage of the rotation–advancement repair is the ability to modify the technique during the procedure as needed to fit the patient.

The landmarks 1 through 9 are marked with gentian violet or methylene blue as follows:

1. Nasal alar base on the noncleft side
2. Peak of Cupid’s bow on the noncleft side
3. Midline of Cupid’s bow (low point of the bow)
4. Peak of Cupid’s bow on the cleft side (medial)
5. Peak of Cupid’s bow on the cleft side (lateral, at the attenuation of the white roll and vermilion–cutaneous junction)
6. Point at the superior aspect of the advancement flap (lateral lip), which sets the “height” of the lip at the philtral ridge
7. Nasal alar base on the cleft side
8. Superior extent of the rotation incision, which should be about at the midline in the crease of the upper lip–nasal columella
9. Back cut incision length (if needed). This extra incision is used to lengthen the rotation incision and increase the degree of rotation of the rotation flap.

After these landmarks have been marked, the distances are measured for symmetry and then the proposed incisions are infiltrated with local anesthetic containing epinephrine. The rotation flap incisions are first incised and the rotation flap is checked for symmetry and a horizontal level at the Cupid’s bow peaks. If the two Cupid’s bow peaks are not in a horizontal plane, then the back cut (incision 8–9) is incised to make it horizontal (□ Fig. 71.6b.)

The lateral lip segment (advancement flap) is incised along the cleft edge and a short distance from point 6 toward point 7. At this point, the nasal lower lateral alar cartilage is dissected free from its overlying skin (□ Fig. 71.6c), if this is desired. The columella is reconstructed with rearrangement and closure of the back cut. The key tension-bearing stitch, which is the stitch that sets the uppermost aspect of the lip muscle, is placed (□ Fig. 71.6d). If alar cartilage has been freed from the overlying nostril skin, it is positioned and held in place with nylon suture tied externally over bolsters (□ Fig. 71.6e). The cleft incision is then closed in layers with absorbable suture in the orbicularis oris muscle, inner lip mucosa (not seen in figure), and then finally the lip skin and vermilion. Nonabsorbable sutures may be used, but some surgeons find that Dermabond (Ethicon, Somerville, NJ) leaves a more pleasing scar and requires less wound care on the part of the child’s caregivers.

Bilateral Cleft Lip Repair

Bilateral cleft lip repair is more technically challenging than unilateral cleft lip repair. In bilateral cleft lip repair, it is necessary for the surgeon to create symmetry, particularly if the lip is

not symmetric (one side is complete and the other side is incomplete). The general technique using specific anatomical landmarks is similar to that for the unilateral cleft. Millard introduced a technique in the 1950s that has remained popular to this time, with various modifications as needed to suit the patient’s unique anatomical situation.

A recent innovation by Cutting and Grayson, nasoalveolar molding, has gained popularity because it permits treating the short columella along with narrowing the cleft width. Nasoalveolar molding requires the use of a prosthesis (□ Fig. 71.7) that is constructed based on an impression of the patient’s nasoalveolar cleft. Orthodontic taping and weekly adjustments to the prosthesis progressively elongate the columella. Surgical correction of the cleft lip is then performed at around 6 months of age. The innovation of nasoalveolar molding has improved the appearance of patients with bilateral cleft lip nasal deformities in a nonsurgical manner.

The repair begins with a determination of the surgical landmarks of the lip. The central lip element, the prolabium, is destined to be the future philtrum and is banked for future columella lengthening (if nasoalveolar molding is not performed). The height of the prolabium dictates the height of the repaired cleft lip. Children with a very small prolabium are problematic because there is no optimal way to lengthen a very short upper lip without creating a scar in an unnatural and unfavorable location.

The surgical landmarks are placed with gentian violet or methylene blue as follows (□ Fig. 71.8):

1. Midpoint of the prolabium, the midpoint of the future Cupid’s bow
2. and 3. Prolabium peaks of the future Cupid’s bow, measured 2 to 3 mm lateral to point 1
4. and 5. Junction of the columella and the prolabium, future superior aspect of the philtrum ridges
6. and 7. The measured height of 2–4 marked at the white roll attenuation on the cleft edge
8. and 9. Similar to 6 and 7 on the opposite cleft edge
- * Point at vermilion, measured distance of 1–2 plus 1 to 2 mm. This creates the hemivermilion flap under the Cupid’s bow.

In bilateral cleft repair, the measurements are much more critical than in unilateral repair because symmetry is created in the design of the lip repair. After the landmarks and incisions have been marked (□ Fig. 71.8a), local anesthetic containing epinephrine is injected. Prolabium incisions are made first, but the incisions at 1–2 and 1–3 are partial-thickness incisions because the mucosal “e” flap is pedicled upon the inferior aspect of the future philtrum at 1–2 and 1–3 (□ Fig. 71.8b). Lateral flaps from the prolabium are raised if one wishes to “bank” them under the nostril for future columella lengthening or to use them in closing the nasal sill. Residual mucosa from the prolabium is used to line the anterior premaxilla (□ Fig. 71.8c). Lateral incisions are made, with care taken to make sure that the “*” vermilion flaps are full-thickness flaps and contain sufficient mucosa to create the future labial tubercle at the middle of the lip under the philtrum. The lateral lip flap mucosa is closed with 5–0 chromic suture (□ Fig. 71.8d). The orbicularis oris muscle in the lateral lip segments is approximated at the midline (□ Fig. 71.8e). Then, the midline “*” flaps are sutured to each other to establish vermilion continuity with both deep

(c) Residual prolabial mucosa is used to line the anterior premaxilla, and full-thickness vermilion flaps are incised. (d) The mucosa of the lateral lip segments is closed with chromic sutures. (e) The fibers of the orbicularis oris muscle are aligned and approximated; the “*” vermilion flaps are sutured together. (f) The philtral flap is then sutured between the lateral lip segments, and the “e” flap is sutured behind the medial vermilion flaps; the lateral prolabial flaps are inset into the nasal sills and closed.

and mucosal sutures (□ Fig. 71.8f). The philtrum with the attached “e” flap is then inserted between the lateral lip segments at the midline, with care taken to “tuck” the “e” flap into the space behind the “*” vermilion flaps, as depicted in panel 8G. The purpose of the “e” flap is to keep the philtrum from retracting superiorly, thus broadening the scar at the vermilion–cutaneous junction, and to provide bolstering and bulk to the vermilion tubercle. The two lateral prolabium flaps are sutured into position beneath the nasal sill (if needed or if future use is planned). The skin is closed with fine nonabsorbable suture, or Dermabond may be used when the edges are closely approximated (panel 8H).

71.6.4 Cleft Palate Repair

Historically, many techniques have been reported for cleft palate repair. The most commonly used palatoplasty procedures today are variations of the Wardill-Kilner-Peet repair (V to Y advancement), the Bardach two-flap repair, and the Furlow repair (double reverse Z-plasty). For many surgeons, the selection of the palatoplasty technique is related to the type of cleft present (complete vs incomplete) and the width of the cleft gap. All three procedures are good methods of repair. Palatoplasty includes treatment of the soft palate musculature with intravelar veloplasty (repair of the muscles within the soft palate with re-orientation of the fibers), except when the Furlow technique is

performed on the soft palate. The Furlow palatoplasty technique can be used on the soft palate, with the Wardill-Kilner-Peet or the two-flap technique used for repair of the hard palate.

Bardach Two-Flap Palatoplasty

This procedure is often used for patients who have complete cleft palate. The procedure relies upon bilateral mucoperiosteal pedicled flaps based upon the descending palatine artery. It is performed by first infiltrating the palate with local anesthetic containing epinephrine. The cleft edges are incised, and lateral relaxation incisions are made along the alveolar ridge (□ Fig. 71.9a). Subperiosteal flaps are elevated with preservation of the descending palatine artery, located as it exits its foramen at the lateral posterior hard palate border (□ Fig. 71.9b). The vascular pedicles are carefully dissected to extend the range of rotation of the flaps. The soft palate muscles are then released from the posterior border of the hard palate. A vomer flap is elevated (□ Fig. 71.9c) so that the nasal mucoperiosteal layer can be closed to seal the nose, with closure beginning anteriorly and proceeding posteriorly toward the uvula (□ Fig. 71.9d). The soft palate muscle fibers are re-oriented to lie horizontally in the soft palate and sutured together (the intravelar veloplasty). The soft palate mucosa and hard palate mucoperiosteal flaps are closed with absorbable suture (□ Fig. 71.9e). The lateral relaxing incisions at the alveolus are

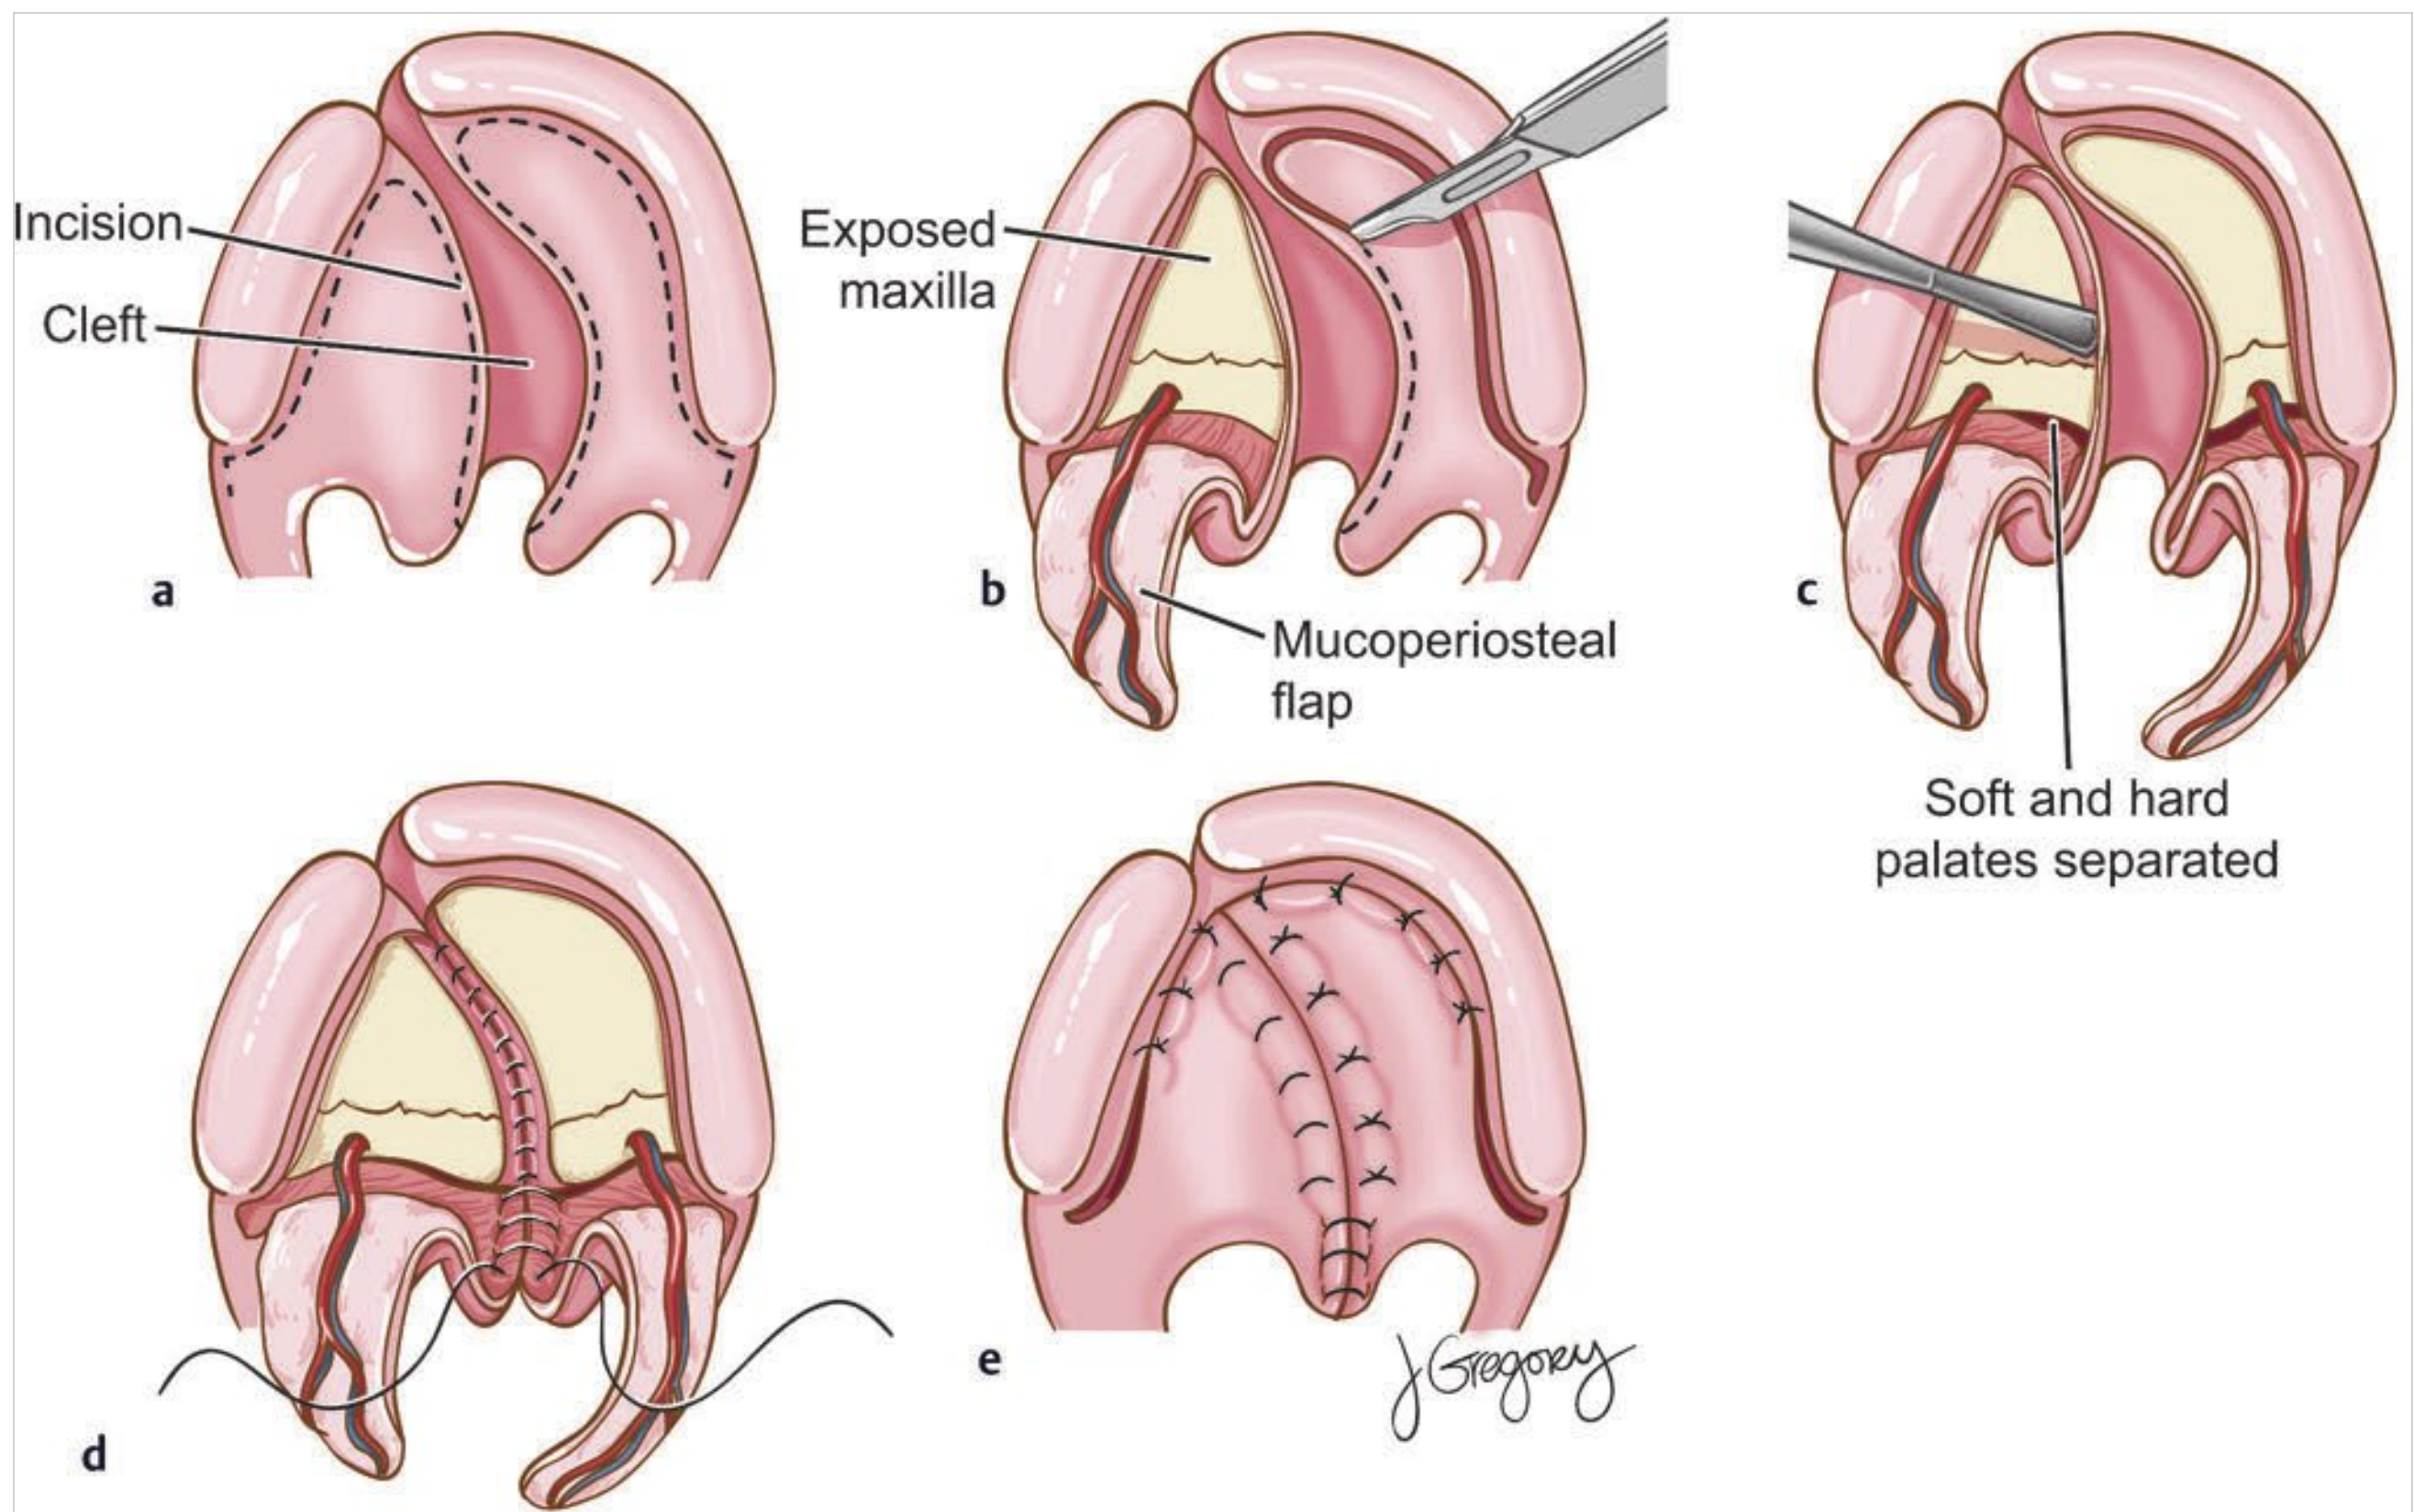

Fig. 71.9 Bardach two-flap palatoplasty. (a) Mucosal incisions. (b) Incisions are made along the cleft edge, allowing the development of nasal and palatal mucosal flaps. (c) The palatal flaps are raised and left pedicled posteriorly. (d) The soft tissues are released to allow full rotation about the vascular supply, the descending palatal artery; the vomer flap is elevated for use in nasal closure, and the nasal mucoperiosteum is closed. The soft palate muscles are reoriented and sutured together. (e) The palatal flaps are rotated and sutured.

Fig. 71.10 Modification of the unilateral palate repair for bilateral cleft repair.

usually left open to close by secondary intention or are packed with microfibrillar collagen.

The benefits of this closure are that it is robust, with modifications easily made to close fairly wide cleft palate gaps (use more vomer flap), and that the Furlow palatoplasty (discussed later) may be used for closure of the soft palate. This procedure is also used with modification for bilateral cleft palate repair, with the midline vomer used to create flaps for closure of each side of the nasal floor (□ Fig. 71.10).

Wardill-Kilner-Peet Palatoplasty (V to Y Advancement)

The V to Y advancement palatoplasty technique is often used to repair clefts of the secondary palate (those beginning at or posterior to the incisive foramen). It also can be combined with the Furlow palatoplasty (on the soft palate). The technique relies upon lateral palatal mucoperiosteal flaps, but they are “pushed back” toward the soft palate, providing some additional length to the palate (although this is somewhat limited). The flaps (□ Fig. 71.11a) are designed such that the “point” of the flap is aimed toward the location of the canine teeth. The mucoperiosteal palate flaps and pedicles are raised (□ Fig. 71.11b), as described for the Bardach two-flap repair. Similarly, nasal mucoperiosteal flaps are raised and closed to create the nasal floor. If the vomer is involved in the cleft, then the nasal floor should be closed on each side separately (□ Fig. 71.11c). The procedure

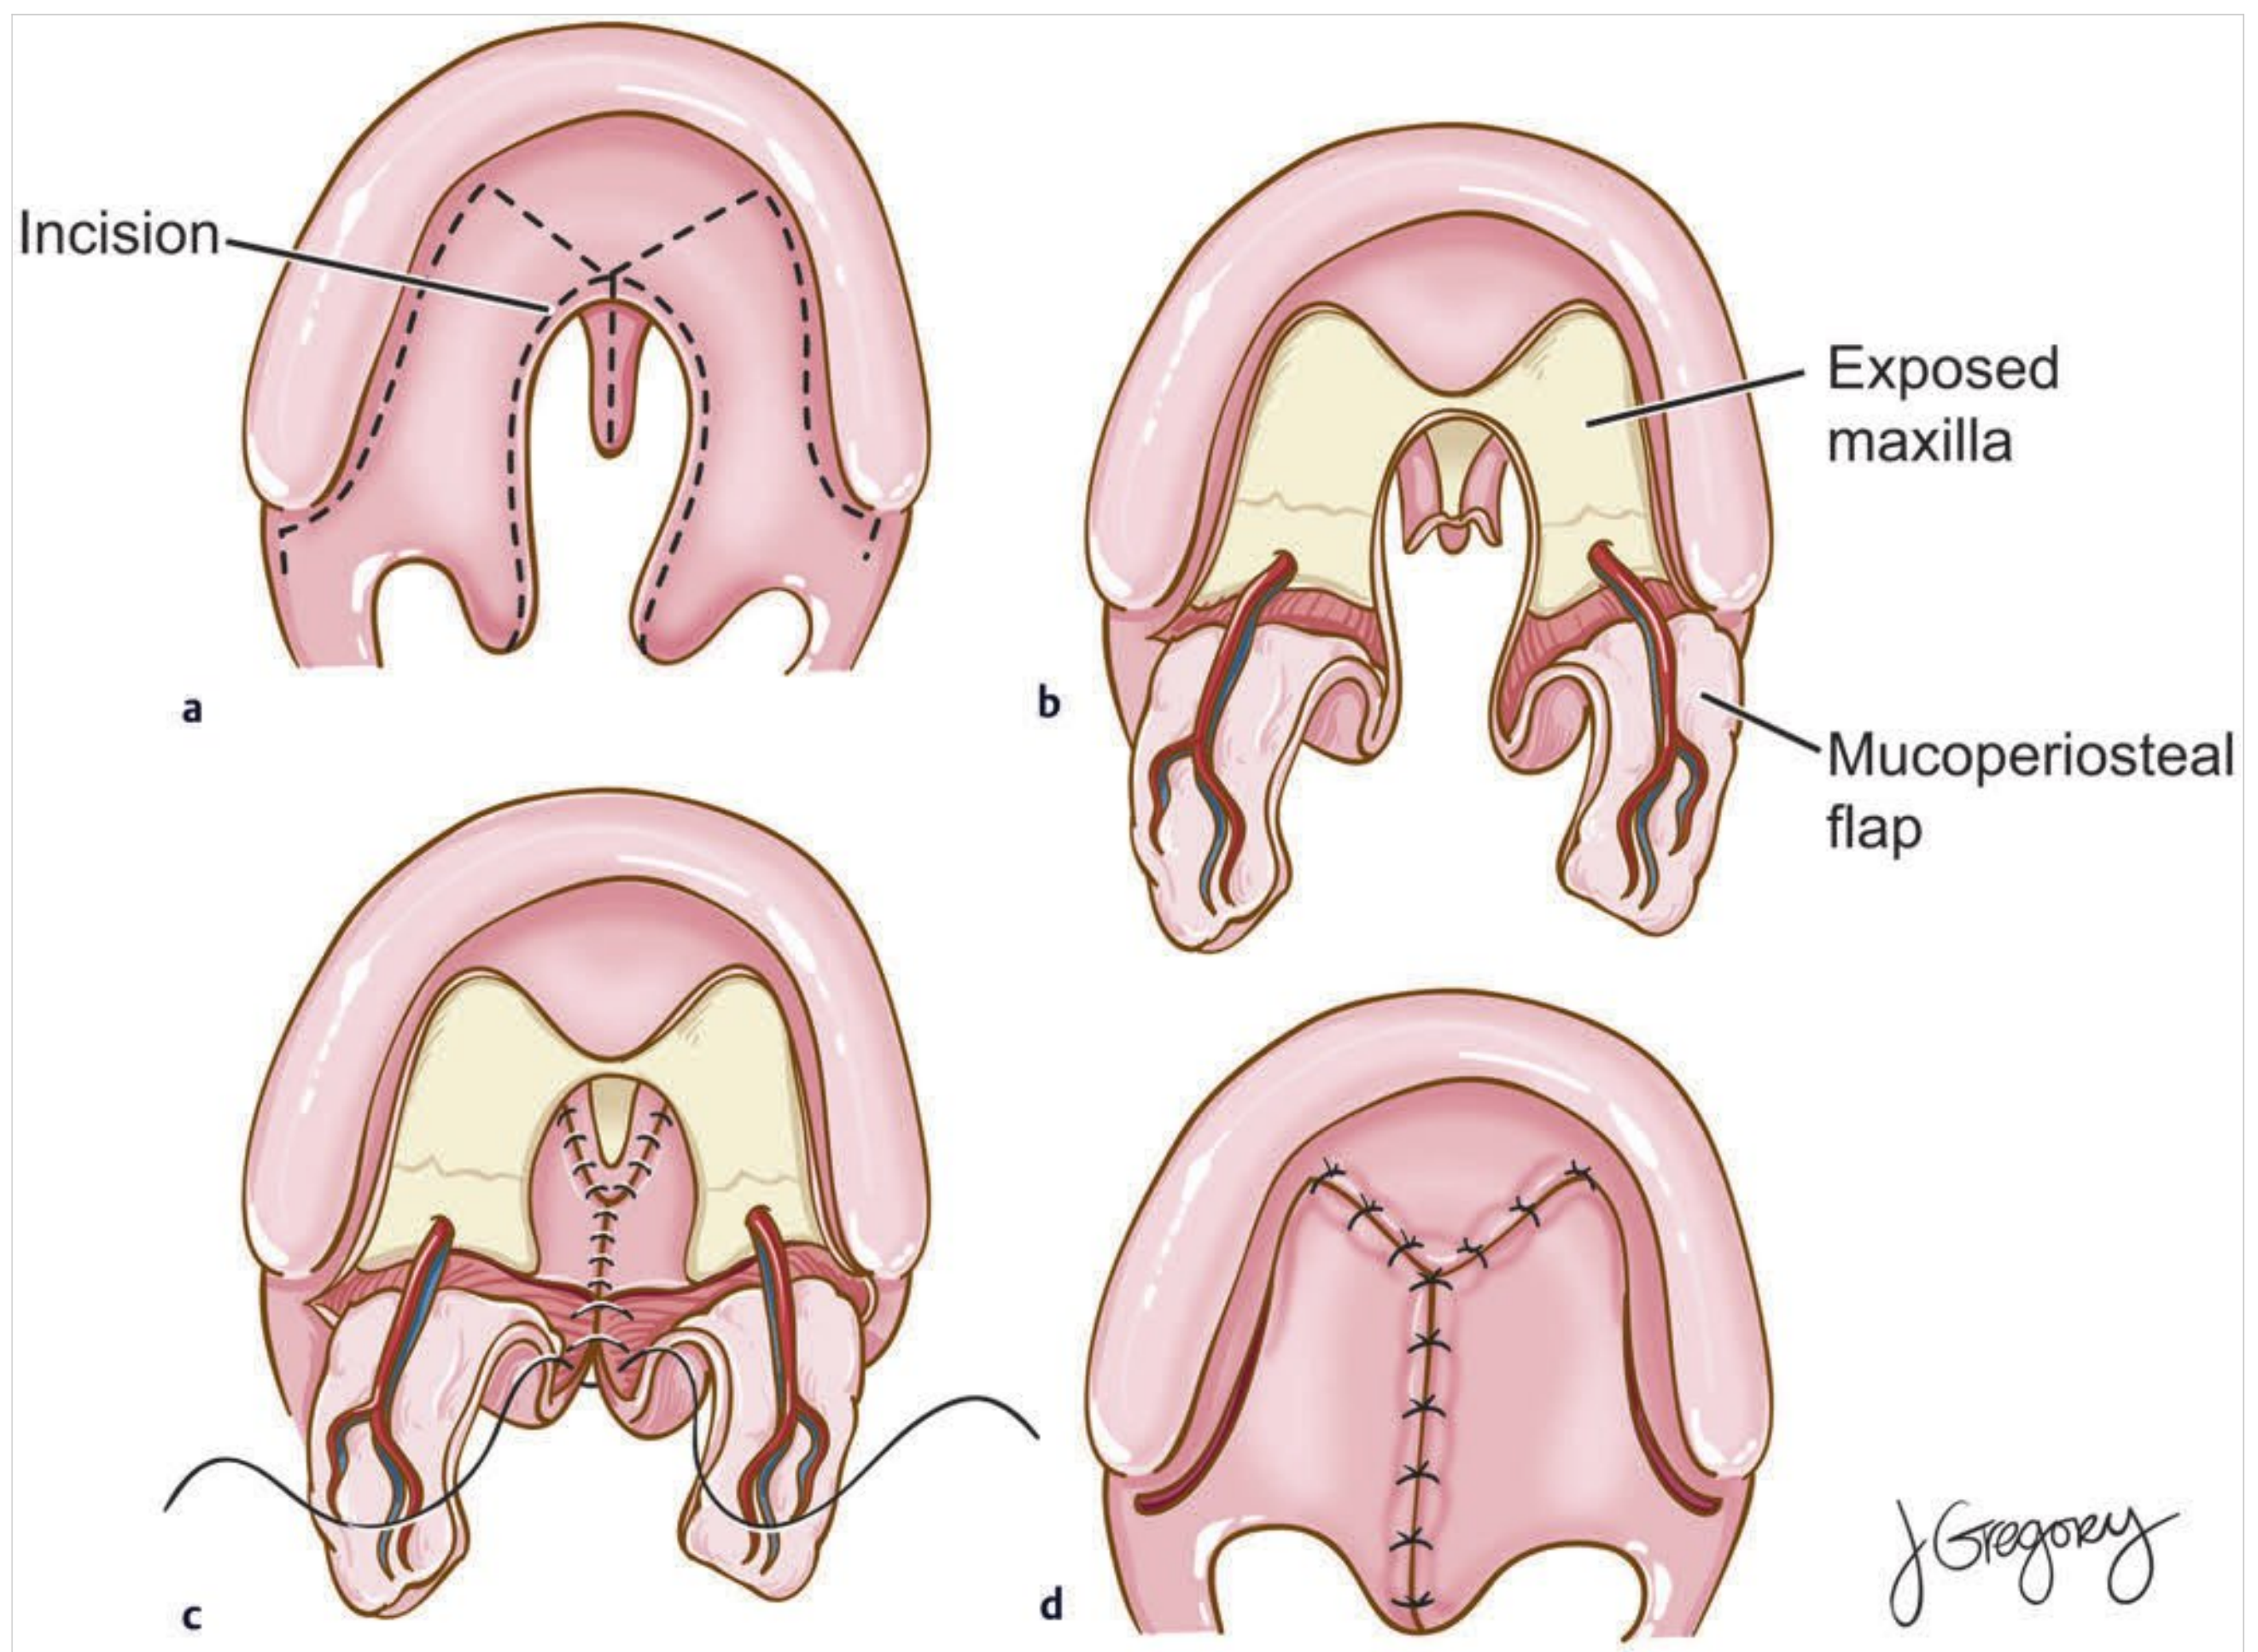

Fig. 71.11 Wardill-Kilner-Peet palatoplasty (V to Y advancement). (a) Incisions. (b) Nasal flaps and palatal flaps, based on the descending palatal artery, are raised. (c) The nasal flaps are repaired, and the soft palate muscles are reoriented and sutured together. (d) The mucosal flaps are rotated and closed, with lateral incisions allowed to heal by secondary intention.

continues with the intravelar veloplasty closure of the soft palate muscles. Finally, the mucoperiosteal flaps are closed at the midline and tacked to the anterior hard palate mucosa. The lateral relaxing incisions are filled with compressed microfibrillar collagen and allowed to close by secondary intention (□ Fig. 71.11d).

Furlow Palatoplasty

The Furlow palatoplasty is radically different from the previously described techniques for repair of the cleft palate. In the previously described techniques, the soft palate is closed with a straight-line closure. In the Furlow technique, the soft palate is closed with Z-plasties on each side of the soft palate, one on the oral side and another on the opposite, nasopharyngeal side. The Furlow technique (“double opposing Z-plasty”) can visibly lengthen the soft palate (because of the nature of the Z-plasty), with the entire soft palate moved closer to the posterior pharyngeal wall (making it easier to close the velopharyngeal space), and it also reorients the soft palate muscle fibers from a vertical to a horizontal direction. For these reasons, it has become a favored choice for cleft palate repair.

After the palate is injected with local anesthetic containing epinephrine, the cleft edges are incised. A Z-plasty is designed with the oral mucosa overlying the soft palate (□ Fig. 71.12a,b). If the surgeon is right-handed, the soft palate muscles are elevated with the oral mucosal flap on the left hemipalate; the plane of dissection is between the soft palate muscles and the submucosa of the nasopharyngeal side of the soft palate (□ Fig. 71.12c). Caution must be taken when this elevation is performed because the nasopharyngeal flap is very thin and easily perforated. The right oral hemipalatal flap is elevated between the submucosa and the soft palate muscle. The oral mucosal flap is much thicker than the corresponding submucosal flap on the nasopharyngeal side. The nasopharyngeal mucomuscular flap is then incised on the right hemipalate from the apex of the cleft toward the lateral pharyngeal wall (□ Fig. 71.12d). The corresponding left nasopharyngeal mucosal flap is incised from the uvula anterolaterally toward the pharyngeal wall (see □ Fig. 71.12d). The nasopharyngeal flaps are interdigitated and sutured into position, followed by the oral flaps (□ Fig. 71.12e,f).

When this technique is used for more extensive clefts involving the hard palate, one usually raises the hard palate flaps and inspects the vascular pedicles before committing to the Furlow

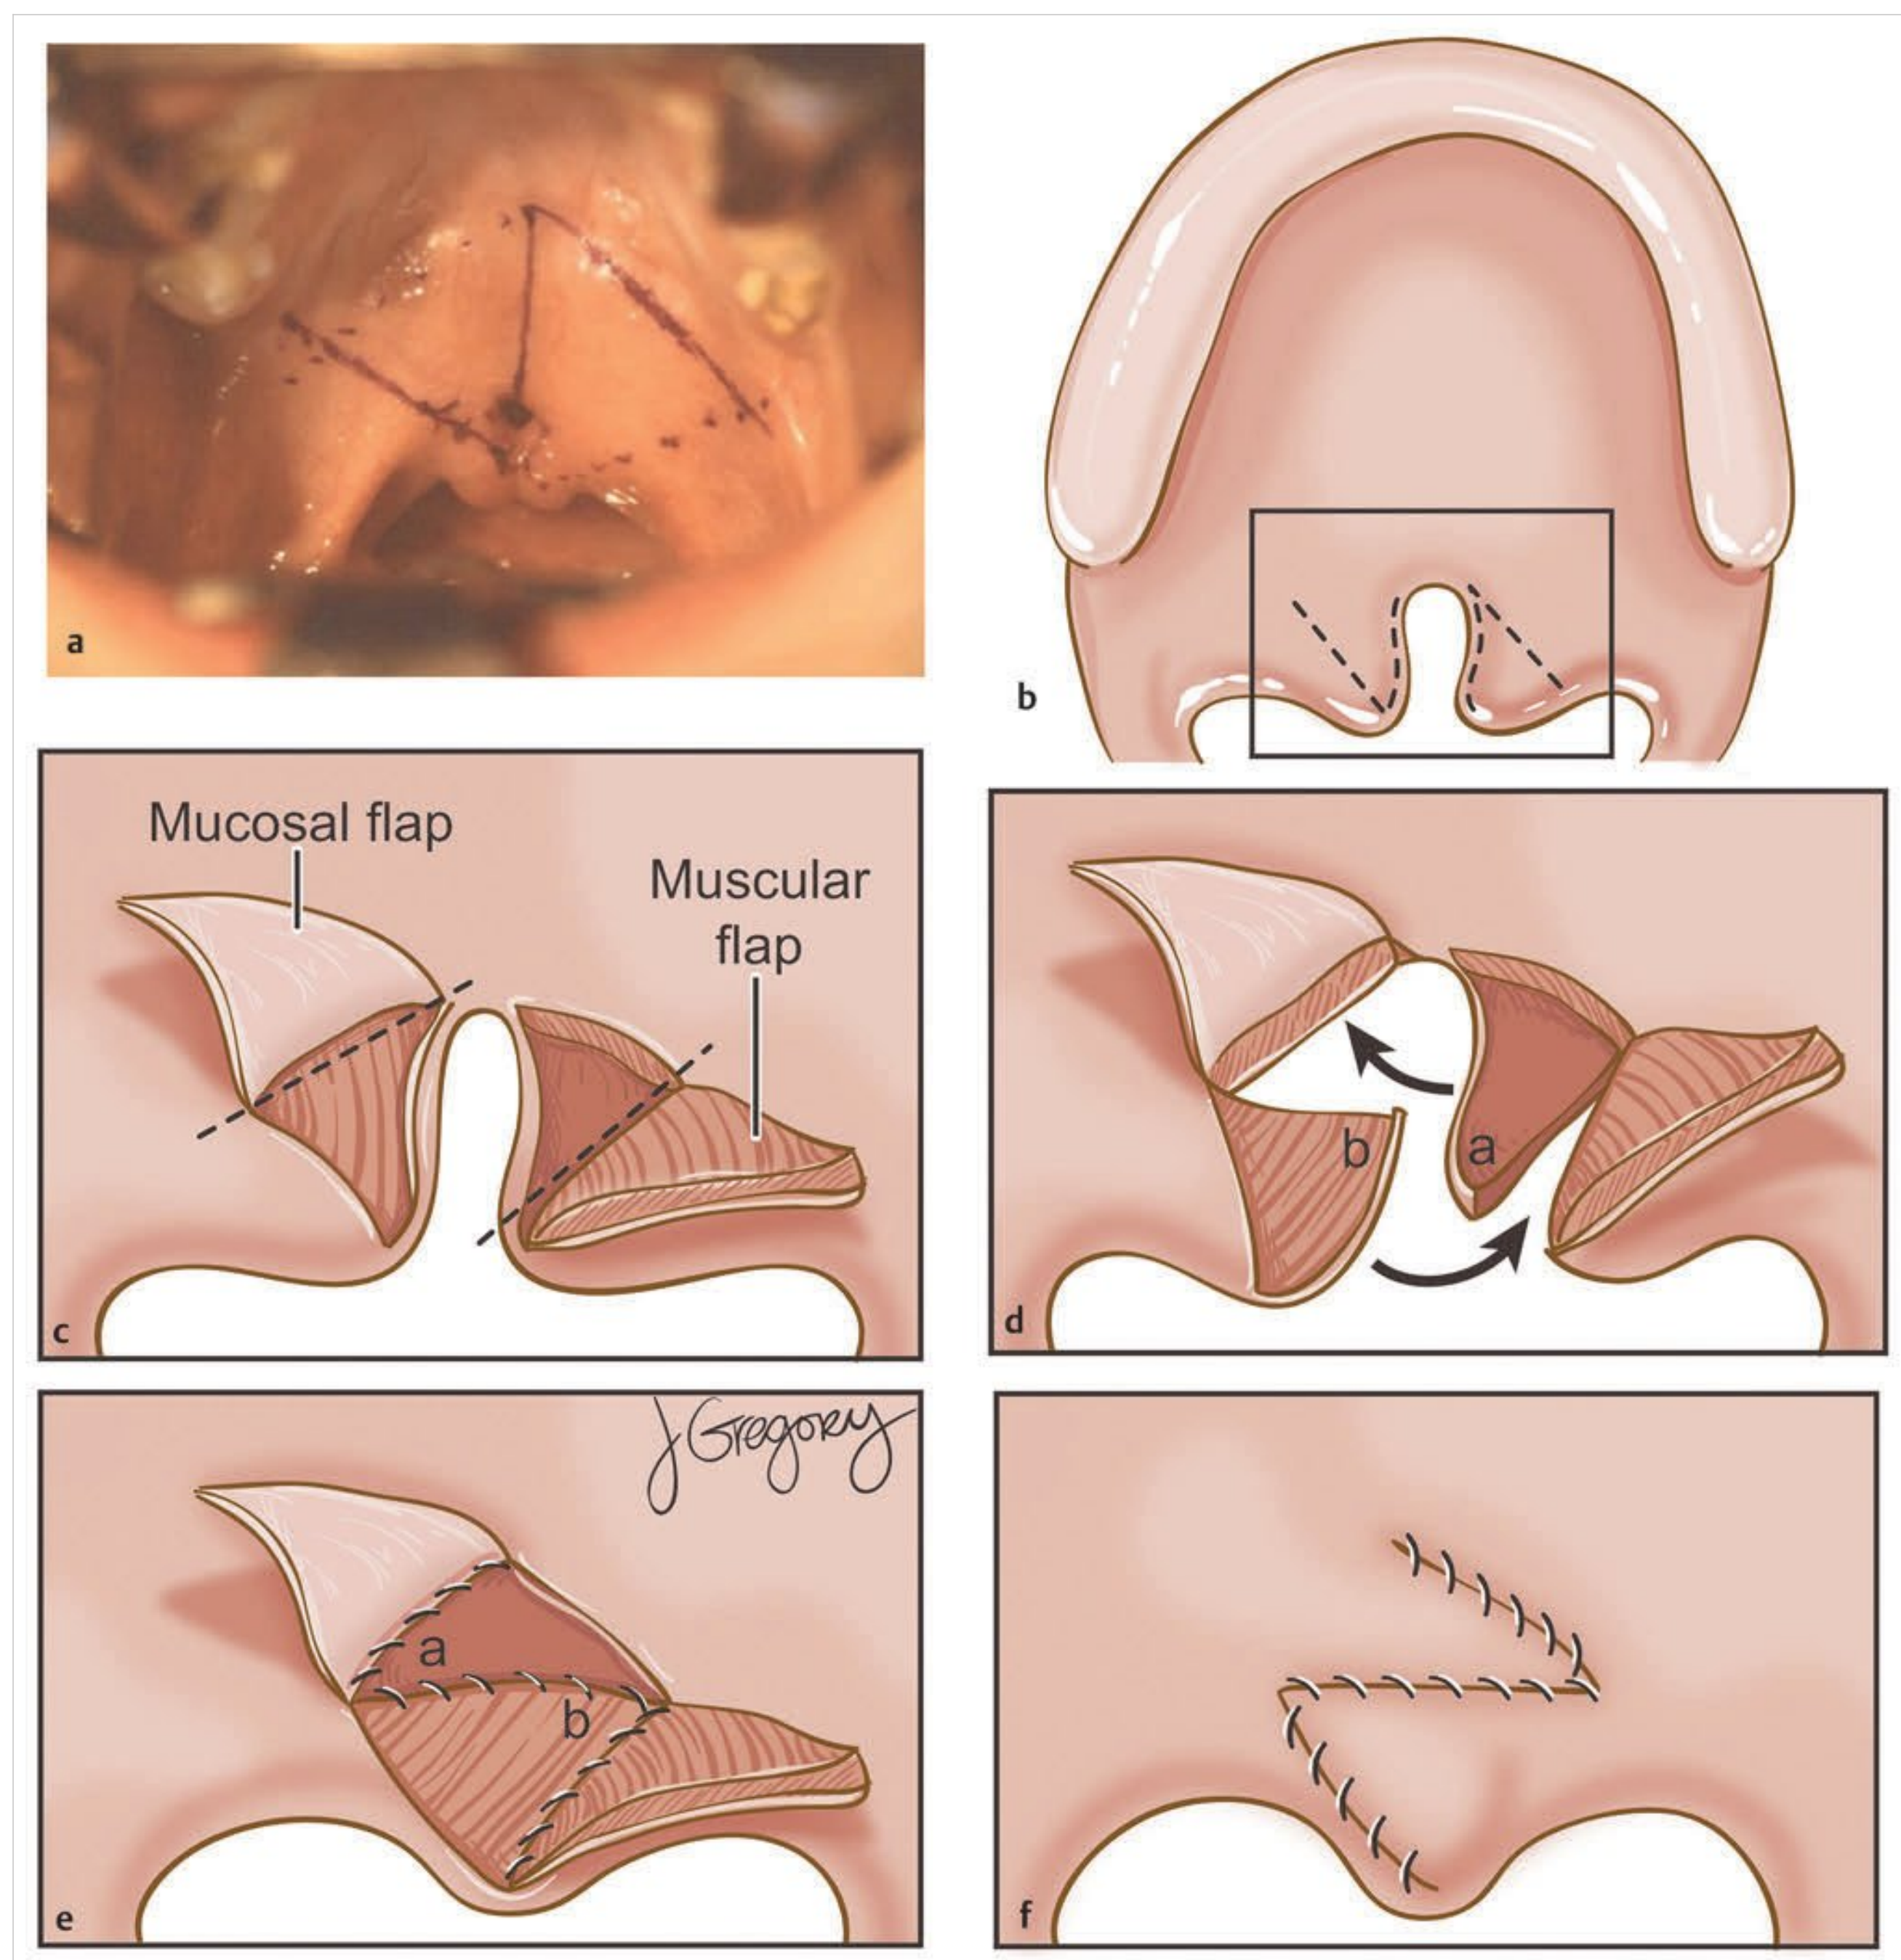

Fig. 71.12 Furlow palatoplasty technique. (a) Double opposing Z-plasties drawn on incomplete cleft palate. (b) The dotted lines represent incisions in the palatal mucosa. (c) The soft palate musculature is raised with the palatal mucosa on the left side, while the palatal flap on the right side is mucosa only; the nasal mucosa (with the musculature on the right side) is incised along the dotted line, and the soft palate musculature is left attached to the right nasopharyngeal mucosal flap, while the left side is mucosa only. (d) The nasopharyngeal mucosal flaps are transposed and (e) sutured together. (f) The nasal mucosal flaps are then transposed in the opposite direction and sutured together. The soft palate muscles are reoriented across the palate and moved posteriorly.

on the soft palate. Following successful dissection around the pedicle, the Furlow incisions and flaps are raised. The procedure is completed as described for each technique.

Complications in Palatoplasty

The most common immediate postoperative complication with all palatoplasty techniques is airway obstruction. This may be

caused by postoperative tongue swelling (due to prolonged compression of the tongue with the mouth gag); thus, periodic inspection of the tongue with release of the gag is required. The most common reason for airway obstruction, however, is a direct effect of closure of the palate and the change in the oropharyngeal and palate shape after the repair. Most babies tolerate the changes following palatoplasty, but airway monitoring (with continuous pulse oximetry and a higher level of nursing

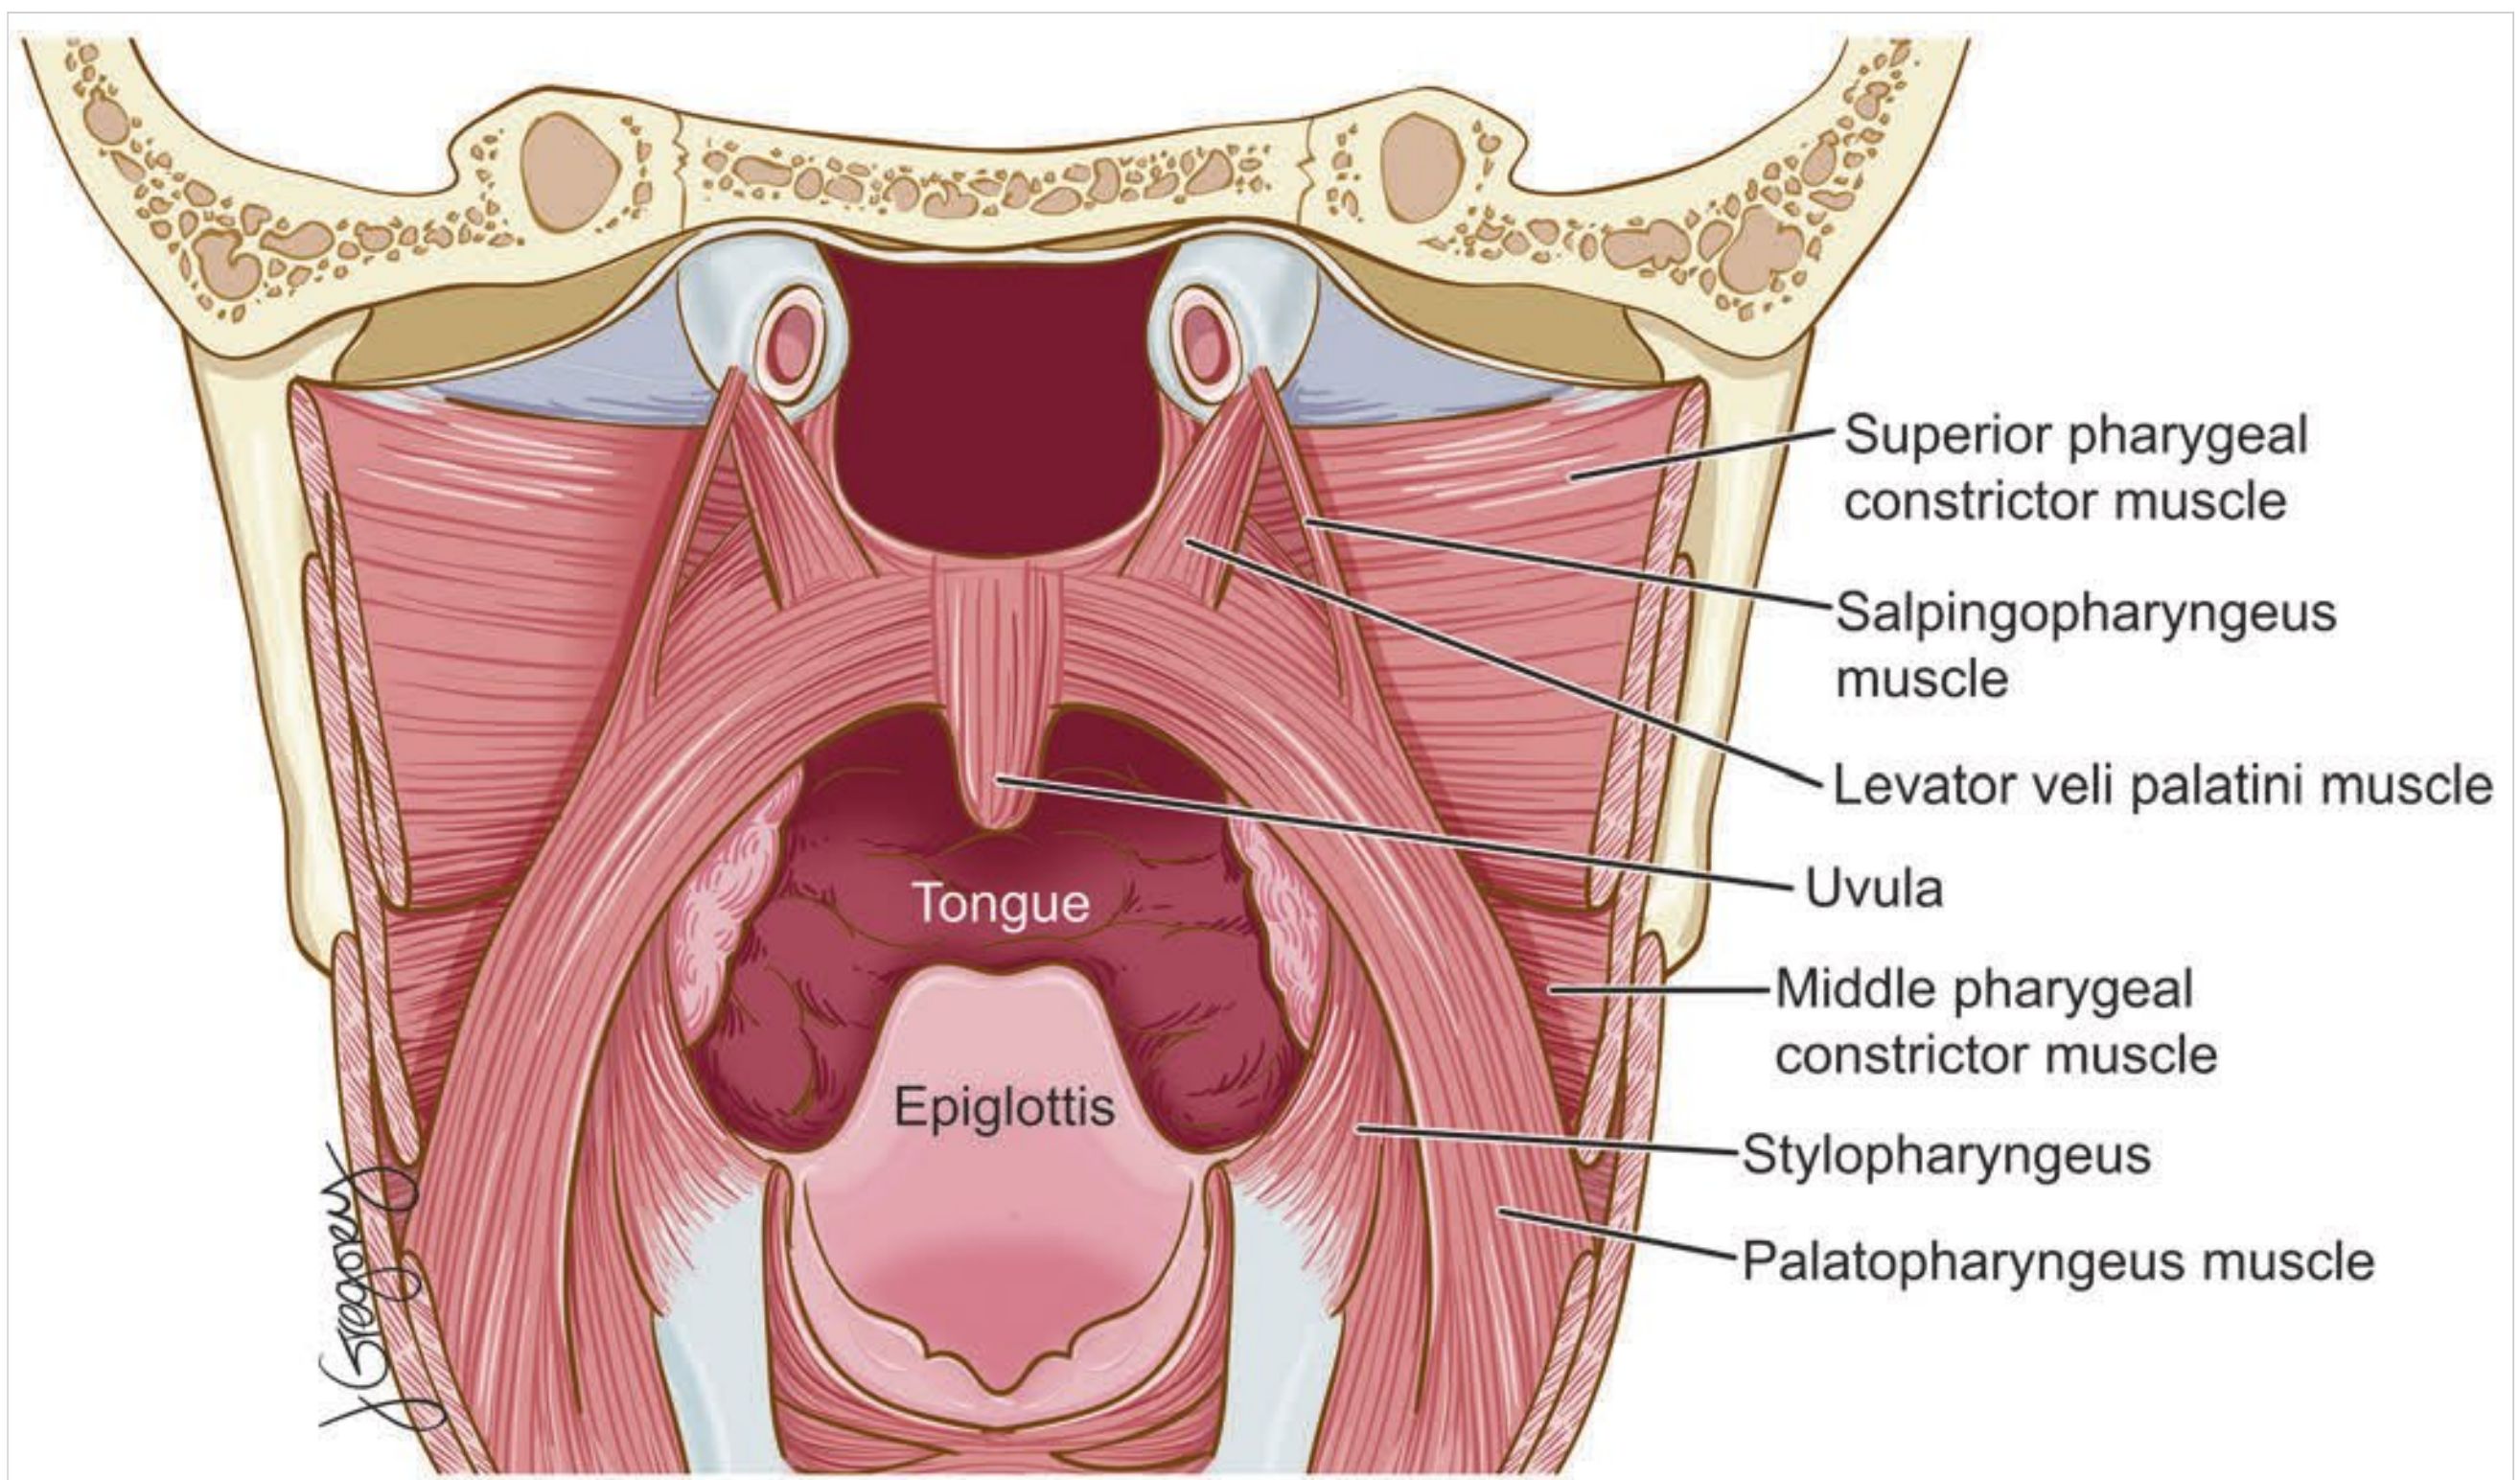

Fig. 71.13 Diagram of the oropharynx and soft palate musculature (posterior view), demonstrating the sphincteric structure of the velopharyngeal valve.

management) is mandatory after all but the most minor palatoplasty procedures. Intraoperative or postoperative hemorrhage is infrequent.

The most common complication after the immediate postoperative period is fistula. Dehiscence of the suture line may occur as a result of tension on the suture line, insufficient tissue, or thin mucoperiosteal tissue. The most likely site of fistula is at the junction of the hard and soft palate, where the mucoperiosteal tissue is thinnest. Fistulas should be allowed to heal for a minimum of 4 to 6 months before a repair attempt is made. Asymptomatic fistulas can be left until another surgical procedure is required.

71.7 Resonance and Speech Disorders

The velopharyngeal valve is a complex mechanism that plays an integral and unique role in human swallowing and speech function. Human evolution has combined the upper airway and digestive tract into a complex neuromuscular pathway with multiple functions. The primary role of the soft palate musculature is to allow positive pressure to build in the mouth for the propulsion of food during the initial phase of swallowing. Later, with the development of oral language, the same muscular valve was recruited to play an essential role in the articulation and resonance of human speech.

71.7.1 Anatomy and Function of the Velopharyngeal Valve

The velopharyngeal valve mechanism consists grossly of the soft palate and the lateral and posterior pharyngeal walls. In a simplified view, the mobile soft palate (velum) acts like a valve, rising and moving posteriorly to meet the pharyngeal walls; this effectively creates a seal and anatomically separates the nasopharynx from the oropharynx at the level of the soft palate (□ Fig. 71.13).

Examination of the complex musculature and tissue properties of this region provides more detail. The most mobile portion of the valve mechanism is the muscle mass of the soft palate. Most of this mass and its mobility is provided by the levator veli palatini, a broad-based muscle that arises from the petrous areas of the temporal bone and cartilaginous portion of the eustachian tube and fans down to insert into its analogous partner at the soft palate midline, creating a sling. As these laterally oriented fibers contract, the mass of the soft palate is pulled both posteriorly and superiorly. This muscle's broad path is underscored by its complicated innervation; it receives fibers from the glossopharyngeal plexus, vagus nerve, and greater petrosal nerve of the facial nerve.

The tensor veli palatini is a smaller muscle arranged in a similar orientation that alone has limited mass to facilitate elevation of the velum. During swallowing, however, the tensor serves the unique purpose of opening the flexible cartilaginous

portions of the eustachian tube, allowing the equilibration of middle ear pressure with atmospheric pressure via the nasopharynx. In conjunction with the musculus uvulae, the two lateral tensors help to stiffen the soft palate and create a more rigid surface against which food can be propelled during initiation of the pharyngeal swallow.

During swallowing, the oral tongue packages the food bolus to be swallowed and moves it posteriorly. The tongue rises against the hard palate and anterior velum to propel the bolus posteriorly. The passage of the bolus between the anterior tonsillar pillars initiates a reflex arc that terminates in stimulation of the pharyngeal plexus of the glossopharyngeal nerve. It is at this junction that the reflexive, nonvolitional swallow begins.

As the soft palate rises and separates the nasopharynx from the oral cavity, the base of the tongue is elevated by the palatoglossus, a slinglike muscle originating from the velum to the sides of the tongue. Tongue elevation also aids in stabilizing the soft palate and constricting the pharynx. The palatopharyngeus arises from the velum and inserts at the posterior border of the thyroid cartilage. As well as stabilizing the velum, the palatoglossus muscle is the first to reflexively elevate the larynx during swallowing to protect the upper airway.

Although the soft palate and its musculature provide most of the bulk and mobility of the velopharyngeal valve, the superior pharyngeal constrictor also has an integral role. During swallowing, the ringlike contraction of this muscle advances the posterior pharyngeal wall anteriorly and medializes the lateral pharyngeal walls. It is this muscle that is truly responsible for the sphincter-like nature of the velopharynx and makes it much more than a simple valve.

This sphincteric action increases oropharyngeal pressure and allows the targeted propulsion of food inferiorly. As a result, the sphincter prevents the nasopharyngeal regurgitation of food particles.

71.7.2 Role of the Aerodigestive Tract in Human Speech

The upper aerodigestive tract is designed for use in respiration and deglutition. As the human airway evolved, the larynx descended, and the pharynx and oral cavity became more suited to an incredible array of sound production. As the human larynx phonates, a buzzing fundamental frequency is created that has little resemblance to the tonality of speech. As the laryngeal sound passes through the oral cavity and nasopharynx, a full array of tones can be made with only slight modifications of the oral structures. These fully expired phonated tones comprise the vowels of all human language. For example, a high, anteriorly placed tongue and horizontal labial opening create a long “e” sound, while a rounded lip and posteriorly arched tongue create an extended “oo.”

Spoken language, however, is not a series of vowels; it is characterized by a combination of resonant vowels and articulated phonemes. Phonemes are created in two ways, and the velum plays an important role in each. During the creation of most linguistic phonemes, the velum is closed, as in a swallow. This closure redirects all phonated expiration through the oral cavity. Through fine, targeted approximations of the tongue with the teeth, anterior hard palate, and soft palate, the consonants are articulated.

For example, to produce the word teeth, a person must close the velopharynx and expire through the mouth. The tongue is tapped against the hard palate directly behind the maxillary incisors to create a “t” sound. Instantaneously, phonation and an oral posture for “ee” create the vowel, and the tongue follows the vowel by inserting between the upper and lower incisors. Phonation ceases, yet expiration continues to create the “th” sound.

However, the production of a nasalized word like man requires initiation with phonation, an open velopharynx, and closed lips. Tightly closed lips allow the production of an “m” sound. The lips part briefly to produce the nasalized “a” vowel. The tongue tip then meets the alveolar ridge, stopping oral airflow again, and phonated air is redirected through the nasal airway, with the “n” sound produced.

It is through these articulated phonemes (nasal and oral) and vowels that the full array of all human speech, independently of language, is created. Because of the integral role of the velopharynx in both speech and swallowing, dysfunction of the velopharynx clearly has implications for an affected individual’s health and ability to communicate.

71.7.3 Velopharyngeal Dysfunction

Dysfunction of the velopharyngeal mechanism is often separated into two major categories. Velopharyngeal insufficiency is characterized by an absence of sufficient anatomy for complete closure. In velopharyngeal incompetence, anatomical bulk and structure are sufficient for closure, but the neuromuscular mechanism is unable to provide adequate closure or correctly timed closure.

The most common cause of velopharyngeal insufficiency in a child is cleft palate. An unrepaired cleft palate causes significant nasal regurgitation and feeding problems in infancy. More subtle cases of submucosal cleft palate, in which the muscles are not joined at the midline, are often not recognized until later in life, when a child’s developing speech is affected by resonance problems. Inadequate velar function predisposes a child to recurrent otitis media secondary to eustachian tube dysfunction.

After surgical reconstruction for cleft lip and palate, it is important to note that the arrangement of the velopharyngeal muscles is still deranged (even after intravelar veloplasty) because of the developmental absence of a midline raphe and decussation of the muscles of the soft palate. It is for this reason that velopharyngeal incompetence often persists despite adequate surgical repair.

Velopharyngeal incompetence is the neuromuscular dysfunction of an otherwise anatomically intact velopharyngeal mechanism. It is much less common than insufficiency. A new presentation of incompetence in an otherwise well child or adult is ominous for a progressive neurologic condition or skull base tumor affecting neurologic control. Resonance disorders of these types are characteristically seen in patients after significant head trauma or skull base surgery.

Two common yet nonpathologic forms of velopharyngeal dysfunction are also described. The first is the hypernasal speech that develops in a child after adenoidectomy. In children with large adenoids, the distance the velum must traverse to achieve adequate closure has been physiologically decreased by

the physical presence of the adenoids. After surgery to remove the adenoids, the child's speech may sound hypernasal as the soft palate is initially unable to traverse the increased distance to the posterior pharyngeal wall (the increase due to the now-absent adenoid pad). These children are often monitored, and recovery of normal speech is typically gradual and complete over 3 to 6 months. Velopharyngeal dysfunction is considered pathologic only if it persists after this period.

Deaf speech is characterized by hypernasality and disrupted resonance patterns. Deaf persons learn speech through visualization and impersonation. Because the function of the velopharynx is visually hidden, it is a part of articulation that is nearly impossible for them to learn. Secondly, it has been proposed that the increased vibratory conduction of nasal resonance provides important tactile feedback for speech production in deaf patients. These marked changes that characterize deaf speech stand as evidence of the important function of the velum. Because of this similarity, patients with abnormal resonance may be mistakenly presumed to have hearing impairment.

71.7.4 Diagnostics

Disorders of resonance are diagnosed primarily clinically. Severe anatomical deficits are apparent on a thorough clinical examination and rarely require additional work-up. Formal evaluation may include lateral neck radiography, nasometry, video nasopharyngeal endoscopy (nasopharyngoscope), and in some cases fluoroscopy.

Nasometry and fluoroscopy are the two modalities offering true functional information during speech. In nasometry, a receptor placed at the nasal aperture measures variations in air pressure during speech. Hypernasality is identified as relatively increased nasal airflow during the production of oral speech sounds in comparison with normative standards. Fluoroscopy is rarely used because of the risks of prolonged radiation exposure in children; however, motion of the soft palate is visualized well.

Video nasopharyngeal endoscopy is usually performed as an evaluation to determine the exact anatomical structure of the velopharynx during speech. A nasopharyngoscope is placed into the region of the choana under topical nasal anesthesia. With a speech pathologist directing the patient, the patient speaks test words and phrases that stress oral pressure consonants while the reviewer observes the closure of the velopharynx during the speech sample. The examination is recorded with both video and audio channels for the interpretation of velopharyngeal function. The patient's nasopharyngeal and velar movement is then graded for complete velopharyngeal closure or incomplete closure. Patients with complete closure are usually referred for speech therapy, whereas patients with incomplete closure who have exhausted speech therapy may be referred for physical management of their velopharyngeal insufficiency. Physical management may consist of surgical management or prosthetic management. The nasopharyngoscope is critical to planning the future surgical treatment of anatomical deficits.

In children with severe craniofacial deformities and syndromic findings accompanying velopharyngeal insufficiency,

imaging studies are chosen accordingly. Intervention is planned based on the nature of the deficit.

71.7.5 Surgical Management of Velopharyngeal Insufficiency

In general, three surgical options are available for patients with cleft palate who have velopharyngeal insufficiency that is not correctable with speech therapy. There is usually a gap in the velopharyngeal valve that the patient cannot close despite maximal attempts. This gap represents the physical cross-sectional area that surgical management must fill for the velopharyngeal sphincter to be able to close. When the gap is due to a notch or groove in the posterior border of the soft palate, or there is a close but incomplete approximation of the soft palate to the posterior pharyngeal wall, a revision operation on the soft palate with a Furlow palatoplasty often is able to correct the velopharyngeal insufficiency. The increased length and closer approximation of the soft palate inherent in the Furlow palatoplasty make it an optimal choice in this situation. In addition, it is unlikely to cause airway obstruction and sleep apnea.

The other surgical procedures, pharyngeal flap and pharyngoplasty, are often used for the treatment of velopharyngeal insufficiency. These procedures can be used in patients who have velopharyngeal insufficiency without a cleft palate. They may be performed after or in combination with any of the previously described cleft palate procedures. Both of these procedures use pharyngeal tissues to create a narrowing of the velopharyngeal valve space.

The pharyngeal flap consists of a superiorly based rectangular flap of tissue harvested from the posterior pharyngeal wall (full thickness of mucosa and muscle; □ Fig. 71.14a). The flap of tissue is inset into the nasopharyngeal aspect of the soft palate (□ Fig. 71.14b), with lateral openings (ports) remaining for nasal breathing and nasal resonance (□ Fig. 71.14c). This procedure is best used when a large central gap is seen during the nasal endoscopy examination, usually in a patient with an adynamic palate. It relies upon lateral wall movement to close the two lateral ports during swallowing and speech. The drawback of this procedure is the risk for postoperative snoring and sleep apnea.

In the pharyngoplasty, the velopharyngeal sphincter is artificially made "tighter" by transposing tissue from the lateral pharyngeal walls up and behind the soft palate to narrow the inlet into the nasopharynx. Superiorly based flaps of tissue are harvested from the posterior tonsillar pillar (mucosa and muscle; □ Fig. 71.15a). They are rotated medially and inset into a site (previously determined during the nasopharyngoscope examination) on the posterior pharyngeal wall behind the soft palate (□ Fig. 71.15b). These flaps narrow the lateral areas of the velopharyngeal sphincter and create a "speed bump" on the posterior pharyngeal wall against which the mobile palate can coapt during speech. The central opening is available for breathing and for air movement during speech. Although this procedure may induce postoperative snoring, the risk for chronic sleep apnea is less than with pharyngeal flap.

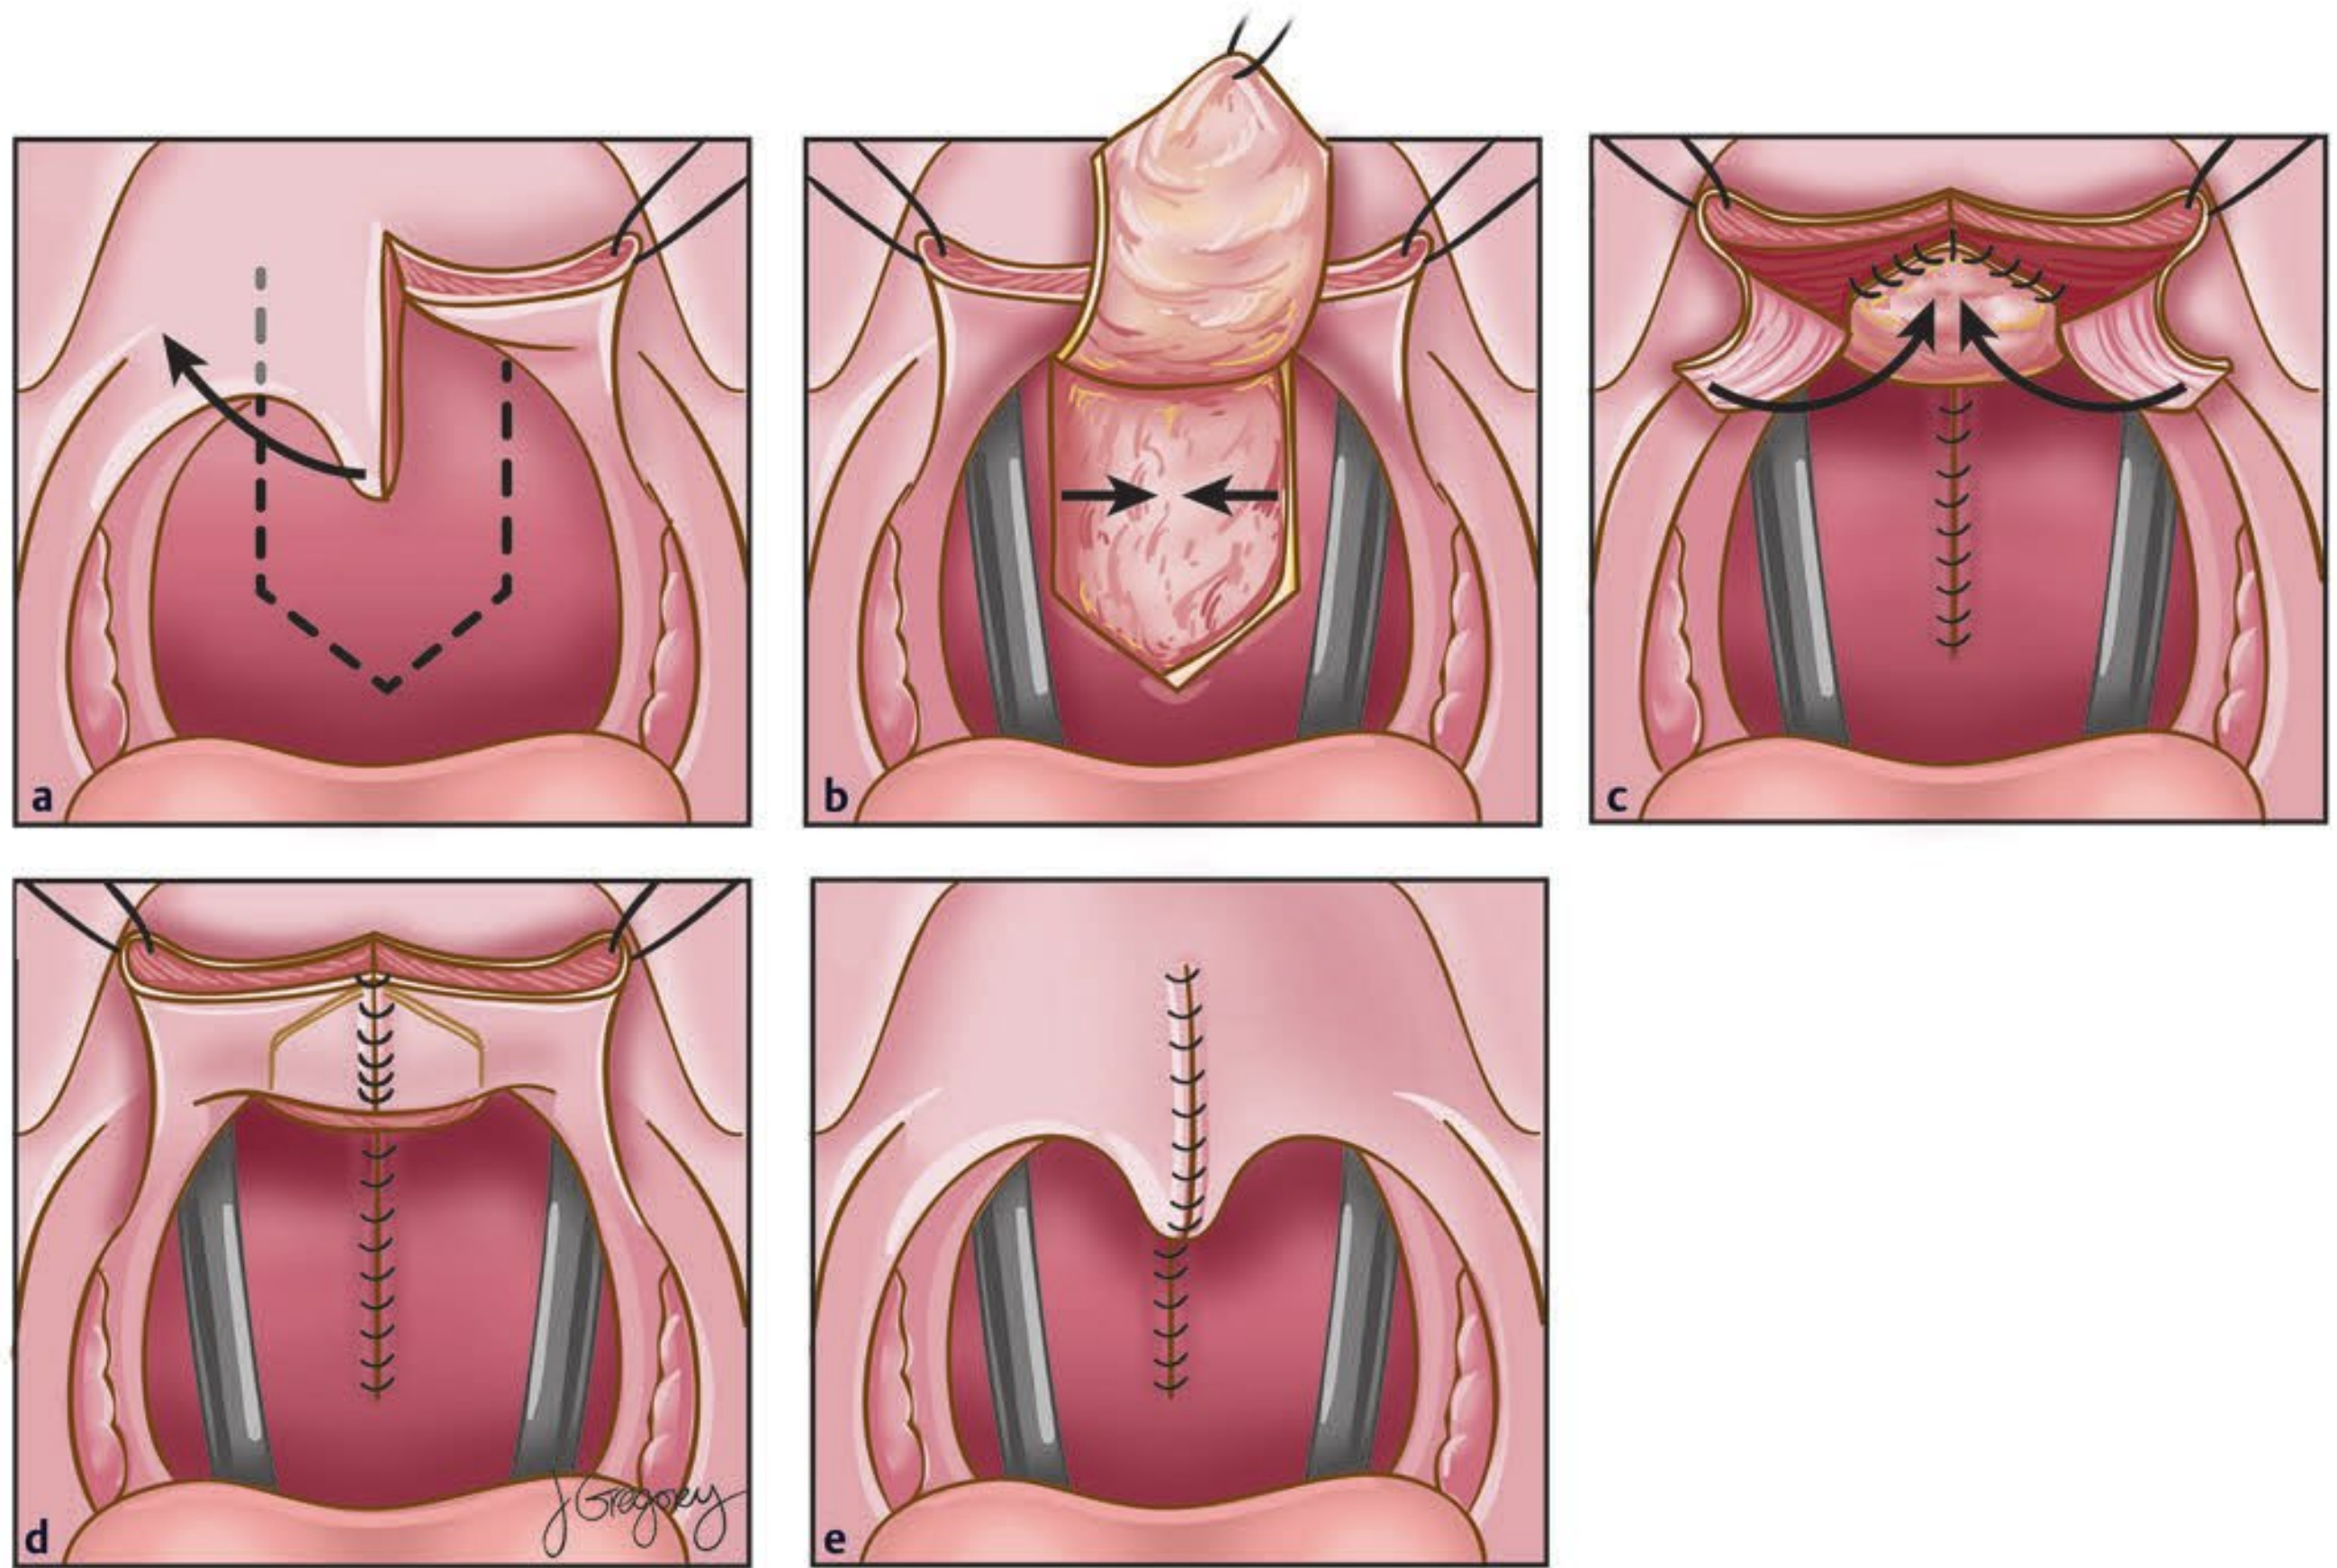

Fig. 71.14 Pharyngeal flap. (a) Superiorly based flap developed from the posterior pharyngeal wall, seen behind the split uvula. (b) The donor site on the posterior pharyngeal wall is closed primarily. (c) The flap is sutured to the nasopharyngeal side of the soft palate. (d) Nasopharyngeal flaps are sutured over the pharyngeal flap. (e) Uvular closure. Lateral ports in which red rubber catheters can fit are left for nasal respiration.

Fig. 71.15 Pharyngoplasty. (a) Superiorly based musculomucosal flaps are raised from behind the posterior pharyngeal pillars. The posterior pharyngeal wall between the base of these flaps is demucosalized. (b) The flaps are transposed and sutured to the denuded posterior pharyngeal wall to provide additional bulk and anterior projection and allow more complete closure of the velopharyngeal inlet.

71.8 Ear and Eustachian Tube Dysfunction

Children with cleft palate are at high risk for the development of middle ear effusion and conductive hearing loss. As described above, the tensor veli palatini muscle is a part of the soft palate musculature that is anatomically disrupted in cleft palate. As the only dilator of the eustachian tube, the tensor veli palatini is physically unable to dilate the eustachian tube until sometime after the cleft palate has been repaired. The development of middle ear effusion (typically mucoid) usually results in a conductive hearing loss. The placement of ventilating tubes (pressure equalization tubes) is required to correct the effusion and conductive hearing loss. Children with cleft palate often require several sets of pressure equalization tubes over a lifetime to prevent hearing loss and protect their ears against the effects of prolonged eustachian tube dysfunction.

71.9 Cleft Palate Team Care

Children who are born with cleft lip and palate face many medical challenges. They usually have numerous needs and may have to see a number of different medical specialists and therapists early in life. Cleft palate and craniofacial teams are groups of specialists who are experienced in cleft and craniofacial care. The minimum team requirements are a reconstructive surgeon (who may be an otolaryngologist, plastic surgeon, or oral surgeon), a social worker, an orthodontist, and a speech pathologist, who meet face to face to discuss patient care coordination. Most teams have other specialists, including audiologists, nurses, ophthalmologists, pediatricians, geneticists, and dentists. The team approach allows a better coordination of care. Most children visit the specialists of the cleft and craniofacial team every 2 or 3 years (or more often if needed). Individual specialists see the patients independently as needed between team visits.

71.10 Roundsmanship

- Cleft lip and palate are the most common congenital malformation of the head and neck.
- Cleft lip and palate occur in approximately 1 in 600 live births in the United States. Native Americans and persons of Asian descent are at the highest risk.
- Cleft lip and palate may occur as an isolated malformation or as part of a syndrome.
- Cleft lip and palate are often a function of both genetics and environment, with some gene mutations now identified in

patients with cleft lip and palate. Environmental etiologies have been identified that increase the risk for clefting.

- Lip embryogenesis begins at the fourth to fifth week and is complete by the end of the sixth week of gestation. Palate embryogenesis follows and is complete by the 10th week of gestation.
- Complete cleft lip and palate occur in 45% of all clefts; cleft lip with or without cleft alveolus occurs in 25% and cleft palate only in 30%.
- “Rule of tens” for surgery. For cleft lip repair: 10 weeks, 10 lb, 10 g of hemoglobin. For cleft palate repair: 10 months, 10 kg, 10 g of hemoglobin.
- Most children who have cleft palate will develop a middle ear effusion with conductive hearing loss. The effusion is treated with the placement of pressure equalization tubes, and more than one set of tubes may be required.
- Team management allows coordinated care for the many problems that children with cleft lip and palate have to face.

72 Airway Disorders in Children

Robin A. Dyleski

72.1 Introduction

The airway of a child is susceptible to various congenital and acquired conditions because of intrinsic factors related to the size, position, and development of the airway. The pediatric airway is considered to begin at the nasal inlet at the nares and lips, and it extends to the main bronchi of the lungs; conditions affecting any of the areas between these sites can cause considerable respiratory difficulty in children. This chapter will address those conditions that affect the portion of the airway comprising the laryngeal and tracheal structures. Sometimes, several conditions may coexist within the same patient, and a careful history, examination, and diagnosis are necessary for adequate treatment and management of the breathing problem.

72.2 Developmental Anatomy

The formation of the aerodigestive tract begins early in fetal development. The fetal larynx, esophagus, trachea, and lungs have important functions in the fetus that change dramatically with the first breath at birth. Within the uterus, the larynx and trachea are essential to the growth and development of the lungs by modulating the “breathing” of amniotic fluid. Certain conditions that prevent the “breathing” of amniotic fluid frequently have significant effects upon the size and proper growth of the fetal lungs. With the newborn’s first breath of air, the larynx assumes three new roles: modulation of airflow into the trachea and lungs, protection of the lower airways (trachea and lungs) from the aspiration of secretions and swallowed food, and vocalization. Many congenital conditions can be understood more easily when the embryologic development of the airway is considered.

The anlagen of the larynx, trachea, and lungs originate from a ventromedial diverticulum in the developing pharynx (foregut) at about the 25th day of fetal development. This diverticulum, also known as the tracheobronchial groove, extends anterior to

the developing esophagus as a solid tubelike structure, extending toward the thorax and developing chest. The caudal end of this structure will develop the trachea and the lung buds, the future lungs. By the fourth week, the esophagus can be distinctly identified.

The formation of the laryngeal anlage is affected by three tissue masses (anteriorly and laterally) at the fourth to fifth week that will become the future epiglottis, false and true vocal folds, arytenoids, and subglottis. By the sixth week of fetal development, the laryngeal structures and trachea are noted to have recanalized and are seen to have a distinct lumen. Later, after recanalization is completed, the fetus will “breathe” amniotic fluid into the lungs buds and subsequently into the developing lungs. The embryonic period of development sees the formation of the structural anatomy of the airway (□ Fig. 72.1).

Because of the complex changes and modulations occurring in the embryologic development of the fetal larynx during the very early stages of gestation, there is a great potential for abnormalities in the structure and canalization of the airway lumen to arise. Congenital conditions such as laryngotracheal cleft, laryngeal webs, and certain cystic lesions are well-known examples of specific problems of developmental anatomy.

Congenital airway disorders usually manifest in the first days to weeks of life; however, they may not be discovered until much later, especially if mild. The discovery of a congenital lesion varies significantly depending upon the location of the lesion and its likelihood to cause symptoms in the child.

The fetal period of growth, starting at the third month of gestation, is marked by further growth of the larynx and trachea and the onset of lung development, along with the necessary muscular and neurologic development. The recanalization of the larynx and trachea is completed by the end of the third month, and the fetus then begins “breathing” amniotic fluid into the developing lungs.

Swallowing occurs in the fetus around the fourth month of gestation. Important neuromuscular reflexes develop in the

Table 72.1 Important components in the assessment of children in respiratory distress

History	Physical findings
History of intubation, instrumentation	Quality of stridor (inspiratory, expiratory, biphasic), constant or intermittent
Timing of the onset of respiratory distress (acute, gradual)	Use of accessory respiratory muscles (subcostal or sternal retraction, tracheal tug, flare of alae)
Qualities of the baby's cry	Oxygen saturation, respiratory rate
Presence of stridor	General appearance
Feeding problems, relationship of feeding to respiratory distress	Observation of feeding difficulties
What makes breathing better or worse	

successive months, with both esophageal swallowing and laryngeal breathing increased. The cellular linings of the larynx, trachea, and lower airway become populated with ciliated respiratory mucosa and squamous epithelium. The cartilages of the larynx and trachea develop enough strength to support a patent airway by the beginning of the third trimester. The onset of the third trimester marks the nearly complete development of the anatomical structures of the larynx and trachea. The larynx is fully capable at this point to complete its functions of respiration, protection, and phonation, even though the lungs and other body organs are often insufficiently developed.

72.2.1 Differences between the Infant and the Adult Larynx

Both the shape of the cartilage and the position of the larynx in the infant vary considerably from those in the mature adult. The thyroid cartilage in the infant is broader and shorter than the thyroid cartilage in the adult. The position of the true vocal folds is noted to be relatively higher within the infant thyroid cartilage, approximately one-half of the way rather than a third of the way from the inferior edge, as in the adult thyroid cartilage. In addition, the upper edge of the thyroid cartilage is usually tucked inside the hyoid bone in the infant, making the larynx higher within the infant's neck. The cricoid cartilage is typically found as high as the C4 vertebra in the infant neck,

compared with a much lower position, at the C6 vertebra, in the adult (□ Fig. 72.2).

72.3 Clinical Evaluation of the Child with an Airway Problem

The evaluation of a child with an airway problem requires a careful and complete history, a perinatal and delivery history, and a thorough head and neck examination (□ Table 72.1). An immediate assessment of the child is necessary to determine the urgency of the respiratory problem. The history includes a detailed assessment of the breathing difficulty, including the nature of the problem, the timing of the onset of the breathing difficulty, the presence of stridor (noisy breathing caused by laryngeal or tracheal disorders), the relationship of the respiratory distress to feeding, sleep and body position, and the presence or absence of cyanosis and apnea. It is imperative to learn whether anything eases or worsens the breathing problem. Sometimes, a video or audio tape made by the parents can help elucidate episodic concerns. Charting the patient's weight gains or losses on a standardized pediatric growth chart will provide information regarding the effect of the respiratory problem on the patient's ability to gain and maintain a normal weight.

Symptoms of stridor, apnea, cyanosis, and tracheal and/or subcostal retractions help not only to determine the severity of the problem but also to narrow the differential diagnosis. Information regarding prematurity and intubation or airway

instrumentation at birth is an important facet of the child's history.

The physical examination includes a thorough head and neck examination and a general observation of the patient's respiration at rest, as well as the patient's voice or cry. For children with respiratory problems, this will include not only chest auscultation but also auscultation of the airway, with the stethoscope positioned over the patient's neck and in front of the mouth and nose to listen for stridor. Attention should be directed to determining if hoarseness or a weak cry is present, the nature of any stridor (including whether it is inspiratory, expiratory, or biphasic), and the presence of tracheal/chest retractions and apnea. Sometimes, feeding the child during the examination will demonstrate the symptoms of the airway problem (□ Fig. 72.3).

The office or bedside examination will often require a flexible laryngoscopic examination, usually via the nostril or transorally for the smallest infants. Careful attention to both inspiratory and expiratory breathing is useful to determine vocal fold function and the effects of obstructive lesions and functional disorders. The flexible laryngoscope examination is usually the most important part of the evaluation of a patient with an airway problem because most pediatric problems can be visualized with this instrument. The flexible laryngoscopy examination,

Fig. 72.3 Infant demonstrating severe sternal retractions.

however, is limited to the diagnosis of conditions affecting the supraglottis and glottis (□ Fig. 72.4a). Typically, one is unable to definitively diagnose with a flexible laryngoscope lesions that are present in the subglottis or trachea (□ Fig. 72.4b). Rarely, with use of the smallest-diameter flexible scopes, can a more distal lesion be visualized.

Radiologic evaluations, including plain X-ray films of the neck and chest, computed tomography (CT), and magnetic resonance (MR) imaging, are recommended for more distal lesions of the airways. These can delineate airway anatomy and the relationship of the airway to mediastinal structures (aortic arch, innominate artery) and identify congenital cardiac and mediastinal malformations. On occasion, ultrasonography or fluoroscopy may assist the diagnosis.

In selected cases, further evaluation with sleep/nap studies may determine the degree of apnea and oxygen desaturation. Pulmonary function assessment and pulmonary consultation are often helpful.

72.4 Stridor

Stridor is a symptom that is of concern to parents and physicians. Stridor is a respiratory noise created when airflow through the airway is turbulent. Airflow turbulence is most often caused by a partial airway obstruction, either anatomical or functional. Stridor is described according to when in the respiratory cycle it occurs. The quality of the stridor is important to note. Stridor may be described as fluttery, harsh, musical, or whistle-like. Stridor is described as inspiratory (commonly associated with supraglottic and glottic conditions), expiratory (commonly associated with tracheal problems), or biphasic (present during both inspiration and expiration, commonly associated with subglottic lesions). Various airway conditions are associated with different types of stridor, so that a description of the type of stridor helps to determine the type of airway lesion (□ Table 72.2).

72.5 Airway Disorders

72.5.1 Laryngomalacia

Etiology

Laryngomalacia is the most common congenital airway disorder and the most common cause of stridor in infants and

Fig. 72.4 (a) View of true vocal folds in a normal pediatric larynx. (b) Endoscopic view of normal subglottis.

Table 72.2 Types of stridor and airway conditions according to location of obstruction

Location	Voice	Stridor	Retraction	Feeding	Cough
Laryngeal: supraglottic	Muffled “hot potato”	Snoring, inspiratory and fluttering stridor	None until late	Difficult to impossible	Not noted
Laryngeal: subglottic	Normal, occasionally hoarse	Inspiratory and expiratory stridor, snoring	Intercostal early, then xiphoid	Normal	Barking (no other place in the airway)
Tracheal	Normal	Expiratory stridor and wheezing	None, except in severe obstruction	Normal	Brassy

Source: From Hartnick CJ, Cotton RT. Stridor and airway obstruction. In: Bluestone CD, Stool SE, Alper CM, et al, eds. Pediatric Otolaryngology. 4th ed. Philadelphia, PA: W. B. Saunders; 2003.

children. Laryngomalacia accounts for approximately 60% of all patients with stridor in this age group. The infant is usually born normally without any airway noise or stridor, but stridor begins variably between 1 and 4 weeks after birth.

Pathogenesis

Laryngomalacia is a specific supraglottic condition that manifests as stridor on inspiration. The stridor is caused by inward collapse of the epiglottis and aryepiglottic folds and by anterior prolapse of the redundant mucosa and cuneiform cartilages found over the arytenoids during inspiration. This collapse causes a variable obstruction of the glottic inlet and creates an intermittent, fluttery, inspiratory stridor. The supraglottic structures are pushed outward during expiration, allowing an unobstructed exhalation. This is to be differentiated from posterior disposition of the epiglottis due to an extremely posterior position of the tongue base, commonly seen in craniofacial disorders and mandibular growth conditions.

The exact cause of laryngomalacia is unknown, but a number of theories suggest that it is a neuromuscular developmental disorder of the larynx. One factor considered to be a contributory cause of laryngomalacia is laryngeal cartilage immaturity, or weakness of the laryngeal structural framework. Underdeveloped neuromuscular control of the pharyngeal and laryngeal supporting musculature is another component leading to laryngomalacia. This may occur in the absence of any other diagnosed neuromuscular conditions but manifest with airway issues, such as apnea and hypotonia.

Gastroesophageal reflux (GER) is strongly associated with laryngomalacia and is well described as a comorbid condition in children diagnosed with laryngomalacia. GER is often seen in the infant during diagnostic fiber-optic laryngoscopic examinations. GER is felt to worsen the symptoms of laryngomalacia, and also to be exacerbated by laryngomalacia. The airway obstruction caused by the inward collapse of the supraglottic structures in laryngomalacia results in an increased negative inspiratory pressure during breathing. This results in increased reflux of the gastric contents into the esophagus and up into the airway and pharynx. The effect of the acidic gastric contents on the laryngeal tissues frequently results in laryngeal edema, especially edema of the arytenoid mucosal region. GER-induced laryngeal edema worsens airway obstruction in children with laryngomalacia, thus exacerbating the general effects of laryngomalacia.

Natural History and Progression, Disease Complications, and Prognosis

Laryngomalacia varies in severity. It can be mild, with minimal symptoms other than intermittent mild stridor, or can be a life-threatening condition causing apnea and failure to thrive in the infant due to inability to feed. The variable severity is due to the variable degree of airway obstruction caused by inward collapse of the supraglottic structures.

In most infants, laryngomalacia responds well to medical treatment of the GER with H₂ blockers or other anti-reflux medications, and improvement of the stridor is expected by the first birthday and resolution of symptoms by the age of 2 years. When infants have significant apnea, exhibit failure to thrive (fail to gain weight or fall off the normal growth curve), or are unable to tolerate GER medical regimens, surgical management is offered.

Presenting Symptoms

Babies who have laryngomalacia usually present within the first few weeks of life with the onset of intermittent, fluttery, or low-pitched stridor. The stridor is usually worsened by an increased respiratory rate, such as occurs during crying, feeding, or excitement; however, in some patients the stridor is loudest during sleep. Tracheal or sternal retractions are usually indications of more severe airway obstruction and are often associated with feeding problems. It is important to evaluate the amount of time that a baby with laryngomalacia needs to take a feeding; normal feedings usually require less than 30 minutes. Babies who need longer than 30 minutes are often at risk for failure to thrive because they expend more calories in feeding than they may be gaining from their formula.

The parents should also be questioned about the amount of “spitting up” or reflux symptoms they observe in the infant. Some infants have severe reflux symptoms and “spit up” after every feeding. Other symptoms that need to be assessed include potential apnea, cyanosis, episodes of complete airway obstruction, and resultant cardiac failure.

Medical Evaluation and Physical Examination

The infant with laryngomalacia is evaluated with a complete history (as described earlier in this section) and a general head and neck examination, with particular care taken to auscultate the baby’s stridor over the chest and neck areas. The chest and

Fig. 72.5 (a) Laryngomalacia with severe inward collapse of the epiglottis and supraglottic structures on inspiration. (b) Laryngomalacia on inspiration following supraglottoplasty (with left cuneiform cartilage resection, right side present), demonstrating improvement in airway.

neck areas are observed for retractions, and a careful assessment of feeding is made in the history.

The main diagnostic examination for laryngomalacia is fiberoptic laryngoscopy. This can be safely performed in the ambulatory setting under topical nasal anesthesia, or via the unanesthetized oral cavity (in the youngest infants). With the fiberoptic laryngoscope in place, the baby is observed and the respiratory cycle is correlated with the laryngeal examination. This examination will usually reveal the following findings: (1) omega-shaped (tubular) epiglottis; (2) short aryepiglottic folds (that pull the epiglottis posteriorly and concomitantly pull the arytenoids anteriorly); (3) redundant arytenoid mucosa prolapsing anteriorly into the glottic opening; (4) prominent cuneiform laryngeal cartilages with prolapse into the glottic opening. These findings are diagnostic for laryngomalacia. There is a reported 15% incidence of concomitant aerodigestive tract anomalies when laryngomalacia is diagnosed (□ Fig. 72.5a).

Treatment

Laryngomalacia is generally considered a medical condition of the airway because about 95% of patients in whom laryngoma-

lacia (plus concomitant GER) is diagnosed can be stabilized, with a decrease in symptoms of airway obstruction, stridor, and GER, through the use of anti-reflux medications until approximately 9 to 12 months of age. Responders have marked relief of their symptoms with normal growth and development.

Patients who have significant apnea, failure to thrive, or significant symptoms that do not respond to anti-reflux medications are usually considered for surgical treatment; they account for fewer than 5% of all patients in whom laryngomalacia is diagnosed. Surgical options require a careful assessment of the specific components of laryngomalacia that are causing airway obstruction in the patient. The usual procedure includes microlaryngoscopy (with the patient spontaneously breathing under general anesthesia), bronchoscopy, and supraglottoplasty (□ Fig. 72.5b). The supraglottoplasty portion of the procedure frequently will include lysis of the aryepiglottic folds and excision of the cuneiform cartilage and redundant mucosa overlying the arytenoid cartilage. The patient is then observed via laryngoscopy upon emergence from anesthesia to confirm that the obstructing portions of the supraglottic larynx have been fully treated at the end of the procedure.

Complications of Medical and Surgical Options

The failure of medical treatment for laryngomalacia may delay definitive surgery. Unrecognized apnea and subsequent oxygen desaturation may occur in this setting. Fortunately, the vast majority of patients respond well to anti-reflux medications, and few patients with laryngomalacia who are initially medically managed proceed to surgical management.

Complications of surgical management are infrequent because of the intraoperative assessment of the efficacy of supraglottoplasty. When the supraglottoplasty is insufficient to relieve symptoms of airway obstruction, the patient may require an additional procedure to relieve airway obstruction, such as revision supraglottoplasty or tracheostomy.

72.5.2 Vocal Fold Paralysis

Etiology

Vocal fold paralysis (VFP) is a neurologic condition that may be congenital or acquired and unilateral or bilateral. VFP is the second most common cause of stridor in young children. There are many causes of acquired VFP, and specific etiologies may be more likely to cause unilateral or bilateral paralysis. In children, acquired VFP is often due to trauma, including birth-related injury, surgical trauma, and blunt or penetrating trauma. Other causes include infectious and inflammatory diseases, such as Lyme disease, Guillain-Barré syndrome, and other bacterial and viral diseases.

In cases of congenital VFP (unilateral and bilateral), the etiology is more frequently a central nervous system or cardiovascular system malformation than in acquired VFP. Congenital VFP may be found as a part of many syndromes.

Pathogenesis

True VFP can be caused by direct neuronal or central nervous system injury from trauma (including indirect trauma, such as

stretch injury), inflammation, or infection or by a malformation of the central nervous system or the vagus nerve. Like all nerves, the vagus and recurrent laryngeal nerves are susceptible to injuries that result in various forms of dysfunction, in this case weakness (paresis) or complete absence (paralysis) of motor and sensory function. The recurrent laryngeal nerve is susceptible to various forms of injury, especially stretch-type injuries, because of its circuitous path (through the chest) to its target organ, the larynx.

In cases of congenital VFP, the pathogenesis is directly related to the underlying etiology of the VFP. In cases of central nervous system malformations, Arnold-Chiari malformation is the most often identified underlying deformity. Arnold-Chiari malformation is often associated with hydrocephalus with or without myelomeningocele and with inferior displacement of the medulla and cerebellum into the foramen magnum. This inferior herniation is felt to cause traction and pressure on the vagus nerves, resulting in impaired neuronal conduction, recurrent laryngeal nerve dysfunction, and VFP, particularly bilateral. Other central nervous system disorders and malformations can directly affect the vagus nerve, from its nucleus to the motor end plates of the nerve itself.

Mediastinal cardiac malformations, with abnormalities of the great vessels, can cause traction injuries to the vagus and recurrent laryngeal nerves. Patent ductus arteriosus is one of the most common causes of unilateral VFP, particularly left-sided VFP. Patent ductus arteriosus, which is treated surgically, is often seen in premature infants, and undiagnosed VFP may actually be present before patent ductus arteriosus is surgically managed.

In the case of infectious or inflammatory conditions, the brainstem itself or the vagus nerve is directly affected by the causative agent. These causes of VFP are in many cases transitory, and the VFP will resolve with time after resolution of the causative infection. In some cases, VFP may become permanent. Many cases of VFP are seen in which no causative agent, infection, or malformation is ever identified, and they remain classified as idiopathic.

Natural History, Disease Complications, and Prognosis

The causes of VFP, both unilateral and bilateral, are extensive (□ Table 72.3). The natural history and prognosis of VFP depend on the cause. In cases of congenital, idiopathic VFP, either unilateral or bilateral, the severity of the symptoms will dictate the

overall prognosis. The symptoms of airway obstruction and/or aspiration are the most important prognosticators of the patient's clinical course. In cases of bilateral VFP, the vocal folds are usually close together, with a more defined abduction paralysis resulting in more symptoms of airway obstruction. If this is not relieved, the patient will develop respiratory distress to a variable degree, with aspiration less likely. Unilateral VFP is more likely to result in aspiration problems unless the normally functioning vocal fold is able to compensate and hyperadduct to achieve glottic closure with the paralyzed side. When the VFP does not result in life-threatening airway obstruction or aspiration, especially when the condition is idiopathic, the expectation is that there will be partial or full recovery of nerve function. This may take several years to occur. At the time that unilateral or bilateral VFP is diagnosed, there is no test that can conclusively predict when recovery may occur, especially in very small children. Most clinicians will opt for observation in asymptomatic or mildly symptomatic children to allow for the possibility of spontaneous recovery of recurrent nerve function.

Presenting Symptoms

The most common presenting symptoms of unilateral VFP include a hoarse voice or cry, stridor, and aspiration or coughing with feedings. In cases of unilateral VFP, the degree of stridor is often mild (if present at all), and the most common symptom prompting consultation is a weak or hoarse cry. Any symptoms of cough or choking with feedings are usually the normal protective function of the larynx in response to actual aspiration during the feeding. These symptoms are found in both congenital and acquired forms of unilateral VFP.

The presenting symptoms of bilateral VFP contrast sharply with those of unilateral VFP; in bilateral VFP, there is usually a strong cry and frequently loud stridor with cry or agitation, in addition to other signs of airway obstruction, such as retractions, cyanosis, and oxygen desaturation. In bilateral VFP, the vocal folds are near the midline with a narrow glottic opening, maintaining their ability to coapt and produce a strong cry; however, because there is abductor muscle dysfunction, they are unable to lateralize properly, resulting in an insufficient glottic space and airway obstruction. The size of the glottic space will influence the degree of airway obstruction; the obstruction worsens with increases as respiratory rate. Aspiration is less common than in unilateral VFP because the narrow glottis inlet reduces inadvertent leakage into the airway during swallowing (□ Fig. 72.6).

Table 72.3 Etiology of true vocal fold paralysis

Organ systems	Congenital	Acquired
Neurologic	Arnold-Chiari malformation, hydrocephalus, peripheral nerve defects (myasthenia gravis), idiopathic	Multiple sclerosis, kernicterus, idiopathic
Cardiovascular	Patent ductus arteriosus, cardiomegaly	Patent ductus arteriosus ligation, repair of coarctation of the aorta, acquired cardiomegaly
Infectious		Guillain-Barré syndrome, botulism, polyneuritis from viral etiology, syphilis, diphtheria
Trauma		Birth canal trauma, postsurgical (thyroidectomy, tracheal reconstruction surgery), direct injury to neck or chest
Other	Tracheo-esophageal fistula, mediastinal masses	

Fig. 72.6 Vocal fold paralysis. (a) Bilateral true vocal fold paralysis on inspiration (note medial position of the true vocal folds). (b) Bilateral true vocal fold paralysis with expiration (note that the true vocal folds are “pushed” apart by the airflow). (c) Unilateral true vocal fold paralysis (note the paramedian position of the the paralyzed right cord).

Medical Evaluation and Physical Examination

The diagnosis of VFP can be difficult in very small children. After a rapid assessment of the severity of the child’s respiratory status, a detailed past and present medical history is obtained. The medical evaluation should detail any other known conditions afflicting the child, such as congenital cardiac or cerebral malformations or known syndromes, as well as any prior surgical interventions for these. Other areas of review must include significant precedent infectious or inflammatory conditions.

When the child is evaluated, an emphasis needs to be placed upon the presence of stridor, including all facets of its quality, its timing, the effect of positioning, and the degree of respiratory distress and airway obstruction. The relationship of feeding to the respiratory symptoms and weight gain is important information that can aid in establishing a correct diagnosis. This information may be directly observed or obtained from caregivers.

The physical examination remains similar to that for any child presenting with an airway problem—namely, a detailed head and neck examination with emphasis on the oral structures and neck. Auscultation of the chest and neck is usually performed to detect stridor; if stridor is heard, it should be characterized by its timing, quality, and frequency. Any heart murmurs are noted.

The diagnosis of VFP depends upon observation of the larynx and vocal folds with the patient spontaneously breathing. Flexible fiber-optic laryngoscopy, with topical anesthesia administered via the nostril or mouth, is usually performed at the bedside or in the office when VFP is suspected. The laryngeal examination notes the appearance of all laryngeal structures, with note taken of the shape and position of the epiglottis and other supraglottic structures, the false and true vocal folds, and the dynamics of laryngeal function during respiration and often swallowing. The vocal folds are observed for their appearance and surfaces, their position relative to each other and the midline, any swelling or mass effect, and movement with both inspiration (abduction) and expiration. The true cord movements may be enhanced with swallowing or cough (involuntary abduction of the true cords occurs following cough). In stable patients, observation with the flexible laryngoscope should be continued until the movement of the vocal folds is determined for both abduction and adduction.

In intubated or unstable patients who are unable to tolerate flexible fiber-optic laryngoscopy, the diagnosis is more difficult, and microlaryngoscopy and bronchoscopy in the operating room or neonatal intensive care unit (NICU) are advisable, when the patient is stable. Patients with severe stridor and airway obstruction may be intubated to secure a stable airway when severe airway obstruction, cyanosis, or desaturation occurs. If intubation is performed in the NICU, it is necessary to have oxygen, appropriate endotracheal tubes, and resuscitation equipment at the bedside. Microlaryngoscopy in the operating room is usually performed with light sedation that can be administered via intravenous or inhalational agents. Close communication between the surgeon and anesthesiologist is mandatory. Once the patient is anesthetized just enough to allow positioning of the laryngoscope, the larynx may be topically anesthetized with (2%) lidocaine solution to permit lessening of the general anesthetic, thus increasing the spontaneous respiratory effort of the patient. With a 0-degree rigid telescope, the larynx is observed under magnification for spontaneous vocal fold motion, and the movements of the true vocal folds are correlated with inspiration and expiration. This process is affected by the depth of general anesthesia, and it may take several minutes before vocal fold movement is clearly observed. Supplemental oxygen is administered via the suction port on the Parsons introducing laryngoscope or via a small, trimmed endotracheal tube placed in the hypopharynx.

Following the complete assessment of true vocal fold movement, the 0-degree telescope is passed distally, and the subglottis, trachea, and primary bronchi are examined to complete the airway assessment.

If the movement of one or both of the vocal folds is impaired, then it is necessary to palpate the arytenoids with a probe to confirm that the cricoarytenoid joint is freely mobile. Other conditions, such as fixation of the cricoarytenoid joint, can infrequently occur in children.

Radiographic studies may be useful in determining the etiology of VFP in children. Plain X-rays of the chest and neck in the anteroposterior and lateral projections can provide helpful information regarding associated malformations and conditions that result in unilateral or bilateral VFP. Plain film chest X-ray is

especially helpful when there has been prior surgical management of patent ductus arteriosus, with the left mediastinal surgical clip plainly visible.

Modified barium swallow, performed in the radiology suite by the speech or occupational therapist, is a valuable video radiology study to evaluate the aspiration of liquids and pastes of various consistencies. The modified barium swallow can also provide specific information regarding aspiration reduction techniques and proper feeding options for children whose VFP results in aspiration. MR imaging and CT of the larynx do not provide specific information that will yield a diagnosis of VFP alone, but they can provide important information regarding associated medical conditions.

Treatment

In general, the treatment of VFP depends upon the etiology of the paralysis. When congenital VFP (either unilateral or bilateral) is diagnosed, the recommended treatment depends upon the severity of the symptoms. When the patient does not have signs and symptoms of airway obstruction, cyanosis, apnea, or aspiration, he or she is usually observed for possible spontaneous recovery. When the symptoms of respiratory distress are severe, operative microlaryngoscopy and bronchoscopy (if not already performed) are recommended to evaluate the airway for any other conditions for which intervention is warranted (e.g., a patient with both laryngomalacia and unilateral VFP from ductus arteriosus ligation). Subsequent tracheotomy is often necessary to maintain a satisfactory and consistent airway, especially in patients with bilateral VFP. Approximately 50% of patients with bilateral VFP have airway obstruction severe enough to require tracheotomy, whereas fewer than 10% of those with unilateral VFP require a tracheotomy for their airway demands. Approximately 50% of patients with Arnold-Chiari malformation have bilateral VFP, and they are in a special treatment category. Hydrocephalus in patients with Arnold-Chiari malformation can result in sufficient pressure on the vagus nerve rootlets to cause bilateral VFP. Often, immediate reduction of the hydrocephalus with a ventriculoperitoneal shunt is effective in reversing the bilateral VFP and restoring normal laryngeal function. In these patients with Arnold-Chiari malformation, the new onset of bilateral VFP is concerning for increased intracranial pressure, and treatment of that condition will often resolve the bilateral VFP.

Similar options exist for children with permanent acquired VFP or congenital VFP that does not resolve spontaneously. These options are used less frequently in pre-school-age children because of concerns about laryngeal growth and possible permanent effects on voice quality. Arytenoidectomy (partial or complete removal of the arytenoid cartilage and posterior portion of the vocal fold), arytenoid adduction (fixation of the medialized arytenoid to a more lateral position), injection of permanent and temporary filler agents (to medialize vocal folds that are too lateral), and thyroplasty procedures are all available surgical options for improvement of the airway and/or voice quality. These procedures are similar to their counterparts in the adult population, with some modifications made because they must be carried out under general anesthesia.

Complications of Medical and Surgical Options

Complications of the treatment of VFP are most commonly related to airway obstruction, apnea, cyanosis, and aspiration, which are found before the diagnosis in many patients with VFP, regardless of its cause. Tracheostomy placement may result in reactions to general anesthesia, tube dislodgement before tract healing, and pneumothorax. Fortunately, these complications are very rarely in properly staffed and equipped pediatric hospitals. Late complications from tracheotomy are also uncommon and include tracheotomy tube occlusion (from dried respiratory secretions), granulation tissue in the distal trachea (at the tip of the tube) and at the stoma, and accidental decannulation (dislodgement of the tracheotomy tube). Nursing care specialists commonly assist in identifying and avoiding such problems during home visits.

The need for a balance between adequate airway patency and vocal quality has made some of the decisions regarding the best treatment for children with VFP a dilemma. Discussions about procedures that may allow decannulation must always consider the effect on vocal quality. It is recommended that children participate in these decisions when they are old enough to comprehend the risks involved in balancing vocal quality with an adequate airway.

72.5.3 Masses and Tumors

Etiology

Masses and tumors of the larynx, trachea, and bronchi may be congenital or acquired. Although most congenital masses are diagnosed soon after birth, some may not become apparent until they enlarge and become symptomatic.

Recurrent respiratory papillomatosis is the most common tumor affecting the airway in young children, but a myriad of benign and malignant neoplasms of epithelial and connective tissue origin are also seen. Some tumors more commonly seen in children include hemangioma (especially in a subglottic location) and neurofibroma. Fortunately, tumors affecting the airways are rare, and it is even more rare for them to be malignant.

Recurrent Respiratory Papillomatosis

Pathogenesis

Recurrent respiratory papillomatosis (RRP) is known to be caused by infection with the human papillomavirus (HPV). More than 100 types of HPV are known, but RRP is most commonly associated with types 6 and 11. HPV infection is generally considered to be vertically acquired from an afflicted mother as a perinatal inoculation during childbirth. Causative information is incomplete because the RRP infection rate is less than 1 per 500, whereas the maternal infection rate would predict an infection rate of 1 per 32 in infants (approximately 2,500 new cases are diagnosed annually). Transoral infection from vaginal and cervical secretions is the most commonly accepted transmission theory. It is believed that firstborn babies of susceptible young mothers have the highest infection rates of RRP. Interestingly, the siblings of RRP-afflicted children do not have

increased rates of infection. The diagnosis is most commonly made around the age of 4 years.

Infection with HPV usually results in the growth of “papillomas,” growths characterized by an irregular, exophytic surface and a nodular or pedunculated appearance. They can affect any part of the airway but tend to form in the glottic regions; the larynx is affected in nearly 100% of cases. Under magnification, the papillomas appear as projections of reddish to tannish tissue with sometimes visible vascular cores. On pathologic analysis, papillomas are covered by stratified squamous epithelium with fibrovascular cores and frequently show signs of dysplasia.

Natural History and Progression, Disease Complications, and Prognosis

Once papillomas form in a patient with RRP, continued growth of the lesions within the airway lumen, most often the larynx, is common. The unrelenting growth of laryngeal papillomas leads to progressive airway obstruction, hoarseness, and eventual death unless they are treated. Patients often have a significant papilloma load when they present.

RRP is a viral disease for which there is no known cure, and intermittent palliative procedures are required to maintain a patent airway. A number of clinical trials have attempted to develop an adjuvant medical regime to cure RRP or at least reduce the burden of multiple airway procedures required to clear the obstructing papillomas; mumps vaccine injection, interferon, 5-fluorouracil, acyclovir, and methotrexate have been tested. All trials showed a delay in disease progression in some patients, but none demonstrated the hoped-for cure for RRP. Ongoing trials of cidofovir show promise, but not all patients appear to respond.

The prognosis in RRP is mixed; spontaneous remission occurs in some patients, but many continue to live with disease. The spontaneous remissions rates seem to be higher at the time of school entry and around puberty, leading some investigators to consider that hormonal factors play a role in remission. It is likely that HPV infection in the laryngeal epithelium becomes dormant because some of the patients with spontaneous remissions experience recurrence as adults. It is hoped that the new vaccines against HPV will markedly reduce this disease by decreasing cervical infection in susceptible women.

Presenting Symptoms

RRP typically presents with hoarseness progressing to a whisper-like voice, stridor, wheezing, and increasing respiratory effort and distress. These symptoms are directly related to the location of papillomas in the larynx. Because the vocal folds are the most commonly affected regions of the larynx, vocal complaints are often the earliest symptoms. More subtle symptoms of progressive respiratory distress may be the presenting signs when the vocal folds are free of papilloma.

Medical Evaluation and Physical Examination

Patients with RRP present in either of two ways, depending upon the degree of airway obstruction. Patients with less severe disease often present to the doctor’s office with chronic hoarseness, whereas patients with severe obstruction present to the

emergency department with symptoms of severe, progressive airway obstruction.

The medical evaluation of both types of patients includes a determination of the degree of respiratory distress, the duration of symptoms (especially hoarseness), and the presence or absence of stridor. Sometimes, small epithelial papillomas may be visualized in the oropharynx, particularly on the tonsils or uvula.

Flexible fiber-optic laryngoscopy is indicated for all but the most extremely symptomatic patients, whose symptoms may worsen significantly if they are upset or crying; they warrant evaluation in the operating room. The laryngeal examination characteristically reveals one or more visible papillomas in the glottic and supraglottic areas. The degree of airway obstruction should be estimated from this examination, to help determine the urgency of the need for surgical removal (□ Fig. 72.7).

Treatment

Currently, the treatment of RRP is surgical palliation with removal of the airway papillomas. Patients who have RRP undergo suspension microlaryngoscopy with bronchoscopy on an intermittent schedule to maintain a patent airway. In severe cases, this interval may be as short as 2 to 3 weeks, which is typical in the youngest children. Often, the interval can be extended as the patients mature.

The surgical removal of papillomas in children may be performed as an ambulatory procedure. In many patients with RRP, general anesthesia is administered via an inhalation technique and maintained with an intravenous agent, which allows suspension microlaryngoscopy to be performed under spontaneous ventilation. After the laryngoscope is placed and lidocaine topically applied to the larynx, spontaneous ventilation allows all areas of the airway to be treated without the need for an endotracheal tube. Papillomas are removed most commonly with carbon dioxide laser, microforceps, or the laryngeal microdebrider. Pathologic inspection is routinely

Fig. 72.7 Recurrent respiratory papilloma in the laryngeal glottis.

performed to monitor for rare malignant degeneration of a papilloma into squamous cell carcinoma.

When anesthesia cannot be maintained with spontaneous ventilation, other techniques, such as jet ventilation or apneic techniques, are used. In addition, children with severely obstructive papillomas may initially require intubation because of an inability to ventilate the partially obstructed airway. The endotracheal tube is gently twisted and pressed into the glottic area and slipped past the obstructing papilloma into the trachea. Generally, the endotracheal tube can be removed once the main obstruction is relieved.

Complications of Medical and Surgical Options

At this time, there is no consensus regarding the medical management of RRP, so the patients in each clinical trial are subject to possible complications of the medical treatment offered. All medical trials contain provisions for palliative surgical treatment of the airway with removal of obstructive papilloma.

In general, children with RRP tolerate the multiple operative procedures well. The main risk of repetitive papilloma removal is the formation of scar tissue on the vocal fold, particularly in the anterior commissure, resulting in poor vocal quality. This risk is diminished by keeping the intervals between procedures as long as possible yet safe for maintaining airway patency and recognizing that these procedures are aimed primarily at the maintenance of a patent airway, not the reduction of hoarseness.

The surgical complications of RRP treatment depend upon the instruments used to remove the papilloma. Although the carbon dioxide laser is commonly used because it removes papillomas with precision, it may rarely cause flash fires in the airway. Use of the laryngeal microdebrider “skimmer” is now common, but like all techniques, it may inadvertently remove normal tissue.

Subglottic Hemangioma

Etiology

Subglottic hemangioma is a congenital vascular tumor found in the subglottis of infants. Subglottic hemangiomas are most commonly discovered in children between 3 and 6 weeks of age. Hemangiomas contain histologic tissue markers similar to those in placental tissue. Subglottic hemangiomas are more commonly found in children who have cutaneous hemangiomas, particularly those that affect the lower third of the face

and upper neck. A subglottic location may be noted up to 10% of the time in this subset of patients with hemangioma. Hemangiomas in the subglottic area result in variable degrees of airway obstruction.

Natural History and Progression

Subglottic hemangiomas, when located in the subglottic space, tend to become symptomatic. Hemangiomas are often sessile, flat lesions when first discovered, but within weeks to months they enter a proliferative phase during which they enlarge. The proliferative phase lasts for several months, with a change of texture and color beginning around the ninth month of life. This change, with softening and a whitish appearance noted on the hemangioma surface, marks the onset of the involution phase. Involution then proceeds for up to 5 to 7 years, with shrinkage of the hemangioma.

The prognosis for a patient with subglottic hemangioma is excellent because these lesions are expected eventually to involute and decrease in size. In addition to maturation and growth of the child’s airway, regression leads to a decrease in symptoms, even when some hemangioma remains.

Presenting Symptoms

An infant with a subglottic hemangiomas usually will have an onset of stridor (usually inspiratory or biphasic) at around the age of 3 to 6 weeks, with a normal cry. The stridor may be associated with retractions in the pretracheal or sternal areas. The stridor progresses from intermittent to constant as the hemangioma enlarges during the proliferative phase. Some infants will develop feeding problems as the stridor worsens and the hemangioma becomes larger.

Cutaneous hemangiomas, present approximately in 50% of children with subglottic hemangiomas, will show similar signs of proliferation. About two-thirds of patients with hemangiomas of the lower third of the face are at risk and have airway hemangiomas. Subglottic hemangiomas are more common in girls.

Medical Evaluation and Physical Examination

A child with a cutaneous hemangioma presenting with inspiratory stridor should be suspected of having a subglottic hemangioma. Progressive worsening of stridor will be noted as the duration of the stridor lengthens. The evaluation includes flexible fiber-optic laryngoscopy (□ Fig. 72.8). Hemangioma may be

Fig. 72.8 (a) Image of subglottic hemangioma in the right posterior lateral subglottis. (b) Close-up view.

suspected by the observation of a reddish mass in the subglottis, particularly the posterolateral areas. Further evaluation requires microlaryngoscopy and bronchoscopy under general anesthesia. Findings include a smooth, dark red, mucosa-covered mass in the subglottis, sometimes with extension onto the edge of the true vocal fold. The mass is usually compressible and isolated to the subglottis. Tracheal involvement usually appears as a flat patch of reddish mucosa without encroachment into the airway lumen. Biopsy of the lesion is inadvisable because of the likelihood of significant bleeding.

Treatment

A subglottic hemangioma, if small, may be monitored and observed; however, the great majority of these are identified because of the significant symptoms they cause. A variety of treatment modalities are available for subglottic hemangioma, both medical and surgical.

Medical treatment is directed toward decreasing the symptoms of the hemangioma. Corticosteroids are the most commonly used agent for rapid airway symptom relief. Dexamethasone, in doses of up to 1 mg/kg/d initially, often will cause a marked decrease in stridor within 24 to 48 hours. Subsequent transition to prednisolone is sometimes used for up to several weeks once the stridor improves. Intralesional steroid use also has a desirable effect on hemangioma size and symptoms.

In the past, transition from systemic steroids to interferon alpha A was advocated for symptomatic hemangiomas. However this has fallen out of favor because of reports of spastic diplegia caused by myelination defects in the central nervous system.

Propranolol (3 mg/kg/d divided into three doses), a new treatment modality, has been observed to have a marked, rapid (within 24 to 48 hours) effect of decreasing the size and symptoms of airway hemangiomas in previously steroid-dependent children. The low dose of propranolol is well tolerated, and the low risk for systemic side effects (transient hypoglycemia and bronchospasm), combined with the dramatic decrease in symptoms, has made propranolol an agent of choice for many babies with subglottic and other airway hemangiomas.

Surgical management is offered in many situations to children with subglottic hemangioma. Excision of the hemangioma is effective in resolving symptoms in many patients. Excision may be performed with carbon dioxide laser, a microdebrider, or open surgical excision. Tracheotomy is an option for patients who cannot be treated medically (do not tolerate medical management) or who have a circumferential subglottic hemangioma. It is likely that medical therapy with propranolol will decrease the number of surgical procedures performed for subglottic hemangioma.

Complications of Medical and Surgical Options

The complications of medical therapy vary with the agent used. Systemic steroids are well-known to have severe systemic effects when used for a prolonged period of time. These include immune suppression, suppression of the adrenal hormonal axis, growth retardation, hyperglycemia, hypertension, and cushingoid appearance.

At this time, no severe side effects have been reported to occur with propranolol therapy. Patients are monitored for

hypotension, bronchospasm, and hypoglycemia; the risk for these decreases after the initiation of therapy, and most children are followed by a pediatric cardiologist while taking propranolol.

Surgical therapies risk the development of subglottic stenosis from scar formation at the site of the hemangioma. Additionally, incomplete resection of the hemangioma risks recurrence of the lesion in those sites where it remains.

72.5.4 Subglottic Stenosis

Etiology

Subglottic stenosis is characterized by a narrowing of the subglottic space, located just under the vocal folds and extending to the trachea. Stenosis can be congenital (absence of prior intubation and instrumentation of the airway, and abnormal size or shape of the cricoid cartilage lumen) or acquired (most commonly after intubation). Subglottic stenosis is the third most common cause of stridor in young children, although it can be found in all age groups. Inflammatory conditions may also cause subglottic stenosis in patients without a history of intubation.

Pathogenesis

The subglottic space in children is especially prone to the development of inflammation from trauma, including intubation injury. The subglottis is the narrowest portion of the pediatric larynx (as opposed to the glottis in adults) and is thus predisposed to injury from an endotracheal tube. The already small size of the neonatal airway, combined with any inflammation or scarring to the mucosal lining of the subglottis, makes it prone to luminal narrowing. It is well established that the placement of an endotracheal tube can cause pressure on the mucosal lining of the cricoid, resulting in decreased capillary refill and subsequent ischemic mucosal injury within hours of endotracheal tube placement. The ischemic damage to the mucosa can progress to edema and, if the pressure on the airway mucosa is unrelieved, ultimately to erosion and ulceration of the mucosa. In the most severe cases, there is the potential for a full-thickness mucosal injury, and even damage to the cricoid cartilage with destabilization of the lumen integrity.

Frequently, granulation tissue will be seen in the region of subglottic injury or at the vocal fold level, molded around the shape of the endotracheal tube on laryngoscopic examination. Healing takes about 3 weeks (once the endotracheal tube pressure is relieved), with ultimate re-epithelialization of the mucosal surface. The healing process results in the variable deposition of scar tissue with thickening of the submucosa in the subglottic space.

Other factors felt to play a role in the development of acquired subglottic stenosis in neonates include mucosal injury from endotracheal tube movement (shearing effect of the tube on the mucosa), injury from repetitive intubations, inflammation from bacterial contamination of the endotracheal tube, and the possibility of an underlying small airway (where even the smallest endotracheal tube is still too large).

The cross-sectional area of the subglottic lumen is related to the luminal radius: $A = \pi r^2$, where A is the cross-sectional

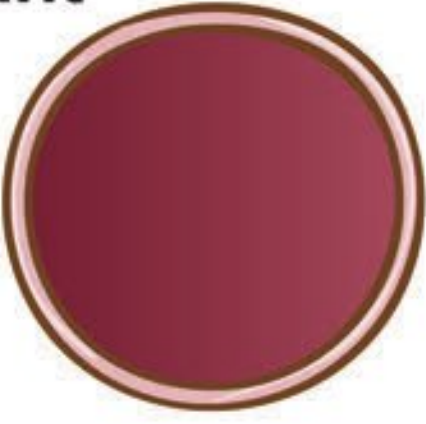

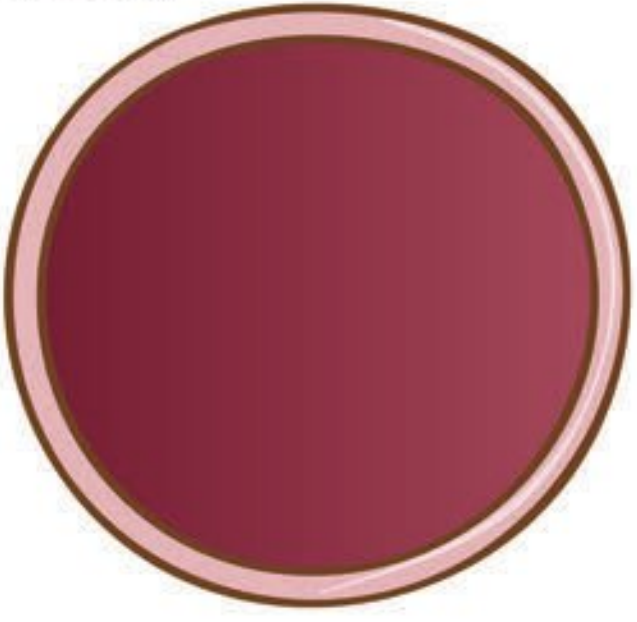

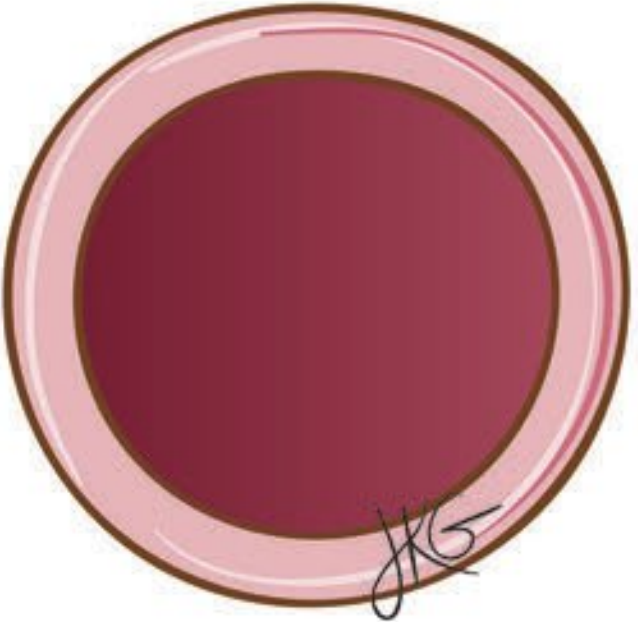

Normal	Edema (1mm)	Resistance	Cross sectional area
Infant 		↑ 16x	↓ 75%
Adolescent 		↑ 3x	↓ 44%
Adult 		↑ 2x	↓ 30%

Fig. 72.9 The same degree of mucosal edema affects the smaller airways of children more severely than those of adults.

area and r is the radius of the subglottic lumen. Thus a very small decrease in the radius, for example from 4 to 3 mm, will decrease the cross-sectional area about 75%. This translates into a 16-fold increase in airflow resistance within the airway. Because of this effect on the luminal area, children are subject to significant respiratory disturbance from even minor respiratory conditions (□ Fig. 72.9).

When the mucosal lining the airway is injured, it responds with an accumulation of inflammatory cells and mediators. The inflammatory response results in the development of edema within the mucosa. Depending upon the degree and severity of the inflammatory response and edema, tracheal intubation may be needed to maintain a patent airway despite the possibility of exacerbating the problem with the subglottic luminal size. Soon after the inciting event, increased fibroblast activity with collagen deposition will develop in the submucosa, and scar tissue will form in any areas of mucosal erosion. This process is stimulated and worsened by associated gastroesophageal reflux and acid contact with the mucosa. Once collagen and

scar tissue are deposited, the lumen remains narrowed. Direct (blunt or penetrating) trauma and endotracheal intubation are associated with the worst stenosis.

Congenital subglottic stenosis is present in babies at birth but may not be evident until an upper respiratory tract infection develops. The most common cause of congenital subglottic stenosis is an abnormally shaped cricoid cartilage or an abnormally formed cricoid with a smaller than normal lumen (□ Fig. 72.10).

Natural History, Disease Complications, and Prognosis

The effects of subglottic stenosis vary greatly depending upon the severity. Subglottic stenosis can range from very mild, with minimal effect on the patient, to life-threatening. Perpetuation of the inciting cause of the stenosis can increase the degree of stenosis, so it is imperative to remove the causative agent as soon as possible. All care should be taken to use appropriately

Fig. 72.10 Intraoperative images demonstrating grade II subglottic stenosis (lower left panel).

sized endotracheal tubes in children, and to ensure that the cuff of the endotracheal tube is located in the proper midtracheal position in order to protect the laryngeal subglottis.

In most cases, once subglottic stenosis has developed and the healing phase of subglottic injury has occurred, the stenosis is considered to have matured and stabilized. At this point, the narrowing becomes relatively fixed (barring any acute inflammation from upper respiratory infections, for example), and it is unlikely to resolve spontaneously. Some cases will continue to worsen because of continued trauma to the mucosa and submucosa from an unremedied inciting condition. Respiratory symptoms in these children may progress to severe distress and fatigue. At this point, it is necessary to secure the child's airway by intubation (if possible) or by tracheotomy (if the lumen will not permit passage of an endotracheal tube). High-potency steroids, such as dexamethasone, are frequently used in an effort to reduce inflammation, stabilize the mucosa, and prevent further edema. Death from airway obstruction may result if this process is delayed.

Subglottic stenosis is classified based upon the degree of narrowing in comparison with normal airway luminal size. The most commonly used grading scale is the Myer-Cotton system, which divides subglottic stenosis into four categories (□ Ta-

Table 72.4 Myer-Cotton grading scale for subglottic stenosis

Grade	Percentage laryngeal luminal obstruction
I	0–50%
II	51–90%
III	91–99%
IV	No detectable lumen

ble 72.4). The categories are valuable in predicting the likelihood of success with the treatment options for subglottic stenosis. Grade I ranges from a normal luminal size to luminal obstruction of 50%, grade II indicates airway luminal obstruction of 51 to 90%, grade III is luminal obstruction of 91 to 99% and grade IV indicates no detectable airway lumen.

In order to grade subglottic stenosis, the airway lumen must be examined and measured during laryngoscopy with the patient under general anesthesia. After inspection of the larynx, subglottis, and trachea, the airway is measured with a standard uncuffed endotracheal tube. The outer diameter of an uncuffed endotracheal tube is of uniform measured size and is used to assess the airway luminal size (although the “size” of a tube is

Table 72.5 Appropriate endotracheal tube size by patient age

Age	Endotracheal tube size (mm)
Premature	2.0–3.0
Birth–3 mo	3.0–3.5
3–12 mo	3.5–4.0
12 mo–2 y	4.0–4.5
2–4 y	4.5–5.0
4–6 y	5.0–5.5
6–8 y	6.0
8–10 y	6.5
10 y–adult	6.5 or larger

designated by its internal, not external, diameter). After placement of an uncuffed endotracheal tube, the airway is observed under magnification (typically a telescope is used) for air bubble escape as the anesthesiologist slowly increases the airway pressure. A normal leak is considered to be at a pressure of 18 to 24 cm H₂O. Lower pressures indicate excessive space around the tube, whereas higher pressures indicate that the tube is too large; the tube is exchanged for a larger or smaller one, and the leak pressure is measured again. The endotracheal tube size with which the pressure is closest to the normal leak pressure is deemed the airway size (□ Table 72.5). Measurement of the airway size is a standard component of the endoscopic airway examination.

Presenting Symptoms

In either acquired or congenital subglottic stenosis, inspiratory or biphasic stridor is heard (biphasic stridor is noted in the most severe cases of luminal narrowing). The stridor may be constant, even during sleep and with quiet respiration. Feeding may be affected, and failure to thrive is frequent because the infant is unable to manage the increased respiratory effort needed to coordinate breathing and swallowing. In this situation, the child forgoes feeding and will lose weight because of the increased caloric energy needed for the work of breathing and the insufficient nutrients obtained from feeding.

Other symptoms of subglottic stenosis include chest and tracheal retractions, and a raspy or rattling sound may be heard during breathing when secretions are located at the stenosis site. Cyanosis and oxygen desaturation are late findings seen when respiratory failure is imminent.

Medical Evaluation and Physical Examination

The child with subglottic stenosis will typically present with stridor as the chief complaint. Because of the variable degree of luminal obstruction, it is imperative to determine the severity of airway compromise at the initial evaluation and take action immediately if there is severe respiratory distress.

In less severe cases, the medical evaluation should focus on any antecedent history of intubation, instrumentation in the airway, and conditions that may have led to airway trauma. The birth history and the need for airway support at birth are

important. The history should reflect the effect of upper respiratory infections and any change in stridor/airway distress caused by those episodes. Feeding problems are important in determining the cause of airway distress.

The physical examination should focus on the airway and include both auscultation and inspection of the airway passages. Flexible laryngoscopy is integral in the diagnosis and should be performed in all but the most unstable children (in whom the airway often will need to be examined in the operating room, with ultimate treatment of the underlying condition). Despite the limitations of flexible laryngoscopy in visualizing the subglottis, it may reveal stenosis, and it is invaluable in excluding other causes of stridor. Ultimately, most children with subglottic stenosis require microlaryngoscopy with bronchoscopy under general anesthesia. Occasionally, imaging studies such as anteroposterior and lateral plain radiographs of the neck, CT fluoroscopy, and MR imaging are helpful in characterizing the stenosis. An evaluation of any coexistent gastroesophageal reflux is important because it is a known exacerbating factor.

Children who are intubated at the time of evaluation for subglottic stenosis present with a history of (often repetitively) failed extubation. The duration of intubation, reason for the initial intubation, and size of current and previous endotracheal tubes are important factors. The degree of prematurity and coexistent cardiac or pulmonary conditions all play a role in the evaluation. These children require evaluation of the airway under controlled conditions, usually in the operating room, with microlaryngoscopy and bronchoscopy. Granulation tissue, edema, and erosion in the subglottis and adjacent glottis are usually seen in patients with subglottic stenosis. The leak around the endotracheal tube is measured and compared with norms.

Treatment

The treatment of subglottic stenosis is tailored according to the degree of respiratory distress it induces. The vast majority of ambulatory children with mild (grade I) subglottic stenosis can be observed and managed expectantly. These children usually do not exhibit signs or symptoms of stridor or respiratory distress until an upper respiratory infection develops. The additional mucosal edema caused by the upper respiratory infection will often lead to the development of mild to moderate stridor, with a croup-like cough. Moderate retractions and distress often lead parents to bring these children for emergency treatment. In such cases, supportive management with corticosteroids for a few days and racemic epinephrine via nebulizer can provide substantial relief of their respiratory distress.

Children with higher grades of subglottic stenosis (grades II through III) frequently have symptoms of airway obstruction sufficient to require more aggressive management. Children with grade IV subglottic stenosis will always be tracheotomy-dependent because they have no discernible airway lumen. The airway obstruction of these children will have progressed from grade III to grade IV during the healing process. Children with grade IV stenosis will always require airway reconstructive surgery after decannulation. Children with grade II and grade III subglottic stenosis are often symptomatic and most often require intervention to improve their airway.

Neonatal Management

Babies with multiple failed attempted extubations who are found to have subglottic stenosis are usually managed based upon the findings at microlaryngoscopy and bronchoscopy. Infants with findings of mild edema, minimal to no mucosal ulceration, normal laryngeal function, and no other cause for the failed extubation attempts are frequently treated with the removal of any granulation tissue, polyp, or cyst found; reintubation with a smaller endotracheal tube (typically 0.5 mm to a full size smaller); the administration of dexamethasone; and observation for several days in anticipation of the reduction of any edema. The infant is then extubated following 48 to 72 hours of dexamethasone therapy (up to 1 mg/kg/d divided into two doses) and observed for the potential need for further airway support.

Anterior Cricoid Split

Some infants with isolated subglottic stenosis may benefit from an anterior cricoid split procedure. For infants who fail the above extubation protocol, or in whom an endotracheal tube of a smaller than usual size has been placed, an anterior cricoid split may be considered. Carefully selected candidates for anterior cricoid split are babies who weigh more than 1,500 g; have stable, controlled cardiac and pulmonary function; and have no other conditions preventing extubation (see Box Criteria for Anterior Cricoid Split).

Anterior cricoid split is performed through a horizontal midline neck incision. The cricoid cartilage is incised vertically to allow the subglottic lumen to expand. In this procedure, the only complete ring of the airway, the cricoid cartilage, is incised in one or more locations to allow the area of the subglottis to

expand. An endotracheal tube one size larger than the tube previously used acts to distract the cricoid edges and stent the airway lumen during the healing period. The infant is then extubated after premedication with dexamethasone (up to 1 mg/kg/d) under controlled conditions, with a tracheostomy tray and intubation instruments immediately available, about 6 to 10 days after the procedure. In the event of respiratory distress or obstruction, the infant is intubated, or a tracheostomy is placed through the prior neck incision (□ Fig. 72.11).

Criteria for Anterior Cricoid Split

1. Weight of more than 1,500 g
2. No assisted ventilation for >10 days
3. Oxygen supplementation requirements <35%FiO₂
4. Stable congestive heart failure for >1 month
5. No hypertension medications required for >14 days
6. Failed extubation two or more times with a laryngeal cause
7. Absence of pulmonary or airway infection

The anterior cricoid split procedure is useful in carefully selected patients and can avoid the need for more involved airway reconstructive surgery (laryngotracheal reconstruction procedures) and for tracheotomy. A current modification of the anterior cricoid split is to add a small piece of cartilage harvested from the conchal bowl or upper portion of the thyroid cartilage lamina as a stabilizing graft.

The complications of anterior cricoid split include failure of the procedure to relieve airway obstruction at the subglottis. Postoperatively, spontaneous ventilation is preferred over

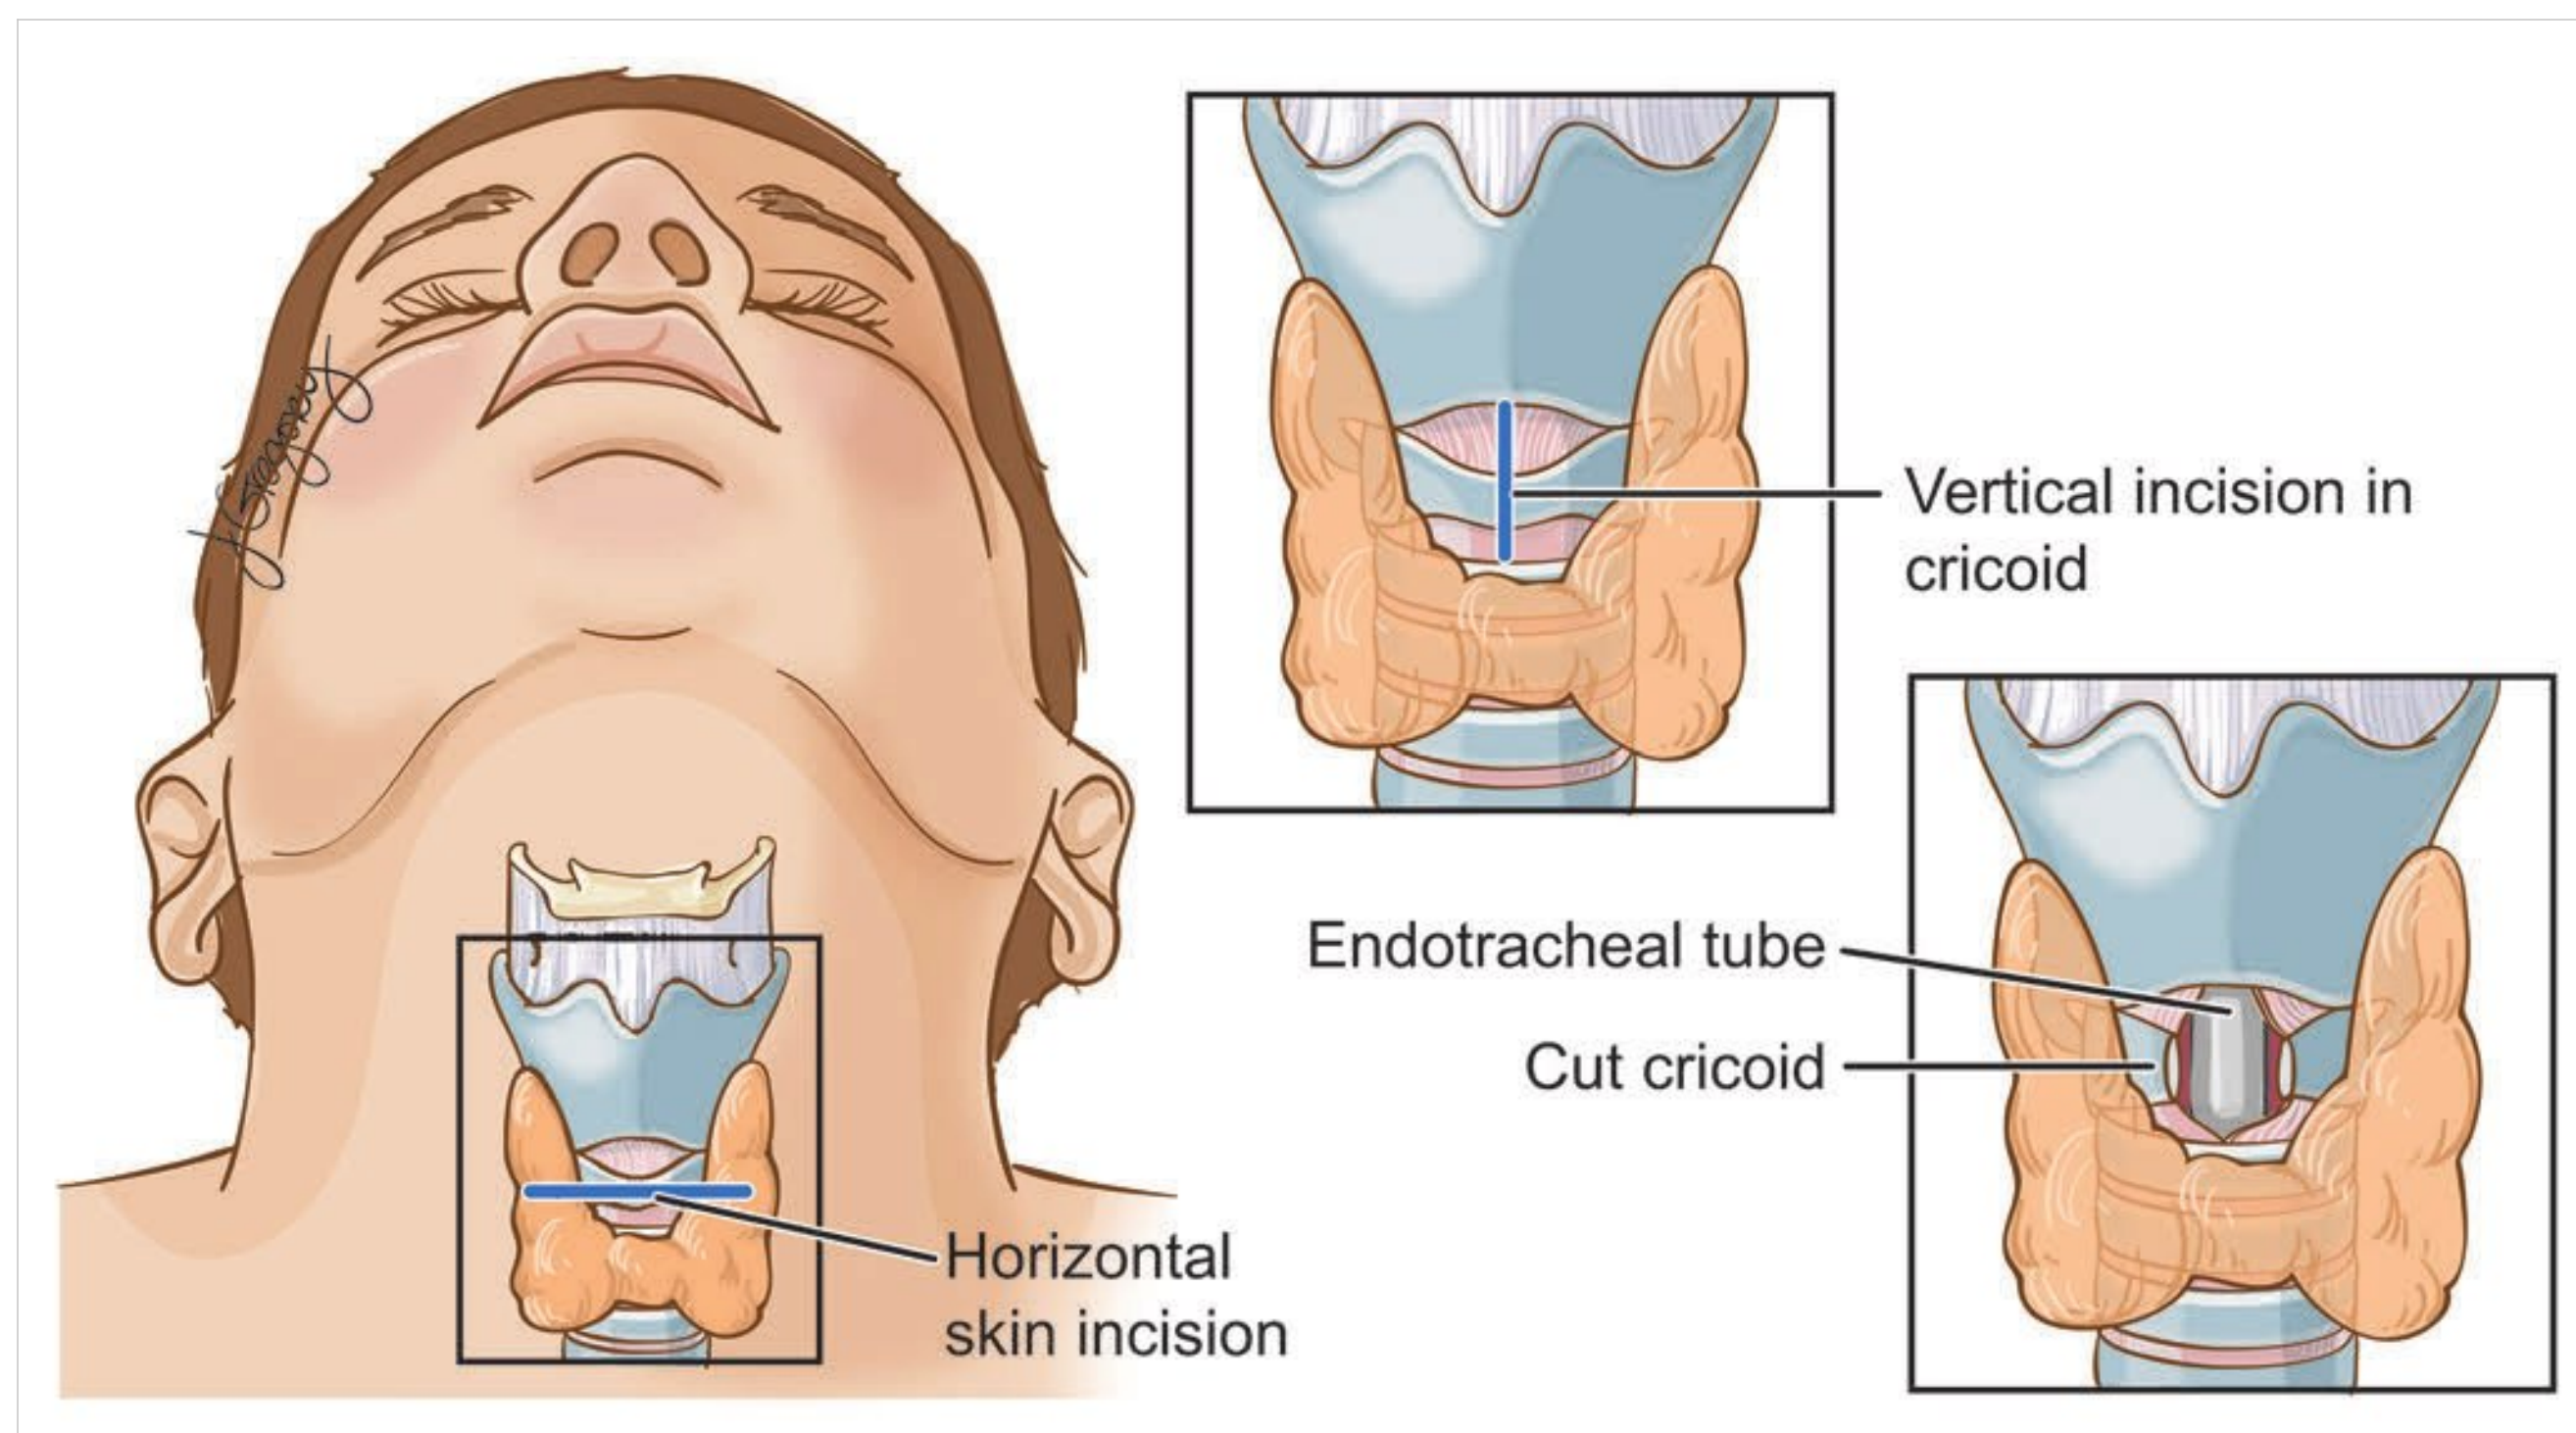

Fig. 72.11 Anterior cricoid split procedure.

mechanical ventilation because the former is associated with lower risk for pneumonia. Intubation must be secure, and the patient must not be accidentally extubated during the 6- to 10-day healing period. Signs of inadvertent dislodgement of the endotracheal tube include subcutaneous air with crepitus, pneumomediastinum, and pneumothorax. If the endotracheal tube becomes dislodged, it is best to reinsert it via the neck wound under direct vision in the emergency setting. Conversion to nasotracheal intubation either over a flexible bronchoscope or telescope allows the most accurate repositioning of the ETT.

Laryngotracheal Reconstruction

Laryngotracheal reconstruction involves expansion of the laryngotracheal structure to relieve an obstructed lumen. Successful laryngotracheal reconstruction requires a careful assessment of the length and exact location of the stenosis, and of the likelihood of continued or future need for prolonged intubation. Also required is optimization of the laryngeal obstruction, including treatment of the cause of the stenosis and the control of gastroesophageal reflux. Any child for whom laryngotracheal reconstruction is being considered must be a suitable candidate for the administration of general anesthesia.

Laryngotracheal reconstruction requires placement of a cartilage graft as well as stenting of the airway lumen. Various graft options are available, including costal cartilage (the most commonly used), auricular cartilage, and thyroid alar cartilage. The ribs are the preferred source of cartilage because of the large amount of donor material available and its excellent strength and robust qualities. Costal cartilage is usually harvested from the fifth or sixth anterior rib via a transverse incision placed under the breast. A generous graft is harvested, with care taken

to avoid injury to the perichondrium on the inner surface of the rib, which will cause pneumothorax.

Use of the thyroid ala cartilage is less frequent unless a small graft is necessary. The benefit of thyroid cartilage for grafting is that the donor site is within the surgical field. It is less useful when robust material is needed to distract the cricoid cartilage in higher-grade stenoses. Auricular cartilage has the least strength as a graft material because of its thinness in very young children. It often does not maintain the needed shape and has a tendency to buckle.

A stent is needed to maintain the airway lumen during the healing period after the procedure. Many patients who undergo laryngotracheal reconstruction require stenting for a prolonged period, extending from weeks to months in some cases. Stent materials vary, but many airways are stented with endotracheal tubes (when stenting is for 1 to 2 weeks) or with Teflon stents (Aboulker stent) for longer-term use. Different stents are used depending upon whether the patient has a preexisting tracheostomy at the time of the laryngotracheal reconstruction and on whether the laryngotracheal reconstruction is done as a single-stage or a double-stage procedure. It is important to note that the stent passes through the larynx, so it will prevent phonation and may increase aspiration while in place. The patient often will have a tracheostomy in place when a long-term stent is needed to maintain the airway. Stenting times increase with stenosis of a more advanced grade or the presence of significant scar tissue, and in previously reconstructed airways. Laryngotracheal reconstruction is performed after optimization of these factors.

The laryngotracheal reconstruction is performed through a horizontal neck incision (□ Fig. 72.12). After the cartilage (usually costal) graft has been harvested, the larynx and trachea are exposed, and a vertical incision is made in the midline of

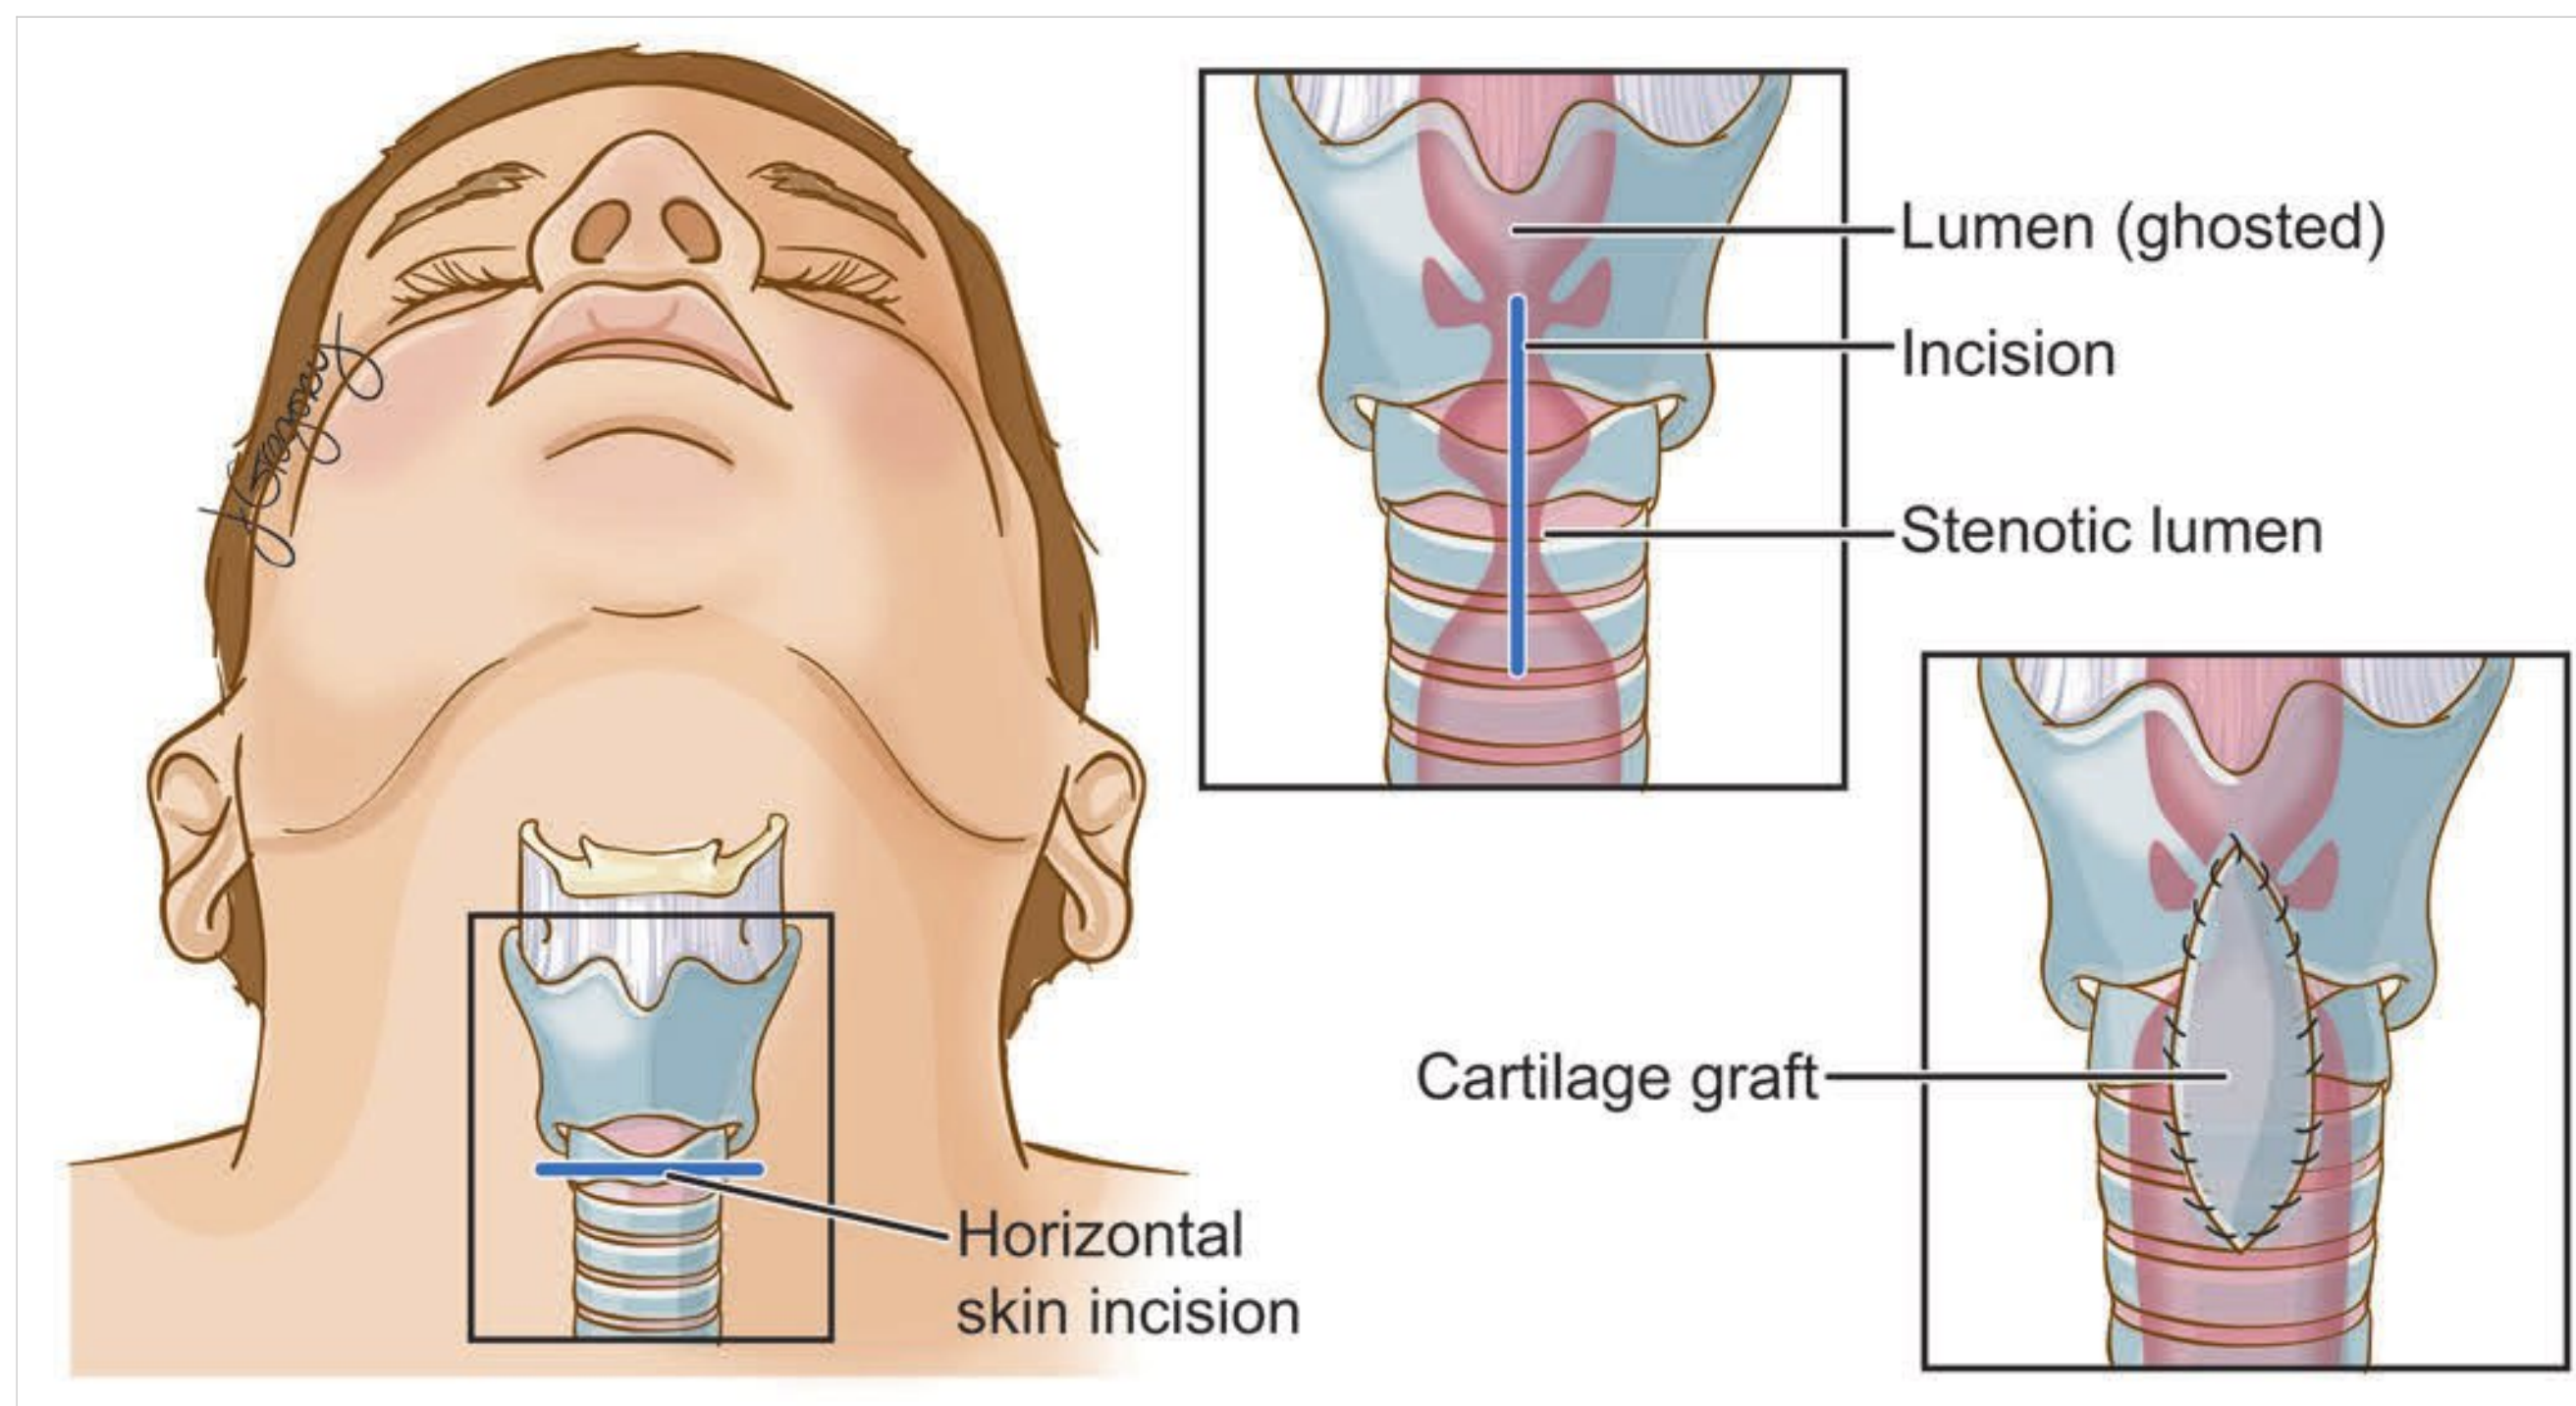

Fig. 72.12 Laryngotracheal reconstruction with cartilage graft procedure.

the cricoid cartilage with entry into the subglottic space. This incision is extended superiorly into the lower third of the thyroid cartilage, with care taken to avoid dividing the anterior commissure. The upper two tracheal rings are incised in continuity with the cricoid incision. At this point, either a stent is positioned into the airway (multiple-stage procedure with a tracheostomy in place) or the endotracheal tube is exchanged for another endotracheal tube that is 0.5 to 1.0 mm larger (single-stage procedure) and placed nasotracheally. The incision into the airway is then widened, and the cartilage graft is shaped to insert into the enlarged cricotracheal incision. The graft is sutured into position with 4–0 polypropylene sutures. A passive drain is placed over the reconstructed airway and the wound closed. If a stent is placed, it is secured with a transcricoid suture to avoid entry into the distal airway and resultant airway obstruction.

The patient is then monitored in a critical care unit (patients undergoing a single-stage procedure are monitored to prevent accidental premature extubation). The endotracheal tube is removed, and similar precautions are taken as for a patient undergoing anterior cricoid split (with a tracheostomy tray, intubation instrumentation, and laryngoscopy equipment at the bedside) following preparation with 24 to 48 hours of dexamethasone to reduce edema.

Patients who undergo double-stage laryngotracheal reconstruction are treated with a stent and a new or established tracheostomy. The stenting period will vary depending upon the patient's unique stenosis pattern. These stents require removal in the operating room, with a small neck incision to release the suture traversing the stent and endoscopic removal of the stent following premedication with dexamethasone. The tracheostomy is maintained until the reconstructed airway lumen is fully healed and adequate patency is ascertained.

In both types of laryngotracheal reconstruction, the endoscopic removal of granulation tissue and subsequent laser removal of residual scar tissue from the airway are often necessary. A carbon dioxide laser with a microscope and micromanipulator hand piece or fiber-optic contact delivery system is most commonly used.

Grade IV subglottic stenosis presents the most complicated situation in the relief of airway obstruction. In the past, four-quadrant laryngotracheal reconstruction was used, with anterior, posterior, and lateral cricoid incisions and prolonged stenting. More recently, cricotracheal resection has gained popularity. In this procedure, the entire airway obstruction is excised, along with the anterior and lateral aspects of the cricoid. Care is taken to avoid recurrent laryngeal nerve injury by maintaining the perichondrium and the posterior portion of the cricoid cartilage. The superior tracheal edge is then secured to the inferior edge of the thyroid cartilage with permanent suture. Stenting is with either an endotracheal tube (in a single-stage procedure) or a traditional Teflon stent and tracheostomy for a period of 7 to 21 days. A high rate of eventual decannulation can be achieved with this procedure.

Endoscopic Management of Subglottic Stenosis

In mild or limited cases of subglottic stenosis, and in postoperative patients following laryngotracheal reconstruction,

endoscopic procedures are common. Scar and granulation tissue can be removed endoscopically with traditional forceps, microdebrider, or carbon dioxide laser. These techniques are very simple and may be repeated as needed to maintain and guide healing in the airway. The topical application of mitomycin C is a well-known treatment that is effective in reducing the development of scar tissue in the airway. Reported complications of mitomycin C application are infrequent. Laser is an acceptable treatment for stenotic lesions that are less than 10 mm in length, retain sufficient support of the cartilaginous structures, and are isolated in either the subglottis or upper trachea. The use of carbon dioxide laser outside these situations has an increased failure rate. Increasingly, high-pressure airway balloons are being applied in patients with airway stenosis. This dilation procedure is quite successful in breaking dense scar tissue and may have a long-lasting effect.

Complications

Complications of the surgical treatment of subglottic stenosis include those that occur during the procedure or in the early postoperative period and late complications. During the procedure, it is important to avoid lateral dissection around the trachea and inadvertent recurrent laryngeal nerve injury. Air leaking from the reconstructed airway into the surgical wound during emergence from anesthesia may result in subcutaneous emphysema with extension into the chest and the development of pneumomediastinum and pneumothorax. Proper passive drain placement helps to reduce this risk, which persists into the healing phase, especially the first few days following the procedure, until the reconstructed airway seals. It is imperative to avoid early drain removal.

Respiratory distress may follow stent migration or mucous plugging of the endotracheal tube or tracheotomy tube. This can be prevented by frequent suctioning and the use of humidified air. Problems associated with the graft itself include resorption and inward dislodgement. These graft issues may result in lumen intrusion and laryngotracheal reconstruction failure.

Late complications of laryngotracheal reconstruction include recurrence of stenosis with the need for revision surgery and endoscopic procedures. The voice may be poor because of the development of scar at the glottic level or true vocal fold paresis. If the graft protrudes into the lumen excessively, there can be continued airway obstruction. Attention to precise surgical technique and careful postoperative care is paramount for decreasing the occurrence of these problems.

72.5.5 Infectious Diseases of the Airway Epiglottitis (Supraglottitis)

Epiglottitis is an infectious process affecting the epiglottis and supraglottic structures. In children, it is most often caused by *Haemophilus influenzae* type B (HIB), whereas adult epiglottitis is often caused by *Staphylococcus aureus*. Epiglottitis presents with a rapid onset of symptoms in children between the ages of 2 and 4 years. HIB causes a generalized infection of the epiglottis similar to cellulitis. The incidence of HIB epiglottitis has dramatically fallen in the United States in the last 20 years with the use of routine immunization against HIB, to the point that HIB epiglottitis has become rare.

Clinical Symptoms

The onset of epiglottitis is relatively rapid, with progression over just hours. The child will develop fever, airway distress, and later on stridor and drooling due to odynophagia. Patients often will lean forward and prop themselves up while sitting into a “tripod” position. These symptoms should make one consider epiglottitis as a diagnosis. The inspiratory stridor associated with epiglottitis is due to increasing edema of the supraglottis and impending obstruction.

Patient Examination and Evaluation

Supraglottitis and epiglottitis are serious medical emergencies with the potential to obstruct the airway. A patient suspected of having epiglottitis must be approached calmly and systematically. In order to reduce the child’s anxiety, parts of the examination may even need to be omitted until epiglottitis has been excluded as a diagnosis. Although the gold standard is laryngoscopy, this may be deferred initially because of the possibility of making the child cry and subsequently obstruct the airway. In mild cases, a lateral neck X-ray may be obtained (as long as the child is accompanied by someone capable of providing emergency airway support). The typical diagnostic finding on lateral neck X-ray is a “thumb”-shaped density representing the swollen, edematous epiglottis. Older and calm children may tolerate fiber-optic flexible laryngoscopy, which visualizes the swollen epiglottis and supraglottis (□ Fig. 72.13).

Children presenting with moderate to significant distress are taken immediately to the operating room for airway examination and management. The airway is inspected after the induction of anesthesia with inhalational agents, at which time the airway is secured, most frequently via intubation. (Alternatively, the patient can be ventilated through a rigid bronchoscope and then changed over to nasotracheal intubation.) The epiglottis is cultured. It is mandatory that a tracheotomy tray be open and ready in the event the airway becomes unstable.

Treatment

Epiglottitis is treated with parenteral antibiotics active against HIB. The culture is used to guide antibiotic therapy in refractory cases. Extubation success can be predicted by examining the supraglottic structures with a fiber-optic laryngoscope, and extubation is often possible after 48 to 72 hours of antibiotic therapy. Children with epiglottitis are expected to make a complete recovery and now rarely require a tracheotomy.

Complications

Epiglottitis is a well-known, potentially fatal infectious disease that is rarely seen today. Late diagnosis and misdiagnosis can result in worsening airway obstruction, hypoxemia, and the sequelae of hypoxia. Because of the rare occurrence of epiglottitis, it is necessary to maintain a high index of suspicion with this clinical presentation.

Croup (Laryngotracheobronchitis)

Croup (laryngotracheobronchitis) is an airway disorder affecting children from 6 months to 3–4 years of age. It is usually caused by a parainfluenza virus but may be caused by other respiratory viruses. Croup is more commonly seen in the cooler months and may affect babies and children repetitively, especially if there is an underlying airway anomaly.

Clinical Symptoms

The typical presentation of croup is a more gradual onset of the symptoms of an upper respiratory infection. The child may have rhinorrhea and a cough with a characteristic barking quality. As the infection progresses, a mild to moderate fever will develop. The child will not preferentially be in any position, nor will he or she appear “toxic” (like the child with epiglottitis); as the illness progresses, the voice will become slightly hoarse, and at this point inspiratory stridor (from narrowing at the subglottis and upper trachea) may become audible. The stridor may become biphasic as it worsens. The child may be symptomatic for 3 to 5 days while remaining infectious for up to 10 to 14 days.

Fig. 72.13 Epiglottitis. (a) Lateral neck X-ray demonstrating thumb sign in dilated hypopharyngeal air column. (b) Intraoperative view of acute epiglottitis; note the swollen epiglottis. (c) Laryngoscopic view of swollen, cherry red epiglottis in epiglottitis.

Patient Examination and Evaluation

The child with croup, despite having stridor, does not appear as ill as the child with epiglottitis. The findings of clear rhinorrhea, barking cough, and stridor all lead to the diagnosis of croup. The chest examination is usually normal. Diagnostic lateral and anteroposterior X-rays will often reveal the typical “steeple” sign indicating narrowing at the subglottic–tracheal junction (□ Fig. 72.14).

Treatment

The treatment of croup (laryngotracheobronchitis) is aimed at decreasing airway edema. The home management of croup typically involves the use of humidification and cool air. Adequate hydration is essential. Most cases of croup are mild forms that can be managed at home.

Fig. 72.14 Croup. Anteroposterior soft-tissue neck X-ray demonstrating the “steeple” sign typically seen in croup

Moderate to severe croup requires additional treatment at the clinic or emergency department. The administration of cool mist, along with nebulized racemic epinephrine, will help to reduce airway mucosal edema. Most children with croup at this stage will also benefit from systemic steroids. Steroids are well-known to reduce airway edema and have a prolonged effect. Most children are discharged home after a short stay at the emergency department. A small percentage of children do not respond well to this protocol and require hospitalization and possible intubation.

Complications

Although most children with croup have a complete resolution of their symptoms, a small number do not respond well to therapy. These children progress and often require endotracheal intubation, which entails a risk for subglottic stenosis because of the inflammation already present in the subglottis (□ Table 72.6).

72.6 Pediatric Tracheotomy

Children who have airway obstruction that is not readily correctible may require tracheotomy to maintain a safe airway. Chronic respiratory failure, pulmonary conditions with ineffective cough, and other medical conditions require tracheotomy. Indications for pediatric tracheotomy are similar to those in adults, except for the duration of intubation. In general, children can remain intubated for up to several months (compared with several weeks for adults) because their more compliant airways are better able to tolerate the presence of an endotracheal tube than are those of adults.

Pediatric tracheotomy in children is routinely performed in the operating room. An anesthesiologist monitors the patient and assists by removing the tube when it is no longer needed. Endoscopic percutaneous tracheotomy is not recommended in children.

72.6.1 Technique

The patient is placed on a shoulder roll with the neck extended. The laryngeal cartilages are palpated, and the skin in the midline over the upper cervical trachea is infiltrated with a small

Table 72.6 Characteristics of epiglottitis and croup

Characteristic	Epiglottitis	Croup
Agent	Haemophilus influenzae type B	Parainfluenza virus
Age	2–5 y	6 mo–2 y
Cough	None	Barky
Drooling	Present	Absent
Stridor	Late, inspiratory	Inspiratory, then biphasic
Rate of onset	Rapid (hours)	Slow (days)
Position	Tripoding (leaning forward)	Any position
X-ray finding	Thumb sign	Steeple sign
Location affected	Supraglottis/epiglottis	Glottis to upper trachea

Fig. 72.15 Technique of pediatric tracheostomy. (a) Pediatric tracheostomy demonstrating vertical skin incision and retraction of the strap muscles laterally. (b) Vertical division of the pretracheal fascia exposing the cricoid cartilage and upper tracheal cartilage rings. (c) Placement of polypropylene stay sutures lateral to the vertical tracheotomy incision. (d) Tracheostomy tube in position with tracheostomy ties secured around the child's neck.

amount of local anesthetic (□ Fig. 72.15). A vertical skin incision is made over the second to fourth tracheal cartilages. The immediate subcutaneous fat is dissected between the skin and cervical fascia and removed. The strap muscles are identified and separated at the midline raphe. The trachea and cricoid cartilage are visualized. Tracheal rings are palpated with a fingertip. Stay sutures are placed in the tracheal lateral to the incision and later marked “RIGHT” and “LEFT.” After identification of the tracheal rings, a vertical incision is made through rings 2 to 4, between the two stay sutures. The endotracheal tube is directly visualized within the tracheal lumen. The skin may be sutured to the tracheal edges, maturing the stoma and reducing the risk for accidental false passage, with 5–0 chromic sutures.

At this point, the anesthesiologist slowly withdraws the endotracheal tube just until the tip of the tube is seen at the tracheal opening. A tracheostomy tube of the appropriate size is directly positioned into the trachea. The anesthesia circuit is attached to the tracheostomy tube, the chest is auscultated for bilateral breath sounds, and the end-tidal carbon dioxide values are observed on the anesthesia machine. Tracheotomy ties are secured around the patient's neck, and the tube may also be sutured to the neck skin if desired. A chest X-ray is taken to check the tube tip position relative to the carina and to check for pneumothorax.

72.6.2 Complications

Pediatric tracheotomy carries a low risk for intraoperative complications in trained individuals. The low risk is due to the superficial position of the trachea in the child. Tracheotomy in children with neck masses or tumors presents unique challenges, and adaptations are necessary in those cases. Improper tube selection is a potential complication leading to an early need to change the tracheotomy tube before an established tract is formed. This increases the risk for accidentally creating

a false passage and a malpositioned tube, with the potential complications of pneumomediastinum and pneumothorax. Potentially fatal mucous plugging occurs from a combination of two conditions, lack of adequate air humidification and insufficient suctioning.

Caregivers must learn the proper care and management of tracheostomy in children. This includes correct techniques for suctioning, cleaning the stoma, and changing the ties, as well as knowing how to change the tube. Visiting nurses can reinforce the proper techniques with caregivers and reduce complications in tracheotomy-dependent children.

72.7 Foreign Bodies in the Airway and Esophagus

72.7.1 Etiology

Children are prone to aspiration and the ingestion of foreign bodies because of their tendency to explore objects by placing them into the mouth. Children who are 3 years old and younger are at the greatest risk for choking on both small objects and small, hard foods. Each year, approximately 150 children die after ingesting or aspirating foreign bodies.

72.7.2 Pathogenesis

Foreign body ingestion and aspiration most commonly occur in children younger than 3 years of age, with far fewer foreign bodies found in the aerodigestive tract in older children. The combination of the oral exploration of objects, a high level of physical activity and running, the introduction of adult types of foods, and access to small objects and toy parts leads to increased risks in the toddler. Small, hard foods, such as popcorn kernels, nuts, and seeds, are the aspirated items most commonly

found in young children. These foods present particular hazards to very young children until all 20 of their primary teeth have completely erupted (usually between 2 and 3 years of age) and they can sit and chew their foods thoroughly rather than hold them within the mouth (increasing the risk for aspiration).

Coins are the most common esophageal foreign body in children younger than 4 years of age, with pennies the most common foreign body extracted. Older children may ingest nickels, quarters, and other objects. The size of the esophagus and the coin diameter are the factors that determine esophageal passage or impaction.

72.7.3 Natural History

A foreign body within the aerodigestive tract usually will cause symptoms that require medical attention and subsequent removal of the foreign body. When foreign bodies are not detected, they may cause significant morbidity and possibly death from complications of their presence.

Foreign bodies within the tracheobronchial tree may present with intermittent symptoms of cough depending upon their location and whether they move around in the large airways. Impacted foreign bodies in the more distal bronchial airways will often cause the formation of a reactive granulation tissue (particularly if they consist of food matter), increased secretions, and subsequent distal pneumonia. Pneumonia that is refractory to appropriate treatment may be caused by an undetected foreign body. Long-standing foreign bodies may erode through the bronchus into the mediastinum or result in bronchiectasis.

Undetected foreign bodies in the esophagus create a risk for esophageal perforation. Long-standing or sharp-edged esophageal foreign bodies may create erosions of the mucosa and then the muscular layer of the esophagus, with ultimate perforation of the esophagus. Esophageal perforation can result in mediastinitis, with high rates of morbidity and mortality. Some children with esophageal foreign bodies may begin to “wheeze” if edema of the tracheo-esophageal wall develops, with resultant narrowing of the tracheal lumen.

72.7.4 Presenting Symptoms

Most children who have a foreign body in the aerodigestive tract present with an episode of choking or coughing after being observed to place an object or food substance in the mouth. These witnessed events require a careful evaluation to exclude an actual aspiration or ingestion of the object.

Airway foreign body aspiration may present with alteration of the voice, stridor, severe coughing, cyanosis, and wheezing, depending upon where the foreign body is located. Children who have bronchial foreign bodies may present with unilateral wheezing, a specific variety of stridor resulting from bronchial obstruction by the object. Oxygen saturation should be measured and hypoxemia immediately treated.

Children who have esophageal foreign bodies may initially not have many symptoms but will ultimately develop dysphagia or odynophagia, reduced oral intake, and drooling; older children will complain of chest pain. Some children who have long-standing esophageal foreign bodies may present with “wheezing” or the new onset of asthma due to swelling of the tracheo-esophageal wall. Disc battery ingestion may present

with severe chest pain within hours of esophageal impaction as a consequence of the leakage of alkali from the battery.

72.7.5 Medical Examination

The examination of a child who has a foreign body in the airway or esophagus and in whom ingestion was witnessed or is suspected should immediately assess the severity of the problem. Airway foreign bodies may cause severe respiratory distress and hypoxemia, creating an urgent management situation. It is important to interview the caregivers/parents to determine the details of the ingestion, time since the incident, and any associated feeding or breathing problems before and after the incident.

Chest X-rays are the most useful imaging studies for both esophageal and airway foreign bodies. Most esophageal foreign bodies in this age group are radiopaque and will easily be seen on anteroposterior chest X-rays. Lateral chest X-rays are helpful in confirming an esophageal location and, in the case of disc-shaped objects, determining whether the object is a disc battery or a coin.

Airway foreign bodies also can be seen on anteroposterior and lateral chest X-rays, if radiopaque. With radiolucent objects, inspiratory and expiratory anteroposterior films may demonstrate air trapping on the affected side (□ Fig. 72.16). In children too young for inspiration–expiration films to be obtained, a bilateral lateral decubitus chest series should be performed, again with observation for mediastinal shift and air trapping. Lung hyperinflation and atelectasis may also be seen when there is a foreign body in the airway.

72.7.6 Treatment

Documented esophageal and bronchial radiopaque and obvious foreign bodies are removed with rigid endoscopy under general anesthesia. Even when no foreign body is visible on radiographic examination, severe or prolonged symptoms often will lead to a diagnostic endoscopic examination under general anesthesia. In patients with severe symptoms of suspected foreign body aspiration, immediate endoscopy with general anesthesia is necessary (□ Fig. 72.17).

Esophageal foreign bodies are usually removed via rigid esophagoscopy under general anesthesia, with protection of the airway. Methods such as Fogarty catheter extraction of a foreign body and flexible esophagoscopy without airway protection may compromise the airway in young children as the foreign body is extracted, and they are not advised. For children who have ingested smooth foreign bodies like coins, a brief period of observation for passage to the stomach, and proper NPO (nil per os) status, may be considered, with progression to rigid endoscopy if unsuccessful. Most coinlike foreign bodies will naturally pass from the gastrointestinal tract after they reach the stomach. If the object is suspected by history or X-ray to be a disc battery, endoscopic removal should proceed without delay in the hope of extracting the battery before leakage of the alkaline contents, which may occur within hours of the ingestion.

Removal of an esophageal foreign body is performed with endotracheal intubation and muscle relaxation, in order to prevent esophageal perforation by the esophagoscope during the procedure. After intubation, the patient is positioned and the

Fig. 72.16 Bronchial foreign body. (a) Upper panel: Inspiratory chest X-ray. Lower panel: Expiratory chest X-ray demonstrating air trapping in the right side of the chest caused by a right bronchial foreign body. (b) Endoscopic images of the removal of a right main bronchial foreign body.

Fig. 72.17 Chest X-ray of a radiopaque esophageal foreign body at the level of the thoracic inlet, with the distinct rim appearance of a disc battery.

esophagoscope is carefully placed into the hypopharynx and then passed through the region of the cricopharyngeus muscle at the esophageal inlet. The scope is slowly and gently advanced, with the lumen always in view. The scope is advanced to the foreign body, the object is grasped with an appropriate forceps (most commonly the “coin-removing” forceps), and the object and scope are removed as a unit, with the foreign body trailing behind the scope. After the foreign body is removed, the esophagoscope is reinserted into the esophagus and the mucosa is inspected for injury from the foreign body. Long-term foreign bodies may have caused erosions of the mucosa or partial-thickness injuries of the muscle of the esophagus. Care must be taken to avoid converting a partial perforation into a full-thickness injury.

Bronchial foreign bodies require rigid endoscopic removal under general anesthesia, preferably with a pediatric anesthesiologist in attendance. Careful preparation of the instrumentation and joint management of the airway with the anesthesiologist are essential to success. The child is brought into the operating room, and general anesthesia is induced via either mask inhalation or a previously placed intravenous line. Careful laryngoscopy, with an inspection of all laryngeal surfaces and the application of a topical anesthetic to the larynx and trachea, is done after an adequate depth of anesthesia is established. Most commonly, the child remains spontaneously breathing throughout the procedure.

A telescope within the rigid bronchoscope is used to inspect the airway, and the patient is ventilated (spontaneously or with assistance) through the ventilating port of the rigid bronchoscope. The airway is examined, the normal bronchus first and then the bronchus with the foreign body. The normal side is initially studied to determine the presence of a single foreign body

and a patent airway for ventilation if single-lung ventilation becomes necessary. Suitable optical forceps (containing a telescope) are selected depending upon the specifics of the foreign body, with the “peanut” forceps most commonly used. The foreign body is grasped and carefully removed, trailing behind the bronchoscope as the bronchoscope is withdrawn from the airway. Care is taken at the glottis because the object may become dislodged from the forceps. The bronchoscope is then reinserted to inspect for complete removal and for any trauma or injury to the impaction site. Granulation is frequently seen in cases of organic or long-standing foreign bodies, and postobstructive pneumonia with purulent secretions may be expected. Rarely, injuries to the bronchus may be noted and include perforation with bronchopleural fistula, pneumothorax, or pneumomediastinum. Children need to be observed following the procedure depending upon the antecedent symptoms and findings on bronchoscopy.

72.7.7 Prognosis

The vast majority of children with foreign body ingestion and aspiration make a complete recovery. In patients with a prompt diagnosis and removal of the foreign object, the postoperative course is usually uncomplicated. Patients with delayed or protracted symptoms of long-standing foreign bodies may require hospitalization for management of the underlying co-morbidities.

72.8 Roundsmanship

- The pediatric larynx is broader and higher in the neck than the adult larynx.
- A careful and complete history is critical in evaluating a child with a breathing problem. The evaluation includes an assessment for stridor and flexible laryngoscopy for a diagnosis.
- Laryngomalacia is the most common cause of stridor in infants. True vocal fold paralysis is the second most common cause of stridor in infants, followed by subglottic stenosis.
- Laryngomalacia is usually accompanied by gastroesophageal reflux. The medical management of laryngomalacia consists of treatment of the gastroesophageal reflux with histamine₂ blockers and proton pump inhibitors, with 95% of cases well controlled.
- Failure to thrive and obstructive apnea are the most common reasons for the surgical management of laryngomalacia. Supraglottoplasty is the procedure of choice.
- A patient with bilateral vocal fold paralysis has a good voice but commonly an inadequate airway due to the paramedian true vocal fold position.

- A patient with unilateral vocal fold paralysis often has a poor voice but a satisfactory airway.
- Left true vocal fold paralysis is more common than right true vocal fold paralysis. The left recurrent nerve has a longer course because it wraps around the ductus arteriosus and aortic arch and is at risk for injury when ductus arteriosus ligation is needed.
- Recurrent respiratory papillomatosis is a chronic condition requiring multiple periodic procedures to remove obstructive papillomas from the airway tract. Human papillomaviruses type 6 and type 11 are the main causative agents. Human papillomavirus vaccination may reduce the rate of recurrent respiratory papillomatosis in children.
- Hoarseness is the most common presenting symptom of recurrent respiratory papillomatosis.
- Hemangiomas are vascular tumors that may cause stridor. They are seen in the posterolateral aspect of the subglottis. The preferred treatment currently is oral propranolol. The hemangiomas usually also respond well to dexamethasone.
- Subglottic stenosis most frequently is acquired as a result of prolonged intubation in children. Treatment options vary depending upon the severity. Laser, balloon dilation, and subglottic expansion surgery for the stenosis are treatment options.

73 Diseases and Disorders of the Pediatric Neck

James M. Pearson

73.1 Embryology and Anatomy

73.1.1 Embryology of the Larynx

The larynx, along with the rest of the respiratory system, is derived from the primitive pharynx. At 3 weeks gestation, the hypobranchial eminence forms. This will become the cartilaginous epiglottis. In the ventral foregut of the embryo, the laryngotracheal groove develops at 3 1/2 weeks. This groove is located posterior to the hypobranchial eminence, between the third and fourth branchial arches. The mesenchyme of the foregut grows in a lateral to medial direction, eventually bisecting this groove. Two separate tubes form that will ultimately become the esophagus and the laryngotracheal apparatus.

At 4 weeks, the cricothyroid and inferior pharyngeal constrictor muscles develop. These and other laryngeal muscles develop from the mesoderm of the fourth and fifth branchial arches and thus are innervated by cranial nerve X (vagus). At 5 weeks, the arytenoid masses appear; at this time, the thyroid and cricoid cartilages form, also derived from the fourth and fifth branchial arches, respectively. At 5 1/2 weeks, the interarytenoid and postcricoid muscles develop. In week 6, the lateral cricoarytenoid muscles appear. Between the weeks 5 and 7, the laryngeal lumen is obliterated, and by 7 weeks, chondrification of the thyroid and cricoid cartilages begins. Between weeks 8 and 10, the vocal folds are formed, while during week 9, the laryngeal lumen is reestablished. By 12 weeks, the arytenoids and corniculate cartilages, both derived from the fifth branchial arch, develop further and undergo chondrification; also at this time, the laryngeal ventricles appear. By 20 weeks, chondrification of the epiglottis takes place, and by 28 weeks, the cuneiform cartilage is seen, derived from the fourth branchial arch (□ Fig. 73.1).

Congenital anomalies result from a failure of the normal sequence of embryonic development. The two arytenoid masses, which are seen by 5 weeks, are initially separated by a notch that is later obliterated. If this obliteration fails to occur, a pos-

terior laryngeal cleft may be seen. Such a cleft may open into the esophagus and cause severe aspiration in the newborn. Failure of the laryngeal lumen to recanalize by week 9 of development results in laryngeal atresia or stenosis.

73.1.2 Embryology of the Thyroid Gland

The thyroid gland derives from a diverticulum between embryologic tongue precursors at the site of the foramen caecum. Apparent at 4 weeks, this ventral (thyroid) diverticulum of endodermal origin is located between the first and second branchial arches. It then descends caudally in mesodermal tissues. By 6 weeks, the diverticulum is typically obliterated. Persistence of the tract of this descent may lead to the formation of a thyroglossal duct cyst later in life. The tract begins at the foramen caecum, passes either superficial to, through, or just deep to the hyoid bone, and continues caudally to the final location of the thyroid gland in the lower neck.

73.2 Anatomy of the Neck

The anatomical space of the neck is defined inferiorly by the clavicle and superiorly by the skull base posteriorly and the mandible anteriorly. The neck may be subdivided superficially by various triangular areas and in cross section by fascial planes.

Broadly, each side of the neck may be divided into two triangles, anterior and posterior, separated by the sternocleidomastoid muscle (□ Fig. 73.2). The anterior cervical triangle is then subdivided into four smaller triangles: digastric, carotid, muscular, and submental. The posterior cervical triangle is subdivided into two smaller triangles: occipital and subclavian. These triangles are separated from one another by various bones, cartilages, and muscles. The contents of the triangles are clinically relevant in discerning structures that

Fig. 73.1 (a–c) Embryology of the larynx.

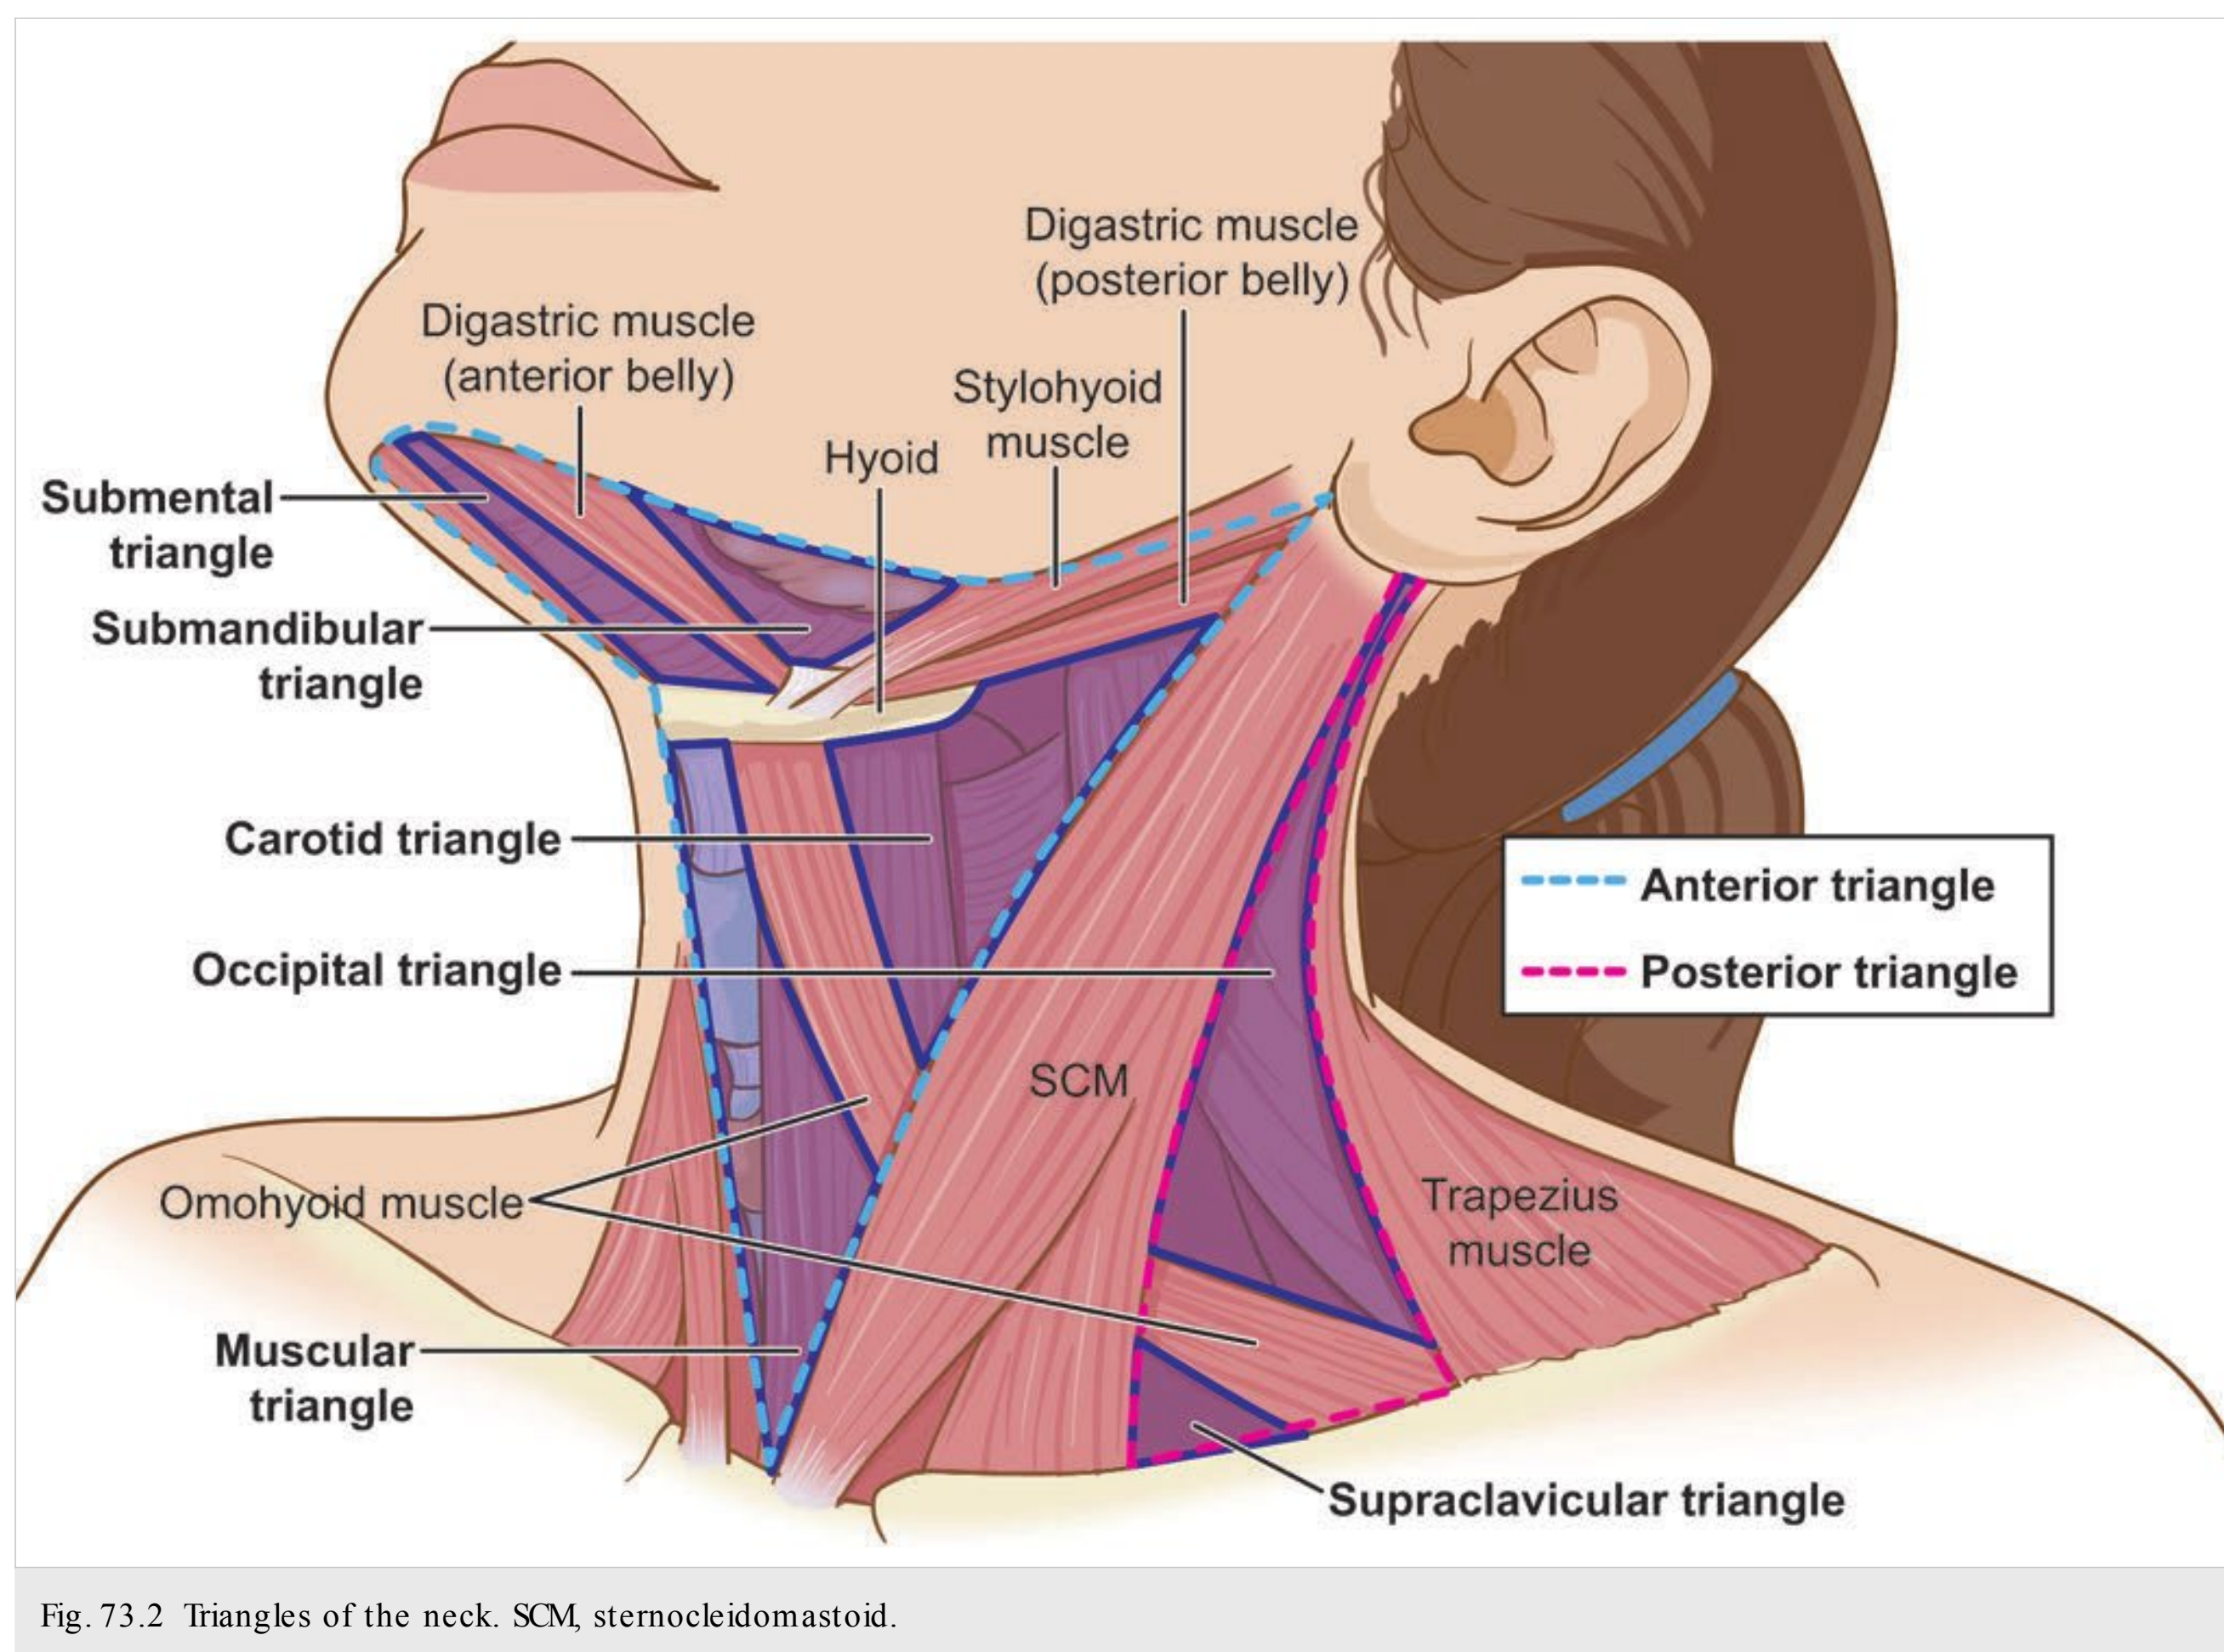

Fig. 73.2 Triangles of the neck. SCM, sternocleidomastoid.

may be involved in various pathologic conditions affecting the neck, ranging from cervical masses to penetrating trauma to infections.

When considered in cross section, the neck may be divided into spaces by anatomical fascial planes that separate the neck spaces and structures. Broadly, the fascial layers may be divided into the superficial and deep cervical fascia (□ Fig. 73.3). The superficial cervical fascia envelops the platysma and the muscles of facial expression. The deep cervical fascia is subdivided into three layers: superficial, middle, and deep. The superficial layer of the deep cervical fascia envelops the trapezius, sternocleidomastoid, and strap muscles. The middle layer of the deep cervical fascia envelops the pharynx, larynx, trachea, esophagus, thyroid and parathyroid glands, buccinator and constrictor muscles of the pharynx, and strap muscles of the neck. The deep layer of the deep cervical fascia (also known as the prevertebral fascia) envelops the paraspinal muscles and the cervical vertebrae. Clinically, the fascial planes of the neck limit and direct the spread of infection and abscesses. Knowledge of the contents of these spaces can aid in differentiating the etiology, symptoms, and sequelae of various deep space neck infections.

Detailed descriptions of the borders and contents of each subtriangle and space are beyond the scope of this introductory chapter. The interested reader is directed to more detailed discussions of this topic.

73.3 Cervical Lymphadenopathy

By convention, the location of the cervical lymph nodes is described in terms of levels. The neck is subdivided into six levels. Level I denotes the neck inferior to the mandible, superior to the hyoid bone, and anterior to the sternocleidomastoid muscle. Levels II, III, and IV lymph nodes lie roughly along the sternocleidomastoid muscle; level II extends from the mastoid process superiorly to the level of the hyoid bone inferiorly, level III between the hyoid bone and the cricoid cartilage, and level IV from the cricoid cartilage to the clavicle. Level V lymph nodes are located posterior to the sternocleidomastoid muscle. Level VI lymph nodes are located in the lower anterior neck medial to the sternocleidomastoid muscle and inferior to the hyoid bone (□ Fig. 73.4).

A thorough examination of the neck is an integral part of any pediatric otolaryngologic evaluation. The entire neck should be visually inspected and manually palpated. Often, lymph nodes will be palpable in the normal pediatric neck. Normal lymph nodes typically exhibit the following characteristics: nontender, mobile with regard to both the skin and deeper structures, spherical or ovoid in shape, and no larger than 10 mm in diameter. During or immediately following a head and neck infection or upper respiratory infection, it is not abnormal to find lymph nodes that are tender to palpation and/or larger than 10 mm. Isolated cervical lymphadenopathy should arouse suspicion in

Fig. 73.3 Fascial planes of the neck demonstrated in an axial section of the neck at the level of C7.

the clinician as to its cause. A detailed history and physical examination may uncover a subclinical infection. Cervical nodal characteristics that are suspicious include the following: nodes that are persistently enlarged to more than 10 mm and/or remain tender for more than 4 to 6 weeks after a precipitating infection has resolved, nodes fixed to skin or underlying structures, nodes larger than 20 mm even in the acute setting, and fluctuance, which may indicate abscess or necrosis within a node.

Physical examination alone may be adequate to evaluate cervical lymphadenopathy. In certain situations, imaging may be indicated. For example, nodes deep to the sternocleidomastoid muscle may not have palpable borders and may be indistinguishable from other masses of the neck. Similarly, when the entirety of a node cannot be palpated, the evaluation of nodal size may present a challenge. Finally, surgical planning and determining the relationship of a node of interest to adjacent structures and major blood vessels are greatly aided by the information provided by imaging. When indicated, radiographic imaging with contrast-enhanced computed tomography (CT) is the modality of choice. Consideration should be given to minimizing the exposure of patients in general, and especially children, to radiation so as to avoid the known serious sequelae of chromosomal damage and risk for future cancers.

The otolaryngologist is often called upon to evaluate cervical lymph nodes in children and to discern normal cervical nodes from pathologic ones. Using the information described above along with the rest of the clinical scenario, the clinician must make a decision to either observe or treat. Furthermore, the

clinician needs to be able to explain the rationale for that decision to the patient, family members, and the consulting pediatrician.

The treatment of cervical adenopathy in children depends on its etiology. Early on, the etiology may not be entirely clear, and the cervical nodes themselves are the focus of attention. When appropriate, a period of watchful waiting may be indicated—for example, during or immediately following a head and neck infection in an otherwise healthy and stable patient who has cervical adenopathy smaller than 20 mm and no suspicious characteristics. The family is reassured that the cervical adenopathy at hand does not demonstrate any suspicious findings and does not warrant any aggressive intervention at that time, and that the child will be closely followed for anticipated regression of the nodes in question. It is helpful if they are provided with a time frame within which to expect improvement or resolution, along with subsequent steps that may be taken if the nodes do not regress. Another option may be to treat with antibiotics cervical adenopathy that is suspected to be secondary to infection. A 10- to 14-day course of amoxicillin with potassium clavulanate, or clindamycin in the penicillin-allergic patient, may be employed. In more suspicious cases, fine-needle aspiration (FNA) biopsy performed in the clinic with cytopathologic interpretation, with or without culture of the aspirate, may be considered. Depending on the age, maturity, and cooperation of the child, this course of action may need to be performed under sedation or general anesthesia.

If there is a significant degree of clinical suspicion, when an FNA biopsy is insufficient or nondiagnostic, or when less

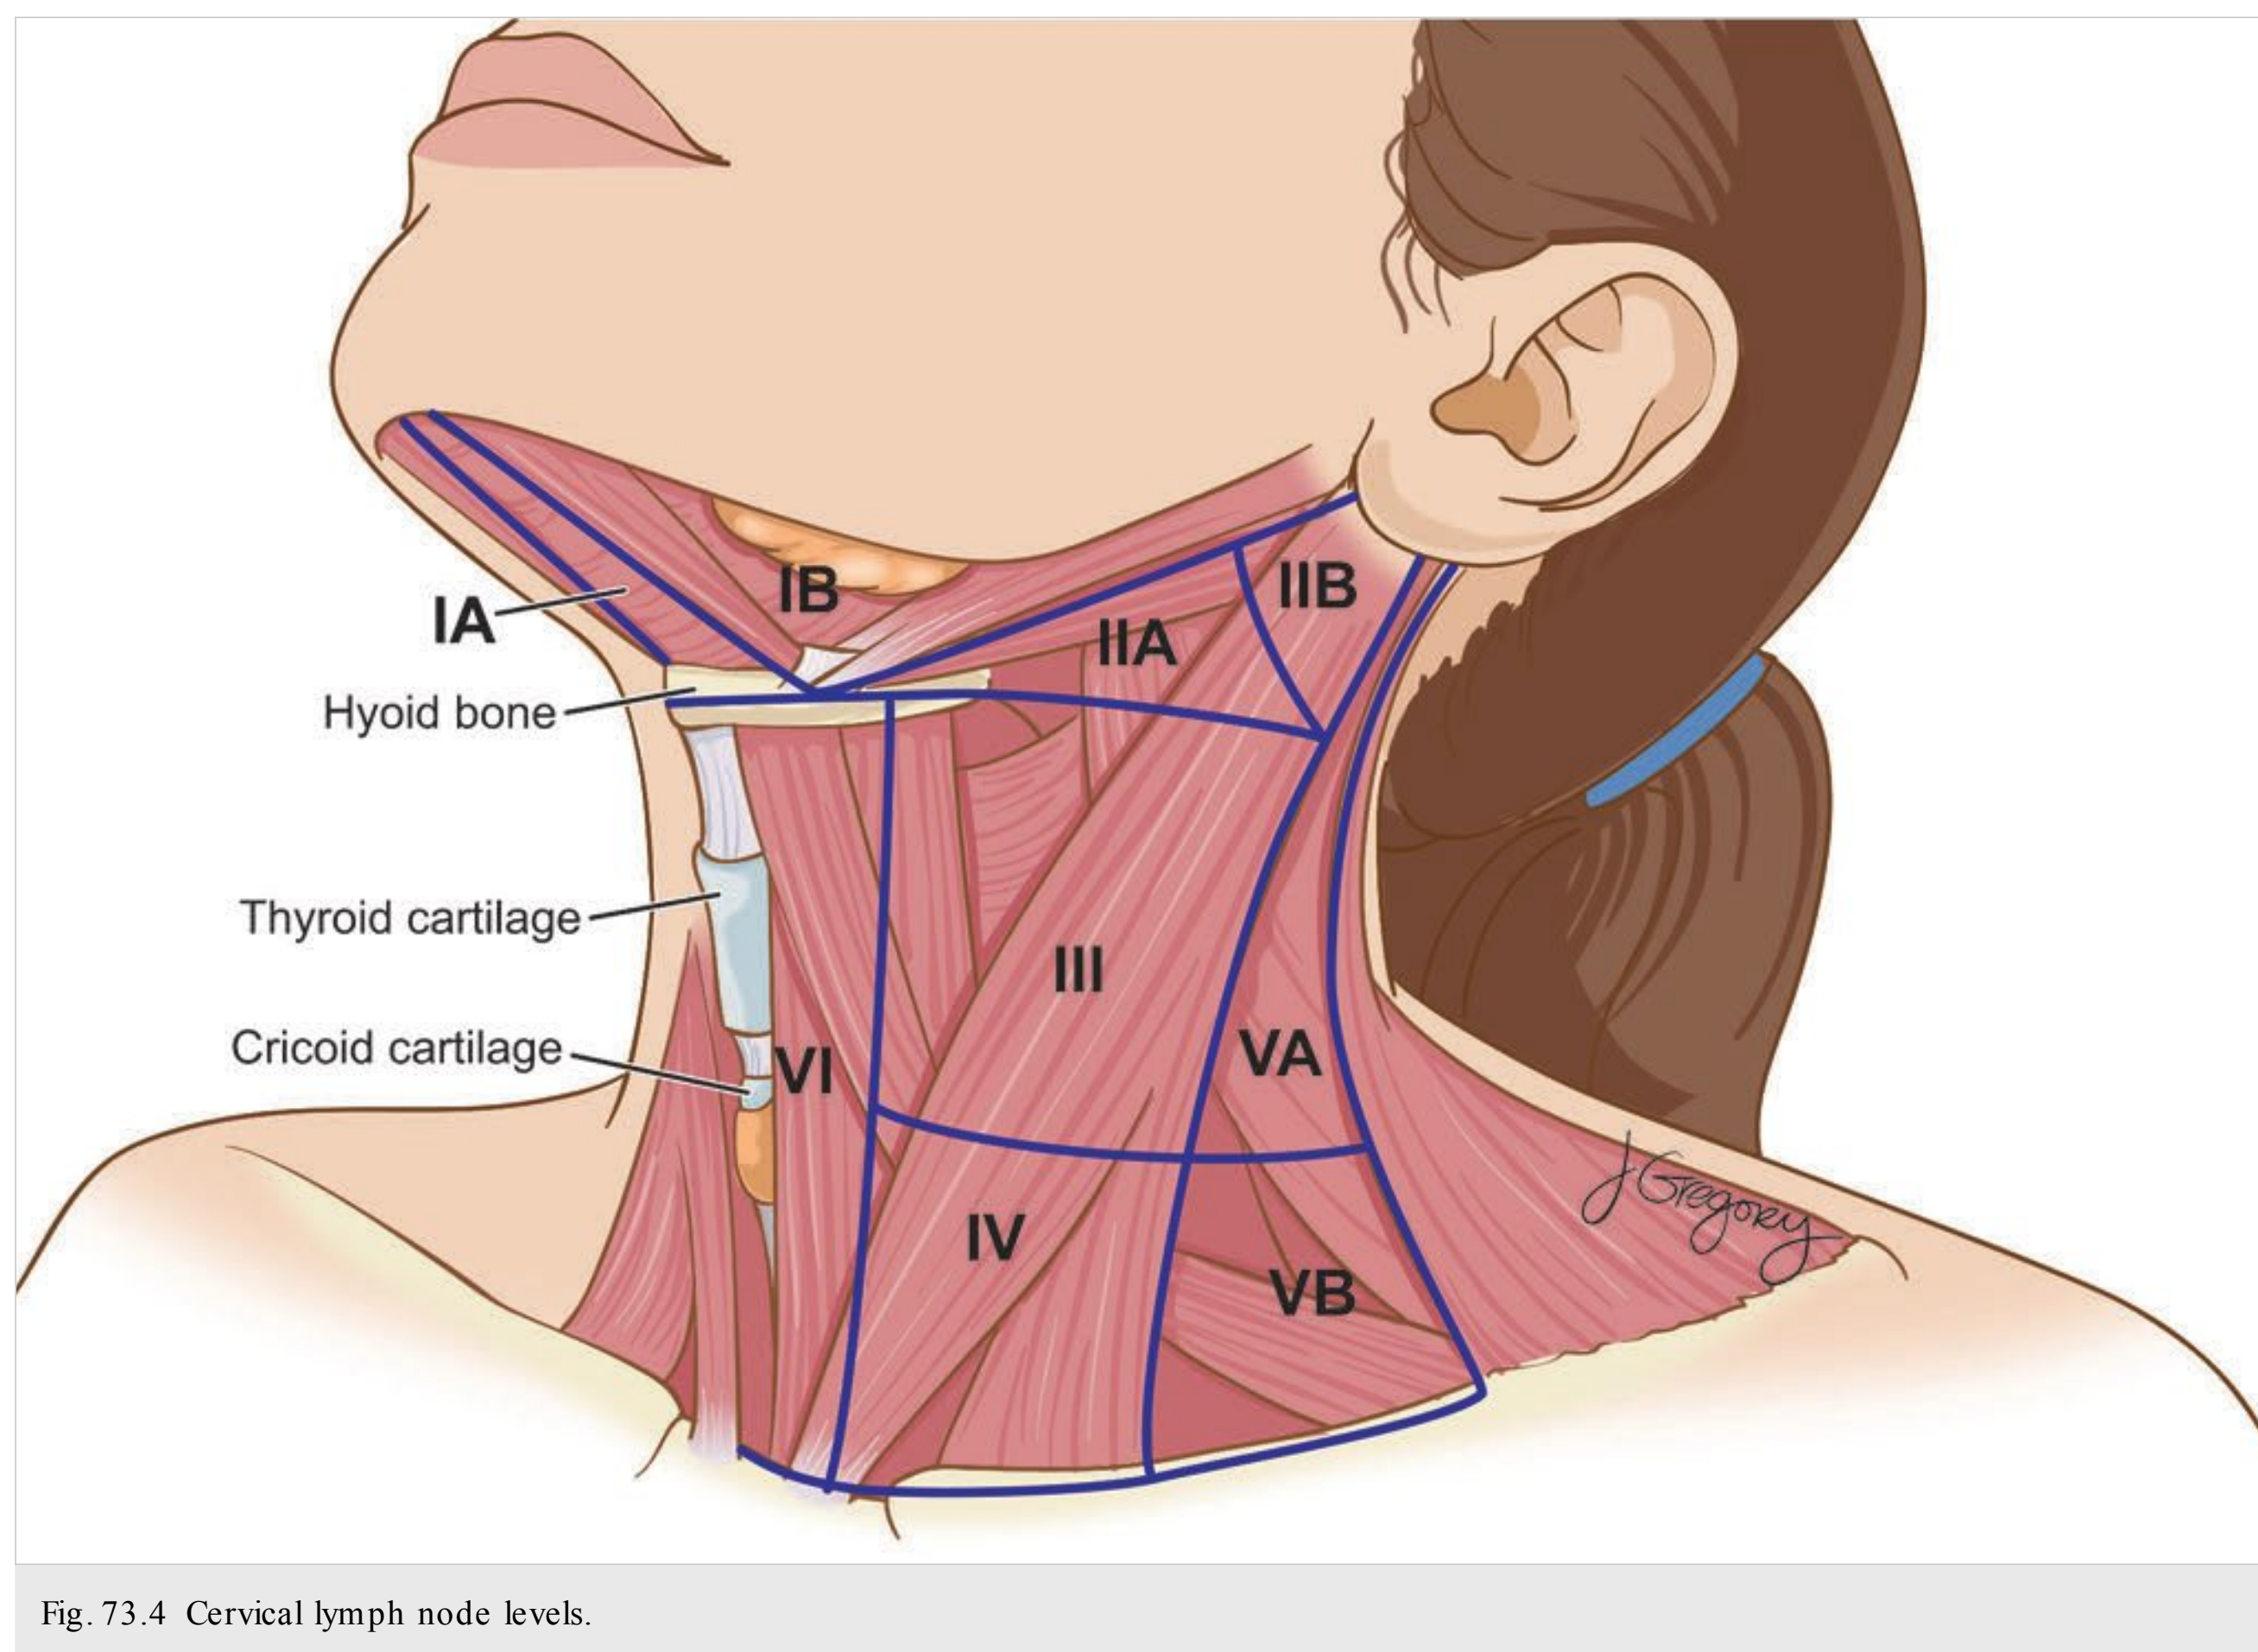

Fig. 73.4 Cervical lymph node levels.

invasive measures do not yield a diagnosis, excisional biopsy of an enlarged cervical node may be employed. This procedure typically requires general anesthesia and must be performed in the operating room. Once the specimen is removed, the surgeon may consider sending it fresh, along with cultures for bacteria (aerobic and anaerobic), fungi, and acid-fast bacilli. A fresh specimen, sent in saline, preserves the option of flow cytometry analysis should the pathologist's interpretation be suspicious for lymphoma.

73.4 Infections of the Deep Neck Spaces

Since their first detailed descriptions in the 1930s, the morbidity and mortality of deep space neck infections have decreased drastically. However, infections of the deep neck spaces are still seen with regularity, and the otolaryngologist is often called upon to diagnose the source or location of infection, differentiate infections from abscesses, and surgically treat appropriate cases. Earlier in this chapter, the fascial planes of the neck were introduced. Here, the cervical spaces defined by those fascial planes will be further explored, along with the etiology, spread, manifestations, and treatment of infections contained therein.

Deep space neck infections are typically polymicrobial infections caused by various oral aerobes and anaerobes, and occasional respiratory or skin pathogens. Common organisms

include the following: *Staphylococcus* species (including methicillin-resistant *Staphylococcus aureus* [MRSA]), *Streptococcus* species (including *S. pneumoniae*), *Fusobacterium necrophorum*, *Bacteroides* species (including *B. fragilis*), *Haemophilus* species, *Klebsiella*, *Escherichia coli*, *Enterobacter*, *Enterococcus*, *Neisseria*, *Eikenella corrodens*, and *Prevotella* (*Bacteroides melaninogenicus*). The preferred empiric therapy is clindamycin, an augmented penicillin, or a third-generation cephalosporin. In children, the preferred alternative is vancomycin and metronidazole given together.

The well-known clinical fact that children have little physiologic reserve and may decompensate quickly must be acknowledged. In other words, children may appear only mildly sick upon presentation yet be gravely ill. However, their clinical condition can rapidly deteriorate to frank sepsis or airway compromise.

The descriptions below pertain to infections of specific cervical spaces, which may be suspected clinically based on their characteristic manifestations and/or radiographic appearance. The relevant anatomy is reviewed, and the common sources, routes of spread, characteristic manifestations, and complications of these infections are discussed, as well as their treatment.

Clinically, the infections often present with systemic symptoms of fever and leukocytosis. Head and neck findings that should arouse suspicion include odynophagia, dysphagia, trismus, "hot potato" voice, and asymmetry or fullness of the

affected cervical region. In more advanced stages, intolerance of secretions (drooling) and difficulty breathing may be seen. Unlike adults, younger children may be unable to describe their symptoms; the clinician must then rely upon a history provided by the family and physical findings alone.

As a general rule, when a deep space neck abscess is suspected, radiographic imaging is often indicated to provide details regarding its size and location, and imaging is useful for surgical planning. If the abscess is not life-threatening and is superficial or limited to the peritonsillar area, treatment is often employed based on the history and clinical examination findings alone, without radiographic studies. When indicated, the preferred study is CT of the neck with intravenous (IV) contrast extending from the skull base to the clavicle.

Generally, the treatment of infections of the deep neck in children, as in adults, involves antibiotic therapy, protection of the airway, and surgical drainage when appropriate. If the airway is compromised, IV steroids may be considered; dexamethasone (up to 0.6 mg/kg/d administered IV and divided into doses given every 6 to 12 hours) is commonly used. If there is concern about impending loss of the airway, intubation may be undertaken prophylactically. In some cases, intubation is not possible, and urgent tracheostomy is the only means of obtaining an airway. In preparation for this, it is prudent to keep intubation and tracheostomy supplies readily available when caring for such patients. Antibiotic therapy is begun empirically with broad-spectrum antibiotics to cover the polymicrobial nature of such infections. If possible, culture is taken from the abscess cavity, and culture and sensitivity testing is performed by the microbiology laboratory. With a small or uncertain abscess, a trial of antibiotics may be appropriate. Clinical improvement is gauged over the following 24 to 36 hours based on symptoms, temperature curve, and other physical findings. For large or rapidly progressive abscesses, surgical drainage is often needed. The surgical approach depends on the site of infection, as detailed below.

73.4.1 Peritonsillar Space

Peritonsillar abscess (□ Fig. 73.5) is the most frequently encountered deep space neck infection in practice. Suspected peritonsillar abscess is an extremely common source of consultation of the otolaryngologist by primary and urgent care physicians. Familiarity with the diagnosis and treatment of this condition and with differentiating abscess from tonsillitis or peritonsillar cellulitis is crucial.

The peritonsillar space is defined by the capsule of the palatine tonsil medially and the superior constrictor muscle laterally. Infections originate from the tonsils or pharynx. Clinical manifestations of a peritonsillar abscess include odynophagia, dysphagia, muffled voice, and trismus. Findings especially characteristic of peritonsillar abscess include contralateral deviation of the uvula across the midline and an inferomedially displaced and enlarged tonsil. Treatment entails perioral drainage by incision and drainage or needle aspiration; antibiotics against streptococci are given orally or IV. Patients with peritonsillar abscess must be able to tolerate adequate oral fluids before discharge. Complications include spread into the lateral pharyngeal space and reaccumulation of the abscess.

Fig. 73.5 Axial computed tomographic scan demonstrates a peritonsillar abscess medial to the left tonsil (arrowhead). (Courtesy of David Dascal, MD, and Mae Mae Chu, MD.)

73.4.2 Lateral Pharyngeal Space

The term lateral pharyngeal space is synonymous with pharyngomaxillary space. Conical in shape, the lateral pharyngeal space extends from the base of the skull superiorly to the hyoid bone inferiorly. This space is subdivided by the styloid process into prestyloid and poststyloid compartments. The prestyloid compartment (also known as the muscular compartment) is located anterior to the styloid process. It contains fat, lymph nodes, the internal maxillary artery, and several nerves (inferior alveolar, lingual, and auriculotemporal). The poststyloid compartment (also known as the neurovascular compartment) is located posterior to the styloid process. It contains the carotid artery, internal jugular vein, sympathetic chain, and cranial nerves IX, X, XI, and XII.

Infections of this space originate from various sources, including the tonsils, pharynx, teeth (especially the third molar), petrous portion of the temporal bone, parotid gland deep lobe, and lymph nodes draining the nose and pharynx. The spread of infection to this space occurs via direct extension from communicating spaces or extension from a peritonsillar abscess. Clinical manifestations include medial displacement of the lateral pharyngeal wall and tonsil, trismus, dysphagia, parotid edema, and fullness of the retromandibular neck. Treatment may involve tracheotomy (for establishment of a secure airway), along with external drainage through the submaxillary fossa. An intraoral approach should not be undertaken because in most cases, the great vessels (carotid artery and jugular vein) are medial to the abscess (between the pharynx and the vessels) and are at great risk for injury.

The complications of a lateral pharyngeal space infection may be quite serious. The most common complication is septic thrombosis of the internal jugular vein. The most common fatal complication is erosion of the carotid artery. Cranial nerve involvement can occur in the setting of involvement of the neural contents of the poststyloid compartment of this space. Mediastinitis may develop following spread along the carotid sheath.

73.4.3 Pterygopalatine Fossa

The pterygopalatine (pterygomaxillary) fossa communicates laterally with the infratemporal fossa via the sphenomaxillary fissure. It contains the maxillary nerve, sphenopalatine ganglion, and internal maxillary artery. Infections here may arise from maxillary molars (especially the third molar) and osteomyelitis of the maxilla in infants. Spread is through direct extension via the open communication, as noted above. Clinical manifestations include gingival pain and edema; cellulitis of the ipsilateral head (including the face, neck, and temporal region); orbital symptoms (lid edema, globe proptosis and fixation, abducens paralysis); severe trismus; and secondary infection of the maxillary sinus. Treatment requires external drainage through an intraoral approach (gingivobuccal sulcus) or a Caldwell-Luc incision.

73.4.4 Masticator Space

The masticator space is the subperiosteal space between the mandibular bone and the periosteum. It contains the mandibular bone, masseter and pterygoid muscles, temporalis muscle tendon, inferior alveolar nerve, and internal maxillary artery. Infections originate from the mandibular molars (especially the third molar). Clinical manifestations include trismus and painful swelling over the posterior ramus of the mandible. Treatment involves external drainage.

73.4.5 Parotid Space

The parotid space contains the parotid gland, cranial nerve VII (facial nerve), external carotid artery, and posterior facial vein. Infections originate from the parotid gland. Clinical manifestations include painful swelling near the angle of the mandible. Treatment involves external drainage via a parotidectomy incision. Complications include infectious spread into the lateral pharyngeal space with the potential for further spread to the mediastinum.

73.4.6 Submandibular Space

The submandibular space is subdivided by the mylohyoid muscle into the sublingual (supramylohyoid) space and the submaxillary (inframyoxyoid) space. The sublingual space contains the sublingual gland. The submaxillary space contains the submandibular gland and lymph nodes (□ Fig. 73.6). Infections here originate most often from the teeth, especially the third molars, but also from the salivary glands, pharynx, tonsils, and sinuses. Clinical manifestations include dysphagia and odynophagia. The treatment approach depends on the location. Sublingual space abscesses are approached intraorally, whereas a submaxillary space abscess is approached externally via a transverse incision below the mandible.

The complications of a submandibular space infection may be severe. Infection in the submandibular space, known as Ludwig angina, is a potentially life-threatening infection of the floor of the mouth and submental and submandibular spaces. Characteristic findings include a hard, “woody” induration of the anterior neck. Immediate attention must be given to airway maintenance because airway obstruction from posterior displacement of the tongue base is the most common cause of death with this condition. Tracheostomy is often indicated, along with external drainage; dental extraction of abscessed teeth is performed when necessary.

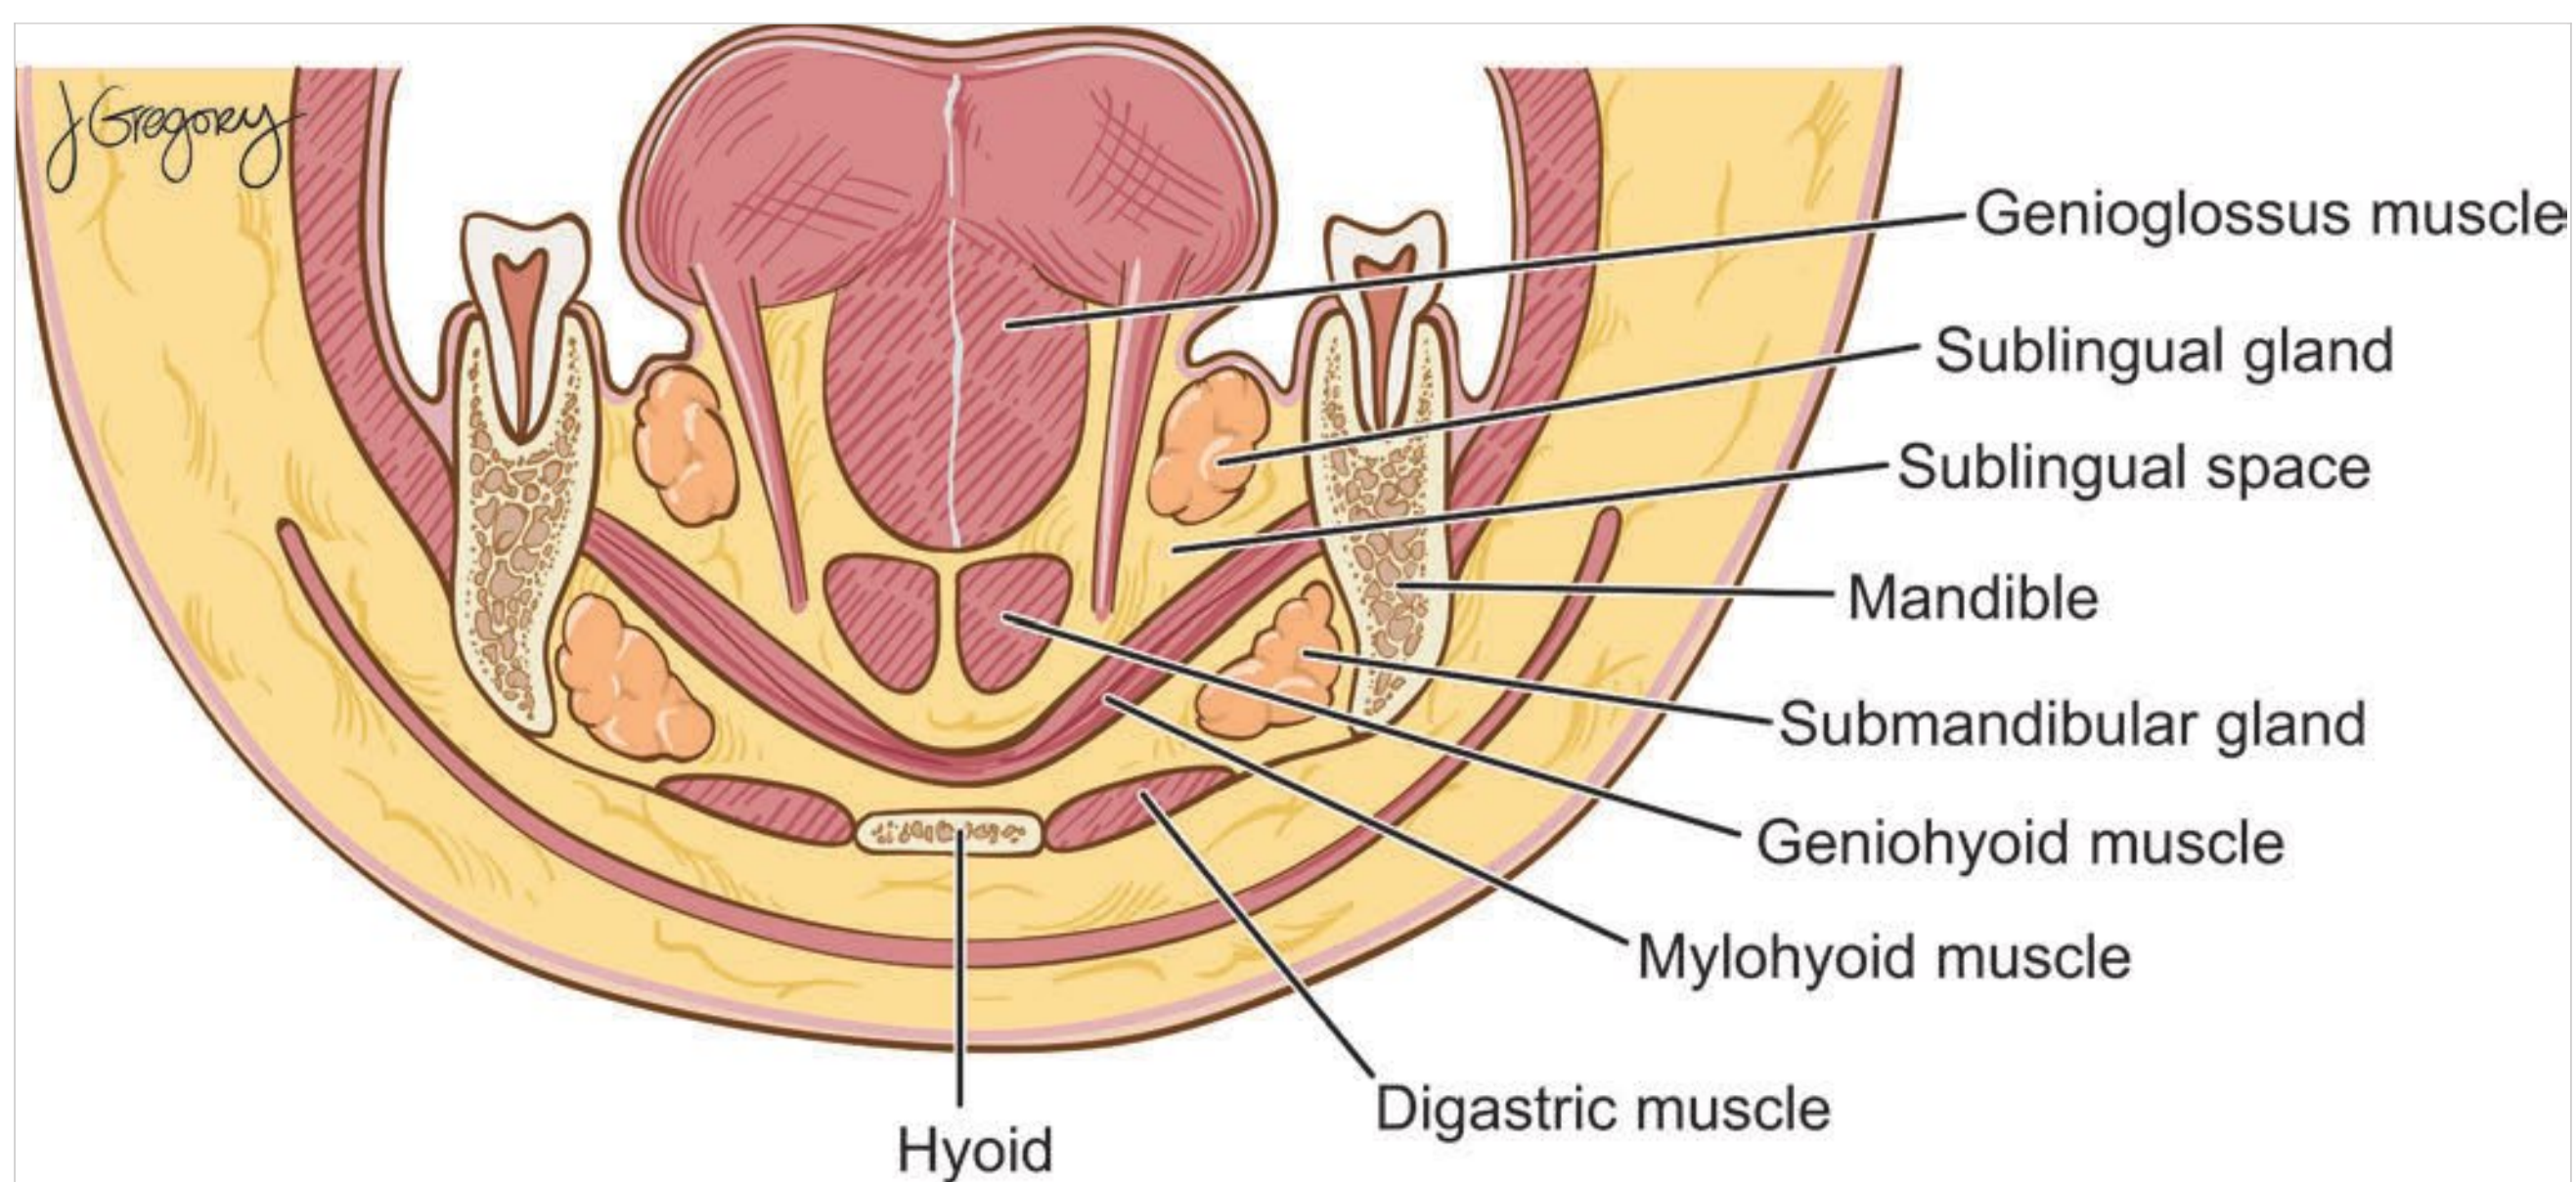

Fig. 73.6 Submandibular space demonstrated in a coronal section of the neck at the level of the hyoid bone.

73.4.7 Carotid Sheath Space

The carotid sheath space contains the carotid artery, internal jugular vein, and cranial nerve X (vagus). Infections here originate from other cervical spaces, including the lateral pharyngeal, submandibular, and visceral spaces. Clinical manifestations include pitting edema over the sternocleidomastoid muscle and torticollis. Treatment entails external drainage. Complications may be serious and include septic shock, carotid artery erosion, endocarditis, and cavernous sinus thrombosis.

73.4.8 Visceral Space

The visceral space contains the pharynx, esophagus, larynx, trachea, and thyroid gland. Infections in this space develop from the tonsils, esophageal perforation, laryngeal trauma with mucosal tear, or acute thyroiditis, or infection may spread from the chest. Clinical manifestations include dysphagia, odynophagia, hoarseness, and dyspnea. Treatment involves surgical drainage via transverse incision along the anterior border of the sternocleidomastoid muscle. Complications include extension into the adjacent mediastinum.

The retropharyngeal space, danger space, and prevertebral space lie adjacent to one another, oriented anteriorly to posteriorly, and are separated by three layers of fascia: the middle layer of the deep cervical fascia, also called the buccopharyngeal-

eal fascia (the most anterior); the alar fascia; and the prevertebral fascia (most posterior; □ Fig. 73.7).

73.4.9 Retropharyngeal Space

Involvement of the retropharyngeal space is seen primarily in young children as a complication of upper respiratory infections. This is a consequence of the relatively larger number of lymph nodes in the retropharyngeal space found in children younger than 4 years of age. The retropharyngeal space extends from the skull base superiorly to the mediastinum inferiorly. The middle layer of the deep cervical fascia, which envelops the pharynx and esophagus, lies anteriorly, while the alar fascia is posterior. Infections in the retropharyngeal space arise from the nose, sinuses, adenoids, and nasopharynx. The clinical manifestations of retropharyngeal space infections include dysphagia, odynophagia, dyspnea, cervical rigidity, muffled voice, and unilateral bulging of the posterior pharyngeal wall. Surgical access may be via intraoral drainage (if caught early) or an external approach. Given the anatomy, mediastinitis is the most worrisome complication of retropharyngeal abscesses.

73.4.10 Danger Space

Just posterior to the retropharyngeal space lies the danger space, between the alar fascia anteriorly and the prevertebral

Fig. 73.7 Fascial planes of the neck demonstrated in a mid-sagittal section of the neck.

fascia posteriorly; this space contains only loose areolar tissue. Infections here are a result of spread from adjacent neck spaces. The danger space is so named because it extends from the base of the skull to the diaphragm and may channel the spread of infection along this course to the lower mediastinum.

73.4.11 Prevertebral Space

The prevertebral space lies just behind the prevertebral fascia and anterior to the vertebral bodies. It contains only areolar tissue. Infections here, which are uncommon in modern times, may result from the anterior spread of vertebral osteomyelitis.

73.5 Neck Masses: Diagnosis and Treatment

When a neck mass is being considered in the pediatric population, a complete differential diagnosis should be formulated based on the clinical scenario. The general categories of the differential to be considered include congenital, infectious and inflammatory, neoplastic, and traumatic etiologies. Congenital neck masses include hemangiomas, vascular malformations and tumors, dermoids, teratomas, thymic cysts, plunging ranulas, branchial remnants, and thyroglossal duct cysts.

73.5.1 Hemangiomas

Hemangiomas are the most common neoplasm of childhood. Epidemiologically, the head and neck are the most common sites of hemangioma (10% of cases in Caucasians), with a higher incidence in preterm infants and females; girls are three times more likely to be affected than boys. Typically, hemangiomas begin as small lesions that develop in the first few weeks of life and begin to enlarge several weeks later (proliferative phase); this phase lasts most of the first year of life. At 6 to 9 months of age, spontaneous regression (involutional phase) typically begins and lasts for several months. The diagnosis is usually made by the history and physical examination alone. With deeper lesions, imaging studies may be needed to delineate their size and extent. In the absence of significant symptoms, watchful waiting is often undertaken because of the expected natural course of involution. Symptoms of airway compromise, visual field involvement, and cosmetic deformity usually warrant consideration for more aggressive treatment. Treatment modalities include intralesional or systemic steroids, propranolol, laser therapy, and surgical excision.

73.5.2 Vascular Malformations

Vascular malformations and tumors can take several forms. They may be classified as purely venous, lymphatic, lymphaticovenous, or arteriovenous. Certain imaging modalities may aid in differentiating the various types from one another. CT, magnetic resonance (MR) imaging, and MR angiography are all employed as indicated. Treatment involves surgical resection. Arteriovenous malformations may be clinically discerned by findings related to their high rate of blood flow, including a palpable thrill, hyperthermia, an audible bruit, visible hypertrichosis, and hyperhidrosis. The treatment of arteriovenous

malformation entails preoperative embolization followed by surgical excision. Commonly employed adjuvant treatments include laser and sclerotherapy.

73.5.3 Dermoids

Dermoids by definition are derived from more than one embryonic layer and made up of a heterogeneous mixture of tissues, such as epithelium, bone, cartilage, and muscle. Clinically, they typically arise in the midline neck, usually in the submental region, are attached to the skin, and are asymptomatic. They may be differentiated from thyroglossal duct cysts, which also occur in the midline neck, by a lack of elevation upon swallowing. Surgical excision is the treatment of choice.

73.5.4 Teratomas

Teratomas are made of mature elements of ectoderm, mesoderm, and endoderm, in addition to immature embryonal tissue. Teratomas may present in newborns with respiratory symptoms due to tracheal compression. These masses are typically large, semicystic, and encapsulated. Ultrasound demonstrates mixed echogenicity and well-defined borders, which differentiate teratomas from lymphatic malformations; the latter are multiloculate with ill-defined borders on sonography. Treatment is by surgical excision.

73.5.5 Thymic Cysts

The third pharyngeal pouch gives rise to the thymus tissue during week 6 of development; by week 9, the thymus descends below the clavicles. Thymic cysts may derive from thymic remnants that persist along the course of embryologic thymic descent, from the angle of the mandible through the midline of the neck.

73.5.6 Ranulas

Plunging ranulas are pseudocysts of the floor of the mouth caused by blockage of a sublingual gland, which leads to the extravasation of mucus. Ranulas may present as a submental mass just off midline with or without an intraoral component in the floor of the mouth. Treatment is by surgical excision of the ranula in continuity with the affected sublingual gland.

73.6 Infectious and Inflammatory Diseases

Infectious and inflammatory conditions associated with pediatric neck masses involve cervical lymphadenitis from various causes, including cat-scratch disease, atypical mycobacterial infection, and Kawasaki disease.

73.6.1 Cat-Scratch Disease

Cat-scratch disease is caused by infection with the gram-negative bacillus *Bartonella henselae*. A history of exposure to cats is the basis for clinical suspicion. The patient will rarely provide this history unsolicited, so it should be explicitly sought in

Fig. 73.8 Strawberry tongue.

clinically appropriate circumstances. Aside from cervical lymphadenopathy, patients are typically asymptomatic. Treatment involves a course of azithromycin, which is usually curative. Surgery is reserved for abscesses requiring drainage.

73.6.2 Atypical Mycobacterial Infection

The atypical mycobacteria that are most often associated with cervical lymphadenitis are *Mycobacterium avium-intracellulare* and *Mycobacterium scrofulaceum*. Clinically, erythema of the overlying skin and spontaneous drainage of the affected nodes should arouse suspicion. The diagnosis is supported by the finding of caseating granuloma on a pathologic specimen. Confirmation of the diagnosis requires identification of the infecting organism. Because the culture of mycobacteria may require several weeks, polymerase chain reaction may be used to identify these organisms more expeditiously.

73.6.3 Kawasaki Disease

Kawasaki disease, also known as mucocutaneous lymph node syndrome, is a multisystem vasculitis. Its precise cause is not known, but an infectious etiology is suspected. Epidemiologically, it is seen most often in children younger than age 5. Clinical signs may include the following: nonsuppurative cervical adenopathy larger than 1.5 cm in diameter; mucosal findings of nonexudative conjunctivitis, fissured lips, or strawberry tongue (□ Fig. 73.8); and skin signs including polymorphous truncal rash, palmar erythema, nonpitting edema of the extremities, and desquamation of the fingers and toes. The diagnosis requires fever lasting more than 5 days and at least four of the clinical signs listed. The most feared complication of Kawasaki disease is coronary aneurysm. Treatment is focused on the prevention of coronary complications and involves aspirin and IV immunoglobulin therapy.

73.6.4 Neoplasms

Neoplasms to be considered in children with a neck mass include rhabdomyosarcoma, lymphoma, and histiocytosis.

Fig. 73.9 Hodgkin lymphoma as seen on an axial computed tomographic scan of the neck. The bulky mass (arrowheads) is located on the right side of the neck medial and posterior to the sternocleidomastoid muscle. The mass displaces the internal jugular vein anteriorly on the right side. (Courtesy of David Dascal, MD, and Mae Mae Chu, MD.)

73.6.5 Rhabdomyosarcoma

Rhabdomyosarcoma is the most common soft-tissue tumor of childhood. Common sites in the head and neck include the orbit, nasopharynx, temporal bone (middle ear and mastoid), and sinonasal region. Biopsy is required for the diagnosis. Treatment depends on the stage of disease. Surgery should be considered for resectable lesions, because tumor staging is based on remaining disease after surgical biopsy and excision. Radiotherapy and chemotherapy are required for tumors that are not able to be completely resected during the biopsy procedure.

73.6.6 Lymphoma

Lymphoma typically presents with asymptomatic adenopathy. Lymphoma of all types is more common in males. The diagnosis is established by lymph node biopsy. The specimen must be sent fresh (not in formalin) to allow flow cytometry analysis. Treatment is nonsurgical. Early-stage disease is treated with radiation, whereas more advanced disease is treated with both radiation and chemotherapy.

Hodgkin lymphoma (□ Fig. 73.9) is rare in children younger than age 5 and much more commonly seen in adolescents and young adults; it is twice as common in males. Cervical and supraclavicular lymph nodes are involved 90% of the time; the Waldeyer ring is rarely involved. Pathologically, the presence of Reed-Sternberg cells (multinucleated giant cells) is pathognomonic. Approximately 90% of patients have a good initial response to treatment. Survival in patients with early-stage disease is approximately 90% but decreases to 35% in those with advanced-stage disease.

Non-Hodgkin lymphoma is seen in children between 2 and 12 years old. Unlike in Hodgkin lymphoma, the Waldeyer ring may be involved. The incidence increases in immunosuppressed

Fig. 73.10 Burkitt lymphoma as seen on an axial computed tomographic scan of the neck. The mass is located on the right side, adjacent to the inner cortex of the mandible (white arrowhead). (Courtesy of David Dascal, MD, and Mae Mae Chu, MD.)

patients. The prognosis is less favorable than for the Hodgkin type of lymphoma.

Burkitt lymphoma (□ Fig. 73.10) is a type of non-Hodgkin lymphoma seen exclusively in children and is associated with Epstein-Barr virus (EBV) infection. Burkitt lymphoma is classified as of either the African type or the North American type of disease. African disease affects the maxilla or mandible. North American disease typically presents with an abdominal mass, with 25% of patients demonstrating head and neck involvement. Treatment involves chemotherapy. The 2-year survival is approximately 50%. Favorable prognostic indicators are age at presentation younger than 12 years and high anti-EBV titers in the North American type. Lymph node biopsy is usually necessary for diagnosis.

73.6.7 Histiocytosis

Histiocytosis is characterized by the abnormal non-neoplastic proliferation of the antigen-presenting Langerhans cell. This disease has a predilection for the anterior cervical lymph nodes. Males are more commonly affected. There are three clinical subtypes: eosinophilic granuloma (disease involving bone only); Hand-Schüller-Christian disease (characterized by fever, bone lesions, and diffuse scalp and ear canal eruptions); the Hand-Schüller-Christian triad is the constellation of diabetes insipidus, exophthalmos, and lytic bone lesions); and Letterer-Siwe disease (rapidly progressive proliferation of histiocytes, generally seen in patients younger than 2 years of age). The diagnosis is made following excisional lymph node biopsy. Treatment options include surgery for limited or focal lesions, radiotherapy for lesions not amenable to surgical excision, and adjuvant therapy for systemic disease. The prognosis is

excellent for patients with limited disease. Hand-Schüller-Christian disease may run a chronic course in more than half of patients. Patients with Letterer-Siwe disease have a 5-year mortality rate of 50% despite chemotherapy.

73.6.8 Fibromatosis Coli

Traumatic neck masses may be related to congenital torticollis (fibromatosis coli) or an arteriovenous fistula. Congenital torticollis presents within the first 6 weeks of life as an asymptomatic neck mass located within the sternocleidomastoid muscle. The diagnosis is based on the history and physical examination. A painless, firm, palpable mass is usually found within the belly of the sternocleidomastoid muscle. Spontaneous resolution is seen in most cases, but muscle shortening may occur. Treatment may involve observation, with physical therapy and range-of-motion neck exercises for infants if torticollis is seen clinically. Surgical release with sternocleidomastoid muscle lengthening is reserved for severe cases, when the child is older.

73.6.9 Laryngocele

Laryngoceles originate from the saccule of the laryngeal ventricle. Clinically, external laryngoceles may present laterally in the neck as a cystic mass located anterior to the sternocleidomastoid muscle. From the laryngeal ventricle, they extend through the thyrohyoid membrane to a position lateral to the thyroid cartilage. Internal laryngoceles are confined within the larynx and do not present as a neck mass. Symptoms associated with laryngoceles may include cough, hoarseness, and globus sensation. Surgery is indicated for symptomatic laryngoceles.

73.6.10 Thyroglossal Duct Cyst

Thyroglossal duct cysts (□ Fig. 73.11) may arise anywhere along the course of the embryologic descent of the thyroid gland from the foramen caecum of the tongue to its final location in the lower neck. Clinically, they are midline and move with tongue protrusion. Movement with tongue protrusion differentiates thyroglossal duct cysts from other midline neck masses. Histologically, the cyst may contain ectopic thyroid tissue. In some cases, the body's only functioning thyroid tissue is contained within this cyst. Thus, ultrasound evaluation is indicated to confirm the presence of thyroid tissue in its typical position in the neck. Thyroid scanning or noncontrast CT of the neck may aid in determining the presence of normal, functioning thyroid tissue.

Surgical excision, the Sistrunk procedure, is the treatment of choice to prevent recurrence. This procedure removes not only the palpable cyst but also any remnants of the thyroglossal duct, which is followed up to the hyoid bone, and subsequently includes the middle third of the hyoid bone and a cone-shaped portion of the base of the tongue. A high recurrence rate is noted when the hyoid bone midsection and tongue base are not included in the thyroglossal duct cyst procedure. Infection of a thyroglossal duct cyst may be the presenting symptom and is usually treated with oral antibiotics active against streptococci and staphylococci. Incision and drainage may be necessary in refractory infections; if performed, the incision site must also

Fig. 73.11 Thyroglossal duct cyst as seen on an axial computed tomographic scan of the neck at the level of the hyoid bone. The cyst is located characteristically in the midline, anterior to and abutting the hyoid bone (arrowheads). (Courtesy of David Dascal, MD, and Mae Mae Chu, MD.)

Fig. 73.12 Second branchial cleft cyst as seen on an axial computed tomographic scan of the neck. The cyst is located on the left side (arrowhead), characteristically anterior to the sternocleidomastoid muscle. (Courtesy of David Dascal, MD, and Mae Mae Chu, MD.)

be excised along with the lesion in the Sistrunk procedure to reduce the risk for recurrence.

73.6.11 Branchial Cleft Derivatives

Remnants of the embryologic branchial arches are a relatively common cause of pediatric neck masses, accounting for 17% of all such masses. Branchial anomalies may take the form of a fistula (having both an internal opening in the aerodigestive tract and an external opening in the skin), a sinus (having either an internal or external opening only), or a cyst. External openings may be found anywhere along the anterior border of the sternocleidomastoid muscle. Internal openings may be found in various locations within the aerodigestive tract, depending on the arch involved. Branchial anomalies may be classified as either first, second, third, or fourth arch anomalies. The tract of a given branchial anomaly courses caudal to the arch derivatives for which it is named and dorsal to the derivatives of the following arch. CT evaluation aids in the diagnosis. Treatment of each anomaly is by surgical excision. An understanding of the anticipated course of each anomaly aids in the safe and complete excision of each lesion.

First branchial arch anomalies appear on the face or are related to the auricle. They are divided into Work types I and II. Work type I anomalies contain only epidermoid elements, present as duplication anomalies of the external auditory canal, and may course near the facial nerve. Work type II anomalies are more frequently seen. They contain both ectoderm and mesoderm and present in the neck. Clinically, they become evident after infection, typically as an abscess below the angle of the mandible. They course through the parotid gland, either

medial or lateral to the facial nerve, and end inferior to or within the external auditory canal.

Second branchial arch anomalies are the most common type. The tract courses deep to second arch derivatives (external carotid artery, stylohyoid muscle, posterior belly of the digastric muscle) and superficial to third arch derivatives (internal carotid artery). Clinically, a second branchial arch anomaly presents as a painless, fluctuant mass in the lateral neck, anterior to the sternocleidomastoid muscle and below the angle of the mandible (□ Fig. 73.12). The tract may open into the tonsillar fossa. Classically, the presentation follows an upper respiratory infection.

Third branchial arch anomalies are rare. The tract courses deep to third arch derivatives (internal carotid artery, glossopharyngeal nerve) and superficial to fourth arch derivatives (vagus nerve) to enter the pharynx at the piriform sinus or thyrohyoid membrane. Clinically, they present lower in the neck and anterior to the sternocleidomastoid muscle.

Fourth branch arch anomalies course from the apex of the piriform sinus inferior to the superior laryngeal nerve to the lower neck. They present clinically as recurrent thyroiditis or recurrent lower neck abscesses.

73.7 Thyroid Disorders

Thyroglossal duct cysts typically present as a midline neck mass anywhere along the embryologic pathway of descent of the thyroid gland. This condition has previously been discussed in greater detail.

73.7.1 Lingual Thyroid

Lingual thyroid tissue may be seen in children in the vicinity of the foramen caecum, located in the midline two-thirds of the way back on the dorsal tongue. Children with lingual thyroid may present with a globus sensation, chronic throat clearing, or asymptotically with a visible mass in the posterior tongue on oral examination.

Like thyroglossal duct cyst, lingual thyroid may be the only functioning thyroid tissue in the body. Ultrasound or CT of the neck should be used to verify if there is thyroid tissue in its typical location in the neck. A thyroid scan may demonstrate the functional status of the lingual thyroid tissue or the thyroid gland. In most cases, a high level of suspicion, combined with the results of thyroid imaging and testing, will make the diagnosis, and biopsy is uncommonly required. Thyroid function testing should be performed because a hypothyroid state commonly accompanies lingual thyroid if it is the only functioning thyroid tissue in the patient. Symptomatic lingual thyroid tissue is treated with thyroid hormone suppression, and in refractory cases, surgical excision may be necessary when symptoms of a globus sensation are not relieved. Consultation with a pediatric endocrinologist is highly recommended.

Aside from thyroglossal duct cysts and lingual thyroid tissue, the incidence of thyroid pathology in the children seen by otolaryngologists in the United States is very low. It should be noted that thyroid nodules in persons younger than age 20 are more likely than those in older adults to harbor cancer, and the finding of a thyroid nodule in a child should be approached with a high index of suspicion.

73.8 Roundsmanship

- Cervical lymph nodes larger than 10 mm or tender for more than 6 weeks after a precipitating infection, fixed to skin, larger than 20 mm in an acute setting, or fluctuant should be considered suspicious.

- When a cervical lymph node biopsy is performed, the surgeon should consider sending the specimen in saline for aerobic and anaerobic bacterial, fungal, and acid-fast bacterial cultures and for flow cytometry, in addition to standard histopathology.
- Deep neck space infections can spread to specific adjacent areas, based on cervical fascial boundaries.
- Polymerase chain reaction testing can speed the identification of acid-fast bacilli infections.
- Kawasaki disease, a multisystem vasculitis, can lead to coronary artery aneurysms.
- Rhabdomyosarcoma is the most common soft-tissue tumor of childhood.
- Complete removal of a thyroglossal duct cyst requires excision of the cyst, the tract up to the hyoid bone, the mid-portion of the hyoid bone, and a conical section of the tongue base.

74 Laryngeal Anatomy

Michael J. Pitman

The structure of the mammalian larynx has developed in response to three important needs: protection of the lower airway from aspiration, sound making (phonation), and the generation and maintenance of positive intrathoracic air pressure to withstand compressive forces acting on the thorax. Although each category of demand has fostered its own special features of laryngeal anatomy, it is on the phonatory function and its anatomical adaptations that this section will focus. The phonatory function of humans is the most versatile, variable, and precise among those of the animals that use the larynx for sound making. It owes its capabilities to the evolution of special mechanisms of central nervous control and to special anatomical features, especially at the histologic level.

74.1 Regional Divisions of the Larynx

The interior space of the larynx is conventionally divided into three regions. The supraglottis includes the space that lies above the vocal folds, beginning at the lateral aspect of the ventricle. This region contains the epiglottis, ventricular folds, superior half of the ventricles, aryepiglottic folds, and arytenoid cartilages. The glottis is the space between the vocal folds. It extends from the lateral ventricle to the subglottis, which begins 10 mm inferior to the vocal fold edge anteriorly and 5 mm posteriorly. The subglottis extends to the bottom of the cricoid and is bounded superiorly by the conus elasticus.

Recognition of this vertical division of spaces is clinically important because of regional differences in the nature of the lymph drainage. Specifically, the supraglottic area has the highest density of lymphatic vessels and drains bilaterally into levels II and III. The lymphatic system of the subglottal area has bilateral drainage into the paratracheal and mediastinal lymph nodes. The glottal region is only sparsely supplied with lymphatic channels, and it drains unilaterally to levels II and III. The vocal

folds serve as a barrier between the lymphatic systems of the supraglottal and subglottal regions.

74.2 Skeletal Elements

The skeleton of the larynx is cartilaginous and is illustrated somewhat schematically in □ Fig. 74.1 and □ Fig. 74.2. The cricoid cartilage, typically described as having the shape of a signet ring with a posterior flat lamina, joins the larynx to the trachea and is, in fact, the only complete ring of the trachea. The thyroid cartilage has approximately the form of an ancient war shield. The two flat alae of the thyroid cartilage meet at the anterior midline to form the angle of the thyroid cartilage, which ends superiorly at the thyroid notch. The human larynx is sexually dimorphic, with the male organ approximately 1 1/2 times the size of the female organ. The thyroid angle and thyroid notch are often prominent landmarks on the anterior neck surface, particularly in men. At the posterior–inferior edge of each thyroid ala, an inferior cornu articulates with the posterolateral region of the arch of the cricoid. The corresponding superior cornu and entire superior margin of the thyroid cartilage are suspended from the hyoid bone by the thyrohyoid membrane.

Articulating with the superior edge of the lamina of the cricoid cartilage are two roughly pyramidal arytenoid cartilages. At the triangular base of each arytenoid is the posterolateral muscular process, the point of attachment of the posterior and lateral cricoarytenoid muscles. The forward-projecting vocal process, at the anterior apex of the base of the arytenoid, is the point of attachment for the thyroarytenoid muscle and the connective tissue of the vocal fold. On top of each arytenoid sits the corniculate cartilage. The cuneiform cartilage is then slightly anterior to it and lies within the aryepiglottic fold. Finally, the triticeal cartilages, which are not always present, lie within the connective tissue between the superior horn of the thyroid cartilage and the hyoid bone. The corniculate, cuneiform, and triticeal cartilages are not of clinical significance.

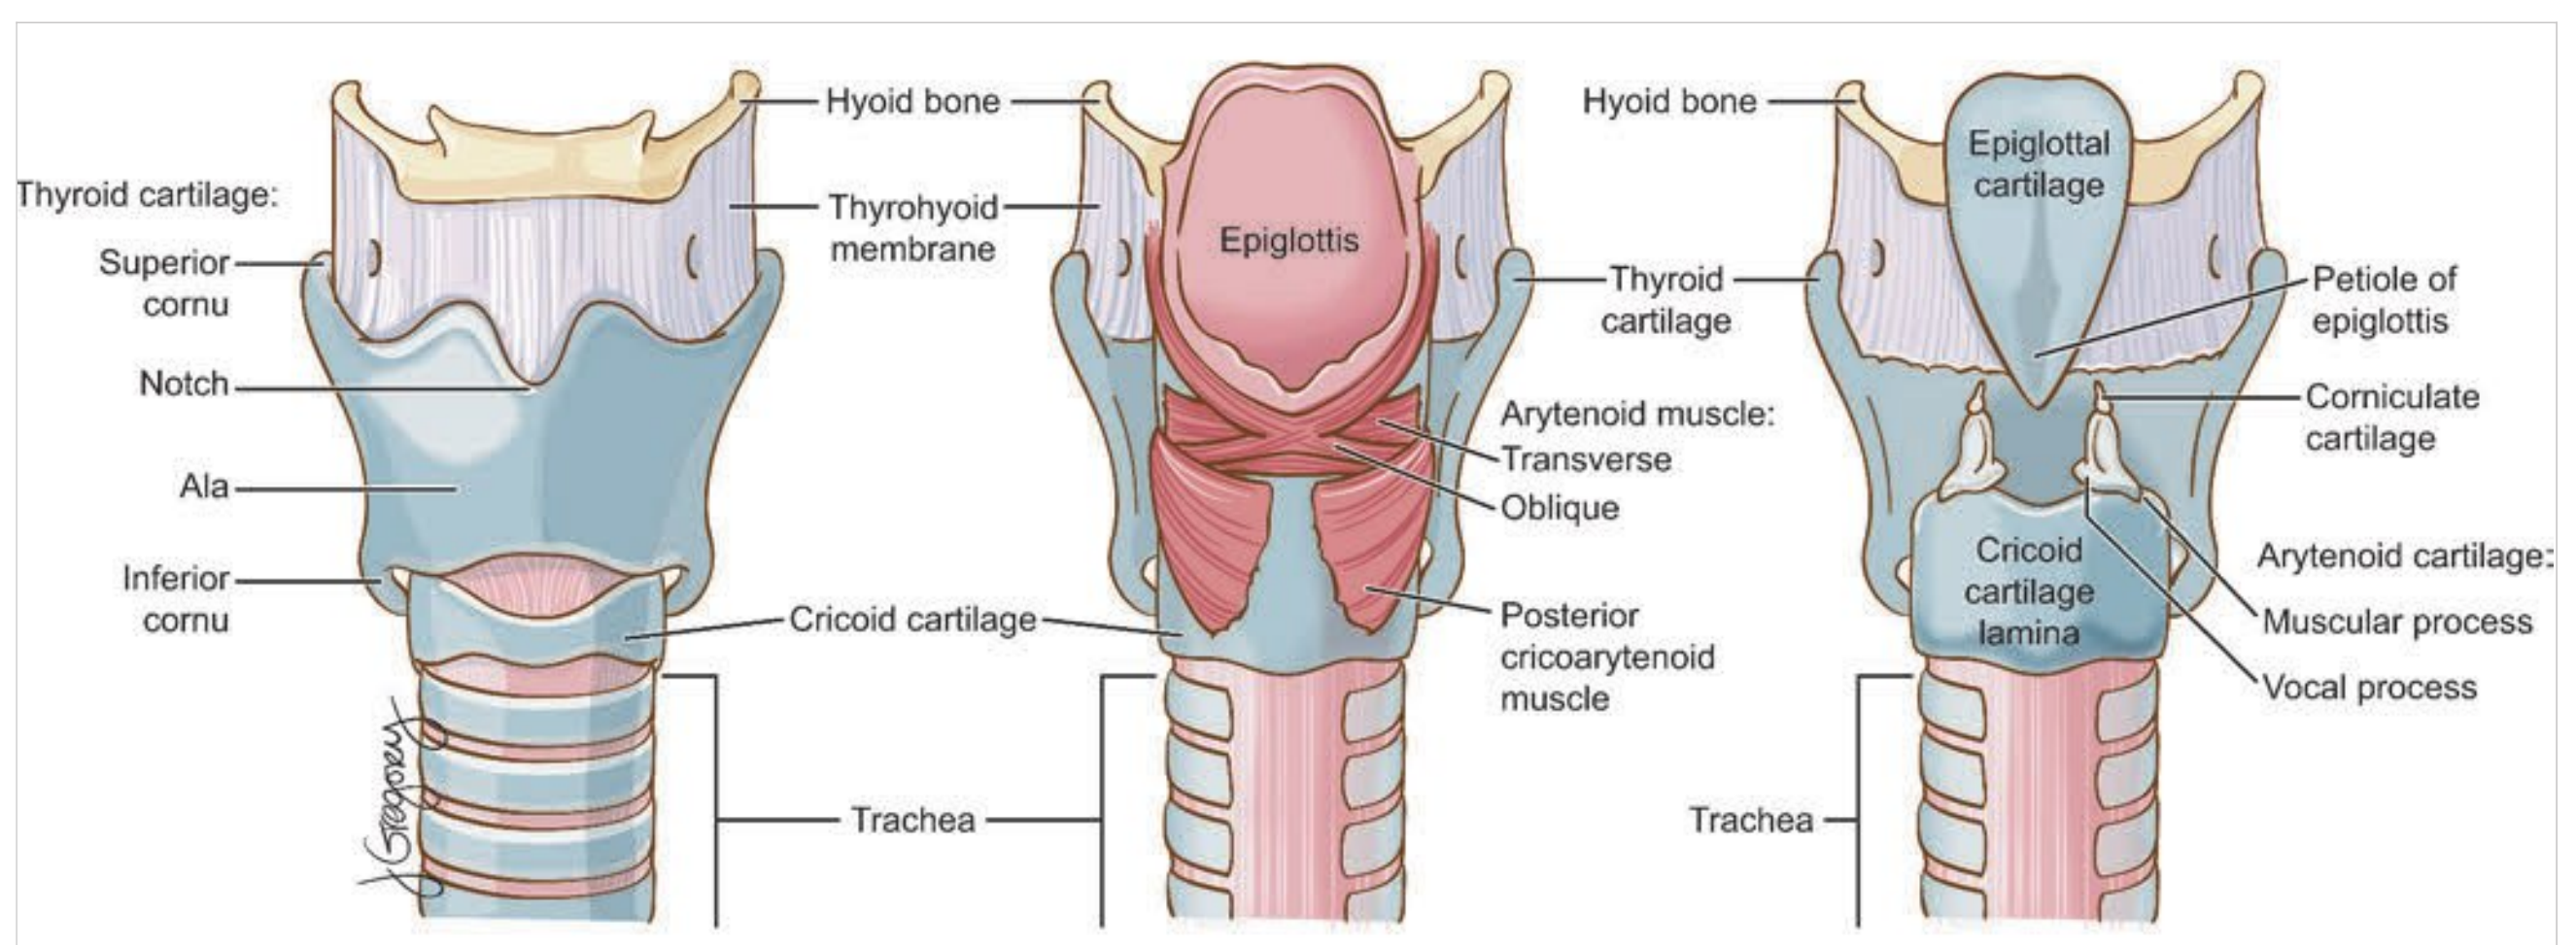

Fig. 74.1 Major structures of the larynx. (a) Anterior view. (b) Posterior view. (c) Posterior view of the cartilage.

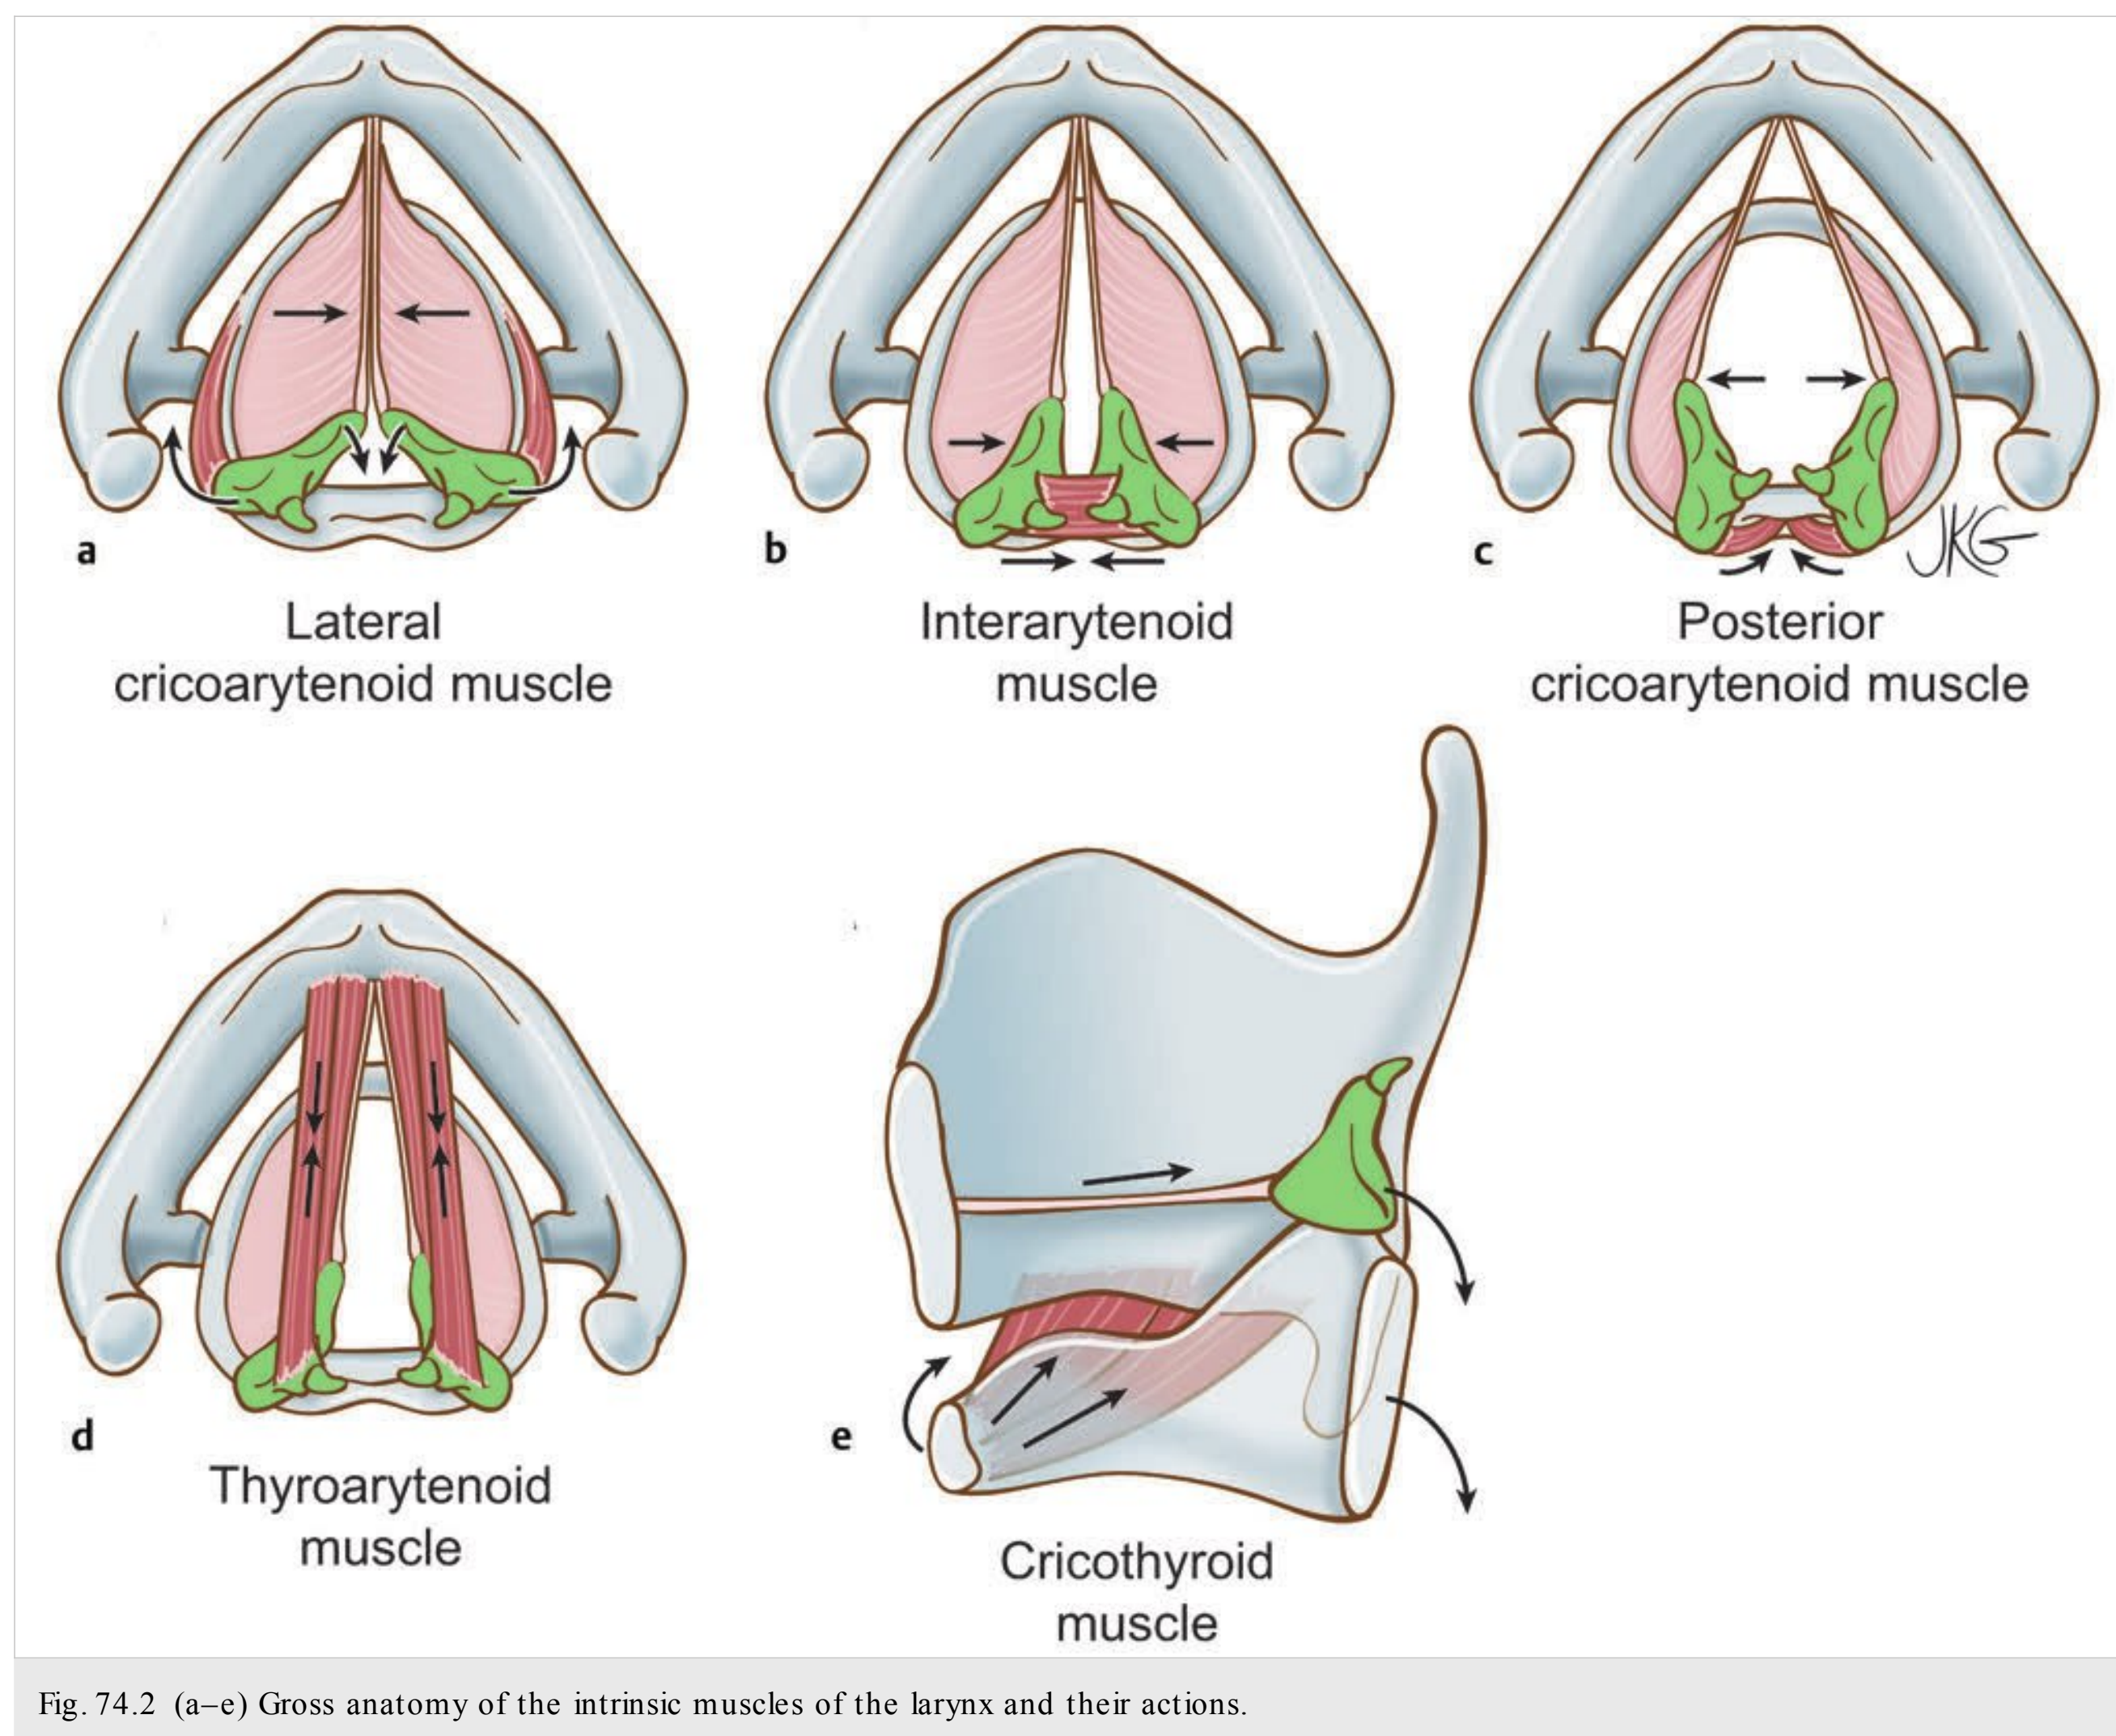

Fig. 74.2 (a–e) Gross anatomy of the intrinsic muscles of the larynx and their actions.

The thyroid, cricoid, and arytenoids are all hyaline cartilage—strong but relatively flexible. Beginning just after puberty, these cartilages begin to ossify, much more rapidly in men than in women. The process continues until most of the cartilaginous tissue has been converted, making the skeleton significantly more rigid.

The remaining significant cartilage is the epiglottis, a leaf-shaped elastic cartilage attached by its stem (the petiole) to the inner surface of the angle of the thyroid. It is curled somewhat along its vertical axis, so that it presents a concave shape to the airway. Because of the epiglottis and the walls formed by the alar portions of the thyroid cartilage, the opening to the intralaryngeal airway faces not upward but rather mostly posteriorly, toward the posterior pharyngeal wall. Sealing of the airway during deglutition is not accomplished by lowering of the epiglottis over the vocal folds, but rather primarily by motion of the entire larynx upward and posteriorly. As this occurs, the epiglottis is forced to retroflex against the pharyngeal wall. The epiglottis, which protrudes above the angle of the thyroid, then acts as a “prow,” diverting ingested materials around the larynx and into the esophageal entrance.

74.3 Intrinsic Musculature and Displacement Forces

The intrinsic muscles of the larynx have small motor units and very rapid contraction times. The conventional approach to their gross anatomy is summarized in □ Fig. 74.2 and □ Table 74.1. All except the cricothyroid muscle are arranged as a quasi-sphincter around the glottis. In general, their combined gross actions serve to firmly seal the entrance to the airway against intrusion during swallowing, to close off the thorax and stabilize the chest wall during expulsive acts, and to withstand thrusting forces imposed by the arms.

Respiration and phonation require somewhat more subtle control of the glottal status and so a more finely individualized control of the intrinsic muscles. It is common to assign specific functions and highly individualized roles to each of the intrinsic muscles. It is important to realize that this approach is too simplistic. The muscles work in synergy, and the position and status of the vocal fold depend on the vector sum of the muscular and aerodynamic forces being generated at any given instant. Thus, in an important sense, the reality is that each muscle is an

Table 74.1 Intrinsic muscles of the larynx

Muscle	Attachments	Action	Innervation
Cricothyroid	Upper margin and exterior surface, anterior cricoid cartilage Lower margin and inferior horn, lateral thyroid ala	Approximate cricoid and thyroid cartilages (visor action) Increase thyroid-to-arytenoid (vocal fold) length	Superior laryngeal nerve
Posterior cricoarytenoid	Muscular process of arytenoid cartilage Cricoid cartilage lamina	Displace arytenoid posteriorly and move vocal process of arytenoid away from midline Open glottis	Recurrent laryngeal nerve
Lateral cricoarytenoid	Muscular process of arytenoid cartilage Superior margin of posterior cricoid ring	Displace arytenoid laterally and move vocal process of arytenoid toward midline Close glottis	Recurrent laryngeal nerve
Interarytenoid Transverse Oblique	Posterior facet of arytenoid cartilage Muscular process of one arytenoid cartilage to apex of the other; continues to lateral edge of epiglottis	Adduct arytenoids, close glottis Brace and stabilize arytenoids	Recurrent laryngeal nerve
Thyroarytenoid	Vocal process and nearby area of arytenoid cartilage to inner surface of thyroid angle	Decrease thyroid-to-arytenoid (vocal fold) length Increase vocal fold tension	Recurrent laryngeal nerve

auxiliary for all of the others. One important consideration is that the posterior cricoarytenoid muscles are the sole abductors of the vocal folds and so are responsible for establishing a glottal opening. There is a tendency in the literature to depict abduction as the result of rotation of the arytenoid cartilages about a vertical axis, but in fact significant rotary motion is prevented by the shape of the cricoarytenoid joint and its associated ligaments. Rather, the cricoarytenoid joint is a true diarthrodial joint; as such, the arytenoid slides along its articular facet, as well as rotates about an axis in the transverse plane. Together, these movements account for the posterior–superior displacement of the vocal process on abduction.

During phonation, the individual muscles are very finely controlled for positioning the vocal folds and adjusting their biomechanical properties. The lateral cricothyroid muscles generate the main adductor forces for glottal closure, along with the interarytenoid muscles, whose added adductor effect helps maintain glottal closure during episodes of high pulmonary air pressure.

The two remaining intrinsic muscles are largely responsible for the adjustment of the biomechanical properties of the vocal folds and so, in large measure, the control of important vocal qualities. Contraction of the cricothyroid muscle causes the vocal folds to lengthen by two different means. Contraction of the more posterior and oblique portion of the muscle pulls the thyroid cartilage forward or, equivalently, displaces the cricoid cartilage backward. This increases the distance between the posterior cricoid lamina and the thyroid angle. As the cricoid lamina moves relatively backward, it carries the arytenoid cartilages posteriorly, thus increasing the thyroid-to-arytenoid distance and lengthening the vocal fold. The second lengthening effect is somewhat less direct. Contraction of the vertical fibers of the cricothyroid muscle causes an approximation of the anterior portions of the thyroid and cricoid cartilages. This causes a rotation of the cartilages about the axis of their articulation at the inferior horn of the thyroid cartilage. The effect of this is to rotate the arytenoids, which ride on the upper edge of the cricoid, relatively backward and away from the thyroid angle, thus

lengthening the vocal fold. Increasing the vocal fold length increases the frequency of vocal fold vibration (see Chapter 75, Vocal Physiology).

The thyroarytenoid muscle forms the muscular body of the vocal fold. Its most medial portion is often referred to as the vocalis muscle. (This portion is not grossly separable from the rest of the muscle mass and is not strictly a muscle in its own right.) Isotonic contraction of the thyroarytenoid muscle shortens the vocal fold, which tends to lower vocal fundamental frequency, whereas isometric contraction increases vocal fold tension, thus raising vocal fundamental frequency. Finally, thyroarytenoid muscle contraction tends to rotate the arytenoid cartilage medially about its transverse plane rotational axis, which assists in closing the glottal space.

74.4 Membranous, Connective, and Secretory Tissues; Laryngeal Folds

Like the rest of the airway, the laryngeal region is lined with pseudostratified ciliated columnar respiratory epithelium, with the exception of one small but critical zone. The medial edges of the vocal folds are covered by stratified squamous epithelium, which is much better able to sustain the considerable collisional, frictional, and shear forces that are generated by phonatory oscillation. The membranous lining on each side is thrown into three anteroposterior folds.

The most superior of these, the aryepiglottic fold, extends from the apex of the arytenoid cartilage to the lateral margin of the epiglottis and plays a role in protecting the airway from intrusion. The ventricular folds and vocal folds are the main functional structures of the larynx. (The older term, vocal cord, still has some currency but has largely been abandoned in the scientific world in favor of the more accurately descriptive term, vocal fold. This is a literal translation of the earlier Latin name, *plica vocalis*. Similarly, the terms true vocal cord and false vocal

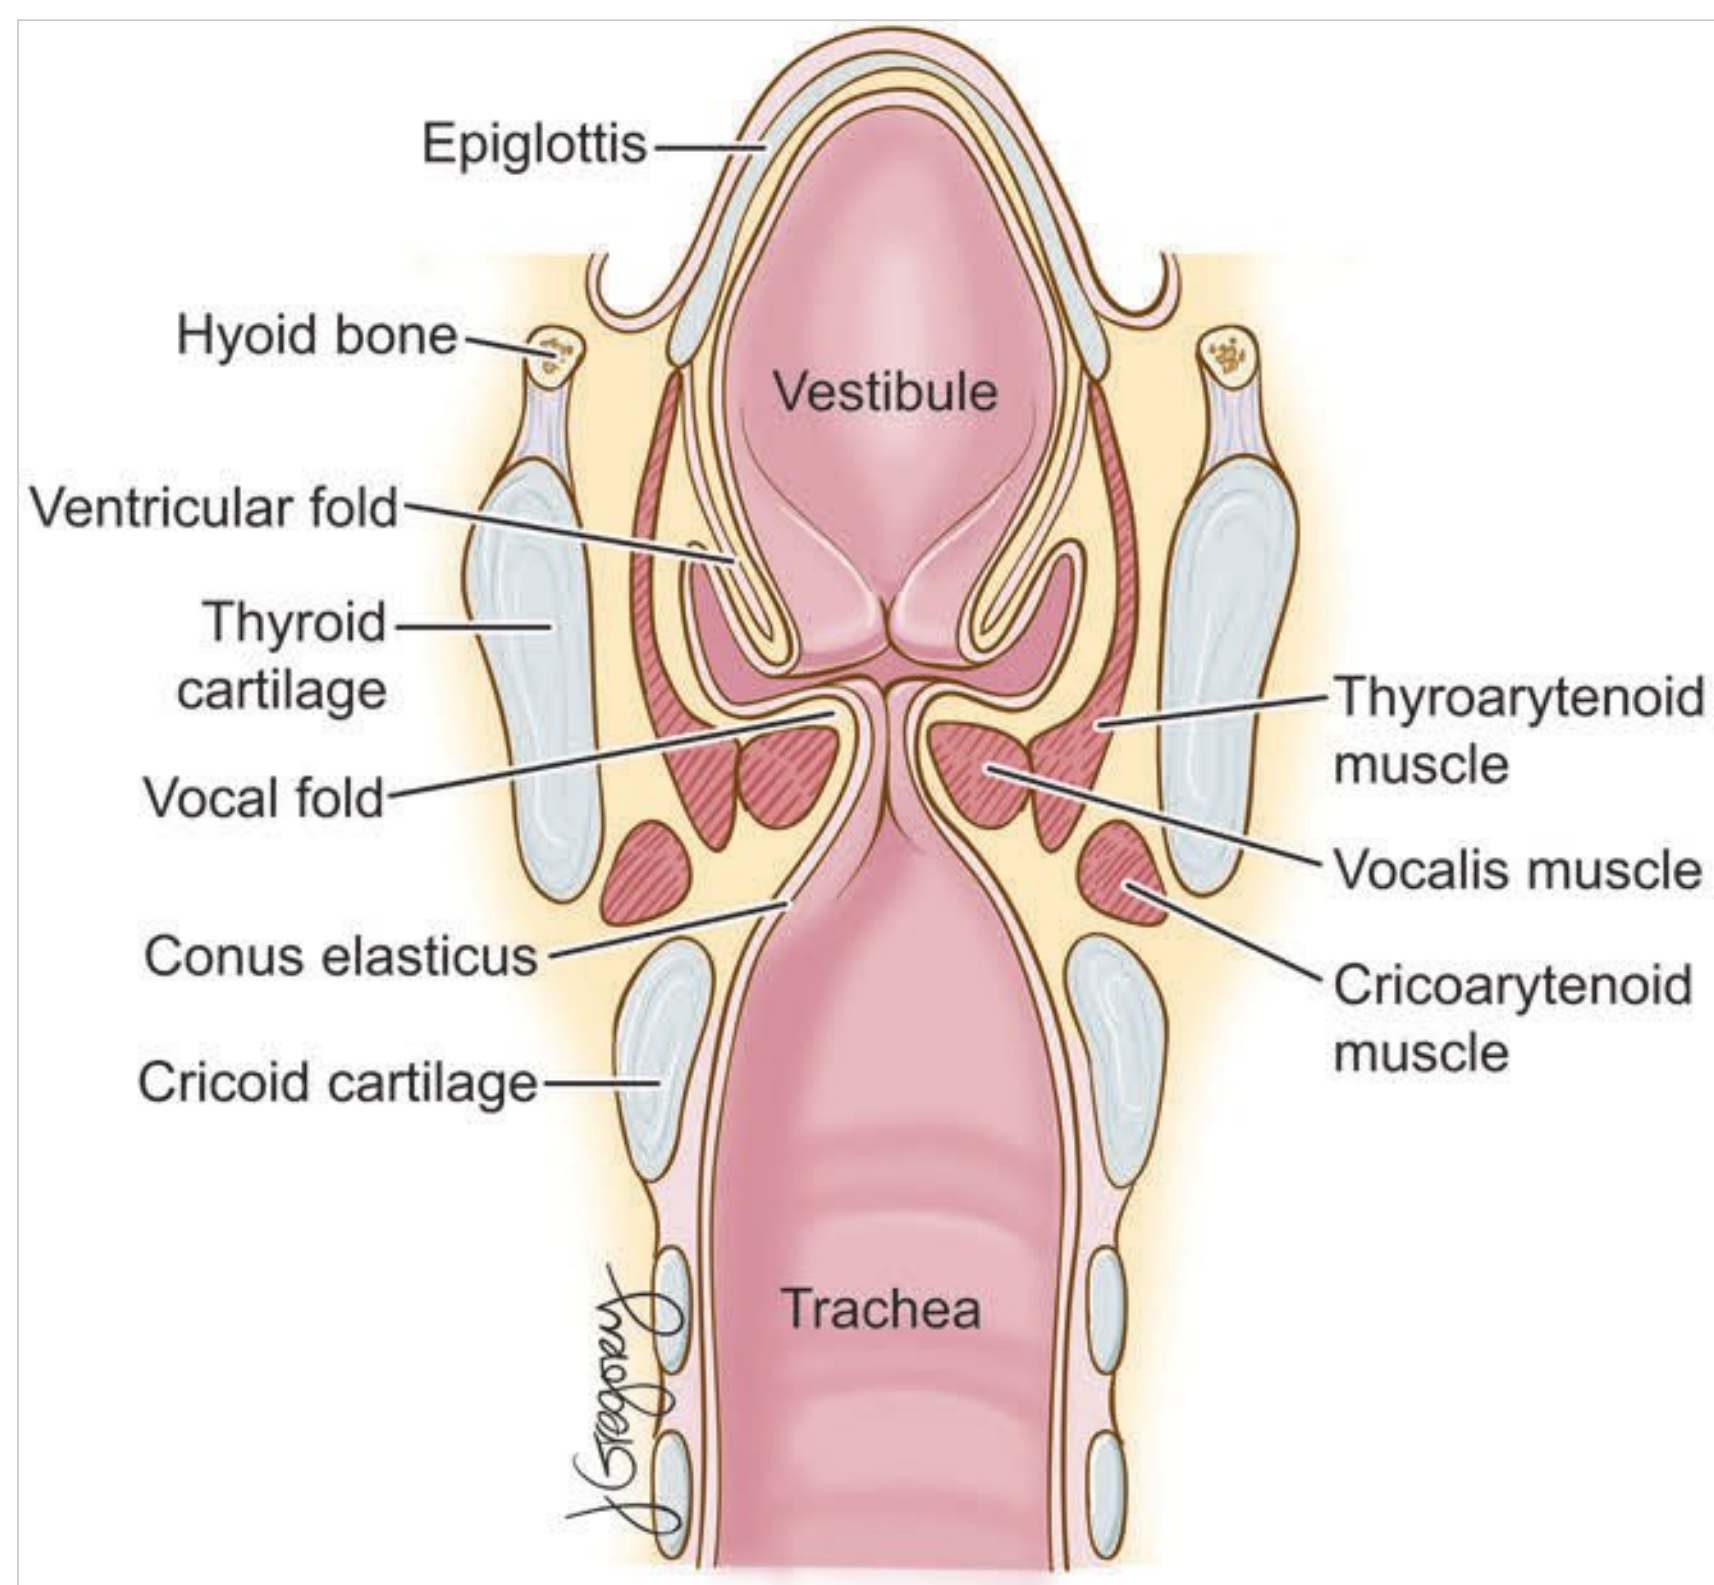

Fig. 74.3 Schematic coronal section illustrating the spatial relationship of the vocal folds and ventricular folds to one another and the entire larynx.

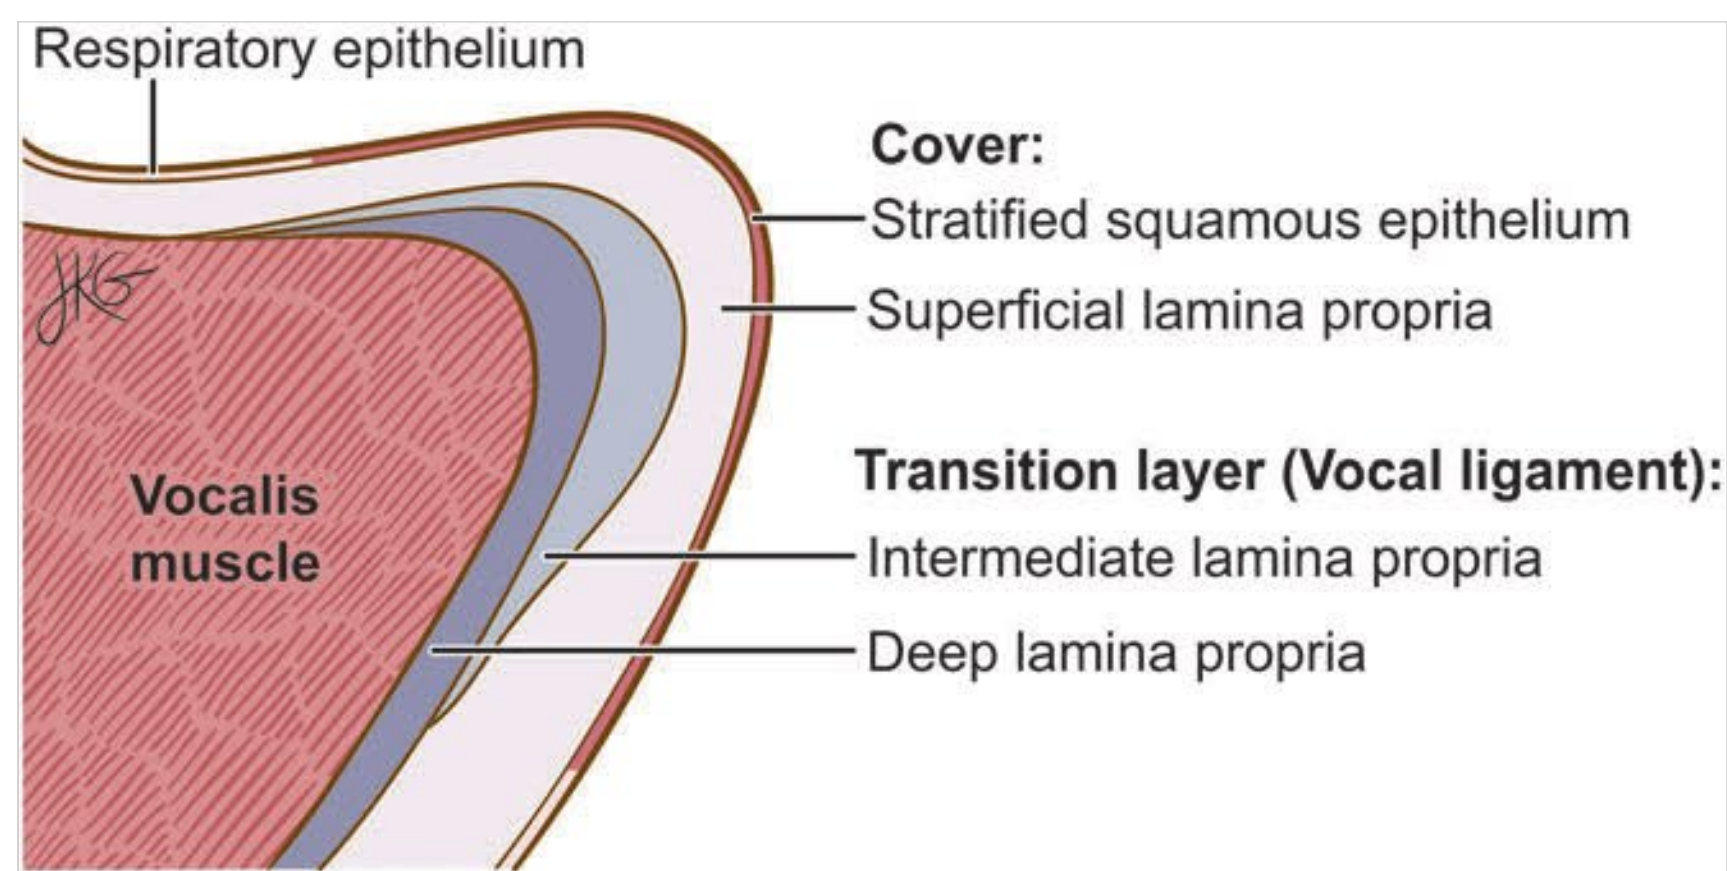

Fig. 74.4 Schematic organization of the five layers of the vocal fold.

cord have generally been replaced by the more accurate terms vocal folds and ventricular folds, respectively.) The main microscopic and gross anatomical features of these folds are shown in □ Fig. 74.3 and □ Fig. 74.4. Each is bulkier than the aryepiglottic folds, each has a distinct internal structure, and each plays a critical role in laryngeal function.

The ventricular folds are multilayered. Just deep to the covering respiratory epithelium is a zone of loosely organized connective tissue, the lamina propria. Deep to this zone is the stroma, a denser connective tissue region that forms the main structural support. Within the stroma is a dense assemblage of secretory glands that provide much of the protective and lubricating mucus of the active glottal region. The ventricular folds contain no intrinsic muscle fibers, although there are some deep muscle fibers that are an extension of the thyroarytenoid. Sphincteric closure of the glottal region can medialize the

ventricular folds, and they may, in cases of disorder, be used to produce an abnormal phonation.

The quadrangular membranes arise from the lateral edges of the epiglottis and nearby inner surface of the thyroid cartilage. Each courses posteriorly downward to attach to the medial surface of the arytenoid cartilage. The inferior margin of the membrane is somewhat thickened and has often—but erroneously—been designated the ventricular ligament.

Much of the unique human ability to produce highly variable and exquisitely controlled phonation is due to the special anatomy of the vocal fold. Structurally, it is divisible into five layers, which are commonly lumped into three regions. In addition, a superficial membrane, referred to as the conus elasticus, lines the funnel-shaped subglottal region. This membrane joins the several periglottal cartilages to one another. It is divisible into a medial cricothyroid ligament and a lateral cricothyroid

membrane and extends inferiorly to become continuous with the lining of the trachea.

The body of the vocal fold is the thyroarytenoid muscle, which lies deep within the fold. Contraction of this muscle can shorten the vocal fold or can increase its stiffness. Although the body of the vocal fold is not strongly involved in phonatory oscillation, it is important for helping to establish the biomechanical properties of the overlying, actively vibrating layers.

Medial to the body of the vocal fold is an organized zone of connective tissue referred to as the lamina propria. On the whole, the connective tissue of this region is not tightly packed, and the interfiber spaces are filled with a considerable amount of fluid-like material (proteoglycans, glycosaminoglycans). The lamina propria is divisible into three layers according to the amount and types of connective tissue fibers (elastin and collagen) and the way in which they are interwoven. Generally, the deeper the layer, the more collagen and the less elastin. The deep and intermediate layers are together referred to as the vocal ligament, while the combination of the superficial lamina propria and the squamous epithelium at the surface is called the vocal fold cover.

When the length of the vocal fold is changed, the physical properties, such as stiffness and thickness, of the vocal ligament and vocal fold cover are altered. This results in a change in the oscillatory response of the vocal fold to the driving air pressure. There is a change in the amplitude and frequency of vocal fold vibration. The rigidity of the body of the vocal fold also plays a role in controlling vocal fold vibration because the freedom of the cover tissues to vibrate is influenced by the freedom of the body to move. So, as vocal fold length increases, the tissues of the vocal fold become stiffer, but the relationship is highly nonlinear and includes significant hysteresis (i.e., the stretch–tension relationship differs depending on whether the folds are lengthening or shortening). Stiffer vocal folds oscillate at higher frequency, but the nonlinearity of the system ensures that the relationship is a complex one.

74.5 Innervation of the Larynx

The larynx is innervated by two branches of the vagus nerve (cranial nerve X), as summarized in □ Table 74.2. The origins of the vagus nerve lie mostly in the nucleus ambiguus of the brainstem, which also gives rise to glossopharyngeal (cranial nerve IX) and spinal accessory (cranial nerve XI) nerve fibers. Two enlargements of the nerve just outside the cranium, the nodose and jugular ganglia, contain the perikaryons of vagal afferent fibers. In the cervical region, the vagus nerve gives off several branches. The superior laryngeal nerve subdivides into an external and an internal branch (which is efferent and innervates the cricothyroid muscle). The internal branch provides sensory innervation to the membranes of the supraglottal region. The recurrent laryngeal nerve branches off the main trunk of the vagus nerve inferior to the level of the larynx. It provides sensory innervation to the glottal and subglottal membranes and motor innervation to all intrinsic muscles of the larynx (except the cricothyroid). It is of some clinical importance to note

Table 74.2 Summary of laryngeal innervation

Branch of vagus	Afferent	Efferent
Superior laryngeal nerve (internal branch and external branch)	Supraglottal mucosa	Cricothyroid muscle
Recurrent laryngeal nerve	Subglottal mucosa	Arytenoid, posterior cricoarytenoid, lateral cricoarytenoid, thyroarytenoid muscles

that the right recurrent nerve loops around the junction of the common carotid and subclavian arteries before traveling superomedially to the larynx, whereas the left recurrent nerve descends into the upper thorax, where it loops around the aortic arch before ascending relatively vertically in the tracheo-esophageal groove back to the larynx. When a patient with a presumed injury of the left recurrent laryngeal nerve is evaluated, it is imperative that imaging extend into the thorax.

74.6 Roundsmanship

- The larynx is divided into the supraglottis, glottis, and subglottis. Each area has a distinct lymphatic drainage that affects both the treatment and prognosis of patients with neoplastic disease.
- The three main purposes of the larynx are protection of the lower airway from aspiration, phonation, and the generation and maintenance of positive intrathoracic air pressure to withstand compressive forces acting on the thorax.
- The cricoarytenoid joint is a true diarthrodial joint. This joint slides and rotates on an axis in the transverse plane.
- There are nine intrinsic muscles in the larynx.
- The medial edges of the vocal folds are covered by stratified squamous epithelium, which is better able than the surrounding respiratory epithelium to withstand the considerable collisional, frictional, and shear forces that are generated by phonatory oscillation.

75 Vocal Physiology

Michael J. Pitman

75.1 Basic Conceptual Framework: The Source–Filter Model

The research of the past 70 years has validated the conceptualization of normal voice as the product of two active processes. The oscillation of the vocal folds results in periodic occlusion of the airway at the glottis, which divides the expiratory airstream into a series of airflow pulses. These glottal closures are the foundation for the generation of a nearly periodic acoustic wave train, referred to as the vocal source signal. This signal, in turn, is altered by the acoustic properties of the supraglottal airway, called the vocal tract. The acoustic characteristics of the vocal tract can be voluntarily modified by changing its shape. The upper airway, then, serves as a vocal tract filter. This source–filter model holds that the two aspects of voice production are essentially independent of each other. The assumption is not strictly true, but it is admissible for everyday clinical purposes.

Phonation is the generation of a periodic signal at the glottis: that is, the production of a source signal. Voice, on the other hand, is phonation that is acoustically modified, or filtered. Control of the vocal tract structures, which results in a modification of the filter’s characteristics, is an articulatory, rather than a phonatory, function. Hence, some qualities commonly said to be vocal, including (most importantly) nasality, are really articulatory. These are outside the realm of vocal function strictly defined and will be not considered here.

The essential features of the source–filter model of voice production are summarized in □ Fig. 75.1, which will serve as a guide to the present brief exploration of vocal physiology.

75.2 The Power Supply: Air Pressure Generation

The acoustic power that is radiated as a voice or speech signal is drawn from the pressurized air that is provided to the vocal folds for phonation, and to the vocal tract directly for some speech sounds (consonant production). The source of pressurized air is, of course, the lungs. While the basic mechanisms of lung inflation and alveolar pressurization for speech are the same as for vegetative pulmonary ventilation, there are specific requirements, problems, and constraints that are imposed by the need for a stable phonatory product that can be easily and precisely modulated to meet the complex requirements of speech while, at the same time, satisfying the body’s more general respiratory demands.

- Lung volumes for speech are typically greater than vegetative tidal volumes. The ventilatory tidal volume at rest is on the order of 0.5 L. However, speech breathing characteristically is initiated at an end-inspiratory lung volume of between 35% and 65% vital capacity (VC), and end-expiratory volume for speech is near (and often less than) REL, which is the rest position of the ventilatory system, at which expiratory and inspiratory recoil forces are equal and opposite. Loud speech is associated with larger lung volumes than soft speech.

- In tidal ventilation, the duration of inspiration is about 40% of the breathing cycle. Speech is normally produced only during expiration, so the interruption required for recharging the lungs must be minimized. Therefore, during speech, inspiration is typically shortened so as to occupy only about 10% of the cycle, with a corresponding increase in the magnitude of peak instantaneous inspiratory airflow.
- Tracheal air pressures during quiet tidal breathing are very modest, ranging between approximately -1 and $+1$ cm H₂O, of which the (positive) expiratory pressure is passively generated by recoil forces created during the preceding inspiratory phase. During speech, however, significantly higher inspiratory (negative) pressure is required in order to achieve rapid inspiration. More importantly, sound production calls for larger positive pressures, most commonly in the range of approximately $+4$ cm H₂O for soft phonation to about $+10$ cm H₂O for moderately loud phonation. Pressures in this range are higher than those usually produced by passive recoil and thus must be actively generated.
- Phonation and articulation for speech purposes require that the tracheal pressure be stable, and that it change only in response to the physiologic demands of the speech process and to the requirements of the linguistic features to be communicated. The mechanics of the lung and chest wall system therefore pose a problem. The recoil forces vary in a nonlinear manner as lung volume changes. Thus, at the end of a large inspiration, such as might occur in preparation for a long speech utterance, the tracheal pressure generated by recoil might well be more than is needed for phonation and speech. On the other hand, as the utterance comes to an end, the lung volume may be very low, in fact below the functional residual capacity (FRC). For this reason, passive pressure will probably be too low to drive phonation, or may be negative. Thus, for speech, active chest wall muscle activity is required to reduce (by delicately controlled inspiratory muscle action) excessively positive passive pressure, or to augment (by expiratory muscle activation) the inadequate or even negative passive tracheal pressure produced when lung volume has been depleted.

An additional problem, often overlooked, results from the fact that normal speech is characterized by large and sudden changes in airflow. As an example, when the word *she* is spoken, the peak airflow for “sh” is approximately 700 mL/s, but just a few tens of milliseconds later, airflow for the “e” is about 125 mL/s. Changes such as this can cause unwanted and sudden alterations of pressure. For speech purposes, therefore, the chest wall system is postured so as to optimize “load regulation.” Compared with their positions during tidal breathing, the rib cage is typically somewhat expanded and the anterior abdominal wall somewhat more contracted, forcing the diaphragm upward a bit.

Unfortunately, the “rules” of breathing for speech are anything but clear. Different individuals appear to have very different ways of solving the biomechanical problems involved, and it is not uncommon for perfectly normal speakers to use ventilatory patterns that seem to fly in the face of the physiolo-

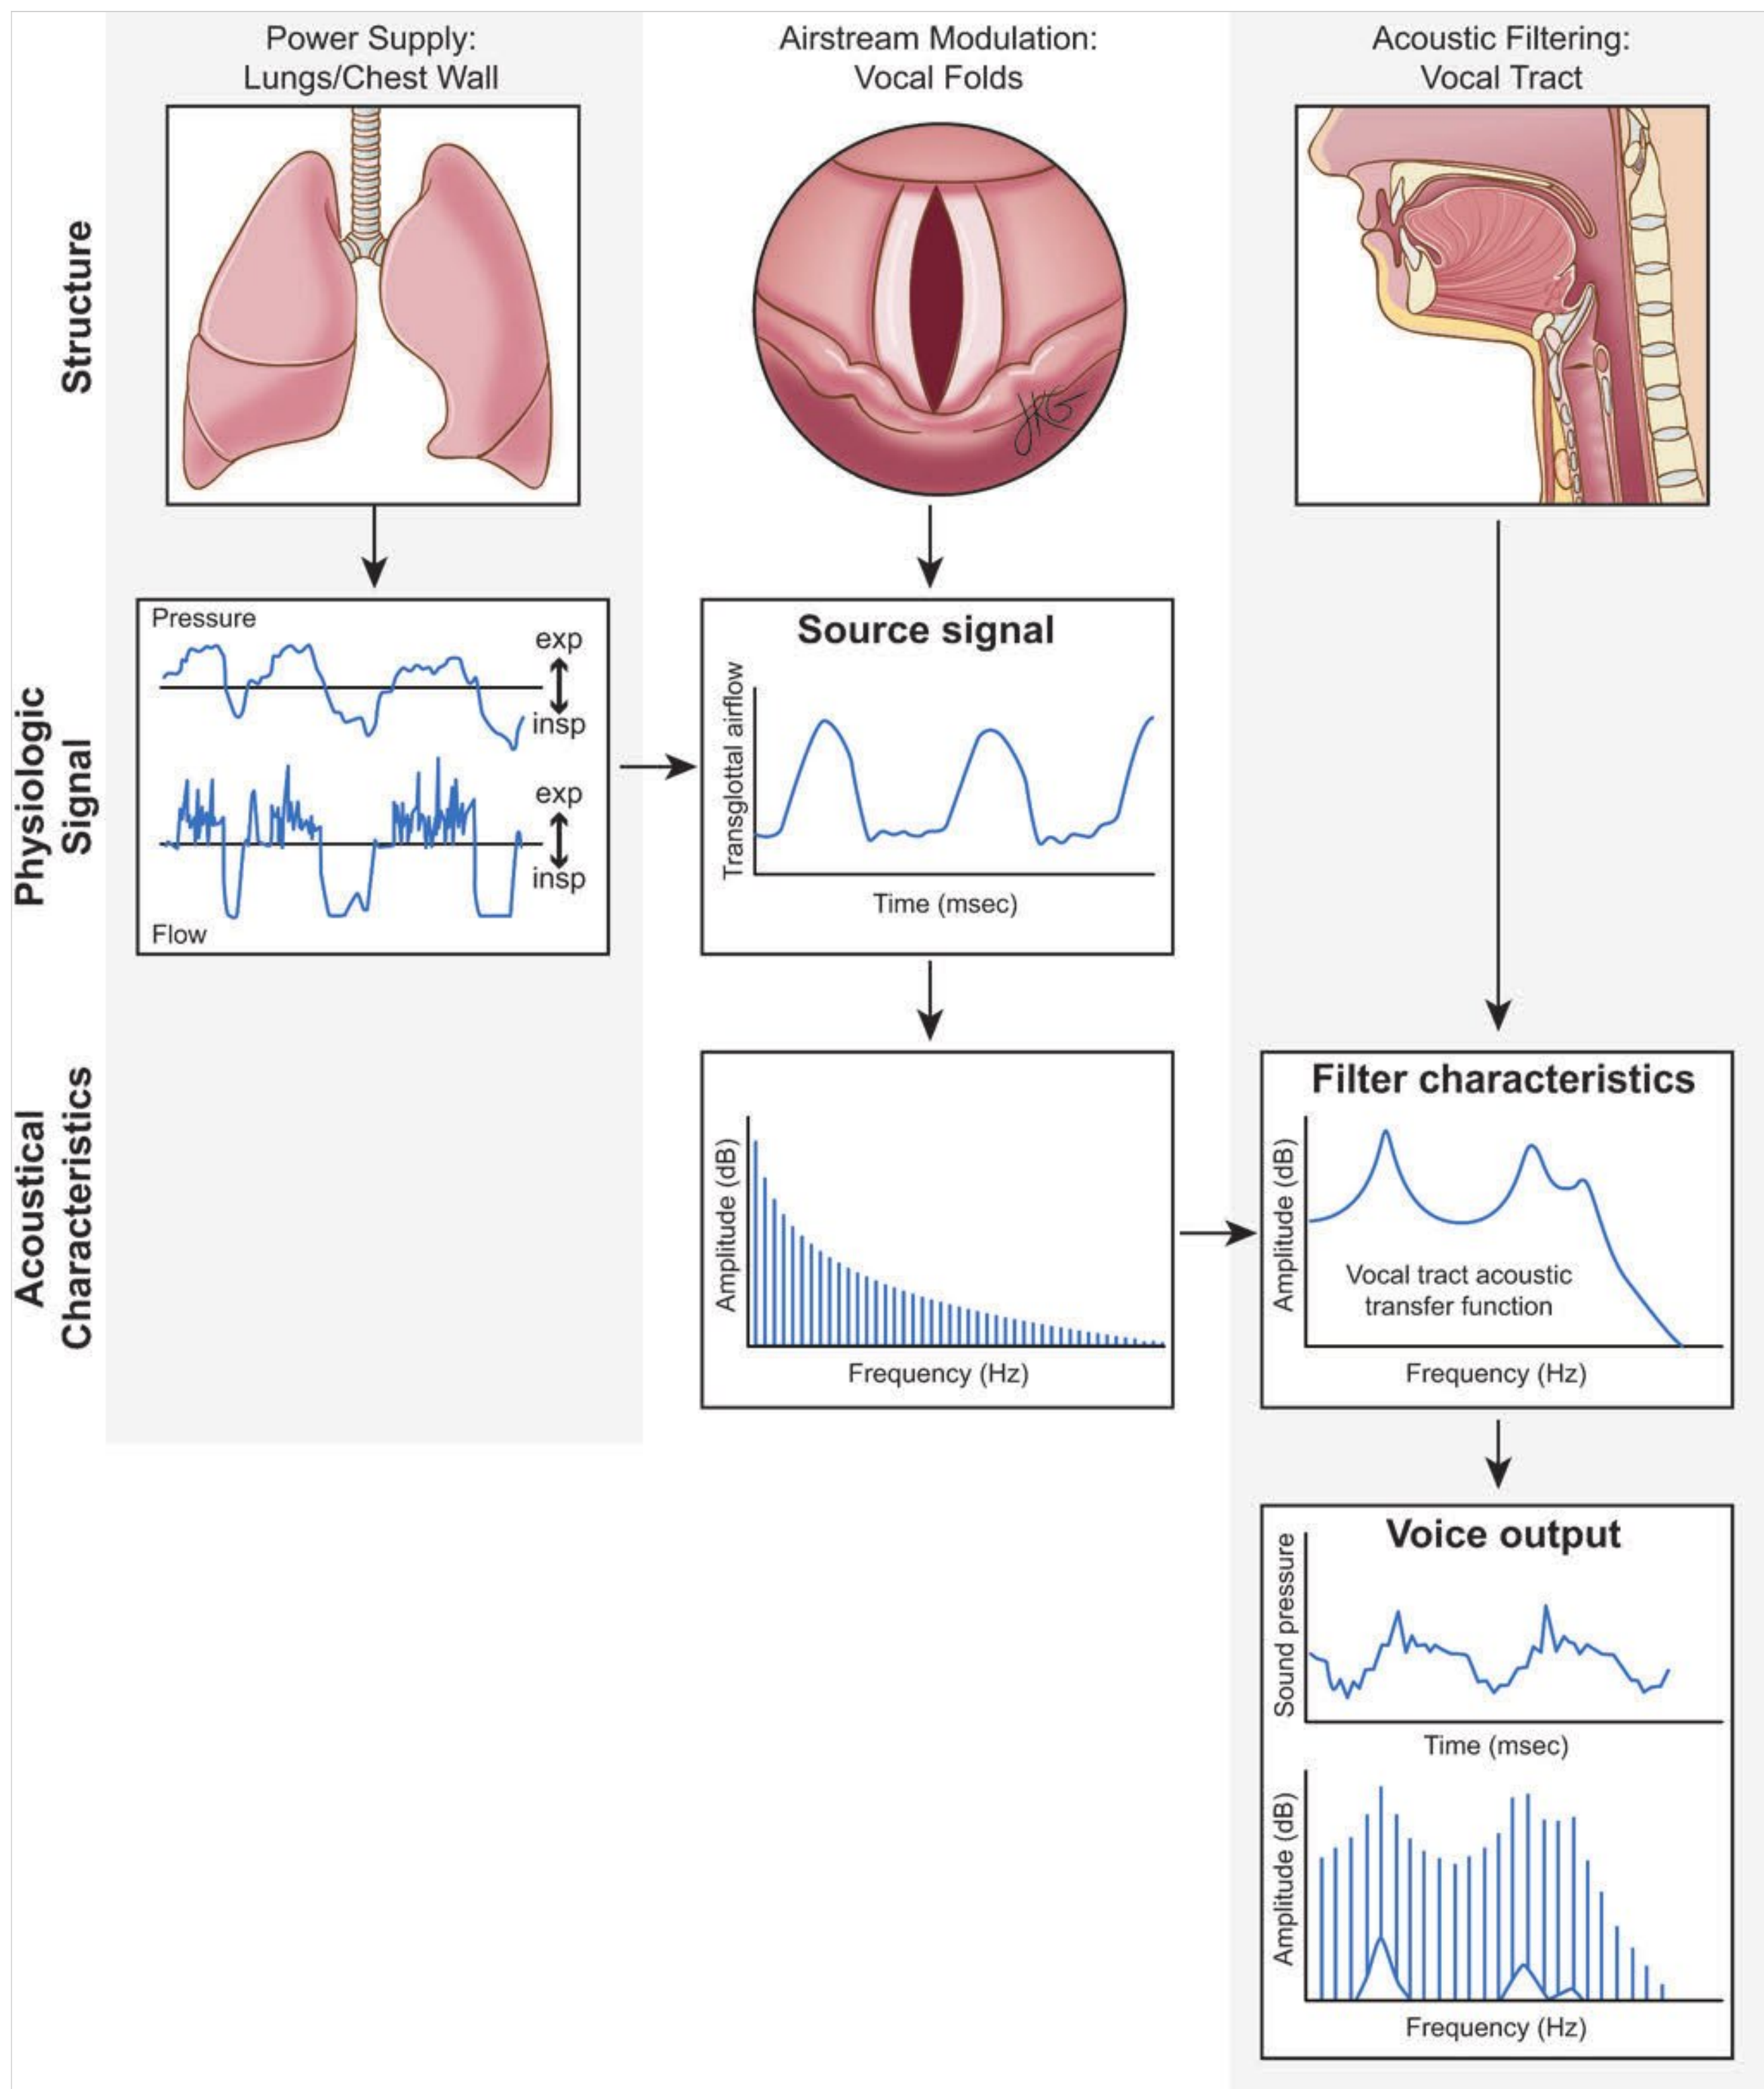

Fig. 75.1 Source-filter model of voice production. The pulmonary reservoir of air provides the power supply, while the airstream is modulated at the vocal fold level to produce a fundamental frequency and harmonics. These frequencies are modulated in the vocal tract.

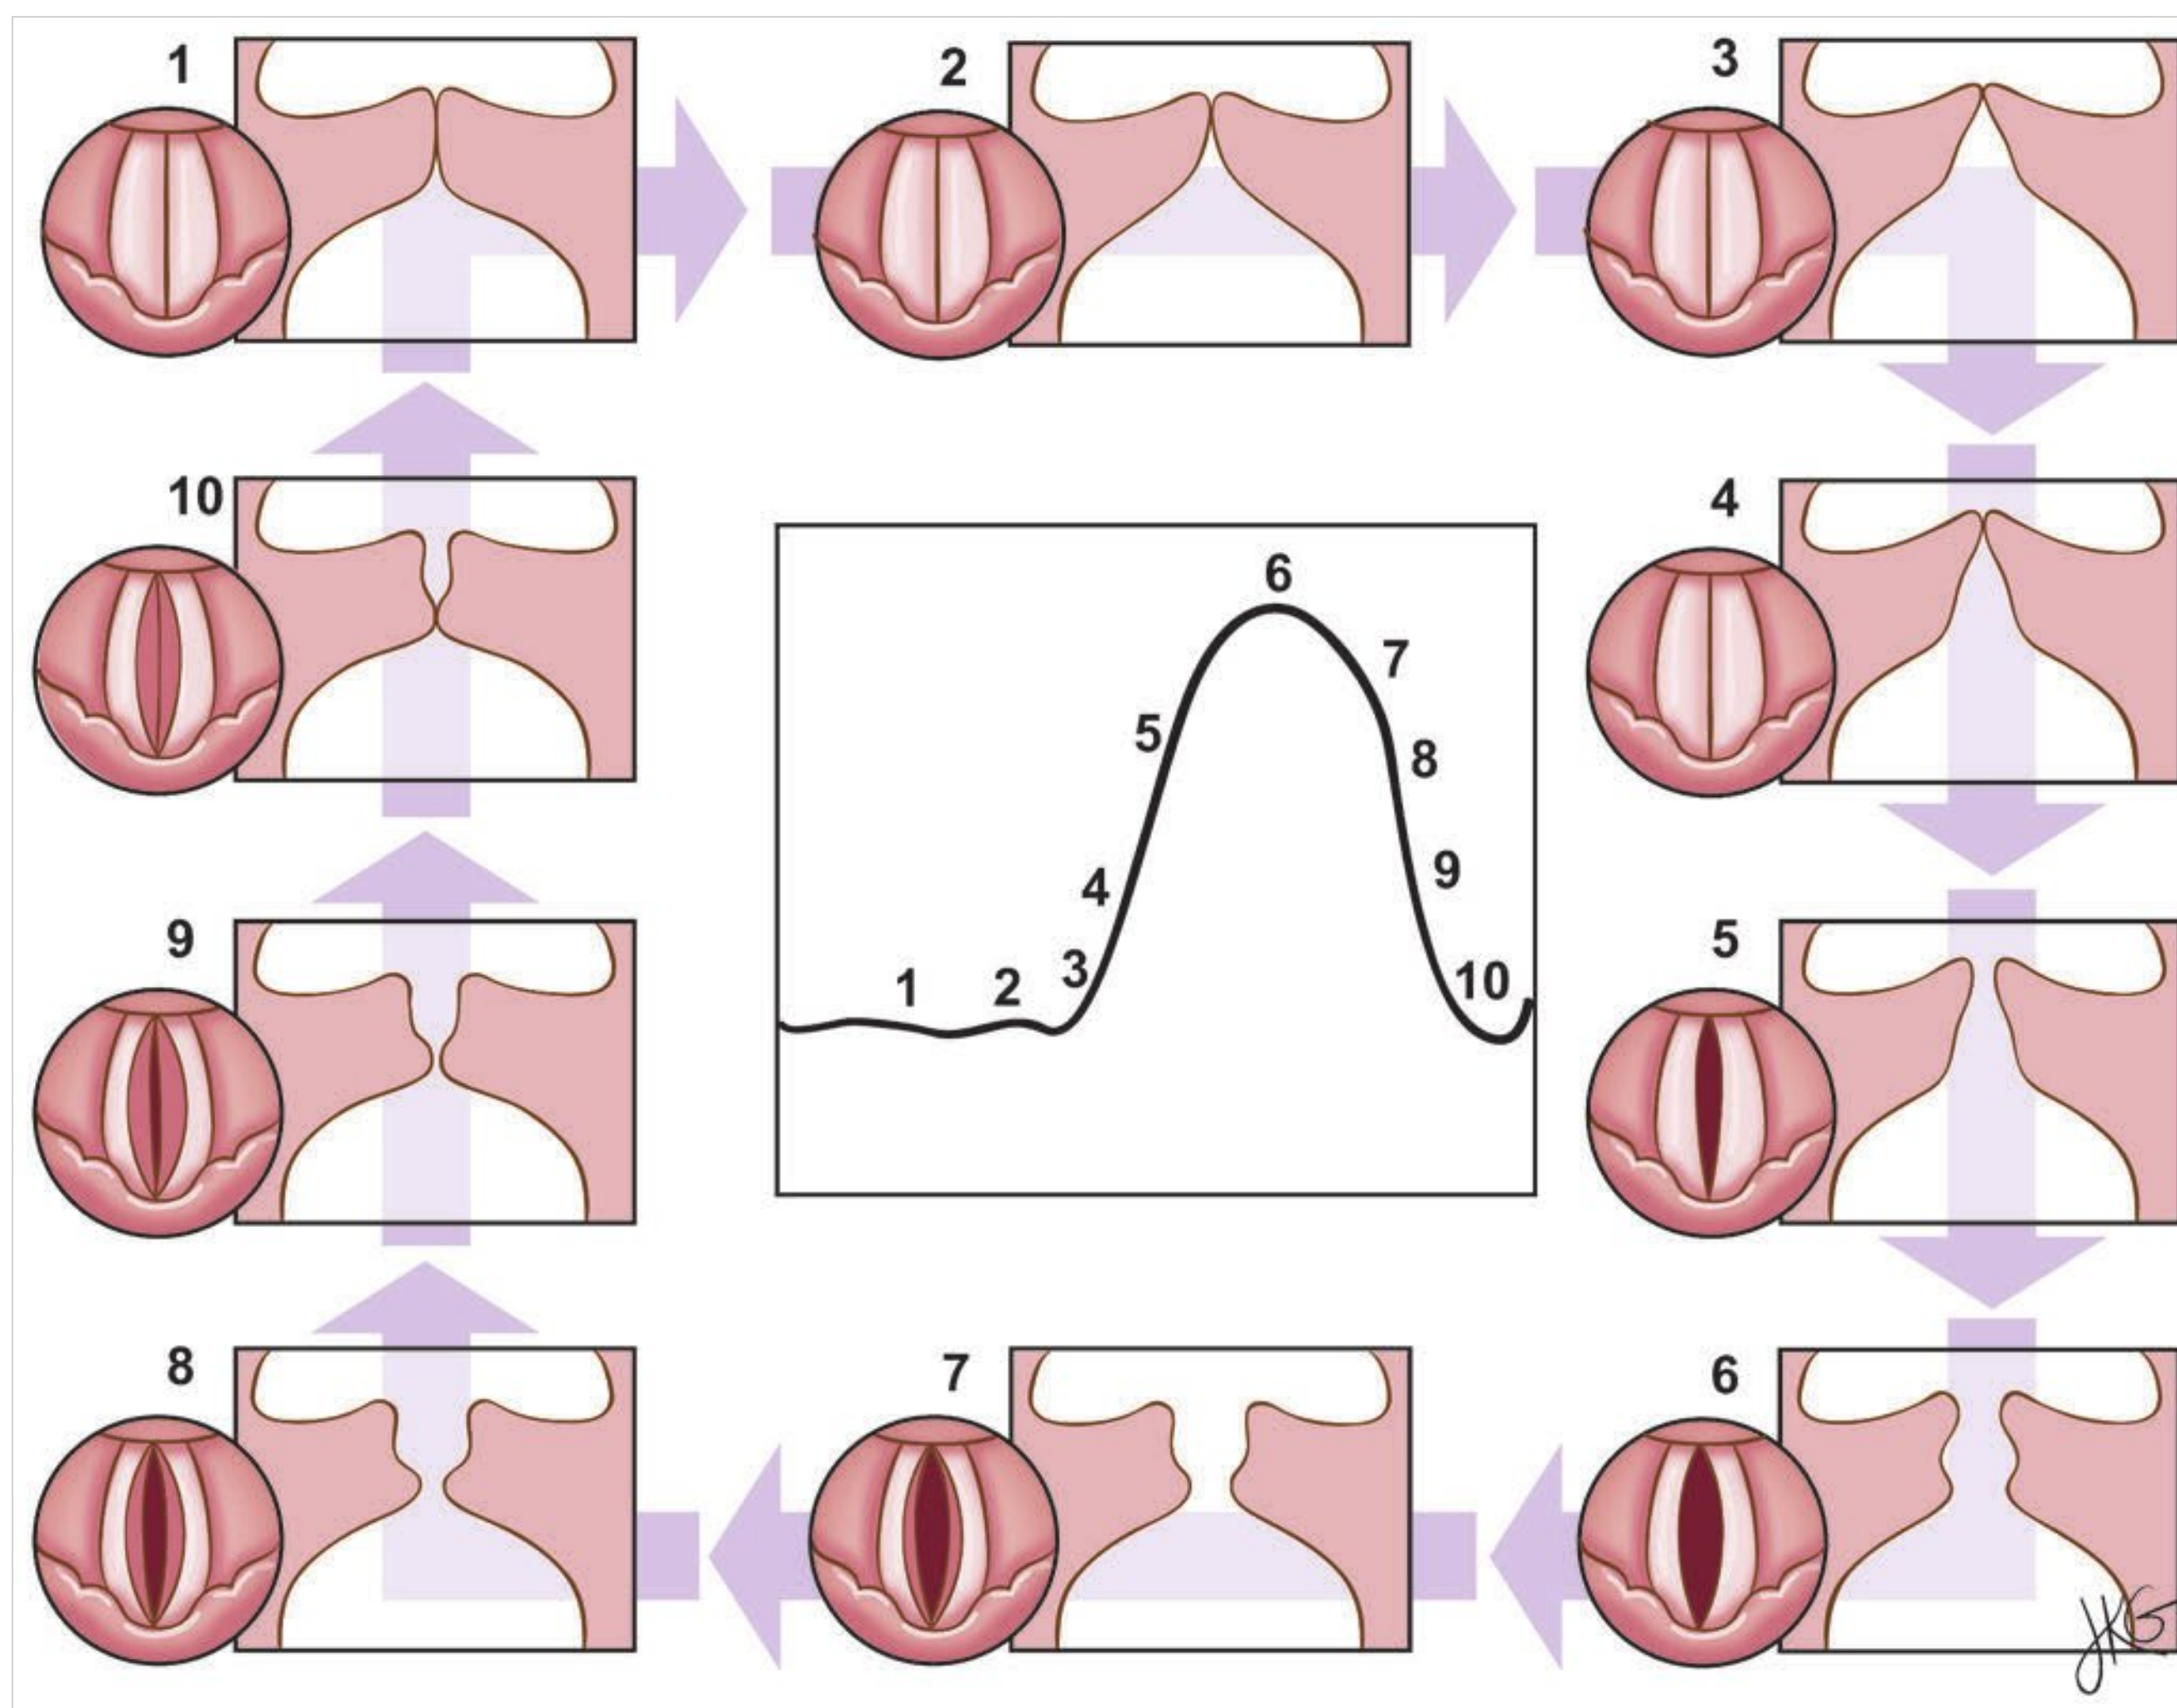

Fig. 75.2 The figures represent the position and contours of the vocal folds in coronal section and from above (insets) throughout the vocal fold vibratory cycle. The inner graph depicts airflow over time. (1) Complete glottis closure. (2) Opening of the lower border of the vocal folds. (3, 4) Progressive opening of the vocal folds. (5) Opening of the top and bottom of the vocal folds. (6) Complete opening of the glottis. (7–9) Closure of the lower border of the vocal folds. (10) Complete closure of the lower border and partial closure of the upper border of the vocal folds.

gists' expectations. Clinical pronouncements about "optimal" breathing patterns for speech, or about the role of ventilatory behavior in most instances of voice disorder, are almost always without empiric or even theoretical foundation and should be viewed with significant skepticism.

75.3 Phonation: Generating the Vocal Source Signal

The modern understanding of source signal production is referred to as the myoelastic–aerodynamic theory of phonation. It holds that the oscillation of the vocal folds is not due to the active rhythmic contraction of muscle fibers, as earlier models had posited, but is rather a passive result of the action of static and dynamic air pressures acting on the vocal folds, whose response is a function of their three-dimensional geometry and their biomechanical or rheologic properties. The aerostatic characteristics of the vocal system and the biomechanical properties of the vocal folds are, to a considerable extent, individu-

ally controllable, but they interact in complex and nonlinear ways and so are far from independent of each other. The regulation of phonation is largely a problem of controlling the trade-offs inherent in the aerodynamic–biomechanical interaction.

75.3.1 The Vocal Fold Vibratory Cycle and the Glottal Source Signal

□ Fig. 75.2 provides a thumbnail sketch of the essentials of one cycle of vocal fold oscillation for the production of a transglottal airflow pulse, which is the basis of the vocal source signal. For more details, see Chapter 74. It is assumed that a tracheal pressure adequate to power the glottal cycle has been created through appropriate ventilatory muscle action.

Initially, the vocal folds have been adducted so as to make full contact at the midline, eliminating the glottal space. Tracheal air pressure acts perpendicularly against the underside of the folds. This pressure has the effect of pushing the lower margins of the vocal folds apart. As a result, a wave of separation begins to move superiorly as the pressure continues to act to "pry" the

vocal folds away from each other. During this interval, vocal fold separation has not reached the upper surface, and so the glottis remains closed and there is no transglottal airflow. However, when the glottis opens as the upper edges of the vocal folds are finally blown apart, airflow through the glottis begins.

At this point, several features need to be considered. One is that almost all of the displacement of the vocal fold tissue is due to movement of the vocal fold cover, not the body (the thyroarytenoid muscle), which is almost always much stiffer than the combination of epithelial and connective tissue that constitutes the cover. Both structures, however, are essentially incompressible and elastic, so when they are displaced, they store energy that represents recoil forces that try to return the edges of the vocal folds to their original position. The greater the displacement from the rest position, the greater the restorative force that is generated. Hence, given the sequence of opening events, the lower edges of the vocal folds are farther from their original positions than the just recently opened upper edges, so the lower edges are subjected to significantly greater force pushing them back toward closure. Furthermore, with the release of air from the glottal space, the air pressure momentarily drops because of inertial effects. Thus, there is slightly less air pressure than previously to oppose the restorative forces.

With the opening of the glottis, another significant aerodynamic force is unleashed. The Bernoulli effect is the drop in pressure of a flowing fluid in a constriction. The vocal folds represent a narrowing in the airway, and when the glottis opens, a flow ensues. The pressure of the air in the space between the vocal folds will therefore be lower than the pressure in the trachea or in the supraglottal region. This means that the force acting to move or keep the vocal folds apart decreases when the open glottis permits airflow. In fact, it is possible for the intraglottal air pressure to be subatmospheric.

When the glottis is wide open and transglottal airflow is at a maximum, the lower margins begin to return to the midline while, thanks to momentum, the upper margins continue to

separate, widening the glottis even more. This widening reduces the amount of constriction and so diminishes the Bernoulli effect. This fact, together with the greater displacement from their rest position that the upper margins have undergone, now puts the upper edges in the same situation that the lower edges were in just before, and the top part of the glottis begins to close. Of course, back in the lower glottal region, the nearing edges increase the amount of constriction in their neighborhood, thus increasing the relatively negative Bernoulli pressure, with the effect that there is now a tendency for the lower edges to be “sucked” together. Ultimately, the lower margins contact each other, the glottis closes, and flow is cut off. Without a flow, there is no Bernoulli pressure acting on the upper edges of the vocal folds, but there is also no tracheal pressure acting on them, so the tissue recoil forces are unopposed and the upper edges, too, are returned to the midline. This restores the glottis to the initial, completely closed position and sets up the conditions for the cycle to repeat.

What this vocal fold motion has accomplished is the release of a puff of air into the vocal tract. This is a physiologic signal whose characteristic shape is shown in □ Fig. 75.1 and in the center of □ Fig. 75.2. Under ordinary circumstances, the glottal movement pattern, and therefore the release of similar puffs of air, repeats at about 110 Hz (repetitions per second) in men and roughly twice as fast, at about 220 Hz, in women. This repetition rate is the fundamental frequency (F_0) of the glottal wave and is the primary determinant of the perceived musical pitch of the voice. On the whole, higher repetition rates are heard as higher pitches, and vice versa. A brief summary of vocal fundamental frequency and its control is provided in □ Table 75.1.

All other things being equal, the amplitude of the transglottal flow pulse is directly related to the tracheal pressure, referred to as the subglottal pressure by the voice physiologist. This amplitude in turn is largely, but not solely, responsible for the sound intensity of voice or speech. Sound intensity is the main determinant of perceived loudness.

Table 75.1 Actions that change vocal F_0

Factors	Action	Related changes and effects		ΔF_0
Static control factors	↑ VF rest length			↓ F_0
	↑ VF mass			↓ F_0
	↑ Baseline stiffness of VF			↑ F_0
	↑ Subglottic pressure			↑ F_0
Dynamic control factors	Cricothyroid muscle contraction	↑ VF length	↓ VF mass per unit of surface area	↑ F_0
			↑ Stretch of VF ↑ VF cover tension	↑ F_0
	Thyroarytenoid muscle contraction	↑ Stiffness of VF body		↑ F_0

Abbreviation: VF, vocal fold.

Table 75.1b Expected ranges of vocal F_0

Register	Female	Male
Modal	140–540 Hz	75–460 Hz
Loft (“falsetto”)	500–1,100 Hz	275– 640 Hz

Fig. 75.3 Vocal fold characteristics of three vocal registers.

75.4 Acoustics of the Source Signal and Vocal Tract

The source signal produced by vocal fold oscillation is a nearly periodic wave train, meaning that it is a train of almost identical waves (see □ Fig. 75.1). Because it is periodic, the source signal is composed of a series of harmonics: sine waves at integer multiples of the fundamental frequency. The source signal can thus be represented, as it is in □ Fig. 75.1 under the heading “Airstream Modulation,” either as a plot of airflow over time (upper plot) or as a series of sine waves of different amplitudes over frequency, which is referred to as a spectrum (lower graph). Thus, one can conceptualize the source signal not as a series of puffs of air but as a “bundle” of related frequencies injected into the bottom of the upper airway. An excellent and valid analogy is the way in which a trumpeter or other brass instrument player produces a series of air pulses by lip vibration into the instrument’s mouthpiece. These air pulses, being nearly periodic, also inject a series of harmonic frequencies into the proximal end of the instrument’s tube.

The vocal tract has acoustic properties determined by its length and shape, as does the tube of a trumpet. Some of the harmonic frequencies pass through the tract or tube relatively

undiminished, while others are more or less attenuated. In short, the tract behaves as a complex acoustic filter. It is possible to plot the filter characteristics of the tract as a sort of “audiogram,” showing the attenuation effect of the vocal tract as a function of harmonic frequency, as has been done in □ Fig. 75.1. This plot is formally said to show the “transfer function” of the vocal tract. When the spectrum that is the product of airstream modulation is introduced into the vocal tract filter, the extent to which any given frequency is transmitted to the filter’s output at the lips is governed by the transfer function. The result, for the example of □ Fig. 75.1, is shown in the lower plot on the far right. The output spectrum now has peaks, harmonics that were transmitted with relatively little attenuation, and valleys, where harmonic frequencies were more strongly attenuated. The associated sound–pressure wave of the output spectrum is shown just above it. It is this pressure wave that reaches the listener’s ear and that the listener perceives as the speaker’s voice.

75.5 Registers

The model of phonation that has been considered thus far is valid for the most common pattern of vocal fold behavior—the

mode that most speakers use most of the time. However, there are other ways in which the vocal folds may be adjusted to produce different vocal registers. Briefly, a register may be defined as a specific and reproducible mode of laryngeal action that is used over a range of contiguous frequencies to produce a consistent vocal quality. There is normally only a little overlap of register frequency ranges. (Musicians typically favor a much more complex—and less precise—definition of register that relies exclusively on perceived vocal quality. There is little agreement, and much acrimonious dispute, among different musical schools of thought about how many registers there are or what they should be called.) The physiologist recognizes three distinct vocal registers; they are schematized in □ Fig. 75.3, which emphasizes the differences, observable on endoscopic examination, in the displacement patterns of the vocal fold edges.

- Modal register, named for the statistical mode (“most common”), is the pattern of ordinary speech and is the one illustrated in □ Fig. 75.2. It employs moderate vocal fold tension, which results in somewhat rounded vocal fold edges. The glottal open phase is only somewhat longer than the closed phase. Moderate air pressure drives the system, producing vocal F_0 values in the mid frequency range (the mean F_0 of conversational speech is approximately 120 Hz for men and 210 Hz for women).
- Falsetto is an old musical term, still in common use, for the register at the highest vocal F_0 values. This register is also often referred to by the more modern term, loft register. High lung pressures are used to drive the vocal folds under very significant tension, such that the vocal folds have a knife edge configuration. The F_0 of phonation in this range is, on average, higher than approximately 275 Hz in men and approximately 500 Hz in women. The oscillatory pattern of the vocal folds is more sinusoidal in this register, and quite often no glottal closure occurs.
- Pulse register, also known, especially in the older literature, as glottal fry, occupies the F_0 range below approximately 30 Hz. It is not uncommon for individual glottal pulses to be sepa-

rately perceptible. There may be a complete absence of tensioning; the vocal folds are floppy and blunt-edged, and the driving pressure is correspondingly low. Relatively brief glottal openings are followed by very long closed periods. Characteristically, vocal fold oscillation is only marginally periodic. A common but not essential feature of pulse register phonation is a “dichrotic” oscillatory pattern, in which a small, short opening is followed immediately by a larger and longer opening. Despite its rough perceptual quality, and notwithstanding its very poor periodicity, pulse register phonation is not inherently indicative of pathology, nor (long-standing clinical biases notwithstanding) is it injurious to the larynx.

75.6 Roundsmanship

- Both source and filter affect the human voice.
- During speech, inspiration as a percentage of the breathing cycle decreases from 40 to 10%
- Tracheal air pressure during speech may increase by 10 times over that during quiet breathing.
- The myoelastic–aerodynamic model of phonation states that the oscillations of the vocal fold cover, under the influence of the intrinsic laryngeal muscles, create the fundamental frequency of vocalization and its harmonics. Signal modification in the vocal tract modifies the harmonic frequencies in a specific way.

76 Pharyngeal Anatomy

Melin Tan

76.1 The Pharynx

The pharynx is a mucosa-lined musculomembranous tube that extends from the base of the skull to the lower border of the cricoid cartilage at the level of the sixth cervical vertebra, where it becomes contiguous with the esophagus (□ Fig. 76.1). It is approximately 12 to 14 cm long and communicates with the nasal, oral, and laryngeal cavities, thus creating three distinct divisions: the nasopharynx, oropharynx, and hypopharynx (□ Fig. 76.2). These three areas share the same general tubular structure of muscle and fascia lined superficially by mucosa.

The primary pharyngeal musculature is composed of three paired, overlapping constrictor muscles known as the superior, middle, and inferior pharyngeal constrictors. Together, the pharyngeal constrictors have a common insertion into the posterior pharyngeal raphe. However, their origins are complex. The superior constrictor muscle has four parts, which arise from four different areas: (1) the medial pterygoid plate and its hamulus; (2) the pterygomandibular raphe; (3) the alveolar process of the mandible; and (4) the lateral aspect of the tongue. The middle constrictor muscle arises from the hyoid bone and the stylohyoid ligament. The inferior constrictor muscle arises from the thyroid and cricoid cartilages. Superiorly, the superior constrictor muscle becomes replaced by the pharyngobasilar fascia, which attaches to the base of the skull at the pharyngeal tubercle. The gap between the superior constrictor muscle and the skull base is called the sinus of Morgagni.

The circular fibers of the constrictors surround the longitudinally running fibers of the palatopharyngeus, salpingopharyngeus, and stylopharyngeus muscles. These three muscles contribute to the movement of the pharyngeal wall. The palatopharyngeus muscle extends from the soft palate and pharyngeal wall to the thyroid cartilage, forming the substance of the posterior tonsillar pillar. It acts to elevate the pharynx and close off the nasopharynx during swallowing. The salpingopharyngeus muscle extends from the eustachian tube cartilage to interdigitate with the palatopharyngeus and acts to raise the pharynx and open the eustachian tube orifice during swallowing. The stylopharyngeus muscle originates at the styloid process, passes between the external and internal carotid arteries, and inserts on the superior posterior border of the thyroid cartilage; some fibers intermingle with the constrictor muscles. Like the salpingopharyngeus and the palatopharyngeus, it acts to elevate the pharynx, but it also minimally dilates the pharynx.

Two fascial layers envelope the muscular layers of the pharynx. The fibrous pharyngobasilar fascia begins at the pharyngeal tubercle of the skull base and extends inferiorly into the superior constrictor muscle. It sits between the skull base and the pharynx and helps to support the rigid structure of the nasopharynx. It thickens at the level of the tonsils and forms a fibrous tonsillar bed before becoming less recognizable at the lower part of the pharynx, where it eventually disappears. The buccopharyngeal (visceral) fascia is contiguous with the internal layer of the deep cervical fascia. Directly posterior to the buccopharyngeal fascia is the retropharyngeal space, which is contained by the alar fascia and communi-

cates with the mediastinum. Posterior to this fascia is the prevertebral space; this extends to the sacrum and then the prevertebral fascia, which envelopes the prevertebral muscles. These layers are particularly important in the spread of infection and malignancy. Their separation also allows the free movement of the pharynx against the vertebral structures during swallowing.

The mucosal lining of the pharynx is a nonkeratinized stratified squamous epithelium. The posterior nasopharynx is distinct in that anteriorly, the mucosal lining is a ciliated, pseudostratified respiratory epithelium. This is consistent with the dominant respiratory epithelial lining of the nose. Posteriorly within the nasopharynx, the respiratory epithelium changes to nonkeratinized stratified squamous epithelium, which extends inferiorly to the rest of the pharynx.

The nerve supply to the pharynx is derived from the pharyngeal plexus, which is formed by the pharyngeal branches of the glossopharyngeal and vagus nerves, with lesser contributions from the superior cervical sympathetic ganglion. The vagus nerve supplies motor innervation. Additionally, through the auricular branch (Arnold nerve), the vagus may carry sensory information from the hypopharyngeal area that is perceived as originating in the external auditory canal and pinna. This explains the referred pain experienced by some patients with lesions in the hypopharynx. Sensory information otherwise travels along the glossopharyngeal nerve and the internal laryngeal branch of the superior laryngeal nerve.

The arterial blood supply of the pharynx comes from the major branches of the external carotid artery, including the ascending pharyngeal artery, tonsillar branches of the facial artery, and palatine branches of the maxillary artery. The primary venous drainage is via the pharyngeal veins, which then drain into the internal jugular vein. Lymphatic drainage of the pharynx is bilateral, which is important clinically in the spread and treatment of pharyngeal cancer.

76.2 Nasopharynx

The subsites of the nasopharynx are (1) the lateral walls, including the fossae of Rosenmüller and eustachian tube orifices; (2) the vault (roof); and (3) the posterior wall. The nasopharynx communicates with the nasal cavity via the choanae anteriorly. It is otherwise bound by the base of the skull superiorly and the upper surface of the soft palate inferiorly. The soft palate separates the nasopharynx from the oropharynx as it creates a narrowing in the pharynx known as the pharyngeal isthmus.

Each lateral wall is formed and supported by the margins of the superior constrictor muscle and the rigid pharyngobasilar fascia. The nasopharynx communicates with the middle ear cavity via the eustachian tube, located in the upper posterolateral wall. The torus tubarius is formed by the cartilaginous eustachian tube, the levator veli palatini muscle, and the overlying mucosa. The fossa of Rosenmüller lies just above the torus and is formed by the salpingopharyngeal fold, which extends from the torus to the posterior wall.

Fig. 76.1 (a) Posterior view of the pharynx. (b) Posterior view of the pharyngeal muscles after removal of the posterior pharyngeal wall.

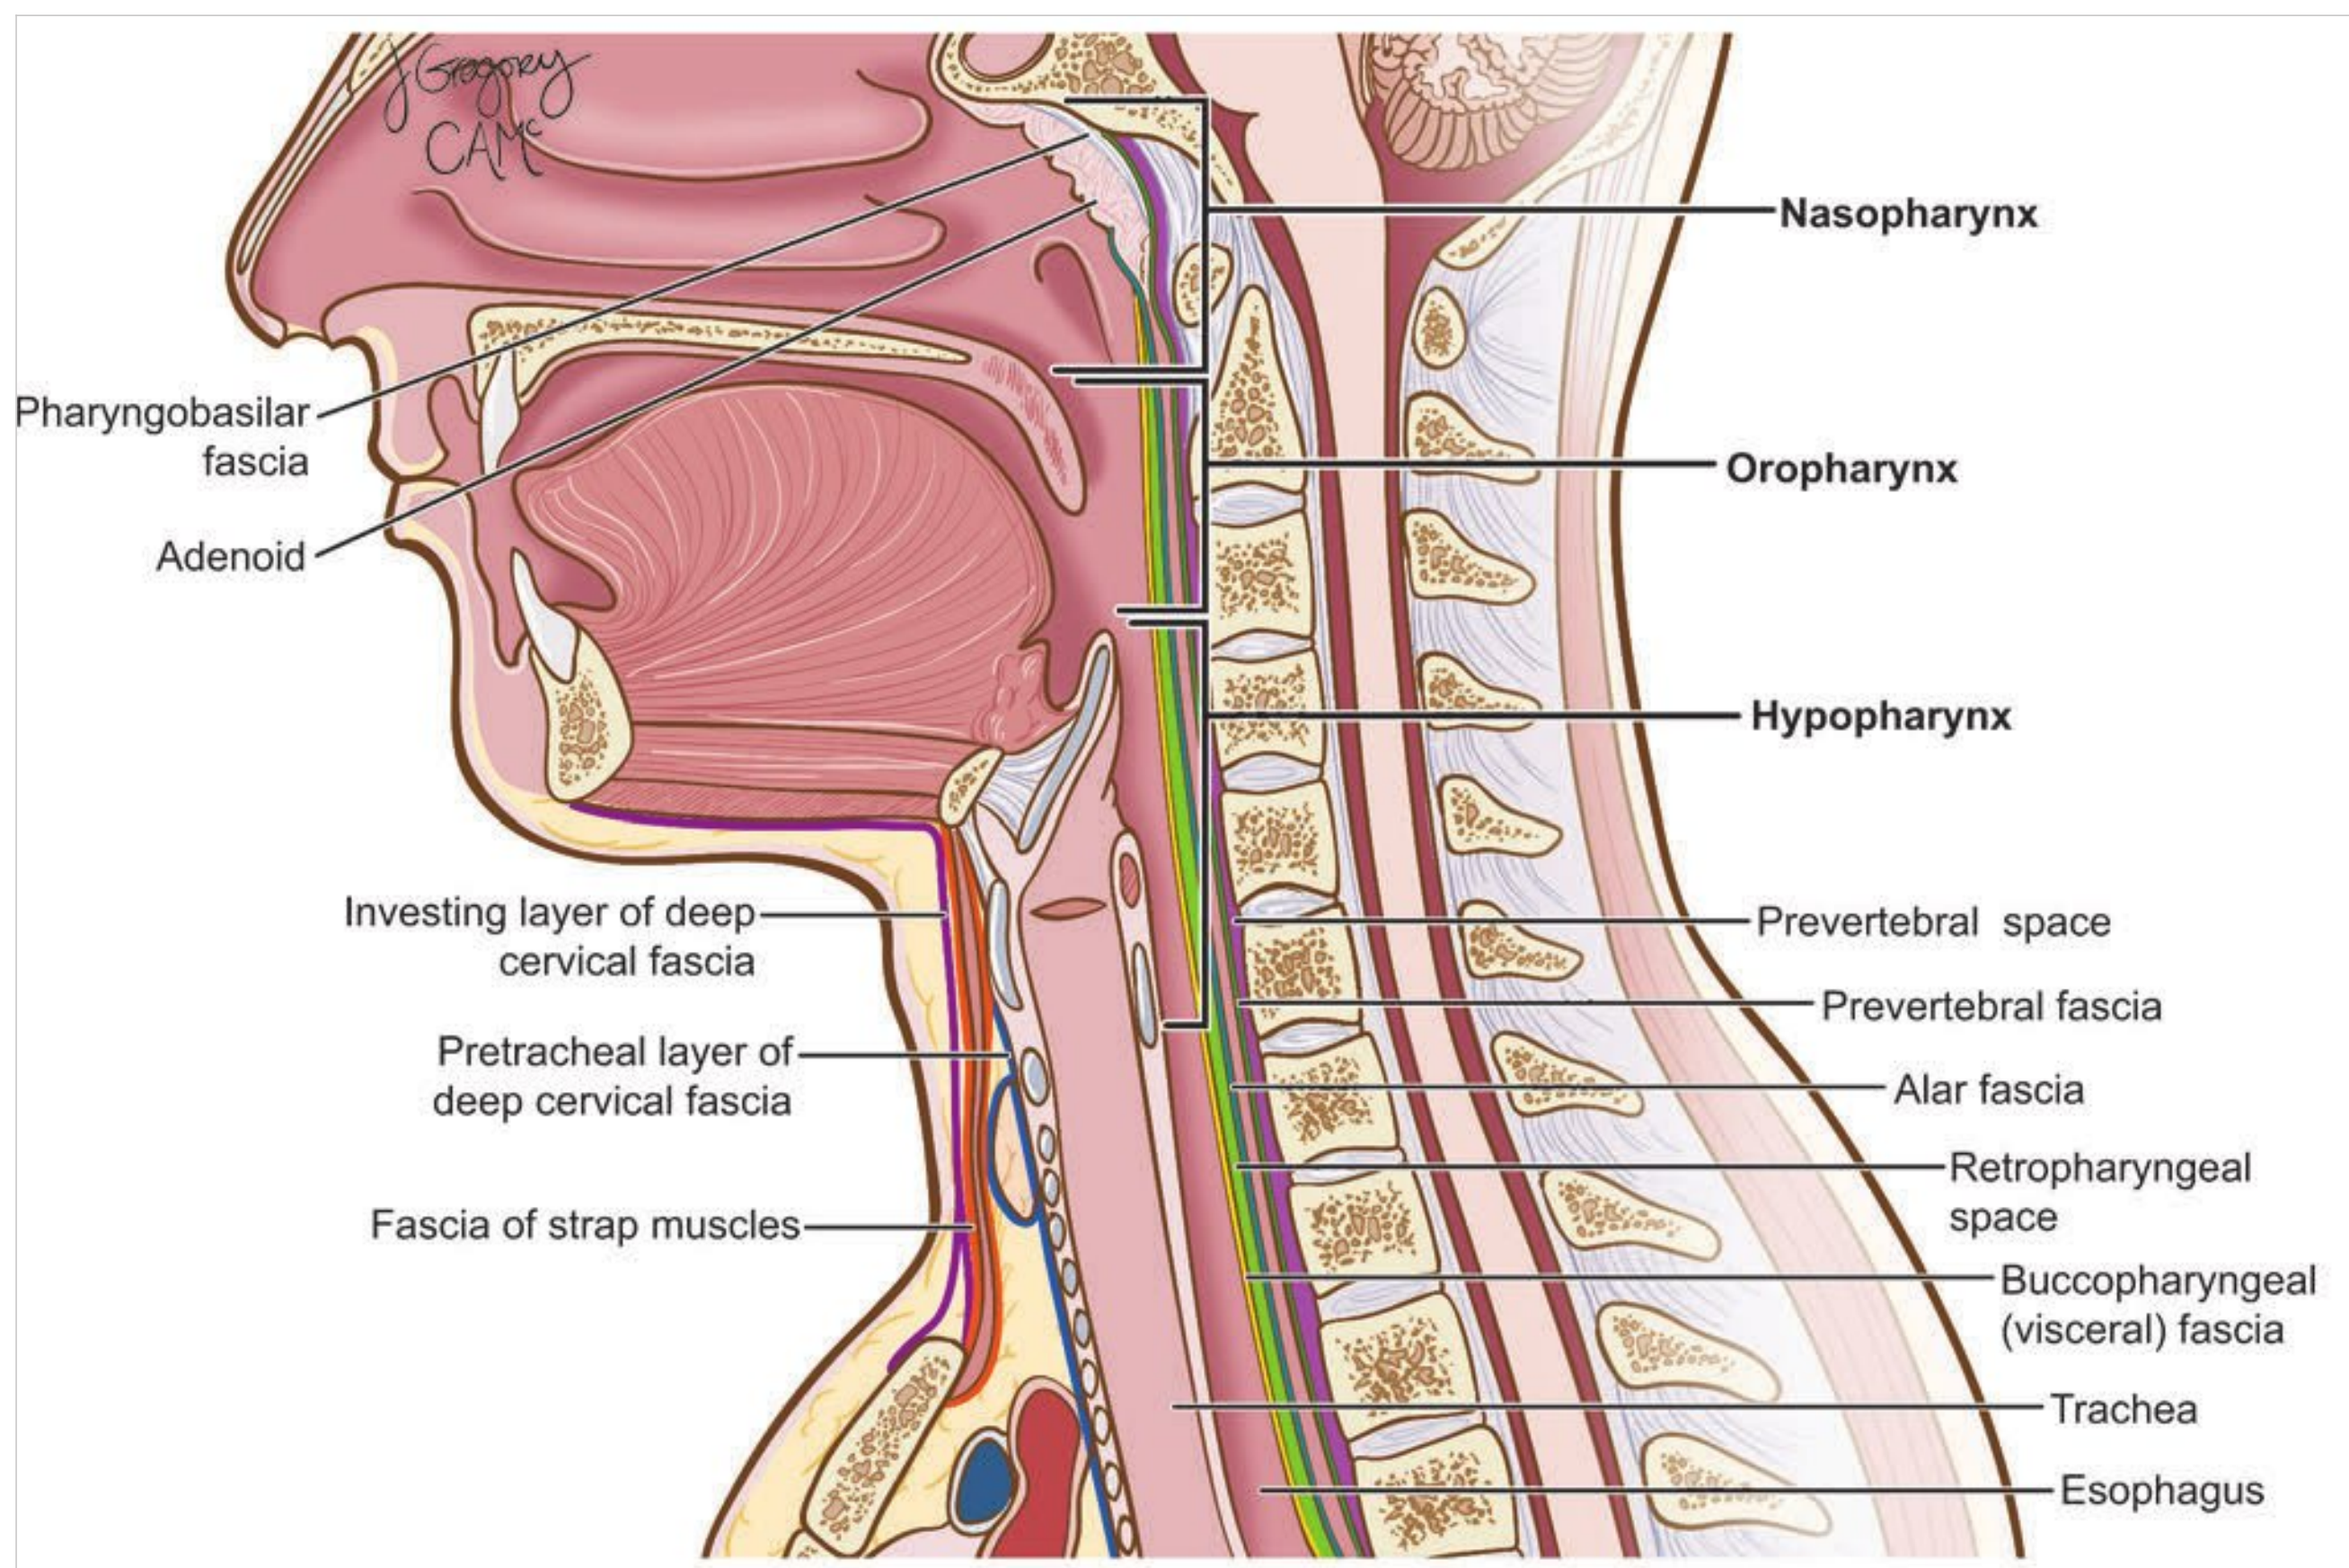

Fig. 76.2 Sagittal view of the neck and pharynx, showing important fascial layers.

The roof of the nasopharynx is created by the basisphenoid and the floor of the sphenoid sinus. Often, there is a depression in the midline of the bony roof, producing a concavity of the mucosa known as the pharyngeal bursa. Occasionally, a cystic mass, known as a Thornwaldt cyst, may be found in this area. Adenoids, or pharyngeal tonsils, are located in the midline roof of the nasopharynx, as well. They form the superior aspect of the Waldeyer ring, a loop of lymphoid tissue at the upper end of the pharynx that also includes the palatine tonsils and lingual tonsils.

Posteriorly, the buccopharyngeal fascia separates the nasopharynx from the deep fascial spaces and is thought to be a barrier to the deep spread of infection and early malignancy. The primary nodal drainage of the nasopharynx is via the retropharyngeal nodes; however, the lymphatic pathways are thought to become obliterated by adulthood as a result of the numerous pharyngeal infections that occur in childhood. Therefore, nasopharyngeal cancers often drain to second-order nodes in levels II, III, and occasionally IV.

76.3 Oropharynx

The oropharynx is the part of the pharynx that communicates with the oral cavity. It extends from the junction of the soft palate and hard palate superiorly to the vallecula inferiorly and the circumvallate papillae anteriorly. The subsites of the oropharynx are (1) the soft palate; (2) the base of the tongue;

(3) the palatine tonsils; and (4) the lateral and posterior pharyngeal wall.

The soft palate plays an important role in separating the nasal cavity from the rest of the aerodigestive tract during speech and swallowing. It remains flaccid during respiration and elevates during deglutition to block communication between the nasal and oral cavities. The Passavant muscle is composed of fibers that arise laterally from the palatopharyngeus muscle and the posterolateral hard palate. When the fibers contract, they raise a ridge of soft tissue known as the Passavant ridge. This ridge opposes the elevated soft palate, thereby closing off the nasopharynx during swallowing. This function is also critical for preventing hypernasal speech.

The base of the tongue is the area of the tongue that is posterior to the circumvallate papillae. It plays a critical role in swallowing by propelling the food bolus into the hypopharynx.

The palatine tonsils are contained in the tonsillar fossa between the anterior and posterior faucial arches. The anterior arch, the glossopalatine fold, is formed by the palatoglossus muscle and its overlying mucosa. The posterior arch is formed by the palatopharyngeus muscle and its overlying mucosa. Deep to the tonsillar fossa are the superior pharyngeal constrictor muscles and the upper fibers of the middle constrictor muscles.

The primary lymphatic drainage of the oropharynx is to level II and level III nodes, the retropharyngeal nodes, and less commonly level V nodes. The palatine tonsils may also drain to the parotid nodes.

76.4 Hypopharynx

The hypopharynx extends from the tip of the epiglottis superiorly to the cricoid cartilage inferiorly, where it empties into the cervical esophagus. It abuts the larynx and is delineated from the oropharynx by the lateral glossoepiglottic folds, which, together with the medial glossoepiglottic folds, form the vallecula. The subsites of the hypopharynx are (1) the piriform sinuses; (2) the posterior pharyngeal wall; and (3) the postcricoid mucosa.

The piriform sinuses are mucosal recesses on either side of the laryngeal inlet. They are bounded by the inner surface of the thyrohyoid membrane, the thyroid cartilage, and the lateral surface of the aryepiglottic fold.

The posterior pharyngeal wall of the hypopharynx is the inferior continuation of the posterior wall of the oropharynx. The landmark between the two is the hyoid bone. The posterior cricoid region is the anterior wall of the hypopharynx from the arytenoid cartilages down to the inferior border of the cricoid cartilage.

The cricopharyngeus muscle sphincter is composed of horizontal fibers that extend from one side of the cricoid cartilage to the other, separating the hypopharynx from the cervical esophagus. It is tonically contracted and relaxes in response to the presence of a food bolus in the hypopharynx, allowing food to enter the esophagus. It then contracts again to close the esophagus and prevent reflux. When it does so, it increases the intrapharyngeal pressure, causing passive dilation of the pharynx (there is no major pharyngeal dilator muscle). Between the upper border of the cricopharyngeus and the lower border of the inferior pharyngeal constrictor muscle is a small, triangular, mucosa-covered space called the Killian dehiscence. It is

through this area that a Zenker diverticulum most commonly arises.

The lymphatic drainage of the hypopharynx is directed to the jugulodigastric lymph nodes and spinal accessory chains. The piriform sinuses drain to level II and level III, and then secondarily to level V. The posterior wall of the hypopharynx drains to level II and level III nodes, as well as retropharyngeal nodes. The postcricoid lymphatics drain to levels III, IV, and VI nodes.

76.5 Roundsmanship

- The nasopharynx, oropharynx, and hypopharynx are divided into subsites for a consideration of function and oncologic factors.
- The layers of the posterior pharyngeal wall influence the spread of malignancy and infection.
- The pharyngeal constrictor muscles form a “sling” that surrounds the pharynx from the skull base to the cricopharyngeus muscle.

77 Physiology of Swallowing

Amy L. Cooper

77.1 Introduction

The term swallowing refers to the entire act of deglutition, from the placement of food in the mouth through the oral and pharyngeal stages of the swallow until entry of the material into the esophagus through the cricopharyngeus and passage onward into the stomach.

77.2 Terminology

The highly complex process of swallowing can be divided into the following four phases: oral preparatory, oral, pharyngeal, and esophageal. These phases are interrelated, and the four phases must be appropriately timed and sequenced for the swallow to be achieved successfully. Approaching the act of swallowing from this perspective has implications for the management of swallowing disorders. As an example, the source of a swallowing difficulty may not be entirely obvious or easily understood; disruption in one phase may impact another phase. In addition, treatment aimed at one phase may enhance or alter the competency of another phase. Swallowing is best understood as a combination of preprogrammed events with neural circuitry that can adapt to change if needed. Therefore, swallowing can be thought of as a programmed response to stimuli rather than a true reflex. The duration and characteristics of each phase of swallowing depend on the type and

volume of food being swallowed and on voluntary control. Swallowing occurs predictably based on the characteristics of the food swallowed and voluntary control.

77.3 Applied Anatomy

Clinicians involved in the diagnosis and treatment of swallowing disorders must be familiar with the basic anatomy of the upper aerodigestive system. Key structures include the jaw and lips anteriorly, the tongue (and its relationship to the velum and nasopharynx), the spinal column (and its relationship to the oropharynx anteriorly), the valleculae, the laryngeal inlet (and its relationship to the epiglottis and hypopharynx), the cricopharyngeus (and its relationship to the spinal column), and the closed esophagus (□ Fig. 77.1). The key muscles of the head and neck used in swallowing are illustrated in □ Fig. 77.2.

77.4 Physiologic Phases of Swallowing

77.4.1 Oral Preparatory Phase

The sensory recognition of food approaching then entering the mouth is critical before oral preparatory movements can be initiated. The oral preparatory phase includes a transfer phase,

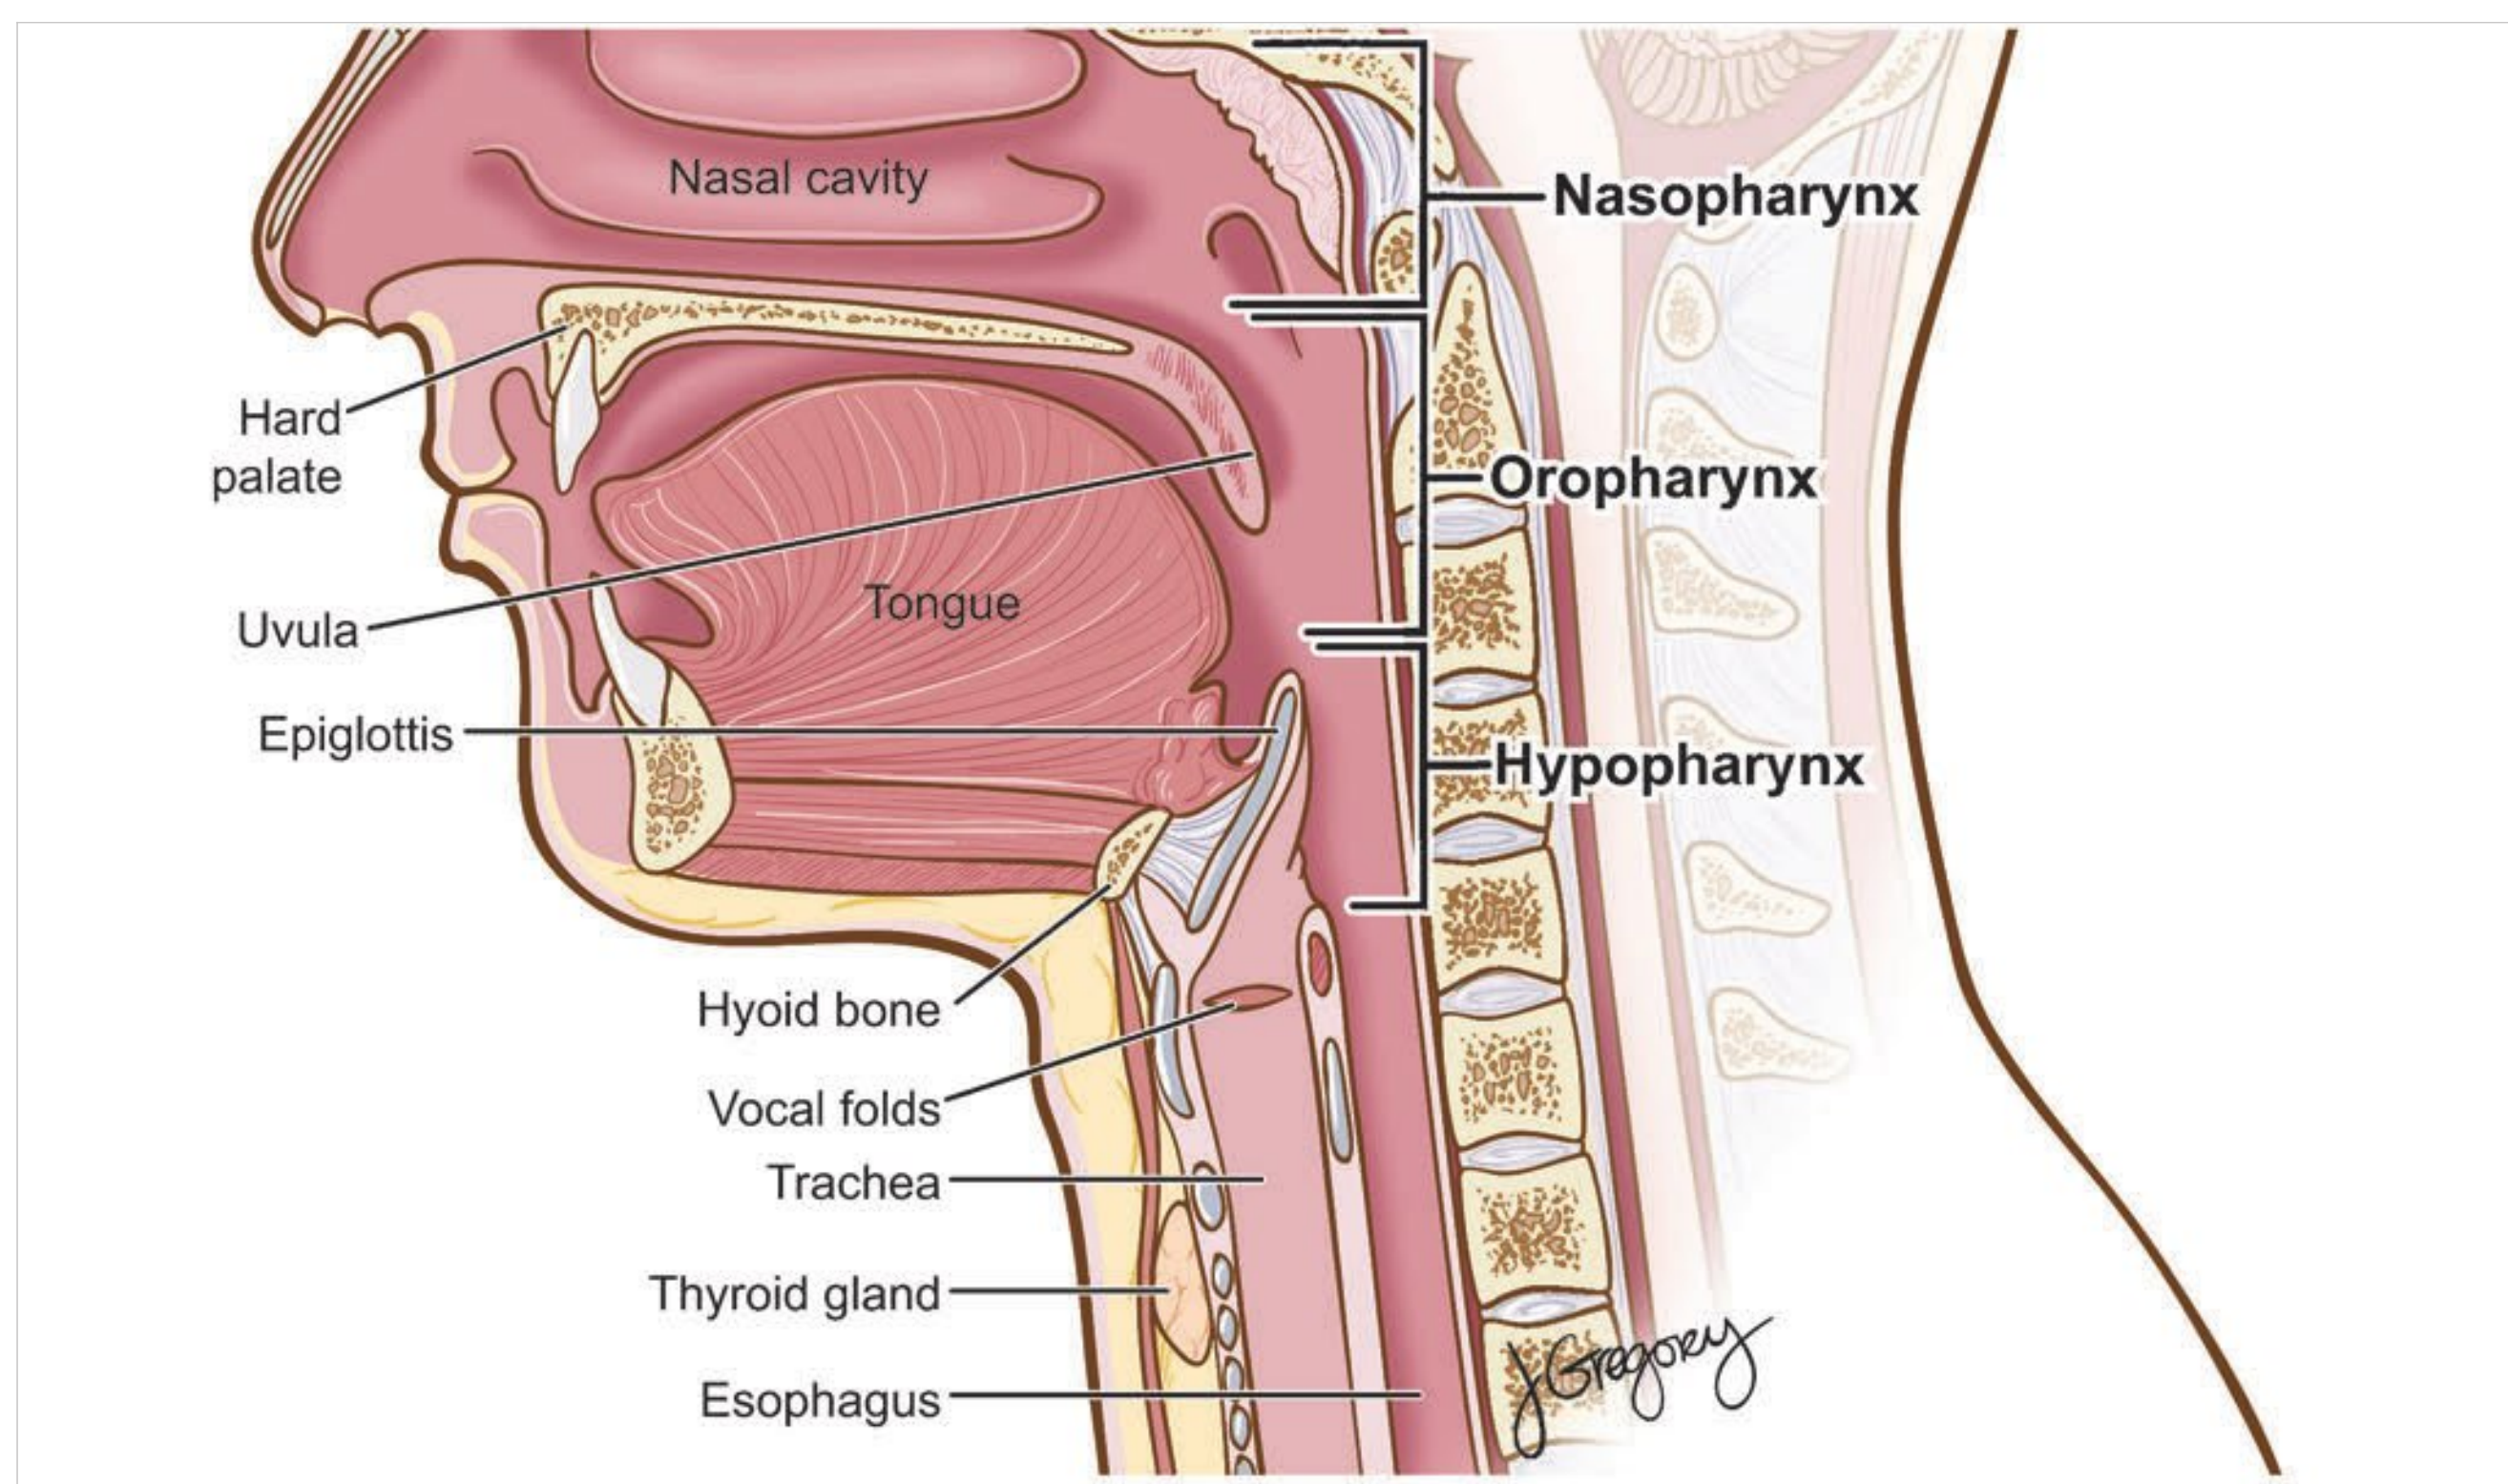

Fig. 77.1 Basic anatomy for swallowing.

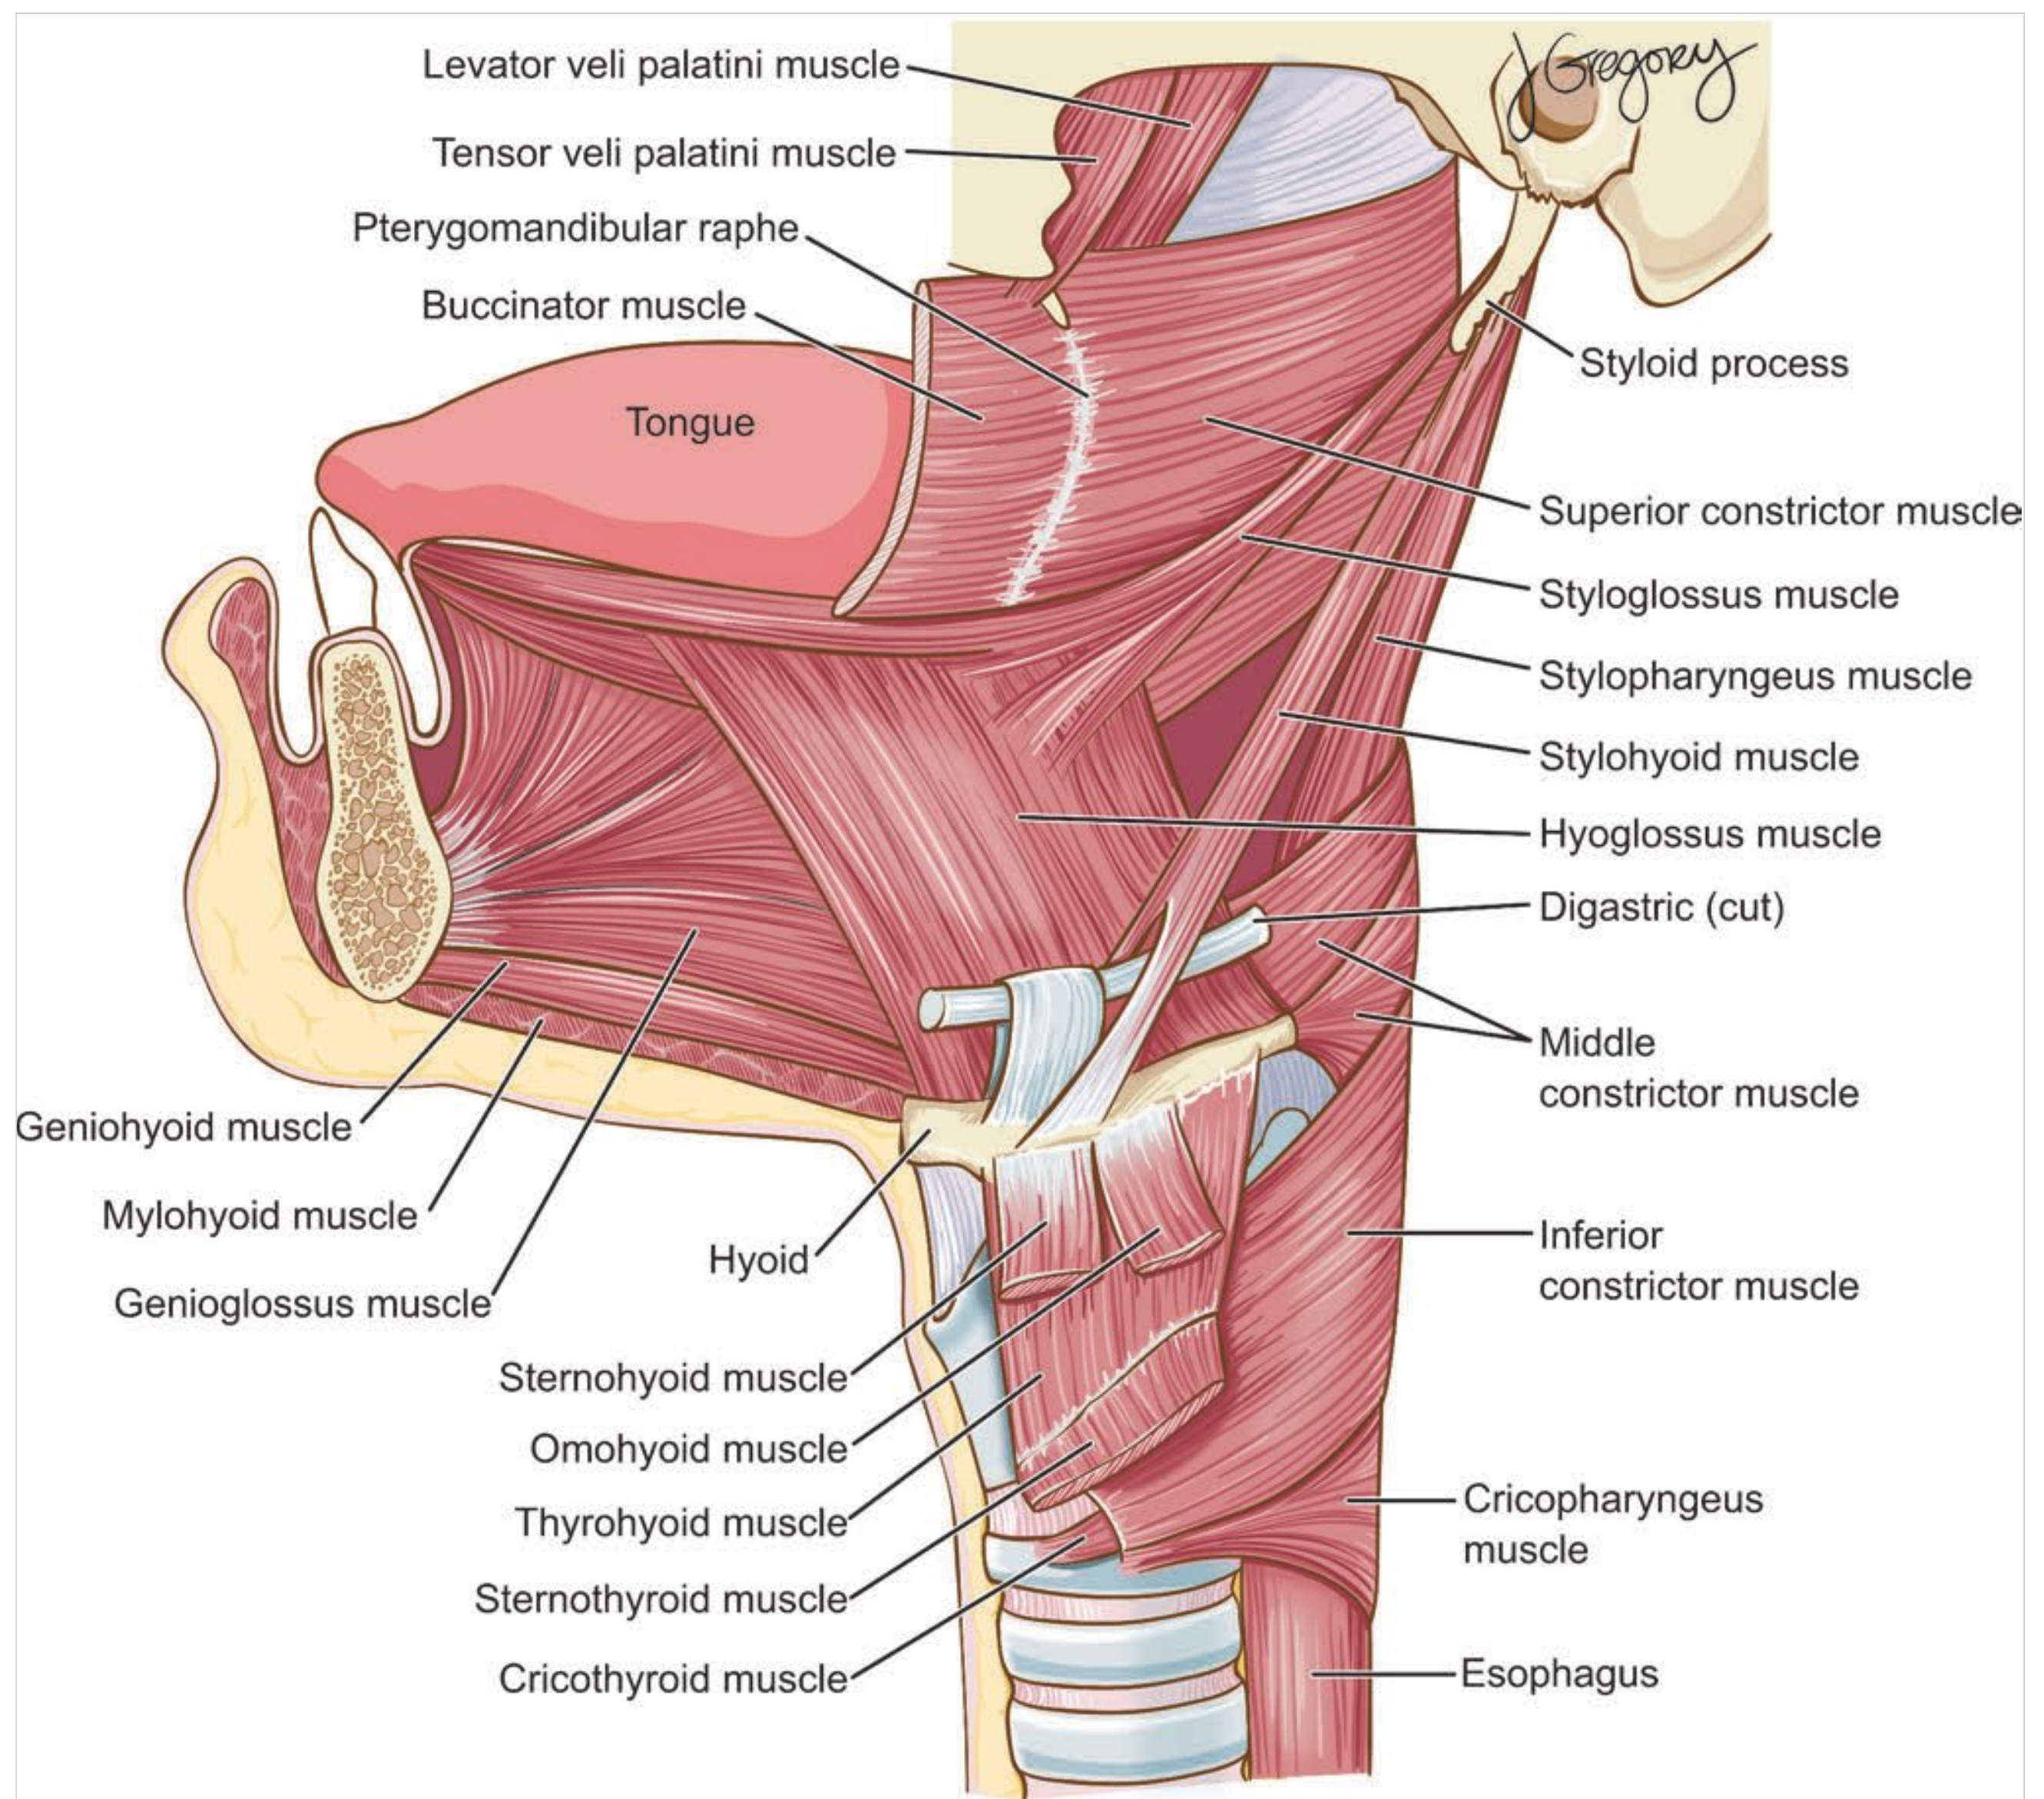

Fig. 77.2 Head and neck musculature relevant to deglutition.

during which the tongue arranges the bolus, a soft mass of food and/or liquid, and moves it posteriorly to an appropriate position for mastication (□ Fig. 77.3a). Mastication involves a rotary lateral movement of the mandible and tongue. Food is chewed, ground, and mixed with saliva to form the bolus to be swallowed. The chewing activity stimulates the salivary glands, and the bolus is lubricated for swallowing ease. Although this activity is not required for a liquid bolus, momentary containment by the tongue is necessary so that the liquid bolus does not prematurely enter the oropharynx. Taste, temperature, viscosity, and bolus size are sensed (cranial nerves V, VII, and IX), and appropriate oral manipulations are carried out to prepare for the oral phase of swallowing.

77.4.2 Oral Phase

The oral phase of a swallow is basically a delivery system and is initiated when the tongue begins to move the bolus

posteriorly (□ Fig. 77.3b). Before the swallow, the tongue (cranial nerve XII) cradles the bolus, pressing its edges against the hard palate as the swallow begins. This contact helps to prevent premature spillage into the oropharynx. When bolus preparation is complete, the bolus is positioned posteriorly on the tongue. The lips, buccal musculature, and velum work in tandem to build pressure and reduce the volume of the oral cavity, driving the bolus posteriorly. When contracted at the initiation of the swallow, the extrinsic tongue muscles (digastric, mylohyoid, and geniohyoid) enable this posterior movement. Any injury, neurologic disorder, or surgery affecting the muscles or nerves involved in the oral preparatory and oral phases of swallowing may negatively impact these phases. Decreased lip or buccal function may negatively impact the oral phase of swallowing with respect to oral containment of the bolus. Similarly, a decrease in tongue function is of concern because of reduced control and transport of the bolus.

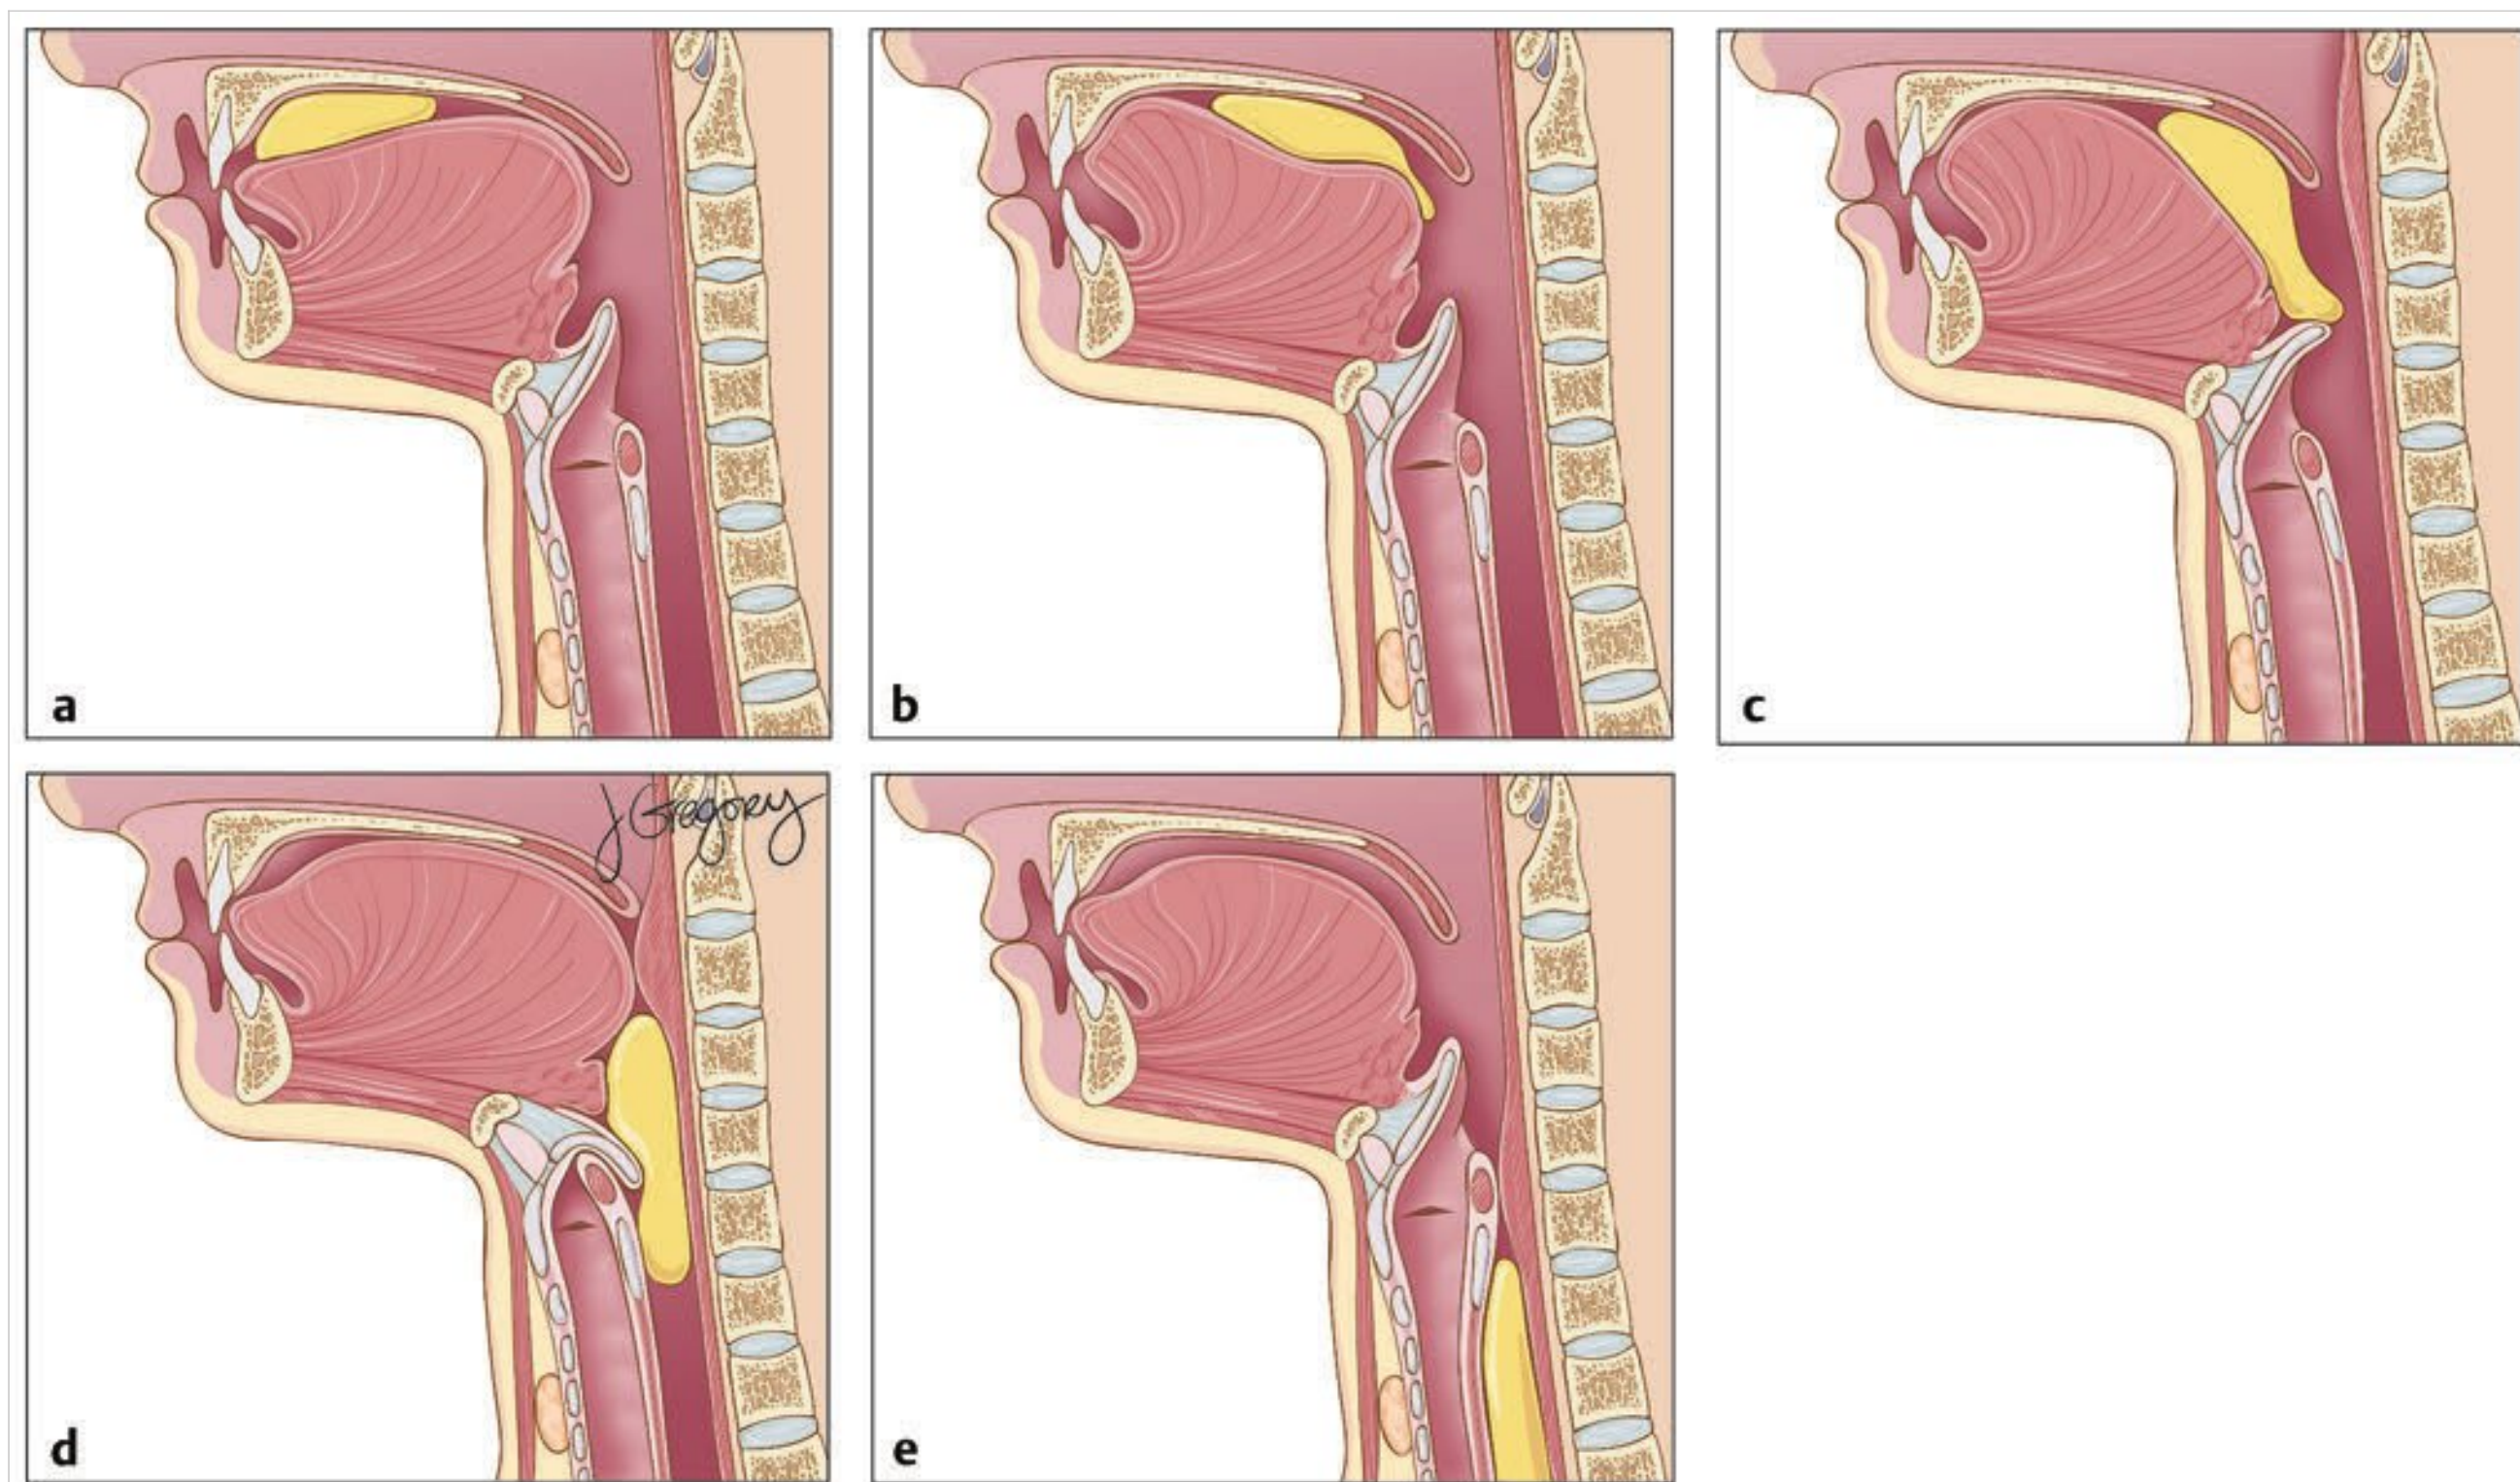

Fig. 77.3 (a–e) Phases of deglutition.

77.4.3 Pharyngeal Phase

The pharyngeal phase begins with triggering of the swallow, which should occur by the time the bolus head reaches the point where the mandible crosses the tongue base (□ Fig. 77.3c). The pharyngeal trigger involves the complex action of tongue elevation, velopharyngeal closure, laryngeal elevation, and relaxation of the cricopharyngeus. All contribute to movement of the bolus through the pharyngeal area without penetration of and/or aspiration into the airway. The pharyngeal phase of swallowing is considered to be an involuntary phase. The major anatomical landmarks for this stage include the epiglottis, valleculae and piriform sinuses, thyroid and cricoid cartilages, larynx, cervical spine, and posterior pharyngeal wall. A number of physiologic activities occur as a result of pharyngeal triggering: (1) elevation and retraction of the velum with complete closure of the velopharyngeal port to prevent material from entering the nasal cavity; (2) tongue base retraction to contact the posterior pharyngeal wall; (3) progressive contraction of the pharyngeal constrictors; (4) elevation and anterior movement of the hyoid and larynx (which help to close off the airway and stretch/open the upper esophageal sphincter); (5) closure of the larynx at the laryngeal aditus (epiglottis and aryepiglottic folds), ventricular folds, and true vocal folds to prevent material from entering the airway; (6) cricopharyngeal sphincter relaxation to allow the upper esophageal sphincter to open and permit material to pass from the pharynx into the esophagus.

77.4.4 Esophageal Phase

Esophageal transit times can be measured from when the bolus enters the esophagus at the upper esophageal sphincter (□ Fig. 77.3d) to when it passes into the stomach at the lower esophageal sphincter. This typically takes 8 to 9 seconds. The upper third of the esophagus is composed of striated and voluntary muscle tissue, the middle third is composed of a mixture of voluntary and involuntary muscle tissue, and the lower third is composed of smooth and involuntary muscle tissue. The peristaltic wave, which begins at the top of the esophagus, pushes the bolus ahead of it and continues sequentially until the lower esophageal sphincter opens to allow the bolus to enter the stomach. The opening or relaxing of the lower esophageal sphincter is referred to as descending inhibition. Primary peristalsis occurs when a swallow induces peristaltic activity, whereas in secondary peristalsis, a propagated contraction wave is initiated in the absence of a swallow. The initiation of secondary peristaltic contractions is involuntary and cannot be sensed. In the event that the bolus becomes trapped or moves more slowly than the primary peristaltic wave (as can happen when the bolus is poorly lubricated), stretch receptors in the esophageal lining are stimulated, and a local reflex response causes a secondary peristaltic wave to form around the bolus, forcing it farther down the esophagus. These secondary waves continue indefinitely until the bolus enters the stomach. Tertiary waves are often seen on barium swallow, manometry, and EGD (esophagogastroduodenoscopy) reports. They are defined

Table 77.1 Summary of cranial nerve participation in swallowing

Cranial nerve	Central nervous system	Autonomic nervous system
V: trigeminal	Sensory: touch, pressure in mouth Motor: muscles of mastication, tensor veli palatini, mylohyoid, anterior belly of digastric	None
VII: facial	Sensory: taste, anterior tongue Motor: orbicularis oris, posterior belly of digastric	Visceral motor: sublingual, submandibular glands
IX: glossopharyngeal	Sensory: taste, posterior tongue Motor: stylopharyngeus	Visceral motor: parotid gland
X: vagus	Sensory: sensation from larynx, pharynx, trachea, esophagus Motor: larynx, pharynx, esophagus	Visceral motor: smooth muscle of abdominal viscera
XI: accessory (cranial portion)	Motor: same contributions as cranial nerve X	
XII: hypoglossal	Motor: intrinsic and extrinsic tongue muscles, except for mylohyoid and anterior digastric muscles

as contractions that occur simultaneously at different levels of the esophagus. These contractions are nonperistaltic, have no known physiologic role, and are observed with increased frequency in elderly people. This phenomenon has been called presbyesophagus in radiographic descriptions.

The esophageal phase of swallowing cannot be managed with therapeutic exercises. Patients with esophageal disorders should be referred to a gastroenterologist or otolaryngologist skilled in the evaluation and treatment of esophageal dysmotility.

77.5 Neural Control of Swallowing

The neural control of swallowing entails a very complex interaction of afferent sensory neurons, motor neurons, and interneurons that control the voluntary and involuntary/reflexive actions of swallowing. The somatic and autonomic components of cranial nerves V, VII, IX, X, XI (cranial portion), and XII are active in producing a normal swallow. Cranial nerve deficits cause changes in function that range from minor to life-threatening. □ Table 77.1 provides a summary of the cranial nerves directly involved in swallowing.

77.6 Summary

Swallowing is a highly coordinated series of events involving the entire act of deglutition, from the placement of food in the

mouth through the oral and pharyngeal stages of the swallow until entry of the material into the esophagus through the cricopharyngeus and passage onward into the stomach. To effectively treat oropharyngeal swallowing disorders, the clinician must be able to define normal anatomy and physiology, as well as abnormal anatomical and physiologic features of the mechanism.

77.7 Roundsmanship

- Normal swallow consists of four distinct yet interrelated phases: oral preparatory, oral, pharyngeal, and esophageal.
- For swallow to be normal, the anatomical structures and their functions must be intact, and their actions must be appropriately timed and sequenced.

78 Voice Evaluation

Amy L. Cooper

78.1 Introduction

Abnormal voice is the product of inadequate or abnormal behavior of the vocal tract structures; an abnormal voice results from abnormal physiology. Because of structural, physiologic, acoustic, and perceptual factors, the evaluation of vocal function is a complex undertaking. In addition, the extraordinarily rapid development of both theory and technology in the past several decades has resulted in an explosive growth of evaluation techniques, many of which are as of yet unproven validity or utility in the assessment enterprise. A thorough review of the rationales, methods, and theoretical bases of vocal evaluation would require more resources than the present circumstances allow. The present purpose, therefore, is to provide a brief introduction to the rationale, methodology, and interpretation of the assessment of vocal function. A brief outline of the case history and the aerodynamic and acoustic factors pertinent to a patient's vocal function will be provided below. The physiologic significance of the phenomena discussed here was engaged in Chapter 75. Optimal diagnosis is essential in planning the therapeutic course.

78.2 Voice History

While the otolaryngologist focuses primarily on the structure of the larynx, the speech language pathologist (SLP) reports functional measures. The larynx is a dynamic structure, and a dynamic vocal assessment combining analyses of structure and function is required for the diagnosis and treatment of laryngeal disorders. The SLP begins by taking a case history incorporating aspects of the patient's medical and social history, which includes an assessment of the patient's vocal demands. The clinician provides a subjective impression of vocal quality (hoarse, breathy, harsh, aphonic, pitch breaks, tremor, diplo-

phonic, strained/strangled, glottal attack, glottal fry, vocal fatigue). These observations are used in conjunction with objective measures (acoustic, aerodynamic) that are discussed below. The behavioral assessment may also yield observations about breath patterns, including clavicular versus abdominal breathing, the presence or absence of stridor, and behaviors such as throat clearing. Additionally, rating scales, including the GRBAS Scale (see Box, below) and the CAPE-V Scale (see Box, below) can help quantify and qualify the degree of vocal aberrance. The Voice Handicap Index-10 (VHI-10; □ Table 78.1) is a questionnaire that can help define the patient's perceived disability in response to a voice disorder.

GRBAS Scale

Items are rated by the examiner on a scale of 0 (normal) to 3 (severe).

- Grade (overall severity)
- Roughness
- Breathiness
- Aesthesia (weakness)
- Strain

78.3 Acoustic Analysis

Acoustic analysis of the voice uses instrumentation to analyze the physiologically relevant properties of a sound wave. It provides measures of frequency, amplitude, disturbance (perturbation), harmonic content, noise, and other variables related to the function of the vocal tract and larynx. These measurements are intended to provide insight into the physiology, origins, and severity of dysphonia.

Table 78.1 Voice Handicap Index-10 (VHI-10)

Item	Grade
	Scale goes from 0 = never to 4 = always
My voice makes it difficult for people to hear me.	0 1 2 3 4
People have difficulty understanding me in a noisy room.	0 1 2 3 4
My voice difficulties restrict my personal and social life.	0 1 2 3 4
I feel left out of conversations because of my voice.	0 1 2 3 4
My voice problem causes me to lose income.	0 1 2 3 4
I feel as though I have to strain to produce my voice.	0 1 2 3 4
The clarity of my voice is unpredictable.	0 1 2 3 4
My voice problem upsets me.	0 1 2 3 4
My voice makes me feel handicapped.	0 1 2 3 4
People ask, "What's wrong with your voice?"	0 1 2 3 4

CAPE-V (Consensus Auditory-Perceptual Evaluation of Voice) Scale

Overall severity, roughness, breathiness, strain, pitch, and loudness are rated on a 100-mm visual analog scale. The rater places a vertical mark along each horizontal line; the far left end of the line represents least impaired status, and the far right end represents most impaired status.

Form:

Hospital #: _____ Date: _____

The following parameters of voice will be rated upon completion of the following tasks:

1. Sustained vowels /a/ and /i/ for 3 to 5 seconds' duration each.
2. Sentence production:

“The blue spot is on the key again.”

“How hard did he hit him?”

“We were away a year ago.”

“We eat eggs every Easter.”

“My mama makes lemon muffins.”

“Peter will keep at the peak.”

1. Spontaneous speech. Prompt as follows:
 - a) New patient: Tell me when your voice problem began, what you were noticing, and what you have done about it.
 - b) Return patients: Tell me what's happened with your voice since last time you were here. What treatment have you had? Did it help?

Legend:

C, consistent

I, intermittent

MI, mildly deviant

MO, moderately deviant

SE, severely deviant

Overall Severity _____ /100

78.4 Aerodynamic Assessment

Measurements of airflow are of particular importance because they describe or quantify the power supply—that is, the subglottal pressure and transglottal airflow—for phonation. When available, spirometry is used to assess lung volume and lung capacity. Essential to insight into vocal efficiency are measurements of subglottal pressure and transglottal airflow. Vocal fold vibration is initiated and maintained by a pressure differential between the subglottal and supraglottal regions. An assessment of subglottal pressure and airflow permits inferences about what is happening at the level of the glottis. Abnormally high subglottic pressure and/or glottal resistance may be a sign of vocal hyperfunction or inflammation. Increased airflow may be a sign of vocal hypofunction or vocal fold paralysis/paresis. These measures are useful in treatment planning and can be used for comparisons before and after medical and surgical intervention. □ Table 78.2 summarizes the normative data for diagnostically significant vocal characteristics and their implications with regard to physiology.

78.5 Evaluation of the Vocal Fold Contact Pattern

The movements of the vocal folds are rapid and complex, and they unfold in three dimensions, as discussed in the chapter on vocal physiology. Endoscopic techniques, including videostroboscopy, videokymography, and high-speed video recording, make it relatively easy to assess the basic features of motion at the upper surface of the vocal folds and, during the glottal open phase, to get some sense of displacements of the glottal walls. However, the way in which the vocal folds contact each other, and the displacements or disruptions that may occur during the glottal closed phase, are hidden from visual inspection. A technique known as electroglottography (EGG) offers a way of visualizing these occult events.

EGG takes advantage of the fact that most tissues, having a high electrolyte content, are fairly good electrical conductors, whereas air is an extraordinarily poor electrical conductor. If electrodes are placed on the body surface over each thyroid ala, a weak high-frequency electric current can be passed between them through the tissues of the neck. During the open phase of the glottal cycle, the electrical resistance of this pathway will be comparatively high because the vocal folds are separated by an insulating volume of air. However, as the amount of vocal fold contact increases during glottal closure, the trans-neck resistance falls, reaching a minimum when the surface area of vocal fold contact is maximal; it then rises again to a maximum when the vocal folds fully separate. The magnitude of the current through the neck is thus a parameter of the vocal fold contact area.

In □ Fig. 78.1, the normal EGG of modal register phonation by a healthy male is compared with the EGG of a female patient who has vocal nodules. The abnormality of the latter pattern is clearly apparent and shows at least one way in which a clinically significant disruption of normal vocal fold contact may manifest. The interpretation of EGG records depends on both quantitative and qualitative methods that offer deeper insight into the bases of phonatory disorder.

Table 78.2 Expected values of diagnostically significant vocal characteristics

Variable	Test item	Expected values	Units	Implication of..	
				Increase	Decrease
Power supply					
Subglottal (tracheal) pressure (P_s)	/pi/	5.4–9.7 ♀ 5.4–7.5 ♂	cm H ₂ O	Speech intensity ↑ Hyperkinetic disorder	Speech intensity ↓ Hypertonic chest wall Hypokinetic disorder

Abbreviation: ST (re 16.35 Hz), semitones relative to 16.35 Hz.

78.6 Sound Spectrography

The ability to examine the acoustic content of the speech signal over time offers a means of assessing many features of the glottal source signal, of the vocal tract filter adjustment, and of the way in which these fundamental characteristics interact. The most common form of such an examination is the sound spectrogram, in which a gray scale is used to represent the evolution over time (horizontal axis) of the intensity of the speech signal as a function of frequency (vertical axis). It is possible to change the analytic parameters of the spectrogram to optimize frequency resolution, time relationships, vocal tract filter characteristics, noise elements, and so forth. This ability to optimize the spectrogram, and so derive the enormous amount of information that is contained in the resulting record, makes spectrography of enormous diagnostic value, especially in patients with complex disorders of the phonatory system.

□ Fig. 78.2, which is the spectrographic analysis of a normal male saying “Joe took father’s shoe bench out,” gives some sense of the kinds of information that can be obtained. Each of

the vertical lines seen during the vowels, for instance, is produced by a single glottal closure that pinches off the airflow (see Chapter 75), whereas the darker horizontal bands during the vowels result from peaks resonances in the vocal tract filter function or energy at nonharmonic frequencies. This can be seen during the “sh” of shoe and the “ch” of bench. The temporal relationships of laryngeal and vocal tract adjustments are relatively easily read by a professional experienced in spectrographic analysis.

78.7 Summary

The voice history and the results of acoustic and aerodynamic testing are critical parts of the diagnostic process. The evaluation of the dynamic physiology of phonatory and nonphonatory behavior is aided not only by visualization of the larynx but also by other forms of measurable documentation of laryngeal function. Of particular interest are the insights offered by inspection of the electroglottographic signal and sound spectrogram.

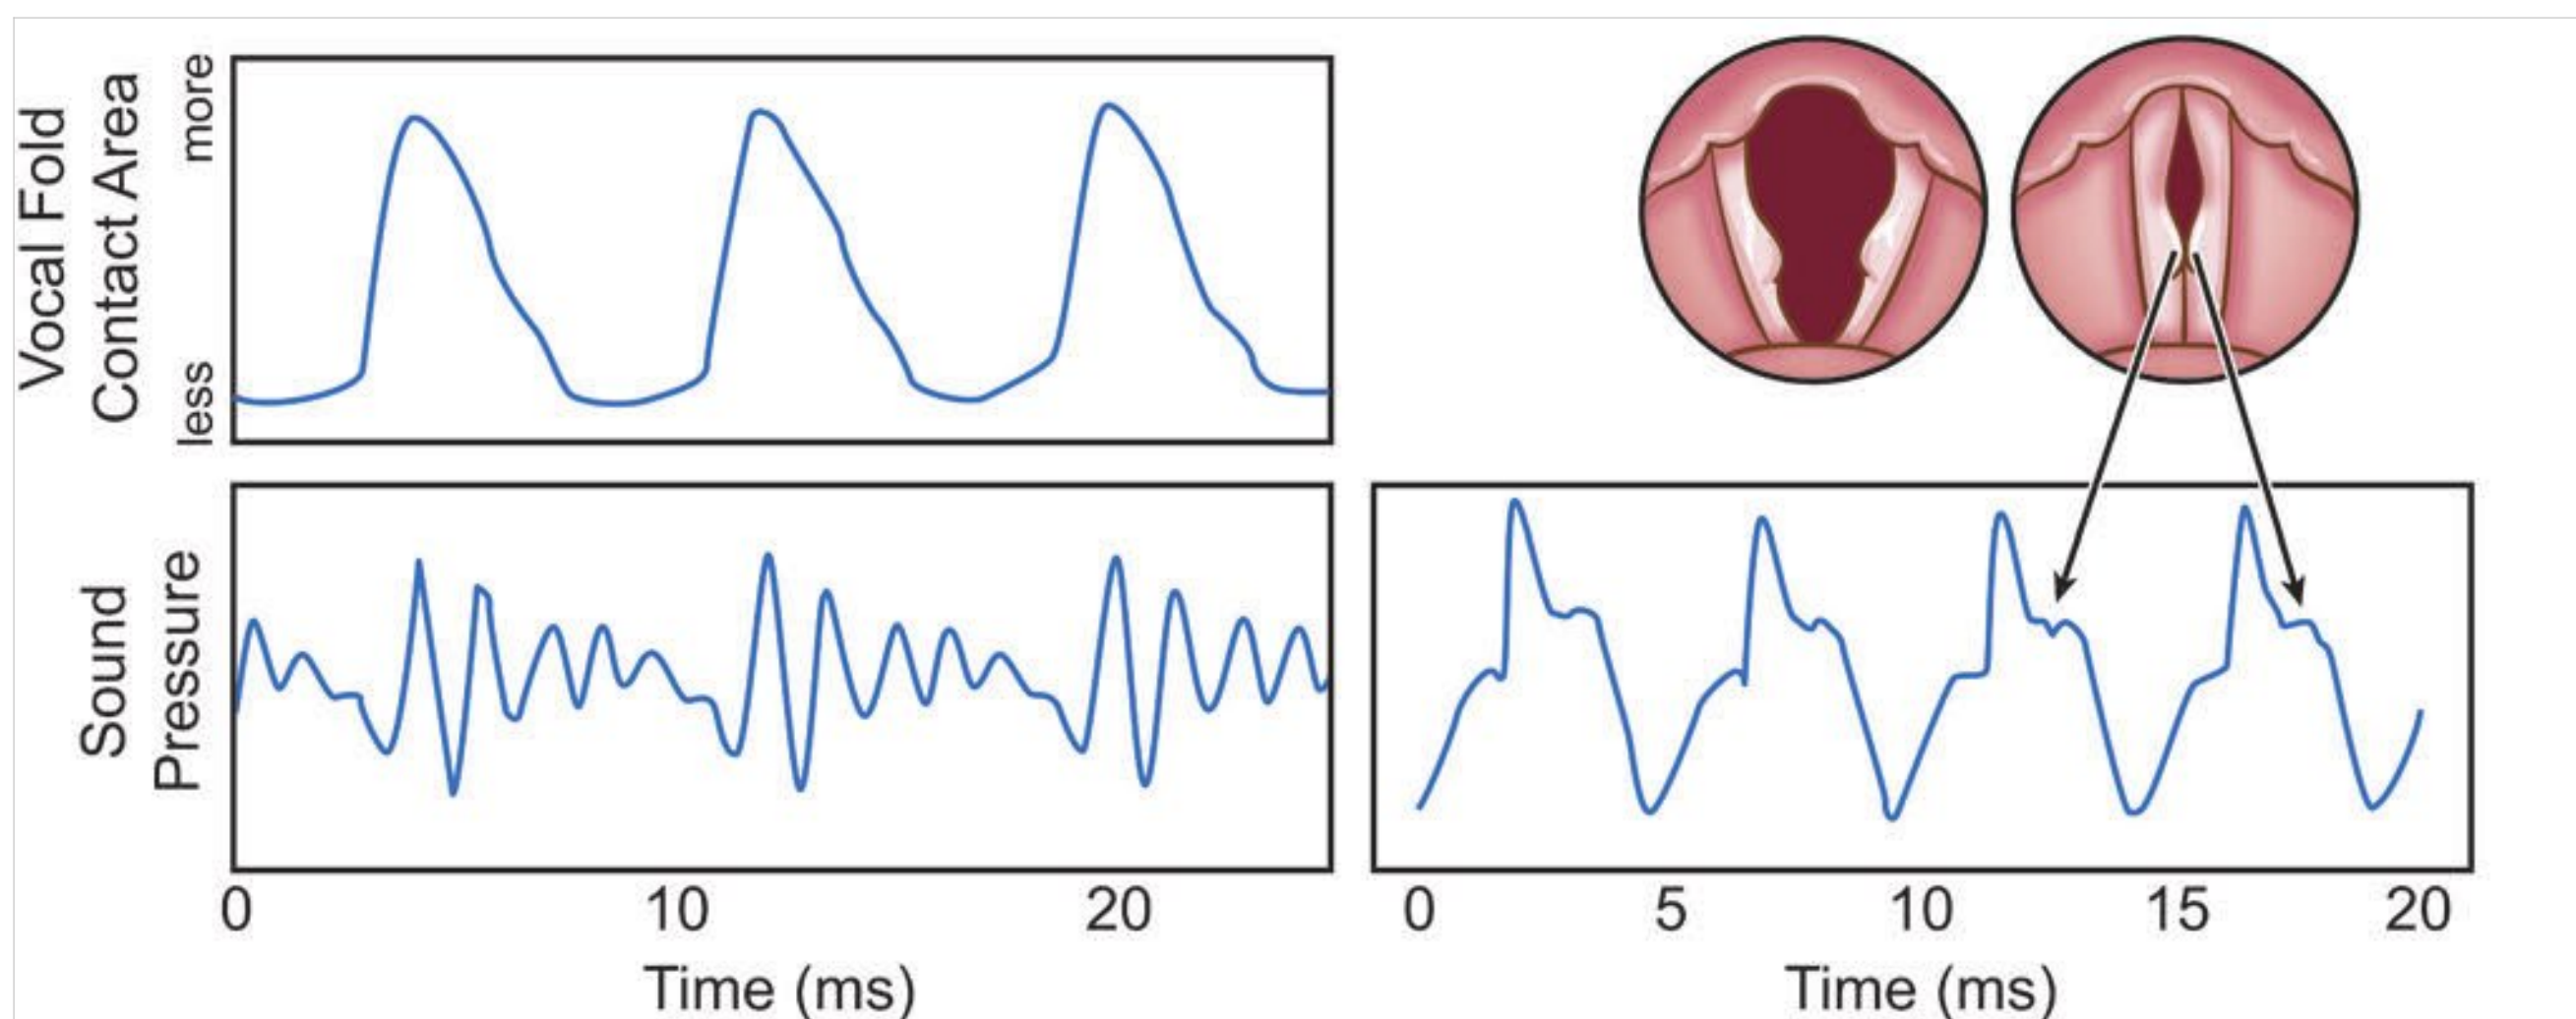

Fig. 78.1 Examples of electroglottographic (EGG) records. Left: The upper trace shows the changes in vocal fold contact area during three glottal cycles of a normal male voice. An increase in contact area (upward deflection) indicates more contact of one vocal fold to the other. It does not necessarily indicate greater glottal closure. The vocal signal generated by these glottal cycles is shown below the EGG. Right: Vocal fold contact pattern of a female speaker with vocal nodules. The protrusion of the relatively compliant masses causes the “shoulders” seen in the EGG record.

Fig. 78.2 Sound spectrographic analysis of a normal male saying “Joe took father’s shoe bench out.” It shows the intensity of the speech signal (the darker the marking, the more intense the sound) as a function of frequency (vertical axis) over time (horizontal axis). Glottal closures, noise elements, resonant frequencies of the vocal tract, and features of speech timing that are important in the assessment of complex speech and voice problems are demonstrated.

78.8 Roundsmanship

- An evaluation of laryngeal function is vital to treatment planning.
- The case history and the acoustic and aerodynamic data add vital information to laryngeal imaging.

79 Laryngovideostroboscopy

Chandra M. Ivey

79.1 Introduction

Videostroboscopy is a technique for evaluating the vibration of the vocal folds. The human vocal folds vibrate too fast for the human eye to detect their motion. A flickered (strobed) light source directly over the vocal folds can effectively momentarily “freeze” this motion so that it can be perceived in pseudo-slow motion.

79.2 Incidence of Disease

Vocal fold irregularity can be seen in almost anyone, but videostroboscopy is used mainly as a tool for evaluating the dysphonic patient. Although visualization with still light via direct or indirect laryngoscopy allows lesions on the vocal cord to be detected, it does not provide a sufficient evaluation of the depth of an irregularity or the impact a lesion has on the vibration of the vocal fold. Videostroboscopy can assist in this evaluation, aid diagnosis and surgical planning, and improve the ability to predict outcomes after phonosurgery.

79.3 Applied Anatomy

Evaluation with videostroboscopy is based on the body–cover principle of vocal fold motion. For “normal” phonation, the vocal fold “cover” (the epithelium and superficial layers of the lamina propria) must move smoothly over the “body” (the thyroarytenoid muscle). The cover and body are attached to each other by the vocal ligament (the intermediate and deep layers of the lamina propria, which comprise the transitional layer;

□ Fig. 79.1). The vocal body shortens and lengthens by relaxation or contraction of the thyroarytenoid and cricothyroid muscles in order to achieve a dynamic frequency range. These relative changes in the body result in tension changes in the cover. A short and relaxed body allows a lax cover to vibrate with large amplitude at lower frequency. A long and stiff body tenses the cover and results in smaller-amplitude vibrations at higher frequency. Any disease process that affects the ability of the cover to vibrate smoothly should cause predictable phonatory changes and be measurable.

According to Talbot’s law, images persist on the human retina for 200 microseconds. Any stimuli presented faster than this are not perceptible as distinct images. When a series of still images are presented, each for less than 200 microseconds, an optical illusion of motion is created. This principle allows still images of multiple cycles of vocal fold vibration to be visually perceived as one cycle in pseudo-slow motion when the images are presented sequentially.

In order for videostroboscopy to work, vocal fold vibration needs to be fairly periodic in nature. The flashes of light can be entrained to a frequency slightly different from that of the vocal folds to give the perception of a moving wave. This is done by catching each cycle of vocal fold vibration in a slightly different position so that it appears to be slowly moving from closed to open. Although each frame captured is from an entirely different vibratory cycle of the vocal fold, the perception on the retina is that of a slowly vibrating vocal fold. □ Fig. 79.2a depicts the difference between stroboscopy and high-speed video imaging of vocal fold motion. □ Fig. 79.2b displays the averaged glottic cycle displayed during stroboscopy.

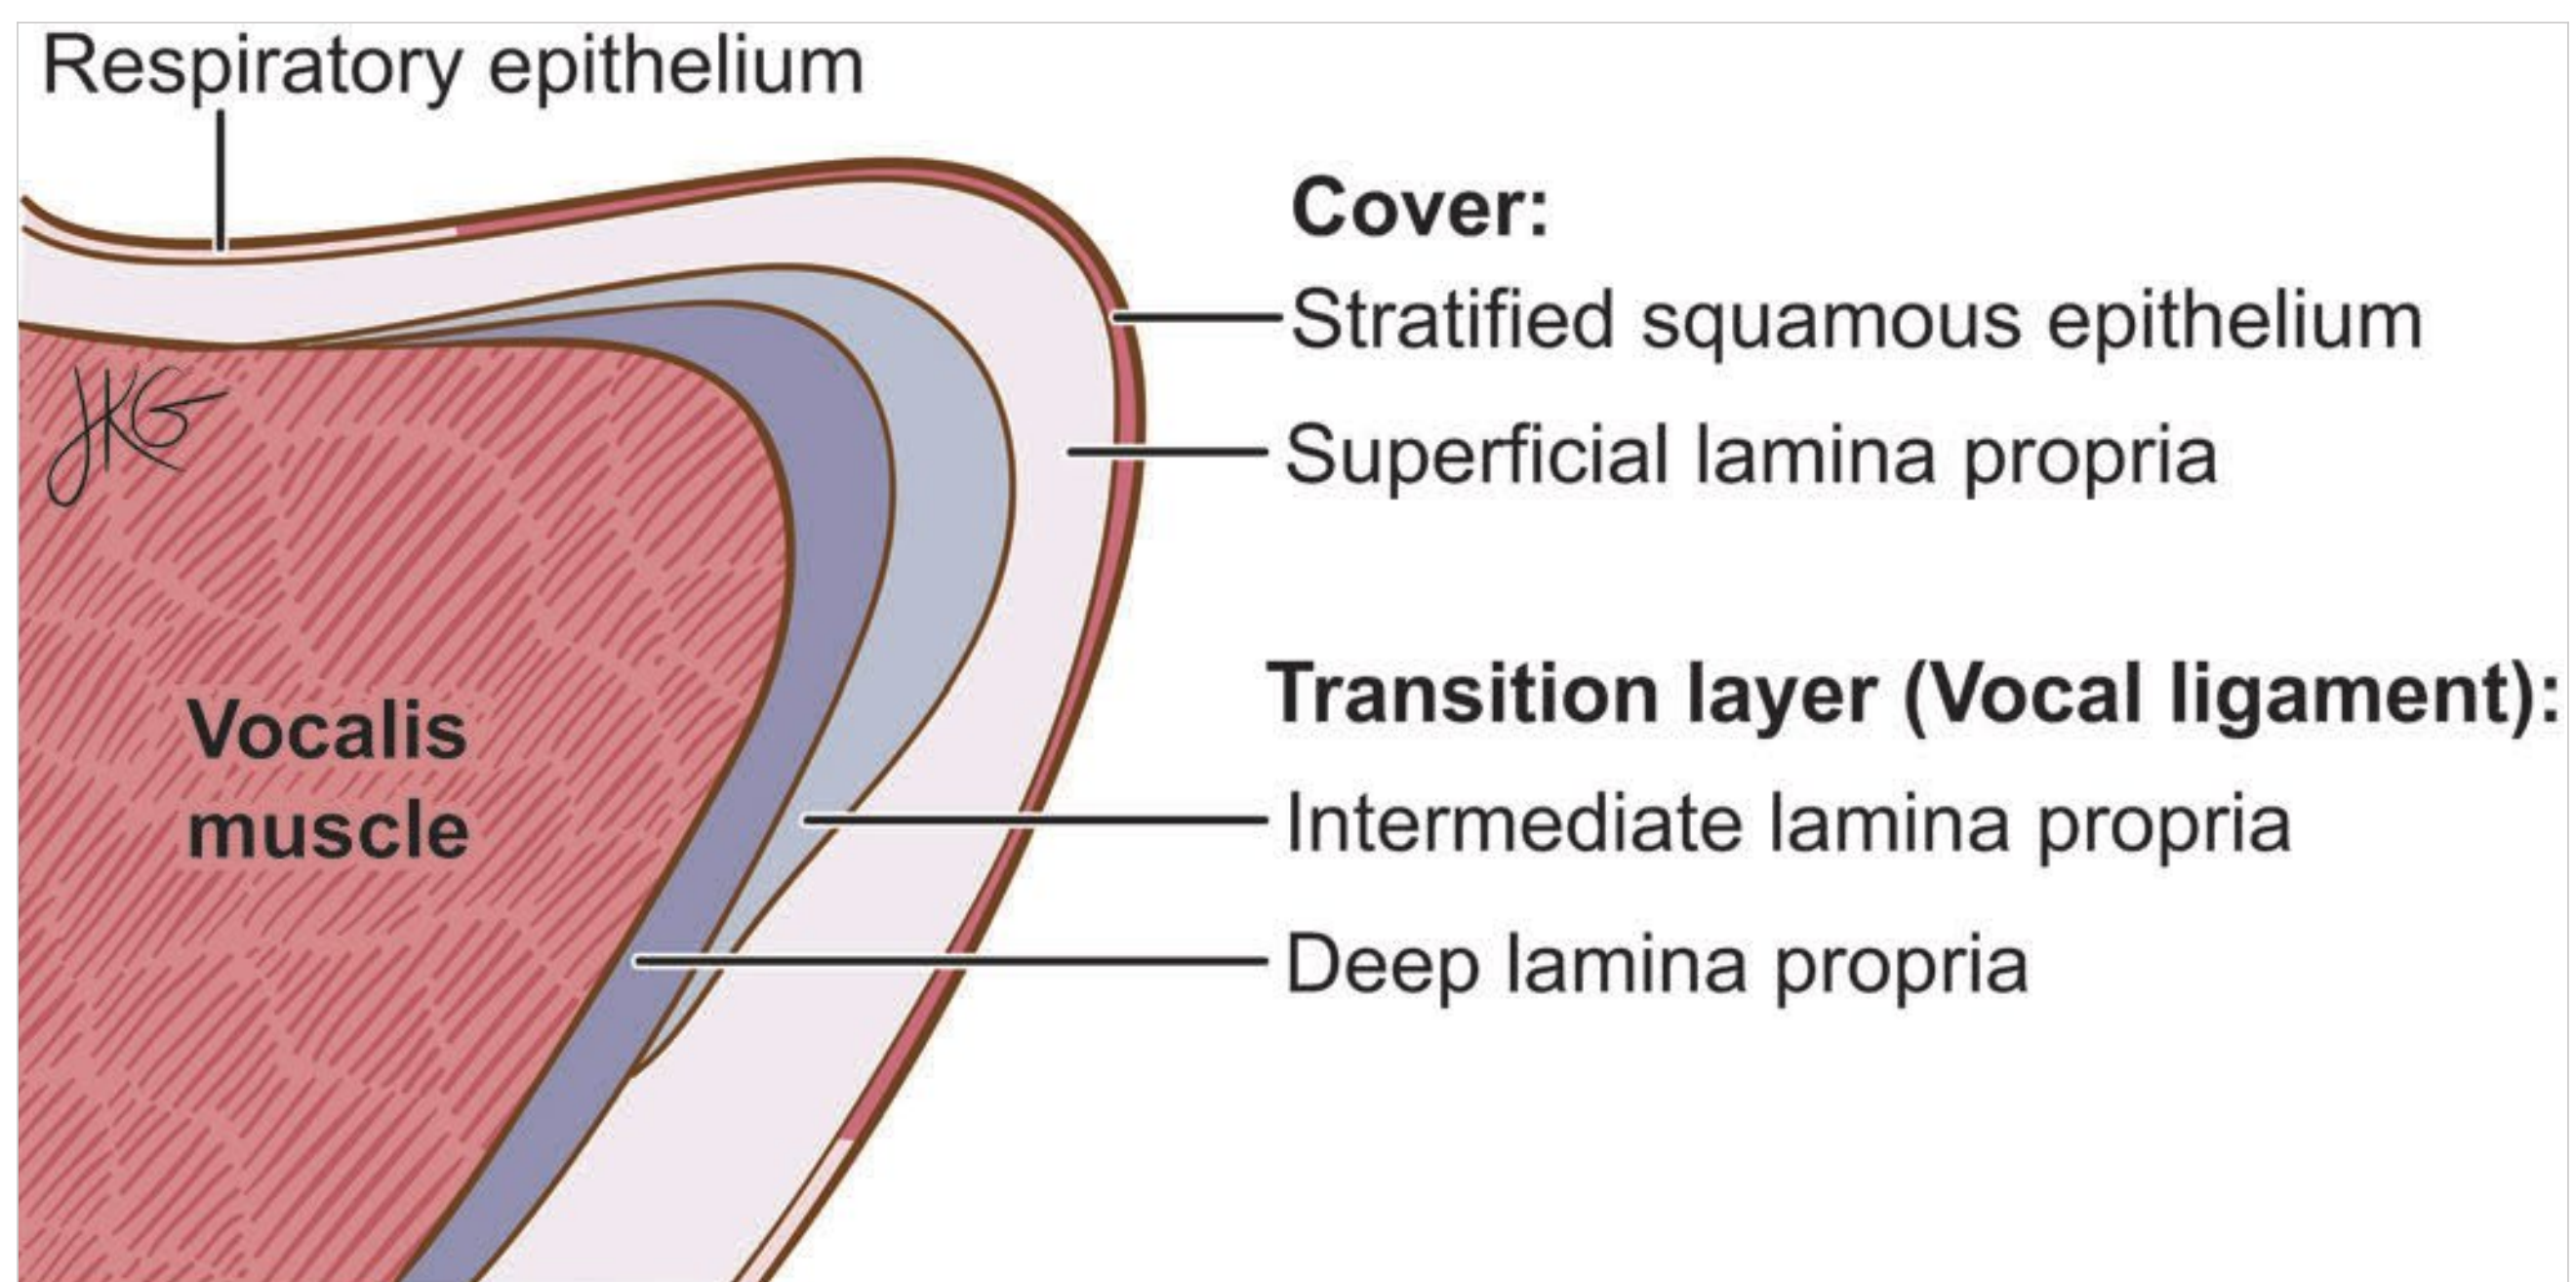

Fig. 79.1 Schematic of the vocal fold layers.

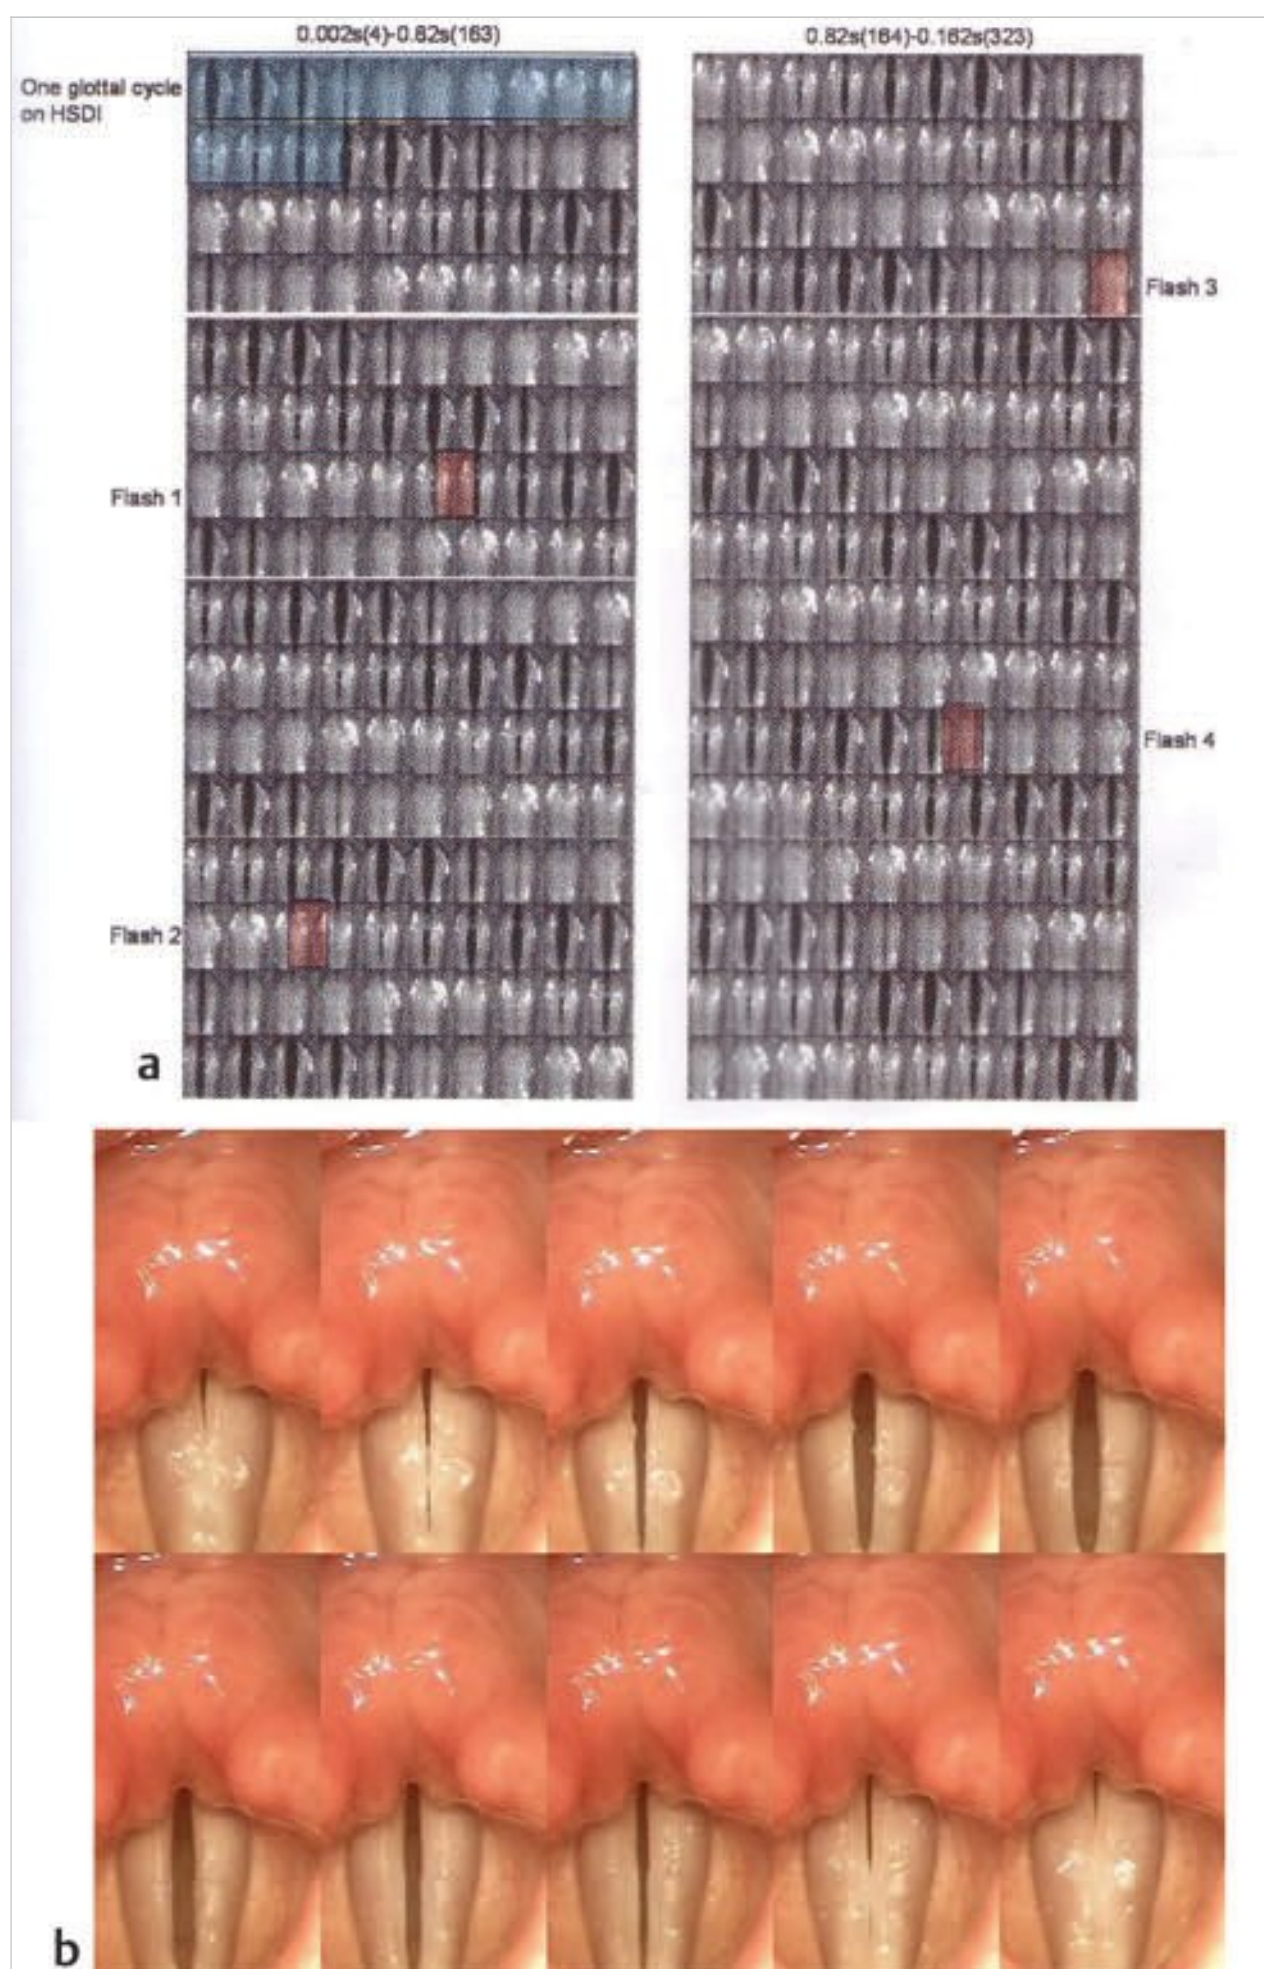

Fig. 79.2 (a) High-speed video of eight glottal cycles, with pink squares indicating the videostroboscopy light flash. Stacking of the pink frames results in a pseudo-slow motion vibration of the vocal folds. HSDI, high-speed digital imaging. (Reprinted with permission from Bless D, Patel RR, Connor N. Laryngeal imaging. In: Freid M, Ferlito A, eds. *The Larynx*. 3rd ed. San Diego, CA: Plural Publishing; 2009.) (b) Videomontage obtained with videostroboscopy.

79.4 Videostroboscopic Evaluation

79.4.1 Equipment

The basic equipment necessary for videostroboscopy includes the following:

1. Laryngoscope: Whether transnasal distal chip technology fiber-optic laryngoscopy or transoral rigid endoscopy is performed, consistent focused images of both vocal folds from the anterior commissure through the arytenoids are important for evaluation.
2. Video equipment: Recording capability allows multiple screenings of the vocal fold movement for a more complete evaluation. Some systems allow slowing the replay or playing the images in a frame-by-frame style, which can assist in a more accurate and consistent analysis.

Fig. 79.3 Laryngovideostroboscopy equipment and examination. (Courtesy of Pentax of America, Montvale, NJ).

3. Microphone: Voice recording allows measurement of the sound decibel (dB) level during videostroboscopy, as well as measurement of the voice fundamental frequency (F_0). These recordings serve as part of the medical record and document vocal changes over the course of treatment.
4. Entrainment system: For videostroboscopy to accurately depict a running image, the light must be triggered in a systematic fashion and relative to the phonatory frequency. The frequency is obtained either by using a laryngeal microphone or by electroglottography (EGG).
5. Strobed light source: This pulses bright light relative to the frequency of the vocal fold vibration to create the perceived slow motion vibration recorded in videostroboscopy.

79.4.2 Technique

Although each physician may have his or her own technique for videostroboscopy, the most important aspect of the evaluation is consistency. A typical examination is shown in □ Fig. 79.3.

Documentation at the patient's modal (or natural) pitch is standard, and the modal pitch should be the first pitch evaluated when data are recorded. The evaluation encompasses approximately 5 seconds of vocal fold vibration at this pitch and at a frequency of approximately 100 Hz higher. Observations are also made while the patient slowly raises his or her pitch to allow evaluation of the cricoarytenoid muscle contribution to phonation. These tasks are often recorded between 60 and 80 dB. Images taken at louder and softer voice ranges can add to the evaluation by changing the body-cover dynamics, which allows irregularities or lesions to be more easily identified. General laryngeal biomechanics are also noted.

Videostroboscopy is extremely useful for the identification and evaluation of irregular vocal fold vibration. Adjunct evaluation with voice recording and with acoustic and aerodynamic analysis can offer additional information for difficult cases or uncertain diagnoses.

79.4.3 Terminology

Many terms are used to describe abnormalities of vocal fold vibration in videostroboscopy:

- **Vocal fold edge:** The vocal fold should be straight from the anterior commissure to the vocal process. Any interruption in this is considered an irregularity.
- **Glottal closure pattern:** Description of the area between the vocal folds when they are fully adducted. Normal vocal folds are considered to have a complete closure pattern. Variations in this pattern that may indicate pathology are incomplete, spindle, hourglass, posterior chink, anterior chink, and irregular chink.
- **Mucosal wave propagation:** Description of the excursion of the moving wave over the body of the vocal fold. Typically, a wave that propagates across 50% of the superior surface of the vocal fold is considered normal. Propagation is typically greater with low-frequency vibration and smaller in high-frequency vibration. Similarly, the propagation increases with louder sounds. Areas of epithelial abnormality may show altered propagation, and in cases of severe scarring there may be absence of mucosal wave altogether.
- **Vocal fold amplitude:** The distance the vocal fold edge and thus the mass of the vocal fold are displaced from the midline during the glottic cycle. The typical amplitude is again 50% of the vocal fold width.
- **Vibratory behavior:** Description of the vibration of the vocal fold cover. In normal circumstances, the vibration of the cover is initiated on the infraglottic surface of the fold; it proceeds perpendicular to the vocal ligament and then across the superior surface of the vocal fold.
- **Phase symmetry:** Description of the cover vibration pattern of one vocal fold with respect to the other. Typically, each wave starts inferiorly and proceeds superiorly then laterally away from midline. When the vibration is in phase, the patterns mirror each other. When vocal fold pathology is present, the wave of one vocal fold may be altered in relation to the other so that they no longer mirror each other, and thus the vibratory patterns will be out of phase.
- **Periodicity:** In order to use videostroboscopy to evaluate the vocal folds, they must vibrate with predictable and measurable rhythm. If a lesion causes the vibration to vary too much from cycle to cycle, the strobe will not be able to sync with the frequency of vibration, and the vocal fold vibration will be perceived as “flickering” instead of moving in a wavelike fashion.

79.5 The Disease Process

79.5.1 Normal Stroboscopic Findings

Under normal conditions, each vocal fold has the same approximate tension and mass, allowing a precise, in-phase mucosal wave on each side. Each vocal fold edge should be straight, and the glottic configuration should show complete closure. The vocal folds tend to be closed for about 40 to 50% of the glottal cycle. The mucosal wave amplitude should be similar from side

to side, and the vibration should proceed in an organized fashion from the infraglottic to the superior surface along the entire length of the vocal fold. The mucosal waves should be in phase, and the vocal folds should have the same periodicity.

79.5.2 Abnormal Stroboscopic Findings

Any epithelial or subepithelial lesion may disrupt the symmetry of the vocal fold edges. These lesions may also affect the glottic configuration because they may prevent full vocal fold closure and cause an hourglass or irregular closure pattern.

An increase in the mass of one vocal fold with respect to the other tends to increase the heaviness of that fold. If the change in mass is generalized, as in polypoid corditis of the vocal fold, it may cause an increased mucosal wave amplitude and propagation along the entire mucosal surface of the vocal fold, as well as an irregular periodicity. If the change in mass is due to the presence of a limited lesion—for example, a cyst or polyp—the area affected tends to move differently from the rest of the fold, causing a local change in mucosal wave and vibration, and likely a phase shift.

An increase in the stiffness of one vocal fold with respect to the other tends to create a reduced mucosal wave and vocal fold amplitude. This can create a phase asymmetry in which one vocal fold appears to be vibrating less. If a lesion affects both the cover and the ligament in a limited area of one vocal fold, videostroboscopy may reveal the absence of a mucosal wave, indicating loss of epithelium (as with scar), an inflamed subepithelial lesion (as with a cyst), or infiltration (as with invasive carcinoma) in that area.

The tension of each vocal fold may also affect the parameters measured with videostroboscopy. Because tension may affect both the mass and the stiffness of a vocal fold, it is important to evaluate whether the tension of each fold appears similar. At times, a vocal fold paresis may decrease the tension of one fold and cause changes in mucosal wave and vocal fold amplitude, resulting in phase asymmetry. Differential tension is often noted when there is a difference between the levels of the vocal folds.

It is important to remember that videostroboscopy is used to record vocal fold vibration in pseudo-slow motion, and then these videos are subjectively analyzed by the otolaryngologist. Consistent patterns of evaluation should be developed for reliable use.

79.6 Roundsmanship

- Videostroboscopy makes possible the evaluation of vocal fold vibration.
- As a consequence of Talbot’s law, still images from multiple cycles of vocal fold vibration are visually perceived as one cycle in pseudo-slow motion when the images are presented sequentially.
- Many terms are used to describe vocal fold vibration in videostroboscopy, including the following: vocal fold edge, glottic closure pattern, mucosal wave propagation, vocal fold amplitude, vibratory behavior, phase symmetry, and periodicity.

- Changes in the mass, stiffness, and tension of the vocal folds are associated with predictable changes in the vibration characteristics displayed by videostroboscopy.

80 Laryngeal Electromyography

Rick M. Roark and Craig H. Zalvan

80.1 Introduction

Since the 1950s, laryngeal electromyography (EMG) has been a useful tool in the diagnosis of various neuromuscular disorders affecting the larynx. The percutaneous placement of needle electrodes within the laryngeal musculature allows the muscles to be studied at rest and during voluntary activation. The interpretation of electrical signals can be useful in determining the site of a lesion, degree of neuronal injury, and prognosis for reinnervation. It can also aid in differentiating between paralysis and mechanical fixation and can guide the injection of spasmodic laryngeal muscles with botulinum toxin.

80.2 Technical Information

Laryngeal EMG is routinely performed in the office setting. Most laryngeal electromyographers use a sensitive multichannel EMG system. A ground electrode is placed on the neck just lateral and inferior to the larynx. A reference electrode is placed away from the neck, typically overlying the angle of the mandible, the posterior triangle near the mastoid, or the clavicle. Both electrodes are amplified and the difference subtracted to generate a signal that best represents the electrical activity of the desired muscle and minimizes the background noise from other muscles, power sources, and other electromagnetic devices.

The sweep speed of the EMG display unit sets the rate at which the signal is horizontally traced to the display screen, with a setting of 10 ms/cm used for most purposes. Faster sweep settings (e.g., 1 ms/cm) facilitate a more detailed examination of signal shapes, whereas a slower sweep offers a more global view of the composite EMG signal. Gain, or sensitivity, of the EMG display adjusts the vertical extent to which the signal will be traced to the display screen and is typically set in the range of 50 to 200 mV/cm. When a general assessment of muscle activation is made, the sweep and gain settings are typically 100 ms/cm and 1,000 mV/cm, respectively. To examine the finer details of neuromuscular status (e.g., hierarchical recruitment of motor units during initial activation), settings of 1 ms/cm and 50 mV/cm are helpful. The indwelling electrode (either a bipolar concentric or a monopolar needle) is inserted at rest into the muscle of choice, followed by various voicing tasks to activate that muscle. Monopolar needles are thinner and cause less damage to tissue, as well as less pain. They record circumferentially at the site of interest and are less costly. Concentric needles do not require an external reference electrode because it is built into the needle itself; as such, a concentric needle results in less interference, which makes it optimal to evaluate the morphology of the laryngeal EMG results.

80.3 Technique

Laryngeal EMG is performed with the patient in a sitting or supine position (□ Fig. 80.1). The head is slightly extended. Landmarks are first palpated: the cricothyroid membrane, the thyroid notch, and the trachea. Ground electrodes (and a reference

electrode, if a monopolar electrode is being used) are placed, and the area is prepared with alcohol. Once the needle is inserted into the skin and the EMG machine is turned on, sharp popping/crackling sounds are heard as the needle is advanced into muscle. The thyroarytenoid, posterior cricoarytenoid, and cricothyroid muscles are typically evaluated with diagnostic EMG.

80.3.1 Thyroarytenoid

To access the thyroarytenoid muscle, the needle is passed through the cricothyroid membrane just lateral to the midline on the side being tested. The needle is then advanced and angled 45 degrees upward and 20 to 30 degrees laterally (□ Fig. 80.2). At times, the needle may penetrate the airway, which will result in a sinusoidal pattern on the screen and a loud monotone feedback from the speaker; it often will also elicit pain and cough from the patient. The needle is withdrawn slightly, repositioned, and advanced; when the needle is redirected, it should not be turned laterally while within the body, but rather withdrawn and turned in the desired direction to minimize tissue trauma. Advancing the needle forward will result in auditory evidence of muscle insertion. Testing of the thyroarytenoid muscle involves a period of rest to assess baseline activity followed by activation tasks; these include /i/ in short bursts, followed by a prolonged /i/ at both high and low pitch, a Valsalva maneuver, and a cough. These tasks adduct the vocal folds and activate the thyroarytenoid muscle. In addition, multiple repeated sniffing maneuvers test for synkinesis because the thyroarytenoid should be relatively quiet.

80.3.2 Posterior Cricothyroid Muscle

This muscle can be accessed in two ways. In young patients, the needle can be passed through the cricothyroid membrane and

Fig. 80.1 Laryngeal electromyography is comfortably performed in an office setting.

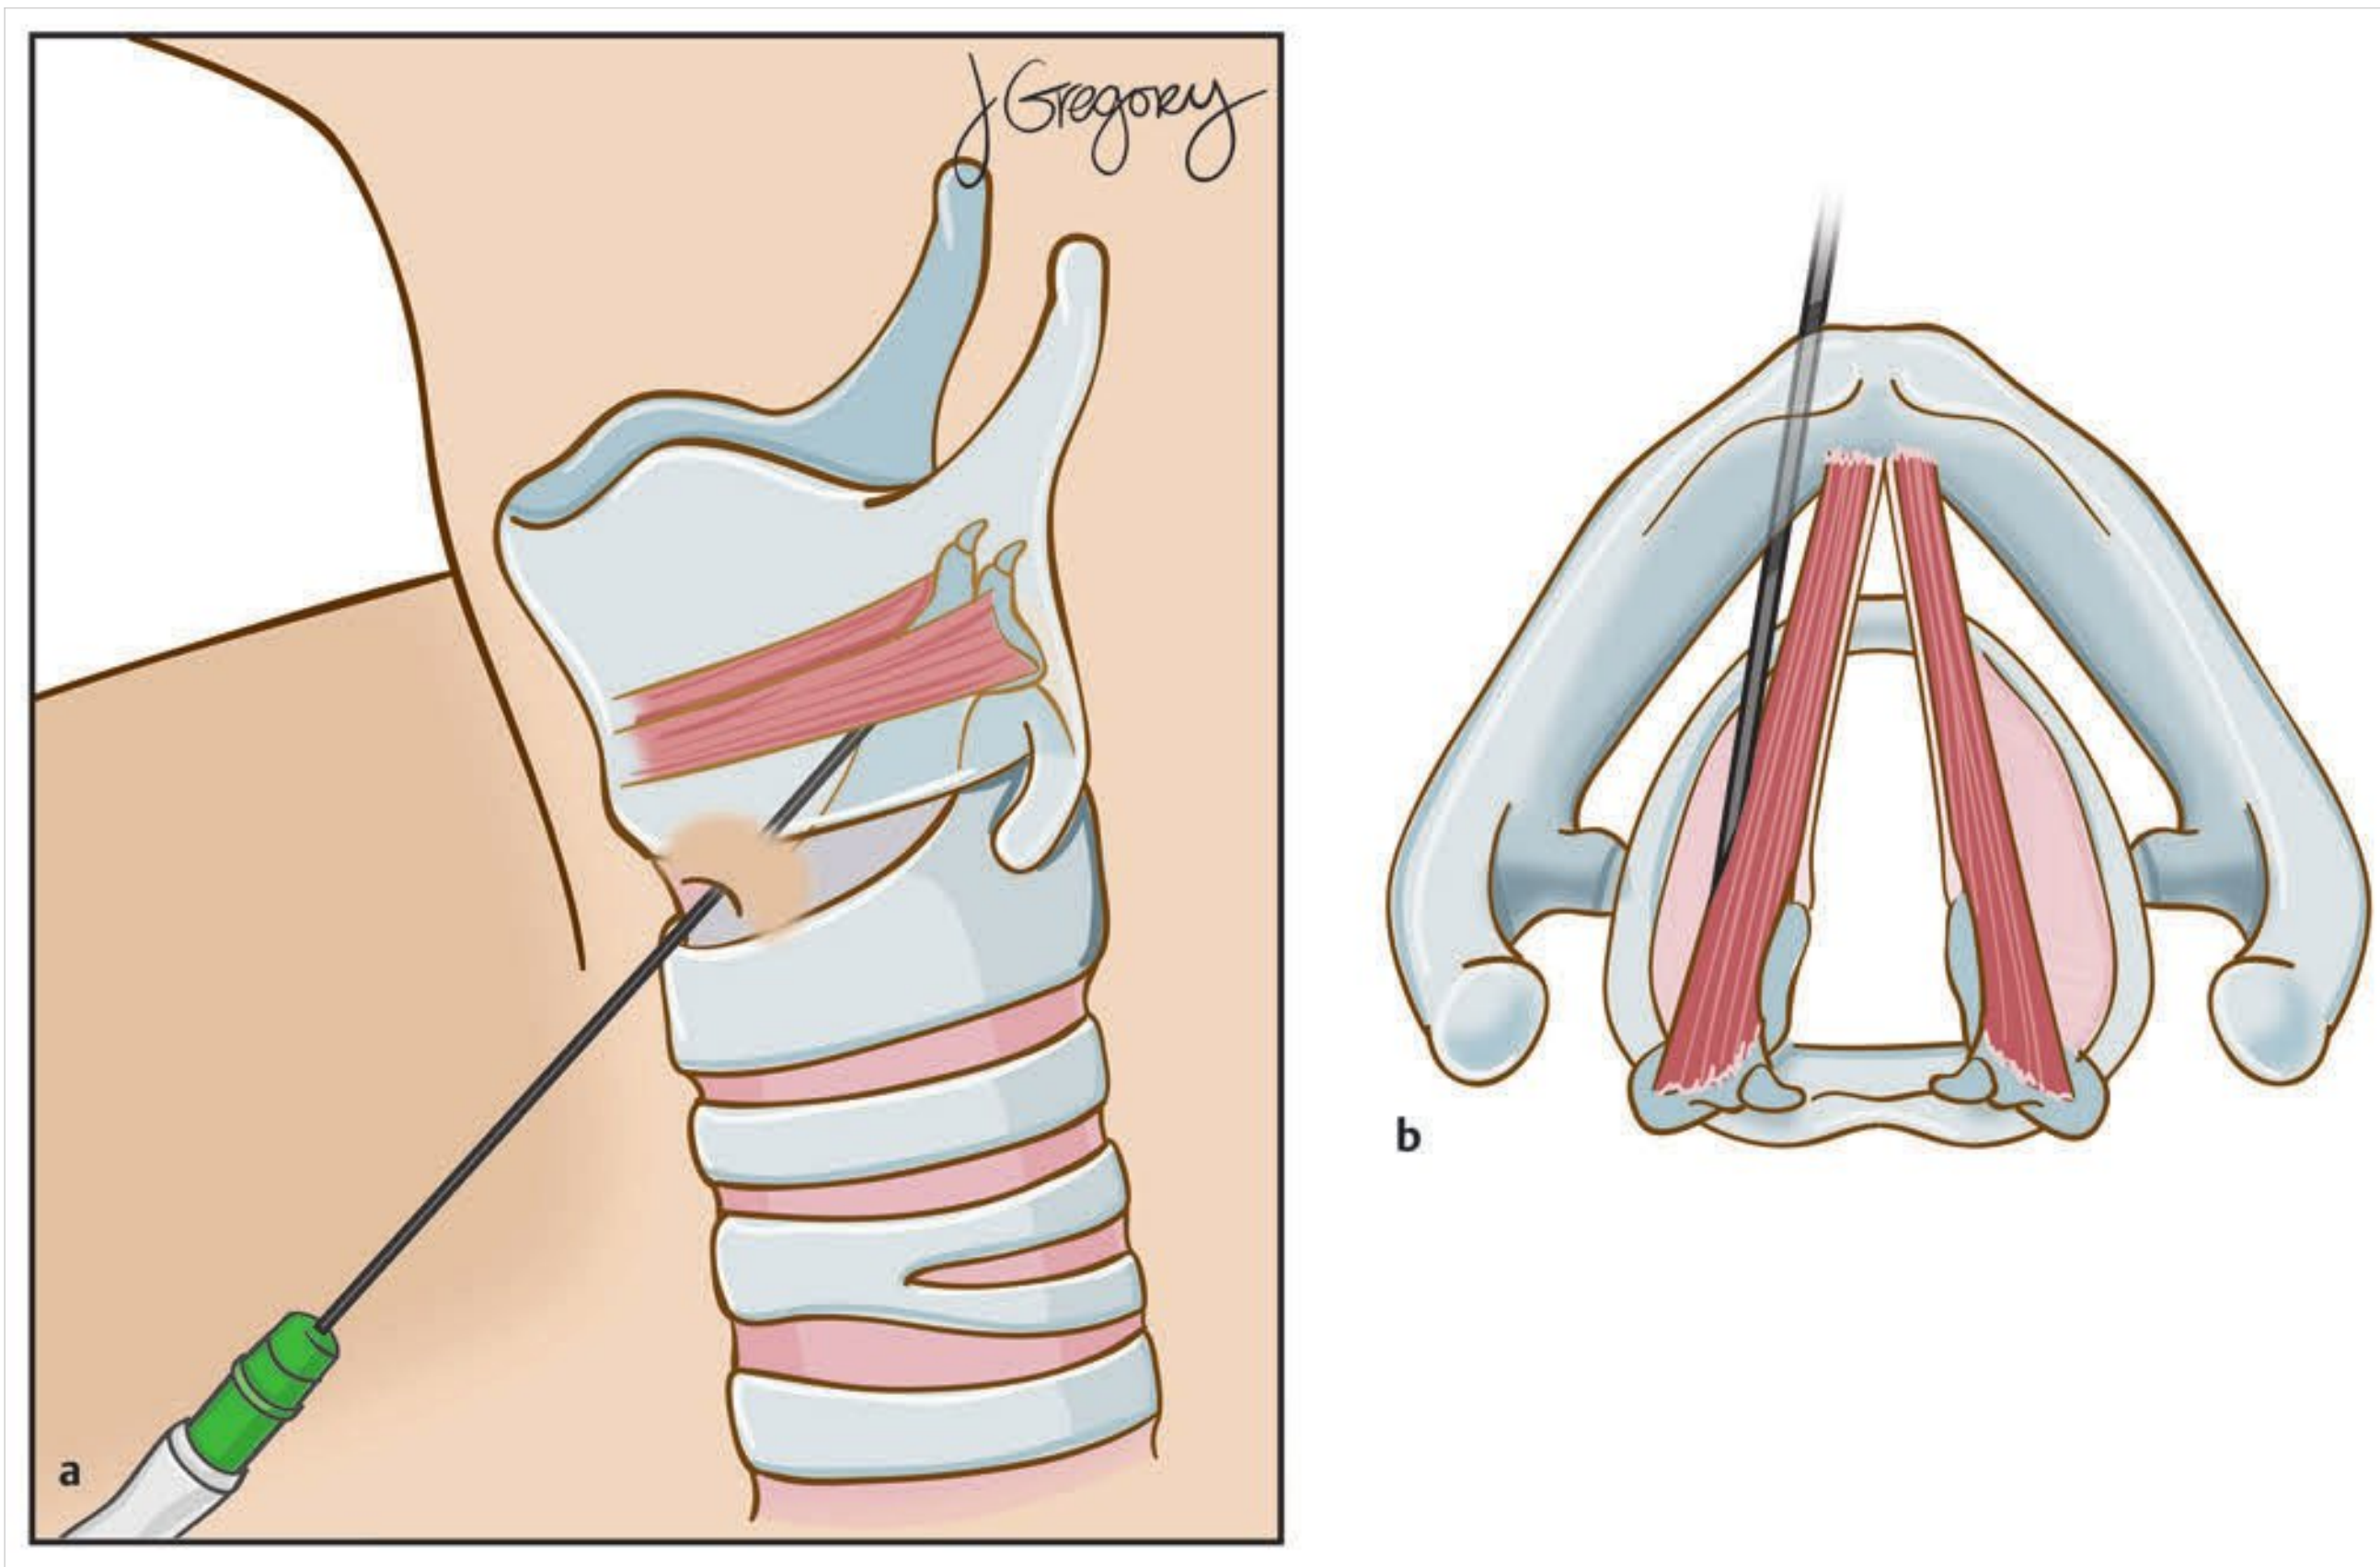

Fig. 80.2 (a) The needle is placed through the cricothyroid membrane just lateral to the midline on the side of interest. (b) The needle is angled upward and laterally until the thyroarytenoid muscle is accessed.

directed into the airway, then slightly inferiorly and laterally into the posterior lamina of the cricothyroid cartilage. The needle is pushed through the cartilage until brisk pops are heard and motor unit action potentials are seen on the screen. The posterior cricoarytenoid is activated by a sniff maneuver. When the cartilage is ossified or the anterior approach is difficult, the posterior cricoarytenoid can be approached from the lateral neck. The larynx is grasped between the thumb on the lateral border and the pointer finger on the thyroid notch (for left posterior cricoarytenoid testing). The larynx is rotated away from the side being injected, and the EMG needle is advanced behind the lateral border of the thyroid cartilage at its lower border until the cricoid cartilage is encountered. At this point, the needle is retracted slightly, and a brisk signal will be heard when the patient sniffs if the posterior cricoarytenoid has been properly located (□ Fig. 80.3).

80.3.3 Cricothyroid Muscle

The cricothyroid muscle is accessed by placing the needle through the skin overlying the cricoid slightly lateral to the cricoid itself. The needle is then advanced slightly medially and along the superior border of the cricoid until brisk potentials are heard and visualized. Absence of EMG activity during a head turn or chin raise will confirm that the needle is not within the strap muscles. To obtain activity of the cricothyroid muscle, the patient is asked to phonate a sustained /i/ at low pitch and then

Fig. 80.3 Lateral approach to the posterior cricoarytenoid muscle.

Fig. 80.4 Normal motor unit configuration (600 mV).

Fig. 80.6 Fibrillation potentials occurring with a polyphasic motor unit potential in a partially denervated thyroarytenoid muscle.

at high pitch. Activation should increase substantially during high pitch phonation.

80.4 Electromyographic Signal Interpretation

Normal motor unit action potential (MUAP): The firing of each laryngeal motor unit creates a compound myoelectric potential called the MUAP. Individual MUAPs may be identified in the EMG signal during low-force activations (□ Fig. 80.4) when few in number, but as additional motor units are recruited and firing rates are increased during greater force demands, the individual shapes become confounded. Normal MUAPs have a distinctive multiphasic wave shape indicating the four phases of compound muscle fiber depolarization. However, the specific MUAP morphology that is observed, with its distinguishing shape and timing characteristics, will depend greatly upon the size and geometry of the detector(s) and the recording setup (monopolar or bipolar). Although many of the important clinical impressions can be obtained when any recording scenario is used, more refined observations must often be paired with the specific electrodes used, the type of recordings, and the experience of the electromyographer.

Recruitment: As the volitional activity of a muscle persists or increases, adjacent motor units are recruited to activate more muscle fibers and increase or maintain the strength of contraction. When recruitment is normal, so many MUAPs are present

Fig. 80.5 Fibrillation potentials from partially denervated thyroarytenoid muscle.

Fig. 80.7 Polyphasic motor unit action potential with increased amplitude (700 mV; arrow) from a thyroarytenoid muscle after recurrent laryngeal nerve injury during thyroidectomy.

that individual MUAPs cannot be identified because they are obscured by one another. When this occurs, it is referred to as a full interference pattern. In cases of neural injury, fewer motor units are recruited, the interference pattern becomes thinned, and it is possible to identify individual units.

Insertional activity: When the needle enters the muscle, there may be brisk, sharp insertional activity due to brisk depolarization of the cell membranes. This typically lasts a few seconds. Prolonged insertional activity for longer than 300 ms may be indicative of muscle membrane instability from either a neuropathic or a myopathic process.

Fibrillation potentials/positive sharp waves: These are initial positive deflections of the MUAPs that are typically sharp, short, and repetitive (□ Fig. 80.5). When present, they are indicative of denervated muscle fibers.

Polyphasic action potentials: A normal MUAP is biphasic or triphasic (phases indicate the number of times an MUAP crosses the baseline). Polyphasic (with four or more phases) action potentials are abnormal (□ Fig. 80.6) and indicate active reinnervation by a damaged nerve. Polyphasic action potentials occur as nerve endings regrow to atrophied muscle fibers. The result of these immature synaptic transmissions is the appearance of MUAPs of lower amplitude and longer duration. The fibers eventually incorporate more muscle fiber units, resulting in increased MUAP amplitude but continued polyphasic morphology (□ Fig. 80.7).

Giant waves: Muscle reinnervation following nerve injury will often be accompanied by one or more nonpolyphasic waves that have abnormally high amplitudes in the EMG signal. Giant waves (□ Fig. 80.8) are formed as the axon branches in the newly reinnervated fibers of a motor unit begin to develop nodes of Ranvier and become myelinated, thus reducing the transport time of the action potential to the fiber end plate and

Fig. 80.8 Giant waves with amplitude of more than 900 mV (arrow).

so reducing the delay times of the fiber depolarization potentials to the recording electrode. Previously, the varied and prolonged delays that caused the depolarization potentials to sum into a polyphasic MUAP during early-stage reinnervation were reduced, causing the potentials now to sum supportively into an MUAP with a shorter duration and a greater amplitude. Although giant waves are consistent with muscle reinnervation physiologically, their presence is inconsistent with normal innervation anatomically because the bundling of fibers constituting the motor unit is closer than in a normal unit, in which fibers are more interspersed. Giant waves indicate a mature state of muscle reinnervation. An absence of vocal fold motion in the presence of giant waves suggests a poor prognosis.

The duration of the MUAP reflects the number of muscle fibers innervated by the axon being studied. Age tends to increase the duration as conduction velocity decreases. Temperature also affects duration, with hypothermia resulting in slower conduction and longer duration. In addition, chronic myopathic and neuropathic disease can increase the duration of the MUAP. The amplitude of the MUAP can similarly be affected by various myopathic and neuropathic conditions. The amplitude directly reflects the number of muscle fibers recorded per given axon. Thus, conditions that damage muscle or block neuromuscular transmission can result in decreased amplitude. Increased amplitude, conversely, is seen with reinnervation and inflammatory conditions.

80.5 Clinical Use

EMG can be a very useful tool in identifying neurologic and myopathic disorders of the laryngeal musculature. Common uses of laryngeal EMG include determination of the prognosis for recovery of a patient with vocal fold paralysis and EMG guidance for botulinum toxin injection. Other indications include testing for vocal fold paresis, myopathy, metabolic disorders, fixation of the cricoarytenoid joint, and other neuropathic conditions that are not covered in this chapter.

80.5.1 Vocal Fold Paralysis

EMG can be a useful tool to assess a patient presenting with vocal fold immobility. EMG does not predict the timing of return of function, nor does it guarantee a return of function. EMG is typically performed at least 3 weeks after an injury to allow wallerian degeneration to result in denervation and to allow fibrillation potentials to arise. Complete denervation is charac-

terized by an absence of recruitment and the presence of fibrillation potentials. In cases of neural recovery, polyphasic waves can be detected. EMG is relatively good at predicting the return of vocal fold function when performed between 2 and 6 months after injury, and a 60 to 90% correlation with clinical outcome has been observed in patients studied. Variability in these outcomes is likely due to timing of the study. Early after injury, the presence of polyphasics suggests an improved prognosis. Increasing recruitment on successive EMGs suggests an active reinnervation process and a higher likelihood of recovery. EMG is even better at predicting the lack of return of vocal fold motion. A lack of movement in the presence of giant waves portends a poor prognosis because maximal neuronal recovery has been achieved and the vocal fold is yet to move. Synkinetic reinnervation plays a large role in preventing vocal fold motion. If there is EMG evidence of significant synkinesis, then a return of motion is less likely. Data are lacking to define what should be considered significant synkinesis. Any synkinesis seen during recovery from a neural injury can lead to vocal fold immobility despite robust favorable EMG findings of return of function. Synkinesis is observed by EMG if there is recruitment in the thyroarytenoid during a “sniff” procedure, or in the posterior cricoarytenoid on phonation.

In addition to determining the prognosis of a patient with vocal fold paralysis, EMG can be useful for identifying the site of neural injury. A normal EMG of the cricothyroid muscle with an abnormal EMG of the thyroarytenoid muscle suggests a peripheral nerve injury below the branching of the superior laryngeal nerve at the nodose ganglion. If both the cricothyroid muscle and the thyroarytenoid muscle show evidence of neuronal injury, it is likely the injury occurred above this division and involves the vagus nerve along its course from the brainstem.

80.5.2 Vocal Fold Paresis

Based on the clinical history and physical examination, vocal fold paresis may be suspected as the etiology of a patient’s dysphonia. It has been shown that this diagnosis is difficult to make based on history and physical examination alone because nearly 20% of patients in whom vocal fold paresis is suspected will have a normal EMG and no paresis. In addition, in the nearly 80% of those who do have paresis, identification of the paretic vocal fold based on physical examination alone is accurate only approximately 30% of the time. Hence, laryngeal EMG is very helpful in confirming vocal fold paresis and in identifying the side of weakness for possible surgical intervention.

80.5.3 Arytenoid Fixation

A normal EMG of the thyroarytenoid and cricothyroid muscles indicates no damage to the recurrent laryngeal nerve or superior laryngeal nerve and can suggest dislocation or fixation of the arytenoid joint. When used in this situation, EMG can be performed soon after injury because there is no need to wait for wallerian degeneration to occur. Causes of fixation include traumatic dislocation, arthritis, and posterior glottic scarring resulting in vocal fold immobility.

80.5.4 Spasmodic Dysphonia

EMG can be useful in diagnosing spasmodic dysphonia and other disorders of the basal ganglia. Intermittent breaks in voicing during connected speech associated with increased muscle firing is characteristic of spasmodic dysphonia. In addition, there is typically a delay between voicing and an increase in laryngeal muscle activity. The main use of EMG in this disorder is to guide injections of botulinum toxin into the thyroarytenoid and posterior cricoarytenoid muscles for therapeutic effect. Hollow needle electrodes can be attached to a syringe with appropriately diluted botulinum toxin, which is injected into the body of the appropriate muscle after electrical confirmation of proper needle placement into the muscle.

80.5.5 Lower Motor Neuron Disorders

Increased activity on needle insertion associated with findings of polyphasic innervation, positive sharp waves, and the presence of fibrillation potentials (□ Fig. 80.8) are common findings in patients with diseases such as amyotrophic lateral sclerosis, degenerative diseases of the peripheral nerves, multisystem atrophy, post-polio syndrome, and Guillain-Barré syndrome. Often, there is also decreased recruitment as remaining nerve fibers cease functioning.

80.5.6 Myasthenia Gravis

Initial EMG of the larynx in patients with myasthenia gravis usually reveals normal insertional activity, amplitude, and

duration of the MUAP. With repetitive stimulation, the amplitude and duration of the MUAP, as well as recruitment, decrease progressively over time.

80.6 Roundsmanship

- EMG is easy to perform in an ambulatory setting with minimal discomfort to the patient. It can be used to indicate the prognosis of a patient with injury, identify joint fixation, and guide the injection of botulinum toxin.
- EMG for vocal fold immobility in cases of iatrogenic trauma should be performed at least 3 weeks after the initial injury.
- EMG is useful in predicting a poor prognosis for functional return after vocal fold paralysis.
- EMG is a useful tool for guiding injections of botulinum toxin into the laryngeal musculature.
- Because EMG does require the use of a needle, insertional pain, bleeding, and rarely a hematoma can be encountered. Caution should be advised in patients with a history of anticoagulation or coagulopathy; however, significant morbidity from EMG is very rare.

81 Diagnostic Testing for Dysphagia

Craig H. Zalvan

81.1 Introduction

Like most diagnostic modalities, the history and physical examination are crucial in understanding the cause of dysphagia. A detailed history will point to the area causing the particular problem, which can then help guide the physician's choice of objective diagnostic testing. The field of dysphagia has experienced tremendous growth over the past few decades, and numerous diagnostic tests are available that can help pinpoint the etiology of dysphagia in many, although not all, cases.

In addition to a complete head and neck examination, including assessment of the cranial nerves, every examination for dysphagia must include visualization of the laryngopharynx (and possibly the trachea) with a flexible laryngoscope. Both anatomy and function are evaluated, including the following: mucosal lesions, velopharyngeal competence, epiglottic retroflexion with closure of the laryngeal vestibule, vocal fold mobility, pharyngeal squeeze, laryngeal elevation, and the presence of pooled secretions at baseline. Based on the history and results of this examination, objective testing is then ordered if deemed necessary. A battery of tests is available, each with advantages and disadvantages. An understanding of how each test is conducted and what information it may provide is necessary so that a prudent choice is made. If chosen correctly, these examinations may confirm a suspected etiology of the dysphagia, as well as its location and severity. Certain examinations can be used with real-time feedback to test the efficacy of swallowing maneuvers used in treatment.

81.2 Modified Barium Swallow

Modified barium swallow (MBS), or videofluorography, has long been the gold standard test for evaluating swallowing function. It is generally obtained to evaluate patients with suspected neurologic compromise, postoperative changes, upper esophageal sphincter dysfunction, or dysphagia to liquid boluses. This test is performed in the radiology suite with a radiologist and speech–language pathologist. The patient sits upright in the fluoroscopy suite and is fed a gradation of barium-coated boluses with consistencies ranging from thin liquid to solid, as well as varying sizes. This is an excellent test for identifying causes of dysphagia in the oral and pharyngeal phases of swallowing, as well as dysfunction of the upper esophageal sphincter. The esophageal phase can also be assessed. Premature bolus spillage, esophageal reflux, adynamic pharyngeal musculature, degenerative changes of the spine, and pooling of secretions are all assessed. Aspiration of material is easily detected, even when silent (absence of cough upon penetration or aspiration). In addition, the function of the cricopharyngeus and upper esophageal sphincter can be assessed, as well as the presence of a Zenker diverticulum. The MBS can be used to assess the success or failure of compensatory mechanisms and strategies taught to the patient; patients swallow while employing the compensatory maneuver, and its effect is observed in real time. The disadvantages of this test are the need for a radiology suite, a large

team of health care workers, radiation exposure, and the inability to directly visualize the structures being assessed.

81.3 Flexible Endoscopic Evaluation of Swallowing and Sensory Testing

Flexible endoscopic evaluation of swallowing and sensory testing (FEESST) allows an evaluation of the oropharyngeal swallowing mechanism, as well as direct visualization of the oropharynx, hypopharynx, and larynx. It is generally employed in similar situations and as an alternative to MBS. This portable test is performed by passing a flexible laryngoscope through the nasal cavity into the pharynx to the level of the tip of the epiglottis. Baseline evaluation of secretions within the nasopharynx, vallecula, hypopharynx, posterior pharyngeal wall, and larynx is performed. The trachea can also be directly visualized. Vocal fold mobility is assessed, as is pharyngeal mobility, cough effectiveness, and pharyngeal squeeze (dynamic medial contraction of the pharyngeal walls during a high-pitched /i/). Sensory testing is then performed. A small puff of air is delivered to the arytenoid mucosa. When this is sensed, normal individuals respond with an abrupt closure of the larynx (laryngeal adductor reflex). The normal threshold is less than 4.0 mm Hg. If a response is not elicited, increasing pressure is used until a continuous pulse at 9 mm Hg is delivered. The absence of reflexive closure indicates the presence of a severe sensory deficit. Finally, foods of multiple consistencies mixed with food coloring are fed to the patient. The timing of the swallow, pooling of secretions, premature spillage, presence of residual food material, and penetration and aspiration before, during, and after the swallow, as well as the ability to clear the bolus, are all recorded.

The FEESST examination has many advantages. It is very easy to perform and highly portable. There is no radiation exposure. Direct visualization from the nasopharynx to laryngopharynx allows a direct evaluation of the anatomy. Neurologic information such as vocal fold mobility and sensation can be tested with FEESST. FEES can be used for biofeedback to help a patient learn swallow maneuvers and protective mechanisms.

The primary disadvantage is poor visualization during the actual swallow, with a brief period of “white out” during epiglottic inversion and pharyngeal contraction. The direct visualization of penetration or aspiration is not possible during the swallow; the presence of either can only be inferred by the appearance of food coloring in the structures of the larynx or subglottis after the swallow has finished. In addition, the cricopharyngeus, esophagus, and oral phase of swallow are not visualized during this procedure. The pooling of secretions in the hypopharynx may suggest cricopharyngeal abnormalities indicating the need for further investigation. Some patients may not be able to tolerate placement of the laryngoscope, either because of discomfort, which is very rare, or an inability to participate in the procedure because of neurologic compromise or mental status deficiencies.

81.4 Barium Swallow

A barium swallow (BS) allows an investigation of the anatomy and function of the hypopharynx, upper esophageal sphincter, esophagus, and cardia of the stomach. The patient swallows approximately 20 mL of thin barium liquid, which is evaluated with fluoroscopy. The barium distends the lumen of the aforementioned structures, so that they can be evaluated. It is ordered predominantly for patients experiencing dysphagia to solids. BS is helpful in the identification of mucosal irregularities, webs, rings, stricture, extrinsic compression, diverticula, foreign bodies, upper esophageal sphincter/lower esophageal sphincter/cricopharyngeal dysfunction, gastroesophageal reflux, airway aspiration, endoluminal masses, and esophageal dysmotility. The advantages of this examination include its noninvasive nature, low cost, and wide availability. The disadvantages include the need for radiation, relative anatomical imprecision, and lack of information about how foods and liquids of various consistencies are handled.

81.5 Transnasal Esophagoscopy

Transnasal esophagoscopy (TNE) has become a powerful tool in the diagnosis of dysphagia. Performed on unsedated patients in an office setting with the use of topical anesthesia, direct visualization from the nasopharynx to the stomach can be performed. Indications for this examination include dysphagia, laryngopharyngeal reflux disease (LPRD), chronic cough, globus, odynophagia, symptoms of gastroesophageal reflux disease (GERD), and suspected foreign body in the esophagus. It is also used as a screening tool for the evaluation of head and neck cancers and of Barrett disease. After the larynx is visualized for gross mobility, pharyngeal squeeze, and pooling of secretions, the patient is asked to swallow, and the endoscope is advanced through the cricopharynx. Cricopharyngeal opening and closure occur in less than 1 second, but the movement is captured digitally and can be reviewed. Cricopharyngeal relaxation is assessed. The scope is then passed toward the stomach with minimal insufflation of air. Mucosal irregularities and anatomical abnormalities, such as esophagitis, ulcers, webs, strictures, diverticula, varices, and masses, can be visualized as the scope is passed. Foreign bodies can also be identified and removed. The gastroesophageal junction is evaluated. Particular attention is paid to the Z-line, where the pale esophageal squamous epithelium transitions to the orange gastric columnar epithelium. It is assessed for continuity and regularity. Longitudinal blood vessels of the esophagus seen traversing the Z-line as well as Z-line irregularity may represent Barrett esophagus, which increases a patient's risk for esophageal carcinoma. A brush biopsy or four-quadrant cupped forceps biopsy of this area should be obtained. The lower esophageal sphincter is assessed for function, as well as for the presence of a hiatal hernia. The scope is then passed into the stomach and retroflexed, and the flap valve (closure of the gastroesophageal junction around the endoscope) is assessed from below. A patent flap valve occurs with a hiatal hernia and can predispose to reflux. Next, water and applesauce dyed with food coloring are swallowed. A normal swallow should allow pureed food to pass in less than 13 seconds. Clear water is then given to flush the esophagus and

allow an assessment of gross motility and peristalsis. The scope is withdrawn, and the mucosal surfaces are again visualized. The advantages of TNE include the office setting, topical rather than sedative anesthesia, minimal time lost from work, and lack of post-examination nausea or fatigue. In addition, this test can readily identify pathology along the entire upper gastrointestinal tract, providing quick diagnostic information. TNE is also less expensive when performed in the office setting. The disadvantages include occasional minor discomfort, the small caliber of the endoscope's operative port (which prevents the use of any equipment other than biopsy forceps), and the limited distal visualization to the stomach.

81.6 pH and Impedance Monitoring

In the past few decades, laryngopharyngeal reflux has been noted to be a significant cause of dysphagia in many patients. Reflux testing has evolved and can be an important tool in diagnosing reflux disease. To evaluate laryngopharyngeal reflux, pH testing is performed by placing a dual pH probe through the nose and into the esophagus. Ideally, this is accompanied by impedance testing, which detects the presence of liquid refluxate, either acidic or nonacidic. The upper probe is placed approximately 1 cm above the upper esophageal sphincter, either under direct vision or with the use of concurrent manometry. The level of acidity and presence of liquid refluxate are then recorded for a 24-hour period. Dietary intake and symptoms are recorded and compared with the pH and impedance tracing to isolate and correlate events with symptoms. A newer pH probe has recently been created that records pH of the nasopharynx only. This new system is more comfortable and provides information about the acidity of the naso-oropharynx for 24 hours. Placement is simple, via visualization of a guiding blinking light at the end of the probe, and a good position is confirmed with the sip of an acidic beverage. This new probe is helpful as a screening tool, but it does not provide the information on esophageal motility that is obtained with manometry (performed with the dual pH probe). pH tests can help guide treatment by quantifying the amount of reflux present, and patients can be evaluated while taking proton pump inhibitors to determine their response to this management. A patient can also be tested while off proton pump inhibitor therapy when it is expected that laryngopharyngeal reflux is not contributing the patient's disease and needs to be ruled out.

Impedance testing can be added to pH testing to evaluate for the presence of nonacidic reflux, which can be a cause of laryngeal symptoms but not respond to acid-suppressive medications. This can be performed at the same time as pH testing. An impedance catheter is placed within the esophagus. A series of electrodes detect changes in the electrical conductivity of the region of the esophagus in which the electrodes lie. Liquid and gas (refluxate) increase conductivity and thus change the impedance of an electrode, denoting the presence of refluxate.

The advantage of pH and impedance testing is that it provides objective information about the role of LPRD/GERD in patients' disorders. In addition, this type of testing has a very high degree of sensitivity. The disadvantages include the discomfort

involved and the need to wear the equipment for 24 hours. The information obtained with this type of testing is subject to interpretation because a consensus on the interpretation of pH and impedance testing data has not been achieved.

81.7 Esophageal Manometry

This procedure involves placing a long catheter through the nose and into the esophagus as one would pass a nasogastric tube. The catheter has numerous pressure transducers along its length. The patient is instructed to swallow both dry and with liquids. The timing of pharyngeal and esophageal contractions, the strength of the contractions, and the sequencing of pressure events are recorded by this multichannel transducer. This test is useful for determining the strength of pharyngeal contraction, cricopharyngeal dysfunction (both patulous and nonrelaxing), esophageal motility disorders, and problems related to the discoordination of pharyngeal and esophageal contraction. Descriptions of absolute pressures and muscular coordination within the pharynx and esophagus are advantages of manometry. This information is easily obtained, is relatively inexpensive, and helps guide future therapy. The disadvantages include the discomfort sometimes involved during catheter placement and the lack of direct visualization of structures during the test.

81.8 Manofluorography

This technique simultaneously combines the fluoroscopic evaluation of swallowing with manometry. The advantage of this test is that it allows a precise temporal coordination of pressure information with the position of the bolus. Unfortunately, more equipment and significant expertise are required. Recent advances in technology are decreasing the level of expertise need to perform this test while increasing its accuracy, but the test is currently prohibitively expensive.

81.9 Scintigraphy

A bolus of food material coated with a short-lived isotope is administered orally to the patient. A gamma ray camera then measures the radioactivity as the bolus passes through the upper aerodigestive tract. Residue of material and aspiration can be detected. Transit of the bolus through the esophagus with timing and directionality can be assessed. The reflux of contents from the stomach and esophagus into the larynx can be assessed for hours after bolus ingestion. The food material is then monitored during its transit out of the stomach into the small intestine. This test is used primarily to study gastric emptying. It is easy to perform, causes no discomfort, and has minimal risk from low-dose radiation. It is sensitive for aspiration and reflux events. Quantitative analysis of the portion of the bolus aspirated can be done. The disadvantages are the need for low-dose radioactive material, the need for a gamma counter and experienced technicians, and the lack of direct visualization of the structures involved. In addition, multiple boluses are not used, and compensatory techniques cannot be assessed.

81.10 Ultrasonography

Ultrasonography is used primarily to evaluate the soft tissue of the oral cavity and oropharynx. Movement of the tongue and intrinsic musculature, the gross morphology, the presence of tumors, and the timing of swallow can be followed. In addition, multiple swallowing attempts can be assessed. Elevation of the hyoid can be tracked with ultrasonography. Endoluminal ultrasonography can be used to study the esophagus and cricopharyngeal region. Because of the lack of radiation, ultrasonography is a good technique to assess the oral and oropharyngeal phases of swallowing in children.

81.11 Computed Tomography and Magnetic Resonance Imaging

When a mass is suspected, the appropriate radiographic testing can be ordered. These techniques are covered elsewhere.

81.12 Conclusion

The history and physical examination should be used to guide the choice of diagnostic testing. In most cases, the cause of dysphagia can be pinpointed to a certain area of the upper aerodigestive tract. Testing is then ordered to confirm the area of dysfunction and/or elucidate the exact nature of the problem. If testing is chosen carefully, rarely does a patient need more than one test to confirm the diagnosis and initiate treatment. □ Table 81.1 outlines the preferred tests for particular problems.

81.13 Roundsmanship

- Dysphagia evaluation requires flexible fiber-optic nasopharyngolaryngoscopy for the examination of the involved anatomy and its function, including mucosal lesions, velopharyngeal competence, epiglottic retroflexion with closure of the laryngeal vestibule, vocal fold mobility, pharyngeal squeeze, laryngeal elevation, and the presence of pooled secretions at baseline.
- Modified barium swallow is generally used to evaluate patients with suspected neurologic compromise, postoperative changes, upper esophageal sphincter dysfunction, or dysphagia to liquid boluses. FEESST can also provide useful information in these situations.
- Barium swallow can aid in the diagnosis of mucosal irregularities, webs, rings, strictures, extrinsic compression, diverticula, foreign bodies, upper esophageal sphincter/lower esophageal sphincter/cricopharyngeal dysfunction, gastroesophageal reflux, airway aspiration, endoluminal masses, and esophageal dysmotility.
- Transnasal esophagoscopy can be used in patients with dysphagia, laryngopharyngeal reflux disease, chronic cough, globus, odynophagia, symptoms of GERD, and suspected foreign body of the esophagus. It is also useful as a screening tool for the evaluation of head and neck cancers and for Barrett disease.

Table 81.1 Comparison of diagnostic tests demonstrating which tests are better suited to detect particular symptoms and define location of etiology

	MBS	FEESSST	TNE	US	Scintigraphy	BS	pH Testing	Manometry	Impedance

Abbreviations: BS, barium swallow; FEESSST, flexible endoscopic evaluation of swallowing and sensory testing; MBS, modified barium swallow; TNE, transnasal esophagoscopy; US, ultrasound.

- pH and impedance testing is highly sensitive can provide objective information in cases of suspected LPRD/GERD.
- Esophageal manometry can document the strength of pharyngeal contraction, hypo- and hyperfunctioning of the cricopharyngeus, disorders of esophageal motility, and problems related to discoordination of pharyngeal and esophageal contraction.

82 Evaluation and Management of the Hoarse Patient

Seth H. Dailey and Sunil P. Verma

82.1 Introduction

The ability to produce voice relies on three major components. The lungs serve as a generator to drive breath. The vocal folds serve as a vibrating source to make sound. The pharynx and oral cavity act as a filter to alter the sound into intelligible words.

The production of voice is integral for communication and enables an individual's personal and professional livelihood. As the ability to produce voice is an innate task, many take it for granted until an actual problem occurs. Hoarseness is a common problem, affecting approximately 20 million people in the United States at any one time.

82.2 Description of the Clinical Disorder

Hoarseness is a symptom of altered voice quality. Dysphonia is a disorder of voice production that impairs communication. Dysphonia may be a result of anatomical or functional components, and in some cases both. Causes range extensively from benign conditions such as muscle tension dysphonia to serious conditions such as a neurologic disease or malignancy. The keys to the diagnosis and management of dysphonia include a thorough history and physical examination that includes excellent visualization of the larynx.

82.3 Differential Diagnosis

- Infectious causes, such as viral, fungal, and bacterial infections. Fungal infections occur most commonly in patients who use inhaled steroids.
- Inflammatory causes, such as laryngopharyngeal reflux, post-nasal drip, allergies, and voice overuse.
- Phonotraumatic lesions, such as vocal fold cysts, polyps, nodules, and scar. These lesions most commonly occur in the mid-musculomembranous section of the vocal fold, where shear stress is the highest.
- Benign neoplasms, such as recurrent respiratory papillomatosis and granular cell tumors.
- Primary malignancies, including squamous cell cancer and minor salivary gland tumors. Secondary malignancies include invasive thyroid cancer and tracheal cancer.
- Neurologic conditions, such as spasmodic dysphonia, tremor, and Parkinson disease.
- Conditions of glottic insufficiency, including vocal fold paralysis, paresis, and presbylarynges. Affected individuals typically experience vocal fatigue and exhibit a diminished maximum phonation time.
- Vascular lesions, such as hemangiomas, varices, and ectasia. These may result in hemorrhage accumulating in the superficial layer of the lamina propria.
- Systemic conditions, including rheumatoid arthritis and amyloidosis. The former typically causes vocal fold immobility, and the latter is a multilobulated mass within the glottis.

- Traumatic lesions, including intubation injuries and external blunt or sharp trauma. Post-intubation hoarseness is a common phenomenon associated with vocal fold hypomobility due to cricoarytenoid joint fixation or recurrent laryngeal nerve neurapraxia. Blunt or sharp trauma is not as common.
- Insult to the vagus nerve or recurrent laryngeal nerve. This may be due to mass effect from lesions, iatrogenic injury, or pathology in the brainstem, neck, and chest.
- Iatrogenic injury to the recurrent laryngeal nerve is the most common cause of vocal fold paralysis. Surgeries with a risk for recurrent laryngeal nerve injury include intracranial surgery; neck procedures, such as surgery to the carotid artery, cervical spine, thyroid, and esophagus; and chest procedures, including pulmonary, cardiac, and vascular surgery.
- Functional voice disorders, such as muscle tension dysphonia.

82.4 Evaluation of the Disorder

82.4.1 History

An excellent history is paramount in the evaluation of hoarseness. During the work-up, the patient should be questioned about the following:

1. Onset: gradual versus sudden. A gradual onset may be associated with neurologic conditions or malignancy. Causes of a sudden onset may include hemorrhage or even muscle tension dysphonia.
2. Duration of hoarseness.
3. Circumstances surrounding the onset.
4. Associated symptoms such as difficulty swallowing and shortness of breath often point to extensive laryngeal conditions.
5. Mitigating factors. Hoarseness that is constant often points to an anatomical lesion.
6. Social history, including tobacco or alcohol use.
7. Voice demands and use, both social and professional.

82.4.2 Physical Examination

All patients with hoarseness should undergo a complete head and neck examination. Special care should be taken with the cranial nerve examination, specifically examination of the palate and tongue for evidence of paresis, paralysis, or neurodegeneration. Neck palpation evaluates for the presence of neck masses, including lymphadenopathy and thyroid lesions.

Endoscopy of the larynx is critical to make a proper diagnosis. Endoscopy should assess for numerous items, including the following:

- Global evaluation of the laryngeal structures, including the epiglottis, arytenoid position, aryepiglottic folds, piriform sinuses, postcricoid area, false (vestibular) vocal folds, and true vocal folds.
- Vocal fold adduction and abduction. Limitations may point to a neurologic etiology, such as recurrent laryngeal nerve damage, or a mechanical etiology, such as joint fixation from rheumatoid arthritis or traumatic scarring.

- Vocal fold epithelium. Leukoplakia may be a result of hyperkeratosis and be associated with dysplasia or malignancy. Erythroplakia has a stronger association with malignancy than leukoplakia.
- Vocal fold vasculature. Normally, the vocal fold vasculature runs parallel to the vocal fold medial edge. Vasculature that travels perpendicular to this often “points” to phonotraumatic lesions. Tortuous vasculature may be associated with papilloma or malignancy. Ectasia and varices are typically results of trauma within the superficial layer of the lamina propria.
- Vocal fold symmetry, including epithelium, vasculature, and height. It is important to examine both vocal folds for abnormalities because phonotraumatic lesions are often bilateral. Specific attention should be paid to the vocal fold height because vocal fold paralysis may cause dysphonia when the two vocal folds differ in height.

An indirect examination of the larynx with a laryngeal mirror is important for many reasons. A mirror examination is a very quick procedure that provides a global view of the laryngopharynx. However, the examination is limited by a patient’s gag reflex, provides only a transient view of the larynx, and does not allow the photodocumentation of findings.

Transoral rigid examination uses a 70-degree angled telescope for laryngeal visualization. Transoral laryngoscopy is best performed in patients with a limited gag reflex and may be carried out with halogen or stroboscopic light. Because of its large diameter, a rigid telescope provides abundant light to illuminate the larynx. A transoral telescope coupled with a camera permits the view to be magnified and recorded. Recording allows the surgeon to review an examination after it is performed and to compare it with later examinations during future visits.

Transnasal flexible endoscopy provides the advantage of being able to evaluate the larynx during connected speech. The examination is performed with the patient in a more “natural” position than during transoral endoscopy and is thought to provide a more accurate evaluation of laryngeal motion. Transnasal endoscopy can be performed with a flexible fiber-optic laryngoscope or a distal chip endoscope. The illumination and image quality are superb with the latter; however, its availability is limited by its expense. Transnasal flexible endoscopes may be coupled with halogen light, xenon light, or stroboscopic light.

The addition of stroboscopic light provides the physician with the ability to evaluate the membranous vocal fold in pseudo-slow motion. For this to occur, the frequency at which the stroboscopic light flashes is coupled to the frequency of the patient’s voice, as measured by a microphone placed along the patient’s neck external to a thyroid ala. The pseudo-slow motion image allows an evaluation of the mucosal wave, amplitude of vibration, any adynamic segments, phase closure, and periodicity. Laryngovideostroboscopy can be essential for the evaluation of a patient with hoarseness.

82.5 Testing

82.5.1 Radiography

Computed tomography (CT) of the larynx with intravenous contrast is helpful if an invasive process such as cancer is sus-

pected or if there has been laryngeal trauma. If vocal fold mobility is compromised, CT or magnetic resonance (MR) imaging is necessary to rule out pathology impinging upon the recurrent laryngeal nerve. The examination must include the vagus nerve from the skull base to the aortic arch.

82.5.2 Electromyography

Electromyography (EMG) is helpful in prognosticating the return of vocal fold motion in patients with 2 to 6 months of vocal fold immobility secondary to a neurogenic cause. It may also distinguish neurogenic from mechanical causes of vocal fold immobility, particularly after intubation trauma. EMG may be helpful in the diagnosis of vocal fold paresis as well.

82.5.3 Microbacterial Testing

Rarely, a culture of the larynx is performed if fungal or bacterial laryngitis is suspected but is atypical in presentation or unresponsive to empiric treatment.

82.5.4 Histopathology

A biopsy can be performed in the office or operating room for any suspected neoplasm.

82.6 Treatment

The etiology of dysphonia is often multifactorial, which is the reason for such a thorough investigation. Because of the numerous causes of dysphonia, it is difficult to describe thoroughly all possible treatment options. In general, the initial findings often dictate the first step in management and the need for further studies. For example, if a neurologic disorder is suspected, consultation with a neurologist specializing in movement disorders may be indicated.

If infection is suspected, then antivirals, antibiotics, or antifungals should be used appropriately. Swish and swallow antifungal medications should not be used because they are topical. Treatment with a systemic medication such as fluconazole is recommended.

Laryngopharyngeal reflux may contribute to voice disorders, causing symptoms of mild hoarseness, throat clearing, and globus sensation. Laryngopharyngeal reflux is managed with lifestyle changes; dietary changes are emphasized, including the avoidance of acidic foods and a decrease in meal sizes. Proton pump inhibitors may be initiated, with patients instructed to take their medication at least 30 minutes before meals.

Rhinitis with postnasal drip may be controlled with saline irrigation, nasal steroids, antihistamines, or anticholinergic nasal sprays. A thorough work-up of allergic or chronic rhinosinusitis may be necessary.

Voice therapy is a key portion of the management of many voice disorders. Speech pathologists may work with patients regularly to improve voicing technique and efficiency. Voice therapy is an important tool for patients with functional voice disorders as well as those with lesions requiring surgery. Voice therapy should be used both before and after surgery to optimize results.

Phonomicrosurgery will benefit patients with benign lesions that are refractory to voice therapy.

Papillomatosis often requires multiple surgeries through a patient's lifetime. Adjunctive treatments include lasers and indole-3-carbinol. Cidofovir may benefit certain patients.

Patients who have spasmodic dysphonia and occasionally laryngeal tremor can be helped with botulinum toxin.

Patients with glottic insufficiency may benefit from voice therapy. In many cases, the vocal folds require augmentation, which may be performed with injection laryngoplasty or type I thyroplasty.

Unilateral type I thyroplasty with or without arytenoid adduction is a definitive treatment for patients who have unilateral vocal fold paralysis.

82.7 Roundsmanship

- Hoarseness is a symptom of altered voice quality. Dysphonia is a disorder of voice production.
- Although laryngopharyngeal reflux is present in many patients with hoarseness, a full work-up is warranted.

- The etiology of hoarseness is often multifactorial, and a proper diagnosis relies on an excellent history and physical examination, especially endoscopy.
- Laryngovideostroboscopy allows the evaluation of membranous vocal fold motion in pseudo-slow motion. Mucosal wave, amplitude of vibration, any adynamic segments, phase closure, and periodicity can be evaluated.
- A proper investigation for idiopathic vocal fold immobility includes CT or MR imaging along the course of the vagus nerve from the skull base to the aortic arch.

83 Laryngitis

Craig H. Zalvan

83.1 Introduction

Laryngitis by definition refers only to inflammation of the larynx. The word laryngitis is commonly used erroneously by patients and physicians to describe symptoms such as change in voice, loss of voice, and/or discomfort in the throat. Laryngeal inflammation can be caused by a wide variety of conditions and associated with a myriad of other symptoms. This chapter will explore the causes of inflammation of the larynx that lead to symptoms referable to the larynx and pharynx. Noninflammatory conditions of the larynx leading to similar symptoms will be covered elsewhere.

83.2 Incidence

Although there are no data on “laryngitis” specifically, in 1996 there were 23.6 cases of the common cold and 36 cases of influenza per 100 people in the United States. Most patients with upper respiratory tract infections will have one symptom or another of laryngitis, and nearly everyone will experience laryngitis at some point in his or her life.

83.3 Classification

Acute laryngitis usually lasts up to 7 days and is typically self-limited. Subacute laryngitis lasts from 1 to 3 weeks. Laryngitis lasting for more than 3 weeks is considered chronic. In addition, patients can have recurrent bouts of laryngeal inflammation lasting for days to weeks. Laryngitis lasting longer than 3 weeks should be evaluated by an otolaryngologist, and direct visualization of the larynx should be performed.

83.4 Applied Anatomy

Laryngitis is confined principally to the mucosa of the larynx, which is covered by respiratory epithelium except for the true vocal folds, which are covered by squamous epithelium. The thin mucosa and superficial lamina propria vibrate together over the deeper layers of the lamina propria and the underlying vocalis muscle. This unique arrangement is easily compromised by edema, which leads to hoarseness.

83.5 The Disease Process

83.5.1 Etiology

Acute laryngitis: Most cases of acute laryngitis are temporary. The vast majority are virally mediated (□ Fig. 83.1) and present as part of an upper respiratory infection with or without other symptoms, such as cough, rhinorrhea, nasal congestion, fever, headache, and malaise. Typically, as the respiratory symptoms improve, so do the voice and throat symptoms. Bacterial and fungal infection (□ Fig. 83.2), although rare, must also be considered.

Fig. 83.1 (a) Normal laryngeal examination. Note the smooth mucosa, sharply defined borders of the arcuate line, smooth vocal fold edges, tan-pale coloration, and moist, glistening surfaces. (b) Viral laryngitis with mid-membranous vocal fold epithelial thickening as well as erythema, edema, and hyperemia of the vocal folds.

Fig. 83.2 Fungal laryngitis. Note the white fungal plaques covering the entire surface of both vocal folds. There are also incidental bilateral granulomas.

In addition to infection, acute vocal trauma from vocal overuse, misuse, or abuse is a common cause of acute laryngitis. Typically, patients will detail a vocal event that precipitated the acute change. Benign conditions such as vocal fold nodules, polyps, cysts, and muscle tension may predispose a patient to acute voice loss and discomfort. In severe instances, vocal trauma may result in vocal hemorrhage and lead to significant vocal fold inflammation and acute vocal changes.

Underlying laryngopharyngeal reflux may be exacerbated by stress, infection, medication, or dietary indiscretion. This can cause acute laryngeal inflammation and acute symptoms such as voice changes, throat clearing, globus pharyngeus, increased glottal mucus, and coughing.

Medications can secondarily lead to acute inflammatory changes by altering laryngeal hydration. Inhaled medication may directly cause inflammation from contact irritation as well as the initiation of a fungal infection. The increased use of inhaled steroids has led to an increase in the frequency of fungal laryngitis in immunocompetent individuals.

Allergies and environmental exposures can result in acute changes in breathing, respiration, mucosal hydration, and mucus production, all of which can lead to acute laryngitis.

Most cases of acute laryngitis are self-limited and improve over 1 to 3 weeks. Symptoms are often alleviated by conservative measures. Very rarely are antibiotics and steroids indicated for acute laryngitis.

However, some cases of acute laryngitis progress to chronic laryngitis after the initial acute phase has resolved. Chronic symptoms often prompt a visit to a medical doctor. Patients whose symptoms have lasted longer than 3 weeks should be evaluated by an otolaryngologist, who can visualize the larynx. This allows an accurate diagnosis to be made and treatment to be directed at the particular cause of the chronic symptoms.

83.5.2 Chronic Laryngitis

Laryngitis that persists more than 3 weeks is considered chronic. Systemic diseases (including collagen vascular disorders), insidious infectious disease, long-term environmental exposures, allergies, medications, and tumors are some of the more common causes of chronic laryngitis. Occasionally, acute laryngitis can cause secondary changes that result in chronic laryngitis. A careful history in a patient with symptoms of acute laryngitis often reveals chronic symptoms that have been present for weeks or months but were recently exacerbated. Laryngitis is often multifactorial. For example, viral laryngitis associated with a cough may cause a vocal hemorrhage, resulting in persistent hoarseness despite resolution of the viral component of the illness. Chronic laryngitis usually presents insidiously and progresses slowly over time. Any vocal changes, throat discomfort, or otalgia in a smoker requires evaluation by an otolaryngologist to rule out the possibility of laryngeal cancer.

83.5.3 Natural History

As stated above, most causes of acute laryngitis are virus-related and self-limited. Chronic laryngitis, if left untreated, can result in permanent changes in the vocal folds, such as thickening of the vocal fold mucosa, polypoid degeneration of the superficial lamina propria, and fibrosis or scarring.

83.5.4 Pathogenesis

Laryngitis is caused by acute or chronic changes to the larynx resulting from an inflammatory process. This involves a combination of humoral and cellular responses to mucosal irritation. The B-cell response to antibody–antigen activation leads to a cascade of inflammatory mediator release, cytokine release, complement activation, and cellular activation. Cell-mediated immunity results in the activation of macrophages, natural killer cells, and cytotoxic T cells. Acutely, tissue inflammation ensues, resulting in vasodilation with subsequent erythema, transudation of plasma with edema, inflammatory mediator release, and tissue destruction. Laryngeal edema, excess or insufficient mucus production, poor laryngeal closure, and mucosal stiffness result in the voice changes and discomfort associated with acute or chronic inflammation. Chronic inflammation can lead to localized fibrosis, scarring of the mucosa and superficial lamina propria, and a granulomatous reaction (□ Fig. 83.3).

83.5.5 Potential Disease Complications

Acute laryngitis primarily causes discomfort of the laryngopharynx and dysphonia. This can lead to missed work, missed performances, and inconvenience for the patient. Rarely is there sufficient edema to cause airway compromise; however, this is may be a concern in a patient with an abnormally narrow glottis secondary to another disorder. Continued or excessive use of the voice during acute or chronic laryngitis can prolong and exacerbate symptoms, as well as lead to mucosal tears, acute hemorrhage, and muscle strain. Maladaptive phonatory behaviors secondary to acute or chronic inflammation can result in benign vocal fold lesions such as nodules, polyps, and cysts, as well as permanent fibrotic changes.

83.6 Medical Evaluation

83.6.1 Presenting Complaints

Dysphonia is defined as any change in voice: breathy, raspy, or rough voice; voice breaks or cracks; change in range; vocal

Fig. 83.3 Chronic laryngitis. Note the thickened mucosa of the entire supraglottis, with thick strands of white mucus; the smooth character of the mucosa is replaced with a rough, corrugated appearance.

fatigue or strain; loss of voice (aphonia) or whisper voice. Patients may describe a globus sensation (the feeling of having a lump in the throat) or discomfort in the throat; sharp pains or dull aches, either unilateral or bilateral, are often exacerbated by talking, swallowing, or eating. Occasionally, patients will have referred otalgia secondary to the shared vagal afferent innervation of the larynx and external auditory canal. In addition, the onset of laryngitis can often be accompanied by other respiratory tract symptoms, such as congestion, fever, headache, cough, and dysphagia. Airway symptoms such as stridor, dyspnea, croupy cough, and recurrent pneumonia should prompt immediate evaluation. Additionally, laryngitis in the setting of a preexisting airway abnormality, such as a tumor, laryngotracheal scarring, or vocal paralysis, can result in respiratory distress with airway compromise.

83.6.2 Evaluation

Most patients with acute laryngitis do not seek a medical evaluation. When symptoms are severe or long-lasting or cause functional difficulties for the patient, a medical evaluation is often obtained.

A thorough history is performed. A description of vocal changes and associated symptoms is obtained, including timing and severity. This is followed by questions about vocal hygiene, demands, use, and abuse, as well as the environment in which the voice is being employed, in order to obtain a sense of the patient's vocal behavior. In addition, information should be acquired about prior treatment, environmental exposures, laryngopharyngeal reflux symptoms, symptoms of allergy, medication use, history of systemic disease, and history of neurologic disorders or symptoms.

A thorough head and neck examination should be performed, followed by a laryngeal examination with a flexible laryngoscope. In cases of dysphonia, laryngovideostroboscopy should be performed as well, to assess vocal fold vibration and glottal function.

Acute laryngitis is often characterized by inflammation of the laryngeal structures with edema of the glottis and supraglottis. Hyperemia and surrounding erythema are more common in acute laryngitis. Excess mucus production is also common. Chronic laryngitis is often associated with excessive dryness of the larynx and mucosal thickening, with decreased mucosal wave on videostroboscopy. In some cases, granulation, keratosis, and fibrosis, as well as benign vocal fold changes such as a polyp, cyst, or nodule, may be seen. Of course, the presence of a malignant lesion must always be considered.

Typically, patients with acute laryngitis do not need further work-up unless the symptoms become chronic or worsen during treatment. Patients who present with recurrent episodes of acute laryngitis should not only be treated for the acute episode but also further evaluated to determine the underlying chronic disorder that predisposes them to these exacerbations.

Most cases of laryngitis, especially chronic cases, are multifactorial, and all the inciting and exacerbating factors need to be identified and addressed (□ Fig. 83.4).

Fig. 83.4 Ulcerative laryngitis. Note the thickened mucosa with white coloration; anteriorly are bilateral tan-brown plaques that are completely stiff on stroboscopy. These areas can be confused with squamous cell carcinoma.

83.6.3 Testing

For patients with chronic laryngitis, further work-up is typically dictated by the response to medication, and a definitive diagnosis is determined by the history and physical examination (including laryngeal videostroboscopy) and failure to respond to treatment. This may include flexible endoscopic evaluation of swallowing and sensory testing (FEESST) for patients with dysphagia, pH testing for those with suspected refractory laryngopharyngeal reflux, modified barium swallow (MBS), allergy testing, and appropriate laboratory testing for suspected systemic disease: thyroid function tests; Lyme titers; erythrocyte sedimentation rate (ESR); C-reactive protein (CRP); angiotensin-converting enzyme (ACE); antinuclear antibody (ANA); rheumatoid factor (RhF); cytoplasmic and perinuclear antineutrophil cytoplasmic autoantibody (c-ANCA and p-ANCA). Electromyography (EMG) of the larynx can be performed for suspected neuromuscular disease. For any suspicious mass or lesion, an unsedated in-office biopsy or direct laryngoscopy with biopsy in the operating room should be performed.

83.6.4 Differential Diagnosis

- Laryngopharyngeal reflux
- Medications
 - Systemic effects
 - Local effects
- Infections
 - Viral
 - Bacterial
 - Fungal
 - Syphilis, leprosy, tuberculosis
- Environmental exposures
 - Smoking
 - Ethanol
 - Toxic inhalants
- Trauma, surgery
 - Vocal fold hemorrhage
 - Intubation
 - Postsurgical inflammation

- Bulimia, vomiting
- Caustic ingestion
- Hormones
 - Oral contraceptive pills
 - Hormone replacement therapy
 - Menopause
 - Menses
- Allergy
- Acute and chronic vocal fold misuse
- Dehydration
- Systemic disease
 - Amyloidosis, systemic lupus erythematosus, Wegener granulomatosis, rheumatoid arthritis
- Tumor
 - Benign
 - Malignant
 - Chemotherapy and radiation therapy

83.7 Treatment

83.7.1 Medical Treatment

The vast majority of patients with acute laryngitis need only treatment for symptomatic relief. Voice rest and modified voice use are instituted when voice changes are present. Hydration is extremely important and can be provided by having the patient drink at least eight glasses of water a day, inhale a cool mist via a personal or room humidifier, and use oral inhalation agents free of anesthetics and irritants (e.g., Entertainer's Secret Throat Relief Spray: www.entertainers-secret.com). Anti-inflammatory medications, antitussives, mucolytics, and nasal decongestants can be prescribed to alleviate acute symptoms. Patients should be counseled to avoid whispering to prevent long-term maladaptive compensatory behaviors. Rarely are antibiotics and antiviral medications warranted. For suspected laryngopharyngeal reflux, a reflux restricted diet is prescribed and proton pump inhibitors may be added, depending on the severity of symptoms and findings on examination. For patients who have severe dysphonia associated with severe laryngeal edema and need rapid resolution of their symptoms, oral or intramuscular steroids can be given. The larynx must be examined before steroids are prescribed to ensure the absence of vocal fold hemorrhage or mucosal abnormalities. The repeated use of steroids is not advised and is an indication of an underlying chronic condition that should be addressed. In cases of suspected fungal laryngitis, antifungal medications such as fluconazole are prescribed. Inhaled steroids should be discontinued; if this is not possible because of severe pulmonary disease, an aerosolized steroid should be prescribed and administered with a spacer at the minimal effective dose.

For patients with chronic laryngitis, an extensive otolaryngology evaluation should reveal the underlying disorder or disorders at which treatment will be directed. In all cases, the conservative treatment outlined above will be useful in alleviating some of the symptoms.

Although voice rest may be helpful in acute situations, it does not address underlying pathologic voice use patterns and is therefore beneficial only for acute treatment. Voice therapy may be helpful for patients with recurrent acute or chronic lar-

ngitis. An evaluation by a speech–language pathologist will direct this aspect of a patient's treatment. Voice therapy helps identify poor vocal behaviors and targets treatment to address these behaviors via vocal retraining and exercise.

Careful follow-up should be arranged in cases of chronic laryngitis to optimize patient outcomes.

83.7.2 Surgical Treatment

Rarely is surgery indicated for cases of laryngitis, either acute or chronic. In acute laryngitis, airway intervention is rarely necessary but should be considered for patients with airway compromise. For patients with chronic laryngitis, biopsy of the larynx may be necessary to obtain a histopathologic diagnosis of an observed mass or lesion. This may be performed in the office with the patient unsedated or in the operating room via direct laryngoscopy with the patient under general anesthesia. Operative treatment may also be warranted in cases of laryngitis that have led to complications of benign vocal fold lesions, such as granulomas, fibrosis, nodules, polyps, or cysts.

83.8 Prognosis

The prognosis for full recovery in most cases of acute laryngitis is excellent, typically with complete resolution of the symptoms within 1 week. In cases of recurrent acute or chronic laryngitis, once the cause of the inflammation is diagnosed, the prognosis is generally excellent. In cases in which laryngitis is complicated by laryngeal fibrosis and scar formation involving the vocal folds, the prognosis for recovery is not as favorable. Chronic symptoms of dysphonia and discomfort may persist despite numerous and aggressive treatments or surgeries.

83.9 Roundsmanship

- Laryngitis by definition refers only to inflammation of the larynx. The word laryngitis is commonly used (incorrectly) by patients and physicians to describe symptoms such as change in voice, loss of voice, and/or discomfort in the throat.
- Most cases of acute laryngitis are virally mediated and require only conservative treatment to provide relief of symptoms in a few days or weeks.
- Recurrent acute laryngitis or the repeated use of steroids is an indication of an underlying chronic disorder.
- The etiology of chronic laryngitis is generally multifactorial.
- Once the multiple causes of chronic laryngitis are identified, the prognosis is excellent, except in cases complicated by vocal fold fibrosis and scarring due to severe or prolonged laryngitis.

84 Systemic Diseases of the Larynx

Melin Tan

84.1 Introduction

The larynx is a complex anatomical organ whose structure and function are influenced by its cartilaginous framework, muscles, mucosa, and cricoarytenoid joints. Many systemic diseases alter the function of the larynx or infiltrate the trachea, leading to a compromised airway and/or compromised phonation. This section will review the laryngeal manifestations of rheumatoid arthritis, systemic lupus erythematosus, relapsing polychondritis, sarcoidosis, Wegener granulomatosis, and amyloidosis. □ Table 84.1 summarizes the incidence of laryngeal findings in these disorders, in addition to their clinical manifestations, examination findings, diagnosis, and treatment.

84.2 Rheumatoid Arthritis

Rheumatoid arthritis is an autoimmune chronic inflammatory disease that affects synovial membranes, leading to bone and joint destruction. It is a systemic disorder with numerous extra-articular manifestations, including serositis, nodule formation, and vasculitis. Laryngeal manifestations of rheumatoid arthritis include cricoarytenoid joint arthritis, node formation on the true vocal folds, and rarely, amyloid deposition.

84.2.1 Incidence

Laryngeal involvement is common in RA; however, the true incidence is unknown.

84.2.2 Clinical Manifestations

Inflammation may occur in the cricoarytenoid joint, which is a true diarthrodial articulation formed by the cricoid and arytenoid cartilages. The symptoms of cricoarytenoid joint involvement are vague and nonspecific. They include globus (a sensation of fullness or tension in the throat), hoarseness, odynophagia, and pain during speaking or coughing. Hoarseness and stridor with exertion are mainly symptoms of chronic disease, as joint ankylosis may develop and cause airway obstruction. Alternatively, acute and chronic disease may be completely asymptomatic.

In addition to affecting the joint, rheumatoid arthritis may affect the membranous vocal fold. Cystic yellow nodes may develop in the submucosal space at the junction of the anterior and middle thirds of the vocal folds. They were first described in 1993 by Hosacko, who called them “bamboo nodes” because of their resemblance to bamboo joints (□ Fig. 84.1 and □ Fig. 84.2). Since that time, bamboo nodes have been identified in several autoimmune diseases. Patients who have bamboo nodes generally present with dysphonia. The nodes are found mainly in patients with seropositive rheumatoid arthritis and tend to recur, in contrast to other laryngeal nodular or cystic lesions. Amyloid deposits are rare but have been found in the larynx of patients with rheumatoid arthritis and other autoimmune diseases.

84.2.3 Examination Findings

In the acute setting, direct laryngoscopy demonstrates inflamed and erythematous cricoarytenoid joints. The true vocal folds may appear normal or slightly edematous. Bamboo nodes are rarely present. Findings in the chronic phase include thickened mucosa over the arytenoids, a narrowed glottic chink, bowing of the vocal folds during phonation, and a variable degree of restricted mobility. The diagnosis is made by the clinical findings and confirmed by serology that shows an elevated erythrocyte sedimentation rate, elevated rheumatoid factor level, decreased complement levels, and an abnormal lupus panel.

84.2.4 Treatment

Medical management includes steroids or other anti-inflammatory medications. Surgical interventions include local injection of steroids into the cricoarytenoid joint or membranous vocal fold. Tracheostomy or cordotomy is performed for a compromised airway. The microsurgical excision of bamboo nodes is controversial because the results are inconsistent, and surgery in the face of such inflammation may lead to severe vocal fold scarring and increased dysphonia.

84.3 Systemic Lupus Erythematosus

Systemic lupus erythematosus is a common autoimmune disease in which circulating immune complexes cause damage to blood vessels, connective tissues, and mucosal surfaces, most often in the skin, joints, kidneys, and lungs. The most frequent otolaryngologic manifestation is the formation of ulcerative lesions of the oral cavity. The larynx is rarely involved, but the mucosa and submucosa of the laryngeal structures may be affected. When the larynx is involved, the glottis and cricoarytenoid joints are the most commonly affected areas.

84.3.1 Incidence

Laryngeal involvement is variable, appearing in from 1 to 30% of affected patients.

84.3.2 Clinical Manifestations

In the acute phase of systemic lupus erythematosus, mucosal ulceration and edema and submucosal hematomas may cause hoarseness, dyspnea, and throat pain. Late effects of the disease include corditis, mucosal thickening, laryngeal scarring with stenosis, and laryngitis sicca with dry, thickened vocal cords. The disease process may also lead to vocal fold fixation, perichondritis, and cricoarytenoid arthritis.

ff

Fig. 84.1 “Joints” seen in “bamboo nodules” in the true vocal folds of a patient with rheumatoid arthritis.

Fig. 84.2 Distinct nodes in rheumatoid arthritis.

Fig. 84.3 Supraglottic edema in sarcoidosis.

Fig. 84.4 Thickened and inflamed laryngeal mucosa in sarcoidosis.

84.3.3 Examination Findings

The diagnosis of systemic lupus erythematosus is based on clinical manifestations of disease involving two or more organ systems. Increased antinuclear antibody (ANA) titers are also sensitive for the disease. Anti-dsDNA (double-stranded DNA) antibody, a subtype of ANA, is highly specific for systemic lupus erythematosus and present in 70% of cases. In patients with an established diagnosis of systemic lupus erythematosus, the laryngeal examination may be completely normal; alternatively, the larynx may be erythematous and edematous, frank ulcerations may be present, and there may be abnormal vocal fold motion.

84.3.4 Treatment

Medical therapy for systemic lupus erythematosus includes high-dose steroids, nonsteroidal anti-inflammatory drugs, and antimalarial drugs. Tracheostomy or cordotomy may be performed for a compromised airway.

Fig. 84.5 Submucosal supraglottic accumulation of amyloid.

84.4 Relapsing Polychondritis

Relapsing polychondritis is a rare disorder characterized by recurrent episodes of inflammation of the cartilaginous and connective tissue. Auricular chondritis is the most common initial presentation, but episodes of inflammation can occur in any cartilaginous area. Laryngotracheal involvement is well recognized and is considered ominous because loss of the supportive cartilaginous scaffolding of the upper respiratory airways may lead to significant morbidity and mortality.

84.4.1 Incidence

From 21 to 50% of patients with relapsing polychondritis have symptomatic airway involvement, with a female predominance of 73:1.

84.4.2 Clinical Manifestations

Symptoms of airway involvement include cough, hoarseness, aphonia, choking sensation, and dyspnea. Patients may also demonstrate tenderness over the thyroid cartilage and anterior cervical trachea if these cartilages are affected. Airway obstruction can occur by several mechanisms: (1) airway encroachment by structures with inflammatory swelling in the active stage of the disease; (2) the formation of a mass of fibrous tissue with cicatricial contraction during the later stages of the disease; (3) dissolution of the tracheobronchial cartilage, with subsequent collapse of the airway during respiration.

84.4.3 Examination Findings

Laryngoscopy and bronchoscopy demonstrate variable findings, including glottic and supraglottic edema, laryngomalacia, tracheomalacia, bronchomalacia, and subglottic stenosis. The diagnosis of relapsing polychondritis is based on the clinical involvement of at least three cartilaginous areas. No serologic tests are sensitive or specific for relapsing polychondritis.

84.4.4 Treatment

The medical treatment for relapsing polychondritis includes steroids and immunosuppressive medications. Intubation in the patient with relapsing polychondritis may be difficult, depending on the degree of cartilaginous destruction in the upper airway. Dynamic obstruction from airway collapse may require continuous positive airway pressure (CPAP) or stenting. Tracheostomy is helpful only for proximal airway disease. Distal airway involvement may lead to death from obstructive respiratory failure if stenting is unsuccessful.

84.5 Sarcoidosis

Sarcoidosis is a chronic granulomatous disease characterized by noncaseating granulomatous inflammation. Although it may involve any organ system, it most commonly affects the lymph nodes, lungs, spleen, and liver. In the larynx, sarcoidosis generally affects the supraglottis, but it can affect any subsite of the larynx and also cause vocal fold paralysis via involvement of the

recurrent laryngeal nerve. Chronic inflammation and granuloma formation distort the involved laryngeal tissues.

84.5.1 Incidence

Laryngeal involvement is estimated to occur in 1 to 5% of cases.

84.5.2 Clinical Manifestations

Initially, the laryngeal involvement may be relatively benign, appearing as pale submucosal nodules. These nodules eventually coalesce to produce pale, edematous tissue affecting mostly the epiglottis and other supraglottic structures (□ Fig. 84.3). Lesions are rarely painful, and the symptoms depend on the site of involvement. The typical presentation is partial airway obstruction from distortion of the involved tissues, as well as dysphonia when the glottis is involved. The clinical course varies from spontaneous resolution to relentless progression and death.

84.5.3 Examination Findings

Laryngoscopy demonstrates edema of the epiglottis and supraglottic structures, or thickening and inflammation of the glottic and subglottic mucosa (□ Fig. 84.4). Chest X-rays demonstrate hilar adenopathy. The diagnosis is confirmed by the microscopic appearance of noncaseating granulomas, epithelioid cells, macrophages, and giant cells with inclusion bodies on biopsy. Alternative granulomatous diseases, such as Wegener granulomatosis, tuberculosis, and fungal infection, must be ruled out. Serologic testing is notoriously insensitive and non-specific, although angiotensin-converting enzyme levels can be used to track the activity of the disease.

84.5.4 Treatment

Medical therapy includes systemic steroids. Small lesions may benefit from intralesional steroid injection, and large lesions may require surgical debulking. Although the benefit is unclear, inhaled steroids may be effective in laryngeal disease. Tracheostomy or cordotomy is performed for airway obstruction.

84.6 Wegener Granulomatosis

Wegener granulomatosis is a well-defined syndrome of necrotizing granulomatous vasculitis of the upper airway, lower airway, and kidneys. Almost all patients with Wegener granulomatosis present with upper airway symptoms, and more than 90% have involvement of the nose or sinuses.

84.6.1 Incidence

Airway involvement affects 15 to 55% of patients with Wegener granulomatosis, and airway involvement tends to develop in patients younger than 30 years of age.

84.6.2 Clinical Manifestations

Wegener granulomatosis results in the development of necrotizing granulomas and necrotizing vasculitis. In the upper

airway, it manifests as mucosal abnormalities, subglottic stenosis, tracheobronchial stenosis, and malacia. Symptoms therefore range from hoarseness and sore throat to cough, hemoptysis, wheezing, dyspnea, and stridor. Patients often have bloody nasal discharge. Stridor can be the first manifestation of airway involvement, and the onset may be sudden or progressive. Subglottic stenosis is the most common cause of stridor in Wegener granulomatosis, and the differential diagnosis in any patient with stridor should include this disease.

84.6.3 Examination Findings

Laryngoscopy and bronchoscopy demonstrate a wide range of mucosal abnormalities, including edema, ulceration, hemorrhage, stenosis, granulomas, and necrosis. Additionally, there may be cartilaginous deformities. The diagnosis is suggested by the clinical findings and by positivity for cytoplasmic antineutrophil cytoplasmic autoantibodies (c-ANCA) on serology. The diagnosis may be supported by biopsy of a site of active disease. Upper respiratory tract biopsy demonstrates acute and chronic inflammation, with granulomatous features and vasculitis of the small and medium-size vessels.

84.6.4 Treatment

Medical therapy for Wegener granulomatosis includes steroids, cytotoxic agents, antibiotics, and immune modulators. Surgical management of the airway includes intralesional steroid injection, airway débridement and dilation, stent insertion, laryngotracheoplasty, tracheal resection, and tracheostomy. Surgical manipulation of the airway should be minimized during active disease because the inflammation will often respond dramatically to medical management, and surgical intervention may result in the exacerbation of inflammation and stenosis.

84.7 Amyloidosis

Amyloidosis is an idiopathic disease characterized by the deposition of fibrillar proteins into tissues. Primary amyloidosis involves the spontaneous deposition of protein, whereas secondary amyloidosis occurs in conjunction with another systemic disease, such as rheumatoid arthritis or multiple myeloma.

84.7.1 Incidence

Amyloidosis accounts for 0.2 to 1.2% of all benign tumors of the larynx.

84.7.2 Clinical Manifestations

Laryngeal amyloidosis is usually a primary disease but it may be secondary with laryngeal localization. Pathologically, it is a deposition of amorphous fibrillar protein that defines amyloid. Laryngeal deposition may be secondary to systemic processes including Immunoglobulin light chain amyloidosis, monoclonal gammopathies or reactive processes related to chronic inflammatory conditions such as arthritis or Crohns disease. Alternatively, it may be an isolated process in the larynx or laryngotracheal complex. It is important to distinguish between primary

and secondary amyloidosis because the distinction alters management. In the secondary form, systemic work up is warranted and the primary disease process is treated, controlling the formation of serum amyloid which then gets deposited into extracellular tissue. In the larynx, amyloidosis is more commonly a localized process; the true and false folds are the most common sites of involvement, followed by the aryepiglottic folds and subglottis (□ Fig. 84.5). Unlike the amyloid in secondary amyloidosis, amyloid here is a proliferation of monoclonal cells with immunoglobulin light chains deposited into tissues. Four patterns of deposition have been described in the larynx: amorphous masses, deposits in vessel walls, deposits in the basement membranes of seromucous glands, and hyalinized rings in adipose tissue. Management generally involves conservative surgery aimed at maintaining airway patency and improving voice.

84.7.3 Examination Findings

Patients typically present with long-standing hoarseness or dyspnea. The typical appearance is a smooth, pinkish gray or waxy yellow submucosal mass without ulceration of the overlying mucosa. There may also be significant obstruction in the subglottic region. Computed tomography shows thickening of the involved tissues. The diagnosis is made by laryngoscopy and biopsy. Light microscopy demonstrates acellular, amorphous, homogeneous, eosinophilic material. Classic Congo red histologic stains demonstrate apple green birefringence under polarized light. Additional diagnostic tests, including complete blood cell count, electrocardiography, renal function studies, and urinalysis, are indicated in consideration of potentially devastating cardiac and renal involvement. Amyloid associated with multiple myeloma must be considered in patients with bone pain and proteinuria. A rectal or abdominal fat pad biopsy will aid in the evaluation for systemic disease.

84.7.4 Treatment

Systemic work up is warranted including laboratory tests of liver and kidney function, electrocardiography, chest x-ray and ultrasound examination of the abdomen. If systemic disease is revealed, the systemic disease process is treated and the larynx can be clinically monitored for resolution and airway maintenance. For primary laryngeal amyloidosis, steroids and antineoplastic agents have not been found to be helpful. The treatment for localized laryngeal amyloidosis is endoscopic microsurgical removal of deposits that interfere with phonation or the airway. Radiotherapy has also been noted to be successful in addition to surgery for airway maintenance. Bronchoscopy is warranted to evaluate for possible extent of disease into the trachea.

84.8 Roundsmanship

- Surgical intervention is based on restoring or preserving function in diseases that often respond to medical management.
- Surgical intervention in an acutely inflamed larynx or trachea may result in an exacerbation of the inflammation and stenosis.

- In the worst case scenario, a tracheotomy may be necessary to secure the airway.
- A high index of suspicion is needed to diagnose systemic disorders presenting with laryngotracheal or esophageal symptoms and signs.

85 Unilateral Vocal Fold Immobility

Jamie A. Koufman

85.1 Introduction

Unilateral vocal fold immobility may be due to laryngeal paralysis or fixation. Paralysis is much more common than cricoarytenoid joint fixation or other structural problems that may affect mobility. For phonation, normal vocal folds come together along their lengths like two hands clapping on a hinge; for swallowing, they close tightly, like a sphincter. The symptoms of unilateral vocal fold immobility depend to a great extent on the position on the vocal fold and the degree to which glottal closure is affected. Voice change, aphonia (absence of voice), dysphonia, and diplophonia (double tone) are the usual symptoms. Aspiration due to uncomplicated (peripheral neuropathic) unilateral vocal fold paralysis is uncommon; aspiration is seen more frequently with a central nervous system problem or concomitantly with superior laryngeal or vagal neuropathy.

85.2 Incidence of Disease

Among patients with laryngeal and voice disorders seen at a voice treatment center, unilateral vocal fold immobility accounts for 1 to 5% of cases, depending to some degree on the referral patterns of the center. At centers performing significant numbers of skull base surgeries and head and neck cancer surgeries, for example, the rates of iatrogenic vocal fold paralysis are relatively high. In addition, unilateral vocal fold paralysis is seen in as many as 1% of patients with endotracheal intubation.

85.3 Terminology and Classification of Process

Unilateral vocal fold paralysis is usually described by the position of the immobile vocal fold: median (in the midline), paramedian (near the midline), intermediate (partly open), or cadaveric (wide open). The latter position is also sometimes called lateralized. When the immobility is caused by a cricoarytenoid joint problem, it may be due to fibrosis, ankylosis, or even dislocation, although posttraumatic cricoarytenoid joint dislocation is uncommon.

85.4 Applied Anatomy

The innervation of the vocal folds is via the superior laryngeal nerve (SLN) and recurrent laryngeal nerve (RLN). The SLN is primarily a sensory nerve, and the RLN is principally motor. The RLN is so named because of its unusual course from the skull base down through the neck within the vagus nerve (in the carotid sheath) and then into the chest; on the left side, it dips under the aorta, and on the right it courses around the innominate artery. Finally, after sweeping around their respective arteries, the right and left RLNs ascend back into the neck in the tracheo-esophageal groove to enter the larynx posteriorly. It is important for the clinician to understand the anatomy of the

RLNs because they may be affected by occult disease anywhere along their lengths, including within the chest.

In addition to the innervation of the vocal folds, it is important to understand the anatomy of the cricoarytenoid complex. The arytenoids articulate with the posterior cricoid by facets on the superior surface. These are synovial joints. The movement of the arytenoids on the cricoarytenoid facets is three-dimensional. Not only do the arytenoids rotate and glide; they also tip and slide anteriorly, almost off the facets. The antagonistic pull of the opposing intrinsic and extrinsic muscles of phonation confer this remarkable degree of mobility on the arytenoids, the functions of which are involved in both phonation and airway protection. The height of the vocal processes of the two arytenoids must match so that the membranous vocal folds are at the same height. If the heights of the vocal processes (and so the membranous vocal folds) are asymmetric, dysphonia will result. Height mismatch of the vocal folds is an important indication for surgical intervention in unilateral vocal fold paralysis.

85.5 The Disease Process

85.5.1 Etiology

Paralytic dysphonia (unilateral vocal fold paralysis) is much more common than cricoarytenoid joint fixation. Fixation may be due to blunt trauma, endotracheal intubation, inflammation secondary to reflux disease, and/or rheumatologic diseases, especially rheumatoid arthritis. In addition, cartilage tumors such as cricoid chondrosarcoma can lead to unilateral vocal fold immobility due to fixation.

Unilateral vocal fold paralysis is most commonly idiopathic, although many patients date the onset of symptoms to an acute upper respiratory infection. After idiopathic vocal fold paralysis, the most common etiologies of unilateral vocal fold immobility are, in decreasing order of frequency, neck and chest surgery (iatrogenic), neurologic diseases, tumors of the neck and chest, endotracheal intubation, and neck and chest trauma (□ Table 85.1).

Among iatrogenic cases, the rank order of occurrence has changed slightly in the last decade, with carotid endarterectomy (38%) now surpassing thyroidectomy (30%) as a cause. Skull base and head/neck cancer surgery accounts for 14% of cases, endotracheal intubation for 10% and cardiac surgery and miscellaneous causes for 8%. The most common tumors associated with laryngeal nerve paralysis are apical lung cancer, thyroid cancer, esophageal cancer, and hypopharyngeal cancer.

85.5.2 Natural History and Progression

The most common symptom of unilateral vocal fold paralysis or fixation is dysphonia (hoarseness), although swallowing problems, cough, and aspiration can occur. In the patient's history, the onset of symptoms is important, in particular whether the onset was sudden or progressive. In general, a progressive onset of symptoms is more likely than a sudden onset to be associated

Table 85.1 Differential diagnosis of unilateral vocal fold immobility: paralysis and fixation

Etiology	Percentage of cases
Paralysis	
Sudden onset	95%
Neck/chest surgery	31%
Idiopathic	23%
Viral neuropathy	16%
Neurologic disorder	9%
Neck/chest neoplasm	8%
Endotracheal intubation	8%
Neck/chest trauma	4%
Gradual onset	5%
Central neurologic disease	50%
Multiple sclerosis	40%
Lyme disease	35%
Brain tumor	10%
Amyotrophic lateral sclerosis	10%
Shy-Drager syndrome	2%
Peripheral neurologic disease	50%
Benign and malignant tumors of head/neck/chest (e.g., thyroid tumors)	50%
Diseases of peripheral nerves (e.g., Lyme disease)	30%
Nerve tumors (e.g., vagus, glomus tumors)	10%
Chest tumors (e.g., apical lung cancer)	5%
Ortner syndrome (paralysis secondary to congestive heart failure)	2%
Fixation	
Sudden onset	
Blunt or penetrating laryngeal trauma with arytenoid dislocation	
Iatrogenic (e.g., endotracheal intubation, esophagoscopy)	
Gradual onset	
Rheumatoid diseases (e.g., arthritis)	
Cricoid cartilage disease/tumors (e.g., chondrosarcoma)	
Granulomatous diseases that affect the larynx (e.g., tuberculosis)	
Laryngopharyngeal reflux (interarytenoid or cricoarytenoid pericapsular fibrosis)	

with tumors affecting one or more of the laryngeal nerves or with a progressive neurologic disease.

When the paralysis is due to a known cause, such as surgery or trauma, almost half of patients regain normal or nearly normal voice within 1 year, even without any treatment, whether or not the paralyzed vocal fold regains movement. In this scenario, the vocal fold may be synkinetically reinnervated. Although this does not result in vocal fold motion, it may provide enough muscle tone to medialize the vocal fold with significant mass. This, and normal function of the opposite vocal fold, result in closure of the glottal gap, with the production of an adequate or even normal voice. In cases in which the RLN was

left intact, complete spontaneous recovery with normal vocal fold motion may occur.

85.5.3 Potential Disease Complications

In addition to the dysphonia that results from vocal fold immobility, when the vocal folds are incapable of closing completely, secondary vocal fold pathologic lesions can develop in the striking zones (where they impact) as a result of the hyperkinetic compensatory processes of speaking. In other words, effortful vocal fold closure can lead to the development of vocal fold polyps, polypoid corditis, nodules, cysts, pseudocysts, and even

Fig. 85.1 Left vocal fold paralysis, with bowing and atrophy.

vocal process granulomas. In addition, if the larynx cannot close during swallowing, aspiration (even aspiration pneumonia) can result.

85.6 Medical Evaluation

85.6.1 Presenting Complaints

Hoarseness (raspiness), diplophonia (double tone), effortful phonation (speaking), odynophonia (painful speaking), air hunger, vocal fatigue, aspiration, and chronic cough are the most common symptoms associated with unilateral vocal fold paralysis. In most patients, the glottal closure symptoms of consequence are hoarseness, vocal fatigue, and effortful phonation.

85.6.2 Clinical Findings, Physical Examination

As noted above, the duration of the onset of the symptoms is important. To determine the etiology, it is also prudent to note any synchronous events, such as an upper respiratory infection or head/neck or cardiothoracic surgery. To understand how urgent the need for vocal rehabilitation may be, it is imperative to inquire about the presence of aspiration, the patient's vocal needs, and how much the dysphonia is impacting his or her life.

Before performing laryngeal endoscopy, one should listen to the voice and note its character and severity. Is it a "wet" voice, suggesting decreased laryngeal sensation? Is there enough projection for conversation in a quiet room or over background noise? What is the quality of the cough? While a full head and neck examination is performed, special attention should be paid to an evaluation of cranial nerve function and a search for the presence of neck masses, especially in the thyroid, to detect secondary causes of the paralysis.

Fig. 85.2 Right vocal fold paralysis, with forward-tipped arytenoid and foreshortened vocal fold. The atrophy is less than that seen in □ Fig. 85.1.

Ultimately, the diagnosis of unilateral vocal fold immobility requires a laryngeal examination. In the past, a mirror examination was performed, but this type of screening technique has become obsolete. Today, the laryngeal examination is most commonly performed with a flexible endoscope that allows an assessment of glottal function. Before the examination, it is worth teaching the patient the /i/sniff maneuver. Pronouncing a vowel like "eeeeee" (/i/) brings the vocal folds together in adduction, and sniffing causes brisk vocal fold opening (abduction). The /i/sniff maneuver is an excellent vocal task for evaluating vocal fold mobility. In addition to vocal fold motion, the position of the folds, evidence of atrophy or bowing, and height of the vocal processes should be noted (□ Fig. 85.1 and □ Fig. 85.2).

The most common findings in unilateral paralysis are hypomobility and bowing of the involved vocal fold, as well as hyperkinetic laryngeal biomechanics with supraglottic and pharyngeal squeezing (□ Fig. 85.3). During high-pitched phonation, axial tilt and/or laryngeal rotation is common in patients with unilateral paralysis and/or bilateral paresis when there is significant asymmetric tension between opposing intrinsic laryngeal muscles, especially if one of the cricothyroid muscles is weak. Axial tilt and rotation are due to unbalanced closure of the right and left sides when one SLN is affected. (These findings are most common in patients with bilateral vocal fold paresis.)

With unilateral paralysis, stroboscopy will show increased amplitude on the paralyzed side, indicating decreased vocal fold tone. Stroboscopy also allows evaluation of the glottal chink, its size, and whether it is predominantly anterior or both anterior and posterior. The clinician should look for the vocal

Fig. 85.3 Left vocal fold paralysis showing compensatory biomechanics.

process-to-vocal process contact point before compensatory biomechanics take over.

Finally, the presence of excessive secretions should be noted, whether there is pooling in the piriform or postericoid area, or if there is penetration into the glottis or trachea. Gross sensation can be tested by palpating the supraglottis with the tip of the endoscope in an attempt to elicit an adductor reflex. Pharyngeal dysfunction is identified by the absence of a medial squeeze of the pharyngeal walls on a high pitched /i/ or the presence of a dilated piriform sinus. A combination of decreased sensation, pharyngeal dysfunction, and pooling secretions should serve as an alert to an increased risk for aspiration (even in a patient with a negative history because the patient could be experiencing silent aspiration).

85.6.3 Testing

The most important test that differentiates vocal fold paralysis from vocal fold fixation is laryngeal electromyography (EMG), which is an electrical neurodiagnostic test performed by placing a fine-needle electrode in the laryngeal muscles. Laryngeal EMG not only determines which muscles and nerves are affected but also indicates the prognosis for recovery. When the patient's prognosis is poor (between 2 and 6 months), one may proceed to a permanent rehabilitation procedure rather than wait a full 12 months, as was done historically. Other aerodynamic and acoustic tests and electroglottography can also be used to assess the severity of glottal closure problems.

When the etiology of the paralysis is unclear, most clinicians recommend a work-up for peripheral neuropathy, including blood tests to rule out vector-borne neurologic disease (e.g., Lyme disease, West Nile virus infection), as well as computed tomography (CT) of the neck to rule out a neoplasm affecting the laryngeal branches of the vagus nerve. At a minimum, a patient with a left vocal fold paralysis requires a chest X-ray to evaluate the thoracic component of the left RLN. CT of the chest may be the preferred examination because it is more sensitive for masses in the aortopulmonary window. If other neurologic symptoms suggest a demyelinating disease, then magnetic resonance (MR) imaging of the head and a neurologic consultation may be ordered.

In cases of idiopathic laryngeal paralysis, the author begins with laryngeal EMG, which can help determine the cause of the paralysis/paresis and whether it is “new” (of recent onset) or “old” (of remote onset). The presence of spontaneous activity implies ongoing denervation (i.e., “new”). Indeed, the radiologic work-up is EMG-guided. If the SLN (tested in the ipsilateral cricothyroid muscle) is not involved, CT of the neck (skull base through superior mediastinum) is obtained. If the SLN is involved (abnormal), then MR imaging of the brain and skull base is ordered, as well.

If, on the other hand, laryngeal EMG shows an “old” neuropathic pattern (characterized by large polyphasic motor units with no evidence of spontaneous activity), radiographic evaluations may be unnecessary. However, in case of doubt, imaging studies are the safe choice to be certain that the cause of the neuropathy is not neoplastic or a pernicious neurogenic pathologic process (e.g., multiple sclerosis).

85.7 Treatment

85.7.1 Medical Treatment

Many patients who have unilateral vocal fold immobility are able to compensate for their glottal closure problem with or without voice therapy. In these cases, the contralateral vocal fold becomes stronger and can be seen on laryngeal examination to cross the midline to achieve closure. In addition, the immobile vocal fold may have adequate tone and a good midline position secondary to nonfunctional synkinetic reinnervation. As many as 30 to 50% of patients with unilateral paralysis will not require surgical treatment. In addition, voice therapy can be very helpful in allowing patients to find adaptive compensatory laryngeal behaviors.

85.7.2 Surgical Treatment

The two basic surgical approaches, injection augmentation and medialization laryngoplasty (“Isshiki thyroplasty”) with or without arytenoid adduction, have different advantages and

disadvantages. Injection augmentation, which can be done in the office setting or in the operating room, involves the injection of an alloplastic material or autologous adipose tissue into the vocal fold itself. Although it requires a skin incision, medialization laryngoplasty provides permanent voice rehabilitation in the majority of cases. Unfortunately, today not many surgeons are skilled in this technique.

Arytenoid fixation from blunt and penetrating trauma is uncommon. It may also be due to traumatic endotracheal intubation and inflammatory joint diseases such as rheumatoid arthritis. The diagnosis of fixation can be confused with that of paralysis until a definitive diagnosis is made by laryngeal EMG and examination under anesthesia with passive mobility testing. Although some laryngologists believe that the arytenoid may be dislocated and then surgically reduced (i.e., “undislocated”), the author has never seen such a case and does not believe that “dislocation” is possible based upon the cricoarytenoid anatomy. On the other hand, damage to the joint can certainly occur, and endoscopic arytenoid repositioning is possible, assuming that the affected arytenoid can be mobilized.

85.7.3 Timing of Surgery and Choice of Procedure for Unilateral Vocal Fold Paralysis

Surgical treatment is reserved for patients with relatively severe glottal closure symptoms and/or aspiration. In the case of paralytic dysphonia, the term relatively is important. The need for surgery in each case is tempered by not only the severity of the dysphonia and/or aspiration but also the patient-specific consequences of failure to intervene surgically.

Patients who have glottal incompetence and obvious clinical and radiographic aspiration, with a risk for the development of life-threatening pneumonia, should undergo some type of glottal closure procedure. Which procedure(s) depend(s) on the symptom severity, prognosis for recovery, and overall medical status of the patient. Although it can be life-threatening, aspiration is a significant problem following unilateral vocal fold paralysis in fewer than 10% of cases.

The prognosis for patients who have aspiration associated with laryngeal paralysis is worst when (1) they have undergone skull base surgery for tumors with sacrifice of multiple cranial nerves (especially nerves IX through XII); (2) they have profound degenerative neurologic diseases such as amyotrophic lateral sclerosis; and (3) they have a history of cerebral vascular accident. For such patients, the surgical procedures may include total laryngectomy, tracheotomy with some type of feeding tube, injection augmentation, or laryngoplasty. For patients with moderate aspiration, even after skull base surgery, ipsilateral medialization with arytenoid adduction and possible cricopharyngeal myotomy will usually suffice to allow normal oral feeding. Such a procedure can usually be performed within 1 to 2 weeks of the skull base surgery. Patients with severe recalcitrant aspiration may require even more radical procedures, including tracheotomy, laryngotracheal separation, or laryngectomy.

The most common concern of the laryngeal surgeon is determining the method and timing for the treatment of patients with different levels of dysphonia, vocal demands, and progno-

ses. Obviously, for patients who have mild to moderate dysphonia and a good prognosis for recovery, no surgery may be appropriate. But what about a 75-year-old clergyman with vocal fold paralysis who is dysphonic? Such a patient will demand that something be done sooner rather than later. In such a case, knowing the prognosis may help answer the question. If the laryngeal nerve has little or no chance of recovery—such as after RLN sacrifice in thyroid cancer surgery—then medialization laryngoplasty with arytenoid adduction (if the posterior commissure is open or if the vocal folds are at different levels) may be an ideal solution to achieve excellent vocal rehabilitation in a timely fashion.

When the prognosis is not evident, laryngeal EMG may be very helpful. When performed between 2 and 6 months after the onset of paralysis, laryngeal EMG can predict the lack of return of vocal fold function with an accuracy of more than 95%. If such a result is found on EMG, a permanent procedure can be performed at that time. “Watching and waiting” or performing additional procedures to temporarily rehabilitate the voice would be unwarranted. If the result of laryngeal EMG is equivocal, a temporizing measure is often helpful in establishing a competent glottis while the result of reinnervation is awaited. Laryngologists now have several injection augmentation techniques and materials with different durability characteristics: temporary, semipermanent/durable, and permanent. Durable injectables will last from 6 months to 2 years. There is controversy as to whether any injectable is reliably permanent. Regardless, the availability of temporary and durable injections allows physicians to employ a practical strategy of achieving early surgical glottal closure with injection augmentation when the prognosis of a patient with vocal fold paralysis is unknown. Watching and waiting is not an appropriate plan unless the patient and surgeon have opted for this after considering temporary alternatives.

There are five techniques for performing injection augmentation and as many different materials. Injection augmentation can be done in the office or clinic setting with an awake patient, or it can be performed in the operating room while the patient is under general anesthesia, with the benefits of a motionless patient and magnification through an operating microscope. In truth, fewer than 25% of injection augmentation procedures are done in the operating room.

Performing procedures under general anesthesia is recommended for patients who are unwilling or unlikely to be cooperative when an awake technique is used (e.g., excessive gag reflex, difficult anatomy). General anesthesia usually allows more precise injection augmentation. If autologous adipose tissue (lipo-injection) is the implant/graft of choice, then general anesthesia is recommended.

For most patients with severe dysphonia and an uncertain prognosis after unilateral vocal fold paralysis, injection augmentation in the office is recommended with temporary or durable substances such as the following: Radiesse Voice Gel (Merz Aesthetics, San Mateo, CA); Cymetra (LifeCell, Branchburg, NJ); or even Radiesse Voice (Merz Aesthetics). In addition, if the paralysis is permanent but it is unclear whether the patient will benefit from vocal fold augmentation, a temporary injection can be used as a trial. The advantage of temporary materials is that they last only a few to several months; of course, this short duration is also a potential disadvantage. Neverthe-

Fig. 85.4 Typical setup for in-office injection with transnasal endoscopic visualization.

less, repeated injections can help a patient over the initial period of relative vocal disability.

There are four different office-based techniques for performing injection augmentation in the awake patient: (1) percutaneous, from below, through the cricothyroid membrane; (2) percutaneous, directly through the thyroid cartilage (suitable only for relatively young patients without significant calcification of the thyroid cartilage); (3) percutaneous, from above, through the thyroid notch; and (4) peroral. All of these methods are done with simultaneous endoscopic (transnasal or peroral) laryngeal visualization (□ Fig. 85.4 and □ Fig. 85.5).

Although some surgeons are proficient in many or all of the above approaches, the most popular technique for office-based vocal fold injection among contemporary laryngologists is the thyrohyoid approach with simultaneous transnasal flexible laryngoscopy. This technique has four advantages:

1. Minimal anesthesia is required.
2. It allows direct visualization of needle insertion.
3. It is well tolerated by patients.
4. There is a relatively easy learning curve for the surgeon.

For patients in whom vocal fold recovery is unlikely (e.g., malignant invasion of the RLN, transection or resection of the RLN, poor laryngeal EMG prognosis, paralysis for 9 to 12 months), a permanent treatment can be offered. If the glottal gap is very small or the patient's life expectancy is short, a "permanent injectable" may be used. Alternatively, a type I laryngoplasty with or without arytenoid adduction or an RLN-ansa cervicalis

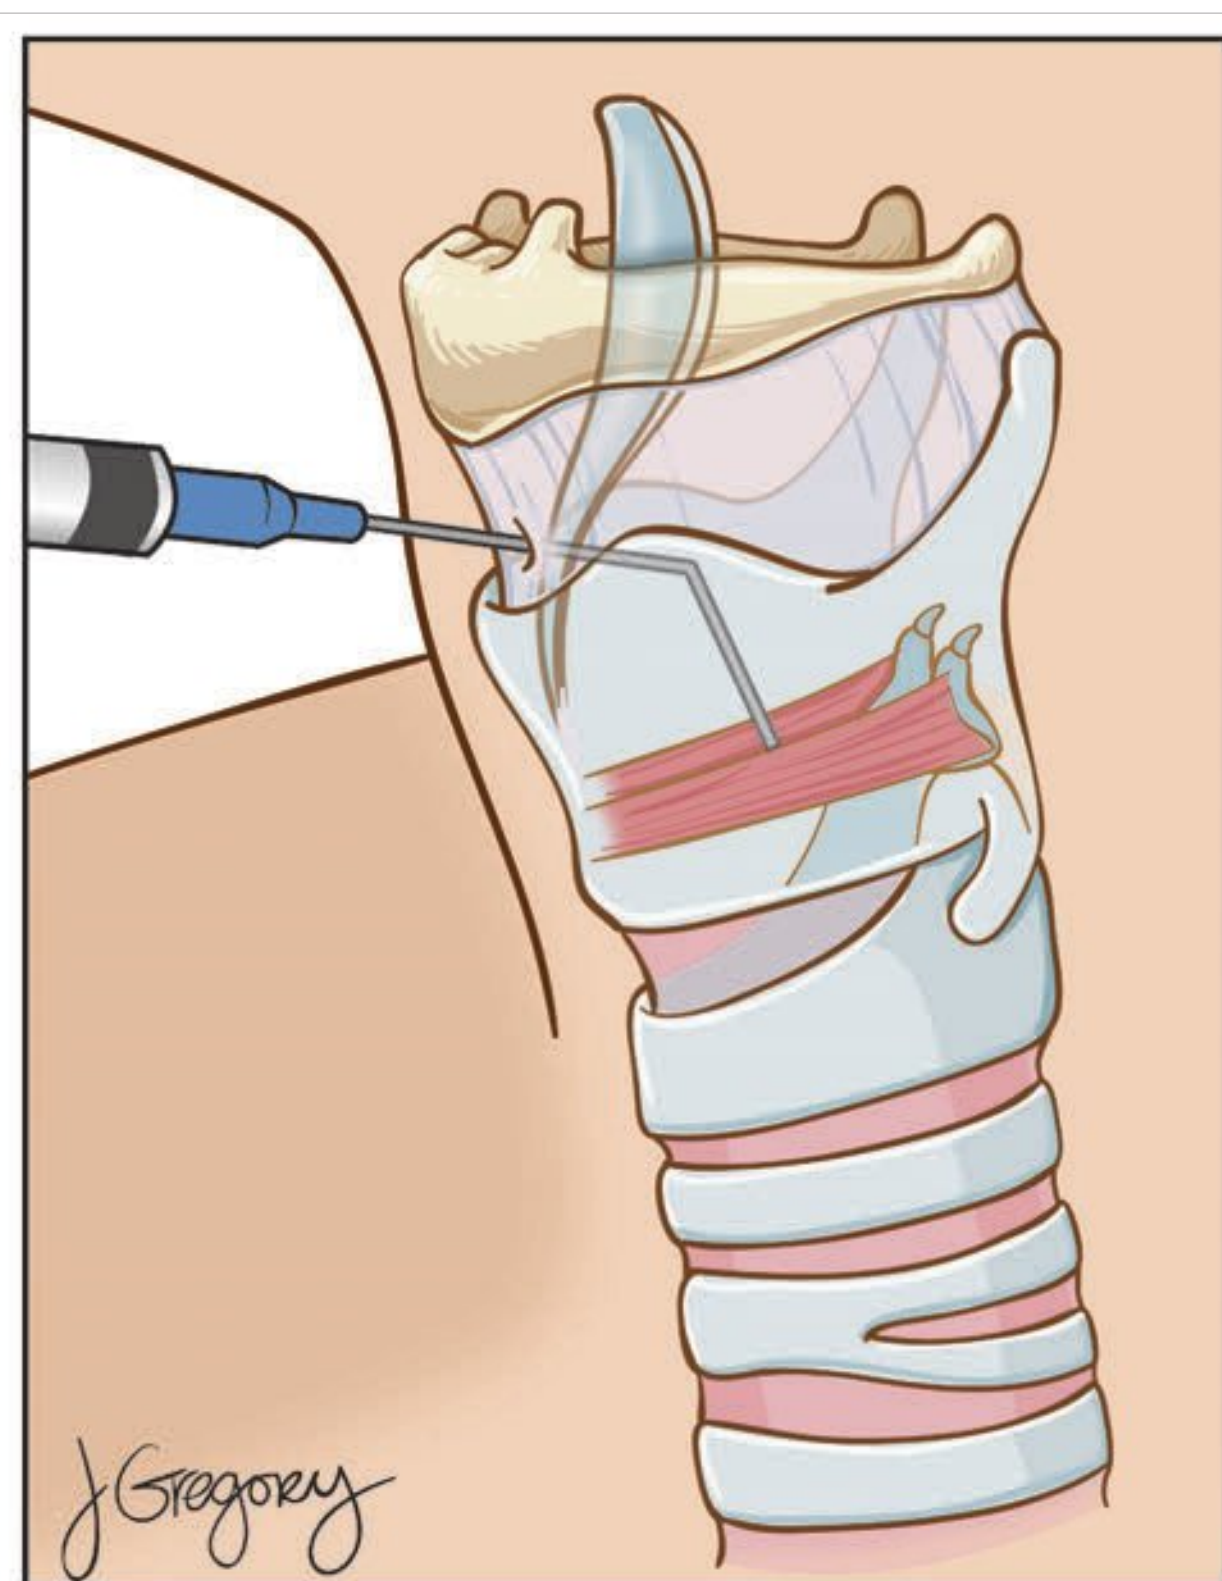

Fig. 85.5 Schematic of the thyrohyoid approach to injection for vocal fold augmentation.

reinnervation procedure (ANSA-RLN) may be performed. ANSA-RLN has a reported successful reinnervation rate of over 95%; it provides vocal fold bulk and tone, but not physiologic vocal fold movement. It takes 3 to 6 months for the innervation to begin to take effect, so a temporary injection must be performed to rehabilitate the voice and bridge this time gap. In reality, ANSA-RLN is the least commonly performed procedure for permanent vocal fold paralysis because of the excellent results and physician familiarity with laryngoplasty techniques, as well as the 3- to 6-month waiting period. Alternatively, ANSA-RLN is an excellent surgical option for pediatric patients because the procedure is performed with the patient under general anesthesia; laryngoplasty is performed with the patient under intravenous sedation, which is unlikely to be tolerated by a pediatric patient. ANSA-RLN is also optimal for immediate reinnervation at the time of RLN resection or transection. A successful ANSA-RLN in this scenario will spare the patient from future surgery for vocal rehabilitation.

Type I laryngoplasty with or without arytenoid adduction is the treatment of choice for the majority of patients with a permanent vocal fold paralysis; this surgery has a 96% success rate with minimal morbidity. The 4% revision rate is usually due to placing an implant too high and interrupting the mucosal wave. Laryngoplasty is performed under intravenous sedation to allow the patient to speak and provide the surgeon with vocal feedback when the implant is sized. Generally, a concomitant flexible laryngoscopy is performed to allow visualization of the vocal folds during the procedure, providing further feedback. Implants are generally made of e-PTFE (expanded polytetra-

fluoroethylene [Gore-Tex]; W. L. Gore Associates, Flagstaff, AZ) or silicone (Silastic; Dow Corning, Midland, MI). The silicone implants can be preformed or custom-carved. Aside from the need for revision, the other significant complication is infection of the implant. Although rare, implant removal is necessary if this occurs.

Arytenoid adduction is an adjunct to type I laryngoplasty. In this procedure, the muscular process of the arytenoid is accessed by removing the posterior aspect of the thyroid ala and medializing the piriform sinus. The process is lassoed with a suture, which is then passed through the paraglottic space and out through the anterior aspect of the larynx. Tension on the suture rotates the arytenoid and corresponding vocal process inferomedially. This corrects height mismatch between the vocal folds and closes a persistent posterior glottal gap, which cannot be done with an implant alone. The decision to perform an arytenoid adduction is made at the time of surgery. If the patient has a breathy voice or there is insufficient projection while the membranous vocal fold is optimally medialized, then most likely a vocal fold height mismatch or posterior glottal gap exists. This can be confirmed by flexible laryngoscopy. The use of arytenoid adduction varies among surgeons. Some may employ it as much as 30 to 40% of the time, whereas others rarely use it. The reason for this disparity is unclear, but it may be due to a lack of training and comfort with the procedure, as well as the increased operative time and risk. An arytenoid adduction adds approximately 30 minutes to the procedure and carries a very small risk for pharyngeal perforation as the piriform is medialized. The patient also experiences more discomfort when swallowing in the immediate postoperative period. In those patients who speak a significant amount, either socially or in business, the vocal improvement provided by an arytenoid adduction is likely worth the minimal risk and discomfort.

85.8 Roundsmanship

- The most common cause of unilateral vocal fold immobility is idiopathic vocal fold paralysis. Some of these cases may actually be due to a viral neuropathy.
- Unilateral vocal fold immobility presenting with progressive (gradual onset) hoarseness is associated with a relatively ominous differential diagnosis, including degenerative neurologic diseases and malignant tumors of the head, neck, and chest.
- Laryngeal electromyography is the most useful diagnostic test to determine the presence of neuropathy and the prognosis of vocal fold immobility.
- The voice symptoms of paralytic dysphonia can usually be surgically corrected by voice therapy, injection augmentation, or medialization (“Isshiki” type I) laryngoplasty with or without arytenoid adduction.

86 Bilateral Vocal Fold Paralysis

Craig H. Zalvan

86.1 Introduction

Bilateral vocal fold paralysis is part of a spectrum of vocal fold immobility potentially resulting in airway compromise. Although there are many causes, only a few are relatively common. The work-up and treatment are coordinated to rule out potentially devastating disorders and ensure airway safety. Most causes of vocal fold paralysis are neurologic in nature, either direct neural trauma or a centrally mediated mechanism. Contrary to popular belief, patients with bilateral vocal fold immobility tend to have normal vocal quality, and most patients present with symptoms of airway obstruction: dyspnea on exertion, exercise intolerance, dysphagia, and stridor. Examination of the larynx demonstrates bilaterally immobile vocal folds with a resultant small glottic or interarytenoid gap. As the gap decreases in size, respiratory distress increases.

86.2 Incidence

Bilateral vocal fold paralysis is a very uncommon finding. Surgical trauma to both recurrent laryngeal nerves (RLNs) occurs in far fewer than 1% of thyroidectomies and other surgeries of the head and neck. Metastatic or direct invasion of the larynx resulting in bilateral RLN involvement is also a rare event. In children, approximately 2 to 5% of cases of bilateral vocal fold paralysis are congenitally acquired. Arnold-Chiari malformation is one of the more common causes of bilateral vocal fold paralysis in children. This malformation occurs in approximately 1 in 1,000 live births. The type II malformation most commonly causes bilateral vocal fold paralysis. Approximately one-third of children born with the type II malformation will have brainstem involvement by the age of 5 years. Of these, one-third will die, most commonly of respiratory complications.

86.3 Classification

Paralysis of the vocal folds is classified as unilateral or bilateral. In bilateral vocal fold paralysis, the position of the vocal folds determines the severity of symptoms. The position of the vocal folds can be described as medial, paramedian, or lateral. The more medial the vocal folds, the greater the degree respiratory compromise; the more lateral the vocal folds, the greater the degree of dysphonia and dysphagia.

86.4 Anatomy

Key anatomical relationships of the RLN along its entire course are important in determining the cause of bilateral vocal fold paralysis. The RLN, a branch of the vagus nerve, exits the brainstem from the medulla and courses through the jugular foramen to enter the neck. At the inferior (nodose) ganglion, the superior laryngeal nerve branches off from the main trunk to course adjacent to the pharynx and medial to the sheath of the carotid artery, further dividing into the internal and external branches. The left RLN/vagus nerve courses anterior to the

carotid over the arch of the aorta, where the two components divide. The left RLN then courses posteromedial to the ligamentum arteriosum, ascends in the tracheo-esophageal groove, and enters posterior to the cricothyroid joint to innervate all motor components of the laryngeal musculature except the cricothyroid muscle. The right RLN branches off from the vagus nerve in the neck anterior to the right subclavian artery and then wraps around the artery to ascend in the right tracheo-esophageal groove before entering posterior to the cricothyroid joint. Familiarity with these anatomical relationships is important in understanding the causes of bilateral vocal paralysis. Any centrally mediated process (e.g., stroke, tumor, or hydrocephalus) can affect both RLNs at the level of the medulla. In all other cases of bilateral vocal paralysis, the cause must affect both nerves along their course if bilateral paralysis is to occur.

A detailed knowledge of the glottic space and arytenoid complex is also important in understanding airflow and vocal dynamics. The posterior glottis, or respiratory glottis, creates most of the space for airflow to occur. This region is the space posterior to the tip of the vocal processes and is bordered by both arytenoids, the interarytenoid muscle, and the mucosa (□ Fig. 86.1). The posterior cricoarytenoid is solely responsible for abduction of the vocal folds. A distance of less than 4 mm between the arytenoid vocal processes is typically required to create stridor at rest (□ Fig. 86.2). Increased airflow during increased activity may result in passive adduction of the vocal folds as a consequence of the Bernoulli phenomenon, leading to stridor in a compromised airway that has a diameter slightly larger than 4 mm.

86.5 The Disease Process

86.5.1 Etiology

The vast majority of cases of bilateral vocal fold paralysis are due to surgical trauma of both RLNs, typically during thyroidectomy (most often completion thyroidectomy in the setting of a preexisting unilateral vocal fold paralysis). In one series of 72

Fig. 86.1 Normal larynx with interarytenoid distance of approximately 2 cm. Arrows highlight the tips of the vocal processes.

Fig. 86.2 Bilateral vocal fold paralysis in a patient with audible stridor. Note the posterior glottic gap of less than 4 mm.

adults with bilateral vocal fold immobility, surgical trauma (37%), malignancies (14%), endotracheal intubation (13%), neurologic disease (11%), and idiopathic immobility (11%) were the most common findings. Vocal fold paralysis is the second most common congenital anomaly of the pediatric airway, constituting 5 to 10% of congenital laryngeal lesions; bilateral paralysis occurs in 30 to 62% of this subgroup of patients. Airway intervention is required in over half of these children, often in the form of a tracheotomy. Arnold-Chiari malformation, hydrocephalus, and myelomeningocele are the most common causes of bilateral vocal fold paralysis in children. The majority of other cases are due to other neurologic diseases or are of idiopathic, iatrogenic, or traumatic origin.

86.5.2 Pathogenesis

Bilateral immobility of the vocal folds is due to systemic neuropathy, direct injury to both RLNs or the nucleus ambiguus, or mechanical fixation of both arytenoids. Airflow is then determined by the final resting position of the vocal folds, which evolves over time. When both vocal folds are immobile in the midline or a paramedian position, airway obstruction is more likely. When both are in the lateral position, breathy dysphonia and aspiration are common. Fixation of both arytenoids is rarely encountered but must be considered after laryngeal trauma or prolonged intubation, or in rheumatoid arthritis. Pressure necrosis, chronic inflammation with immune complex deposition, and fibrosis can result in immobility of the larynx if both arytenoids are affected. Neural integrity is intact, but effectively there is no mobility secondary to the failure of arytenoid rotation. The Box Causes of Bilateral Vocal Fold Paralysis in Adults (p. 670) and the Box Causes of Bilateral Vocal Fold Paralysis in Children (p. 671) summarize the differential diagnosis for bilateral vocal fold paralysis in adults and children, respectively.

Causes of Bilateral Vocal Fold Paralysis in Adults

- Iatrogenic
 - Thyroid and parathyroid surgery
 - Complete thyroidectomy
 - Tracheal resection
 - Cervical esophagectomy
 - Neurosurgery
 - Brainstem, skull base surgery
 - Anterior spinal approach surgery (with preexisting unilateral vocal fold paralysis)
 - Birth trauma
 - Contralateral carotid endarterectomy
 - Endoscopic laryngeal surgery (usually laser)
 - Radiation-induced fibrosis or chondronecrosis
- Malignancy
 - Laryngeal
 - Metastatic disease to the neck, brainstem, or mediastinum
 - Extension of pulmonary neoplasm
 - Lymphoproliferative disorders
- Central nervous system disease
 - Arnold-Chiari malformation
 - Neuromuscular disease
 - Amyotrophic lateral sclerosis, Shy-Drager syndrome, myasthenia gravis, Guillain-Barré syndrome, multiple sclerosis, Charcot-Marie-Tooth disease
 - Hydrocephalus
 - Cerebral vascular accident
- Systemic
 - Infectious
 - Lyme disease
 - Syphilis
 - Tuberculosis
 - Invasive fungal infection
 - Rheumatologic
 - Systemic lupus erythematosus, rheumatoid arthritis, relapsing polychondritis
 - Sarcoidosis
 - Wegener granulomatosis
 - Amyloidosis
- Metabolic
 - Hypocalcemia, hypokalemia, diabetes mellitus
- Local factors
 - Bilateral arytenoid dislocation
 - Bilateral arytenoid ankylosis
 - Blunt and penetrating trauma
 - Laryngospasm
 - Intubation injury
- Idiopathic

Causes of Bilateral Vocal Fold Paralysis in Children

- Neurologic
 - Arnold-Chiari malformation
 - Myelomeningocele
 - Hydrocephalus
- Iatrogenic
 - Cardiac surgery
 - Tracheo-esophageal fistula repair
- Systemic
- Traumatic
 - Intubation
 - Birth trauma
- Idiopathic

86.5.3 Natural History

Spontaneous recovery from bilateral vocal fold immobility occurred in 13% of adult cases in one retrospective case series, with most patients requiring tracheotomy for initial management. Of these cases, 15% were due to intubation injury, and of these, 44% recovered mobility in one or both vocal folds. In contrast, 48 to 60% of children recover.

Tracheotomy is required in fewer than 50% of adult patients with bilateral vocal fold paralysis. The rate of children requiring tracheotomy varies; study results range from 19 to 68%

86.5.4 Potential Disease Complications

The most feared complication is airway obstruction and death from asphyxiation. Dysphonia, ineffective cough, chronic aspiration, aspiration pneumonia, and dysphagia are also common complications. Some patients experience chronic systemic fatigue due to the effort expended on respiration.

86.6 Medical Evaluation

86.6.1 Presenting Complaints

Contrary to popular belief, patients with bilateral vocal fold immobility tend to have a relatively normal vocal quality. Complaints are often of diplophonia, decreased vocal projection, vocal fatigue, vocal strain, and compensatory muscle tension. Breathy dysphonia occurs when there is lateral displacement of one or both immobile vocal folds with increased, unregulated airflow. Patients may also present with dysphagia, weak cough, and pneumonia secondary to loss of the laryngeal closure protective mechanism. The presentation of bilateral vocal fold paralysis is highly variable. At one extreme, a person may be completely asymptomatic, with normal voicing and respiration and no distress. This patient may describe intermittent episodes of feeling short of breath and mild stridor or “wheezing,” typically during an upper respiratory illness; often, asthma is diagnosed. At the other end of the spectrum, the most typical presentation includes the onset of respiratory distress, shortness of breath, labored breathing, and stridor. Patients will complain of a “wheeze” during inspiration that represents stridor, which tends to be inspiratory early in the onset of bilat-

eral vocal fold paralysis but may become biphasic as the obstruction becomes more pronounced (depending on the resting position of the vocal folds). Following surgical trauma to both RLNs, patients may become acutely symptomatic after extubation in the operating room or recovery room, with stridor and distress. The symptoms may develop more insidiously over time as the vocal folds slowly medialize. These patients tend to adjust to the slow compromise of the larynx and may not have symptoms of obstruction until there is an abrupt change in the larynx. Any cause of laryngeal inflammation (e.g., laryngopharyngeal reflux, upper respiratory infection with laryngitis, weight gain) can exacerbate an already compromised larynx and lead to an acute exacerbation of symptoms.

86.6.2 Physical Examination

The examination of a patient with bilateral vocal fold paralysis begins with observation of the patient. Again, the degree of airway compromise dictates the degree and severity of the physical findings. A patient may be completely comfortable and appear calm or may present with extreme anxiety and a sense of impending doom. The vocal quality may be completely normal or characterized by breathiness, raspiness, and diplophonia. In addition, the patient may exhibit respiratory distress with labored breathing, stridor, the use of accessory muscles, supraclavicular retraction, and cyanosis. Flexible laryngoscopy is performed in the office setting, recovery room, or operating room if RLN damage is suspected. Laryngeal endoscopy on the operating room table after thyroidectomy or completion thyroidectomy in patients with preexisting unilateral vocal fold paralysis is helpful in identifying a bilateral paralysis and allowing rapid reintubation before the patient decompensates. The position of the vocal folds, size of the glottic airway, and presence of interarytenoid scarring or any other mechanically obstructive lesion are all noted. Videostroboscopy helps to ascertain vocal fold vibration and glottic closure on phonation.

86.6.3 Testing

Diagnostic laryngeal electromyography (EMG) can aid in developing a prognosis for recovery in cases of surgical trauma or neuropathy. Immediately after surgery, EMG can differentiate between vocal fold fixation (which is a very rare event) and traumatic RLN neuropathy. EMG performed 2 to 6 months after injury will help define the prognosis. If there are multiple polyphasic potentials and significant recruitment, the prognosis is favorable. Giant waves with no vocal fold motion, fibrillation potentials, poor recruitment, and synkinesis all portend a poor prognosis. In addition to aiding in the prognosis, EMG can help diagnose certain neurologic, metabolic, or myopathic causes of bilateral immobility. For more details, the reader is referred to Chapter 80 (Laryngeal Electromyography).

Imaging is necessary in cases of noniatrogenic bilateral vocal fold paralysis. A chest X-ray is typically adequate to assess most tumors of the chest and mediastinum, although it is not as sensitive as computed tomography (CT) or magnetic resonance (MR) imaging in identifying masses in the cardiopulmonary window. MR imaging and/or CT from the vertex of the brain to the inferior aspect of the aortic arch should be performed to look for a lesion along the course of both RLNs, Arnold-Chiari

malformation, brainstem lesions (tumors, metastatic disease, cerebrovascular anomaly), and other lesions of the brain.

The diagnostic laboratory work-up is usually limited but may include measurements of Lyme titer, fluorescent treponemal antibody absorbed (FTA-ABS), cytoplasmic antineutrophil cytoplasmic autoantibody (cANCA), purified protein derivative (PPD), rheumatoid factor (RF), antinuclear antibody (ANA), angiotensin-converting enzyme (ACE), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) during investigations for a systemic cause of bilateral immobility in patients with a suggestive medical history.

Pulmonary function testing may be ordered to assess the degree of upper airway obstruction. The results can be highly variable, and pulmonary function testing should not be used as the primary diagnostic tool. Typically, blunting of the inspiratory curve is seen during forced inspiration, as well as flattening of the expiratory curve. Most studies show no correlation between pulmonary function testing results and glottic airway size; however, pulmonary function testing can be useful for the evaluation of airflow after intervention to demonstrate increased airflow.

An endoscopic evaluation should be performed in the operating room in cases of suspected interarytenoid scar formation or ankylosis of the cricoarytenoid joint. The latter does not occur often, but both should be suspected in patients with long-term intubation or a history of trauma to the neck or larynx. Palpation of the joint, independent motion of the arytenoids, and range of motion of the arytenoids are assessed. In addition, the subglottis and trachea should be inspected for signs of trauma, narrowing, or granulation.

86.6.4 Differential Diagnosis

There are multiple causes of bilateral vocal fold paralysis, and the frequencies of each differ between adults (see Box Causes of Bilateral Vocal Fold Paralysis in Adults (p.670)) and children (see Box Causes of Bilateral Vocal Fold Paralysis in Children (p.671)).

86.7 Treatment

86.7.1 Medical Treatment

Airway safety is the primary concern in patients with bilateral vocal fold paralysis. Postoperative patients may develop stridor and respiratory distress immediately upon extubation or, more commonly, during the few hours after extubation. Measures such as therapy with intravenous steroids, heliox, racemic epinephrine, and humidified oxygen may achieve a short-term resolution of respiratory distress. If respiratory distress continues or oxygen desaturation develops, emergent reintubation is performed. In rare cases, an emergent tracheotomy must be performed if the airway cannot be secured by intubation. A second attempt at extubation is made after the administration of intravenous steroids, typically 24 hours later. If a second attempt fails, tracheotomy is then performed to secure a safe airway. A tracheotomy provides the most stable and safe airway, as well as the best possible vocal result.

Patients with borderline toleration of their bilateral vocal fold paralysis may be candidates for botulinum toxin injection of

both thyroarytenoid muscles. This results in immediate vocal fold bowing and long-term atrophy after serial injections, so that the glottic airway enlarges slightly. Although the change in the airway is minimal, it may be sufficient to provide a safe airway and obviate the need for a tracheotomy in these borderline patients. The injections generally need to be repeated every 6 to 12 months.

Patients who do not present with airway distress, significant dysphonia, or dysphagia can be monitored without intervention. Many patients will recover function of at least one vocal fold. Others with persistent bilateral paralysis remain stable and never require further intervention. These patients should be cautioned about acute respiratory compromise in the setting of laryngeal edema. They should be instructed to contact their physician or go to the nearest emergency room immediately upon having any symptoms of airway distress. In these cases, conservative management with humidification, oral steroids, and mucolytics is often sufficient.

86.7.2 Surgical Treatment

As noted above, a tracheotomy provides the most stable and safest airway, as well as the best possible vocal result. Unfortunately, tracheotomy remains a very difficult social and physical burden for the patient. In addition, a long-term tracheotomy is associated with the potential complications of granulation formation, tracheal stenosis, dysphagia, aspiration, cellulitis, and skin breakdown.

For those patients who fail extubation, or have chronic symptoms of shortness of breath, stridor, exercise intolerance, or recurrent acute airway episodes necessitating hospitalization, procedures exist to create a more patent airway. The same procedures are available to patients who already have a tracheotomy but desire decannulation. Before performing a destructive procedure, the surgeon should be certain that recovery will not occur. To that end, the procedure should be delayed until either 1 year after the inciting injury or EMG evidence of a poor prognosis has been obtained.

The most conservative surgery involves a carbon dioxide laser posterior transverse cordotomy, which is performed endoscopically. An incision is made that separates the vocal process from the membranous vocal fold. This is generally done unilaterally but may be done bilaterally if a unilateral procedure fails to create an adequate airway (□ Fig. 86.3).

Alternatively, an endoscopic medial arytenoidectomy can be performed with a carbon dioxide laser (□ Fig. 86.4). The medial wall of the arytenoid is removed, with or without a partial cordotomy. Traditionally, a complete arytenoidectomy was performed endoscopically by ablating the entire arytenoid or transcervically via laryngofissure. Because of the increased morbidity of these procedures, they have mostly been abandoned.

Laterofixation of one vocal fold can be performed via transcervical placement of a suture that wraps around the vocal process and posterior membranous vocal fold. Traction on the suture lateralizes the vocal fold. It is then tied in place over the strap muscles. In order to avoid a tracheotomy, laterofixation can be used as a temporary procedure in cases of surgical trauma to the RLN in a patient with a known intact RLN whose prognosis for recovery is good. The suture can be removed once

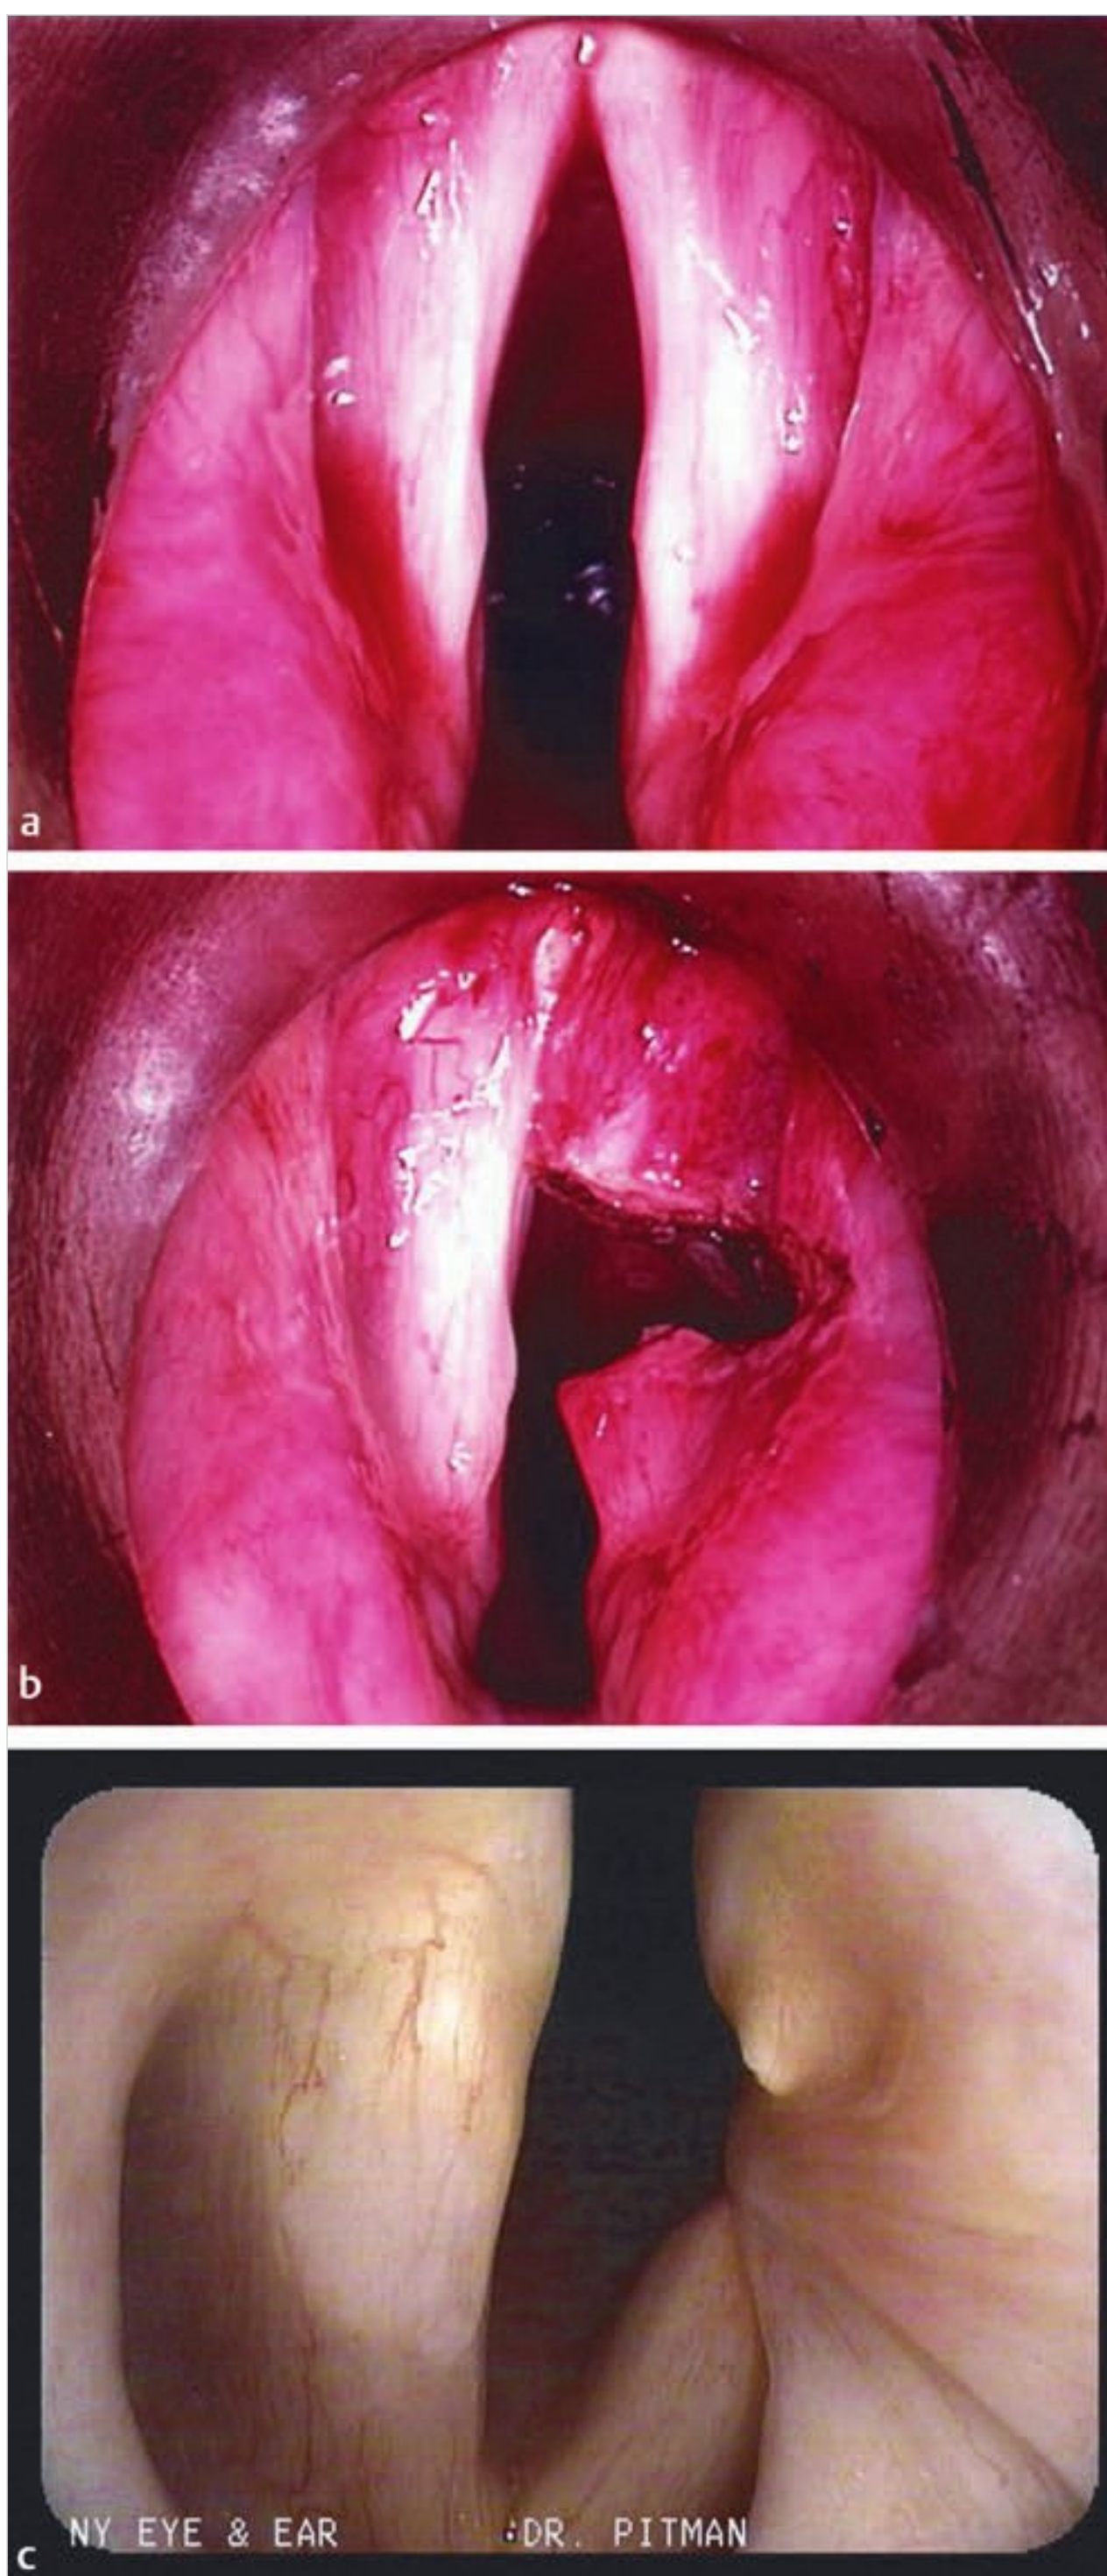

Fig. 86.3 Bilateral vocal fold paralysis (a) before posterior transverse cordotomy, (b) immediately after cordotomy, and (c) after healing is complete.

function has been restored. This suture technique can also be used as a permanent treatment. Although the technique is generally seen as nondestructive, the suture can saw through the membranous vocal fold with an irreversible outcome similar to that of a posterior transverse cordotomy.

Fig. 86.4 Intraoperative view of medial arytenoidectomy.

A newly described technique is the abductor suture technique. This technique is truly reversible. It is a modification of the arytenoid adduction suture technique, which is often used in unilateral vocal fold paralysis. In the abductor technique, a permanent suture is placed through the muscular process of the arytenoid and then directed posteroinferiorly and tied to the inferior cornu of the thyroid cartilage. This procedure abducts the vocal process, thus enlarging the airway. It also allows adduction to occur if it is present. In the small series performed, all six patients had an improved airway; five were decannulated. Four patients had no vocal change, and two had increased breathiness.

These procedures can all be performed without a tracheotomy. The patients need to be selected carefully, with the full understanding of possible airway compromise from edema caused by the procedures. The procedures are also performed in patients with a tracheotomy so that they can be decannulated after intervention.

Overall, the success of these surgical procedures ranges from 80 to 100% when decannulation is used as the means of comparison. However, the literature lacks standardization of the success rates, and the results are varied with regard to complication rates. When performing these procedures, one must balance the benefit of an enlarged airway against the potential complications, which include aspiration resulting from an enlarged unprotected glottis, weak and breathy dysphonia, the urgent need for postoperative tracheotomy, surgical failure with the need for revision, or inability to decannulate the patient. The voice is always weaker after these procedures, excluding the arytenoid abduction procedure. The larger the airway, the better the breathing but the weaker the voice. This tradeoff must be well communicated to the patient. The patient must understand and accept it. The surgeon must negotiate this tentative balance when performing the surgery. The management of each case is based on the patient's clinical needs and physical findings, and the treatment is selected is based on the expertise and experience of the surgeon.

Because destructive procedures are irreversible, a conservative approach should be taken during surgery. A 20% revision rate is to be expected. A second or even a third procedure with further resection of the arytenoid or vocal fold or surgery of the opposite side is preferable to excessive resection resulting in dysphonia or aspiration.

Laryngeal pacing and laryngeal reinnervation are potential treatment options in the near future. They are both in the experimental phase and aim to rehabilitate a larynx dynamically and restore vocal fold motion. Currently, a handful of patients have undergone these procedures, with mixed results. The standard of care still remains a tracheotomy for acute airway compromise. Secondarily, and often preferred, is a destructive procedure of the glottis to establish a larger airway caliber in patients unlikely to experience spontaneous recovery of laryngeal function and in those wishing to undergo decannulation.

86.8 Prognosis

Depending on the etiology, many patients with bilateral immobility will recover at least one functioning vocal fold. Patients with iatrogenic injury to a nerve or malignant involvement of a nerve are far less likely to show recovery. For those patients with little or no airway compromise, the prognosis is good for a normal quality of life. With even minor recovery of vocal fold abduction, airway intervention is typically not required. Intermittent respiratory distress associated with laryngeal edema is typically treated medically and resolves. Overall, approximately 50% of patients with permanent bilateral vocal fold paralysis will need surgical intervention. Spontaneous recovery of function in at least one vocal fold will occur in 20 to 60% depending on the etiology.

86.9 Roundsmanship

- Many patients with bilateral vocal fold paralysis present with a normal voice.

- Airway compromise is the chief concern.
- Early electromyography can help identify patients with a poor prognosis for return of function and thus allow earlier surgical intervention.
- Tracheotomy is necessary in approximately 50% of patients with bilateral vocal fold paralysis.
- Bilateral thyroarytenoid botulinum toxin injection can result in a stable airway and avoid the need for tracheotomy or other permanent surgical procedures in selected cases.
- Surgical intervention can result in a safe airway, decannulation, and the preservation of adequate voice and swallow function.
- In destructive surgery to restore the glottic airway, one must balance the size of the airway against the ensuing dysphonia. Initial conservative surgery is ideal.

87 Laryngopharyngeal (Airway) Reflux

Jamie A. Koufman

87.1 Introduction

Reflux is an expensive, high-prevalence disease, and it remains somewhat controversial because neither standardized diagnostic tests nor standard treatments exist. In addition, divisions between the medical specialties (otolaryngology, pulmonology, gastroenterology), each focusing on its own anatomical subdivision, has led to academic turf wars and further fragmentation of the medical care of patients with diverse manifestations of reflux. Nevertheless, reflux (particularly laryngopharyngeal reflux) affects almost half of patients with laryngeal and voice disorders, globus, and dysphagia, so the management of reflux is very important in the field of otolaryngology.

87.2 Prevalence of Reflux in America

Today, physicians and their patients are more attentive to esophageal and, to a lesser extent, airway reflux, particularly when its symptoms are “silent.” This term has captured the public’s awareness because people with silent reflux do not have heartburn and indigestion, the symptoms most commonly associated with esophageal reflux. Indeed, it is more common to underdiagnose or misdiagnose airway reflux because patients with laryngopharyngeal reflux usually do not have typical digestive symptoms.

The increased awareness of reflux diseases among physicians is not just a matter of experience and education; it is also a consequence of the fact that the prevalence of esophageal and airway reflux has skyrocketed since the 1970s. A comprehensive review of 20 prevalence studies reported the following: (1) The prevalence of reflux in America has increased by 4% per year since 1976. (2) Today, 40% of the American population has reflux, 22% has gastroesophageal reflux, and another 18% has airway (laryngopharyngeal) reflux. (3) Reflux-caused esophageal cancer has increased more than 650% in the last two generations, and esophageal adenocarcinoma is the fastest-growing cancer in America. (4) Barrett esophagus (a precancerous esophageal condition) is equally common (8%) among patients with esophageal reflux and those with airway reflux. These trends have been attributed primarily to the obesity epidemic and the use of food additives; however, it now appears that there may be more to the story. The American diet may be responsible for the reflux epidemic.

87.3 Terminology: Classification of Reflux Disease

Patients call it simply “acid reflux,” but medical specialists have many different names and designations for diseases and disorders related to the backward flow of gastric contents into the esophagus and airway. In fact, different specialists use different terms that reflect their viewpoints (□ Table 87.1). For example, when describing reflux, gastroenterologists generally refer to gastroesophageal reflux disease, which describes their focus, the esophagus and esophagitis. However, when the airway is involved, gastroenterologists use terms like atypical, silent, or extra-esophageal reflux. Airway specialists, such as otolaryngologists, generally use the term laryngopharyngeal reflux because the larynx and pharynx are the primary target organs when reflux escapes above the esophagus. The term silent reflux can be erroneous because most patients with reflux, particularly airway reflux, do have symptoms. Symptoms by definition cannot be silent, and the disease is not “silent” simply because the symptoms do not include heartburn or abdominal discomfort. It is worth noting that some people with reflux actually have no symptoms. Two groups of patients who warrant esophageal screening, even if they are completely asymptomatic, are those who have had heartburn that has abated and those older than 40 years of age with a family history of esophageal cancer or Barrett esophagus. In these two groups, reflux can be truly silent (no symptoms) and still associated with significant clinical disease.

Why are there so many different terms? Besides otolaryngologists and gastroenterologists, many other specialists, including allergists, pulmonologists, pediatricians, internists, family practitioners, anesthesiologists, and critical care specialists, regularly encounter the diverse manifestations of reflux. Because this chapter on reflux has been written for otolaryngologists, it makes sense to divide the aerodigestive tract into two basic components: the airway and the esophagus. These overarching designations make great sense; this chapter is entitled “Laryngopharyngeal (Airway) Reflux,” but justifiably the title could have been “Airway Reflux” because the term airway reflux is more encompassing and descriptive than laryngopharyngeal reflux. In this chapter, the terms airway reflux and laryngopharyngeal reflux are used interchangeably, as are esophageal reflux and gastroesophageal reflux disease. As expected, the most popular terms across the medical literature are laryngopharyngeal reflux and gastroesophageal reflux disease.

Table 87.1 Most Common Medical Terms for Acid Reflux

Gastric reflux	Gastroesophageal reflux disease	Laryngopharyngeal reflux
Extraesophageal reflux disease	Supraesophageal reflux disease	Esophagopharyngeal reflux
Gastropharyngeal reflux	Atypical reflux disease	Esophageal erosions
Barrett esophagus	Reflux esophagitis	Silent reflux
Esophageal reflux	Airway reflux	

87.4 Applied Anatomy

The esophagus, airway, and lungs make up the aerodigestive tract (□ Table 87.2). It is important to recognize that these structures and their functions are closely interrelated. The normal swallow represents a series of highly coordinated neuromuscular activities. After food is chewed and a bolus is formed, the tongue pushes it back to the oropharynx; the swallow is then initiated. After this, the swallow is an unconscious, brainstem-directed sequence. The tongue acts as a piston, forcing the bolus into the pharynx. Next, pharyngeal contraction propels the bolus downward. Meanwhile, there is reflex inhibition of respiration, and the larynx closes tightly to prevent aspiration. The bolus then travels the length of the esophagus, propelled by peristalsis, until it reaches the lower esophageal sphincter, which, like the upper esophageal sphincter, should open, allowing the bolus to pass, and then close behind it. Once inside the stomach, the bolus should remain there, where the process of digestion proceeds because of the presence of acid-activated pepsin.

Gastric reflux occurs when one or more flaws in the anatomical structures and/or their functions are present. Gastroesophageal reflux disease (GERD) is usually associated with (1) low pressure in the lower esophageal sphincter (LES), (2) transient LES relaxations (with or without increased intragastric pressure), and/or (3) esophageal dysmotility. In laryngopharyngeal reflux (LPR), the mechanisms of reflux are related to transient LES relaxations and poor upper esophageal sphincter (UES) function. Indeed, in many patients with reflux-related globus (the sensation of a lump in the throat), the UES pressure may be too low, too high, and/or poorly coordinated with pharyngeal and upper esophageal function.

One last anatomical consideration: the thresholds for acid- or pepsin-related tissue injury are vastly different for the esophagus and for the larynx. Just looking at normative pH monitoring data, 50 episodes of esophageal reflux per day are considered normal; by contrast, as few as three episodes of reflux into the laryngopharynx per week can lead to severe disease. Addition-

ally, laboratory experiments have shown that the threshold for peptic injury in the esophagus is a pH below 4, compared with a pH below 5 for the larynx.

87.5 The Disease Process

87.5.1 Etiology: Risk Factors

Until 1980, the prevalence of obesity in America was stable, at approximately 15%. Since then, its rise has been astonishing. Today, more than 30% of Americans are obese, with a body mass index (BMI) above 30. Not surprisingly, the obesity trend in the United States parallels the rise of prepackaged and fast food, and especially the increased use of saturated fats and high-fructose corn syrup. Interestingly, patients with airway reflux (LPR) tend not to be obese. Furthermore, the prevalence of reflux in the 20- to 29-year-old age group is almost as high (37%) as it is in older people.

For more than two decades, otolaryngologists have recognized that the excessive consumption of carbonated beverages, especially caffeinated colas, is associated with LPR. In 2010, the American Beverage Association reported that the average 12- to 29-year-old consumes 160 gallons of soft drinks annually, or almost a half-gallon of soft drinks a day. The main problem is the acidity. Most beverages in bottles and cans have a pH of less than 4 and are just as acidic as stomach acid itself. However, soft drink consumption is only part of the picture.

Only in the past few years has the root cause of the American “acidity epidemic” become known and linked with the reflux epidemic. In 1973, following an outbreak of food poisoning (botulism), Congress enacted Code of Federal Regulations Title 21, Part 110, “Current Good Manufacturing Practice in Manufacturing, Packing, or Holding Human Food,” mandating that the FDA ensure the safety of processed food crossing state lines. This was accomplished through the acidification of bottled and canned foods, which was intended to prevent bacterial growth and prolong shelf life. Today, almost everything in a bottle or a can has a pH of less than 4, and it appears that the acidity in food is a major risk factor for reflux disease. We also believe that the restriction of dietary acidity can have dramatic therapeutic benefits and should be a routine part of any antireflux therapy program. Identified causes and risk factors for reflux are summarized in □ Table 87.3.

87.5.2 Pathophysiology

Esophageal reflux may occur during the night or day, but typically GERD results from nighttime reflux, whereas LPR occurs during the daytime.

Table 87.2 Components of the Aerodigestive Tract

Nose, nasopharynx, and sinuses	Oral cavity, oropharynx, and pharynx
Hypopharynx and larynx	Trachea and lungs
Esophagus	Upper esophageal sphincter
Esophageal body	Lower esophageal sphincter
Stomach and small intestines	

Table 87.3 Most Commonly Reported Causes and Risk Factors for Reflux

Ethanol	Chocolate	Tobacco, smoking
Overeating, obesity	Tight clothing, belts	Carbonated beverages
Lying down after eating	Esophageal dysmotility	High-fat and fried foods
Xerostomia (e.g., after irradiation) ^a	Late-night eating (within 3 hours before bedtime)	Low pressure in lower esophageal sphincter

^aThe risk for reflux is extremely high in patients with irradiation-induced xerostomia, and reflux-related esophageal cancer is the most common subsequent cancer in patients who have been treated with irradiation.

The most common mechanism of reflux is transient LES relaxation. Unfortunately, the actual causes of this are so obtuse and numerous that the phenomenon remains rather mysterious. Clearly, increased intragastric and intra-abdominal pressure resulting from overeating, carbonation, certain medications, and too-tight clothing is a factor.

The typical patient with esophageal reflux has heartburn and indigestion, is obese, and experiences supine nocturnal reflux, esophageal dysmotility and LES dysfunction. Conversely, the typical patient with airway reflux/LPR has no gastrointestinal symptoms, is not overweight, has normal esophageal motility, but has UES dysfunction.

The UES is supposed to act as a second barrier (in addition to the LES), and under normal circumstances it prevents esophageal refluxate from entering the throat. The overlap of patients who have both LPR and GERD is approximately 25%. Despite this, it is felt that the pathophysiologic mechanisms in these two populations of patients with reflux are different, for reasons that are unknown.

The acid (pH) thresholds for cell damage of the larynx and esophagus are different. In general, esophageal damage occurs at a pH below 4 and laryngeal damage at a pH below 5. (Because the pH scale is logarithmic, a pH of 4 is 10 times more acidic than a pH of 5.) This variable pH threshold for laryngeal and esophageal tissue damage has important implications for both the diagnosis and treatment of LPR and GERD. Contrary to traditional belief, recent data indicate that it is not acid but pepsin that produces tissue injury. The confusion comes from the fact that the activation of pepsin, the primary and powerful proteolytic enzyme of the stomach, requires acid. As such, previous focus had been on acid, which actually is just the facilitator of pepsin activity. Without pepsin, acid itself is not nearly as damaging.

87.5.3 Cell Biology of Reflux and Carcinogenesis

The relationship between GERD and its progression from esophagitis through gastric metaplasia (Barrett esophagus) to dysplasia and finally adenocarcinoma has been well established. More controversial is the relationship between LPR and laryngeal cancer. It has been shown in humans with LPR, laboratory animals, and cell cultures that activated pepsin becomes tissue-bound, enters cells by endocytosis, and then adversely alters protective cell proteins, including E-cadherin (the mortar between squamous epithelial cells), carbonic anhydrase (responsible for maintaining adequate intracellular acid–base balance), and stress proteins (responsible for cell survival following stress).

Notably, laryngeal epithelial damage (e.g., the protein changes outlined above) occur with activated pepsin at pH 5. Recent studies have demonstrated that pepsin in laryngeal epithelial cell cultures upregulates all of the genetic markers associated with squamous cell carcinoma of the larynx. Clearly, the relationship between laryngeal cancer and reflux remains to be proved. However, considering these findings, the author strongly recommends pH testing and treating patients with laryngeal cancer as if they had severe LPR.

87.6 Medical Evaluation

87.6.1 Symptoms and Manifestations of Airway Reflux

Of the many reported symptoms and manifestations of airway reflux, the most common are hoarseness, sore throat, chronic throat clearing, excessive throat mucus, chronic cough, choking episodes, shortness of breath, a sensation of a “lump in the throat” (globus), difficulty swallowing (dysphagia), and asthma (□ Table 87.4).

87.6.2 Diagnosis

The symptoms and manifestations of airway reflux go beyond those typically associated with esophageal reflux, and there are red flags that make airway reflux highly likely. Awakening in the middle of the night from a sound sleep coughing and even gasping for air “like a fish out of water” (i.e., laryngospasm), chronic cough for more than 2 months (with a normal pulmonary evaluation), a chronic sensation of a lump in the throat other than during an actual meal (globus), morning hoarseness, chronic intermittent hoarseness, and difficulty swallowing (dysphagia), among others, can all be symptoms of LPR (□ Table 87.5).

At present, there are many different ways to diagnose LPR. Unfortunately, there is still no single “gold standard” diagnostic test. The available methods are the following: (1) symptoms (reflux symptom index) and findings (reflux finding score); (2) conventional (sedated) and transnasal esophagoscopy; (3) reflux testing (pH monitoring and impedance); (4) biopsy (pepsin detection, histology, and other markers); and (4) a “diagnostic” therapeutic trial of antireflux treatment. Importantly, esophagoscopy cannot diagnose reflux; it only reveals the presence or absence of complications of reflux, such as Barrett esophagus and esophageal erosions, allowing the conclusion that pathologic reflux is present. However, the absence of complications does not allow one to conclude that pathologic reflux is not present; rather, it can only be concluded that if pathologic reflux is present, it has not resulted in visible complications.

Table 87.4 Symptoms of Airway Reflux

Regurgitation	Dysphagia (difficulty swallowing)
Chest pain	
	Dyspnea (shortness of breath, difficulty breathing)
Choking episodes	
Vocal fatigue	Globus (sensation of a “lump in the throat”)
Voice breaks	Food becoming stuck
Chronic throat clearing	Airway obstruction
Excessive throat mucus	Wheezing
Postnasal drip	Chronic cough

Presently, there is no one diagnostic reflux test that provides more accurate information than the combination of pharyngeal, UES, and esophageal manometry with ambulatory 24-hour dual pH probe (simultaneous pharyngeal and esophageal) monitoring. Impedance monitoring is, in the author's experience, a much inferior choice for diagnosing airway reflux, although it is a good supplement to pH testing because it may identify injurious nonacid reflux. Under development are new diagnostic tests that are specific for airway reflux and use pepsin as a marker.

87.6.3 Differential Diagnosis

Many conditions can be misdiagnosed as reflux; likewise, reflux in many cases can be mistaken for something else (□ Table 87.6).

Reflux should be considered in the differential diagnosis of almost all inflammatory and neoplastic conditions of the airway, but other etiologies must be considered, as well.

87.7 Treatment

Airway reflux (LPR) can be associated with minor symptoms (e.g., throat clearing) or with life-threatening disease (e.g.,

laryngeal stenosis, cancer, airway obstruction). It stands to reason that there cannot be any "one-size-fits-all" therapeutic regimen. Meanwhile, lifestyle, dietary, medical, and surgical treatment options are available.

87.7.1 Lifestyle and Dietary Treatment

Obesity and reflux go together, especially when the patient overeats; consumes a lot of fried and fatty foods, chocolate, and carbonated beverages; and eats late at night. Those are among the high-risk behaviors for reflux disease. Interestingly, smoking also causes reflux. The recommendations for lifestyle and dietary modifications are summarized in □ Table 87.7.

87.7.2 Medical Treatment

There are several different approaches to medical treatment: antacids, acid suppressants, mucosal protection, and pro-motility agents. These may be used alone or in combination, depending on the patient's reflux pattern and disease severity.

Antacids, once the cornerstone of antireflux treatment, are now reserved for patients with mild and intermittent symptoms or are used as adjunctive therapy to alleviate primarily heartburn in patients with recalcitrant disease. Today, proton pump inhibitors (PPIs) are the most commonly used antireflux drugs, followed by histamine₂ antagonists. Many different PPIs are available on the market today, and they account for \$15 billion in annual sales in the United States alone.

PPIs provide the best acid suppression of any antireflux medication. However, their use has become more controversial in recent years because of concerns about rebound hyperacidity following drug cessation and side effects, as well as short- and long-term complications. When PPIs are used for airway reflux, they should be taken in twice-daily doses (before breakfast and before the evening meal). Patients with nocturnal reflux are also usually given a histamine₂ antagonist at bedtime because histamine₂ antagonists work better than PPIs during sleep.

Prokinetic agents (including baclofen, metoclopramide, erythromycin, and domperidone) can help improve gastric emptying, esophageal function (peristalsis), and sphincter function. They should be reserved for patients who demonstrate poor esophageal motility and/or sphincter function. Metoclopramide and domperidone should be used with caution because they can cause significant and permanent side effects. The numerous side effects of metoclopramide include irreversible tardive dyskinesia, and domperidone is not approved by the FDA for use in the United States.

Table 87.5 Common Presentations of Airway Reflux

Dental caries and erosions	Posterior glottis stenosis
Esophageal spasm	Arytenoid fixation
Esophageal stricture	Paroxysmal laryngospasm
Esophageal cancer	Globus pharyngeus
	Laryngeal cancer
Endotracheal intubation injury	
Contact ulcers and granulomas	Paradoxical vocal fold movement
Vocal nodules and polyps	Recurrent leukoplakia
Pachydermia laryngitis	Polypoid degeneration
Laryngomalacia	Laryngospasm
Vocal cord dysfunction	Sudden infant death syndrome
Sinusitis and allergic symptoms	Sleep apnea
Asthma	

Table 87.6 Differential Diagnosis of Airway/Laryngopharyngeal Reflux

Paradoxical vocal fold movement	Laryngospasm	"Vocal cord dysfunction"
"Irritable larynx"	Allergic rhinitis	Postnasal drip
Sinusitis	Vasomotor rhinitis	Asthma
Vocal cord granulomas	Muscle tension dysphonia	Vocal nodules and polyps
Infectious diseases: viral, bacterial, and fungal	Neoplasms	

Table 87.7 Recommended lifestyle and dietary modifications for reflux

General lifestyle recommendations	Top ten foods and beverages to avoid	Ten best foods for a patient with reflux
Stop smoking. Smoking causes reflux.	Onions (may not affect all patients)	Bananas (rich, low-acid fruit, although they are also a trigger food for 5% of people)
Avoid wearing clothing that is too tight, especially trousers, corsets, bras, and belts.	Peppers, hot sauce (including bell and black pepper)	Melons (best fruits for most patients with reflux: watermelon, cantaloupe, honeydew)
Avoid exercising right after eating (especially weight lifting, jogging, and yoga).	Citrus fruit and juice (naturally acidic, and more is added)	Aloe vera (great thickener and good for digestion)
Do not lie down right after eating, and do not eat anything within 3 hours before bedtime.	Deep-fried food (different from sautéed)	Rice and whole grains (brown rice, bulgur wheat, and whole-grain bread are best)
Elevate the head of the bed if there is nighttime reflux, with symptoms of hoarseness, sore throat, and/or cough in the morning.	Fatty meats (bacon, pork, lamb, some fatty steaks like rib eye)	Salads and vegetables (excluding onions, tomatoes, garlic, and peppers)
An overweight patient should start a low-acid, pH-balanced diet.	Alcoholic beverages	Oatmeal (one of the best breakfast foods)
	Chocolate (one of the most common foods that trigger reflux)	Ginger (spicy, zesty flavor and good for reflux)
	Almost all bottled and canned beverages (almost all are acidified)	Poultry (baked or grilled, not fried)
	Carbonated beverages (Coca-Cola, Pepsi-Cola, and all other “soft drinks”)	Tofu (coagulated soy milk is a vegetarian staple protein)
	Anything eaten before bedtime is a “worst for reflux” food	Fish (all seafood—raw, grilled, baked, boiled, or broiled—is good for reflux)

Many patients with airway reflux need long-term medical treatment, but many also can discontinue their medications after the acute phase improves as long as they remain compliant with a reasonable maintenance antireflux diet.

87.7.3 Surgical Treatment

The primary surgical option for the treatment of reflux is a Nissen fundoplication, in which the dome of the stomach is wrapped around the esophagus and then sewn in place to produce a tight angle where the esophagus enters the stomach. The procedure is generally performed laparoscopically and is by far the single most effective treatment for both esophageal and airway reflux. There is controversy surrounding which patients with LPR are the best candidates for a fundoplication. Surgical treatment is often recommended for patients with lung disease related to reflux and for patients who cannot tolerate or fail medical treatment. When chosen correctly, the procedure is extremely effective, although the benefit can decrease over time if the wrap loosens; this may occur in as many as 10 to 30% of patients. A Nissen fundoplication can be associated with dysphagia, a gas bloat syndrome, dumping syndrome, and vagus nerve injury.

87.8 Roundsmanship

- LPR (laryngopharyngeal reflux)/airway reflux and GERD (gastroesophageal reflux disease) are both on the rise and presently affect as many as 40% of the American population.

- The increase in acid reflux may be due to the acidification of canned and packaged foods.
- The action of pepsin, facilitated by an acidic environment, may be the primary cause of tissue damage in LPR.
- Fragmentation between specialties (otolaryngology, gastroenterology, and pulmonology) has resulted in controversy and confusion about how to diagnose and treat reflux disease optimally.
- Only pharyngeal pH monitoring can positively confirm the diagnosis of LPR.
- When combined with a healthy antireflux diet, medical treatment with antacids, acid-suppressive medications, and/or prokinetic agents is effective in managing the vast majority of patients with reflux disease. Surgery (Nissen fundoplication) should be reserved for those who have complications of reflux disease and those shown to be suboptimally managed with medical treatment.

88 Neurologic Disorders of the Larynx

Jihad Achkar and Phillip C. Song

88.1 Introduction

Neurolaryngology is the study and management of laryngeal dysfunction secondary to problems of neural control and coordination. Common neurolaryngologic disorders include entities that are specific to the larynx (e.g., spasmodic dysphonia, vocal fold paralysis and paresis), as well as others associated with more global neurologic problems (e.g., stroke, amyotrophic lateral sclerosis, basal ganglia pathology). The laryngopharynx depends on complex coordination between the central and peripheral neural pathways for the proper functioning of its multiple tasks. Neurologic disorders affecting either of these two pathways, or both, may have a significant impact on breathing, airway protection, swallowing, and phonation. Sensory deficits, motor weakness, or both compromise the function of the laryngopharynx, and the resultant dysphagia, aspiration, and dysphonia are frequently presenting symptoms in patients with neurologic disease. These problems are best addressed in a multidisciplinary manner, with coordination among an otolaryngologist, a neurologist, and a speech–language pathologist.

In this chapter, we attempt to highlight specific characteristics in the head and neck examination and laryngeal testing that are germane to recognizing neurologic disorders of the larynx. We also describe the presentation and approach to the treatment of several neurologic disorders that have a major impact on the laryngopharynx. Spasmodic dysphonia is discussed in Chapter 89, and vocal fold paralysis is covered in Chapter 85 and Chapter 86.

88.2 Classification of the Disease Process

In general, neurologic diseases that affect the larynx can be categorized according to three broad themes of dysfunction: dyscoordination, hypofunction, and/or hyperfunction. Dyscoordination is a problem in the timing and sequence of motor events. Swallowing problems are often due to dyscoordination because a very tight and precise series of motor events (sequential contraction and elevation of the pharynx and larynx coordinated with relaxation of the cricopharyngeus and opening of the upper esophageal sphincter) occurs after a sensory trigger (oropharyngeal and pharyngeal sensory innervation). Often, there is a mixture of sensory and motor issues, but the problem is generally not purely within the peripheral nervous system. The classic example of a hypofunctional laryngeal disorder is vocal fold paralysis/paresis, which can occur in a purely motor form (recurrent laryngeal nerve paralysis), in a mixed motor and sensory form (high vagal injury), or as a manifestation of central nervous system (CNS) dysfunction (stroke, multiple sclerosis, amyotrophic lateral sclerosis). Hyperfunctional laryngeal disorders are generally central in origin. The classic hyperfunctional disorder is spasmodic dysphonia, which results in spasm of the intrinsic laryngeal muscles during vocalization.

88.3 Anatomy

Understanding the innervation of the larynx is key to evaluating patients with throat symptoms related to neurologic disorders. The recurrent laryngeal nerve (RLN) and superior laryngeal nerve (SLN) are the two branches of the vagus (10th cranial) nerve responsible for proper functioning of the laryngopharynx. They provide motor and sensory innervation to laryngeal and hypopharyngeal structures that allow breathing, airway protection, swallowing, and phonation.

88.3.1 Recurrent Laryngeal Nerve

The RLN nuclei lie within the nucleus ambiguus of the medulla oblongata. Axons exit with the vagus nerve through the jugular foramen and descend within the carotid sheath to branch off the vagus low in the neck. The right RLN loops around the anterior aspect of the right subclavian artery, whereas the left RLN loops around the aortic arch in the same manner. Each ascends in the tracheo-esophageal groove and enters the larynx just posterior and medial to the cricothyroid joint to innervate the intrinsic laryngeal muscles. A well-described anomaly of the right RLN has been found to occur in approximately 5 in 1,000 persons, in which the right RLN branches off the vagus at the level of the cricoid cartilage and enters the larynx directly without looping around the subclavian artery (nonrecurrent). This occurs in conjunction with an anomalous right retroesophageal subclavian artery. The RLN supplies motor innervation to the intrinsic muscles of the larynx, including the thyroarytenoid, lateral cricoarytenoid, posterior cricoarytenoid, and interarytenoid muscles. The posterior cricoarytenoid is the only muscle with the function of abducting the vocal folds. Although topographic distribution of the adductor and abductor fibers is seen in the brainstem and the distal portions of the RLN, in the main trunk of the nerve, the adductor and abductor fibers are mixed. The intrinsic laryngeal muscles are unilaterally innervated with the possible exception of the interarytenoids, which have crossing muscle fibers and may share a bilateral nerve supply. Neurologic disorders with resultant RLN palsies have the potential to affect all the major functions of the laryngopharynx.

88.3.2 Superior Laryngeal Nerve

The superior laryngeal nerve (SLN) branches off from the main trunk of the vagus high in the neck. Its sensory cell bodies lie in the nodose ganglion just superior to its branching point. It descends in the neck lateral to the pharynx and medial to the carotid sheath, and it divides into internal and external branches approximately 2 to 3 cm superior to the superior pole of the thyroid gland at the level of the hyoid bone. The internal branch enters the larynx, along with the superior laryngeal artery, through the thyrohyoid membrane. It supplies sensory innervation to the supraglottis. The external branch descends inferomedially on the pharyngeal constrictors to supply motor innervation to the cricothyroid muscle. The cricothyroid muscle is

the tensor of the vocal folds and regulates the frequency of phonation.

Palsies of the SLN cause supraglottic sensory dysfunction, leading to a significant increase in the risk for aspiration. They may also lead to pitch alteration that can be detrimental to the function of professional voice users.

88.4 The Disease Process

88.4.1 Etiology and Pathogenesis

Neurologic disorders affecting the larynx have different etiologies, and the symptoms depend on the region of the nervous system affected.

Parkinson Disease

Parkinson disease is a disease of the basal ganglia and one of the most common neurologic disorders to affect the laryngopharynx. Parkinson disease is the result of progressive degeneration of the basal ganglia, mainly dopaminergic neurons of the substantia nigra pars compacta. Recent research suggests a genetic etiology, and ongoing investigation is under way to identify specific genes and pathways.

Stroke

Stroke is caused by the sudden interruption of blood supply to a brain region. The resultant corresponding neurologic deficits may vary in degree and distribution.

Multiple Sclerosis

Multiple sclerosis is an immune-mediated inflammatory disease of the CNS that results in the demyelination of axons. The subsequent neurologic deficits correspond to the affected regions of the brain.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis is an idiopathic neurodegenerative disease of upper and lower motor neurons. It leads to muscle weakness, atrophy, and spasticity.

Tremor

Essential tremor is a common movement disorder. It usually occurs with voluntary movement (action tremor), and to a lesser extent with posture holding. The tremors generally have a characteristic frequency of 4 to 10 Hz and mostly affect the upper extremities, neck muscles, and throat. Essential voice tremor is believed to be the phonatory manifestation of essential tremor.

Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder affecting the neuromuscular junction. Autoantibodies target acetylcholine receptors, leading to a decrease in the number of receptors at motor end plates, with resultant weakness and fatigue of voluntary muscles.

88.4.2 Natural History and Progression

The severity of the symptoms of Parkinson disease vary greatly among individuals. It is not possible to predict how quickly the disorder will progress. The disease itself is not fatal, although secondary complications, such as pneumonia, fall-related injuries, and choking, may be.

Stroke is the third most common cause of death in the United States, and almost 5% of the population past the age of 65 years is affected. Dysphagia occurs in 27 to 50% of patients with stroke. The presence of dysphagia after a stroke significantly increases morbidity and mortality rates.

The course of multiple sclerosis varies among patients, and the disease may be remitting-relapsing, primary progressive, or secondary progressive in presentation. Multiple sclerosis, like other immune-mediated diseases, is more common in women and is estimated to have a female-to-male ratio of 3:2. Multiple sclerosis has been found to affect an estimated 400,000 individuals in the United States, but the highly variable disease course and presentation pose difficulties in diagnosis, and thus the actual numbers may be higher.

Respiratory muscle affliction is the symptom most detrimental to patients with disease progression of amyotrophic lateral sclerosis; dependence on mechanical ventilation ensues, and eventual death follows, usually at about 3 years after the establishment of a diagnosis.

Essential tremor is not life-threatening, although it can make communication difficult. Most individuals with myasthenia gravis lead a normal or nearly normal life with treatment. Occasionally, a myasthenic crisis can result in respiratory failure, which requires immediate emergency medical care.

88.5 Medical Evaluation

The history of the present illness in suspected cases of neurologic dysfunction of the larynx needs to encompass a wide range of systems that may be beyond the head and neck. The neurologic history, an assessment of risk factors for stroke (e.g., hypertension, atrial fibrillation, hypercholesterolemia, smoking, patent foramen ovale), and the family history are important aspects of the history that may be relevant. Establishing the clinical course in the history is important because many neurologic diagnoses are based on the patient's symptoms and presentation, and specific diagnostic tests are not available. For laryngologic disorders, the presentation, symptoms, and examination characteristics may be subtle, especially at the onset, and a high degree of specificity needs to be established in order to recognize pathology. Specific questions about vocal strain, breathiness, vocal fatigue, and tremors may reveal important pathology. For instance, vocal fatigue, a common symptom of functional voice disorders, may be a manifestation of myasthenia gravis when it rapidly follows mild to moderate voice use. Vocal tremor is common in the elderly and is occasionally subtle enough to go unnoticed by physicians if they do not suspect the diagnosis. The findings associated with these disorders may not be the ones that are the most distressing to the patient and may have to be elicited through close questioning.

Dysphagia along with hoarseness should raise suspicion of a deeper neurologic condition. As previously mentioned, patients with vagus nerve injury experience motor and sensory conse-

quences. Motor deficits can manifest as hypotonicity of the pharyngeal constrictor muscles, dilatation of the piriform sinuses, and vocal fold immobility. This affects the pharyngeal phase of swallowing and causes food material to pool in the dilated piriform sinuses. The loss of sensation and inability to protect the airway from the pooled material puts the patient at a serious risk for aspiration.

Among the rare manifestations of neurologic diseases affecting the larynx are stridor and breathing difficulties. Bilateral vocal fold paralysis, laryngospasm, and adductor laryngeal breathing dystonia may present primarily with stridor and difficulty breathing.

An accurate and thorough history helps direct the remainder of the evaluation toward the probable cause of the patient's complaints. After the history, a thorough head and neck examination and laryngoscopy are the next steps.

88.5.1 Clinical Features

The hallmark symptoms of Parkinson disease include bradykinesia, resting “pill-rolling” tremor, loss of postural reflexes, and rigidity. Voice and speech dysfunction can be subtle presenting symptoms in the early stages. Vocal symptoms include a monotonous, soft, and breathy voice that is typically perceived by patients to be of normal volume. There is often a flat affect to the voice, as well as to the facial features. Parkinson disease results in a loss of the “emotional” conveyance of the voice. Other symptoms may include difficulty initiating speech, vocal tremor, and sluggish articulation. Swallowing is not particularly a problem in patients with early parkinsonism. However, altered voluntary swallow may lead to drooling in some patients later in the course of the disease.

Manifestations can vary widely and depend on the region of the CNS affected. Patients often present with a mixture of motor and sensory deficits, with or without cognitive impairments. Generally, patients who have had a cerebrovascular accident may be globally debilitated, with cognitive deficits in addition to specific problems encountered within the larynx. When the insult involves the sensory and/or motor nuclei of the vagus nerve, laryngopharyngeal dysfunction ensues. As previously mentioned, the RLN and SLN branch out from the vagus to innervate the laryngopharynx and allow normal functioning. Therefore, multiple tasks, including swallowing, voicing, and breathing, are affected. If a patient with stroke presents with a weak, breathy voice, vocal fold paresis is generally suspected. Dysphagia can result from sensory and/or motor deficits leading to poor coordination during swallowing. The insensate supraglottis (SLN, internal branch) also predisposes patients to life-threatening aspiration. Typical symptoms of multiple sclerosis include limb weakness, eye symptoms (visual acuity and field defects), vertigo, and dermatomal sensory dysfunction. Dysphonia from glottal insufficiency can occur as a consequence of vocal fold immobility. Dysphagia and dysarthria are common presenting symptoms, as well.

In amyotrophic lateral sclerosis, lower motor neuron degeneration causes muscle weakness and atrophy, whereas degeneration of upper motor neurons presents with spasticity and abnormal reflexes. Patients can present with laryngopharyngeal dysfunction affecting any of the tasks of swallowing, phonation, articulation, and breathing. Oropharyngeal symptoms are

present in as many as 25% of patients with amyotrophic lateral sclerosis. Involvement of the tongue, palate, and pharyngeal wall musculature can cause velopharyngeal insufficiency, dysarthria, and dysphagia. Pharyngeal muscular dyscoordination leads to frequent episodes of aspiration pneumonia that often have fatal consequences. The mixed dysarthria pattern of amyotrophic lateral sclerosis includes effortful, slow, short phrases with inappropriate pauses, imprecise consonants, and a strained or strangled voice, as well as decreased frequencies and volume.

It was formerly believed that essential voice tremor does not present as an isolated entity without other signs of tremor. In fact, Sulica et al have recently shown that half of vocal tremors occur with very subtle upper extremity symptoms that are no more severe than those seen in normal persons of similar age. In addition, patients with spasmodic dysphonia frequently present with a superimposed tremor component, causing an erroneous labeling of essential tremor as spasmodic dysphonia. Sulica et al also reported that one-third of the patients they reviewed had been given a diagnosis of spasmodic dysphonia. Vocal symptoms include voice instability that is very rhythmic in nature, increased phonatory effort, and decreased intelligibility. Voicing worsens with stress and during public speaking or telephone use. Alcohol will often relieve patients' tremors, adding further to the risks for misdiagnosis. The diagnosis is based on the clinical features and laryngoscopic findings. Endoscopy usually reveals involvement of the entire laryngopharynx with rhythmic tremors, albeit variably among individuals.

In myasthenia gravis, the most common presentation includes ptosis and diplopia. Otolaryngologic manifestations include dysphonia, dysphagia, and weakness of the muscles of mastication. Around 27% of patients report speech and swallowing difficulties as early symptoms. Voice symptoms include vocal fatigue, difficulty sustaining pitch, hypernasality, intermittent aphonia, and rarely stridor. A review of 40 cases of myasthenia gravis manifesting primarily in the larynx has recently been published. It details the presenting symptoms, examination findings, and treatment options. Dysphonia may result in subtle changes of voice (difficulty with high frequencies or inability to project or sustain volume or pitch).

88.5.2 Physical Examination

The neurolaryngologic assessment should focus primarily on function. Most throat conditions that are related to neurologic impairment have subtle, functional findings that unless actively elicited are easily missed.

The face and neck muscles should be evaluated for spasticity or asymmetry. Function of the vagus and glossopharyngeal nerves can be inferred by testing the gag reflex and observing for palatal deviation. Articulation difficulties almost always indicate a neurologic disorder.

Critical listening to the quality of the vocal signal is an invaluable skill in the evaluation of vocal complaints. An air leak during coughing signifies glottic incompetence. Severe vocal fold bowing and thinning in Parkinson disease may very well present with breathiness and hypophonia. Glottic incompetence may also reflect vocal fold weakness. A rhythmically tremulous voice quality during sustained /i/ phonation is highly suggestive of vocal tremor. A singer's inability to reach the high

notes he previously hit easily during a glissando may represent SLN palsy, and this should be included in the differential diagnosis.

88.5.3 Testing

Laryngoscopy

Laryngoscopy is the critical component in the physical examination of patients with voice and swallowing difficulties. Flexible nasolaryngoscopy provides a general overview of the larynx in a physiologic position and allows the larynx to be examined during a variety of tasks. The examination should include tasks that are cortical (speaking and singing), volitional (simple /i/ or /a/), nonvolitional (spasms), vegetative (coughing, throat clearing, swallowing, and breathing), and emotional (laughing). Repetitive phonatory tasks may induce vocal fatigue and elicit evidence of subtle paresis and weakness. Video recording and archiving the examination allows a serial review of motion and function.

Weak adduction, vocal fold bowing, and a persistent chink in the mid-musculomembranous region are the most common findings in patients with Parkinson disease. During videolaryngoscopy in patients with stroke, the larynx is observed for gross asymmetries in configuration or movement. Unilateral vocal fold paralysis (RLN) generally manifests as an immobile vocal fold lying in the paramedian position. Hypotonicity of the lateral pharyngeal wall muscles and the resultant dilatation of the ipsilateral piriform sinus are commonly noted. The hallmark finding in myasthenia gravis on videostroboscopy is fluctuating impairment of vocal fold motion, bilateral or unilateral, and glottic incompetence in the absence of other structural abnormalities. Laryngeal electromyography (EMG) should be performed to confirm myasthenia gravis. Tensilon testing involves the administration of edrophonium (Tensilon), an anticholinesterase, to patients with suspected cases. The test result is considered positive if EMG demonstrates improved strength.

Laryngeal Electromyography

Laryngeal EMG evaluates electrical activity in the intrinsic laryngeal muscles and is a tool to differentiate neurologic vocal fold immobility from immobility with mechanical causes. Laryngeal muscle dyscoordination from synkinesis following nerve injury can cause vocal fold immobility and airway compromise and is accurately inferred by laryngeal EMG. Laryngeal EMG also offers the potential to predict the return of nerve function after a neurologic insult, and a patient may be directed toward early intervention when signs of a poor prognosis are elicited on laryngeal EMG.

Flexible Endoscopic Evaluation of Swallowing

Dysphagia may be evaluated via flexible endoscopic evaluation of swallowing (FEES). While the examiner keeps the flexible scope hovering at the level of the nasopharynx and looks down, different food consistencies are presented to the patient to observe bolus clearance. Pooling of secretions in the hypopharynx, penetration (entry of food into the larynx), or aspiration (passage beyond the vocal folds) may be observed. The treatment plan is determined accordingly.

Modified Barium Swallow

Different food consistencies are presented to the patient to test food bolus clearance. Swallowing maneuvers such as chin tuck–head turn and improvements in pre-swallow sensory input have shown benefit in decreasing the risk for aspiration and improving swallowing.

88.5.4 Differential Diagnosis

The full differential diagnosis of neurologic disorders that affect the larynx is extensive. □ Table 88.1 summarizes the differential diagnosis of neurologic disorders causing dysphagia, and □ Table 88.2 lists those causing vocal fold paresis and paralysis with dysphonia.

88.6 Treatment

The treatment of the laryngeal manifestations of a stroke is tailored according to the nature of the neurologic impairment. From least invasive to most invasive, interventions may include the following: dietary modifications, swallowing maneuvers, gastrostomy tube placement, vocal fold augmentation/medialization, and pharyngoplasty (open neck surgery to address a dilated piriform sinus). Pharyngoplasty results in a shallower pouch that collects less material and decreases the risk for aspiration. The treatment of glottic insufficiency in patients with stroke should aim for airway protection and voice improvement. Treatment options range from awake in-office injection medialization to open type I thyroplasty procedures. Medialization laryngoplasty increases airway protection by improving the valve effect and producing a stronger cough. Physical and occupational therapy should be a routine component of the recovery plan after a cerebrovascular accident.

Standard L-dopa treatment has not shown significant benefit for laryngeal symptoms related to Parkinson disease. Injection augmentation of the vocal folds has demonstrated temporary vocal improvement but requires repeated procedures and has limited benefit in severe cases. Bringing two nonpliable vocal folds together in the setting of poor lung effort and weak power supply can sometimes result in poorer voice quality. Behavioral therapy shows consistent beneficial results. Lee Silverman Voice Treatment (LSVT), an intensive voice therapy program that emphasizes the production of a loud voice with maximum effort, has shown excellent results in patients with bradykinetic speech. It allows patients to overcome the false perception that their usual-volume voicing is normal and leads to volume gain that is very beneficial. Swallowing function appears to improve after the treatment, as well. It has been shown that oral phase swallowing abnormalities are reduced by 51% after LSVT.

Steroids have been shown to be beneficial in the acute setting and are the mainstay for the treatment of multiple sclerosis. Plasmapheresis in severe attacks that are unresponsive to steroids has shown good results. Rehabilitation of speech and swallow dysfunction, as well as targeted treatment for specific deficits at the glottic level, is usually recommended for patients with multiple sclerosis.

The treatment of amyotrophic lateral sclerosis is generally supportive, with the goals of maximizing the strength and reserve of the tongue and pharyngeal muscles and reducing the

Table 88.1 Differential diagnosis of neurologic disorders causing dysphagia

Central nervous system disorders causing dysphagia	Peripheral nervous system disorders causing dysphagia
Delirium	Vocal fold paresis/paralysis
Dementia	Myasthenia gravis
Traumatic brain injury	Amyotrophic lateral sclerosis
Stroke/cerebrovascular accident	Progressive supranuclear palsy
Wallenberg syndrome	Post-polio syndrome
Cerebral palsy	Guillain-Barré syndrome
Neurodegenerative diseases	Neuropathy: diabetic, HIV infection
Parkinson disease	Myopathy
Huntington disease	Oculopharyngeal muscular dystrophy
Multiple system atrophy	Muscular dystrophy
Arnold-Chiari malformation	Dermatomyositis
Wilson disease	Polymyositis
Multiple sclerosis	Cricopharyngeal achalasia
	Botulism
	Lyme disease

risk for aspiration. Symptom-based approaches are adapted to target affected organ systems. Velopharyngeal insufficiency and hypofunction of the tongue can be treated with the placement of a palatal prosthesis. Close collaboration with a speech–language pathologist is vital for voice rehabilitation, articulation, and swallowing.

The first-line treatment of essential tremor is pharmacologic. Propranolol and primidone have become the mainstays of treatment. Propranolol affects peripheral β -adrenergic receptors in skeletal muscle, resulting in symptomatic relief in up to 50% of patients. Primidone has approximately equal efficacy via a centrally acting mechanism of action. Unfortunately, neither of them has shown a consistent benefit in improving vocal tremor. Methazolamide, a carbonic anhydrase inhibitor, was recently shown to be promising in patients with vocal tremors; however, the results have not been supported by a subsequent blinded

investigation. Botulinum toxin treatment has been tried for the treatment of vocal tremors with variable results. Botulinum toxin can be useful for reducing the amplitude and velocity of tremors.

The treatment of myasthenia gravis is usually pharmacologic, typically with anticholinesterase medication. When necessary, immunosuppressive agents, such as corticosteroids, azathioprine, cyclosporine, and intravenous immune globulin, may be included. Plasmapheresis and thymectomy may also be employed as immunomodulating therapies.

88.7 Conclusion

Neurologic disorders of the larynx comprise a diverse group of problems that affect swallowing, voice, and respiration. The key

to a correct diagnosis is to look comprehensively beyond the anatomy of the larynx and to evaluate function, physiology, and motion with various laryngeal tasks. The neurologic manifestations may be subtle and intermittent, and thus awareness of the different possibilities enables the correct diagnosis. Testing for neurolaryngologic disorders should include perceptual auditory analysis, laryngeal examination, neurologic testing, FEES and/or modified barium swallow, and EMG. Multidisciplinary approaches are best suited for the diagnosis and treatment of these complex entities.

88.8 Roundsmanship

- The laryngopharynx depends on complex coordination between the central and peripheral neurologic pathways for proper functioning, and neurologic disorders affecting either, or both, may have a significant impact on breathing, airway protection, swallowing, and phonation, with resultant dysphagia, aspiration, and dysphonia.
- The key to a correct diagnosis is to look comprehensively beyond the anatomy of the larynx and to evaluate function, physiology, and motion with various laryngeal tasks.
- An accurate and thorough history helps to direct the remainder of the evaluation toward the probable cause of the patient's complaints.
- Critical listening to the quality of the vocal signal is an invaluable skill in the evaluation of vocal complaints, along with perceptual auditory analysis, laryngeal examination, neurologic testing, FEES and/or modified barium swallow, and EMG.

- These entities are best addressed in a multidisciplinary manner, with coordination among an otolaryngologist, a neurologist, and a speech–language pathologist.

89 Spasmodic Dysphonia

Michael J. Pitman

89.1 Introduction

Spasmodic dysphonia (SD) is a neurologic disorder of unknown origin that causes vocal fold spasms during speech. The spasms result in either excessive glottal closure or prolonged lateralization of the vocal folds, causing vocal breaks. The disease was first described by Traube in 1871 but was not accurately characterized as SD until 1968 by Aronson. Originally thought to be due to abnormalities of the basal ganglia, recent evidence suggests that the etiology is not so simple or localized.

89.2 Incidence of Disease

Although the exact prevalence of SD is unknown, there are thought to be 50,000 to 100,000 patients with this disorder in the United States. Of these, 62% are female. The typical age at onset is 39 to 45 years, but the condition has been known to begin anywhere between the second and ninth decades of life. Adductor SD occurs in 82% of patients, whereas 17% have abductor SD. Patients with adductor breathing dystonia or singer's dystonia comprise the remaining 1%

89.3 Classification of the Disease Process

89.3.1 Adductor Spasmodic Dysphonia

In adductor SD, voice breaks are due to spasmodic hyperadduction of the vocal folds that interrupt phonation. As a result of the spasms, which generally occur with voiced vowels, vocal fold closure interrupts phonation, causing a strained or strangled vocal quality with intermittent vocal breaks.

89.3.2 Abductor Spasmodic Dysphonia

In abductor SD, voice breaks are due to spasmodic hyperabduction of the vocal folds that interrupt phonation. Patients have prolonged breathy voiceless breaks because of difficulties with voice onset following voiceless consonants such as /h/, /s/, /f/, /p/, /t/, and /k/. In addition, pitch changes and uncontrolled rises in vowel fundamental frequency may make them sound as if they are on the verge of crying.

89.3.3 Tremor

SD, like other neuromotor disorders, is frequently associated with tremor. In SD, the tremor is often localized to the larynx and pharynx. If tremor is present, then the SD is classified as the predominant type "with tremor" (e.g., adductor SD with tremor). This is clinically significant because the tremor aspect of the disorder does not respond as well as the spasms to treatment with botulinum toxin.

89.3.4 Adductor Breathing Dystonia and Singer's Dystonia

Because of the infrequency of these disorders, they will not be covered in depth here beyond being defined. Adductor breathing dystonia presents as persistent inspiratory stridor with normal voice and cough. Examination reveals paradoxical movement of the vocal folds on inspiration. Singer's dystonia has the symptoms of adductor SD, but the symptoms occur only during singing.

89.4 Applied Anatomy

All laryngeal muscles are involved in SD. In fact, in these patients, the findings of SD can be seen on an electromyographic (EMG) evaluation of the palatal muscles. It is the balance of the SD effect on the laryngeal muscles that determines whether a patient will have predominantly abductor SD, adductor SD, or occasionally mixed symptoms. In adductor SD, the thyroarytenoid and lateral cricoarytenoid muscles predominate. In abductor SD, the posterior cricoarytenoid muscles predominate. Occasionally, the interarytenoid or cricothyroid can play an influential role. Determination of which muscles are causing a patient's symptoms helps guide treatment with botulinum toxin injections.

89.5 The Disease Process

89.5.1 Etiology

SD is a focal dystonia that affects laryngeal muscle control during speech. The term dystonia refers to a syndrome of sustained muscle contraction. Focal dystonias involve abnormal activity in only a few localized muscles. The etiology of SD is currently unknown. Idiopathic dystonias, such as SD, are thought to be due to abnormalities of neurotransmitters in the basal ganglia (putamen, head of caudate, and upper brainstem). Despite this, it is clear the etiology of SD is more complex. It may be the phenotype of multiple abnormalities. Although a genetic basis of SD has not been established, 12% of patients will have a relative with some type of dystonia.

89.5.2 Pathogenesis

A study by Simonyan et al suggests that the pathophysiology of SD may be related to specific brain abnormalities in the corticobulbar and corticospinal tracts. Both diffusion tensor imaging and neuropathologic data show specific white matter changes along these tracts and in the brain regions contributing to them. Specifically, the genu of the internal capsule was found to have a decreased quality and density of axonal tracts. These changes suggest a deficiency in the connection between the cortical and subcortical regions, which is essential for voluntary voice production.

Ali et al used H₂¹⁵O positron emission tomography (PET) to examine speech-related changes in regional cerebral blood flow before and after botulinum toxin injection. Their data demonstrated differences between patterns of cerebral activity in patients with adductor SD and patterns in neurologically normal controls. Decreased activity was observed in sensory areas known to play a crucial role in coordinating oral–laryngeal movements. Three to four weeks after botulinum toxin therapy, the hypoactivity in the sensory areas normalized, with motor and premotor regions exhibiting an increase in cerebral blood flow. These changes may result in the more efficient processing of sensory signals and a return of normal inhibition. The findings of this study suggest that the pathophysiology of SD is related to abnormalities in sensory cortical areas as well as motor areas, and they may explain the efficacy of botulinum toxin beyond a simple weakening of the muscles injected.

89.5.3 Natural History and Progression

Patients with SD can associate the onset of their symptoms with either an upper respiratory infection (33%), parturition or pregnancy (10%), or a major life stressor such as divorce or a death (42%), whereas the remainder cannot identify an inciting event. The symptoms are generally progressive over the first few months to years and then stabilize. They do not spontaneously resolve. Approximately 15% of patients will develop dystonia elsewhere, most commonly cervical torticollis or writer’s cramp.

89.5.4 Potential Disease Complications

Complications of the disease are mostly psychosocial and economic, caused by the impact of the dysphonia on patients’ psyche and ability to communicate.

89.6 Medical Evaluation

89.6.1 Presenting Complaints

Patients present with dysphonia similar to that described in the section on classification of the disease process. Their symptoms are usually worse when they speak on the phone, publicly, or during periods of stress. There may be improvement with sedatives such as alcohol and benzodiazepines. Most can whisper normally, and some can sing or yell without difficulty. As stated, SD will often begin after an upper respiratory infection or in association with a major life stressor. Because of this and the presence of normal-sounding speech between vocal breaks or during certain phonatory tasks, the symptoms are often regarded as “psychological.” Often, a patient will have visited many physicians and mental health professionals over years looking for a diagnosis and cure.

89.6.2 Clinical Findings, Physical Examination

Often, the diagnosis of SD is clear once the patient begins to speak. Nonetheless, it is vital that a complete history be taken and a physical examination performed, including a review of

systems. The physician should inquire about the events surrounding the onset of the disorder, its duration, and its severity. One should ask about the presence of other neurologic disorders or symptoms, as well as other areas of the body that may be affected by dystonia. A patient may have discomfort due to other focal dystonias that he or she is unaware of until directly questioned. The presence of other neurologic symptoms not associated with dystonia or tremor suggests that the SD may be secondary to another disease process.

A full head and neck and neurologic examination should be performed, with the examiner looking for signs of other neurologic diseases that may cause SD or be misconstrued as SD.

The most pertinent aspect of the physical examination is a subjective evaluation of the voice. This is performed by listening closely for phonatory breaks during the entire evaluation. In addition, the patient can be asked to count from 70 to 90 or to repeat sentences created to stimulate the phonatory breaks characteristic of SD (see Box Sentences Constructed to Stimulate the Phonatory Breaks of Spasmodic Dysphonia (p.688)). The patient is often asked to repeat the sentences in a whisper to see if the breaks subside, as would be expected in SD. Although this is less reliable, patients may also be asked to sing a familiar song to see if it can be done without phonatory breaks.

Sentences Constructed to Stimulate the Phonatory Breaks of Spasmodic Dysphonia

- Sentences that elicit adductor breaks when spoken include the following:
 - “Eat apples and eggs.”
 - “The dog dug a new bone.”
 - “We mow our lawn all year.”
 - “Early one morning, a man and a woman were ambling along a 1-mile lane, running near Rainy Island Avenue.”
- Sentences that elicit abductor breaks when spoken include the following:
 - “How high is Harry’s hat?”
 - “Did he go to the right or to the left?”
 - “When he comes home, we’ll feed him.”
 - “He saw half a shape mystically cross a simple path, at least 50 or 60 steps in front of his sister Kathy’s house.”

89.6.3 Testing

Laryngoscopy or laryngovideostroboscopy with a transnasal endoscope is the primary test performed. The examination should be normal except for vocal fold spasms coordinated with vocal breaks. Having the patient read the sentences listed in the Box (see Box Sentences Constructed to Stimulate the Phonatory Breaks of Spasmodic Dysphonia (p.688)) with the endoscope in place often stimulates breaks. Laryngopharyngeal tremor may also be evidenced on examination if it is part of the disorder.

EMG is not typically used for the diagnosis of SD, although a typical burst of activity may be seen before a spasm.

When the diagnosis of SD is unclear, a trial injection of botulinum toxin may be used. The injection will mitigate SD but will not relieve or may even worsen muscle tension dysphonia (MTD), helping the clinician to distinguish between the two. In

similar fashion, a trial of voice therapy will mitigate the symptoms of a patient with MTD but provide minimal relief to a patient with SD.

A neurologic consultation, brain magnetic resonance imaging, or computed tomography is reserved for patients with neurologic symptoms inconsistent with SD.

89.6.4 Differential Diagnosis

The main differential of SD is MTD. MTD is a disorder in which muscle tension and inefficient phonation result in dysphonia. The symptoms of MTD should persist during whispering, and the dysphonia should be consistent. This is in contrast to SD, in which normal fluent speech often occurs between phonatory breaks and the breaks are not present during whispering. The presentations of MTD and SD are not always typical, so it may be difficult to distinguish between the two disorders, especially when a consistent vocal strain is present. As previously discussed, a trial of botulinum toxin or voice therapy may help distinguish between SD and MTD.

89.7 Treatment

89.7.1 Medical Treatment: Botulinum Toxin

The oral medications used for dystonia, such as anticholinergics, benzodiazepines, and baclofen, provide minimal relief and have poor side effect profiles at the doses needed to affect the voice. Botulinum toxin injections are the current treatment of choice. Unfortunately, their effect is temporary, and injections must be repeated approximately every 3 months. Botulinum toxin is contraindicated in a small subset of patients (see Box Contraindications to Botulinum Toxin Injections (p.689)).

Contraindications to Botulinum Toxin Injections

- **Pregnancy:** The use of botulinum toxin by women who are pregnant or lactating is not recommended.
- **Aminoglycosides:** The recent use of aminoglycosides interferes with neuromuscular transmission and may increase the effect of botulinum toxin therapy.
- **Preexisting neurologic disorders (e.g., myasthenia gravis, Eaton-Lambert syndrome, motor neuron disease affecting the neuromuscular junction):** Caution should be used when botulinum toxin is administered to patients with these disorders, especially if large doses are required. Although the amount of toxin that enters the systemic circulation after injection is minute, hyperkinetic symptoms can theoretically occur.

Botulinum toxin is produced by *Clostridium botulinum*. It causes a chemical denervation by splicing fusion proteins (SNAP [soluble NSF attachment protein]-25, syntaxin, synaptobrevin) and blocking the release of acetylcholine at the synaptic junction (□ Fig. 89.1). Botulinum toxin A and botulinum toxin B are used in humans, A much more often. The clinical effect of botulinum toxin in SD is classically thought to result from the inhibition of acetylcholine release at the neuromuscular junction, weakening

the laryngeal muscle and its spasms. Recent evidence shows that the toxin is found to directly affect not only extrafusal muscle fibers but also afferent muscle spindle output. It may also alter cerebral function, although this likely a secondary effect. These alternative pathways of botulinum toxin function are more likely to be responsible for its therapeutic effects than is weakening of the involved muscles.

To be effective, the botulinum toxin must be injected directly into the muscle, the thyroarytenoid for adductor SD and the posterior cricoarytenoid for abductor SD. A dosing protocol must be established for each patient individually because each person has a unique sensitivity. As such, each patient is started with a standard low dose. This is then increased or decreased based on the patient's side effects, symptom response, and individual needs. The onset of the botulinum toxin effect is usually within 48 to 72 hours, and the effect lasts 3 months until another injection is desired. Once an optimal dose is established for a patient, it will usually remain constant for years.

Dosage

The dosing protocols of individual practitioners may vary slightly; the one presented herein is the author's. Botulinum toxin is reconstituted with 4 mL of preservative-free 0.9% sodium chloride to create a concentration of 2.5 units/0.1 mL. The units needed for injection are drawn into a 1-mL syringe. If necessary, additional saline is drawn up so that the injection volume is 0.1 mL to allow optimal dispersion of the medication through the muscle. Traditionally, the botulinum toxin is injected within 24 hours of reconstitution, but recent studies show that if the toxin is frozen, the potency is stable for 4 to 8 weeks.

For the treatment of adductor SD, percutaneous injection of botulinum toxin into each thyroarytenoid muscle is performed at a starting dose of 0.75 units per muscle.

For the initial treatment of a patient with abductor SD, 5 units are injected unilaterally into the posterior cricoarytenoid muscle. The patient returns 2 weeks later for a contralateral injection if the results are not optimal. Before injection, flexible laryngoscopy is performed to confirm that the injected vocal fold is weakened and that adequate abduction is present so that airway compromise will not occur after a contralateral injection. If this is the case, then 1.25 units is injected into the contralateral posterior cricoarytenoid muscle. Once the optimal dosing is established, both sides can be safely injected at the same visit.

Patients are given a diary so that they can rate their voice and toxin side effects before the injection, then every day for 2 weeks after the injection, and then weekly until the next injection. This diary aids in the assessment of botulinum toxin dosing effectiveness and helps determine the optimal timing and dose for the next injection.

Technique

A Teflon-coated 27-gauge needle attached to an EMG unit is used to inject the botulinum toxin. EMG helps to localize the tip of the needle within an active area of the muscle for an optimal injection of toxin. When the needle is thought to be within the muscle, the patient is asked to perform a task to fire the muscle

Fig. 89.1 Biochemistry of botulinum toxin A. BN, botulinum neurotoxin; SNAP, soluble NSF attachment protein; SNARE, SNAP receptor.

in question: sniff for the posterior cricoarytenoid; /i/ for the thyroarytenoid, lateral cricoarytenoid, or interarytenoid; glissando or high-pitched /i/ for the cricothyroid. If the needle tip is within the correct muscle, the EMG should be activated accordingly. Once crisp action potentials are obtained, the toxin should be slowly injected.

Thyroarytenoid injection: The needle is passed through the skin over the superior edge of the cricoid, just lateral to midline. The needle is advanced through the cricothyroid membrane and then as superiorly and laterally as possible into the right or left thyroarytenoid muscle. An attempt should be made to perform this maneuver completely submucosally so that airway stimulation and coughing are avoided (□ Fig. 89.2).

Posterior cricoarytenoid injection: Either of two approaches can be used, transcricoid or lateral. The lateral approach is more often used. For the lateral approach, the larynx is grasped and rotated away from the site of the injection. The needle is passed through the skin just anterior to the sternocleidomastoid muscle at the height of superior aspect of the anterior cricoid ring. It is advanced to the posterior border of thyroid ala. The needle is then stepped posterior to the ala and advanced toward the posterior aspect of the cricoid. To confirm position, the needle tip can be balloted on the cricoid by applying pressure on the anterior aspect of the cricoid. The needle tip is then pulled slightly retrograde, and the position is confirmed with EMG (□ Fig. 89.3). For the transcricoid approach, 2% lidocaine is

injected into the trachea for anesthesia via a cricothyroid membrane puncture. The needle with the toxin is then passed over the top of the cricoid just lateral to midline, through the airway, toward and through the lateral aspect of the posterior plate of the cricoid (□ Fig. 89.4). This is done under laryngoscopic guidance. After the needle has passed through the cricoid, the position of the needle tip is confirmed on EMG (see □ Fig. 89.4).

Interarytenoid injection: After the trachea has been anesthetized as above, the needle is passed through the midline of the cricothyroid membrane and then upward at 45 to 60 degrees into the muscle, which sits above the posterior plate of the cricoid. The needle is passed under laryngoscopic guidance, and the intramuscular position is confirmed with EMG (□ Fig. 89.5).

Cricothyroid injection: The needle is passed 1 cm lateral to midline over the superior border of the cricoid. It is passed straight posteriorly so that it is directed toward the medial border of the thyroid ala. Once the muscle is entered, a glissando or high-pitched /i/ is performed to confirm position (□ Fig. 89.6).

Complications

In all cases, if a patient is underdosed, the mitigation of symptoms will be suboptimal. After injection for adductor SD, a patient who is overdosed may have a raspy or a weak and breathy voice, and may occasionally aspirate liquids. If this problem is

severe, the patient can be instructed to perform a supraglottic swallow until the symptoms resolve. It may take days to weeks, but the side effects always resolve because the effects of botulinum toxin are temporary. Complications after injection for abductor SD include airway compromise. A patient may experience stridor or dyspnea on exertion, and airway obstruction can occur. Careful dosing at the beginning of treatment with staged injections to evaluate botulinum toxin sensitivity will help avoid such a disastrous consequence.

89.7.2 Surgical Treatment

Botulinum toxin injections are the first line of therapy because of their efficacy and minimal risk. Because of the morbidity of surgery and risk for complications, they are reserved for patients who fail botulinum toxin injections, no longer want to receive them, or have developed resistance to the toxin. The benefit of these operations, in both the short and long term, is in question. As a result, surgery for SD is a secondary procedure and is performed consistently at only a few institutions internationally. Before these procedures become more widely accepted, long-term follow-up data and reproduction of the results by other surgeons will be needed.

Dedo proposed and popularized recurrent laryngeal nerve resection for SD. This was the first and only procedure that achieved widespread use. Unfortunately, over the long term, the majority of patients experienced a return of their phonatory spasms. For this reason, the procedure was abandoned.

Isshiki proposed the type II laryngoplasty for adductor SD. This procedure relaxes and lateralizes the vocal folds. The

anatomical alteration prevents the vocal fold spasm from forcefully obstructing airflow and causing a vocal break. If the surgery is overdone, a patient's speaking voice can be excessively raspy and breathy. In Isshiki's series of 41 patients, excellent results were reported in 70% after 6 months. Conflicting results have been presented by surgeons who could not replicate Isshiki's success.

Recurrent laryngeal nerve denervation and reinnervation was first described in 1999. In this procedure, the adductor branch of the recurrent laryngeal nerve is transected bilaterally. The distal branch is then reinnervated with the ansa cervicalis, and a lateral cricoarytenoid myectomy is performed. The ansa cervicalis reinnervation results in tone of the thyroarytenoid and lateral cricoarytenoid muscles and prevents reinnervation by the laryngeal nerves affected by SD. A retrospective study by Chhetri et al showed long-term (mean of 49 months) improvement in both patient subjective voice evaluation and expert perceptual voice evaluation. Of the patients, 26% had continued voice breaks, 30% had significant postoperative breathiness, 6% resumed botulinum toxin injections, and another 6% were undecided whether or not they should return to injections. Despite these results, 83% of patients said they would recommend the surgery. A Canadian group was able to reproduce these results in six patients who were treated without complications. One patient required continued botulinum toxin therapy.

A final surgical option for adductor SD is a bilateral thyroarytenoid and lateral cricoarytenoid myectomy. This procedure weakens the vocal folds bilaterally to prevent spasms. It is staged and performed under local anesthesia, and the breathiness is titrated to decrease the risk for overresection. Short-term results in five patients revealed improved fluency in all. Long-term studies are needed, especially in light of the failed history of myectomy for other dystonias, such as blepharospasm. After myectomy for blepharospasm, not only did symptoms usually recur, but the muscle often became dysfunctional secondary to fibrosis and scarring.

89.7.3 Voice Therapy

Voice therapy is of minimal benefit for the symptoms of SD. It is helpful in resolving the poor compensatory behaviors that patients have developed in attempts to decrease their spasms. Often, these behaviors spontaneously resolve after injections are begun, but that is not always the case. Voice therapy is also helpful when the clinician is unsure about whether a patient has SD or MTD. As noted, MTD should respond well to voice therapy, whereas SD does not.

89.8 Prognosis

Although the prognosis of surgery for SD is unclear, the results of botulinum toxin injections are well known. Patients report 90% and 71% of normal voice function after injection for adductor and abductor SD, respectively. Unfortunately, the effects are temporary, and the injections are somewhat painful. They also need to be repeated approximately every 3 months. It is evident the optimal treatment for SD has yet to be discovered.

89.9 Roundsmanship

- SD was originally thought to be due to abnormalities of the basal ganglia, but recent evidence suggests that the etiology is not so simple or localized.
- Alternative pathways of botulinum toxin function are more likely to be responsible for its therapeutic effects than is weakening of the involved muscles.
- Of patients with SD, 62% are female. The typical age at onset is 39 to 45 years, and 82% of patients have adductor SD, whereas 17% have abductor SD.
- The most pertinent aspect of the physical examination is a subjective evaluation of the voice.
- Botulinum toxin dosing must be individualized for each patient to optimize the benefit and minimize the morbidity of treatment. It will often take multiple injection cycles to identify the optimal dose.
- Occasionally, traditional injections of the thyroarytenoid muscle and posterior cricoarytenoid muscle are not effective, and the injection of alternative muscles must be contemplated.
- Surgical alternatives have shown promise as secondary treatments but must be viewed skeptically without long-term follow-up or reproducibility by multiple surgeons.

90 Benign Lesions of the Larynx

Ted Mau

90.1 Introduction

Benign laryngeal lesions encompass a broad range of abnormalities with disparate pathophysiologic characteristics. They include lesions caused by vocal trauma, congenital or acquired structural aberrations, benign epithelial proliferations caused by human papillomavirus (HPV), and others. Although these lesions are often grouped together in the classification of head and neck diseases because of their common location and benign nature, each must be understood as a distinct entity with regard to pathogenesis, prognosis, and treatment.

90.2 Incidence of Disease

With the exception of papillomas, the incidence of benign laryngeal lesions is not precisely known. It would be reasonable to infer that lesions of the vocal folds occur in a subset of people with a self-reported voice disorder, and it has been estimated that 6% of the general public have a voice disorder at any given time. Of patients who seek treatment for their voice problems, 15 to 30% have been found to have benign vocal fold lesions in large series. The incidence of lesions caused by vocal trauma is likely highest in individuals whose occupations require heavy voice use: foremost in teachers, followed by counselors, attorneys, clergy, singers, call center workers, and others. Among nodules, polyps, and cysts, the incidence of nodules is the highest.

The incidence of laryngeal papilloma is likely close to the incidence of all forms of recurrent respiratory papillomatosis, estimated at 1.8 per 100,000 in U.S. adults.

90.3 Applied Anatomy

Most benign laryngeal lesions develop on the vocal folds. The fine structure of the vocal fold mucosa is crucial to an understanding of benign vocal fold lesions and their surgical management. The human vocal fold has a layered structure not found in other vocalizing mammals, and it is this unique composition that makes it possible for this seemingly simple pair of tissue folds to produce the acoustic range heard in speaking and sing-

ing. The vocal fold mucosa is made up of the epithelium and the lamina propria (□ Fig. 90.1).

Histologically, the lamina propria consists of three layers: a superficial layer containing loosely organized elastin fibers in an extracellular matrix, an intermediate layer rich in longitudinally oriented elastin fibers, and a deep layer made up of predominantly collagen fibers. The superficial layer of the lamina propria (SLP), also called the Reinke space, is the most relevant for vocal fold surgeons. This layer imparts to the vocal fold mucosa its unique properties of self-sustained oscillation. Once lost through disease or trauma, it does not regenerate. Recognition of the importance of the SLP in phonatory function has led to the abandonment of the vocal cord stripping procedure in the treatment of benign vocal fold lesions. Deep to the three layers of the lamina propria lies the thyroarytenoid muscle, which tenses and relaxes to adjust the tension within the lamina propria and so modulate the frequency of vibration.

90.4 The Disease Process

90.4.1 Vocal Fold Nodules, Polyps, and Cysts

Terminology, Etiology, and Pathogenesis

There is no universally agreed-upon terminology for lesions caused by vocal trauma, commonly referred to as nodules, polyps, and cysts. There is some overlap in terminology, and even in the histologic appearance of these entities. What follow are commonly, though perhaps not universally, accepted definitions.

Nodules are bilateral, symmetric, or nearly symmetric lesions at the mid-membranous vocal folds (□ Fig. 90.2). Nodules tend to be white to opaque and firm. After reaching a certain size, they can produce the classically described “hourglass” glottic closure pattern during phonation. Nodules are produced by vocal trauma but can also result from severe chronic cough. The repeated stress of mechanical impact between the two vocal folds is maximized at the point of largest vibratory amplitude during phonation, which is at the midpoint of the membra-

Fig. 90.1 Layers of the vocal fold mucosa.

nous vocal folds. Nodules form as a tissue response to injury and consist of thickened epithelium over a dense fibrous stroma rich in collagen. Epithelial keratosis accounts for the white appearance, and the dense fibrous stroma accounts for the firmness on palpation.

Polyps are also caused by vocal trauma, so they also tend to occur at the midpoint of the membranous vocal folds. They are more frequently unilateral but can occur bilaterally. They can be broad-based, pedunculated, or attached by a narrow mucosal stalk to the vocal fold, and they can vary in size from submillim-

eter lesions to lesions spanning almost the entire length of the membranous vocal fold. Polyps have been variably classified based on their gross appearance, as well as their composition. They can be translucent, vascular/hemorrhagic, fibrotic, or a combination thereof (□ Fig. 90.3). Like nodules, polyps form as a tissue response to injury. In this case, the initiating event may be leakage from traumatized microvasculature that results in focal edema and eventual organization into a hyalinized stroma. Hemorrhagic or vascular polyps contain vascular telangiectasia and organized thrombus, suggesting the key role of vascular injury, deranged repair, and proliferation in the persistence of these types of polyps.

Cysts are entirely subepithelial and reside within the SLP. Two types are commonly acknowledged (□ Fig. 90.4). A mucous retention cyst presumably results from an obstructed mucous gland duct. An epidermoid inclusion cyst can be congenital, iatrogenic, or possibly induced by vocal trauma. The cyst cavity is lined by squamous epithelium and has a keratin-rich and cholesterol-like filling. Finally, a superficial, translucent, broad-based polyp is referred to by some as a pseudocyst. It is “pseudo” in that it does not have a squamous epithelial lining.

Natural History and Progression

Because nodules, polyps, and some cysts are caused by vocal trauma, their fate is intimately tied to the patient’s vocal behavior. If vocal trauma remains unabated, the lesions may enlarge and plateau at a certain size. On the other hand, most nodules will improve with voice rest and resolve with the cessation of traumatic vocal use. Some may not reverse completely, leaving smaller nodules that may be functionally acceptable. Polyps and cysts are more variable in their response to a reduction in vocal trauma. Small, hyaline polyps are more likely to regress,

Fig. 90.2 Nodules at the junction of the anterior and middle thirds of the vocal folds.

Fig. 90.3 Vocal fold polyps. (a) Translucent. (b) Hemorrhagic.

whereas translucent, hemorrhagic, and fibrotic/hyaline polyps may persist despite favorable modifications in vocal behavior. Cysts will not resolve with behavior modification, but the associated edema will improve along with vocal function. In the case of a cyst, excision is generally required to restore an acceptable voice.

Fig. 90.4 Vocal fold cyst.

Potential Disease Complications

Left untreated, nodules, polyps, and cysts will continue to interfere with vocal function. Over time, nodules and polyps that may have been amenable purely to voice therapy may progress so that behavior modification alone is no longer sufficient for resolution of these lesions and the patient's dysphonia.

90.4.2 Reinke Edema/Polypoid Corditis

Terminology, Etiology, and Pathogenesis

Reinke edema, also known as polypoid corditis or polypoid degeneration, is found almost exclusively in smokers and is much more prevalent in females (□ Fig. 90.5). Unlike polyps, which are discrete masses, Reinke edema entails polypoid transformation of the vibratory mucosa along the entire length of the membranous vocal fold. This reflects chronic exposure of the vocal fold mucosa to smoke, as opposed to the localized mechanical or vascular trauma that gives rise to polyps. Although Reinke edema is sometimes mislabeled as simply a vocal fold polyp, the distinction between the two is important because they differ in etiology, anatomy, and surgical management. The term edema is descriptive of the gross appearance of the lesion but a misnomer at the histologic level. The SLP is not simply edematous but is transformed into a myxomatous stroma with unfavorable vibratory properties.

Natural History and Progression

Many smokers may have varying degrees of Reinke edema. They may remain asymptomatic aside from a gradual lowering of the pitch of their speaking voice and an increase in roughness, two hallmarks of the smoker's voice. As smoke exposure continues, the size and degree of the Reinke edema may increase, creating pedunculated lesions that function like a ball

Fig. 90.5 Reinke space edema. (a) Mild. (b) Severe.

valve at the glottis. Because Reinke edema tends to be bilateral (but not necessarily symmetric), the ball valve component may cause mild to moderate airway obstruction. Some patients may seek medical attention after their voice or breathing has gradually deteriorated to an unacceptable point, or after a discrete episode of vocal trauma leads to an acute increase in the size of the lesion and symptom severity. Keratosis may also develop on the overlying epithelium and sometimes leads to concern for malignancy and biopsy. This keratosis, as well as Reinke edema, has not been associated with an increased risk for vocal fold malignancy. In fact, persons with Reinke edema are at a lower risk for developing laryngeal squamous cell carcinoma. Smoking cessation does not reverse the tissue change or reduce the lesion size, but it does prevent progression.

Potential Disease Complications

The deleterious effects of Reinke edema on the voice are self-evident in the rough quality and low frequency of the typical “smoker’s voice.” The effect of chronic airway obstruction from significant Reinke edema on cardiopulmonary health is unknown. Acute airway obstruction from sudden enlargement of Reinke edema due to mechanical trauma is possible.

90.4.3 Granulomas

Terminology, Etiology, and Pathogenesis

Granulomas in the larynx are not the immunologically mediated granulomas referred to elsewhere in medicine. They are akin to masses of granulation tissue and are found most often at the vocal processes (□ Fig. 90.6). Occasionally, they are observed on the medial surface of the arytenoid body. They occur as the result of mechanical injury followed by an exuberant and aberrant reparative response. Mechanical injury can result from intubation (intubation granuloma) or vocal trauma (contact granuloma). Certain types of vocal behavior involve more forceful contact between the arytenoids and may be more likely to cause contact granulomas than other hyperfunctional vocal behaviors. Chronic cough and throat clearing fall into this category. The vocal hyperfunction that leads to granuloma formation can be a compensatory response to vocal fold paresis, atrophy, or other forms of glottic insufficiency. In the face of normal laryngeal anatomy, granulomas may form secondary to phonatory inefficiency and hard glottal onsets. Laryngopharyngeal reflux (LPR) is a commonly accepted etiologic factor for granulomas, although there is an obvious incongruence between the high estimated prevalence of LPR and the relatively rare finding of granulomas. It is likely that LPR is a major contributor to the development and persistence of granulomas once a mechanical injury has occurred, such that the injured mucosa is susceptible to a level of LPR that is ordinarily insufficient to cause symptoms on its own.

Natural History and Progression

It is likely that many granulomas develop and resolve on their own after the initial traumatic event. It is difficult to surmise what percentage of those brought to medical attention would regress on their own because intervention, chiefly in the form of acid suppression therapy and behavioral management, is in-

Fig. 90.6 Left vocal process granuloma.

variably implemented. Surgical excision alone carries a recurrence rate of more than 50%

Potential Disease Complications

When large enough, granulomas will result in dysphonia. Acute enlargement of granulomas causing acute airway obstruction has been reported in isolated cases.

90.4.4 Papillomas

Terminology, Etiology, and Pathogenesis

Laryngeal papillomas, like their better-known counterpart in the genital tract, are “warts” caused by HPV. Unlike other entities described in this chapter, papillomas are neoplasms and have the potential (albeit a low one) for malignant transformation. They tend to develop at the transition between squamous epithelium and respiratory epithelium. Because the true vocal folds are lined with squamous epithelium while the surrounding structures are lined with respiratory epithelium, laryngeal papillomas are most often found on the true vocal folds. Papillomas have a distinct, warty appearance, with vascular stippling due to the fibrovascular stalks that project to the surface (□ Fig. 90.7). More than 70 types of HPV have been identified. Some are associated with malignancy in the genital tract and are considered high-risk types. The low-risk HPV types 6 and 11 account for the vast majority of laryngeal papillomas.

Natural History and Progression

Untreated, laryngeal papillomas grow and produce progressively larger lesions locally. In the population with an adult onset, the rate of growth is highly variable among individuals and even within individuals when the lesions are followed for several years. Papillomas can also develop in noncontiguous sites in the proximal or distal airway; the likelihood is estimated to

Fig. 90.7 Massive laryngeal papilloma obstructing the airway around an endotracheal tube.

be 10% The soft palate, another structure with a squamous–respiratory epithelial transition, is a potential secondary site. More commonly, poorly controlled laryngeal papillomas lead to tracheal and even bronchial disease, presumably via a combination of airborne and iatrogenic seeding. Papillomas secondary to HPV type 11 are known to be more aggressive; these patients have a more severe laryngeal papillomatosis and a higher rate of development of tracheal and bronchial disease.

Potential Disease Complications

The most serious consequence of laryngeal papillomas is malignant conversion leading to squamous cell carcinoma of the larynx or tracheobronchial tree. The risk for conversion is 3 to 7% Airway obstruction due to poorly controlled disease can be life-threatening. This is particularly a problem with tracheal papillomas, which are sometimes overlooked, less accessible surgically than laryngeal disease, and so less amenable to complete eradication.

90.4.5 Sulcus Vocalis

Terminology, Etiology, and Pathogenesis

A sulcus is a linear indentation, groove, or furrow. Sulcus vocalis is variably defined, and the term has been used to describe several entities that share the gross feature of a linear depression along the medial surface of the vocal fold. This can range from a focal deficiency of the SLP to invagination of the epithelium into the vocal ligament (□ Fig. 90.8a). Sulci may be physiologic in that they do not affect vocal fold vibration. They can be congenital, in which case they are often bilateral. A sulcus can also be acquired (e.g., following excision of a vocal fold lesion that leaves a focal defect of the SLP). Theoretically, a sulcus may also be acquired after the rupture of a vocal fold cyst. Sulcus deformities have been categorized into three types by Ford. Type I is

physiologic and includes congenital sulcus with little voice impact and sulcus due to vocal fold atrophy. The mucosal wave is normal or minimally altered. Type II, or sulcus vergeture, consists of a contracted band along the medial vocal fold edge with adherence of the epithelium to the intermediate and deep layers of the lamina propria and a markedly reduced or absent mucosal wave. In type III, or sulcus vocalis, a pit-shaped, focal stiffness involves the vocal ligament, and the condition is associated with severe dysphonia (□ Fig. 90.8b). The voice is typically thin with an elevated pitch, and patients complain of vocal fatigue and lack of projection.

Natural History and Progression

Sulcus vocalis will not change once formed. Patients may develop poor compensatory phonatory behaviors as they try to optimize their voice in the face of a sulcus.

Potential Disease Complications

No consequence beyond vocal impairment has been reported.

90.4.6 Saccular Cysts and Laryngoceles

Terminology, Etiology, and Pathogenesis

The laryngeal saccule is a blind pouch that extends superiorly from the anterior roof of the ventricle. A saccular cyst is a mucus-filled saccule sealed off from the laryngeal lumen and may be congenital or acquired. An anterior saccular cyst is localized and usually overhangs the anterior glottis. A lateral saccular cyst tends to be large and bulges the mucosa of the false vocal fold and aryepiglottic fold. This is sometimes called a congenital saccular cyst when noted in newborns with airway obstruction. A laryngocele is an air-filled dilatation of the saccule. It is believed to form after prolonged exposure to elevated intralaryngeal pressure in the setting of congenital weakness of the saccule lining. A laryngocele can be thought of as a large saccule that has become symptomatic. An internal laryngocele is confined within the cartilaginous laryngeal framework and appears as a submucosal swelling of the aryepiglottic fold. A mixed laryngocele is one that extends through the thyrohyoid membrane, lies lateral or external to the thyroid lamina, and can manifest as a lateral neck mass. A mixed laryngocele has both internal and external components.

Natural History and Progression

Saccular cysts and laryngoceles may enlarge over time. They may also remain relatively stable for long periods of time but suddenly enlarge in response to mucosal inflammation.

Potential Disease Complications

Saccular cysts and laryngoceles may cause voice change, dysphagia, and airway obstruction. They also may be secondary to a malignant neoplasm in the ventricle obstructing the introitus of the saccule. In this case, the mass would be the etiology of the saccular cyst or laryngocele. Isolated cases of sudden death due to rapid expansion of a saccular cyst causing airway distress have been reported.

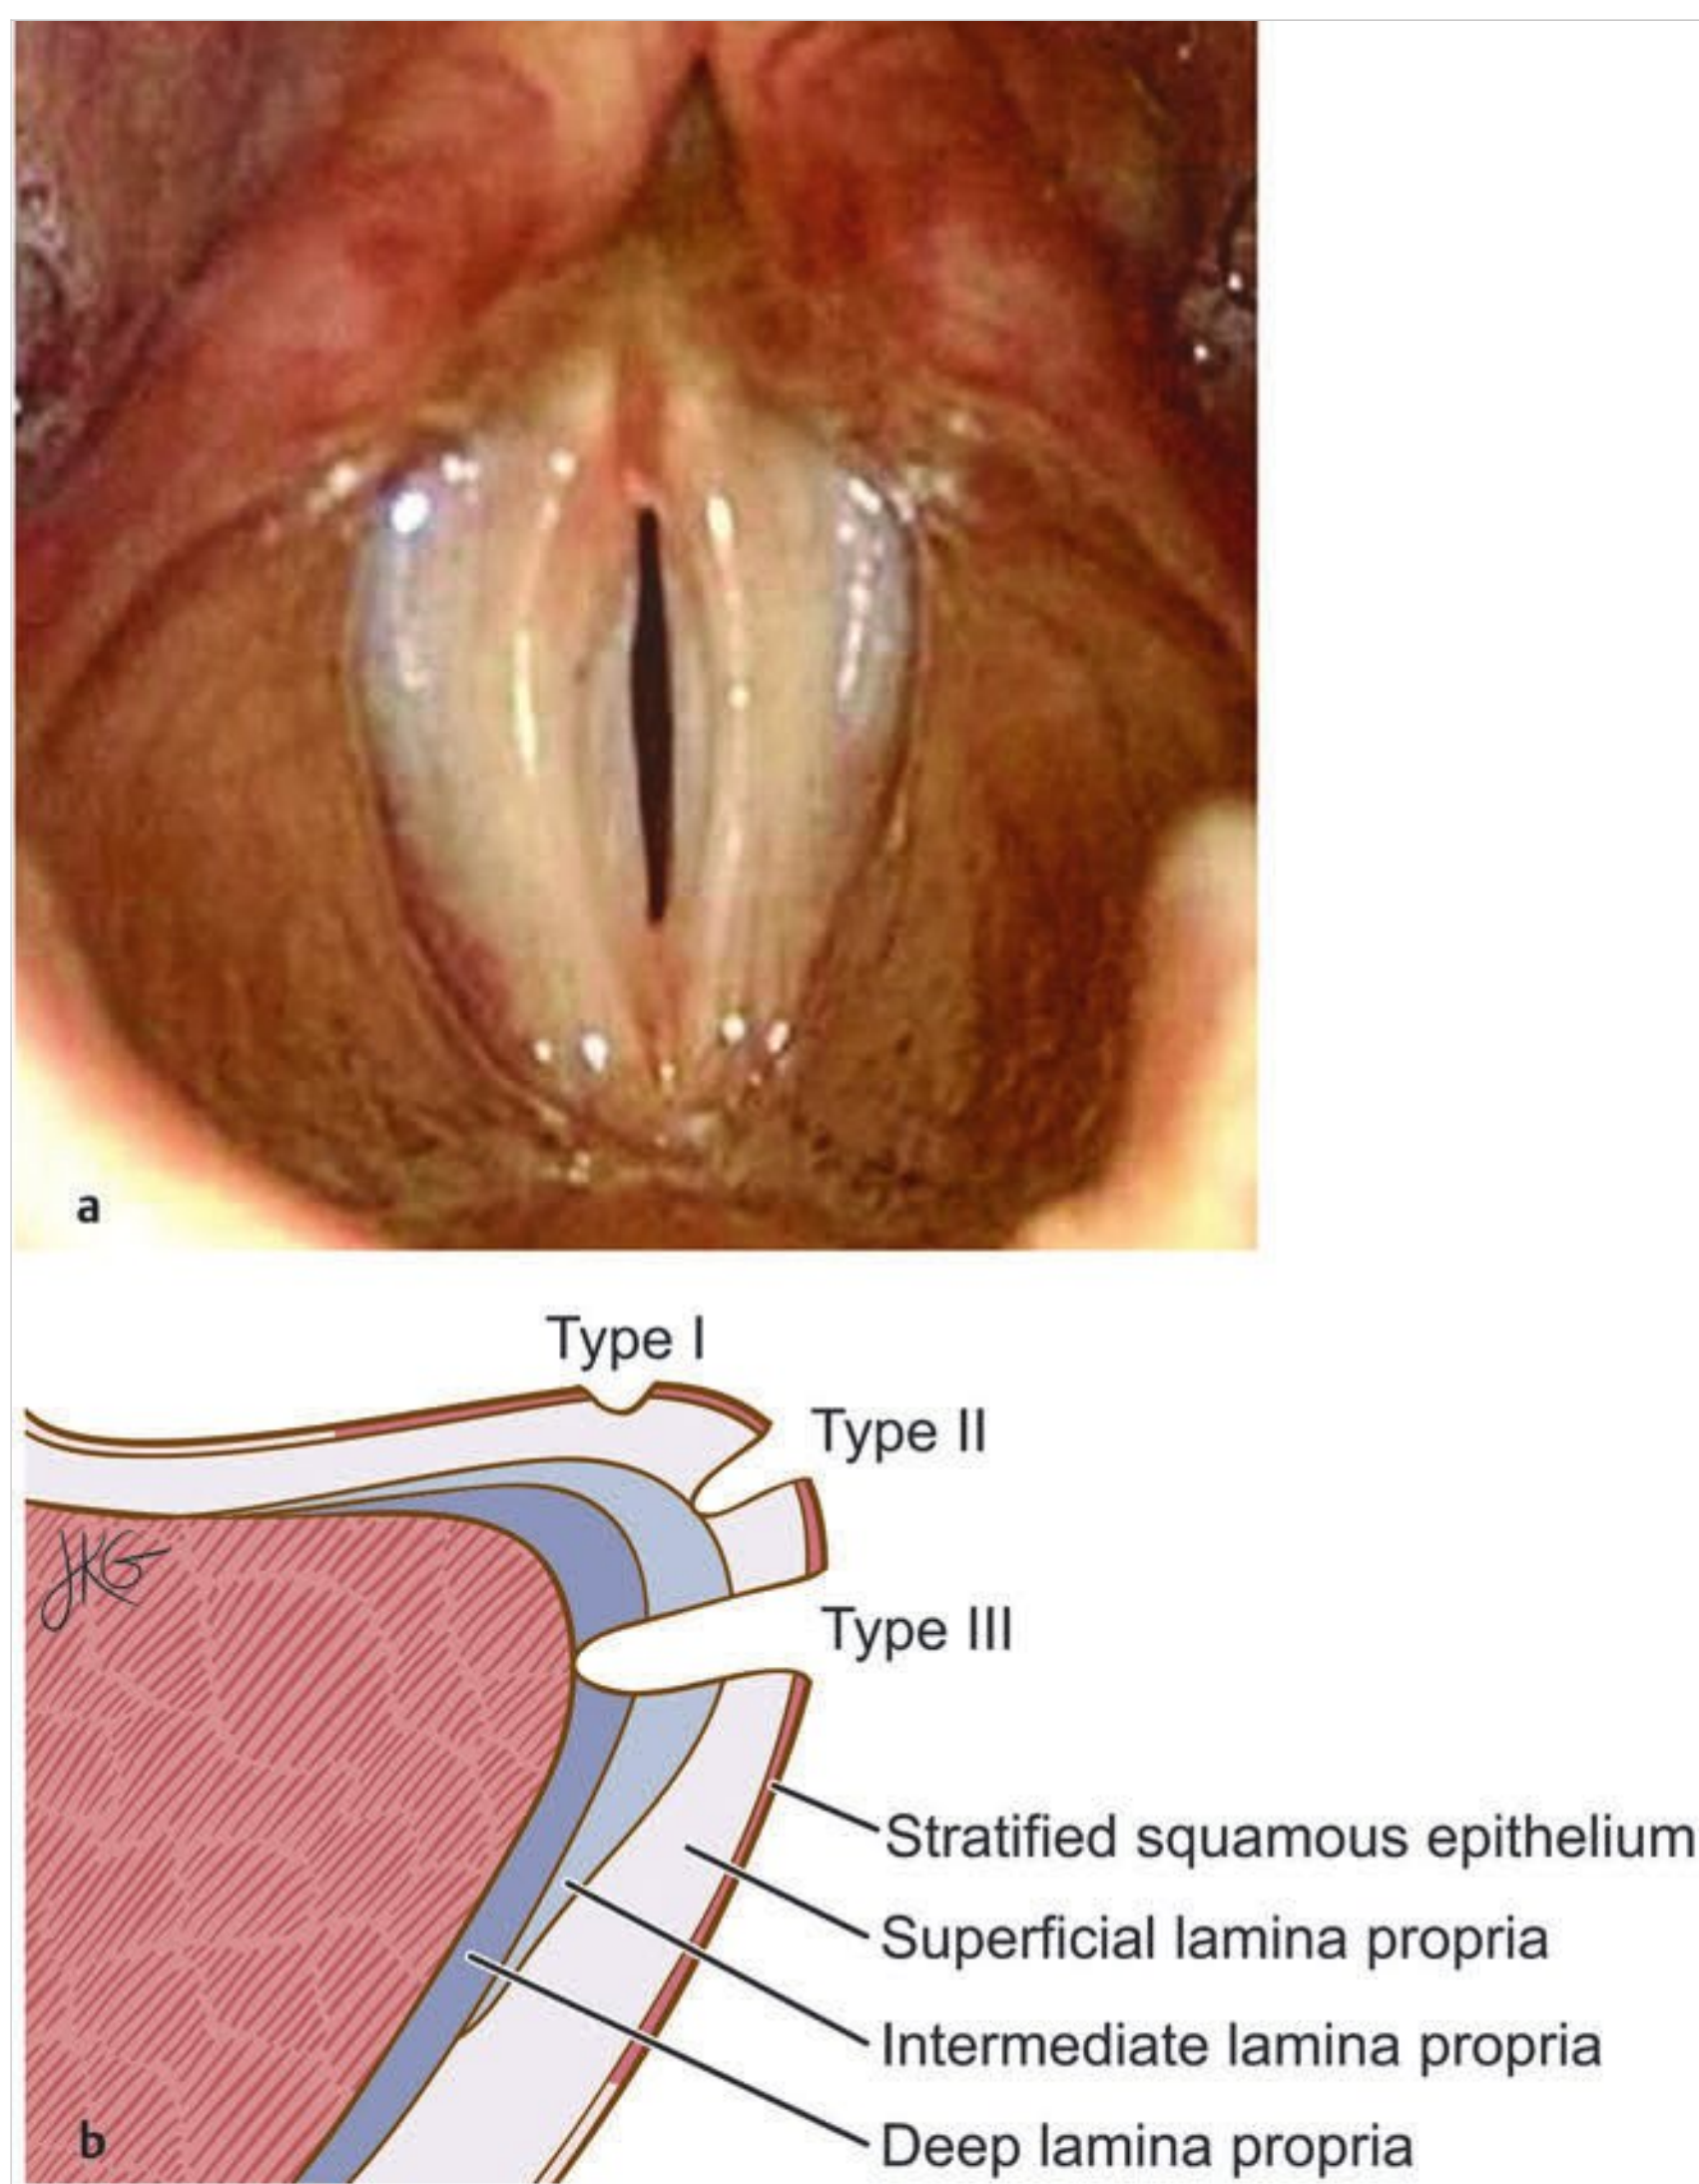

Fig. 90.8 Sulcus vocalis. (a) Bilateral sulci can be seen. (b) Sulcus vocalis classification. The schematic is only intended to illustrate the depth of involvement and not the size or shape of the defect.

90.5 Medical Evaluation

90.5.1 Presenting Complaints

The most common presenting complaints of benign laryngeal lesions relate to voice. The patient may describe a decline in voice quality—for example, an increase in roughness or raspiness. Sometimes, the complaint can be less tangible, such as the development of vocal fatigue or the lack of ability to raise vocal volume. The onset, duration, and progression of vocal symptoms are useful elements of the history. For example, lifelong dysphonia suggests a congenital lesion, such as a sulcus vocalis, whereas a steady progression of dysphonia may be due to a neoplastic process. Patients with a benign vocal fold lesion are unlikely to have any periods of normal voice, unlike patients with functional voice disorders.

Certain lesions have the potential to enlarge sufficiently to cause airway obstruction. Most of the time, however, progression is gradual, and patients present for their dysphonia before the development of dyspnea. Large saccular cysts or laryngoceles may cause swallowing discomfort or frank dysphagia if they impede epiglottic inversion during the swallow cycle.

90.5.2 Physical Examination and Testing

A dysphonic voice quality should be noted. The relative severity of the overall dysphonic quality can be recorded as mild, moderate, or severe and serves as a basis for comparison during follow-up examinations or after interventions. Subjective scales such as the GRBAS scale may be used to evaluate the voice. Patients' voices are evaluated on a scale of 0 to 3, with 0 normal and 3 severe. The overall grade, roughness, breathiness, asthenia, and strain are scored according to this scale. Objective voice measures such as acoustic parameters can be obtained. Any stridor should be noted. The key part of the evaluation consists of laryngoscopy, which can be considered an extension of the physical examination.

90.5.3 Laryngoscopy

Laryngoscopy can be carried out by indirect visualization with a mirror, transorally with a rigid angled endoscope, or transnasally with a flexible laryngoscope. Under most circumstances, this should suffice to identify Reinke edema, granulo-

ma, papilloma, and submucosal bulges from saccular cysts and laryngoceles. Reinke edema involves distortion of the entire normal straight edge of the membranous vocal fold and may be bulky enough to produce a pedunculated mass with a smooth mucosa. Granulomas are distinguished mainly based on their location at the vocal processes or on the medial arytenoid bodies. Papillomas have a wartlike appearance with a distinct vascular stippling that may be discernible if the image quality is good. Some sulcus vocalis lesions, as well as some nodules, polyps, and cysts, may be sufficiently pronounced to be clearly visualized on routine laryngoscopy. Unilateral hemorrhagic polyps, for example, are easily identifiable. It may be difficult to discern smaller, bilateral vocal fold lesions as nodules versus polyps, or a smooth unilateral lesion as a polyp versus a cyst. For these situations, as well as to identify finer sulcus vocalis lesions and their effect on vocal fold vibration, videostroboscopy is recommended.

90.5.4 Videostroboscopy

The vocal folds are visualized under stroboscopy to produce a pseudo-slow motion video of vocal fold vibration (see Chapter 79 for more details on videostroboscopy). This allows the lesions to be seen at slightly different angles as they rock along the medial surface of the vocal fold if they are so located. This procedure also provides an assessment of the impact of the lesions on mucosal wave propagation, vibratory amplitude, glottal closure, and vibratory phase symmetry. Alterations in these parameters help differentiate lesions, as well as prognosticate potential surgical complexity and voice outcome. Nodules may cause a small to moderate decrease in the vibrational amplitude. Polyps, depending on their size, cause variable alterations in vocal fold amplitude and the mucosal wave simply by mass effect. The mucosal wave, although altered, is generally present or somewhat reduced. In contrast, cysts are distinguished by a significant reduction in the mucosal wave. This stroboscopic difference stems from the depth of the lesion and its adherence to the vocal ligament. As such, the pliability of the vocal fold cover is decreased, and mucosal wave propagation is severely retarded by the presence of the cyst. Although a polyp may be as large as or larger than a cyst, it involves the SLP and is not coupled to the vocal ligament. It therefore impacts the wave less. Videostroboscopy is also crucial in the assessment of sulcus vocalis. It reveals the impact of the lesion on mucosal wave propagation and estimates the depth of the sulcus.

90.5.5 Radiographic Imaging

Imaging has little role in the work-up of most benign laryngeal lesions except in the case of saccular cysts and laryngoceles. In these cases, computed tomography or magnetic resonance imaging of the neck is used to determine their anatomical extent and aid in surgical planning.

90.5.6 Differential Diagnosis

Laryngeal malignancies can mimic benign lesions. The most common laryngeal malignancy is squamous cell carcinoma and its variants. Much less common are salivary or mucous gland

tumors, cartilaginous tumors, sarcomas, and neuroendocrine tumors. Lymphomas have also been reported.

Various autoimmune and connective tissue disorders can manifest in the larynx. Bamboo nodules or rheumatoid nodules are submucosal masses found at the mid-membranous vocal folds. Because of their location, they can be mistaken as nodules caused by vocal trauma. Bamboo nodules have been described in isolated case reports of rheumatoid arthritis, systemic lupus erythematosus, progressive systemic sclerosis, Hashimoto thyroiditis, Sjögren syndrome, relapsing polychondritis, and mixed connective tissue disease. Sarcoidosis causes a pale, pink swelling of the supraglottic mucosa primarily. Amyloidosis is a disease of abnormal protein deposition and can be localized to the larynx. Amyloid deposits in the false vocal folds, ventricular floor, and true vocal folds can have a mass effect on the airway and cause dysphonia. The typical lesion is a multilobulated, irregular, smooth submucosal mass with an orange–yellow discoloration.

A history of prior vocal fold injection in the setting of a vocal fold abnormality should raise the possibility of a Teflon granuloma or superficial injectate in the SLP. These may not present as discrete lesions. Part or all of the membranous vocal fold may appear stiff, with a convex contour.

90.6 Treatment

90.6.1 Medical Treatment

With the exception of papillomas, most benign laryngeal lesions may not require treatment simply by virtue of their presence. Treatment is often implemented with the goal of symptom reduction, rather than lesion elimination. Most often, the treatment is surgical in nature.

Voice therapy plays several roles in the management of selected benign laryngeal lesions. Voice therapy is the first-line treatment for nodules and certain types of polyps that may reverse with the cessation of phonotraumatic vocal behavior. Voice therapy may be adjunctive in the treatment of laryngeal granulomas. For lesions that require excision, perioperative voice therapy may decrease the likelihood of persistence of the hyperfunctional vocal mechanism that contributed to lesion formation. Finally, if excision is expected to lead to a decline in voice quality because of necessary sacrifice of the vibratory mucosa, postoperative voice therapy serves to extract the best possible voice from a deficient sound source.

Acid suppression therapy with proton pump inhibitors is commonly used in the management of benign laryngeal lesions if LPR is thought to be a contributing factor. LPR is certainly not a factor in the development and propagation of all benign vocal fold lesions, and it is likely that it is currently being overdiagnosed. It is widely accepted that acid suppression therapy is central to the treatment of laryngeal granulomas. Acid suppression therapy is commonly employed postoperatively to minimize the likelihood of exposure of the surgical site in the larynx to acid.

Several adjunctive therapies have been used in addition to the surgical removal of papillomas. They are indicated when disease is extensive or a rapid return of papillomas requires frequent surgical extirpation. Generally, more than four surgical treatments per year will prompt a discussion of the use of

adjuvant therapies. Oral indole-3-carbinol is a nutritional supplement found in high concentrations in cruciferous vegetables such as broccoli, cabbage, brussels sprouts, and cauliflower. Indole-3-carbinol is thought to modulate the proliferation of epithelial cells indirectly by altering estrogen metabolism. Although its benefit in controlling recurrent respiratory papillomatosis has only been suggested in a relatively small study, indole-3-carbinol has virtually no side effects. A cyclooxygenase-2 (COX-2) inhibitor, celecoxib, is currently being investigated for its effectiveness against recurrent respiratory papillomatosis in a Phase II multicenter randomized controlled trial. COX-2 is overexpressed in papillomas, and celecoxib has been shown to reduce papilloma cell proliferation in cell lines. Preliminary data seem to support the efficacy of celecoxib in achieving disease regression in a small group of patients. Results from the Phase II trial are pending. Cidofovir is a selective inhibitor of the herpesvirus DNA polymerase. It is commonly used off label as a surgical adjunct in an intralesional manner. Data on efficacy show an overall trend suggestive of benefit, although a large-scale randomized controlled trial is lacking. Cidofovir has also been administered intravenously in severe cases with lower airway involvement. Interferon alfa modulates the host immune response to increase antiviral activity. Its use in treating recurrent respiratory papillomatosis has been limited by a significant side effect profile. Finally, an angiogenesis inhibitor (bevacizumab) has shown some promise as a surgical adjunct when applied intralesionally.

Inhaled corticosteroids have been used in combination with proton pump inhibitors to treat laryngeal granulomas, although their efficacy as a single agent is unknown. Injection of botulinum toxin type A into the vocal fold adductors has also been used as a treatment for granulomas resistant to conventional management. In addition, patients who have granulomas secondary to laryngeal hyperfunction used to compensate for vocal fold atrophy may benefit from bilateral vocal fold injection augmentation to decrease the need for such hyperfunction.

90.6.2 Surgical Treatment

All techniques are carried out under general anesthesia via direct laryngoscopy with an operating microscope unless otherwise noted.

Cold Knife Excision

Polyps and cysts that fail to resolve after adequate voice therapy and remain symptomatic are typically excised with micro instruments in a microflap technique, described in Chapter 93 (Instrumentation and Techniques of Phonosurgery). Cold knife excision can also be used to reduce the size of Reinke edema by debulking the diseased stroma in a similar microflap fashion. Complications with the cold knife technique relate mainly to excessive removal of the normal vocal fold lamina propria or epithelium, leading to vocal fold stiffness and permanent dysphonia.

Powered Laryngeal Microdébrider

The chief advantage of the microdébrider is rapid debulking of lesions in cases in which mucosal preservation is not war-

ranted. The main application is in papilloma removal, in which the toothed Tricut version of the débrider blade allows rapid debulking (Medtronic, Minneapolis, MN). The flat Skimmer version of the blade (Medtronic, Minneapolis, MN) minimizes the destruction of normal vocal fold mucosa and the underlying SLP. The microdébrider can also be used to debulk large granulomas. As with the cold knife technique, the main complication of microdébrider use is the loss of normal vocal fold lamina propria and epithelium, leading to permanent dysphonia.

Coblator

The Coblator (ArthroCare ENT, Austin, TX) is also excellent for debulking large amounts of papilloma. Compared with the microdébrider, it has the advantage that coblation minimizes bleeding. In contrast, it cannot be used near the epithelial basement membrane of the vocal fold because it does not provide enough control to precisely remove papilloma without excessive damage to the SLP or surrounding normal epithelium.

Carbon Dioxide Laser

The carbon dioxide laser can be used in an ablative fashion to remove papilloma. It can also be used in an excisional manner, akin to a hot knife, to remove large amounts of papilloma or a laryngocele. Both the internal and external parts of a laryngocele can be excised transorally with a carbon dioxide laser. Although the technique is rare, some authors use the laser at a low-power setting to assist in the dissection of vocal fold polyps or cysts. In all cases, the laser settings and technique used should be optimized to minimize irreversible thermal damage to the tissue adjacent to the target lesion. The most feared complication of laser use is an airway fire. Safety precautions include the avoidance of flammable inhalational anesthetic agents, the avoidance of flammable endotracheal tubes, protection of the endotracheal tube balloon with a saline-soaked pledget, the use of an FiO₂ (fraction of inspired oxygen) below 30% and the application of moist towels to cover the patient's head and face.

Angioselective Lasers

The pulsed dye laser (PDL) and the pulsed potassium titanyl phosphate (KTP) laser have found increasing use in the treatment of benign vocal fold lesions. Both have wavelengths that coincide with the absorption peaks of oxyhemoglobin. Because of their angioselectivity, there is a theoretical advantage in their use for the treatment of lesions associated with rich vascularity, such as papillomas. Their use has been extended to the treatment of Reinke edema, granulomas, some polyps, dysplasias, and limited malignancies. The main advantage of these lasers is that they are delivered via a fiber that can be placed in the working channel of a flexible laryngoscope, allowing treatment to be carried out in an unsedated fashion in the office setting and avoiding the need for general anesthesia. In addition, their selective absorption by oxyhemoglobin decreases collateral damage to surrounding nonvascular tissue, such as the SLP. During direct laryngoscopy, these lasers can be used for the selective photoablation of vessels feeding hemorrhagic polyps, minimizing bleeding and optimizing the surgical field. They can

also be used to treat the residual papilloma that is not excised at the anterior aspect of one of the vocal folds in order to prevent a glottic web when papilloma has been excised anteriorly from the other vocal fold. The papilloma treated with the photoangiolytic laser will slowly involute from ischemia without risk for the formation of an anterior glottic web. Like all lasers, photoangiolytic lasers are associated with a risk for airway fire when used in conjunction with an endotracheal tube, and all safety precautions must be applied.

90.7 Prognosis

Because the lesions discussed in this chapter are of a benign nature, the overall prognosis is excellent. The likelihood that vocal fold nodules, polyps, and cysts will resolve with a combination of behavioral and surgical intervention is excellent. Reinke edema can be surgically reduced to achieve an acceptable vocal outcome. Granulomas almost always resolve, although the time and intervention required may vary considerably. Focal, early laryngeal papillomas may be eradicated, but patients who have diffuse disease may require long-term, episodic maintenance with surgical procedures. Vaccination against HPV should lead to a greatly reduced incidence of disease in the decades to come. Sulcus vocalis has been a challenging entity to correct surgically. Advances in the treatment of sulcus vocalis may require novel techniques and materials to restore lamina propria defects. Finally, saccular cysts and laryngoceles can be managed successfully with surgery.

90.8 Roundsmanship

- The superficial layer of the vocal fold lamina propria is critical in normal vibratory function and must be maximally preserved in the surgical treatment of benign lesions. It does not

regenerate once lost through disease or trauma. Vocal cord stripping is no longer an acceptable surgical procedure.

- Videostroboscopy should be performed in the assessment of vocal fold polyps, cysts, and sulcus vocalis to assess their impact on the mucosal wave, estimate the depth of their involvement, and enhance diagnostic accuracy.
- Benign-appearing laryngeal lesions with an atypical appearance should raise the possibilities of malignancy and of autoimmune, infectious, or connective tissue disorders.
- Voice therapy is the first-line treatment for patients with vocal fold nodules and some polyps. For patients whose lesions require excision, voice therapy still has a role in addressing the hyperfunctional vocal behavior that resulted in the development of such lesions in the first place.
- Acid suppression therapy and behavioral management, not excision, should be the first-line treatment for laryngeal granulomas.

91 Adult Laryngotracheal Stenosis

Amanda Hu and Tanya K. Meyer

91.1 Introduction

Adult laryngotracheal stenosis is one of the more challenging disease entities faced by the airway surgeon. There is no treatment strategy that can be uniformly applied to all patients to guarantee excellent results. The larynx and trachea are both semirigid tubular structures. When injury occurs and wound healing progresses, circumferential scar contracture can cause narrowing of the airway. Furthermore, the larynx functions as a sphincter, opening to allow airflow and closing to allow phonation and facilitate swallowing. Scarring of the larynx may cause fixation of the vocal folds with airway compromise. Surgical attempts to open the airway statically may subsequently compromise phonation and swallowing. The plethora of surgical techniques available attests to the complexity of this problem.

91.2 Incidence of Disease

The true incidence of adult laryngotracheal stenosis is difficult to estimate. Prolonged intubation constitutes the most common cause of adult laryngotracheal stenosis in the modern era (□ Fig. 91.1). The population incidence of laryngotracheal stenosis as a result of prolonged intubation is estimated at 1 in 200,000 adults per year. In the 1970s, Whited estimated that approximately 12% of patients intubated for more than 12 days would develop significant posterior glottic injury. This landmark article has led to changes by which many preventative measures are used in intubated patients to prevent laryngotracheal injury and has contributed to the practice of recommending a tracheostomy after 7 to 10 days of intubation.

91.3 Classification

There are several classification systems for laryngotracheal stenosis. These staging systems categorize the severity of disease to improve communication, help prognosticate the outcomes of surgery, and compare different methods of treatment. One commonly used classification system is the Cotton-Myer system (□ Fig. 91.2), in which stenosis is graded on a scale from I to IV based on the degree of subglottic luminal obstruction. This is the simplest system; it is used more often in the pediatric population and only for subglottic stenosis. A system for grading the extent of posterior glottic stenosis was created by Bogdasarian and Olson in 1980 (□ Fig. 91.3). There are four types, based on the degree of injury and arytenoid mobility and on the prognosis. A third clinical staging system is the McCaffrey system (□ Table 91.1 and □ Fig. 91.4). This system is based on the location and length of the stenosis; the higher the stage number, the worse the prognosis for decannulation.

91.4 Applied Anatomy

The adult trachea is approximately 10 to 13 cm in length and 2.0 to 2.5 cm in diameter. It starts at the inferior border of the cricoid cartilage and extends to the bifurcation of the carina.

The fibromuscular tube of the trachea is supported by cartilaginous rings. These rings occupy the anterior two-thirds of the tracheal circumference and are incomplete posteriorly. There are approximately 14 to 20 tracheal rings.

The blood supply of the trachea is the same as that of the esophagus. The upper trachea is supplied by the inferior thyroid artery and tracheo-esophageal branches of the subclavian artery. The lower trachea is supplied by branches from the intercostal and internal mammary arteries. Because the blood supply approaches the tracheo-esophageal groove laterally, circumferential dissection of the trachea should be avoided to prevent devascularization.

The larynx is divided into the supraglottis, glottis, and subglottis. The supraglottis is defined as the area above the vocal cords and includes the ventricular folds, epiglottis, and arytenoids. The glottis includes the true vocal cords and the anterior and posterior commissures. It extends inferiorly from the true vocal fold edge 1 cm anteriorly and 5 mm posteriorly. The subglottis extends from the lower border of glottis to the inferior border of the cricoid. The glottis is the narrowest part of the adult airway, whereas the subglottis is the narrowest part of the pediatric airway.

91.5 The Disease Process

91.5.1 Etiology and Pathogenesis

Before the advent of prolonged intubation, most cases of laryngeal stenosis resulted from an infectious disease such as syphilis, diphtheria, tuberculosis, or typhoid fever. After World War II, with the advent of modern antibiotics and vaccinations, this etiology waned and was replaced by blunt trauma to the neck through motor vehicle accidents. Since the 1950s and the poliomyelitis epidemic, there has been a dramatic increase in the use of endotracheal tube intubation and mechanical ventilation with prolonged intubation. Correspondingly, prolonged intubation became and remains the predominant cause of laryngotracheal stenosis. Other etiologies are less commonly encountered and include iatrogenic injury, autoimmune and inflammatory conditions, and following radiotherapy. Some cases of laryngotracheal stenosis are idiopathic. Common etiologies of adult laryngotracheal stenosis are listed in □ Table 91.2. Some etiologies of interest are highlighted below.

Trauma

The most common cause of laryngotracheal stenosis is mechanical trauma from endotracheal intubation. This usually results in posterior glottic stenosis because the tube rests in the posterior commissure, applying pressure to the interarytenoid area, vocal processes of the arytenoids, and posterior cricoid plate. This pressure causes ischemic necrosis of the mucosa, leading to mucosal ulceration, bacterial infection, perichondritis and chondritis, and cartilage resorption (see □ Fig. 91.1). As the phases of wound healing progress, submucosal fibrosis occurs with scar contracture. Because the larynx and trachea are semi-

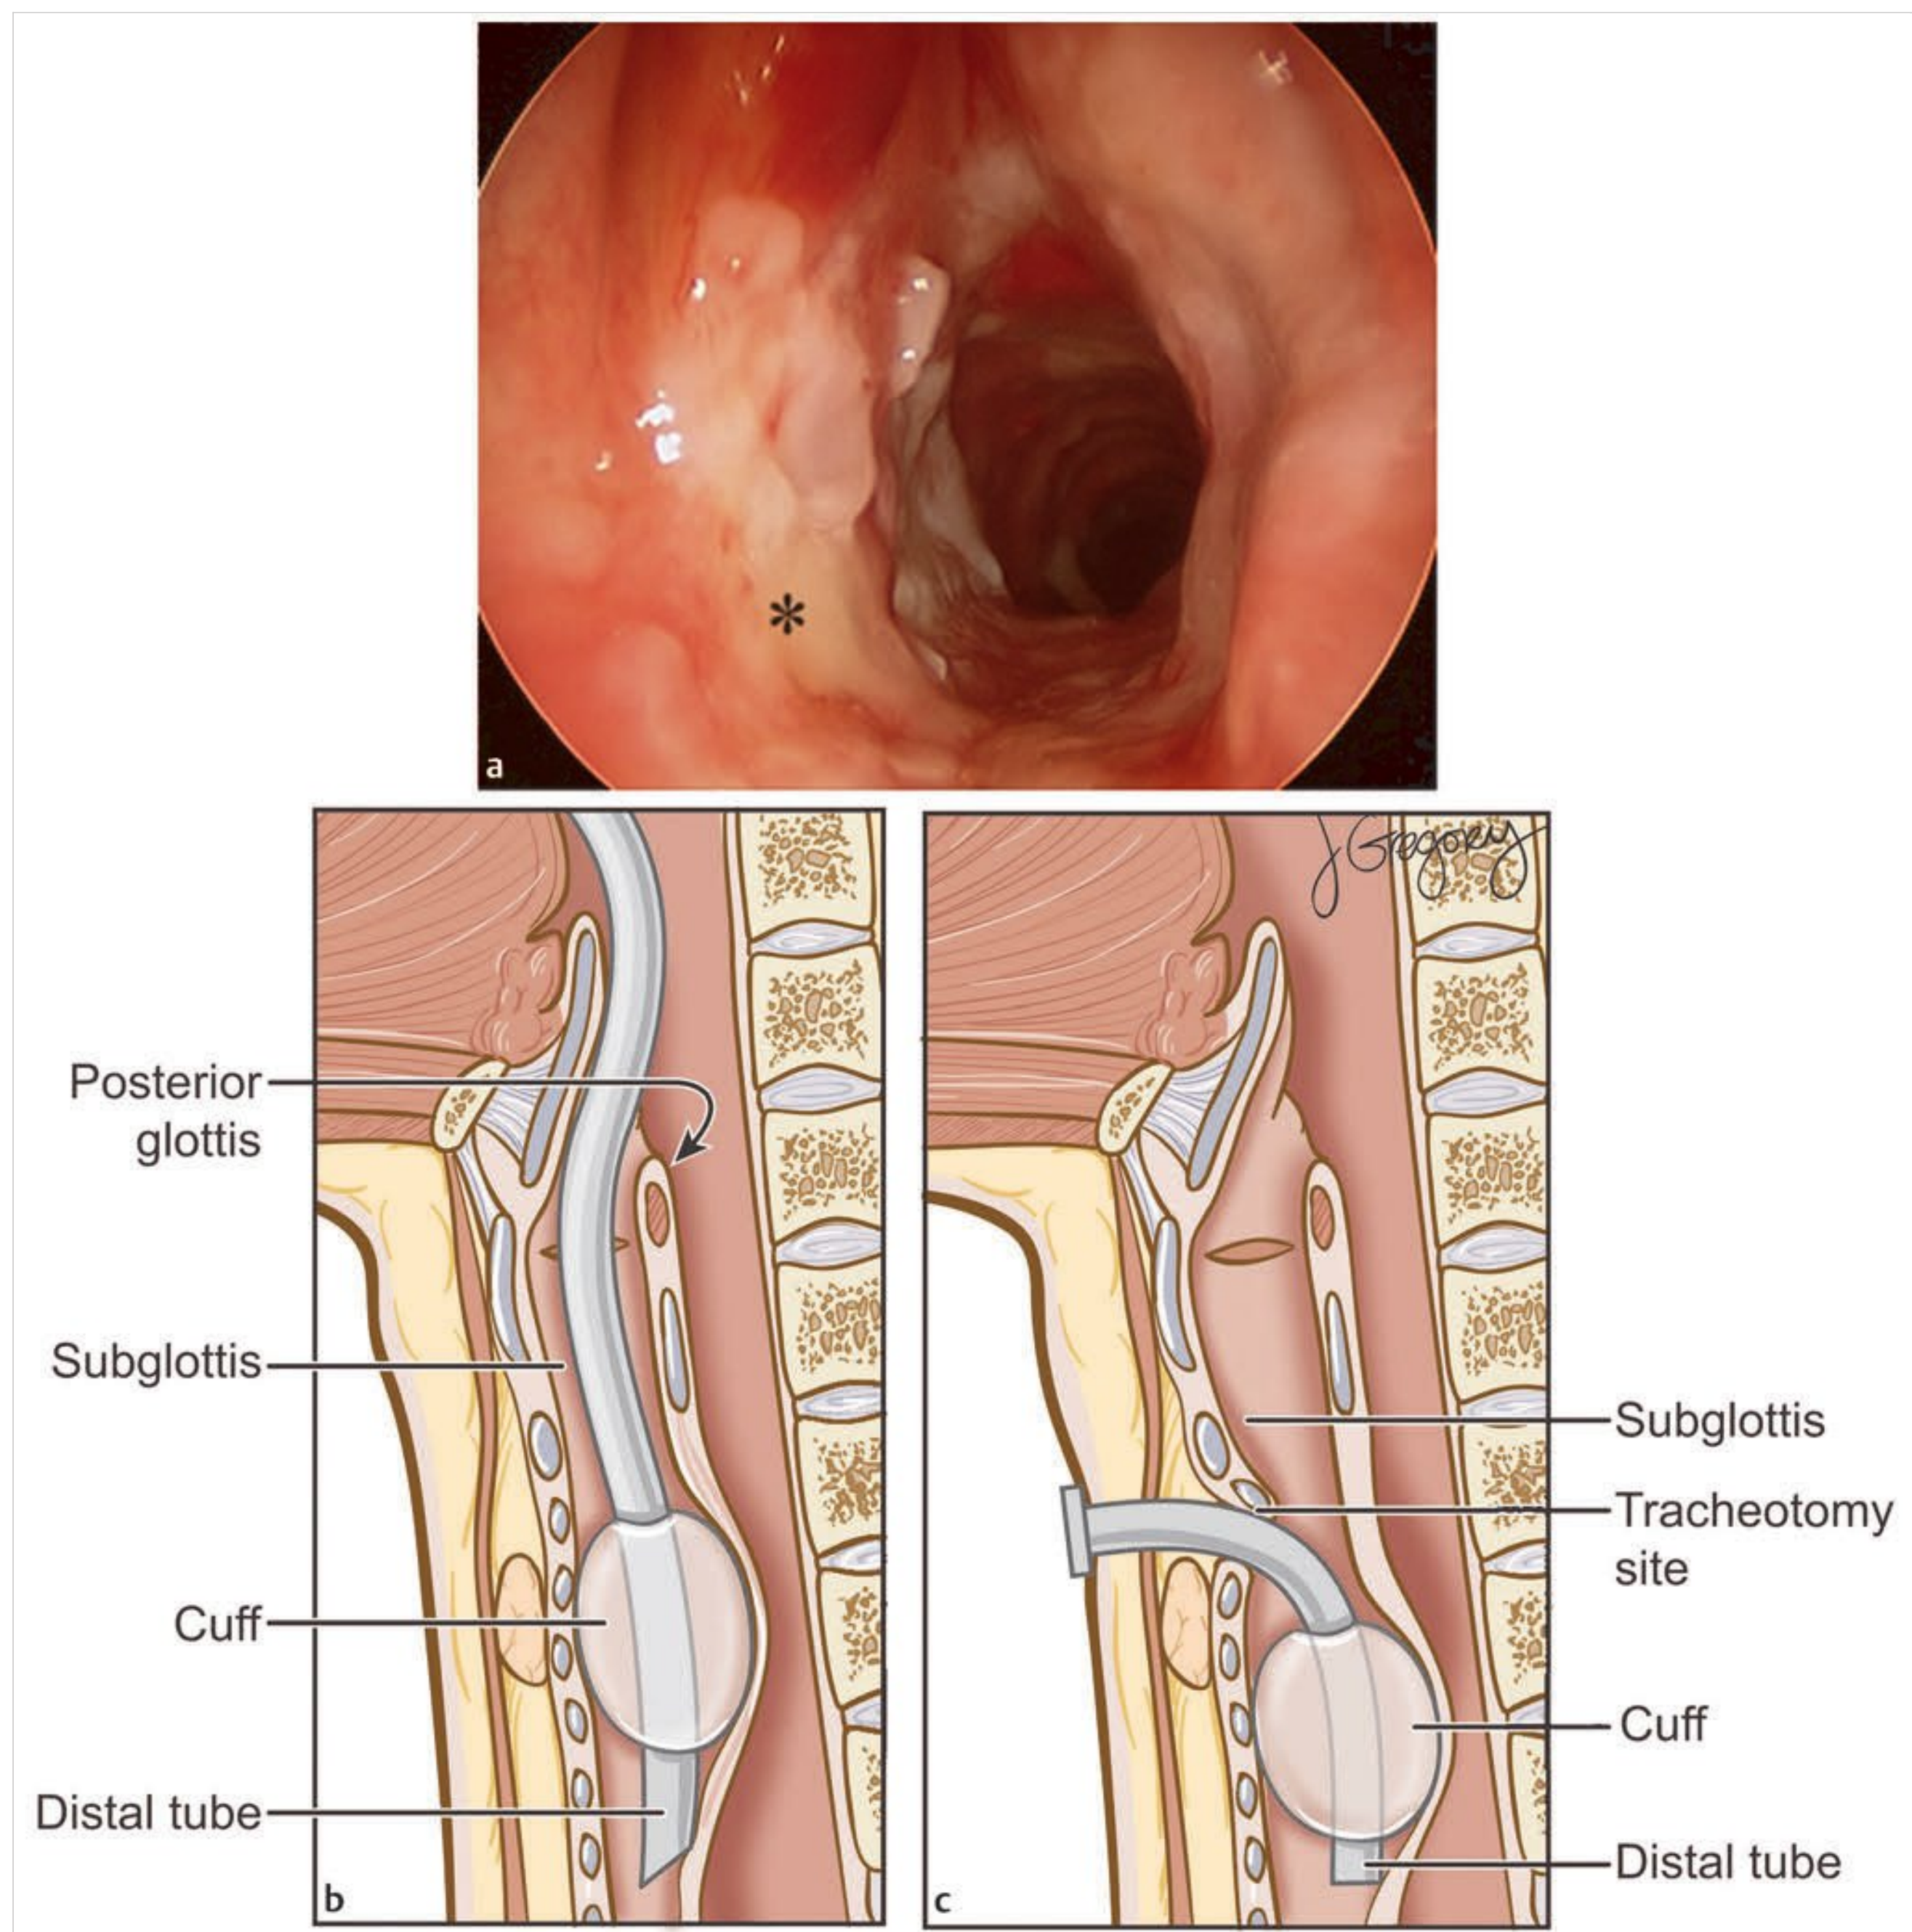

Fig. 91.1 (a) Endoscopic view of typical posterior glottic injury resulting from prolonged intubation. Notice that the mucosa covering the posterior glottis is absent, with cricoid cartilage exposure (asterisk), granulation at the cricoarytenoid joint, and irritation and granulation at the site of endotracheal tube pressure on the distal anterior tracheal wall. (b) Schematic of areas of injury due to intubation: posterior glottis, subglottis, cuff, and distal endotracheal tube tip. (c) Schematic of areas of injury due to tracheostomy: subglottis (if a high tracheostomy), tracheostomy site, cuff, and distal endotracheal tube tip.

rigid tubes, this causes stenosis of the airway. Factors related to the risk for stenosis include the following: tube size and composition, number of intubations, length of intubation, elective versus urgent intubation, concomitant nasogastric tube placement, laryngeal motion during intubation, and concomitant laryngopharyngeal reflux disease. High-pressure cuffs can also contribute to laryngotracheal stenosis. Modern practices use low-pressure cuffs, and cuff pressures are routinely monitored in patients who are chronically intubated or tracheotomized.

Tracheostomy can contribute to multiple airway abnormalities. A tracheostomy placed too high may cause cricoid erosion and subglottic narrowing. Excessive tracheal cartilage removal during fenestration at the time of tracheostomy can cause destabilization of the anterior tracheal wall. As healing occurs after decannulation, an “A-frame” stenosis can develop, often with associated malacia (□ Fig. 91.5). Finally, stomal granulation tissue can develop and mature into cicatrix, and cuff and distal tube tip injury can occur.

(b) Type II, posterior commissure stenosis with scarring in the interarytenoid plane and internal surface of the posterior cricoid lamina. (c) Type III, posterior commissure stenosis with unilateral cricoarytenoid joint ankylosis. (d) Type IV, posterior commissure stenosis with bilateral cricoarytenoid joint ankylosis.

Systemic Disease

Among the systemic diseases that can cause laryngotracheal stenosis, granulomatosis with polyangiitis, traditionally known as Wegener granulomatosis, is the most common. Granulomatosis with polyangiitis is a multisystem autoimmune disease of unknown etiology. Its hallmark features include necrotizing granulomatous inflammation and pauci-immune vasculitis in small and medium-size blood vessels. Commonly involved organs include the upper and lower airways, lungs, and kidneys. Specific otolaryngologic findings include serous otitis media, ocular inflammation, epistaxis, sinusitis, nasal inflammation, saddle nose deformity, septal perforation, oral ulceration, palpable purpura, and skin ulceration. About one-fifth of patients will have subglottic stenosis.

Granulomatosis with polyangiitis is usually associated with the presence of diffusely staining cytoplasmic antineutrophil cytoplasmic autoantibodies (c-ANCA) directed against the serine proteinase 3 antigen (PR3-ANCA). Serum testing for c-ANCA and perinuclear antineutrophil cytoplasmic autoantibodies (p-ANCA) should be considered for patients with idiopathic subglottic stenosis. c-ANCA is 90% specific for granulomatosis with polyangiitis and varies with disease activity. p-ANCA is less specific. A negative c-ANCA does not eliminate the diagnosis of granulomatosis with polyangiitis. Limited granulomatosis with polyangiitis is often more difficult to diagnose than generalized forms, and serologic markers and biopsy may not be diagnostic. The medical treatment of granulomatosis with polyangiitis involves cyclophosphamide, prednisone, and trimethoprim/sulfamethoxazole. Surgical treatment should ideally be pursued after medical management has led to disease remission.

Relapsing polychondritis is another autoimmune disease with airway involvement. It generally presents with multiple areas of cartilage involvement, such as auricular and nasal cartilage inflammation. This results in a seronegative, nonerosive inflammatory polychondritis. Serum testing shows an increase in the erythrocyte sedimentation rate, and a cartilage biopsy should be performed. Treatment options include corticosteroids, nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, dapsone, methotrexate, and azathioprine.

Sarcoidosis is an idiopathic systemic disease characterized by the formation of noncaseating granulomas. It is more common in African-American women. Sarcoidosis may cause epiglottic swelling and subglottic stenosis. Other otolaryngologic manifestations include cervical lymphadenopathy, Heerfordt syndrome (uveoparotid fever), septal perforation, pulmonary hilar lymphadenopathy, and cranial neuropathies (e.g., facial paralysis and sudden sensorineural hearing loss). Diagnostic investigations include measurement of angiotensin-converting enzyme (ACE) and calcium levels, chest radiography, and purified protein derivative (PPD) testing (negative result). Medical treatment includes corticosteroids for acute exacerbations and conservative surgery.

Idiopathic Subglottic Stenosis

Idiopathic subglottic stenosis is a rare, nonspecific, progressive inflammatory disorder that causes subglottic and proximal

Table 91.1 McCaffrey classification of laryngotracheal stenosis

Stage	Description	Prognosis for decannulation
1	Lesions are confined to the subglottis or trachea and are less than 1 cm long.	90%
2	Lesions are subglottic stenoses longer than 1 cm within the cricoid ring without extension into the glottis or trachea.	90%
3	Lesions extend into the upper trachea but do not involve the glottis.	70%
4	Lesions involve the glottis with fixation or paralysis of one or both vocal folds.	40%

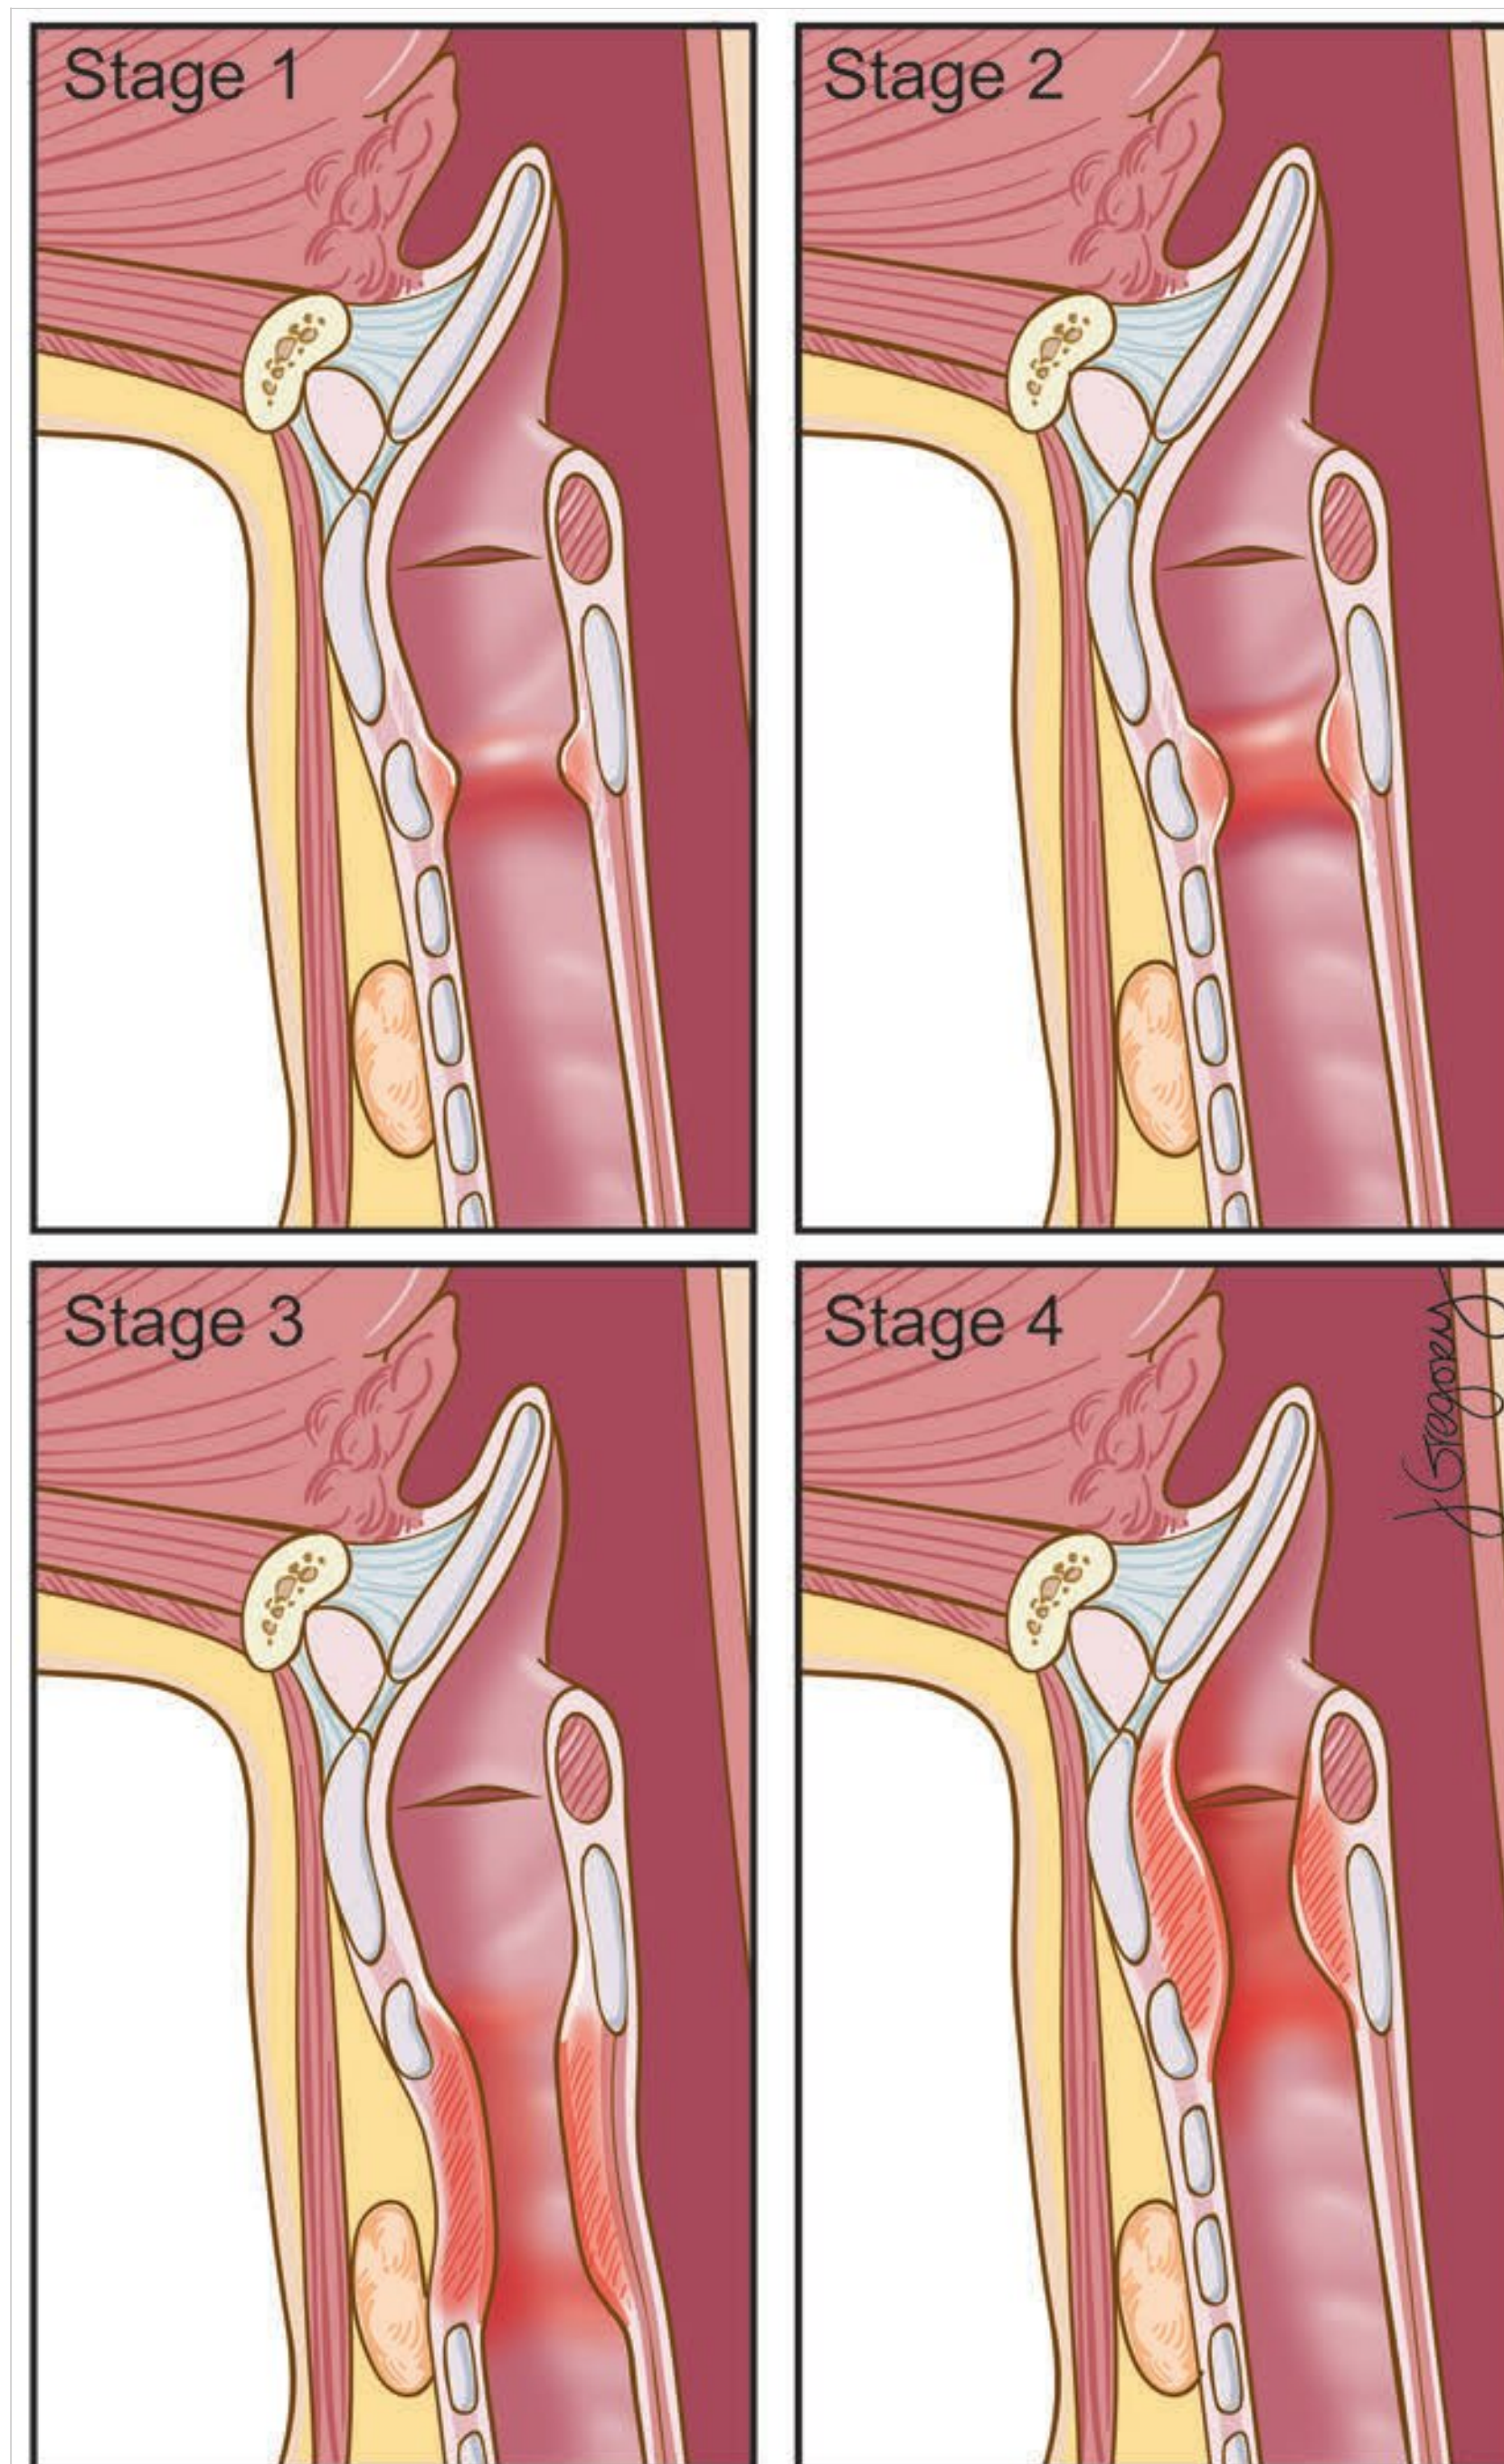

Fig. 91.4 McCaffrey classification of laryngotracheal stenosis. Stage 1: Lesions are confined to the subglottis or trachea and are less than 1 cm long. Stage 2: Subglottic stenoses longer than 1 cm are within the cricoid ring without extension into the glottis or trachea. Stage 3: Lesions extend into the upper trachea but do not involve the glottis. Stage 4: Lesions involve the glottis with fixation or paralysis of one or both vocal folds.

Table 91.2 Etiologies of adulty laryngotracheal stenosis

Trauma	Infection	Neoplastic lesions	Idiopathic
Endotracheal intubation	Syphilis	Benign	Laryngopharyngeal reflux
Tracheotomy	Diphtheria	Malignant	
External laryngotracheal injury	Tuberculosis		
Iatrogenic injury	Typhoid fever		
Following radiotherapy	Systemic disease, granulomatosis with polyangiitis (Wegener granulomatosis)		
	Relapsing polychondritis		
	Sarcoidosis		

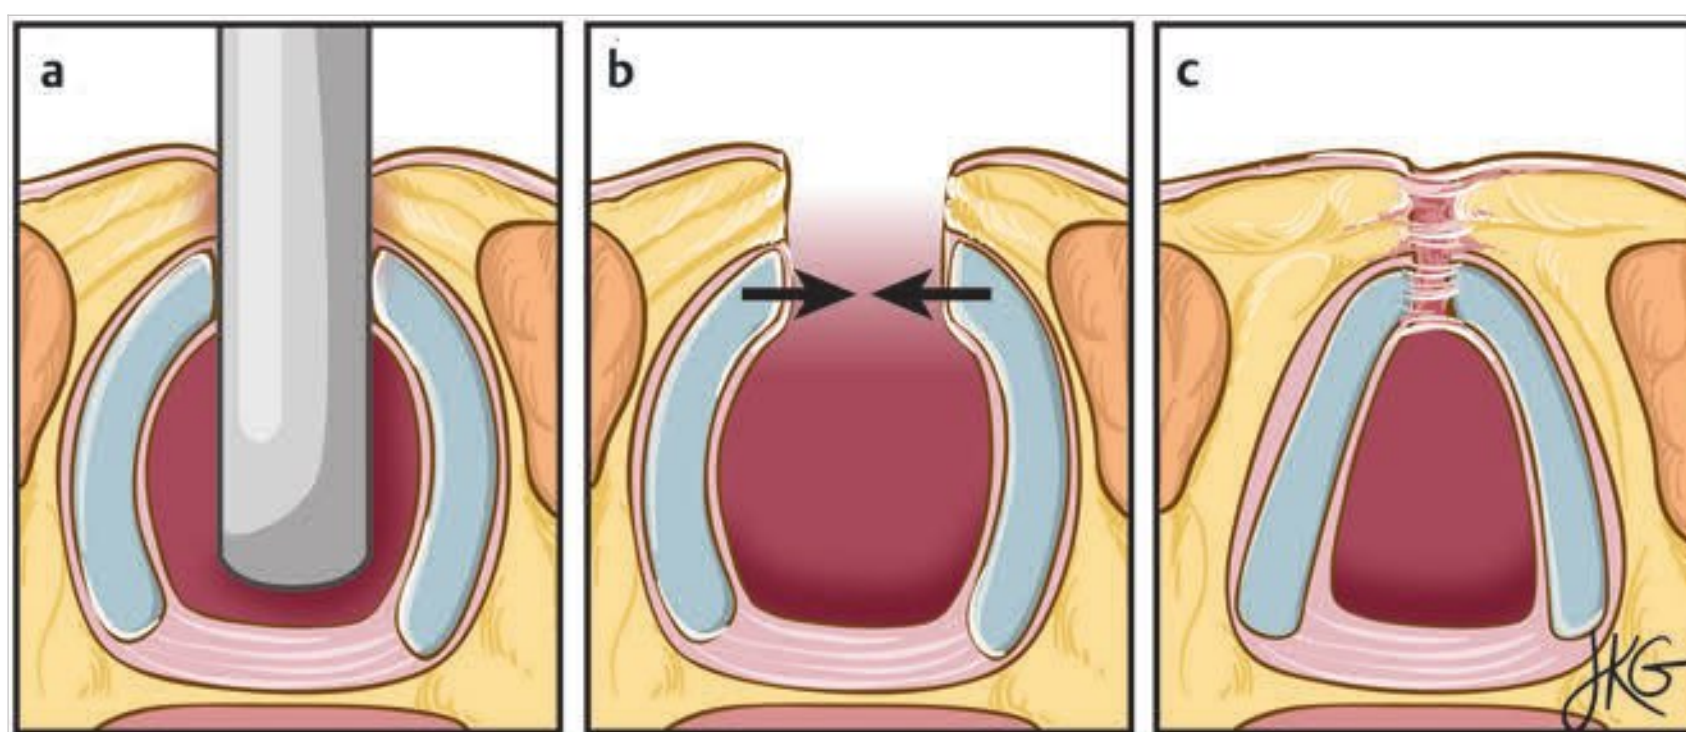

Fig. 91.5 (a–c) Evolution of an “A-frame” stenosis. Cross-sectional diagrams of the trachea at the stoma site. After the tracheotomy tube is removed, the anterior tracheal wall is destabilized (arrows), causing an A-frame stenosis, often with associated malacia.

tracheal stenosis. This disease affects middle-aged women (30 to 50 years of age) and is a diagnosis of exclusion made after other etiologies have been ruled out. It has been speculated, although not proved, that laryngopharyngeal reflux disease may contribute to idiopathic subglottic stenosis.

91.6 Medical Evaluation

91.6.1 Presenting Complaints

Symptoms often develop gradually and patients compensate, so airway narrowing can be quite advanced at the time of presentation. Presenting complaints include dyspnea (on exertion or at rest), exercise intolerance, inability to lie supine, and cough. Hoarseness may indicate glottic involvement. A misdiagnosis of refractory asthma may be made. A past medical history of intubation, tracheostomy, neck surgery, neck trauma, laryngopharyngeal reflux disease, or autoimmune disease is important. Previous operative reports of dilations or reconstructions should be obtained.

91.6.2 Clinical Findings, Physical Examination

Initially, stridor, patient discomfort or fatigue, use of accessory muscles, supraclavicular contractions, and vocal quality should be noted to assess the acuity of the airway and severity of the dyspnea, as well as the urgency or emergency of the situation.

The secondary goal of the clinical examination for a patient with suspected laryngotracheal stenosis is to determine the nature of airway dysfunction at all levels. The surgeon's choice of intervention is significantly affected by the ability to safely manipulate the patient's airway during general anesthesia and in the perioperative period. The physical examination should specifically include factors that affect ease of intubation and airway exposure, including mouth opening, Mallampati score, neck size, cervical mobility, laryngeal position, and cervical scars.

Because intubation can cause airway injury at multiple levels and is the most common cause of airway stenosis, it is essential to survey the entire airway for structural and functional deficits. Flexible laryngoscopy and bronchoscopy are critical in the assessment of dynamic airway function. The upper airway is evaluated for signs of sleep apnea, the larynx is inspected for appropriate neurologic function (sensation and vocal fold movement) and evidence of cicatrix, and the subglottis and trachea are examined for stenosis and malacia. It is important to evaluate the airway while the patient is awake and spontaneously ventilating because malacia is often elicited only when the patient is asked to cough volitionally. Most patients can tolerate bronchoscopy in the clinic with topical lidocaine, but this can also be performed in the operating room under light sedation.

Direct laryngoscopy and tracheobronchoscopy are performed under general anesthesia. The larynx is palpated to differentiate cricoarytenoid joint ankylosis from paralysis, and also to measure any areas of stenosis or abnormality. With a Hopkins rod-lens telescope, the distance of the stenosis from the superior

surface of the vocal cords and the length of the stenosis can be determined. A small needle can be inserted into the airway through the cricothyroid space and at the sternal notch to determine the relation of the stenosis to these structures.

91.6.3 Testing

Testing includes serologic studies for autoimmune disorders, pulmonary function tests, chest radiography, and tissue biopsy. Fine-cut computed tomography from the hyoid to the carina will show subglottic or tracheal narrowing but will not give any information regarding glottic function or dynamic airway collapse.

91.6.4 Differential Diagnosis

The differential diagnosis of adult laryngotracheal stenosis is listed in □ Table 91.3.

Etiology of stenosis	Differential diagnosis
Congenital	Tracheomalacia, laryngomalacia, laryngeal cleft, congenital cysts
Infection	Laryngotracheobronchitis (croup), bacterial tracheitis
Trauma	Vocal cord paralysis, foreign body, external compression
Neoplasm	Benign: recurrent respiratory papillomatosis, subglottic hemangioma Malignant: squamous cell carcinoma of the larynx, chondrosarcoma
Systemic disease	Asthma, paradoxical vocal fold motion

91.7 Treatment

91.7.1 Medical Treatment

Comorbidities such as obstructive sleep apnea, diabetes, laryngopharyngeal reflux, and obesity should be optimized before any surgical intervention. Systemic inflammatory disease should be managed by an appropriate specialist. Inhaled, topical, and oral corticosteroids can be used. The prolonged use of oral steroids can have significant side effects, including cushingoid body habitus, hyperglycemic reaction, exacerbation of anxiety or depression, acne, increased intraocular pressure, gastrointestinal irritation, and avascular necrosis of the hip. Racemic epinephrine and heliox may be helpful in temporarily stabilizing the patient in situations of acute exacerbation of airway compromise. Voice and breathing retraining therapy administered by a knowledgeable speech–language pathologist can significantly help patients cope with their airway and voice limitations.

91.7.2 Surgical Treatment

When a surgical option is chosen, several factors must be considered: the location, length, and quality (soft vs fibrous) of the stenosis; dynamic malacia; associated impairment of vocal fold motion; extent of functional impairment; and medical comorbidities of the patient.

Endoscopic surgery is the method most commonly used to treat all levels of laryngotracheal stenosis. The major disadvantage is that laser incision or ablation of scar necessarily leaves a raw operative bed, potentially allowing the re-formation of cicatrix and a need for repeated procedures. About three-quarters of patients treated with endoscopic dilation as primary therapy will have recurrent stenosis and require subsequent treatment. Patients who are good candidates for endoscopic treatment include those with supraglottic or glottic stenoses, Cotton-Myer grade 1 or 2 subglottic stenoses, and soft or immature tracheal

Location of stenosis	Surgical approach	
Supraglottic	a) Endoscopic b) Open	
Glottic	Anterior	a) Endoscopic b) Open: laryngofissure
	Posterior	a) Endoscopic <ul style="list-style-type: none"> • Carbon dioxide laser lysis of the interarytenoid synechia • Advancement of a posteriorly based mucosal flap • Posterior cordotomy/cordectomy • Arytenoidectomy b) Open posterior cricoid split with graft
Subglottic	a. Endoscopic (radial incision and dilation) b. Anterior cricoid split c. Anterior–posterior laryngotracheoplasty d. Cricotracheal resection	
Tracheal	a) Endoscopic (radial incision and dilation) b) T-tube and stents c) Segmental resection d) Augmentation e) Slide tracheoplasty	

stenoses of minimal thickness (<1 cm). An endoscopic approach is often used initially, followed by an open procedure after recurrence.

Open surgical procedures can be broadly divided into two categories: laryngotracheal resection and laryngotracheal expansion. Laryngotracheal resection removes the area of stenosis, whereas laryngotracheal expansion enlarges the area of stenosis by splitting the airway and inserting a graft—often autologous rib cartilage.

Supraglottic Stenosis

Supraglottic stenosis is rare and can be caused by trauma, caustic injury, or infection. Endoscopic laser ablation of abnormal tissue is occasionally successful. If restenosis occurs, an external open approach is used, either via a transhyoid pharyngotomy or laryngofissure. Efforts are made to remove scar and preserve mucosa to cover denuded areas with mucosal flaps. If necessary, a buccal graft can be harvested for further coverage. A laryngeal stent is used during the healing process. Alternatively, a supraglottic laryngectomy can be performed.

Glottic Stenosis

Anterior Glottic Stenosis/Web

An anterior glottic web can be congenital or traumatic. In adults, it is most often iatrogenic, resulting from bilateral vocal fold surgery causing scarring at the anterior commissure. This disease can be managed by an endoscopic or an open approach. If the anterior glottic web extends less than 5 mm infraglottally, then endoscopic lysis of the web can be performed with a laser

or cold steel instrumentation. Lysis alone is rarely successful. Adjunctive procedures include injection of corticosteroids into the area of lysis, topical application of mitomycin C, and endoscopic placement of a Silastic keel with removal at 2 to 4 weeks.

If there is significant infraglottic extension of cicatrix, an anterior laryngofissure with resection of scar tissue, resurfacing with mucosal grafts, and placement of a soft, molded laryngeal stent should be performed.

Posterior Glottic Stenosis

Posterior glottic stenosis may also be managed endoscopically or by open surgery. The surgical choice is guided by the extent of posterior glottic involvement, as described in the classification of Bogdasarian and Olson. Type I is managed with endoscopic lysis of the interarytenoid synechia (□ Fig. 91.6). Patients with type I posterior glottic stenosis have an excellent prognosis for decannulation, and many regain normal vocal fold motion. Types II and III can be managed with endoscopic laser resection of posterior scar tissue and advancement of a posteriorly based mucosal flap from the posterior cricoid mucosa. Type IV stenosis is the most severe, defined by bilateral cricoarytenoid joint ankylosis with scarring and contracture of the interarytenoid space. An endoscopic laser posterior cordotomy can statically enlarge the posterior respiratory glottis (□ Fig. 91.7) while maintaining some phonatory function of the anterior glottis. An open or endoscopic arytenoidectomy can remove additional tissue, although patients may have postoperative dysphagia after resection of the lateral lamina of the arytenoid. It is important to counsel patients considering these procedures that they will be trading some voice and swallowing function

Fig. 91.6 Development of posterior glottic stenosis type I: interarytenoid synechia. (a) Endotracheal tube in place showing the development of florid posterior glottic granulation tissue and subglottic edema. (b) When the tube is removed, the granulation tissue prolapses into the airway. (c) If the granulation fronds fuse together, an interarytenoid synechia can develop.

Fig. 91.8 (a–c) Radial incision and dilation of idiopathic subglottic stenosis.

for airway improvement. Open approaches include a posterior cricoid split with insertion of a rib cartilage expansion graft to separate the interarytenoid space. Alternatively, if the transcervical approach allows the restoration of arytenoid motion after scar resection, then the posterior glottis can be covered with a buccal graft or an advanced pharyngeal flap to prevent restenosis and restore glottal competence without a permanent deterioration of voice or swallowing function.

Subglottic Stenosis

Endoscopic Management

Endoscopic radial incision and dilation is the procedure most commonly used for subglottic stenosis (□ Fig. 91.8). The stenotic area is incised with either sharp instrumentation or a laser. Dilation can be performed pneumatically or with rigid instrumentation. Theoretically, the radial incisions allow the preservation of intervening areas of mucosa, which will then epithelialize the dilated area and retard the re-formation of scar.

Adjunctive procedures include the topical application of mitomycin C to the dilated area. Mitomycin C is an antineoplastic antibiotic derived from *Streptomyces caespitosus* that preferentially inhibits fibroblast proliferation. One study showed a statistically significant increase in the success rate of endoscopic treatment of acquired upper airway stenosis from less than 20% to 75% when topical mitomycin C was added to the treatment regimen. Unfortunately, the efficacy of mitomycin C has been questioned in other studies, and possible complications include eschar formation (which can acutely obstruct the airway) and risk for malignancy. Other adjuncts that have been used include intralesional and systemic corticosteroids, perioperative antibiotics, and antireflux medications. Despite these measures, restenosis unfortunately commonly occurs.

Anterior Cricoid Split

Anterior cricoid split is a type of laryngotracheal expansion. It was first used in premature infants as an alternative to tracheotomy in the management of acquired subglottic stenosis. The anterior cricoid cartilage is divided in the midline, and the upper first and second tracheal rings are also split. This procedure allows the cricoid ring to expand. The patient may need to remain intubated for up to 10 days after the procedure, but a tracheostomy is ideally avoided.

Anterior and Posterior Laryngotracheoplasty

Anterior laryngotracheoplasty and posterior laryngotracheoplasty are laryngotracheal expansion procedures used in type III or IV subglottic stenosis or when an endoscopic procedure has failed. A laryngofissure is used to gain exposure, the anterior and/or posterior cricoid ring is divided in the midline, and cartilage grafts are placed to maintain expansion of the laryngotracheal framework. Cartilage grafts can be harvested from rib or nasal septum. This procedure requires a tracheostomy and usually placement of an endoluminal stent to support the grafts.

Cricotracheal Resection

When the stenosis involves the subglottic area but spares the vocal folds and leaves a small “antrum” of normal subglottis, the patient is a candidate for a cricotracheal resection (□ Fig. 91.9). In this procedure, the stenotic tissue associated with the anterior cricoid ring can be resected and normal trachea inset into the demucosalized posterior cricoid plate. Some surgeons choose to place a “Grillo suture” from the chin to the presternal skin to encourage patients to remain in cervical flexion and prevent unnecessary tension on the anastomosis. In properly selected patients, the success rate can be over 90%. Most of these patients will develop some postsurgical voice change that may be permanent.

Tracheal Stenosis

Endoscopic Management

The endoscopic management of tracheal stenosis is very similar to that of subglottic stenosis. Laser or sharp instrumentation can be used for the incision or resection of cicatrix. Dilation can be performed with rigid or pneumatic instrumentation. Adjunctive measures include mitomycin C, intralesional and systemic corticosteroids, perioperative antibiotics, and antireflux medications.

T-Tube and Stents

In patients who have isolated tracheal or subglottic stenosis and normal laryngeal function, airway stenting can be judiciously considered. The role of airway stents is controversial in benign tracheal stenosis. Although the stent will provide imme-

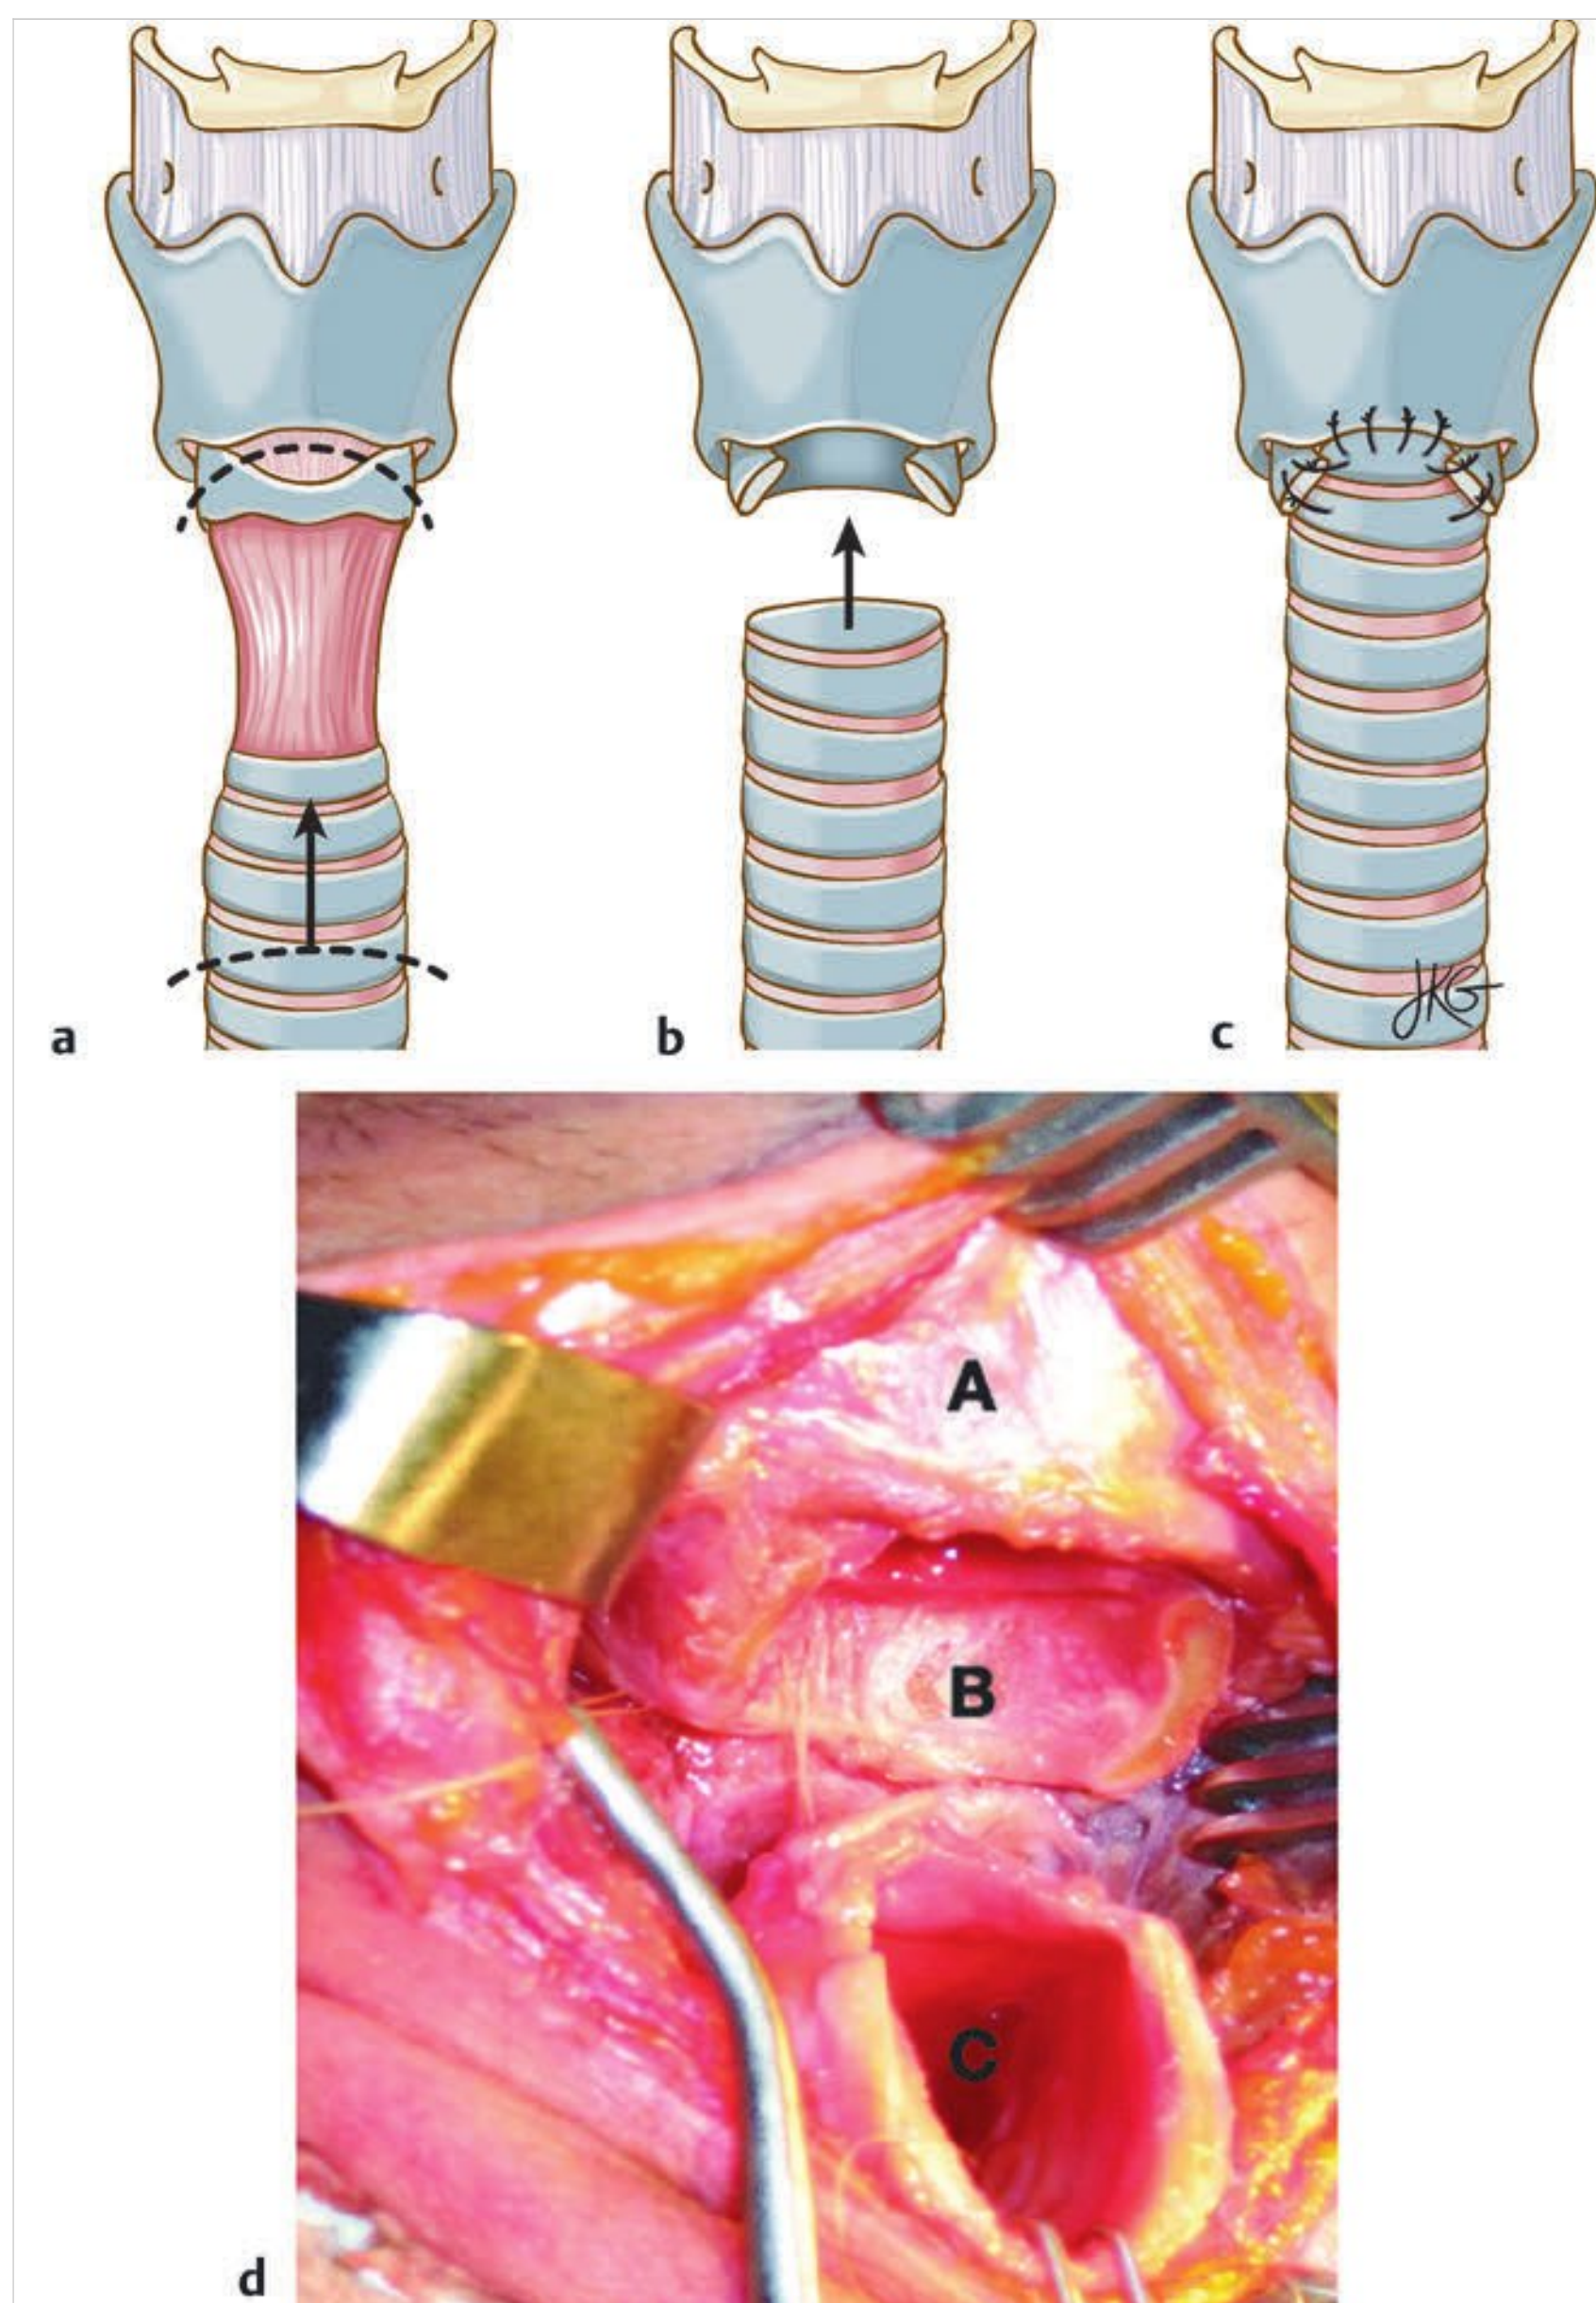

Fig. 91.9 Cricotracheal resection. (a–c) The stenotic tissue and anterior cricoid ring are resected, and normal trachea is advanced and inset into the demucosalized posterior cricoid plate. (d) Intraoperative view. A, thyroid cartilage. B, posterior cricoid plate with mucosa removed. The anterior arch of the cricoid has been resected. C, normal trachea, to be inset into the cricoid bed.

mediate relief of the airway narrowing, the risks for the development of mucous plugs or granulation, stent migration, and long-term propagation of the damaged tracheal segment are serious considerations. Stents are most often selected for use in patients with malignant airway obstruction or inoperable lesions, and occasionally for the temporary support of a surgical repair.

For properly selected patients who require an airway appliance but cannot speak around a tracheotomy tube or whose tracheotomy tube cannot be capped because of suprastomal or subglottic stenosis, a T-tube can be used for airway support both inferior and superior to the stoma. This appliance is placed through an existing tracheal stoma and extends over the length of the stenotic or malacic segment. The external limb of the T-tube anchors the appliance in the proper position within the trachea to prevent migration, and it also allows access to the lumen for suction and the instillation of saline or medications. The external limb is not to be used as an airway but rather is

kept capped to allow the patient to breathe and phonate through the glottis. This appliance does not have an inner cannula and is prone to mucous plug occlusion, especially if the external limb is left open and the natural process of humidification of inspired air in the upper airway is bypassed.

Segmental Resection

If the stenosis or malacic segment is isolated to the trachea, then a simple resection with an end-to-end anastomosis can be performed with a better than 90% success rate (□ Fig. 91.10). Grillo et al reported on a series of 503 patients who underwent surgical treatment for post-intubation tracheal stenosis. A total of 471 patients reported good (87.5%) or satisfactory (6.2%) results. Complications included granulation, dehiscence, laryngeal nerve injury, airway obstruction, mediastinitis, hemorrhage, infection, myocardial infarction, tracheo-esophageal fistula, pneumothorax, deep venous thrombosis, recurrent stenosis, and death.

Fig. 91.10 (a) Segmental resection and (b) primary anastomosis of segments for isolated tracheal stenosis.

Augmentation

Augmentation tracheoplasty can be performed with autologous material such as rib cartilage, periosteum, pericardium, pedicled muscle flaps, composite grafts, esophagus, omentum, or solvent-preserved dura. Cartilage is commonly used as graft material for several reasons. It is a rigid autologous tissue. It derives its nutrition through diffusion and as a result can survive without a direct vascular supply. The surgical procedure follows the same principles as those used for other laryngotracheal expansion procedures.

Slide Tracheoplasty

A slide tracheoplasty can be used when segmental resection is not possible because of the length of abnormal trachea. This procedure is usually used for congenital stenosis in children and is not routinely applied in cases of traumatic stenosis (□ Fig. 91.11).

91.8 Conclusion

This chapter has briefly reviewed key aspects in the evaluation and management of laryngotracheal stenosis. Treatment options are based on the severity and position of the stenosis. This is a challenging disease to manage, and patients need to be appropriately counseled regarding the risks and expectations of intervention.

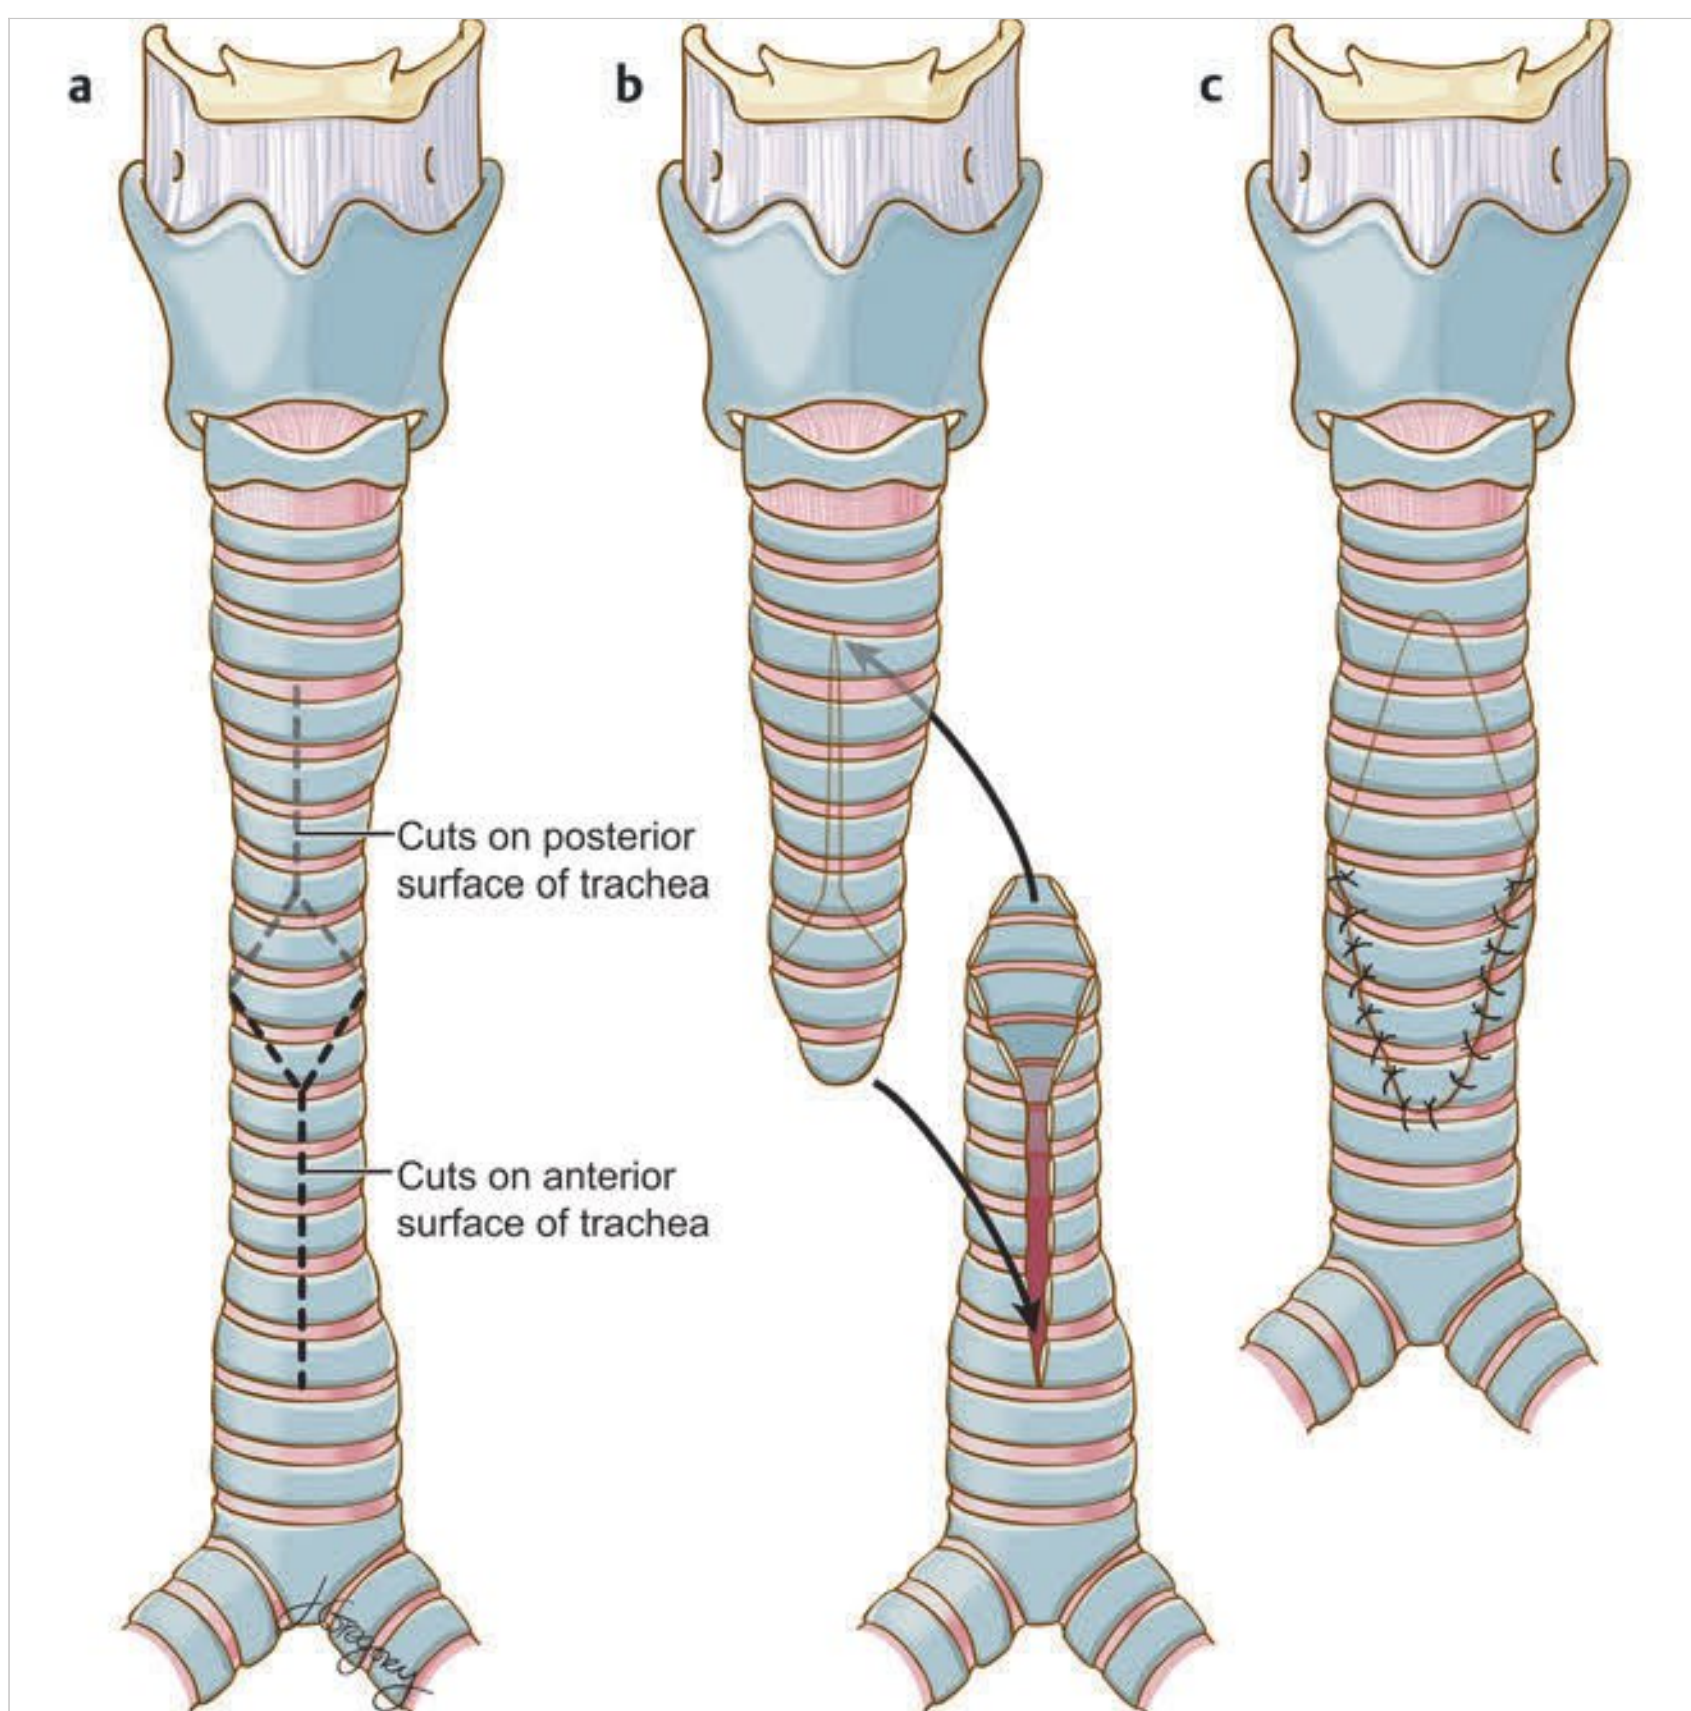

Fig. 91.11 (a-c) Slide tracheoplasty for congenital stenosis or other scenarios with limited tracheal length.

91.9 Roundsmanship

- The most common cause of laryngotracheal stenosis is prolonged endotracheal intubation; other causes include systemic inflammatory disease, infection, and neoplasm. Idiopathic subglottic stenosis is a diagnosis of exclusion.
- Airway obstruction may initially be misdiagnosed as asthma refractory to conventional treatment.
- Three important classifications for laryngotracheal stenosis are the Myer-Cotton, Bogdasarian and Olson, and McCaffrey systems.
- The surgeon's choice of intervention is significantly affected by the patient's underlying medical conditions, the ability to safely access the airway, and the nature of the airway deficits.
- Endoscopic incision and dilation can be used successfully to treat subglottic and tracheal stenosis. The main disadvantages are the risk for restenosis and the need for repeated procedures.
- Stents and T-tubes should be used judiciously in carefully selected patients. They both carry a significant risk for mucous plug formation and fatal airway obstruction.
- Open surgical procedures can be broadly divided into two categories: laryngotracheal resection and laryngotracheal expansion. Laryngotracheal resection removes the area of stenosis, whereas laryngotracheal expansion enlarges the area of stenosis by splitting the airway and inserting a graft.
- Placement of a tracheotomy tube is a time-honored option for patients with significant medical comorbidities or complicated multilevel stenosis.

92 Laryngeal Trauma

Steven David Schaefer

92.1 Introduction

External laryngeal injuries are rare, accounting for only 1 in 30,000 emergency room visits. Early and careful management of these injuries has a profound consequence on the immediate probability of the patient's survival and long-term quality-of-life. Our approach to these injuries has been to apply the basic principles of laryngeal mechanics to repeated observation and to the refinement of medical and surgical treatment over the past 25 years.

92.2 Applied Anatomy and Physiology

The human larynx is a highly evolved respiratory sphincter. The laryngeal skeleton, which is a derivative of the second through sixth branchial arches, consists of the hyoid bone, three single cartilages (the thyroid, cricoid, and epiglottic cartilages), and three paired cartilages (the arytenoid, corniculate, and cuneiform cartilages). The cartilages are suspended together by fibrous ligaments and membranes. Phonation is the product of chest compression of subglottic air overcoming the elastic and muscular forces of vocal fold closure. Acting as a sound source, the larynx cycles between these two forces to produce a tone that is modulated by the vocal tract (broadly, the vocal tract can be defined as extending from the diaphragm to the lips). The complex interaction between vocal fold tension, mass, length, and mucosal covering and subglottic air pressure is best described by the myoelastic–aerodynamic theory. As we seek to repair the traumatized larynx, we must employ an understanding of laryngeal anatomy and physiology to guide us in deciding between medical and surgical management, and the extent of surgical treatment (see Chapter 74 for a detailed discussion of laryngeal anatomy and physiology).

92.3 The Disease Process

92.3.1 Etiology and Pathogenesis

External laryngeal injuries are now uncommonly seen in most emergency departments for several reasons. First, the overall incidence of neck trauma adjusted for the population has declined in comparison with the incidence in the early 1990s, reflecting safer designs in automobiles and decreasing violent crime in the United States. Second, the most severely injured patients die at the scene of the accident or assault and are not counted in estimates of laryngeal trauma. Third, the larynx is afforded partial protection by its position in the neck. Anteriorly, the inferior projection of the mandible partially shields the larynx from direct trauma; posteriorly, the rigid cervical spine protects the larynx. Nonetheless, injuries occur, and the resultant damage to the larynx is usually characteristic of the mechanism of injury. The mechanisms of external laryngeal injury can be divided into blunt trauma (including clothes-

line, crushing, and strangulation injuries) and penetrating trauma.

Anterior blunt injuries are most commonly the result of motor vehicle accidents. If no seat belt is worn or if only a lap belt is used, the driver is thrust forward during rapid deceleration with the neck hyperextended. This position removes the bony protection of the mandible, exposing the larynx to anterior crushing forces. If the larynx then strikes the steering wheel or dashboard, it may be compressed between these objects and the cervical spine.

Clothesline injuries occur when the rider of a vehicle, such as a motorcycle or snowmobile, encounters a fixed horizontal object, such as a clothesline at neck level. This type of injury imparts the full momentum of the rider and the vehicle over the relatively small anterior neck, resulting in massive trauma. Many of these injuries lead to immediate death from a crushed larynx or separation of the cricoid from the thyroid or tracheal cartilage. The latter injuries are frequently accompanied by disruption of one or both recurrent laryngeal nerves. Strangulation injuries occur from manual compression, from assaults with strangulation by a soft object, or from attempted suicides by hanging. Typically, the initial finding may be hoarseness or abrasions on the overlying skin of the neck. However, these injuries may later (in 12 to 24 hours) be associated with marked edema of the larynx and resultant loss of airway. The magnitude of the force sustained to the anterior neck should be considered in the management of such patients to avoid subsequent potential loss of the airway. Overall, in blunt trauma to the anterior neck, fractures of the thyroid cartilage occur more frequently than of all other airway cartilages combined.

Injury from gunshot wounds depends on the type of weapon used, the effective range of the weapon, and the ammunition. Gunshots at close range impart intense energy to the soft tissues and are usually fatal. Low-velocity handguns (commonly used in domestic assaults) generally have only a moderate blast effect on surrounding tissue. These injuries may be misleading on initial examination because of the bullet's erratic course in soft tissues. High-velocity weapons, such as hunting rifles and military assault weapons, impart a significant amount of kinetic energy to the tissues. In these injuries, tissue viability is widely compromised, and initial impressions as to the extent of wounding are frequently inadequate. Knife injuries do not destroy tissue distant to the path of injury, and their course may be accurately estimated from the entrance and exit wounds.

The pediatric larynx is injured less often than the adult larynx. Situated higher in the neck than the adult larynx, the child's larynx is afforded greater protection by the caudal projection of the mandible. However, the pattern of injury reflects a dynamic between the loose attachments of the overlying mucous membranes and ligaments and the increased elasticity of the cartilaginous framework. Furthermore, the cross-sectional area of the pediatric larynx compared with that of the adult larynx is decreased. The combination of potentially increased soft-tissue injury and edema with decreased cross-sectional area makes the pediatric airway especially vulnerable to embarrass-

ment. These injuries may be difficult to recognize because of the lack of obvious cartilaginous fractures.

92.4 Medical Evaluation

92.4.1 Acute Medical Evaluation and Management

When a patient with a neck injury presents to the emergency department, the first priority is to establish an airway. This may be very difficult and often requires emergent tracheotomy or cricothyroidotomy. Care should be taken to avoid manipulation of the neck. Until a cervical spine injury has been excluded, no extension of the neck should be allowed during either orotracheal intubation or tracheotomy. After the airway is secured, venous access should be obtained with at least two large-bore cannulas. Isotonic fluids are administered as needed to maintain circulation. The patient is then disrobed and examined for other injuries. If the patient is unstable after these measures, immediate surgery is needed. However, if the patient is relatively stable after these measures, diagnostic assessment may proceed. The minimum radiographic evaluation consists of a cervical spine series and a chest radiograph. After full assessment of all injuries, the various physicians involved should determine the order of management and proceed accordingly.

92.4.2 Secondary Medical Evaluation

The presentations of external laryngeal trauma vary from obvious open fractures to subtle aberrations of laryngeal function.

History

Understanding the mechanism of wounding is important to deciding on the immediate course of treatment and predicting the potential injuries. A patient arriving in the emergency department after striking the steering wheel with the anterior neck may appear stable within the first minutes after the accident. Within the next several hours, the initially normal findings of the examination, including laryngoscopy, may evolve into life-threatening endolaryngeal edema and hematomas. In such an example, the history of significant energy being imparted to the neck should alert the physician to the potential for an evolving

catastrophic event. In contrast, a low-energy accidental blow of the fist or other less intense blow to the larynx can result in a displaced thyroid cartilage fracture. In penetrating trauma, the type of weapon and ammunition used, the range at which the injury occurred, and the anatomical site of the wound must all be considered. Having seen all of these events, we advocate that any patient with a history of trauma to the central compartment of the neck be considered to have a potential airway injury until proved otherwise.

Physical Examination

In our experience, only respiratory distress seems to correlate with the severity of blunt injury (□ Table 92.1). Visual examination of the neck may reveal an open fracture or laryngocutaneous fistula, or more often nothing in the case of blunt trauma. The larynx should be palpated for crepitus. Tenderness to palpation, although not specific, is often present in significant injury. The skin of the neck may reveal contusions or abrasions from blunt trauma or a line pattern indicative of a strangulation injury. Penetrating injuries are examined for an entrance and an exit wound, and the most likely path of travel of the projectile should be determined. Open wounds are not explored with instruments, nor are they probed to avoid dislodging a hematoma and initiating further bleeding. The cervical spine should be palpated for any bony step-off fractures, dislocations, or tenderness. Hemoptysis may reveal an injury to the upper aerodigestive system, but it is often difficult to differentiate from bleeding caused by associated facial trauma.

External laryngeal injuries are often associated with a change in voice. A patient with severe trauma may be entirely aphonic. More commonly, a dysphonic voice is present secondary to alterations in the larynx, or the voice is muffled secondary to supraglottic or upper vocal tract injury. Hematomas of the true vocal folds add mass to these vibratory units and lower the fundamental frequency of vibration. Paresis of the vocal fold from damage to the recurrent laryngeal nerve or from mechanical dislocation of the cricoarytenoid joint may cause a weak, breathy voice. Finally, any injury to the larynx that changes the airflow patterns has the potential to alter the voice.

Among the most serious alterations of laryngeal function is the abnormal flow of air through the upper airway. In instances of cricotracheal separation, the partially transected airway may

Table 92.1 Presenting symptoms of 68 patients with laryngeal trauma

Note: Groups I through IV refer to the form of management and are discussed in □ Table 92.2. In group IV (patients with the most severe injuries), the severity of injury did not correlate with the presenting symptoms.

be maintained solely by a bridge of mucous membrane between the cricoid and trachea. In gunshot wounds, the path of the missile serves as a laryngocutaneous fistula and allows respiration despite obstruction at the glottic or supraglottic level. In this instance, airflow from the wound will be obvious, and no attempt should be made to cover, compress, or otherwise manipulate such a wound until the surgeon is ready to secure the airway. Stridor may be caused by bilateral vocal fold paresis or disruption or may result from any combination of unilateral immobility and subglottic, glottic, or supraglottic edema or hematoma. If severe enough, edema alone with healthy vocal fold movement may cause stridor. As discussed above, in some patients the edema or hematoma can evolve over a few hours, which may permit a recognition of subglottic, glottic, or supraglottic airway compromise. In many other patients, the airway compromise is too rapid to permit a distinction among inspiratory, expiratory, and mixed stridor. A third, more subtle form of laryngeal dysfunction is aspiration, which is usually caused by immobility of one or both vocal folds. Although not immediately clinically apparent after injury, aspiration may present later as pneumonia.

After the initial examination and securing of the airway, examination of the endolaryngeal anatomy is attempted. Since the 1980s, flexible fiber-optic laryngoscopic examination has made possible an improved nonoperative evaluation of the injured larynx. After careful insertion of the laryngoscope through the nares, the oropharynx and hypopharynx are examined for injury. The larynx is examined for hematomas and lacerations, and their size and location are noted. The arytenoids are evaluated for full range of motion during phonation and respiration. Partial limitation of range of motion indicates a structural deformity or dislocation of the arytenoids, whereas complete immobility is more suggestive of recurrent laryngeal nerve injury. Failure of the true vocal folds to meet in the same horizontal plane may indicate a structural change in the laryngeal framework or superior laryngeal nerve injury. In minor injuries with sufficient glottic closure to trigger a strobe, videostroboscopic laryngoscopy is helpful to reveal small alterations secondary to either muscle or mucosal injuries. Finally, exposed cartilage is recorded, along with the integrity of the surrounding mucous membrane.

92.4.3 Testing

Laryngeal Imaging

Plain films may identify gross fractures but are limited to a two-dimensional image of the relevant anatomy. Magnetic resonance imaging offers superior soft-tissue definition but does not permit visualization of the laryngeal hard tissue. In contrast, computed tomography (CT) permits an evaluation of the laryngeal skeletal and soft tissue in a noninvasive manner. We recommend reserving CT for patients in whom laryngeal trauma is suspected by history but in whom the extent of injury is not obvious on physical examination. Such patients are those who have only one sign or symptom of laryngeal trauma, such as hoarseness, and minimal physical findings suggestive of laryngeal injury. In this instance, CT may allow the surgeon to confirm the lack of injury in a noninvasive manner without direct, operative laryngoscopy and the concomitant need for

general anesthesia. CT may also be used to identify the patient with minimally displaced midline or lateral thyroid cartilage fractures that are otherwise unremarkable and minimally symptomatic. Such unrepaired lateral displacement of the thyroid cartilage impairs phonation by disrupting complete vocal fold closure or laryngeal valving. In a relatively small number of patients with massive edema or hematomas without lacerations, direct laryngoscopy has been insufficient to visualize the laryngeal framework. In these patients, CT is employed to search for laryngeal fractures. If none are detected, the patient undergoes a tracheotomy to preserve the airway and is observed, so that open exploration is avoided.

The management of injuries to the larynx is based on the mechanism and extent of injury found during the initial assessment. The first priority is always securing the airway. The long-term priority is the restoration of normal laryngeal function. To meet these goals, the initial management can be encompassed in four questions. First, does the patient have a tenuous airway? Given the propensity for central compartment neck trauma to compromise the laryngeal skeleton, this question should be cautiously answered. Second, how can the extent of injury best be evaluated? These options can include fiber-optic laryngoscopy, CT, or direct laryngoscopy. Third, after the first two questions have been satisfied, is the injury likely to heal spontaneously with a result equal to or better than that of surgical intervention? Fourth, if the outcome of the injury is in doubt or so severe as to require surgical treatment, which procedures are indicated? The answers to the last two questions require a thorough knowledge of laryngeal mechanics and experience (□ Fig. 92.1). The latter is increasingly difficult to acquire, given the rarity of these injuries.

92.5 Treatment

92.5.1 Medical Management

Medical management assumes that the patient does not require a tracheotomy and has an otherwise stable airway. If the patient has only the following injuries, we recommend close observation within the first 24 hours after injury and head-of-bed elevation. These injuries include (1) minor endolaryngeal mucosal lacerations without involvement of the anterior commissure or free margin of the true vocal fold; (2) single, nondisplaced, nonangulated fractures of the thyroid cartilage without overlying mucosal lacerations or exposed cartilage; (3) nonobstructing endolaryngeal edema; and (4) small, stable hematomas that are not causing respiratory embarrassment. Corticosteroids may be useful if given early after injury.

92.5.2 Surgical Management

Surgical treatment is indicated in injuries that will not spontaneously recover and therefore require surgical restoration of the traumatized larynx. These injuries are those (1) involving the anterior commissure or free margin of the true vocal fold, (2) resulting in exposed cartilage, (3) leading to multiple or displaced fractures of the thyroid cartilage or any fracture of the cricoid cartilage, (4) causing vocal fold paralysis or sufficient airway compromise to require intubation or tracheotomy, (5)

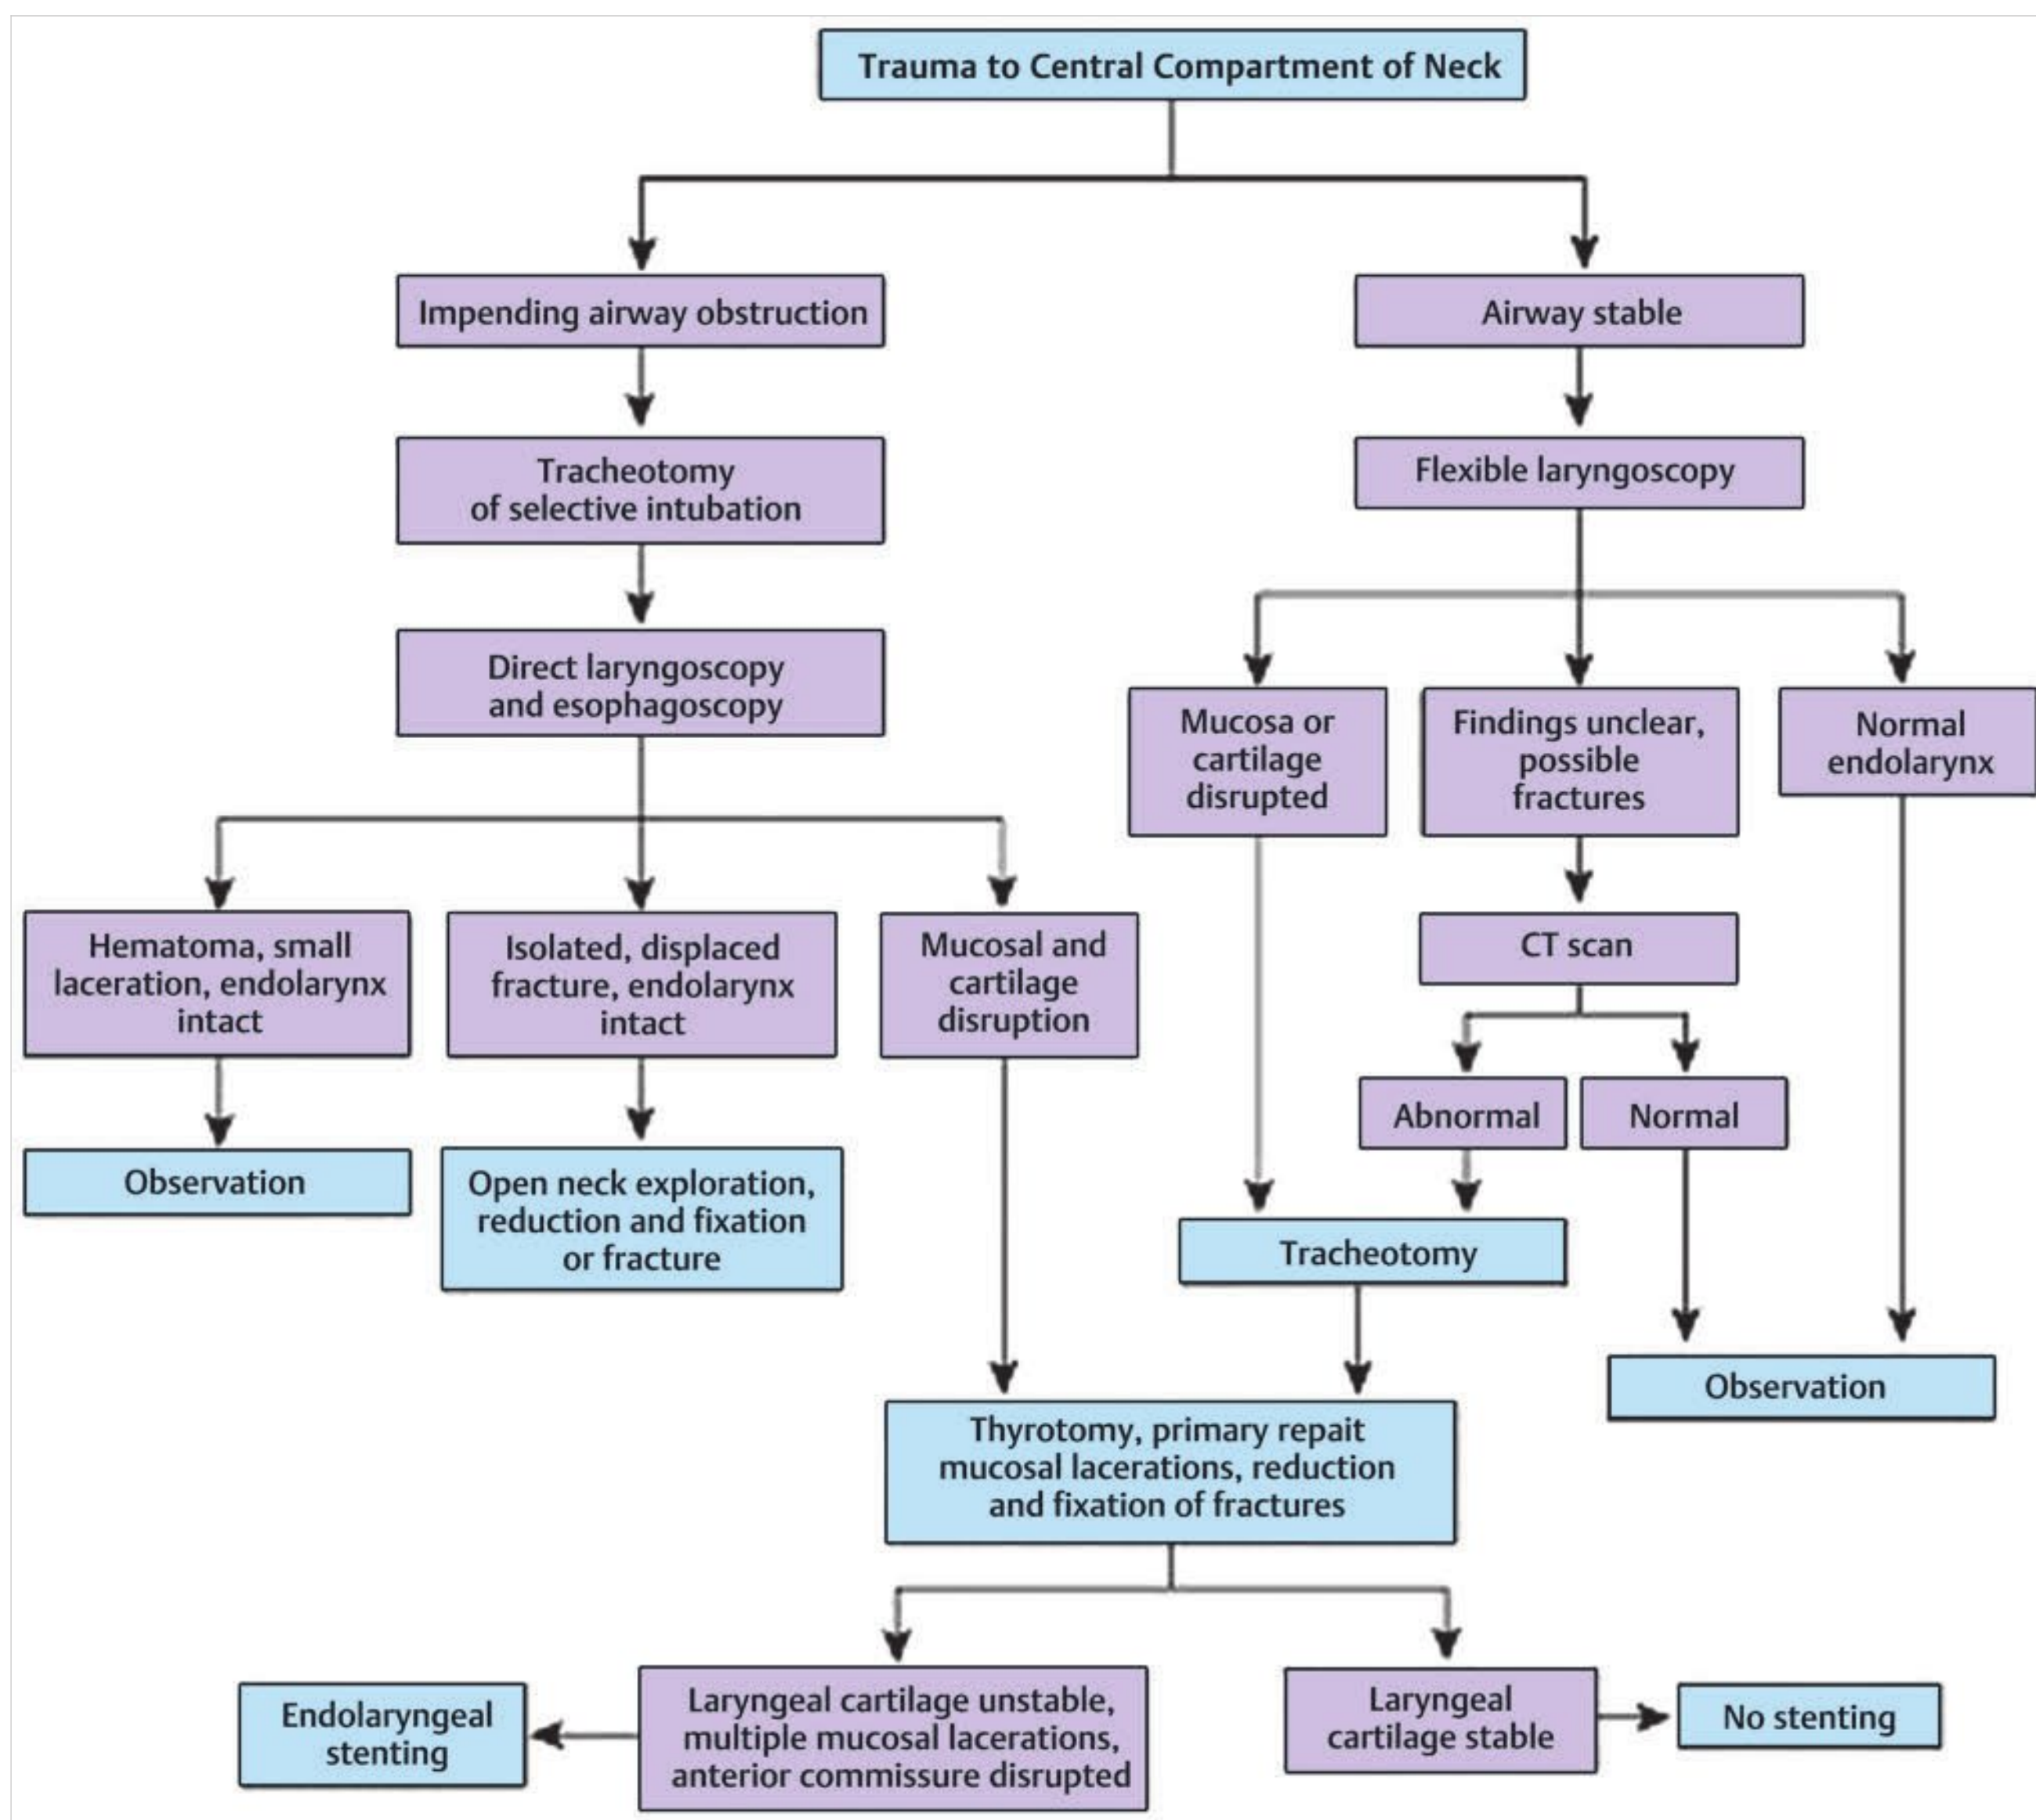

Fig. 92.1 Management protocol for the acutely injured larynx. CT, computed tomography. (Source: Adapted from Schaefer SD. The treatment of acute external laryngeal injuries. *Arch Otolaryngol* 1991;117:35.)

resulting in glottic or transglottic lacerations, and (6) associated with trauma to another area of the neck that requires surgical intervention. Repair of the larynx should be coordinated with all surgical teams involved and with the anesthesiologist. The person responsible for the airway at each stage of the procedure should be designated before the patient is brought to the operating room. Plans for emergently obtaining an airway and the instruments required for surgery should also be established.

The most conservative, reliable method of securing an airway in a patient with laryngeal injury is local tracheotomy while the patient is awake. Endotracheal intubation may further damage the larynx, be exceedingly difficult, interfere with subsequent examination and repair of the larynx, and convert an urgent procedure to an emergent one. Endotracheal intubation is acceptable when (1) the endolaryngeal mucous membrane is in-

tact, (2) the laryngeal skeleton is minimally displaced, and (3) the intubation is performed by one highly skilled in such procedures.

After local tracheotomy or the selective use of intubation, general anesthesia is induced followed by operative, direct laryngoscopy. The larynx is examined for exposed cartilage, hematomas, lacerations, and range of motion of the true vocal folds. The subglottis is evaluated for injury to the cricoid and trachea. Rigid esophagoscopy is performed to rule out injury to the esophagus.

Management of the traumatized pediatric airway presents special problems. Endotracheal intubation in the injured pediatric larynx has all of the same risks outlined above for the adult. The option of local tracheotomy is not feasible in a frightened, injured child. The time margin of error is also less because the

arterial oxygen saturation drops more rapidly than in an adult. In this instance, rigid bronchoscopy is performed to secure the airway under direct visualization. A tracheotomy may then be performed over the bronchoscope.

After an airway has been obtained and endoscopy performed, and following review of the CT findings, the need for open exploration and repair is reevaluated. In patients with edema, hematomas, nondisplaced fractures of the thyroid cartilage, healthy true vocal fold motion, and no injury to the anterior commissure or free margin of the true vocal fold, no further surgery is usually indicated. Anesthesia is discontinued, the head of the bed is elevated, and the patient is observed carefully. Serial flexible fiber-optic laryngoscopic examinations are performed to ensure proper healing, and the tracheotomy tube is removed as soon as removal can be tolerated.

In patients with more severe injuries, surgical exploration is performed. In the past, controversy existed as to the optimal time for repair. Some authors had advocated delay of repair for 3 to 5 days to allow edema to subside, making it easier to identify mucosal lacerations. We believe that the best results are obtained with early repair, avoiding the morbidity of leaving open wounds in a contaminated field. Following exposure of the endolarynx via a thyrotomy, mucosal lacerations are meticulously repaired with 5-0 or 6-0 absorbable sutures. Dislocated arytenoids are reduced. In most injuries, wounds can be closed with adjacent mucosa. In cases involving military weapons or other instances in which the loss of tissue is large, regional mucosal flaps or skin grafts may be used to complete the lining of the larynx. After repair of the injured mucous membrane and muscle, the anterior commissure is reconstituted by suturing the anterior margin of the true vocal fold to the outer perichondrium. Regardless of the need for stenting, as is discussed below, reconstituting the anterior commissure is essential to maintain the scaphoid shape of this site and to preserve a normal voice. The thyrotomy is closed with permanent sutures, wire, or fixation plates.

The advantages of using a stent should be weighed against the risk for additional damage to the mucosa. Stents are recommended for injuries involving the anterior commissure, massive lacerations, comminuted fractures of the thyroid cartilage, and cases in which the architecture of the larynx is not maintained by open fixation of the fractures. The advantages of stenting in these instances are decreased web formation at the anterior commissure, decreased synechiae from extensive lacerations, and better support of the laryngeal architecture during healing. The placement of an endolaryngeal stent without open reduction and internal fixation of fractures and without closure of lacerations is unsatisfactory because both the injuries and the larynx are too complex to benefit from the placement of a lumen keeper. The choice of stents ranges from finger cots filled with foam rubber to commercially manufactured polymeric silicone stents. If preformed stents are not available, a finger cot stent can be made by packing it with gauze, or a silicone stent can be made from an endotracheal tube. This endotracheal tube stent is created by clapping the tube and then placing it in the autoclave for heating and reshaping (□ Fig. 92.2).

All should be roughly in the shape of the larynx and made of soft material to avoid further mucosal damage. The stent should extend from the false vocal fold to the first tracheal ring to add stability and prevent endolaryngeal adhesions. Ideally, the stent should be secured in such a manner as to be easily removed with endoscopic techniques. Following repair of the laryngeal wounds, the strap muscles are reapproximated, and the wound is closed over a drain.

Various other injuries may also be encountered during surgery. As much as one-third of the anterior cricoid or trachea can be repaired by using the sternohyoid muscle and its overlying fascia. Loss of the anterior third of the thyroid cartilage or hemiglottis can be repaired by the closure of mucosal lacerations over a stent. If open reduction and internal fixation with stenting are unsuccessful in restoring the laryngeal architecture because of massive tissue loss, partial or total laryngectomy may be necessary. The decision for partial or total laryngectomy should be based on the defect, according to the same guidelines used in oncologic reconstruction. However, total laryngectomy has not been necessary in large series of cases of laryngeal trauma and is more likely to be considered acceptable management for military wounds.

Fig. 92.2 Examples of a finger cot and a shaped endotracheal tube. These can be used as laryngeal stents if preformed stents are not available.

Table 92.2 Voice and airway results in evaluable patients by treatment group

Group	Voice			Airway			Total (N=115)
	Good	Fair	Poor	Good	Fair	Poor	
I	20	0	0	20	0	0	20
II	38	3	0	40	1	0	41
III	18	3	0	21	0	0	21
IV	22	10	0	31	0	2	33

Source: From Schaefer SD. The acute management of external laryngeal trauma. A 27-year experience. *Arch Otolaryngol Head Neck Surg* 1992;118(6):598–604.

Note: Group I patients had no airway compromise and were judged to have reversible injuries. They were managed by observation only. Group II patients had airway compromise and were considered to have reversible injuries. They were managed by tracheotomy, direct laryngoscopy, esophagoscopy, and observation. Group III patients were judged to have irreversible laryngeal fractures and/or lacerations that required management by open reduction and fixation of disrupted cartilage and/or mucous membrane. Group IV patients had more severe injuries, as discussed, and management differed from group III in that endolaryngeal stents were used.

92.5.3 Postoperative Care

We prescribe postoperative antibiotics for 5 to 7 days in an effort to reduce infection and the formation of granulation tissue. However, we are unaware of published verification of this practice. The head of the bed should be elevated, as tolerated, to minimize edema. The patient should be encouraged to ambulate as soon as ambulation can be tolerated. If a tracheotomy is present, routine care is provided. Stents placed at the time of surgery should be removed as soon as possible to prevent further mucosal damage, usually 10 to 14 days after surgery. Decannulation may be performed as soon as the stent is removed. Follow-up examinations should be scheduled for at least 1 year to assess the return of true vocal fold function and to monitor the development of subglottic stenosis. Proton pump inhibitors should be routinely used to prevent reflux, which may cause increased scarring of laryngeal tissues. When possible, nasogastric tubes are avoided to reduce reflux and prevent the posterior cricoid mucosal erosion associated with their use.

92.6 Complications

Complications after the repair of external laryngeal trauma include impaired vocalization, respiration, and deglutition. Postoperative granulation tissue may be seen after removal of the stent. This is best managed by prevention with meticulous closure of all mucosal lacerations at the time of surgery. Postoperative antibiotics and early removal of the stent may reduce the amount of granulation tissue. Profuse granulation tissue that persists may be debulked with the use of endoscopy.

Vocal fold immobility may cause a weak voice if unilateral; bilateral vocal fold involvement may result in aphonia and respiratory compromise. Unless the recurrent laryngeal nerve was known to be severed at the time of surgery, medialization procedures should be delayed for at least 6 months to permit delayed recovery. If after 6 months no mobility is present, electromyography is recommended. This permits differentiation between laryngeal denervation and arytenoid fixation, as well prognostication of the return of vocal fold function. At 6 to 12 months in the patient with a unilaterally denervated larynx, a medialization procedure may be performed to strengthen the voice or prevent aspiration. Further treatment of the denervated larynx and of laryngeal and/or tracheal stenosis is discussed elsewhere.

92.7 Prognosis

The outcome after laryngeal trauma depends on the extent of the original injury and the quality of subsequent repairs. For patients who do not require operative intervention, the prognosis for a full return of function is excellent. Patients requiring surgical intervention have an excellent chance of eventual decannulation with an adequate to good voice. Long-term complications after repair are uncommon. In our series of 139 patients with acute laryngeal trauma managed as presented in this chapter, only 2 patients were left with a poor airway, as defined by the inability to be decannulated (□ Table 92.2). Time to decannulation in the patients undergoing tracheotomy along with exploration ranged from 14 to 35 days, whereas those with stents (usually reserved for more severe injuries) needed 35 to 100 days to decannulation. All but 13 of the 115 evaluable patients achieved a good voice; those 13 were classified as having a fair voice. In conclusion, the goal of the acute treatment of laryngeal injuries is preservation of the airway and the maintenance of laryngeal function.

92.8 Roundsmanship

- The early diagnosis and management of acute external laryngeal trauma are essential to optimal preservation of the airway and voice.
- Any individual with significant trauma to the anterior neck should be considered to have a laryngeal injury until proved otherwise.
- Flexible fiber-optic laryngoscopy is the cornerstone of the diagnosis of laryngeal injuries. Injuries may evolve over hours after the initial examination of the larynx and neck, and their potential airway complications may not fully manifest at first.
- Computed tomography should be employed when the findings can best direct the course of treatment, rather than routinely.
- Surgery is reserved for patients with thyroid and cricoid cartilage fractures and with mucosal lacerations. Laryngeal stenting is useful for unstable thyroid and cricoid fractures, large endolaryngeal lacerations, and disruption of the anterior commissure.

93 Instrumentation and Techniques of Phonomicrosurgery

Corbin D. Sullivan and Jonathan M. Bock

93.1 Introduction

Phonomicrosurgery is a highly specialized microsurgical technique designed to restore a patient's normal voice. Improved understanding of vocal fold histology, the innovation of microflap surgery, and the development of micro instruments has allowed surgeons to successfully restore vocal fold function after the surgical treatment of most benign vocal fold lesions.

93.2 Pertinent Anatomy

Successful surgery depends on a thorough understanding of vocal fold surgical anatomy. Hirano described the histology of the vocal fold as a complex layered structure with an outer epithelium, three layers of lamina propria, and the underlying vocalis muscle (□ Fig. 93.1). The superficial layer of the lamina propria (SLP) is critical to maintaining normal vocal fold vibratory mechanics. Before Hirano's description, vocal fold stripping was commonly performed, essentially removing all layers of the lamina propria and epithelium above the muscle. The technique was imprecise and required healing of the entire vocal fold mucosa by secondary intent. After such an injury, epithelium regenerates, but the SLP does not have this capacity. This disordered and incomplete healing results in scarring and vocal fold stiffness. The more nuanced understanding of vocal fold histology introduced by Hirano led to the discovery that preservation of as much of the original architecture of the vocal fold as possible resulted in improved voice outcomes. This led directly to the central tenet of the microflap procedure: restoring normal vocal fold vibratory mechanics while preserving as much normal tissue architecture as possible. Most benign lesions involve only the epithelium and the SLP, just deep to the vocal fold epithelium, and are therefore amenable to microflap excision. The microflap limits the incision to the

epithelium, and the benign lesion is then dissected free of the SLP with maximal tissue preservation and subsequent excellent voice outcomes.

93.3 Indications for Phonomicrosurgery

Successful phonomicrosurgery begins with proper patient selection. This includes a complete work-up and careful decision making regarding medical versus surgical management. Videostroboscopy is crucial to evaluate the effect of the lesion on vocal fold mucosal wave propagation, to diagnose the type of lesion, and to identify areas of possible scarring or sulcus. Conservative management may be warranted initially because many phonotraumatic lesions resolve without surgery. Such management will likely include voice therapy as well as the treatment of any underlying disorders contributing to the patient's pathology. Occasionally, a trial of strict vocal rest and steroids may be indicated. Indications for phonomicrosurgery of benign phonotraumatic lesions include failure of conservative measures to resolve the dysphonia to a point at which the voice returns to normal or has improved enough that the patient's morbidity is minimal. Other indications may include biopsy of surgical diseases such as papilloma and suspected carcinoma. When surgery is recommended, a thorough discussion of the operative indications, risks (oral and dental injury, tongue numbness and pain, taste changes, permanent hoarseness and airway compromise, need for further surgeries, inability to achieve exposure), benefits (diagnosis, improved voice), and alternatives (observation, medical treatment, possible in-office biopsy or laser procedure) is completed with the patient to ensure proper patient education regarding the planned procedure. Patients should be counseled to discuss stopping any blood thinners with their primary care physician before surgery if at all possible.

Fig. 93.1 Vocal fold microanatomy. Knowledge of vocal fold anatomy is crucial to perform successful phonomicrosurgery.

Fig. 93.2 Intraoperative room arrangement for phonomicrosurgery. The operating room table is generally turned 90 degrees away from anesthesia to allow room for the microscope, laser, surgeon's chair, and endoscopic towers.

93.4 Phonomicrosurgery Technique

93.4.1 Anesthesia and Perioperative Considerations

Appropriate communication with the anesthesiologist is essential throughout the process of microlaryngoscopy. Short-acting paralytic agents are generally used to allow easier laryngeal exposure. The anesthesiologist is asked to use the smallest allowable endotracheal tube, typically a 5.0- or 5.5-mm tube. Jet ventilation with 100% oxygen is used when adequate surgical exposure is not possible with an endotracheal tube or when surgery within the trachea or bronchus is anticipated. When laser use is a possibility, the endotracheal tube should be laser-safe, the FiO_2 should be kept below 30% to avoid airway fire, the patient's eyes should be protected with wet gauze, and wet towels should be placed over the patient's face. The patient's bed is generally turned 90 degrees away from anesthesia to allow easy interaction between the operating surgeon and the anesthesia team while affording complete access to the airway, with room for placement of operating room equipment (□ Fig. 93.2). Universal precautions should also be observed by all operating room personnel, including wearing protective glasses, and appropriate warning signs should be posted for those who may enter during the laser portion of the procedure. A rigid bron-

choscopy set should be immediately available to secure the airway if necessary, and a tracheotomy set should also be available for the possible emergent airway.

93.4.2 Instrumentation

Excellent surgical exposure of the larynx is crucial for successful phonomicrosurgery, and numerous laryngoscopes are available to facilitate success (□ Fig. 93.3). The laryngoscopes used in phonomicrosurgery allow wide endolaryngeal exposure with binocular vision and bimanual instrumentation; often, a suction port is built into the laryngoscope for the clearance of smoke plume during laser procedures or for directing jet anesthesia. The authors prefer to start with either a regular Dedo (Pilling, Teleflex Medical, Research Triangle Park, NC; □ Fig. 93.3a) or laser Dedo laryngoscope (□ Fig. 93.3b) for most patients because the wider posterior aperture and square corners provide excellent working space and instrument support during phonomicrosurgery. The Ossoff-Pilling laryngoscope (□ Fig. 93.3c) is useful because it has a smaller endolaryngeal profile and often allows exposure of an anterior larynx while still permitting binocular vision and binocular instrumentation. The larynx of nearly every patient can be exposed with one of these two laryngoscopes with experience. The Ossoff-Karlan laryngoscope (Pilling) has a triangular back port, suction apparatus, and wide endolaryngeal posterior opening, which allows facile surgical exposure and laser use in the posterior larynx

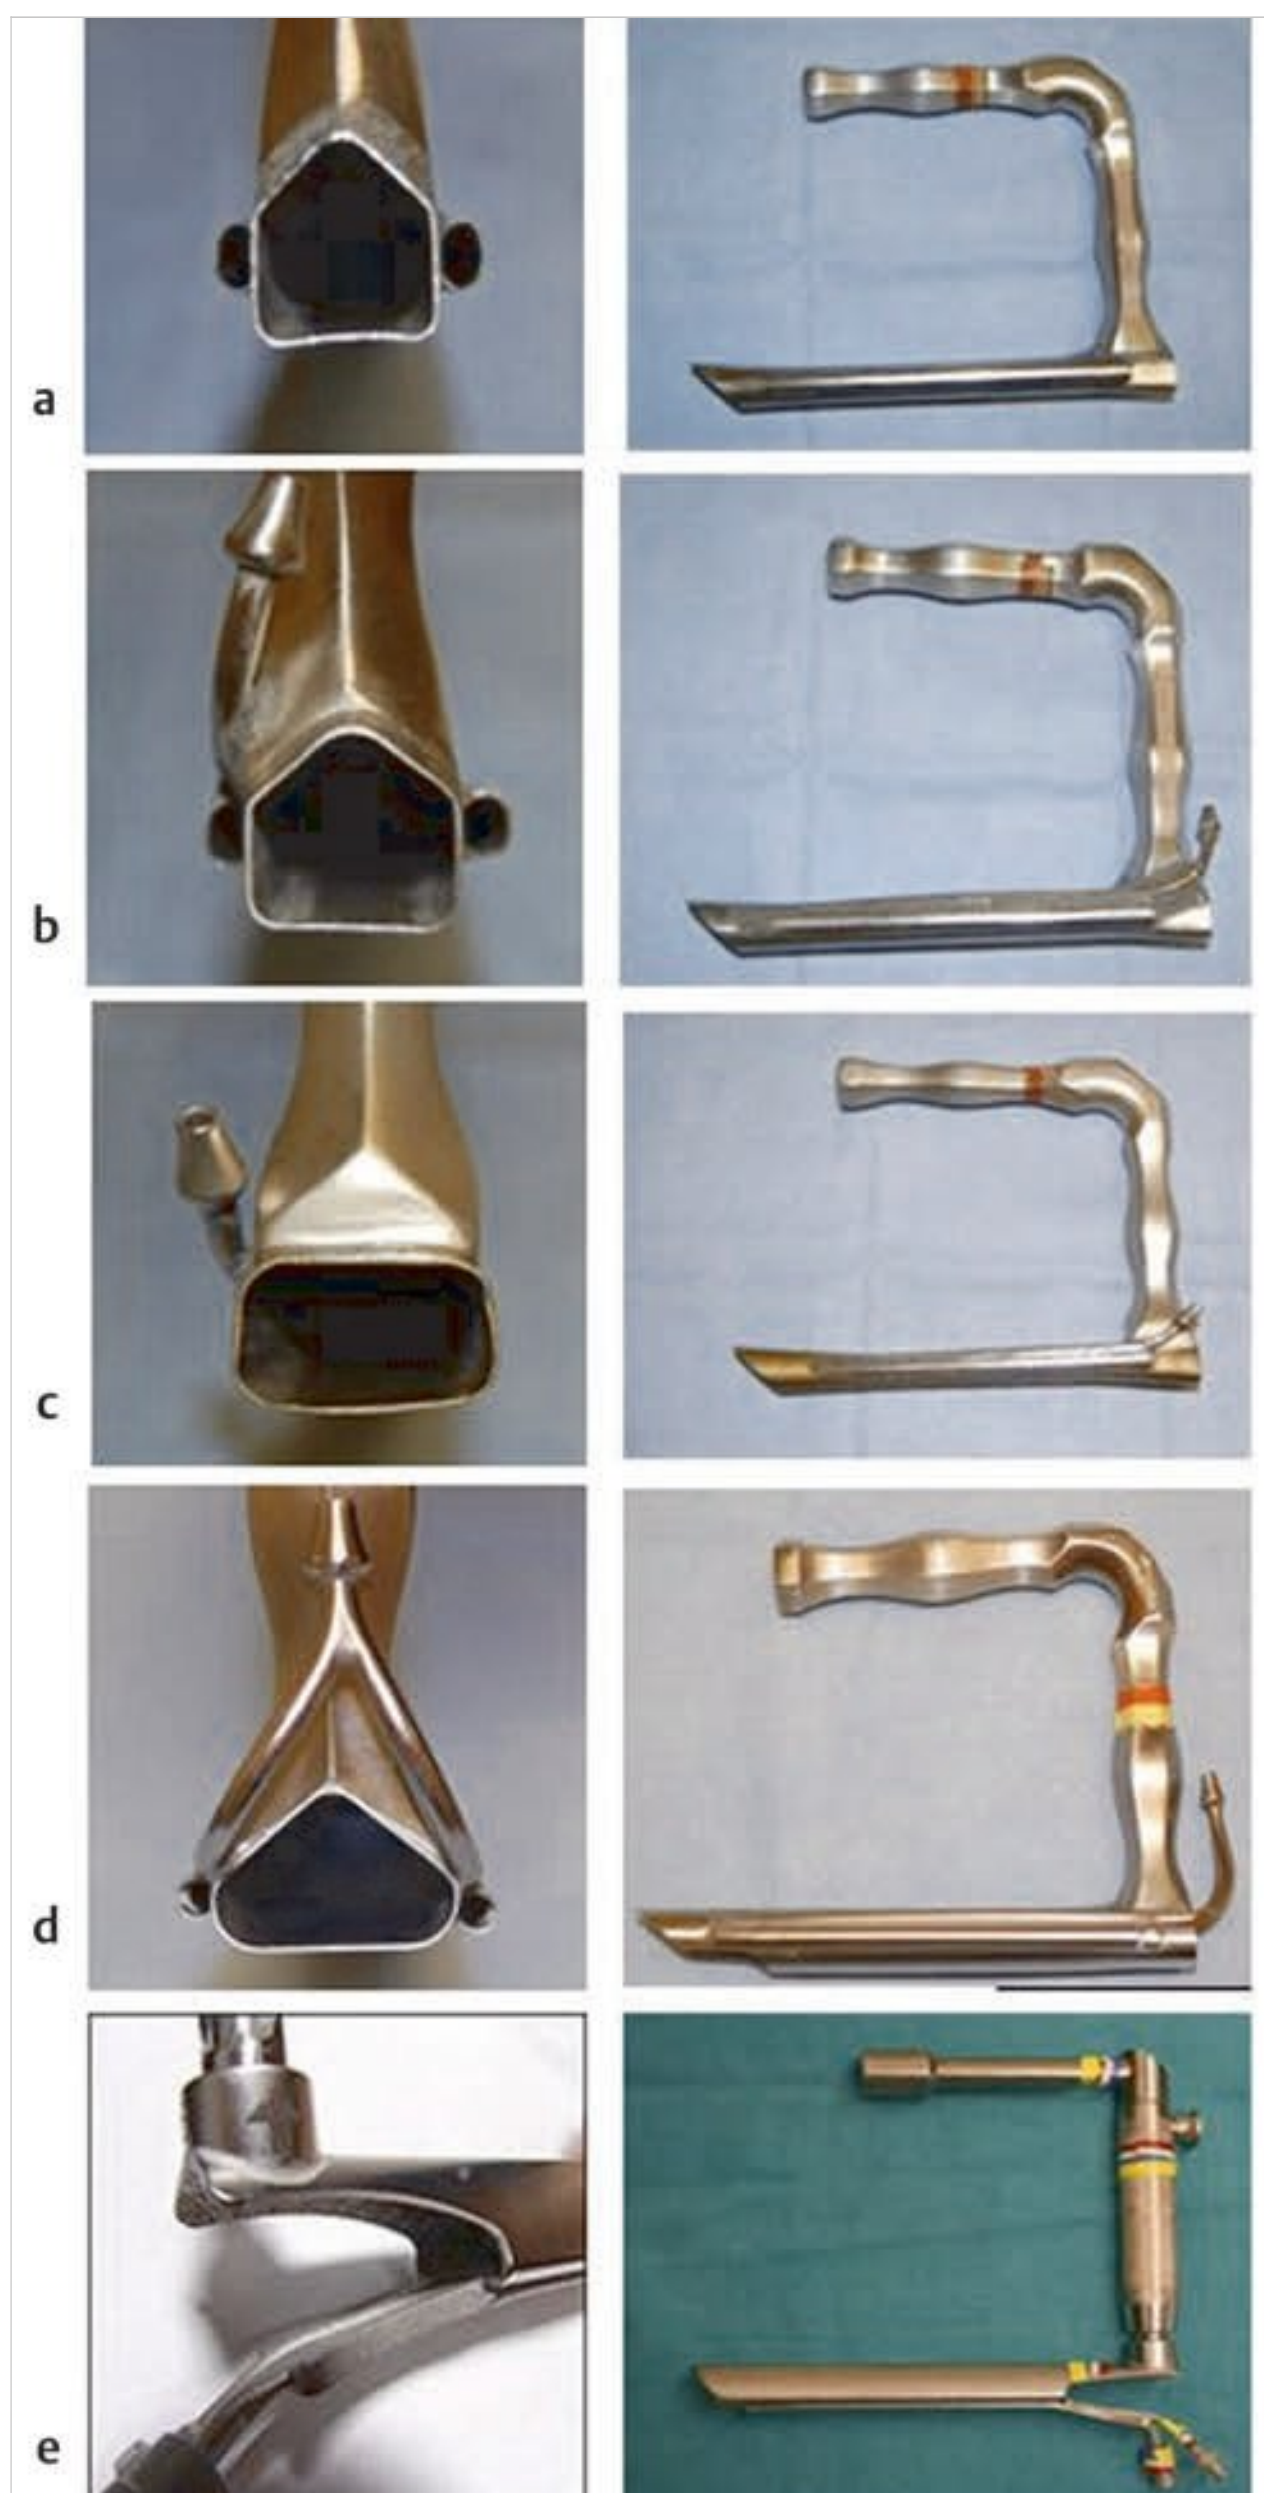

Fig. 93.3 Various laryngoscopes can be used for proper laryngeal exposure. (a) Dedo laryngoscope. (b) Laser Dedo laryngoscope. (c) Ossoff-Pilling laryngoscope. (d) Ossoff-Karlan laryngoscope. (e) Zeitels Universal Modular Glottiscope.

(□ Fig. 93.3d). The Zeitels Universal Modular Glottiscope (Endo-craft, Providence, RI) is also widely used and offers a true gal-lows suspension exposure of the larynx (□ Fig. 93.3e). A wide range of other laryngoscopes is available depending on surgeon experience and preference.

Microsurgical instruments are also critical to the success of a phonosurgical procedure. A variety of instruments are needed, including 0- and 90-degree blunt probes for laryngeal palpa-tion, a sickle knife to make mucosal incisions, flap elevators of various sizes to elevate mucosal flaps (□ Fig. 93.4), micro cup forceps (□ Fig. 93.5), basket graspers, and microsuctions (□ Fig. 93.6). A variety of laryngeal injection devices are also

available, including a butterfly needle, a Xomed injector (Med-tronic Xomed, Jacksonville, FL), and a Zeitels injector for the subepithelial infusion of saline or epinephrine into the Reinke space or the injection of steroids or cidofovir. Steiner laryngeal suction cautery devices are also available if larger amounts of hemorrhage are anticipated. Photo documentation is essential in laryngology, and modern technology allows exceedingly high-quality imaging. Both 0- and 70-degree operating tele-

scopes assist in the physical examination of the endolarynx, anterior commissure, and subglottis.

Proper surgical positioning starts with the precise support and positioning of the operating surgeon. Adequate support of the surgeon's arms is crucial for successful surgery because any mild tremor in movement is hugely magnified under the surgical microscope. In addition, proper surgeon positioning with a neutral shoulder and neck position allows comfortable working during prolonged surgical procedures and decreases the long-term incidence of neck and shoulder injuries. Chairs with finely adjustable arm supports are much preferred over the use of a Mayo stand, and many excellent versions are available (□ Fig. 93.7).

93.4.3 Patient Positioning

The patient is placed in the prone position on the operating table, often with the table rotated 180 degrees to allow more room for the surgeon's legs under the head of the table. The operating room table is then turned 90 degrees from anesthesia to allow the laryngologist the most freedom of access and movement around the patient's head (see □ Fig. 93.2). An upper tooth guard must be used unless the patient is edentulous, in which case dentures should be removed, and wet gauze should be used to protect the upper alveolus. If the patient is partially edentulous, the remaining teeth are at particular risk during suspension laryngoscopy because of the uneven pressure that is applied over their surface during suspension. Unrolled moist gauze can be used to pack the open spaces between the teeth to disperse this pressure and add stability to the maxillary teeth during suspension laryngoscopy.

93.4.4 Operative Exposure

The approach to the initial exposure should be relatively consistent. The endotracheal tube is secured to the one side of the mouth, and the teeth or gums are protected. The patient is placed in the sniffing position with flexion of the lower cervical vertebrae and extension of the head at the atlanto-occipital joint. The laryngoscope is advanced down the side of the pharynx opposite the endotracheal tube. The laryngoscope is carefully placed underneath the epiglottis and advanced down to

Fig. 93.7 Carl Zeiss Meditec (Dublin, CA) microsurgeon chair with individual full arm supports and powered vertical height refinement, allowing total arm support and neutral ergonomic surgeon positioning during prolonged microsurgical cases.

the level of the true vocal cords under direct visualization. Before suspension, the oral cavity is inspected to ensure that the scope is adequately supported and that the lips are not being pinched. The posterior glottis can be examined by placing the laryngoscope behind the endotracheal tube and lifting forward, or by switching to jet anesthesia if indicated. Once the laryngoscope is properly positioned, the suspension apparatus is employed to expose the larynx and provide hands-free support of the patient's tissues for surgery. The suspension apparatus should be directly attached to the operating room table, not to a Mayo stand on the floor, because this allows easy adjustment of table angle during surgery and prevents inadvertent patient injury due to movement of the suspension galleys independently of the patient. Photo documentation with 0- and 70-degree operating telescopes can then be accomplished, and further refinement of the laryngoscope position can be completed based on endoscopic imaging of the larynx.

The surgeon can often anticipate difficulty with exposure based on the patient's examination and history. A patient with a Mallampati score of III or IV, poor mouth opening, a retrusive mandible, trismus, significant obesity, prominent incisors, previous cervical spine fusion, poor head extension/chest flexion, or radiation edema may pose a challenge for exposure. There are many adjustments in exposure technique than can be employed when laryngeal exposure is difficult. A shoulder roll induces neck extension and is counterproductive to obtaining the optimal neck flexion angle for laryngeal exposure. Elevating the head with folded blankets or clicking the table head up can assist in exposing the anterior larynx by increasing neck flexion. To enhance laryngeal exposure, anterior laryngeal counterpressure can also be applied with an assistant's hand, or with tape carefully placed from one side of the operating room table to the other across the patient's neck over a gauze pad to protect the skin (□ Fig. 93.8). If the epiglottis is retroflexed or "floppy," gauze can be wrapped around the tongue to protrude the tongue and pull the epiglottis upward and out of the field while the laryngoscope is introduced. A perforating towel clamp can also accomplish this same purpose. Alternatively, the epiglottis can be directly grasped and elevated with a large alligator as the laryngoscope is passed beneath. At times, a smaller tooth

Fig. 93.8 Optimal patient positioning for microlaryngoscopy requires flexion at the neck and extension of the head to allow the best possible exposure. To assist with exposure, anterior laryngeal counterpressure can be applied with tape carefully placed from one side of the operating table to the other across the patient's neck over a gauze pad to protect the skin.

guard can also be useful, especially if the patient has prominent incisors. This may increase the risk for dental injury unless the guard has been made specifically for the patient. The best or most efficient method to attain exposure ultimately depends on the skill level and experience of the surgeon, but excellent exposure is necessary before the operation is continued.

93.4.5 The Microflap Surgical Procedure

Evaluation of the vocal fold lesion is begun by palpating the vocal fold with a straight or right-angle probe and noting the pliability of the lesion and its intracordal depth, any associated sulcus deformity, glottic webs, feeding vasculature, and possible extension into the subglottis or laryngeal ventricle. Vasoconstrictive agents are an essential component of phonosurgery because they allow a dry operative field and obviate the use of electrocautery for hemostasis. Three commonly used vasoconstrictive agents, in order of decreasing potency, are cocaine, diluted epinephrine (generally 1:10,000 concentration), and oxymetazoline. Each is considered adequate for most procedures, and the choice is largely based on surgeon preference. Cocaine is the most potent vasoconstrictor and has the added advantage of conferring a topical anesthetic effect, but it does have some systemic absorption and can also trigger positive urine drug testing postoperatively. Both cocaine and epinephrine can have powerful cardiovascular effects, including hypertension and tachycardia. Oxymetazoline has the least systemic toxicity but is also the least effective vasoconstrictor. The agent of choice is applied via pledget for at least 1 to 2 minutes before incision to ensure adequate tissue penetration and vasoconstriction. If epinephrine is used, it may also be applied via subepithelial infusion, which has the dual benefits of vasocon-

striction and augmentation of the subepithelial or Reinke space. Augmentation increases the distance between the epithelium and vocal ligament, decreasing the risk for injuring the vocal ligament during incision. It may also clearly define a sulcus deformity or invasive lesion where the epithelium is adherent to the underlying vocal ligament. If laser use is anticipated, a saline-soaked pledget is placed into the subglottis to protect the endotracheal tube cuff before surgery.

The position of the incision for the microflap is recommended based on the nature and position of the surgical lesion. Generally, a medial incision is made for vocal fold polyps and striking zone lesions such as nodules; a lateral incision is made for intracordal cysts that are more adherent to the vocal ligament or for the excision of diffuse polypoid corditis (Reinke edema). Before incision, if the vasoconstrictive agents were topically applied, a subepithelial infusion with saline may be performed to augment the Reinke space. Incision into the vocal fold is made under microscopic guidance with a sickle knife, with care taken to incise only the vocal fold epithelium (see □ Fig. 93.4). The knife is often stabilized with both hands during incision. Any bleeding is then stopped by using a large or micro pledget to repeat the application of vasoconstrictor. These agents are reapplied throughout the case as needed. Anterior or posterior extension of the incision can be easily accomplished with an up-biting scissor (see □ Fig. 93.5).

The flap elevator is then used in the ipsilateral hand with a laryngeal microsuction in the opposite hand to define the surgical plane under the epithelium. The flap elevator is angled to allow the atraumatic “heel” of the elevator to ride on the vocal ligament, thereby stabilizing the instrument, avoiding injury to the ligament, and ensuring maximal SLP preservation. Meticulous blunt and sharp dissection is often necessary to separate fibrosis surrounding the lesion from the epithelium and vocal ligament. This is often the case in chronic inflammatory conditions or a vocal fold cyst. Retraction of the epithelium with the velvet-eye microsuction allows the evacuation of any bleeding or serous fluid that may obstruct the field while keeping the vocal fold tissues on light tension. Using this instrument is more difficult than grasping the flap, but it is advantageous because of the constant fluid evacuation and the decreased risk for flap tearing as the suction will fall out of the surgical field if too much retraction is applied. Flap elevation proceeds in a lateral to medial direction until the entire lesion is freed from any scarring to the deeper vocal fold structures. Firmly adherent or particularly dense scarring may need to be incised or trimmed with a laryngeal microscissor.

When the lesion has been fully mobilized, it is grasped with a micro cup or basket grasper. The grasper is placed in the contralateral hand, and the surgical assistant guides the flap elevator or appropriate scissors—up, left, or right cutting—into the laryngoscope in the ipsilateral hand. The lesion is delivered as the final dissection is performed. It is removed in one piece if possible. If the epithelium will be clearly redundant, as is often the case with a polyp, the lesion does not need to be completely dissected out because it can be removed while still adherent to the redundant component of the epithelium. The remaining vocal fold epithelium is then redraped, and if there is remaining redundant epithelium, it is excised to allow the closest possible approximation of the epithelial edges for a “straight line” closure. At the completion of the resection, the surgical site is

again inspected with 0- and 70 degree endoscopes to evaluate the surgical outcome. Postoperative photo documentation is then performed. Topical lidocaine (4%) is often applied at the end of the case to decrease the incidence of laryngospasm on emergence, and the laryngoscope is then carefully removed from the oral cavity. The teeth and lips are inspected for injury.

93.4.6 Postoperative Care and Voice Rest

Postoperative care following phonomicrosurgery involves pain management and vocal rest, both to varying degrees depending on the indications for and extent of surgery. Postoperative pain is usually minimal, and acetaminophen alone is often sufficient. The use of vocal rest after surgery varies markedly between practitioners, and some do not use it at all. Most laryngologists recommend roughly 1 week of strict voice rest following phonomicrosurgery. After the first postoperative visit on approximately day 5 to 7, the patient is placed on “modified voice use,” meaning that the patient should not speak in a voice louder than can be heard at arm’s length (the “arm’s-length rule”). As a general guideline, the patient is allowed to speak for 10 minutes that day, then the allowance is doubled each day thereafter. The patient should refrain from significant phone use during the first few weeks, continue to use voice rest in noisy situations (bars, restaurants, concerts), and avoid singing, shouting, or screaming. Professional vocalists are often restricted from singing for at least 3 to 4 weeks postoperatively and are encouraged not to return to full performance for 2 to 3 months after surgery. Postoperative voice therapy and a measured return to performance or work requirements are critical for patients. Patients are generally examined with repeated videostroboscopy before a full return to work is allowed. The utility of these postoperative examinations lies in the careful inspection for the return of the mucosal wave, any untoward complications, or the return of signs of vocally abusive behavior. They can help guide the laryngologist in counseling the patient on a vocal behavior as well as postponing the return to work should healing be slow.

93.5 Risks and Adverse Effects of Phonomicrosurgery

Severe complications during phonomicrosurgery are rare. Many practitioners place their patients on perioperative proton pump inhibitor therapy to prevent laryngeal inflammation if they are concerned about laryngopharyngeal reflux. Most of the discomfort following phonomicrosurgery often involves tongue swelling and tenderness due to prolonged pressure from suspension laryngoscopy. Many patients will note some lingual paresthesia and dysgeusia following surgery that generally resolve within several weeks. Rarely, erosions along the lingual surface of the mandible and tooth pain can present postoperatively and war-

rant careful clinical follow-up. Dental injuries are a rare but predictably unfortunate consequence of the laryngeal exposure process despite the use of tooth guards, and all patients should be counseled about this before surgery. Edentulous patients may also have erosions of the maxilla from direct pressure of the laryngoscope. Oral and pharyngeal lacerations can also occur during exposure and are usually mild in nature. Postoperative stridor and airway compromise due to laryngospasm or redundant laryngeal tissue (from the excision of large polyps or stenosis surgery) can result in a requirement for emergency airway management, and all patients are counseled on this risk before surgery. Lastly, in some patients, it is simply not possible to achieve proper direct laryngoscopic exposure because of anatomy, cervical spine fixation, poor mouth opening, or other confounding factors. For these patients, in-office flexible laryngoscopic surgical techniques may be more appropriate.

93.6 Roundsmanship

- Phonomicrosurgery is predicated on the anatomical structure of the vocal fold. Mucosal dissection and resection can be performed under microscopic guidance while the important underlying tissues of the vocal fold are carefully preserved.
- Proper instrumentation is essential for successful phonomicrosurgery, including laryngoscopes that provide binocular microscopic vision and bimanual instrumentation, operating telescopes that allow a thorough and exact laryngeal examination, and microsurgical instruments that facilitate vocal fold incision, dissection, and lesion excision.
- Laryngeal exposure can be challenging, and the surgeon needs to be prepared to try different laryngoscopes and patient positioning strategies to facilitate an adequate surgical view.
- Meticulous dissection of the epithelium away from the underlying vocal ligament is paramount in microflap elevation, maximally preserving the superficial lamina propria while removing the epithelial or intracordal lesion that is interfering with vocal fold vibratory mechanics.

94 Voice Therapy

Amy L. Cooper

94.1 Introduction

Voice therapy is an approach to treating voice disorders that involves vocal and physical exercises coupled with behavioral changes. The purpose of voice therapy is to help patients attain the best possible voice and the most relief from the vocal symptoms that are bothersome. Patients are referred to voice therapy when they have a voice disorder that does not warrant surgical intervention, when behavioral modification may decrease the likelihood of the need for surgical intervention, or when they require postoperative rehabilitation. The therapy is almost always initiated by referral from an otolaryngologist. It is extremely important for the otolaryngologist to strongly encourage voice therapy candidates to follow through with the recommended treatment; patients are sometimes put off by the time commitment therapy may entail (weekly sessions for up to 2 months). In a retrospective review of 294 charts at two voice institutions in Atlanta, 38% of patients did not adhere to the physician's recommendation to attend voice therapy. Of those who initiated follow-through, 47% did not return after the initial speech–language pathology evaluation session. Not unlike other therapies intended to change health behavior, voice therapy involves structured treatment sessions and follow-up work to be completed outside the therapy sessions to reinforce the behavior change. Also, not unlike other health care professionals, voice therapists must deal with the problems of resistance to change and lack of patient follow-through outside the therapy sessions.

94.2 Indications for Voice Therapy

The goal of voice therapy is to restore the best voice possible. The therapy program will vary from patient to patient, but in all cases the goal is a voice that is functional for employment and social communication. Voice therapy is conducted to address one of three types of disorders: hyperfunctional, hypofunctional, or dysfunctional. In each of these cases, a vocal fold lesion and/or neurologic abnormality may contribute to the voice disorder.

The most commonly observed voice problems are related to vocal hyperfunction. Hyperfunctional voice disorders are characterized by increased perilaryngeal and/or supralaryngeal tension. A decrease in these types of tension is targeted during voice therapy in order to improve glottal efficiency. Benign lesions, including nodules and polyps, are often present in conjunction with vocal hyperfunction. In these cases, therapy is geared not only at improving vocal efficiency but also at facilitating the healing of benign lesions.

Hypofunctional voice disorders result from incomplete or inconsistent glottal closure. Common diagnoses associated with vocal hypofunction include vocal fold paralysis or paresis and Parkinson-related dysphonia. Therapy techniques will typically consist of exercises to improve glottal closure, or to maximize resonance for improved vocal quality.

Patients who do not fit into either of the above categories are characterized as having a dysfunctional voice disorder. In these cases, the vocal mechanism is intact, but the patient is incapable of using the mechanism in an appropriate manner to attain adequate voice. Relevant diagnoses include puberphonia, paradoxical vocal fold movement, psychogenic dysphonia, and/or conversion disorders. In general, these diagnoses are well managed with voice therapy, although some patients may require psychological counseling, as well.

94.3 Evaluation

Voice therapy should be recommended only after a thorough examination of the vocal folds, preferably via videostroboscopy, as well as an analysis of vocal function. Videostroboscopy is a technique that allows a detailed visualization of not only the patient's laryngeal anatomy but also the patient's phonatory biomechanics. During laryngovideostroboscopy, the extremely rapid vibration of the vocal folds appears as a pseudo-slow motion event (see Chapter 79 for a more in-depth discussion of laryngovideostroboscopy). An evaluation of vocal function includes a detailed history and perceptual evaluation of the voice, as well as the collection of aerodynamic and acoustic data (see Chapter 78 for more information on voice evaluation). Pertinent information to be collected includes the medical history, any vocal misuse, and signs and symptoms of laryngopharyngeal reflux.

94.4 Treatment

A particular therapy regimen is individually developed based on each patient's (1) vocal fold pathology, (2) vocal demands, (3) baseline vocal behavior, and (4) compliance. Therefore, a voice therapy program for an 80-year-old retiree is likely to vary significantly from the voice therapy program for a 20-year-old college student. Uniformly, the individualized voice therapy program will incorporate the following:

- Application of the principles of vocal hygiene to the daily use of the voice
- A series of therapeutic vocal exercises aimed at altering vocal fold vibration and increasing the efficiency of the system through a balancing of the four subsystems of voice: respiration, phonation, resonance, and articulation

Both vocal hygiene and vocal exercise are important for success in voice therapy. Vocal hygiene consists of reducing environmental and behavioral factors that may cause damage to the vocal folds, including inadequate hydration, smoking, excessive alcohol intake, exposure to chemicals/fumes, excessive talking at loud volumes, and laryngopharyngeal reflux.

Management strategies differ among voice patients depending on whether their problems are related to vocal fold hyperfunction or hypofunction. The most commonly observed voice problems are related to vocal fold hyperfunction. Numerous

exercises are geared at reducing the amount of “work” required for speaking. A voice therapy program for an individual with vocal hyperfunction would be selected from a variety of approaches, depending on the individual’s causative and sustaining influences. For example, a trial lawyer who uses frequent glottal attacks may benefit from learning to reduce her rate of speech, adopting a smoother or more legato vocal style, opening her mouth more widely, and varying her intonation. The voice therapist is expected to select those therapy approaches that facilitate an easy, smooth style of voicing.

In the case of a patient with vocal fold hypofunction, treatment may be geared at increasing loudness or improving articulatory precision. A common neurologic voice disorder is Parkinson-related dysphonia. The Lee Silverman Voice Treatment has been demonstrated to be effective for treating this kind of dysphonia. The purpose of the treatment is to increase loudness, but it often results in improved respiratory output, decreased glottal incompetence, and overall improved intelligibility.

The vocal exercise regimen is developed on an individual basis to address specific biomechanical problems associated with particular voice disorders. □ Table 94.1 provides examples of 25 voice therapy facilitators and the vocal parameters affected. Selected therapy techniques facilitate a “target,” or a more optimal vocal response by the patient. A part of voice therapy is searching with patients to find the selected therapy technique that seems to help them produce the desired vocal response. In the case of patients with degenerative organic pathology, voice therapy may be conducted to maintain the current level of function as long as possible and reduce ineffective compensatory behaviors. Therapy may be performed preoperatively or postoperatively. Preoperative voice therapy may be undertaken in an effort to eliminate vocally abusive behaviors and begin modeling postoperative voice production. Postoperative voice therapy is designed to help patients adjust to structural changes and to optimize healing in the postoperative period. It is of paramount importance that patients be made aware that restoring the voice to a previous or idealized level may not be possible.

Yawn, sigh	*	*	*

There are cases in which the voice may never return to its previous state. An important component of voice therapy is counseling patients during this dramatic realization and managing their expectations.

The optimal voice for a particular patient should be reliably achieved in the clinical setting; otherwise, it is almost certain that the patient will fall short of the target voice in the real world. Carryover into everyday speech is essential. Skill drills should remind the patient of what he or she should be doing with his or her voice throughout the day. The clinician will focus on rebalancing respiration, phonation, and resonance; this is more important than individual skill drills. The clinician will also explicitly describe the need, purpose, and function of each therapeutic activity. It may be necessary to help a patient find a good voice despite the presence of pathology. This may involve developing the safest voice possible before the completion of medical or surgical treatment.

94.5 Special Considerations

There are some differences in the overall management of voice disorders in children versus those in adults. The age of the person, physical size of the laryngeal structures, and cognitive ability to understand the goals of therapy will dictate what can be done. As in all patients, heavy emphasis is placed on the evaluation in young children because certain pathologies, such as polyps, cysts, and recurrent respiratory papilloma, may be better managed surgically. Voice therapy for school-age children is usually geared at reducing hyperfunctional behaviors. The clinician will identify the situations in which the child is doing things that are vocally abusive and will work with teachers and family members to identify triggers and sustaining factors. A heavy burden is placed on family members to track vocally abusive behaviors outside the clinic setting. Children are often willing to reduce target behaviors when motivated by rewards and attention from caregivers. Obviously, a child must know that he or she has a voice problem before anything can be done about it. This is a major challenge because the child may remain unaware that there is a problem despite the best attempts of the physician, clinician, and parents. Therapy attempts are often deferred until the child matures enough to understand the problem more fully and to be an active participant in the therapy process.

A person of particular interest is the “professional voice user.” This term can be used to describe any individual with heavy vocal demands, but in this case it is used to refer specifically to a performer. To achieve a better understanding of the demands that a performer makes on the vocal mechanism, it is useful to know something about the music or type of theater with which the performer is familiar. The goals of therapy are slightly different from those for a nonperformer. With a performer, there are no degrees of freedom with respect to the desired outcome, whereas with other voice patients, there is much more latitude

in the range of vocal behaviors that constitute an acceptable outcome. Speech pathologists are always concerned about environmental contributors to voice disorders, but conditions in the performer’s world may be somewhat unfamiliar. Studios, concert halls, rehearsal spaces, and practice rooms may be filled with dust, fumes, and ambient noise, and the temperatures may be variable. Additionally, stage direction, set design, and costume design must be considered. Another major source of pressure is that the professional voice user is constantly being judged by audiences, critics, conductors, managers, agents, coaches, and teachers. Rehabilitation professionals working with a performer need to be prepared for intense emotional reactions with regard to voice difficulties. The ongoing education and counseling, both a part of a voice therapy program for any patient, must be handled with special thoroughness and exquisite sensitivity in the case of the professional voice user.

Voice therapy should be performed only by a licensed speech–language pathologist who has training in voice disorders. Referring a patient to a clinician with little experience or interest in voice is not advisable because the odds of success decrease dramatically. In summation, voice therapy is individualized and is an essential component of treatment for many patients with voice disorders.

94.6 Roundsmanship

- Voice therapy is an approach to treating voice disorders that involves vocal and physical exercises coupled with behavioral changes.
- Voice disorders are hyperfunctional, hypofunctional, or dysfunctional.
- Voice therapy may be conducted as part of a conservative treatment plan, or it may be undertaken pre- and postoperatively when surgical management is deemed necessary.
- Voice therapy is best administered by a licensed speech–language pathologist who has a particular expertise in the area of voice disorders.

95 Lasers in Laryngology

Philip A. Weissbrod

95.1 Introduction

Lasers have been used in laryngeal surgery since the 1970s. Originally used only in the operating room, they have become a mainstay in both office- and operating room-based laryngologic surgery. The original surgical laser, the carbon dioxide laser, is coupled to an operating microscope by way of an articulated arm and directed with a micromanipulator. More recently, with improved laser and fiber technology, a variety of lasers have been developed that deliver energy via fibers passed through the operating channel of a flexible laryngoscope. This has revolutionized the use of lasers in laryngology by making it possible to apply them in the awake office patient as well as in an operating room setting.

Lasers used in the operating room have great precision because of the stable surgical field provided by a patient under general anesthesia. However, as a consequence of the aforementioned advances, an increasing number of procedures can be effectively done in the office. The benefits of office-based procedures include avoidance of general anesthesia, decreased cost to the patient and the medical system, decreased procedure time, and few complications. For patients with disease processes that require multiple procedures, office-based surgery provides a safe and effective alternative to multiple trips to the operating room.

Despite improvements in technology, there are still instances where an operating room based approach is advantageous, especially in oncologic resections, situations where bleeding is expected, and where bulky or diffuse disease will make awake treatment difficult to complete in the office secondary to limitations in anesthesia.

95.2 Laser Terminology, Principles, and Mechanism of Action

The term laser is an acronym that stands for light amplification by stimulated emission of radiation. There are some fundamental physics principles and terminology that must be understood to fully appreciate how lasers work and how lasers differ from one another. Photons, the basic unit of light and radiation, are integral to laser function. Photons have no mass, can act as a wave or a particle, and can be either absorbed or emitted by an atom. The basic unit of emission from a laser is a photon; therefore, we can discuss lasers as having certain characteristics of a wave, such as frequency, amplitude, and wavelength. Frequency is the number of times a wave repeats in a second and is measured in hertz (Hz). Amplitude is the height of a wave. Wavelength is the distance between waves and determines the color of a laser (□ Fig. 95.1).

Lasers use the excitability of atoms or more specifically electrons to create photons. When an atom absorbs energy, its electrons enter into an excited state. When the electrons return to their ground state, energy is released in the form of a photon, a process called spontaneous emission. When an excited electron interacts with a photon equal to the energy difference between

the electron's ground state and excited state, the photon will encourage the electron to release a photon, returning the electron to its ground state. The released photon will be identical to the original photon in wavelength, frequency, and phase. Because the original photon is not absorbed by the atom, there are now two identical photons. This process is called stimulated emission. Lasers take advantage of this principle to produce multiple photons with the same characteristics.

During the operation of a laser, absorption, spontaneous emission, and stimulated emission are all taking place. Initially, atoms are energized from the ground state to the excited state by a process called pumping. These atoms decay via spontaneous emission and emit photons, which are reflected back into the laser medium. Some of the photons are absorbed by atoms in the ground state, and others collide with atoms in the excited state. When photons collide with atoms in the excited state, this results in stimulated emission and increases the total number of photons. Optical amplification occurs when the number of photons being emitted is greater than the number of photons being absorbed, resulting in a continuously increasing number of photons. In order for optical amplification to occur, it is necessary to have more atoms in an excited than in a ground state so that emitted photons will not simply be absorbed by another atom in its ground state. This critical mass concept is called population inversion.

The external energy source that initially excites the atoms from the ground state is called the pump source. The source of the atoms that are pumped is termed the gain medium. The gain medium determines the laser's wavelength, or color. Gain mediums are housed in a space called the optical cavity and can be a gas, solid, or semiconductor depending on the type of laser.

Initially, when photons are produced, they are traveling in a multitude of directions. In order to encourage them to travel in a unified direction, they are reflected off mirrors (optical resonators) placed on either side of the optical cavity. One mirror has the capability to allow photons to leave the optical cavity in the form of a laser beam, or electromagnetic radiation, when triggered. The output can be in the form of a continuous wave of radiated energy or in a pulsed form (□ Fig. 95.2).

The settings for most types of medical lasers include power, on-off interval, pulse width, and laser spot size or shape. Power

Fig. 95.1 Wave characteristics.

Fig. 95.2 Schematic of a laser unit.

Table 95.1 Correlation of tissue temperature with cellular injury

Tissue temperature (°C)	Cellular injury and tissue response
42–25	Beginning of hyperthermia, conformational changes, shrinkage of collagen
50	Reduction of enzymatic activity
60	Denaturation of proteins, coagulation of collagens
100	Tissue drying and formation of vacuoles
>100	Beginning of vaporization and tissue carbonization
300–1,000	Thermal ablation, photoablation, and disruption

is the amount of energy that a device emits and is measured in watts (W). The measure of emitted or received energy is called radiant energy. It is measured in joules (J) and accounts for power delivered over time.

-

When energy delivered to tissue is considered, the area over which the energy is delivered, or spot size, is of relevance. The spot size of a carbon dioxide laser can be adjusted by manipulating the depth of focus of the microscope or by altering the laser spot size directly. With a fiber-based laser, moving the fiber closer to the field can decrease the spot size. Irradiance is power divided by area. Similarly, fluence, the total energy absorbed by a cross-sectional area, accounts for the distribution of energy over area.

-

In the case of a circular spot, the equation would be the following:

-

Therefore, as the fiber moves closer to the tissue, the radius decreases, and the irradiance and fluence increase significantly. Ul-

timately, the reason why these concepts are important at the tissue level is that light energy is transformed into heat, which alters cellular structures. The degree to which tissue is heated determines the extent of damage (□ Table 95.1).

Aside from adjustments to the power and spot size, the pulse width, or length of time in which a single burst of power is delivered, can alter the way in which tissue responds to a laser. Running a laser in continuous mode means that the energy at any given point in the “on” mode is constant. Alternatively, energy can be delivered in discrete pulses to minimize the transference of heat to surrounding tissue. The pulse duration should be less than the time necessary for heat to be conducted away from a laser-heated region. The time required for heat to dissipate is known as the thermal relaxation time. Thermal diffusion time, or the time that it takes for heat to flow into the tissue, is determined by characteristics specific to certain tissues, such as density, water content, and specific heat. If the pulse width is less than the diffusion time or relaxation time, thermal confinement exists. By keeping the pulse width shorter than the thermal diffusion or relaxation time, the zone of necrosis (□ Fig. 95.3), or extraneous tissue injury, can be minimized.

95.3 Laser Applications in Laryngology

The clinical culmination of the above equations and terms is represented by the concept of selective photothermolysis. When lasers of different wavelengths are used (□ Fig. 95.4), specific tissues will absorb energy selectively according to the concentration of water or the presence of pigment, as in blood or melanocytes. Therefore, the selection of a suitable laser relates to the inherent qualities of the laser and the characteristics of the tissue being treated. Although many lasers have been used over the past 20 years, a few have come to the forefront

Fig. 95.3 Tissue alterations as a distance from incident laser.

for application in treating diseases of the larynx. In general, they can be separated into lasers that target the wavelength of oxyhemoglobin and those that target water (□ Table 95.2).

The 585-nm pulsed dye laser and the 532-nm pulsed potassium titanyl phosphate (KTP) laser are two examples of lasers that target oxyhemoglobin and embody the concept of selective photothermolysis. The absorbance peaks of oxyhemoglobin are 541 and 571 nm. When this chromophore is targeted, energy can be directed specifically to the subepithelial microvasculature that supplies a lesion, where it will cause involution. Combining this directed therapy with pulsed energy delivery reduces collateral damage to surrounding tissues by respecting the thermal relaxation time of laryngeal tissue. Inadvertent lasering of healthy tissue during procedures has minimal voice implications, and studies have shown no long-term fibrotic injury from the use of these lasers. In the case of the true vocal folds, this is of vital importance because preservation of the superficial lamina propria and mucosa, the vibratory elements of the vocal fold, is maximized. Both the pulsed dye laser and the KTP laser are used to treat laryngeal papillomas, granulomas, Reinke edema, vocal fold polyps, leukoplakia, vascular lesions, ectasia, varices, dysplasia, and early glottic carcinoma. Given that these are fiber-delivered lasers, they are suitable for use in the operating room or office setting when directed through the operating port of a flexible laryngoscope.

As mentioned previously, office-based procedures have a number of benefits for patients; avoidance of anesthesia risk is the most substantial, especially for those who have medical comorbidities such as cardiopulmonary disease. Other benefits include a shorter recovery from anesthesia, shorter procedure times, and reduced cost to the medical system. Disadvantages of office-based procedures include patient discomfort, increased difficulty in treating the vocal fold because of movement, decreased reliance on biopsy for operative decision making, a potential increase in the total number of procedures for a given patient as a consequence of the ease of procedure administration, and perhaps decreased efficacy in comparison with operating room-based procedures.

The lasers in the other broad class used in laryngology are those that target water, such as the carbon dioxide laser and the thulium laser. These are better cutting instruments and have better hemostatic properties. They tend to generate more heat,

Fig. 95.4 Wavelengths of common laryngeal lasers. Nd:YAG, neodymium:yttrium-aluminum garnet; UV, ultraviolet.

Table 95.2 Common laryngeal lasers

Laser	Wavelength (nm)	Target chromophore	Delivery system
Potassium titanyl phosphate (KTP)	532	Oxyhemoglobin	Fiber-optic
Pulsed dye	585	Oxyhemoglobin	Fiber-optic
Neodymium:yttrium-aluminum garnet (Nd:YAG)	1,064	Oxyhemoglobin	Fiber-optic
Thulium (Tm)	2,013	Water	Fiber-optic
Holmium (Ho)	2,150	Water	Fiber-optic
Carbon dioxide (CO ₂)	10,600	Water	Mechanical arm or photonic mirrored fiber

which causes tissue ablation instead of involution. Although at times desirable, this feature can lead to greater heat transfer and an increased thermal effect on surrounding tissues, with the potential for increased scarring and fibrosis after treatment in comparison with the pulsed 500-nm lasers discussed previously.

The lasers that target water serve as excellent tools for the treatment of diseases such as recurrent respiratory papillomatosis and stenosis of the larynx or trachea, and for the resection of benign and malignant neoplasms. The most widely used laser in this class is the carbon dioxide laser. It is still used primarily in the operating room and delivered via a mechanical arm with articulating mirrors. Because it is in the invisible spectrum, a second coaxial helium-neon laser is used as an aiming beam. The beam is aimed with a micromanipulator hand piece attached to the microscope. This allows the precise delivery of carbon dioxide laser energy to a given lesion. The carbon dioxide laser is an excellent tool for laryngeal surgery but is limited in that it must be delivered in the direct line of sight. Recently, a new mirrored fiber delivery system has been developed that allows “fiber”-based delivery of the carbon dioxide laser.

Another recent advancement in carbon dioxide technology has come in the form of the AcuBlade (Lumenis, Yokneam, Israel), a robotic delivery system for carbon dioxide laser microsurgery. The device enables the surgeon to create an incision of varying length, shape, and depth, so that energy can be delivered in a uniform distribution along the length of an incision and a user is prevented from inadvertently incising too deeply. Proponents cite reduced surgical times, improved precision, less collateral tissue damage, and patient safety as benefits of the AcuBlade.

The thulium laser has effects on tissue similar to those of the carbon dioxide laser, but there is some experiential evidence that hemostasis is improved because of a greater thermal effect on tissue adjacent to ablated regions. The thulium laser is an extremely effective device for tissue ablation and cutting. Because it is delivered via a fiber, it can be used in the office as well as in the operating room.

95.3.1 Laser Safety, Risks, and Adverse Events

The use of lasers in both the office and the operating room requires that protective measures be taken for patients, physicians, and staff. All lasers require that staff and patients protect their eyes with glasses or goggles that are specific to the wavelength. For patients undergoing general anesthesia, all exposed skin in the perioral and facial region should be covered with moist towels, and eye protection should include the placement of moistened eye pads, ideally covered by paper tape.

Lasers have the potential to ignite combustible gas and plastic polymers. For this reason, to prevent fires, a laser-safe endotracheal tube should be used that consists of a metal-guarded tube or a polymer tube wrapped in metallic foil. The endotracheal tube balloon should be protected by placing a saline-soaked pledget in the subglottis, and the FiO₂ should be kept below 30% during laser applications. Should a fire occur, surgeons must be familiar with appropriate airway fire management. The procedure should be halted, gases shut off, and the endotracheal tube removed. If possible, direct visualization of the region allows the removal of remaining burning debris and flammable material. Saline should be flushed into the airway, and rigid bronchoscopy, reintubation, or tracheotomy should be considered to secure the airway.

95.4 Roundsmanship

- Lasers rely on photons to deliver energy to tissue.
- Optical amplification is necessary to achieve stimulated emission of radiation.
- Relevant chromophores in laryngology include oxyhemoglobin and water.
- The concept of selective photothermolysis is key in choosing lasers for laryngology procedures.
- Initial management of an airway fire includes turning off the gas and removing the endotracheal tube.

96 Tracheo-Esophageal Puncture

Melda Kunduk and Andrew J. McWhorter

96.1 Rationale and Goals

Total laryngectomy is the definitive operation for malignancy of the larynx. It has evolved since its introduction by Billroth in 1873 but remains challenged by the functional deficits that it entails. Loss of oral communication is the greatest and most isolating of these deficits. Restoration of voice requires re-creation of a system with a generator, vibrator, and resonator. The three commonly used systems today are esophageal speech, artificial laryngeal speech, and tracheo-esophageal speech. In all three approaches, the pharyngoesophageal segment is used as the vibratory tissue to replace the vocal folds, and the resonator remains the pharynx, mouth, and nose. Esophageal speech requires regurgitation of air as the generator. It is a difficult technique to master and often requires extensive rehabilitation. The artificial larynx uses an external vibratory source such as an electrolarynx. It is limited by its mechanical sound quality with poor pitch modulation. Tracheo-esophageal speech has the advantage of restoring lung-driven speech that follows the normal cadence of respiration. There is typically greater volume and more voice modulation with tracheo-esophageal speech than with the other two methods.

Multiple procedures were originally developed by Conley and many others to create a mucosal shunt from the tracheostoma into the esophagus, but none was reliable enough to become widely used. Similarly, early attempts to deliver air into the esophagus with a diverse array of prostheses met with limited success. Drawing on an original description by Guttman, who reported a butcher who had fistulized himself with an ice pick and maintained a tracheo-esophageal fistula directly through the parting wall, Singer and Blom developed a technique as well as a prosthesis to create a safe fistula that restored voice in 90% of their patients. This technique was further enhanced by the

development of more technologically advanced prostheses that provided a well-tolerated pathway and protected the airway from esophageal contents. Many developments have expanded on the original description of Singer and Blom, but all are based on the same principle in regard to both the procedure and the prosthesis.

96.2 Technique

The posterior membranous tracheal wall is visible through the stoma and lies below the level of the cricopharyngeus in the proximal cervical esophagus. The tracheo-esophageal puncture is a controlled fistula through this parting wall. It can be performed at the time of laryngectomy (primary) or at a later date (secondary). The primary puncture is performed following removal of the larynx and before closure of the pharynx. A fine, right-angle clamp is placed into the proximal cervical esophagus through the open pharynx from the laryngectomy defect. An incision is made over the clamp 1 to 1.5 cm below the superior border of the posterior tracheal wall in the stoma. A 14F to 16F red rubber catheter is then inserted, passed inferiorly, and secured (□ Fig. 96.1). Alternatively, kits are available with which a measurement is made and the prosthesis is placed.

The original technique described by Singer and Blom was a secondary puncture. As originally described, rigid esophagoscopy is performed, and ballottement of the posterior membranous wall of the trachea is performed at the planned site for puncture within the stoma. After the position has been confirmed by visualization through the scope, the scope is turned 180 degrees so that the more distal lip sits posteriorly and protects the posterior esophageal wall. A needle is placed through the membranous tracheal wall into the esophagus. This

Fig. 96.1 Primary tracheo-esophageal puncture. (a) Incision over right angle passed through pharynx into proximal cervical esophagus. (b) Right-angle tips visible 1.5 cm below superior margin of the posterior tracheal wall. (c) Passing the catheter into the esophagus. (d) Advancement of the catheter into the pharynx. (e) Redirection of the catheter inferiorly into the distal esophagus. (f) Completed puncture with the catheter in position. (Courtesy of A. M. Pou and R. C. Hamaker.)

Fig. 96.2 Secondary tracheo-esophageal puncture with transnasal esophagoscope. (a) Patient is seated with the esophagoscope in position and the hemostat dilating the fistula puncture. (b) Patient with the prosthesis in place after sizing, visible at the stoma and in the esophagus on video monitor.

tract is then enlarged, and a catheter or prosthesis is placed. In a patient who has been irradiated or a patient with difficult access, rigid esophagoscopy can be difficult to perform. Flexible esophagoscopy can be used in a similar manner, with care taken to avoid injury to the posterior esophageal wall as the scope is not protecting it. Koch described using a Seldinger technique with a peel-away catheter, like those used in vascular access procedures. This facilitates placement of the catheter inferiorly, and it is rapid and easy to perform.

Alternatively, a secondary puncture can be performed in the office in an awake patient. Some instruments have been developed to facilitate this, but none has had a greater impact than the transnasal esophagoscope. The procedure was originally described in 2003 by Bach et al. It has the advantage of visualization similar to that of the operating room approaches, but with the added benefit of the patient being awake and upright. This prevents gravity from collapsing the esophagus, and air insufflation and patient swallowing open the esophagus for improved visualization. The patient is seated upright in the examination chair, and the posterior membranous trachea is injected with local anesthetic at the planned puncture site within the stoma. Typically, 1 to 2 mL of 1% lidocaine with 1:100,000 epinephrine is used. The technique is otherwise the same as the secondary puncture in the operating room, with either a needle or a stab incision performed following ballottement and confirmation of position with the transnasal esophagoscope in the proximal esophagus. Again, either a catheter or a prosthesis can be placed at this time (□ Fig. 96.2). This technique has proved to be a successful and reliable way to create a tracheo-esophageal puncture. It is even applicable in patients with complex pharyngoesophageal defects repaired with free flap and gastric pull-up reconstructions. □ Fig. 96.3 demonstrates the step-by-step performance of the procedure as seen from the esophageal lumen.

Successful tracheo-esophageal voice creation does not depend only upon the puncture; it can be enhanced with other

recommended preparatory steps for alaryngeal voicing. The performance of a unilateral pharyngeal plexus neurectomy or an inferior constrictor–cricopharyngeal myotomy at the time of laryngectomy has been popularized by Hamaker and repeatedly demonstrated to be very beneficial in the acquisition of good tracheo-esophageal voice. Both of these procedures allow the patient to have better reflux of air with less resistance for voicing. A neurectomy should not be performed bilaterally because it will result in an adynamic pharynx with increased dysphagia and a hollow voice. If a myotomy and a neurectomy are both performed, they should be ipsilateral. Similarly, the creation of an accessible stoma enhances the acquisition of hands-free speech by facilitating the use of an appliance for hands-free speech as well as finger occlusion. Suspending the trachea to the sternal or clavicular periosteum helps by reducing downward pull on the stoma. Release of the sternal heads of the sternocleidomastoid muscle flattens the anterior neck, effectively bringing the stoma forward. Addressing the pharynx and the stoma with these important steps is the key to the successful acquisition of tracheo-esophageal speech; they are more important than the puncture itself.

96.3 Risks and Adverse Effects

The only contraindication to performing the procedure as a primary puncture is separation of the parting wall. Separation can be suture-bolstered but carries an unwarranted increased risk for leak and infection. There are no contraindications to secondary puncture as long as the stoma and esophagus are accessible and patent. Microstomia and esophageal stricture should be addressed before puncture. There are, however, patients who are poor candidates for tracheo-esophageal speech. Lack of dexterity or visual acuity may limit the patient's ability to care for the prosthesis. Similarly, poor cognition or unfavorable social circumstances may prevent the patient from managing the continued care required for prosthesis and voice maintenance.

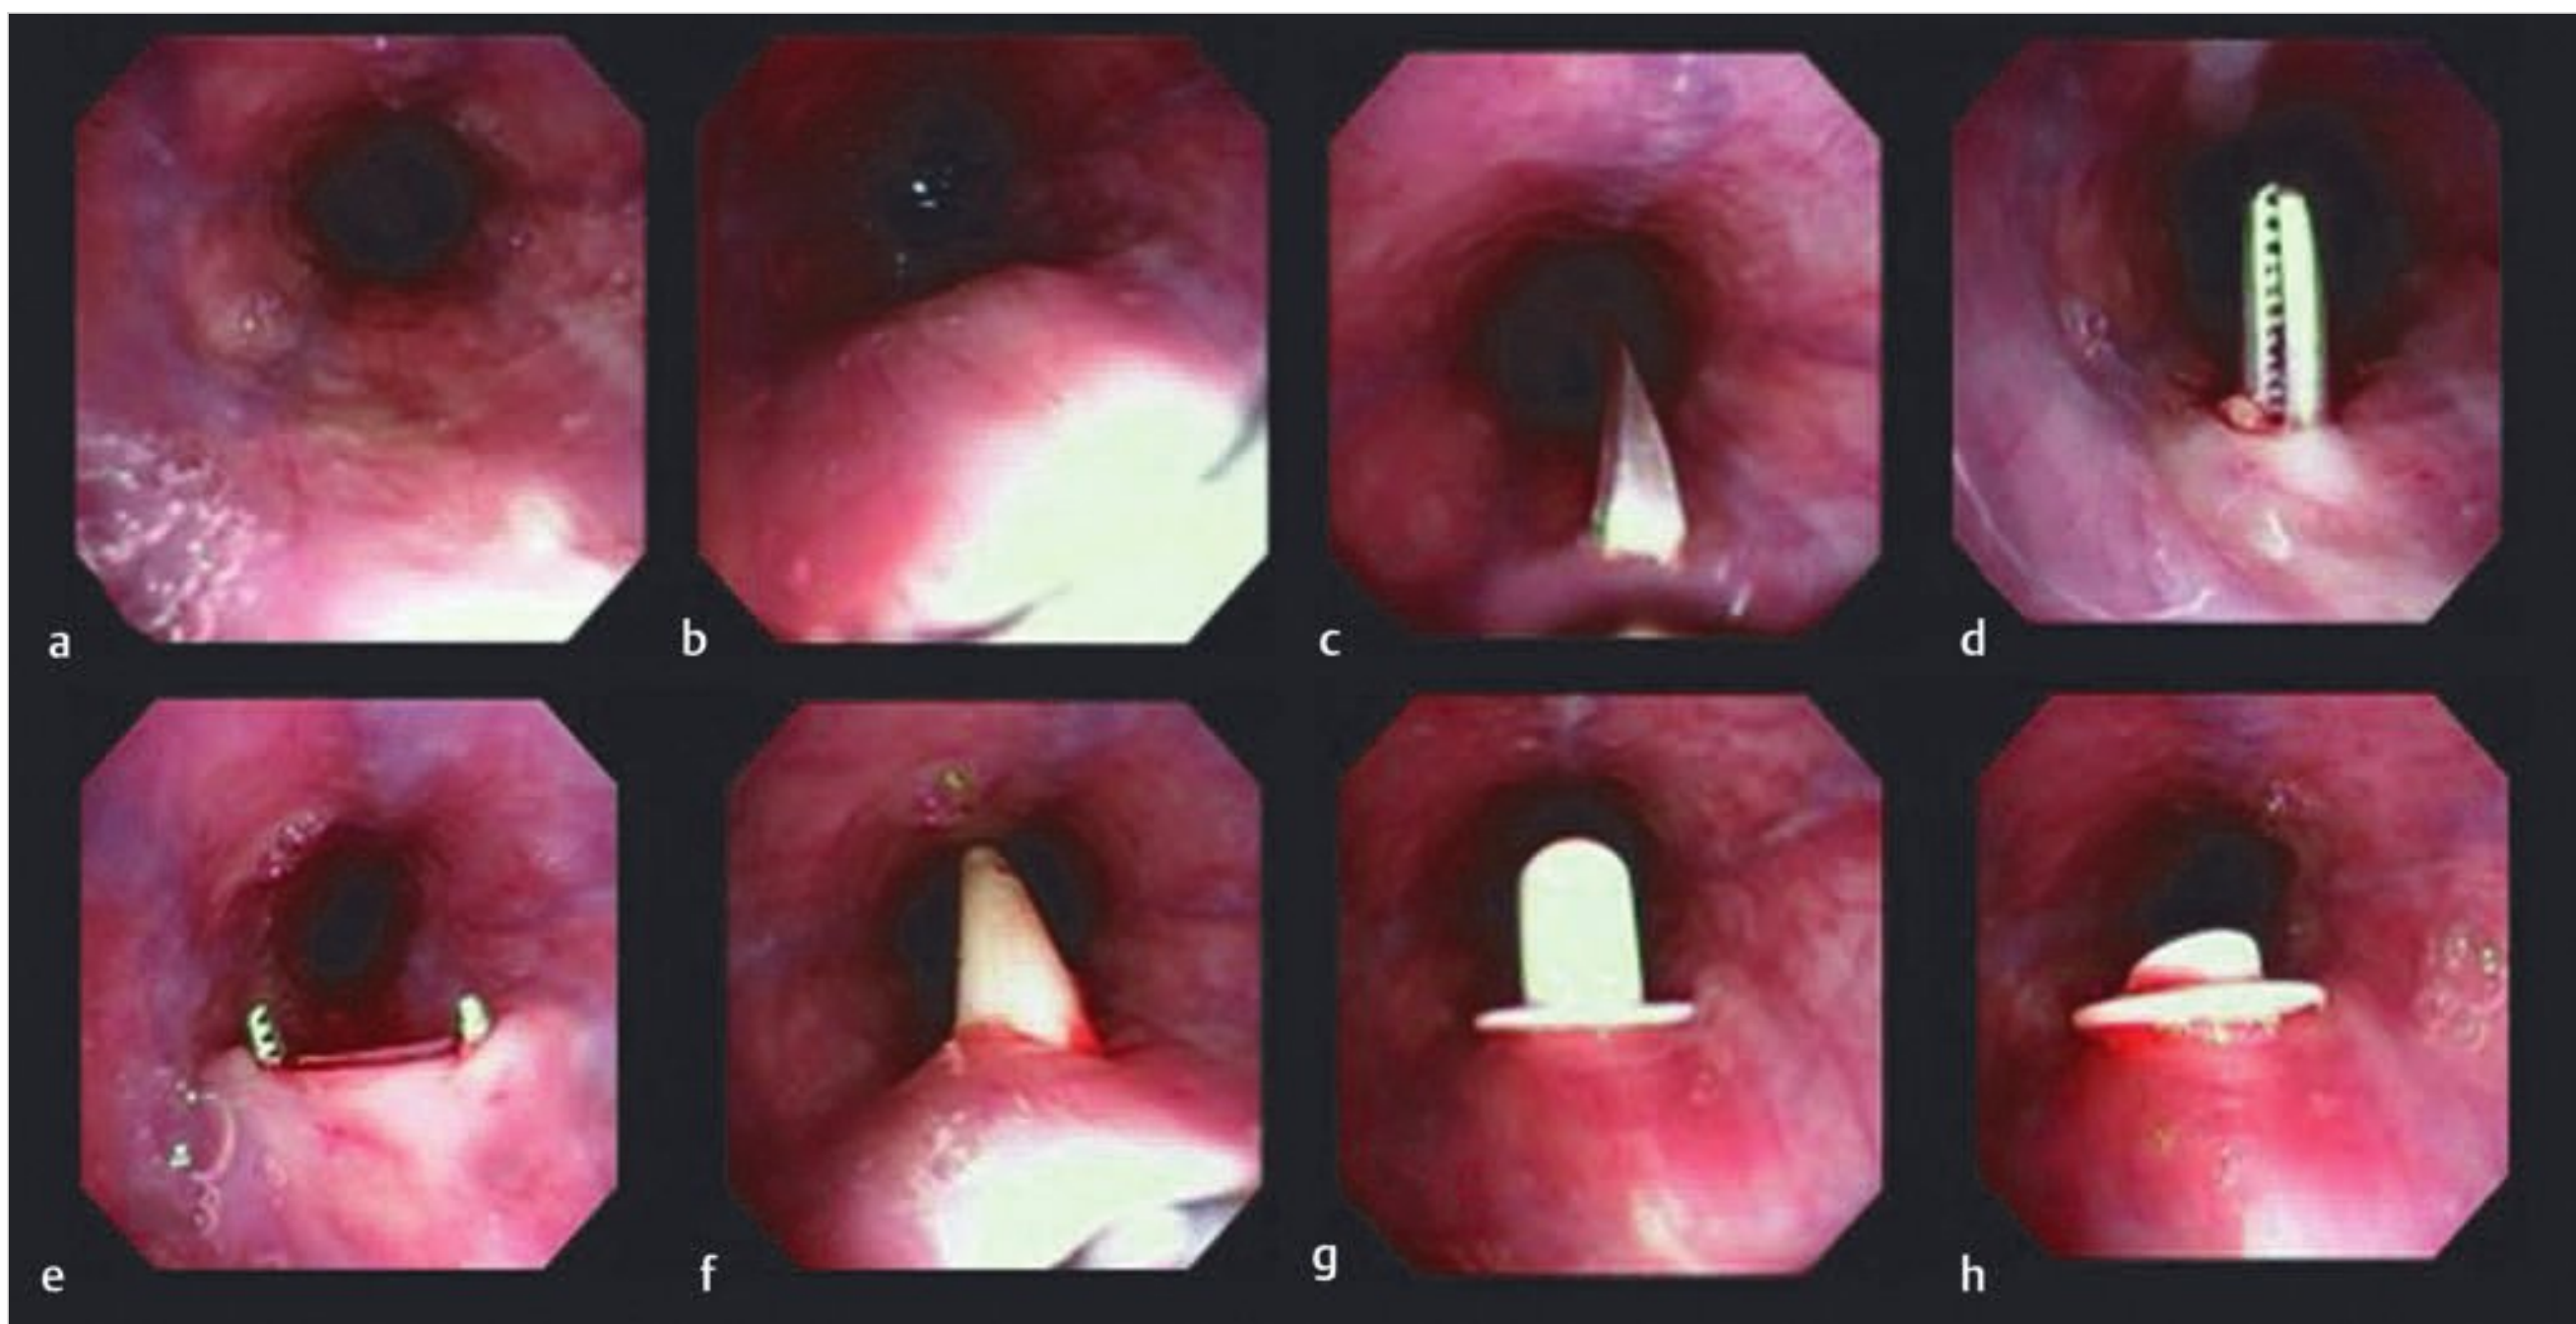

Fig. 96.3 Secondary tracheo-esophageal puncture with transnasal esophagoscopy view. (a) Proximal cervical esophagus. (b) Confirmation of position, with indentation visible. (c) No. 11 blade incision. (d) Placement of hemostat through incision. (e) Dilation of tract with spread of hemostat. (f) Placement of dilator through fistula. (g) Measurement of length of fistula tract with sizer. (h) Prosthesis in position.

Controversy initially existed as to the timing of the puncture. It was generally accepted that primary puncture had a better voice outcome, but other authors have demonstrated that when planned for properly, secondary puncture is equivalent to primary puncture. There are pros and cons to both approaches. Primary puncture can provide access for a feeding tube without the need for a nasogastric or gastric tube. It does require additional procedures aside from prosthesis placement. The prosthesis length is more likely to change with primary than with secondary puncture as the tissues mature in the healing process. Alternatively, secondary puncture allows exact placement of the fistula following healing and maturation of the stoma, especially in the setting of postoperative radiation. Some studies have suggested that after chemoradiation and salvage total laryngectomy, tracheo-esophageal puncture should be performed secondarily because of the potentially increased risk for pharyngocutaneous fistula with primary puncture.

In the perioperative period, the risks of the procedure are low. The most dangerous, although thankfully rare, risk is mediastinitis. Infection at the puncture site with parting wall abscess has been described, but the most common complication is dislodgement of the prosthesis or catheter with loss of the fistula.

More significant are the problems associated with voice acquisition and maintenance of the fistula on a long-term basis. Close teamwork with the speech–language pathologist is essential in assisting patients with both voice and prosthesis management. Pharyngoesophageal spasm is the greatest barrier to the acquisition of fluent speech. This should be a rare occurrence and is typically avoidable with the performance of a primary pharyngeal plexus neurectomy or cricopharyngeal my-

otomy. The spasm is clinically suspected but can be confirmed through fluoroscopy or endoscopy while the patient is voicing. Secondary neurectomies and myotomies can be performed. A less invasive alternative is botulinum toxin A injection into the pharyngoesophageal segment. This is highly effective, and the result may be permanent. Most common are problems with the prosthesis, such as dislodgement, potential foreign body aspiration, and prosthesis failure, which is usually secondary to fungal overgrowth. The patient should be trained to manage dislodgement with replacement of a prosthesis or a catheter into the fistula. A foreign body is easily managed through the immediately accessible stoma. Fungal overgrowth is the most common cause of prosthesis failure and leak due to loss of the valve competence (□ Fig. 96.4).

Most troublesome are the problems associated with the fistula itself, especially thinning of the parting wall or enlargement of the fistula tract, creating peri-prosthesis leakage and aspiration. Close teamwork with the speech pathologist is invaluable. Downsizing the tract with a smaller catheter or a prosthesis with a larger posterior flange is the least invasive management alternative. Suture tightening of the fistula tract can be successful, as can the injection of collagen around the prosthesis. These problems can be difficult to manage and may require closure of the fistula with repuncture after healing.

Tracheo-esophageal puncture provides a safe and reliable method for voice restoration following total laryngectomy. Although multiple adjustments are necessary for the patient without a larynx, effective communication is most important to quality of life. Rehabilitation with the speech–language pathologist eases this transition and should be initiated in the preoperative period. Primary versus secondary puncture is less important in voice acquisition than are pharyngoesophageal segment

Fig. 96.4 Fungal overgrowth (arrow) on a tracheo-esophageal prosthesis causing valve failure from incomplete closure, as seen on transnasal endoscopy.

preparation with myotomy or neurectomy and appropriate stoma creation.

96.4 Roundsmanship

- Tracheo-esophageal puncture can be performed as a primary or secondary procedure with equal success.

- Primary puncture has the advantage of providing alternative access for feeding, but the prosthesis length is likely to change.
- The only contraindication to primary puncture is separation of the parting wall at the time of surgery.
- Secondary tracheo-esophageal puncture can be performed easily in the office under local anesthesia with transnasal esophagoscopy.
- The key to successful tracheo-esophageal voice acquisition is appropriate patient preparation with pharyngoesophageal myotomy or pharyngeal plexus neurectomy and appropriate stoma creation.

97 Evaluation and Management of Esophageal Disorders

Catherine Rees Lintzenich and Kristin K. Marcum

97.1 Introduction

Esophageal disorders are common in the general population, and patients with associated symptoms frequently present to the otolaryngologist. Symptoms may include dysphagia, throat pain, globus sensation, heartburn, and regurgitation. Esophageal disorders account for the majority of swallowing complaints in young adults and a large proportion of swallowing complaints in older adults.

97.2 Esophageal Anatomy

The esophagus is a muscular conduit connecting the pharynx to the stomach for the transport of food. The normal esophagus is approximately 26 cm in length. It begins at the lower border of the cricoid cartilage opposite the transverse process of C6 and ends at the level of T10. At an early period in fetal development, the stomach is separated from the pharynx by the esophagus, which begins as a foregut structure. The future esophagus extends from the pharyngeal tube as far caudally as the liver outgrowth. By the end of the third week of development, the primitive foregut develops a ventral diverticulum from which the tracheobronchial tree develops. As a result of ingrowth by two lateral septa, the tracheo-esophageal septum gradually partitions this diverticulum, resulting in the formation of an anterior respiratory primordium and a posterior esophagus. During the fourth and fifth weeks of development, growth of the heart and liver allows the esophagus to stretch. As the esophagus elongates, its lumen is nearly completely obliterated, and recanalization occurs by week 8 to 10.

The mature esophagus is a collapsed tube beginning at the upper esophageal sphincter (UES) and coursing through the diaphragmatic hiatus at the lower esophageal sphincter (LES). The UES is more aptly described as the pharyngoesophageal segment because it is made up of the cricopharyngeus muscle, part of the inferior pharyngeal constrictor, and the most superior portion of the longitudinal esophageal muscular fibers. The cricopharyngeus muscle is a sling-shaped muscle arising from the posterior cricoid cartilage; it is tonically contracted, opening for swallowing and belching. The LES has a normal resting tone of 10 to 40 mm Hg and is normally positioned at or just below the diaphragm. The LES is not a true anatomical sphincter and is reinforced by the crura of the diaphragm. The esophagus comprises four layers: the mucosa, including stratified squamous epithelium, the lamina propria, and the muscularis mucosae; the submucosa; the muscularis propria; and the adventitia. The muscularis propria consists of proximal skeletal muscle and distal smooth muscle, which are arranged as inner circular muscle and outer longitudinal muscle. The cervical esophagus is composed primarily of striated muscle, and the distal two-thirds of the esophagus is composed of smooth muscle. A section consisting of mixed striated and smooth muscle between these areas is known as the transition zone. The innermost mucosal layer changes from nonkeratinized stratified squamous epithelium to columnar epithelium at the squamocolumnar

junction. The squamocolumnar junction can be recognized from the irregular Z-line separating the light pink esophageal squamous mucosa and the darker pink columnar gastric mucosa (□ Fig. 97.1). The gastroesophageal junction is defined by the proximal margin of the gastric folds and the termination of the esophageal linear blood vessels. The squamocolumnar junction and gastroesophageal junction are normally located at the same level; however, the two are not one and the same. In patients with Barrett esophagus, the squamocolumnar junction is more proximal in the esophagus than the gastroesophageal junction, and in patients with a hiatal hernia, the gastroesophageal junction is more proximal than the diaphragmatic indentation.

The esophagus is innervated by both sympathetic and parasympathetic chains. There is also intrinsic innervation of the esophagus via nerve plexus. The Auerbach (myenteric) plexus is found between the circular and longitudinal muscles and functions to mediate intrinsic motor control of the esophagus. The Meissner plexus is within the submucosa and innervates the muscularis mucosae and secretory glands.

Swallowing begins when a food bolus is propelled into the pharynx from the mouth. The initiation of the swallow is voluntary, but the pharyngeal and esophageal phases that follow are involuntary. During ingestion of a meal, the pharyngeal constrictors contract, the UES relaxes, and distention of the proximal striated muscle initiates primary peristalsis. A rapidly progressing pharyngeal contraction then transfers the bolus through the relaxed UES into the esophagus, coordinated by the medullary swallowing center. As the UES closes, a progressive circular contraction begins in the upper esophagus and proceeds distally along the esophageal body to propel the bolus through the relaxed LES. Peristaltic pressures normally ranging from 30 to 180 mm Hg are generated. The LES subsequently closes with a prolonged contraction, preventing movement back into the esophagus. The mechanical effect of peristalsis is a stripping wave, so called because it strips the esophagus clean from its proximal to its distal end. Esophageal distention signals

Fig. 97.1 Normal squamocolumnar junction.

secondary peristalsis to clear any remaining food. Finally, tertiary peristalsis consists of nonperistaltic contractions that may occur spontaneously or after swallowing.

Both the UES and LES are tonically contracted at rest. The closed state of the UES is primarily the result of continuous neural excitation. The resting state of contraction of the UES assists in preventing regurgitation and aspiration. It is believed that the tonic contraction of the LES is a function of the muscle itself and not dependent on neural effects. The stimulation of inhibitory fibers results in LES relaxation. The resting tone of the LES is typically between 15 and 45 mm Hg and is affected by a wide array of events, foods, drugs, and hormones. LES relaxation occurs not only in response to swallowing but also in response to esophageal distention.

97.3 Diverticula

Esophageal diverticula are small pouches or sacs in areas of weakness created by herniation of the lining of the esophagus through the muscular wall. True diverticula include all three layers of the esophagus, whereas in false diverticula, the mucosa and submucosa herniate through the muscular wall. The most common type of diverticulum is a Zenker diverticulum, which is a (false) pharyngoesophageal pulsion diverticulum typically associated with an underlying motility disorder and/or cricopharyngeal dysfunction. A Zenker diverticulum occurs proximal to the UES in the hypopharynx and involves the Killian triangle between the cricopharyngeus muscle and the raphe of the inferior pharyngeal constrictor muscles. A Killian-Jamieson diverticulum protrudes through a muscular gap (Killian-Jamieson triangle) in the anterolateral wall of the cervical esophagus inferior to the cricopharyngeus, superior to the circular muscle of the esophagus, and lateral to the longitudinal muscle of the esophagus. Killian-Jamieson diverticulum also has been called lateral cervical esophageal diverticulum. Zenker diverticulum is felt to be associated with chronic cricopharyngeal dysfunction and/or reflux. Symptoms include dysphagia, regurgitation, malodorous breath, cough, and aspiration. Zenker diverticulum is most readily diagnosed on fluoroscopic esophagram (□ Fig. 97.2), although it may be seen on esophagoscopy at times. For symptomatic diverticula, endoscopic or open treatment can be performed, including a complete cricopharyngeal myotomy. For endoscopic diverticulotomy, the cricopharyngeal muscle is divided completely with a laser or surgical stapler device, effectively marsupializing the pouch so that it no longer collects food or saliva. In an open diverticulectomy, complete excision of the pouch is performed along with a cricopharyngeal myotomy (see Chapter 98 for further discussion of Zenker diverticulum).

97.4 Embryologic Disorders

Several esophageal disorders are a direct result of embryologic development disorders. The most common congenital anomalies are esophageal atresia and tracheo-esophageal fistula, which often present together as a result of failure of recanalization of the embryonic esophagus. The most common scenario is a distal tracheo-esophageal fistula and proximal atresia. Other, less common congenital abnormalities include esophageal

Fig. 97.2 Zenker diverticulum esophagram.

duplication cyst, which may present as a neck mass, and dysphagia lusoria, which is caused by compression of the esophagus by an anomalous retroesophageal right subclavian artery. Dysphagia lusoria is often associated with a nonrecurrent laryngeal nerve, and it may not present until middle age, when vessel elasticity is compromised. Children with tracheo-esophageal fistula may present very early in life with feeding difficulties, drooling, or respiratory distress. These children need to be evaluated for comorbidities because as many as 50% of them may have a cardiac or other abnormality. Radiographs may demonstrate a large amount of air in the stomach and proximal intestine. There may be inability to pass a nasogastric tube past 9 to 13 cm from the nares. Treatment for tracheo-esophageal fistula or atresia is urgent surgical repair in the newborn child. Dysphagia lusoria may be diagnosed by esophagram revealing a pulsatile horizontal bar at the obstruction site.

97.5 Cricopharyngeal Dysfunction

Cricopharyngeal dysfunction results from abnormal relaxation of the cricopharyngeus muscle and/or abnormal coordination between the pharynx and cricopharyngeus. Laryngopharyngeal

Fig. 97.3 Cricopharyngeal bar.

reflux may contribute to cricopharyngeal dysfunction when chronic acid irritation triggers a neural reflex to increase UES pressure. The symptoms can be hard for patients to localize but are typically at the level of the cricoid cartilage or the suprasternal notch. Globus sensation and the sensation of effortful swallow or food sticking in the throat are common. Patients may describe a “choking” sensation, as well. It is very important to rule out distal esophageal problems in the presence of cricopharyngeal abnormalities because the cricopharyngeal dysfunction may be the result of compensation for a more distal esophageal problem. On fluoroscopic studies, the cricopharyngeus may appear prominent, looking like a “bar” during deglutition (□ Fig. 97.3). Cricopharyngeal manometry is the best test for confirming cricopharyngeal dysfunction. The treatment of this region includes swallowing therapy, dilation, botulinum toxin injection, or cricopharyngeal myotomy (see Chapter 98 for further discussion of cricopharyngeal dysfunction).

97.6 Infectious and Inflammatory Disorders

There are many causes of nonspecific esophagitis that may present as heartburn or odynophagia. The most common infectious cause of esophagitis is *Candida albicans*. Patients often present with pain and dysphagia and are at increased risk if immunocompromised or on long-term antibiotics. Examining the oral cavity is not sufficient because esophageal candidiasis can present without findings of fungus in the oral cavity or pharynx. The fungal infection is suspected when white plaques with an erythematous base are seen on esophagoscopy (□ Fig. 97.4). Treatment includes topical or systemic antifungals. Topical treatment may begin with nystatin swish and swallow (400,000 to 600,000 units four times daily or clotrimazole troches (one 10-mg troche dissolved slowly five times daily). With topical agents, successful therapy depends on adequate contact time between the agent and the oral mucosa. If the

Fig. 97.4 *Candida* esophagitis.

patient does not respond to these local measures, the preferred therapy is oral fluconazole. A minimal starting dose is a 200-mg loading dose, then 100 to 200 mg daily for 14 to 21 days. When this treatment fails, biopsy with fungal culture should be performed.

Pill-induced esophagitis can cause punctate ulcerations that form as a result of prolonged contact of the esophageal mucosa with medications. The mechanism of pill-induced esophagitis is felt to involve delayed transit of the medication through the esophagus and local chemical irritation. Some of the more common offenders include tetracyclines, potassium chloride, doxycycline, aspirin, and bisphosphonates. Risk factors for pill-induced esophagitis include improper administration of medications (e.g., ingestion of the pill with inadequate volumes of fluid and/or taking medications just before lying down). The extent of injury caused by pill-induced esophagitis can range from superficial inflammation to deep ulceration and stricture formation. In general, pill-induced esophageal injuries heal without intervention within a few days, but avoiding the injurious drug is paramount. All medications should be converted to a liquid form, if possible, while the esophagus is healing. Acid suppression may be a useful adjunct treatment. A suspension of sucralfate may serve to layer a protective coating on the esophageal mucosa and promote healing. Patients should be instructed to remain upright and to drink copious amounts of water after taking the medication. For the patient who is unable to eat or drink because of severe odynophagia, a temporary period of parenteral hydration or alimentation may be required.

Eosinophilic esophagitis is an uncommon disorder of esophageal inflammation. According to an American Gastroenterological Association (AGA) consensus panel, eosinophilic esophagitis is a clinicopathologic disease characterized by the following: (1) symptoms including but not restricted to food impaction and dysphagia in adults; (2) feeding intolerance and symptoms of gastroesophageal reflux disease (GERD) in children; and (3) the presence of 15 or more eosinophils per high-power field on esophageal mucosal biopsy. The cause of the disorder is unknown, but it is increasingly diagnosed and has been linked to allergies. Two main hypotheses have been proposed to explain the pathogenesis of eosinophilic esophagitis. The first holds that

Fig. 97.5 Eosinophilic esophagitis. Note the mucosal edema, longitudinal furrows, “crepe paper mucosa,” and white exudate.

a response to a food or an allergen triggers cytokine production. Recent studies exploring elemental diets in children have found that these diets can lead to a complete resolution of esophageal eosinophilia, confirming that food allergies are related to eosinophilic esophagitis in at least some patients. The second theory holds that GERD causes peptic damage to the epithelial tight junctions, which leads to increased permeability and subsequent recruitment of inflammatory cells, especially eosinophils. One of the consensus diagnostic criteria is the presence of 15 or more eosinophils per high-power field on biopsy. The esophageal mucosa is unique in the gut because it is normally devoid of any resident eosinophils. However, eosinophils accumulate in disease states such as GERD, Crohn disease, collagen vascular disease, connective tissue diseases, and drug-associated esophagitis. Therefore, a careful work-up to rule out existing conditions must be made before eosinophilic esophagitis can be diagnosed. The differential diagnosis in these cases must take into consideration the patient’s history, clinical presentation, endoscopic features, and precise enumeration of eosinophils per high-power field. Adults with eosinophilic esophagitis usually do not have elevated eosinophil or immunoglobulin E levels in peripheral blood smears. Adults classically present with dysphagia to solids, food impaction, or strictures. Endoscopy may reveal trachealization of the esophagus with a ringed appearance; however, the esophagus may look normal, and therefore a high index of suspicion is warranted. The endoscopic features of eosinophilic esophagitis include longitudinal furrowing, friability, edema, longitudinal shearing, raised white lesions, whitish exudates, “crepe paper mucosa,” a narrow esophagus, and transient or fixed rings (□ Fig. 97.5). In the review by the AGA panel, 86% of patients were found to have rings, strictures, or a narrow esophagus. Although none of these features can be classified as pathognomonic, in the appropriate clinical context, the presence of more than one of these findings is strongly suggestive of the diagnosis. After endoscopy and biopsy, the treatment options include ingested or topical steroids, allergy evaluation, and elimination trials. Caution is advised during esophagoscopy because patients with eosinophilic esophagitis are prone to superficial lacerations and are at higher risk for esophageal perforation.

Polymyositis is a type of muscle weakness due to inflammation and degenerative changes in striated muscle. Proximal muscle weakness in the shoulder and hips is the most common presenting symptom. When associated with skin rashes, the disorder is termed dermatomyositis. Peristalsis is diminished and poorly coordinated, and the esophagus may be dilated. Manometry reveals decreased UES pressure and reduced peristaltic waves. The goals of treatment are to improve muscle strength and to avoid the development of extramuscular complications. In patients with dermatomyositis, resolution of the cutaneous manifestations is an additional goal. Patients with polymyositis are generally referred to rheumatology for an immunologic work-up and treatment. Treatment generally consists of glucocorticoids; other treatment options can include azathioprine or methotrexate. Patients may be on systemic steroid therapy for as long as a year.

GERD is the backward flow of gastric contents into the esophagus and overall the most common cause of inflammatory esophagitis. Further backward flow into the pharynx is known as laryngopharyngeal reflux (LPR), or extraesophageal reflux. Typical symptoms of GERD include regurgitation, heartburn, and chest pain. Symptoms of LPR include dysphagia, intermittent dysphonia, throat clearing, globus sensation, and cough. The mechanism of GERD is related to transient inappropriate LES relaxations and gastric distention. The mechanism of LPR is less well understood but may involve inappropriate UES relaxation, as well. Refluxate may consist of food, gas, stomach acid, bile acids (bile reflux), or esophageal contents (esophagopharyngeal reflux). Esophageal injury from reflux may manifest as erosive esophagitis (□ Fig. 97.6) or peptic stricture. Endoscopic changes in the mucosa of the esophagus are not required for the diagnosis of reflux (nonerosive reflux disease). Reflux is frequently seen in the setting of a hiatal hernia. Prolonged GERD predisposes to Barrett esophagus and adenocarcinoma. However, the “spectrum of disease” approach has been challenged by the view that GERD may be a disease with “categories,” such as nonerosive disease, erosive esophagitis, and Barrett esophagus, and that conversion from one disease state to another is distinctly unusual. Data suggest that although GERD may progress in severity, the reported rates of progression are relatively low over a 20-year period. GERD is often evaluated with ambulatory pH monitoring and manometry. Manometry may confirm that the pH probe is in the correct location, as well as evaluate for motility disorders. All proton pump inhibitors should be held before the ambulatory pH monitoring. The AGA recommends that endoscopy with biopsy be performed for patients with GERD and dysphagia who have not responded to an empiric trial of twice-daily proton pump inhibitor therapy. The treatment of reflux includes lifestyle modifications and acid-reducing medications, such as proton pump inhibitors. Proton pump inhibitors do not physically stop reflux; instead, they reduce the acidity of the refluxate (increase the pH). Unfortunately, weakly acidic refluxate or even refluxate with a neutral pH may be injurious to the esophageal lining and cause reflux symptoms.

Barrett esophagus is a potentially serious complication of long-standing GERD. It occurs when the normal stratified squamous epithelium of the distal esophagus has been replaced by intestinal columnar epithelium (metaplasia). Barrett esophagus is the most significant outcome of chronic GERD and a risk factor for esophageal adenocarcinoma. Thus, it is recommended

Fig. 97.6 Erosive esophagitis.

that patients with prolonged GERD symptoms, especially middle-aged white men, undergo endoscopic screening for Barrett esophagus. If Barrett esophagus is confirmed, these patients require continued endoscopic surveillance to detect the development of dysplasia and adenocarcinoma. The risk for esophageal adenocarcinoma in Barrett esophagus is approximately 0.5% annually, but the risk increases substantially in patients with longer (>3 cm) affected esophageal segments and with high-grade dysplasia. The goal of surveillance is to detect cancer at an earlier and potentially curable stage. Endoscopic surveillance guidelines suggest four-quadrant biopsies at 2-cm intervals along the entire affected length of the esophagus at varying time periods depending on the presence or severity of dysplasia.

97.7 Trauma

Esophageal injuries may be iatrogenic or induced. Mallory-Weiss tear is an incomplete tear of the esophageal mucosa and laceration of submucosal arteries resulting from increased abdominal pressure. It is commonly associated with retching in alcoholics and may present as upper gastrointestinal bleeding. In Boerhaave syndrome, increased abdominal pressure causes all three layers of the esophagus to rupture; patients have severe symptoms of hematemesis, chest pain, and hypovolemic shock. Esophageal perforations, whether due to trauma or instrumentation, including endoscopy and nasogastric tube placement, should all be considered otolaryngologic emergencies. In patients at risk for esophageal perforation, tachycardia, chest pain, dysphagia, or dyspnea should be immediately evaluated.

97.8 Foreign Body Ingestion

Foreign body ingestion is most common in children. Foreign bodies tend to lodge at three areas of natural constriction in the

esophagus: the level of the cricopharyngeus, the aortic arch, and the LES. Patients who have esophageal foreign bodies present with drooling, dysphagia, or dyspnea from compression of the adjacent membranous posterior tracheal wall. Common esophageal foreign bodies include coins, food, toys, and disc batteries. Upon the patient's presentation to the emergency department, both lateral and anteroposterior films should be obtained. If there is a concern for foreign body ingestion by history, physical examination, or imaging findings, the patient should undergo endoscopy. Disc batteries can often be differentiated from coins by the appearance of a small double ring on an anteroposterior film or a slight "step-off" on a lateral film (□ Fig. 97.7). Disc battery damage is predominantly from an external current that causes electrolysis of tissue fluids, generating hydroxide. Any patient who has ingested a disc battery should be taken urgently to the operating room. Airway compromise from esophageal edema has been reported as early as 3 hours after ingestion, and esophageal injury has occurred in patients with a battery lodged for less than 2 hours. The longer the battery has been in the esophagus, the more edematous the mucosa becomes and the more tightly the battery adheres to the mucosa, making extraction more difficult and dangerous. If the battery remains in place, ulceration and perforation can occur. Treatment depends on the extent of injury and parallels that for ingested caustic materials, discussed below. In the case of any suspected esophageal foreign body, general anesthesia with endotracheal intubation is recommended to protect the airway. The otolaryngology team should perform the intubation in the case of a second foreign body in the oropharynx or hypopharynx. After removal of the foreign body, the esophagus should be assessed for underlying pathology, such as stricture. Complications from the removal of foreign bodies are uncommon but may include esophageal perforation and delayed stricture formation.

Fig. 97.7 Note the double ring of a disc battery on anteroposterior view.

97.9 Ingestion of Caustic Materials

Ingestion of caustic materials generally occurs in children but may occasionally also occur in adults, most commonly in psychotic persons, the elderly, or prisoners. Alkaline ingestion causes liquefaction necrosis and more severe damage than acidic ingestion, which causes coagulation necrosis. The coagulum that forms in acid ingestion may help to limit the depth of penetration of the caustic substance. The severity of oropharyngeal and external injury does not always correlate with the severity of esophageal injury. Symptoms include drooling, mouth pain, stridor, chest pain, and abdominal pain. The oral cavity may appear normal, and a normal appearance does not rule out esophageal injury. Injury occurs in stages; within the first 24 hours, a dusky edema develops and ulceration may appear; then, submucosal inflammation occurs over the next few days, followed by a sloughing of the superficial layer at 5 to 7 days. Fibrosis of the deep layers with scar and stricture may develop in 1 to 4 weeks. The general consensus recommends endoscopy within the first 24 to 48 hours of presentation. Delayed evaluation may increase the risk for perforation on endoscopy. Esophageal injury is graded at the time of endoscopy. Grade 1 injury consists of edema and erythema, and patients with grade 1 injury can usually be fed normally and discharged home. Grade 2 esophageal injury consists of linear ulcerations and necrotic tissue with whitish plaques of necrosis. These lesions rarely progress to esophageal stenosis, although some patients may require esophageal dilation. Grade 3 esophageal injury is characterized by circumferential injury, which may be transmural with mucosal sloughing. Patients with grade 3 injury require

Fig. 97.8 Corkscrew esophagram.

placement of a feeding tube under direct vision or intravenous nutrition. Grade 3 injuries carry a higher risk for stricture in the future. The feeding tube not only provides a method for nutrition but also serves as a stent to maintain a lumen during stricture formation. Patients with evidence of grade 4 injury (perforation seen on radiology or endoscopy) have a very poor prognosis and a high fatality rate due to systemic complications. Some grade 3 and most grade 4 injuries will require temporary diversion or esophagectomy. Long esophageal strictures have been reported in up to 40% or more of pediatric patients who have grade 2 or grade 3 injury following an alkali ingestion. In 80% of the patients in whom strictures ultimately develop, the strictures develop within 8 weeks after the ingestion. Corticosteroids are controversial; some authors report benefit for grade 2 or 3 injuries, but most authors opine that steroids do not decrease the rate of stricture. Charcoal, gastric lavage, and emetics are contraindicated. The induction of vomiting is contraindicated because vomiting may lead to additional esophageal injury if the gastric contents come in contact with the esophageal mucosa. Diluting or neutralizing agents are not effective in preventing esophageal injury and may lead to vomiting.

97.10 Esophageal Motility Disorders

Motility disorders may be classified as hypo- or hyperkinetic disorders. Hyperkinetic motility disorders include nutcracker esophagus and distal esophageal spasm, both of which usually present with noncardiac chest pain. The diagnostic work-up includes manometry with an assessment of esophageal pressures along the pharynx and esophagus. Manometry reveals normal peristalsis with high-amplitude esophageal contractions in nutcracker esophagus versus nonperistaltic contractions (with

normal or elevated pressure) in esophageal smooth muscle in distal esophageal spasm. Newer testing includes impedance, which examines bolus transit along the esophagus. In distal esophageal spasm, the esophagram may show a “corkscrew” appearance, but it is more commonly normal (□ Fig. 97.8). Treatment consists of nitrates, calcium channel blockers, anticholinergics, and possibly dilation or botulinum toxin injections in advanced cases. Nutcracker esophagus is treated with antireflux therapy, calcium channel blockers, and/or nitrates to decrease the amplitude of the contractions.

Hypokinetic motility disorders include achalasia and progressive systemic sclerosis. In achalasia, degeneration of the Auerbach plexus results in aperistalsis and a poorly relaxing LES. Symptoms may include progressive dysphagia, vomiting, malodorous breath, chest pain, and weight loss. Progressive systemic sclerosis is an autoimmune disease that causes small-vessel vasculitis, widespread collagen deposition, and fibrosis of smooth muscle in the lower two-thirds (smooth-muscle portion) of the esophagus. Symptoms include severe GERD, dysphagia, and tight sclerotic skin. The work-up includes manometry and barium swallow. In achalasia, manometry most often reveals an esophageal amplitude of less than 30 mm Hg and an increased LES pressure with poor relaxation. Diagnosis by barium swallow may reveal a pointed “bird’s beak” appearance at the LES, air–fluid levels, and/or aperistalsis (□ Fig. 97.9). Progressive systemic sclerosis is also diagnosed by barium swallow. The flaccid, dilated esophagus is similar to that seen in achalasia; however, the LES is patent. Manometry will show normal UES pressure, loss of tone of the LES, and aperistalsis because only smooth muscle is affected. The treatment of achalasia can include serial dilation; a Heller myotomy of the esophagus, LES, and cardia; botulinum toxin A injections to the LES; and calcium channel blockers to decrease LES pressure. Progressive systemic sclerosis has a higher risk for reflux because the LES is incompetent. Treatment includes antireflux medication, calcium channel blockers, and systemic steroids.

97.11 Esophageal Stenosis

Esophageal stenosis may be due to a multitude of conditions, including stricture, esophageal rings, and uncommonly Plummer-Vinson syndrome. Esophageal strictures may develop from a multitude of causes, including reflux, radiation injury, and caustic ingestion, among others. The proximal esophagus is particularly susceptible to radiation-induced stricture after treatment for head and neck cancer because of its more tenuous blood supply. An esophageal lumen narrowed to less than 13 mm generally will cause symptoms of dysphagia. Esophageal rings include both type A and type B rings. Type A rings uncommonly develop from muscular hypertrophy at the proximal LES. Type B rings, or Schatzki rings, occur at the squamocolumnar junction and are associated with reflux and hiatal hernias (□ Fig. 97.10). Plummer-Vinson syndrome may occur in patients with a long history of iron deficiency and is more common in middle-aged women of Scandinavian descent. Patients may present with microcytic anemia, cheilitis, splenomegaly, and dysphagia due to a degeneration of esophageal muscle that leads to the formation of cervical pharyngoesophageal webs. Because of an increased risk for esophageal carcinoma, patients

Fig. 97.9 Achalasia “bird’s beak” esophagus.

warrant close follow-up. Other treatments include cautious dilation and iron supplementation. Esophageal stricture is usually treated by serial dilation with balloons, bougies, or Savory dilators. Type A esophageal rings are often treated with botulinum toxin A injection, whereas type B Schatzki rings can be treated with dilation. Antireflux therapy is advisable to prevent recurrence.

97.12 Esophageal Neoplasms

Neoplasia in the esophagus is relatively uncommon but when present is typically malignant. In 2012, there were 17,460 new cases of esophageal carcinoma in the United States and 15,070 deaths. The two main pathologies are squamous cell carcinoma and adenocarcinoma. For most of the 20th century, the vast majority of esophageal cancers were squamous cell carcinomas. In the 1960s, squamous cell carcinoma accounted for more than 90% of all esophageal tumors in the United States, whereas esophageal adenocarcinomas were considered so uncommon that some authorities questioned their existence. For the past three decades, however, the frequency of adenocarcinoma of the esophagus, esophagogastric junction, and gastric cardia has increased dramatically in Western countries, so that adenocarcinoma now occurs with greater frequency than squamous cell carcinoma. Risk factors for squamous cell carcinoma of the esophagus include alcohol and tobacco abuse, and it is usually found in the thoracic esophagus. The incidence rates for esophageal squamous cell carcinoma were highest in blacks (8.8 per 100,000 per year) and Asians (3.9 per 100,000 per year). In contrast, adenocarcinoma presents in the distal esophagus at the gastroesophageal junction and is associated with GERD and Barrett esophagus. Adenocarcinoma is largely a disease of Caucasians and males, with the incidence in males outnumbering that in females by as much as 6:1. Barrett esophagus is usually

Fig. 97.10 Schatzki ring. (a) Radiograph. (b) Esophagoscopy appearance.

discovered during endoscopic examinations of middle-aged and older adults, whose mean age at the time of diagnosis is approximately 55 years. Patients who have an esophageal malignancy typically present with dysphagia and weight loss due to mechanical obstruction. Under most circumstances, esophageal cancer is identified at a late, incurable stage. Endoscopic resection is considered appropriate therapy for neoplastic lesions limited to the superficial mucosal layers because these tumors have low rates of lymph node metastasis (<3%). There is less consensus, however, with regard to lesions that extend to the muscularis mucosae. Most centers consider endoscopic treatment for this early neoplasia acceptable, although others disagree. Esophagectomy is preferred for lesions that invade the submucosa, given the significantly higher rates of lymph node metastasis associated with these lesions. There is some hope that with increased screening and surveillance for Barrett esophagus in patients who have GERD, adenocarcinoma will be detected at an earlier and potentially curable stage. However, at this time, palliative care remains a high priority for patients with advanced disease.

97.13 Roundsmanship

- Esophagitis due to infectious, caustic, medical, or irritant causes should be evaluated in patients with throat pain.
- Reflux may cause esophagitis, with sequelae of strictures, motility disorders, and intestinal metaplasia.
- Eosinophilic esophagitis should be considered in adults with a history of food impaction, persistent dysphagia, or gastroesophageal reflux disease (GERD) that fails to respond to medical therapy. In children, symptoms that may be associated with eosinophilic esophagitis vary by age and include feeding disorders, vomiting, abdominal pain, dysphagia, and food impaction.
- Esophageal foreign bodies should be imaged with two views; disc batteries lodged in the esophagus must be emergently removed by endoscopy.

- Esophageal masses are predominantly malignant. Adenocarcinoma is increasing in frequency to become the most common esophageal neoplasm in the United States.

98 Management of Oropharyngeal Dysphagia

Neel Bhatt and Stacey L. Halum

98.1 Introduction

There are many diverse and frequently occurring pathologies that lead to oropharyngeal dysphagia. Although the presentations of dysphagia may often appear similar, careful investigation, including a thorough clinical history and selective imaging methods, can help identify the underlying pathology. In this chapter, important causes of oropharyngeal dysphagia are outlined, with particular emphasis placed on the evaluation and treatment of each disorder. Topics discussed in this chapter include the management of aspiration, cricopharyngeal dysfunction, Zenker diverticula, neurogenic dysphagia, and dysphagia following therapy for head and neck cancer.

98.2 Evaluation and Management of Aspiration

98.2.1 Description of Dysphagia with Aspiration

Aspiration is characterized by the improper passage of oropharyngeal or hypopharyngeal contents into the larynx and lower respiratory tract, beyond the level of the true vocal folds. Aspiration may occur throughout any age group, but its frequency appears to be greatest among the elderly because of the increasing incidence of dysphagia with aging. Aspiration occurring with deglutition or secondary to laryngopharyngeal reflux events is often related to a multitude of reasons, such as a weak cough reflex, lack of motor coordination/function, or impaired laryngeal sensation. Many of the causes are discussed in greater detail throughout this chapter.

The risk for developing aspiration pneumonia from inhaled oral contents necessitates the proper and effective prevention of recurrent aspiration. The oropharyngeal bacteria within the aspirated contents are believed to be the nidus for infection in the development of aspiration-related pneumonia. The chief pathogens responsible for pneumonia are *Streptococcus pneumoniae* and *Haemophilus influenzae*, which normally colonize the nasopharynx and oropharynx. Chemical pneumonitis, which may occur acutely or chronically, is irritation and damage of the lung parenchyma after the aspiration or inhalation of noninfectious agents. Many studies suggest that approximately half of healthy adults aspirate small quantities of oropharyngeal contents. However, as a consequence of low bacterial counts in the oropharyngeal contents, a vigorous coughing reflex, epithelial ciliary transport, and both cellular and humoral immunity, the aspirated contents typically do not lead to the development of pneumonia in healthy individuals.

98.2.2 Differential Diagnosis of Dysphagia with Aspiration

The differential diagnosis of dysphagia with aspiration is important to consider because populations at high risk for aspiration

tend to have a multitude of cardiac and pulmonary comorbidities. Pulmonary edema, often seen among individuals with decompensated heart failure or fluid overload, may present similarly to aspiration pneumonia with shortness of breath, dyspnea on exertion, and tachypnea. Unlike aspiration pneumonia, pulmonary edema tends to present with crackles on pulmonary auscultation. A chest radiograph will generally show bilateral opacities, compared with dependent lobe opacification in aspiration pneumonia. Leukocytosis tends to be absent in pulmonary edema. A beta-natriuretic peptide (BNP) test and echocardiography can further clarify the etiology of a patient's complaint.

In the diagnosis of aspiration pneumonia, the possibility hospital-acquired or community-acquired pneumonia must be considered. Atypical organisms, not normally observed in aspiration pneumonia, may be detected with appropriate antigen testing, serology, or culture. Finally, fluoroscopic or endoscopic evaluation can help in determining whether aspiration is the likely causative means for the development of pneumonia.

98.2.3 Evaluation of Dysphagia with Aspiration

The clinical features of aspiration pneumonia vary considerably based on its severity. Generally, patients who have aspiration pneumonia present with a cough productive of purulent sputum, fever, chills, pleuritic chest pain, and shortness of breath. The aspiration event or events leading to pneumonia are typically not observed, a situation often described as “silent aspiration.” Therefore, the diagnosis is usually made based upon the clinical presentation, suspicion of aspiration risk, and radiographic evidence demonstrating infiltrates in the dependent pulmonary lobes. In patients at high risk for the development of silent aspiration pneumonia, early antibiotic therapy may be warranted based on symptoms alone (fever, dyspnea and cough) because plain radiographs can miss approximately one-third of developing pneumonias. Although CT is highly sensitive for the detection of pneumonia, its time-consuming nature and high cost make it impractical for the diagnosis of aspiration pneumonia, which generally requires expedient recognition and the initiation of treatment to avoid associated symptom progression and respiratory decompensation.

Speech Pathology Evaluation

Patients presenting with aspiration pneumonia should undergo a videofluoroscopic evaluation of swallow (modified barium swallow [MBS]) or a flexible endoscopic evaluation of swallow (FEES) with a speech–language pathologist. Although there is ongoing debate about which swallowing assessment tool is the most sensitive for detecting aspiration and predicting future risk for aspiration pneumonia, both MBS and FEES are overall highly sensitive (>85%) in detecting aspiration (□ Fig. 98.1). Bedside swallowing evaluations may be considered, but their sensitivity for detecting aspiration is significantly lower than

Fig. 98.1 A patient with impaired sensation demonstrates no cough reflex upon aspiration of a thick nectar bolus during flexible endoscopic evaluation of swallow (FEES). The material in the subglottic airway (arrow) was effectively cleared when the patient was cued to voluntarily cough and swallow.

that of MBS and FEES, especially in patients with silent aspiration (absence of spontaneous cough reflex).

98.2.4 Treatment of Dysphagia with Aspiration

Antibiotic Therapy

Antibiotics are always indicated for acute or chronic aspiration pneumonia. For nontoxic patients, early and aggressive antibiotic therapy is essential to prevent the progression of symptoms and avoid the need for parenteral antibiotics and hospitalization. Such cases typically can be managed with broad-spectrum antibiotics, such as ceftriaxone with azithromycin, levofloxacin, or moxifloxacin. In the inpatient setting, the goal remains to provide broad coverage that includes gram-negative bacteria, so that third-generation cephalosporins, fluoroquinolones, and piperacillin are appropriate antibiotic choices. If the patient has been recently hospitalized, antibiotics may be required that cover specific pathogens, including methicillin-resistant *Staphylococcus aureus* (MRSA), *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*. Sputum cultures with the early initiation of culture-directed antibiotic therapy are important in management.

Positioning Maneuvers and Swallowing Exercises

During the MBS or FEES, the speech–language pathologist can determine whether compensatory swallowing techniques can be employed to minimize the aspiration of food contents. Swallowing techniques are widely recommended as compensatory strategies for individuals with oropharyngeal dysphagia, although the efficacy of some techniques remains controversial. The benefits of the following techniques are highly dependent on the mechanism of the swallowing dysfunction. They must be tailored to fit the patient’s specific swallowing deficits and

must be feasible based on the patient’s comorbidities, cognitive abilities, and motivation. The most basic recommendations are postural techniques, which include chin tuck, head turn, and head tilt. The chin tuck maneuver brings the patient’s chin closer to the chest, thereby decreasing the size of the laryngeal opening by moving the base of the tongue and epiglottis posteriorly. In the head turn technique, the patient turns the head toward the weaker, less sensate, or damaged side (e.g., a patient following a stroke or peripheral paresis). With this technique, twisting the neck toward the injured side prevents a food bolus from traveling down the weaker side of the pharynx, allowing it to be more efficiently propelled along the stronger side. In the head tilt maneuver, the patient tilts the head toward the stronger side, encouraging bolus transmission down this side. Other swallowing maneuvers include the supraglottic swallow, super-supraglottic swallow, effortful swallow, and Mendelsohn maneuver. Each technique requires more deliberate action with each swallow. In the Mendelsohn maneuver, the patient physically holds up the larynx to keep it elevated immediately after swallowing. This technique is usually indicated for individuals with limited laryngeal excursion and a reduced cricopharyngeal opening. The supraglottic swallow is helpful for patients with aspiration during the swallow, especially patients with reduced laryngeal sensation. Patients are instructed to hold their breath throughout the entire swallow, then cough immediately thereafter to prevent aspiration. Finally, the super-supraglottic swallow is a slightly modified version of the supraglottic swallow, in which patients perform a Valsalva maneuver while holding their breath to maximize posterior glottic closure during the swallow.

Exercises can also be prescribed to help strengthen the muscles of deglutition. The patient can practice forceful swallowing, which helps to generate more pressure during actual swallowing. In the falsetto exercise, the patient practices phonation while sliding up a scale to the highest pitch possible. This particular exercise results in a level of laryngeal elevation similar to that in swallowing. The breath-hold exercise, in which the patient inhales and holds the breath for a few seconds, helps strengthen the airway closure at the level of the vocal folds. Additional exercises are used to strengthen the tongue and increase the range of motion of the jaw, lips, and tongue. For pharyngeal constrictor and strap muscle strengthening, Shaker exercises are often prescribed, in which the patient performs repetitive, gentle cervical flexion against gravity while in a supine position.

Surgical Management

The surgical management of chronic aspiration is often warranted when improvement is not observed with medical management or speech–language therapy. The type of surgery depends on the mechanism of aspiration.

A wide variety of surgical options are available, including vocal fold medialization with or without arytenoid adduction, vocal fold injection augmentation, chemical or surgical cricopharyngeal muscle (CPM) myotomy, pharyngoplasty procedures, supraglottoplasty procedures, and various forms of laryngeal suspension. Vocal fold medialization or injection augmentation, for example, may be indicated in patients who have persistent and incomplete glottic closure due to unilateral vocal

fold motion impairment, vocal fold scarring, or a decrease in vocal fold tissue. In patients with cricopharyngeal achalasia, chemodenervation with botulinum toxin and CPM myotomy via a transcervical or an endoscopic approach are appropriate options. Temporary injection with botulinum toxin may precede definitive surgical treatment because it can be useful in predicting candidates who are likely to improve with a surgical CPM myotomy.

Beyond individualized surgeries to minimize aspiration, a gastrointestinal procedure such as a feeding gastrostomy may be required if the patient's swallowing function is not capable of supporting adequate nutrition. In patients who are already dependent on a gastric feeding tube and continue to have problems due to reflux-related aspiration, the tube can often be advanced into the jejunum to help prevent reflux. When oropharyngeal secretions lead to chronic aspiration (as seen in cerebral palsy), these can be controlled with the surgical excision or botulinum toxin injection of salivary glands or the ligation of salivary ducts. In extreme cases, separation of the airway and digestive tract is necessary. These approaches render patients aphonic, and they must rely on alternative communication devices or on esophageal or tracheo-esophageal prosthetic speech. There are numerous long-term surgical options. Two that are potentially reversible include laryngotracheal separation and tracheo-esophageal diversion. In both, a tracheostoma is created. In the separation, the proximal end of the trachea is closed upon itself in a blind pouch, whereas in the diversion it is anastomosed to an esophagotomy to divert aspirate into the esophagus. The gold standard and the most definitive option for preventing aspiration is a total laryngectomy. This should be reserved for patients whose swallowing dysfunction is not expected to improve with time.

98.3 Evaluation and Management of Cricopharyngeal Muscle Dysfunction

98.3.1 Description of Cricopharyngeal Muscle Dysfunction

The CPM, a major contributor to the upper esophageal sphincter (UES), is an essential muscle in the mechanism of swallowing. The CPM is tonically contracted at baseline, then relaxes and dilates during swallow to permit bolus advancement through the UES into the esophagus. Normal UES function relies not only on the neuromuscular integrity of the CPM but also on the function of the surrounding muscles of deglutition. Thus, UES dysfunction can be either primary or secondary in nature; primary dysfunction occurs when the CPM itself is responsible for dysphagia, whereas secondary dysfunction typically occurs as a result of more global problems with dyscoordination or neuromuscular swallowing dysfunction (e.g., decreased laryngeal elevation or weak pharyngeal propulsion). Primary UES dysfunction is often idiopathic but may result from peripheral neurogenic injury or from disease processes like polymyositis. In primary UES dysfunction, the CPM exhibits chronic hypertonicity and spasm, failing to relax/dilate to allow bolus to advance through the UES. Because laryngeal elevation in an anterosupe-

rior direction and pharyngeal propulsion are necessary to draw open the UES and advance bolus through the UES, respectively, secondary UES dysfunction occurs when the CPM fails to open normally because of poor anterosuperior elevation of the larynx and/or decreased pharyngeal bolus pressure during swallowing. Patients who have poor laryngeal elevation and pharyngeal function, such as those who have had a stroke or have undergone extensive irradiation of the neck (strap muscles), may have such secondary UES dysfunction on videofluoroscopic swallowing examinations. The thyrohyoid muscle is particularly important in anterosuperior elevation of the larynx during swallow, which results in secondary mechanical opening and stretching of the CPM to allow bolus advancement. Experimental therapies such as implantable electrical stimulation and magnetic devices to promote bolus advancement through the UES have typically targeted methods to pull the larynx or cricoid in an anterosuperior direction to mechanically open the CPM. Patients with lack of laryngeal elevation during swallow and weak pharyngeal propulsion subsequent to stroke, irradiation, or other etiologies often fail to respond well to CPM myotomy or CPM chemodenervation because of insufficient opening of the UES for bolus transport despite the absence of underlying primary CPM resistance. In contrast, patients with isolated primary UES dysfunction have a much better response to CPM surgical and chemodenervation treatments.

98.3.2 Differential Diagnosis of Cricopharyngeal Dysfunction

There are a multitude of pathologies that are important to consider in the evaluation of CPM dysfunction. A thorough work-up, including endoscopy, can help eliminate other conditions that may be easily mistaken for CPM dysfunction. Diffuse or focal esophageal spasm and esophageal motility disorders typically present with dysphagia, regurgitation, and the sensation of a food bolus sticking to the throat. Individuals with esophageal spasm and motility disorders often will describe noncardiac chest pain, an important distinguishing characteristic of CPM dysfunction. Generalized pharyngeal or base of tongue weakness can also mimic CPM dysfunction, although patients often demonstrate pooling of bolus in the piriform sinuses and vallecula after swallowing. In cases of isolated pharyngeal weakness, the pharyngeal constrictors will fail to effectively propel bolus through the CPM, thus resulting in piriform pooling and the appearance of poor CPM dilation/opening on videofluoroscopic study. If such a situation is suspected, CPM dilation with botulinum toxin injection can be helpful in distinguishing CPM dysfunction from isolated pharyngeal weakness. If the procedure fails to relieve the swallowing dysfunction, aggressive pharyngeal constrictor strengthening exercises should be initiated.

Esophageal strictures also present with symptoms similar to those previously discussed. Strictures may develop in a primary process, such as fibrosis or neoplasm, or secondarily, such as in patients who have chronic acid reflux or are taking certain medications. A thorough clinical history can help elucidate potential causes of secondary esophageal stricture. When a primary process leading to stricture is suspected, endoscopy with biopsy can effectively differentiate it from other etiologies.

Fig. 98.2 Cricopharyngeal muscle (CPM) dysfunction. A prominent CPM bar is seen on radiographic modified barium swallow (arrow). This patient ultimately underwent endoscopic CPM myotomy with excellent response. There is also an incidental cervical esophageal web seen anteriorly (arrowhead).

98.3.3 Evaluation of Cricopharyngeal Muscle Dysfunction

The presentations of individuals experiencing CPM achalasia are varied. Patients often experience the sensation of solid food becoming stuck at the level of the cricoid during swallowing; they also experience choking or coughing. Although the diagnosis of CPM achalasia may be suggested by a thorough history and physical examination, endoscopic and radiographic evaluations are necessary steps in the evaluation. Endoscopic examination will rule out another cause of dysphagia, such as vocal fold dysfunction or laryngopharyngeal carcinoma. Radiographic studies can determine if a cricopharyngeal bar, dyscoordination, or pharyngeal diverticula are present (□ Fig. 98.2).

The presence of a CPM bar alone is neither highly sensitive nor specific for CPM dysfunction, and manometry assessment should be considered in equivocal cases. Manometry of the UES is sensitive and specific in detecting CPM hypertonicity in experienced hands, although the reliability and accuracy of the results can be suboptimal in institutions without special expertise in UES assessment.

98.3.4 Treatment of Cricopharyngeal Muscle Dysfunction

CPM achalasia is typically unresponsive to medical intervention, such as therapy with systemic muscle relaxants. Botulinum toxin injection is a nonsurgical treatment option for relaxing the UES. Botulinum toxin promotes muscle relaxation by inhibiting the release of acetylcholine at the neuromuscu-

lar junction. Periodic injections of botulinum toxin into the CPM can provide temporary muscle relaxation and relieve dysphagia. The duration of action of botulinum toxin typically ranges from 3 to 9 months in most patients. The use of botulinum toxin is not a permanent solution for individuals with CPM achalasia and best serves as a trial of therapy when it is unclear if a myotomy will be effective. If the patient's symptoms improve upon administration of the botulinum toxin, then CPM achalasia is likely the correct diagnosis. In-office injection with electromyographic guidance can be effective in the treatment of elderly patients who have significant comorbidities and cannot undergo general anesthesia. If patients can tolerate general anesthesia, botulinum toxin injection is often performed simultaneously with dilation of the UES because it is believed that fibrosis of the CPM may coexist with CPM neurogenic changes in many patients who have primary UES dysfunction.

The risks of botulinum toxin are generally related to inaccurate injections or diffusion of the toxin, which can lead to paralysis of the adjacent muscles (posterior cricoarytenoid, inferior pharyngeal constrictor, upper esophageal musculature), temporarily worsening dysphagia or impairing vocal fold motion. This is much more common after in-office injections. Unfortunately, as described above, these are often performed in sicker patients and can result in severe morbidity or even mortality secondary to increased dysphagia. Therefore, many practitioners have abandoned in-office injections for this set of patients.

After conservative management (e.g., swallowing exercises, head-positioning maneuvers) has failed, surgical intervention for CPM achalasia is warranted provided that previous clinical evidence, videofluoroscopy, and in some cases manometry support the diagnosis. There are several approaches for the treatment of CPM achalasia. The most widely used technique is transcervical cricopharyngeal myotomy. This surgery is typically performed under general anesthesia, often with placement of an esophageal bougie or orogastric tube to improve visualization of the CPM fibers and prevent esophageal mucosal violation during the myotomy. The CPM fibers, which extend in horizontal bands originating from the posterior lateral border of the cricoid cartilage, are carefully incised, and a segment of muscle may be removed to prevent recurrent fibrosis of the muscle edges.

The CPM may also be readily exposed via an endoscopic technique. Endoscopically, the submucosal prominence of the CPM is exposed in the postcricoid region with either a Weerda (Karl Storz, Tuttlingen, Germany) or Slimline (Karl Storz) diverticuloscope. After the scope is suspended, the prominence should be examined and palpated under microscopy to ensure correct positioning. With carbon dioxide laser, the mucosa is incised in the midline to reveal the underlying transverse running muscle fibers (□ Fig. 98.3).

These are carefully and completely transected until the underlying buccopharyngeal fascia is identified. Leaving the fascia intact is a crucial step. It provides a protective barrier preventing leakage into the danger space with resultant infection (mediastinitis). If there is any question about the integrity of the underlying fascia, closure with fibrin glue and/or endoscopic suture reapproximation of the mucosa should be performed.

98.4 Evaluation and Management of Zenker Diverticulum

98.4.1 Description of Zenker Diverticulum

Zenker diverticulum is a false diverticulum consisting of an outpouching of hypopharynx mucosa and submucosa. The diverticulum typically occurs in an area of muscle weakness in a region between the inferior constrictor and the CPM known as the Killian triangle. Although the exact mechanism for the development of a Zenker diverticulum is not known, it is believed to be secondary to high intrabolus pressures generated by failure of the CPM to adequately relax during swallowing.

Fig. 98.3 Endoscopic cricopharyngeal muscle (CPM) myotomy. The CPM fibers retract laterally under the mucosa as they are transected with the carbon dioxide laser. The horizontal fibers of the CPM (asterisk) can be appreciated during the carbon dioxide laser dissection. A defocused laser beam can be appreciated at the superior edge of the defect (bottom of figure).

Zenker diverticula typically occur in older adults beginning after the sixth decade of life; however, they have been described in much younger individuals, including children. Early in the development of a diverticulum, oropharyngeal dysphagia to solids is the most common presenting feature. Over time, the size of the diverticulum increases, leading to the retention of food and secretions in the pouch. Particularly when a diverticulum is large, patients may have halitosis, dysphagia, cough, weight loss, regurgitation, aspiration, and even recurrent pneumonia. The prevalence of Zenker diverticula among the general population is low (0.01 to 0.11%).

98.4.2 Differential Diagnosis of Zenker Diverticulum

The evaluation of a Zenker diverticulum requires consideration of other, similarly presenting pathologies. Diverticula can occur anywhere along the esophageal lining, although they occur more frequently in the middle and distal portions of the esophagus. If a diverticulum protrudes through the anterolateral wall of the cervical esophagus just inferior to the CPM and lateral to the longitudinal muscle of the esophagus (the Killian-Jamieson space), it is called a Killian-Jamieson diverticulum. Esophageal diverticula most typically present with dysphagia, regurgitation, achalasia, and aspiration. As previously discussed, esophageal spasms and strictures may present with clinical features similar to those of Zenker diverticula. For each differential diagnosis, fluoroscopic evaluation with barium contrast can identify the specific location of the diverticulum.

98.4.3 Evaluation of Zenker Diverticulum

The diagnosis of Zenker diverticulum is determined by a barium swallow study (□ Fig. 98.4). Manometry is not typically performed; however, it may prove helpful in determining the etiology of the diverticulum. Endoscopy may be indicated if the barium contrast study or history suggests the possibility of neoplasm. Although FEES is generally not a very sensitive test for detecting a Zenker diverticulum, patients with a Zenker diverticulum can occasionally be noted to have the classic finding of delayed regurgitation of bolus back into the hypopharynx several seconds after swallowing. FEES can also be important in excluding causes of secondary dysphagia, such as vocal fold paresis and base of tongue weakness.

Fig. 98.4 Zenker diverticulum on barium esophagram. (a) Posteroanterior view demonstrates a large, circular sac just to the left of midline that measures just over 3 cm in maximal diameter. (b) On lateral view, the barium-filled sac can be appreciated posteriorly, with the cricopharyngeal muscle-containing party wall visible between the sac and the esophageal lumen.

Fig. 98.5 Endoscopic Zenker diverticulum. (a) A small Zenker sac is exposed, with the sac posterior (asterisk) and the esophagus anterior (double asterisk) to the parting septum; the septum contains the cricopharyngeal muscle. (b) After stapling, most of the septum has been divided, but the base of the septum remains, which can be further transected with a laser if desired. The esophageal lumen is visible (double asterisk) as well as the residual posterior sac (asterisk).

98.4.4 Treatment of Zenker Diverticulum

The treatment modality for symptomatic Zenker diverticula is predominantly surgical. Several surgical methods are used. In the choice of a method, the many factors to be considered include the health and physiologic age of the patient. As discussed previously, CPM dysfunction is believed to be a major mediator in the development of Zenker diverticula. Therefore, cricopharyngeal myotomy must be performed alone or in conjunction with a procedure that addresses the diverticulum. In patients who cannot tolerate a surgical procedure, botulinum toxin injection into the CPM alone often results in dramatic symptom relief.

Similar to CPM myotomy, the surgical management of a Zenker diverticulum can be performed via an external or an endoscopic approach. Several endoscopic procedures are routinely used in which the party wall is transected in the midline to create a common cavity encompassing the diverticulum and the esophagus. Regardless of the technique, transoral surgery requires direct visualization of the septum, esophageal lumen, and diverticular pouch (□ Fig. 98.5a). When an endostapler is used, the septum between the esophageal lumen and the diverticulum is divided and the edges are sealed by the staples (□ Fig. 98.5b).

Alternatively, a laser can be used to incise the septum between the esophagus and the Zenker sac. Because the septum contains the CPM, the procedure involves a CPM myotomy; simultaneously, a common cavity and continuity between the sac and proximal esophagus are created. One reason for the failure of stapler diverticulotomy in small sacs is an incomplete CPM myotomy when the CPM extends beyond the base of the sac. For patients who cannot tolerate general anesthesia, flexible endoscopic procedures may be used. In general, endoscopic procedures cause fewer complications, require a shorter hospital stay, and allow a more rapid resumption of an oral diet.

In some cases, severe kyphosis, osteophytes, and/or a limited oral opening prevent adequate exposure of the Zenker diverticulum via a transoral approach, and an external approach is required. In conjunction with a cricopharyngeal myotomy, a diverticulectomy or diverticulopexy may be performed. Diverticulectomy consists of suturing or stapling the neck of the diverticulum and excising the pouch. Because of the risk for postoperative leak at the base of the diverticulum, this procedure carries a higher risk for mediastinitis. In addition, care needs to be taken to avoid excessive excision of the esophageal wall, which can result in postoperative esophageal stenosis. There-

fore, the excision is often performed with a bougie in place to prevent excessive resection. Diverticulopexy is performed by inverting the diverticulum and anchoring the pouch to the posterior pharyngeal wall. This procedure is typically recommended for patients with extensive comorbidities because there is no excision or division of the esophagus or pharynx, thereby decreasing operative and recovery time and the risk for postoperative mediastinitis.

98.5 Evaluation and Management of Neurogenic Dysphagia

98.5.1 Description of Neurogenic Dysphagia

Dysphagia is a common manifestation of a disease or disorder of the central or peripheral nervous system. For functional swallowing to occur, a multitude of neural pathways and muscles must coordinate properly. Lesions in the cerebral cortex, basal ganglia, brainstem, or cerebellum may prevent normal swallowing function. Examples of such neurogenic pathology include stroke, traumatic brain injury, benign or malignant neoplasms, cerebral palsy, myasthenia gravis, and multiple sclerosis. Degenerative diseases such as Alzheimer disease, Parkinson disease, Huntington disease, Wilson disease, amyotrophic lateral sclerosis, dementias (frontotemporal, Lewy body, vascular), olivopontocerebellar atrophy, and progressive supranuclear palsy may also cause neurogenic dysphagia. Finally, iatrogenic injury to the territories of cranial nerves IX, X, and XII can result in significant neurogenic dysphagia.

Acute stroke causing a lesion in the cerebral cortex is by far the most common cause of central neurogenic dysphagia. Dysphagia from stroke usually occurs with hemiplegia. However, as seen in patients with small lacunar infarcts or specific brainstem lesions, dysphagia may occasionally be the only clinical neurologic sign. Dysphagia following stroke is often transient if direct brainstem injury is not involved. The vast majority of patients who have had a stroke recover their swallowing function. Those with persistent dysphagia have significantly higher rates of morbidity and mortality from their stroke. Therefore, it is important that patients with stroke be screened for dysphagia, and stroke needs to be considered in the differential diagnosis for patients with isolated dysphagia.

The most common causes of peripheral neurogenic dysphagia are injuries affecting cranial nerve IX, X, or XII. Of these, iatrogenic injuries to cranial nerve X are the most common, often

occurring at the time of skull base surgery, cervical spine surgery, or carotid endarterectomy. Distal injuries affecting the recurrent laryngeal nerve in isolation result in unilateral vocal fold paralysis, often with coexistent UES dysfunction. With high cranial nerve X injury, patients are more likely to have dysphagia because the paralyzed vocal fold often remains in a lateral position, impairing glottic closure during swallowing. More significantly, superior laryngeal nerve involvement results in impaired laryngopharyngeal sensation, exacerbating the risk for aspiration.

98.5.2 Differential Diagnosis of Neurogenic Dysphagia

In most of the aforementioned neurologic disorders, dysphagia is a very common feature. This association necessitates a thorough evaluation for other etiologies of dysphagia often obscured by the neurologic disorder. In patients with neurodegenerative diseases, the course of dysphagia tends to worsen progressively. Therefore, the sudden development of worsening dysphagia should prompt investigation into additional causes, such as neoplasms, strictures, and diverticula, as discussed throughout this chapter.

98.5.3 Evaluation of Neurogenic Dysphagia

In all patients with dysphagia, signs of coexisting neurologic deficits, such as dysarthria, blunted affect, velopharyngeal insufficiency, and vision changes, warrant further evaluation by a neurologist to assess for a systemic neurologic disorder. Although many patients may present with a well-established diagnosis of stroke, traumatic brain injury, or iatrogenic neurogenic injury, other neurologic diseases can manifest with more subtle changes, and dysphagia can be an initial complaint. For example, patients who have myasthenia gravis, which affects the neuromuscular junctions, present with variable difficulty swallowing that worsens throughout a meal or the day. Often, the laryngeal, oral, and velopharyngeal muscles are all affected, while CPM function remains normal. Because of the velopharyngeal involvement, patients often experience nasal regurgitation of bolus during swallowing and may have problems with hypernasal speech. Videofluoroscopy shows dysfunction in the oral preparatory phase and the pharyngeal phase. Although myasthenia gravis is caused by antibodies to nicotinic acetylcholine receptors, acetylcholine antibody receptor testing has poor sensitivity (60%), so a therapeutic trial of pyridostigmine is often the most reasonable initial step when myasthenia gravis is strongly suspected. If further diagnostic testing is needed, the diagnosis can usually be confirmed with single-fiber electromyography. As another example, amyotrophic lateral sclerosis can present with progressive motor neuron death leading to bulbar weakness. During progression of the disease, patients tend to have increasing difficulty with solids as a consequence of inadequate generation of muscle force in both the oral and pharyngeal phases of swallowing. The insufficient force and failure of the CPM to relax decrease UES opening and increase dysphagia. Clinically, many patients with amyotrophic lateral sclerosis will present with dysphagia, weight loss, and

recurrent episodes of aspiration pneumonia, and often with coexisting dysarthria (slow, slurred speech).

In individuals suspected to have neurogenic dysphagia, FEES is a reasonable screening approach because it is highly sensitive in the detection of aspiration. However, videofluoroscopic swallow study is still considered the gold standard for evaluating patients with neurogenic dysphagia because the test allows direct visualization of the oral preparatory phase, reflex initiation, and pharyngeal transit more clearly than does FEES alone.

98.5.4 Treatment of Neurogenic Dysphagia

With many specific neurologic diseases, either peripheral or central in origin, the management of dysphagia varies considerably, depending on the disease process. The overall goal of managing neurogenic dysphagia is to prevent aspiration while maintaining adequate nutrition. For individuals who are unable to meet their nutritional requirements by mouth because of severe dysphagia, gastrostomy can help to supplement nutrition. The incorporation of postural and swallowing techniques, as discussed earlier in this chapter, should also be emphasized to further limit aspiration. Based on the cause of the disease, food consistency should be optimized to facilitate ingestion. For most patients with neurogenic causes of dysphagia, liquids pose a greater challenge than solids. Therefore, attempts should be made to increase the viscosity of fluids when beneficial.

Patients with isolated cranial nerve X injury (recurrent laryngeal nerve and/or superior laryngeal nerve) often experience significant improvement in swallowing after surgical treatment to improve glottic closure (injection laryngoplasty or medialization laryngoplasty with arytenoid adduction) and CPM myotomy to minimize resistance at the UES. In such cases, pharyngoplasty to minimize pooling in the piriform sinus on the paralyzed side can also be considered. In patients with systemic neurologic diseases and more diffuse neuropathy, cricopharyngeal myotomy or botulinum toxin injection can be performed as a treatment if there are signs of CPM dysfunction with retention of an adequate oral phase, pharyngeal peristalsis, and reflex mechanisms. Many individuals with neurogenic dysphagia have severe deficits in these aforementioned phases of swallowing, making cricopharyngeal myotomy or relaxation an ineffective intervention.

98.6 Evaluation and Management of Dysphagia following Head and Neck Cancer Therapy

98.6.1 Description of Dysphagia following Head and Neck Cancer Therapy

The standard treatment modalities for patients with locally advanced head and neck cancer involve surgical resection, chemotherapy, and radiation therapy. These options, although often curative in eliminating the cancer, can be extremely disfiguring and disruptive of normal anatomy and neuromuscular function,

Fig. 98.6 Multifactorial dysphagia in a patient with head and neck cancer. Flexible endoscopic evaluation of swallow (FEES) images of a patient with previous irradiation for a base of tongue malignancy, impaired sensation, and deficient laryngeal elevation during swallowing. (a) Intact vocal fold mobility noted. (b) Pooling in the vallecula and silent aspiration noted (arrow) with diluted applesauce. (c) Graham cracker bolus with severe laryngeal penetration. (d) Upon instruction, the patient could adduct the vocal folds and then repetitively complete forceful swallows and chin tuck to advance the bolus without aspiration.

leading to dysphagia. The extent and type of dysphagia following treatment for head and neck cancer varies considerably depending on the location of the cancer, tissues removed, methods used for reconstruction, and type of rehabilitation therapy. For instance, it has been well established that irradiation to the base of the tongue can lead to swallowing dysfunction secondary to prolonged oral preparatory times, slowed bolus transit times, and increased oropharyngeal residues (□ Fig. 98.6). Patients with laryngeal or hypopharyngeal malignancies who undergo irradiation or chemoradiation protocols are more likely to have problems of impaired laryngeal sensation, weak laryngeal elevation, and impaired UES opening.

98.6.2 Differential Diagnosis of Dysphagia following Head and Neck Cancer Therapy

Because therapies for head and neck cancer are inherently associated with a high rate of dysphagia, dysphagia or aspiration secondary to other causes may be unsuspected or missed in patients with head and neck cancer. In the clinical management of a patient following therapy for head and neck cancer, it is important to identify the expected level of dysphagia following treatment. If the patient experiences symptoms that are unexpected or far more severe than anticipated, a thorough work-up should be conducted to assess for other causes, such as stroke, esophageal neoplasms, diverticula, strictures, and achalasia.

98.6.3 Evaluation of Dysphagia following Head and Neck Cancer Therapy

Radiation therapy leads to the fibrosis and necrosis of tissue, which are particularly difficult to treat because there are no

beneficial long-term management options for reversing the damage. The tissue damage leads to oropharyngeal complications, including xerostomia, mucositis, and strictures. Therapeutic doses of radiation have the capacity to significantly damage salivary glands, causing a permanent decrease in salivary flow. Patients will often complain that boluses of dry foods such as crackers and breads become stuck, and water is required to advance the bolus, compensating for the decline in saliva production. Mucositis, which is characterized by irritation and ulceration of the oral mucosa, is also a common manifestation of radiation therapy. Clinicians will often recommend that a patient maintain proper oral care while avoiding spicy or irritating foods. Although xerostomia and mucositis are common in patients with dysphagia after irradiation for head and neck cancers, neither of them alone has been shown to alter bolus transit times; typically, the patients who have been treated with irradiation and have the greatest swallowing impairment are those with a combination of mucositis, xerostomia, and severe alterations in anatomy and neuromuscular function. One possible alteration in anatomy is the development of a stricture that physically impedes bolus passage at the level of the pharynx or esophagus. Typically, strictures respond well to esophageal dilation, which can be done as standard blind bougie dilation or, in tight cases, dilation over a wire. In cases of complete stenosis, a dual endoscopy approach or “rendezvous procedure” (retrograde flexible esophagoscopy via the patient’s gastrostomy site with antegrade esophagoscopy and dilation) can be performed under fluoroscopic guidance with recanalization of the esophagus.

In the most severe cases of dysphagia, there is often impaired neuromuscular function that attenuates the laryngeal protective mechanisms present in a normal swallow. For example, laryngeal elevation anterosuperiorly is a critical movement for triggering UES opening and protecting the laryngeal inlet from aspiration. In many patients who have undergone irradiation,

severe fibrosis of the strap muscles, such as the thyrohyoid muscles, develops and causes them to be dysfunctional, with absence of laryngeal elevation during swallow, aspiration, and piriform sinus pooling. Although neuromuscular stimulators, magnetic devices, and laryngeal repositioning surgeries are currently being explored for the “frozen larynx” syndrome, to date there is no actual cure for this problem. Aggressive swallowing therapy with a speech–language pathologist remains the standard of care. There may be some benefit to initiating swallowing therapy early in the course of irradiation, before fibrosis and dysphagia have developed, although this remains controversial. Finally, in addition to functional motor impairments, many patients have severe impairment of sensory function, resulting in loss of cough reflex and silent aspiration. Therapy with supra-glottic/super-supraglottic swallow may help reduce aspiration and facilitate modest dietary intake, but generally these patients are at extremely high risk for aspiration pneumonia and pneumonitis because they do not have a reactive cough during secretion-related or reflux-related aspiration events. In severe cases of chronic aspiration, tracheo-esophageal diversion, laryngotracheal separation, or total laryngectomy must be considered.

The management of dysphagia following treatment for head and neck cancer requires proper imaging studies, including MBS or FEES. MBS can more accurately determine the presence of deficits with each stage of the swallow. FEES permits direct visualization of the neuromuscular function and anatomical deficits contributing to the dysphagia, which can be beneficial if some type of augmentation or surgical treatment is anticipated.

98.6.4 Treatment of Dysphagia following Head and Neck Cancer Therapy

Therapy with swallowing maneuvers, postural techniques, and swallowing exercises, as discussed previously, is critically important to help prevent and manage dysphagia following head and neck cancer therapy. In patients at high risk for dysphagia after therapy, a pretreatment assessment of swallowing should be considered. This formal evaluation by a speech–language pathologist before oncologic intervention allows time to develop specific compensatory maneuvers and plan rehabilitation. In addition, a pretreatment assessment can determine the baseline oropharyngeal function, which may assist in developing the most appropriate surgical plan for preserving swallow function. If patients undergoing radiation therapy or chemoradiation therapy develop dysphagia during or after their treatments, they should meet with a speech–language pathologist early in the course of their dysphagia so that they can work on techniques to curb the development of tissue fibrosis and maintain muscular strength and coordination.

In addition to the surgical options already outlined in this chapter, patients with head and neck cancer may benefit from augmentation procedure(s) to help minimize the underlying anatomical defects that are impairing swallow function. For example, patients with oropharyngeal malignancy in whom severe velopharyngeal insufficiency develops after therapy may

benefit from a palatal augmentation/pharyngoplasty procedure. Those with large base of tongue defects after cancer resections (with resultant pooling in the defect) may benefit from lipoinjection augmentation of the tongue defect to help minimize pooling. Patients with unilateral vocal fold paralysis or loss of vocal fold tissue may benefit from some type of vocal fold augmentation, with lipoinjection a reasonable option for mild glottic closure impairment and muscular flap reconstruction an option for larger defects. Because of the high risk for poor wound healing, extrusion, and/or laryngocutaneous fistula after irradiation, standard medialization laryngoplasty with synthetic implants should be performed with great caution in cancer patients who have previously been treated with irradiation to the neck.

Depending on the sites involved with head and neck cancer, a variety of deficits may be demonstrated. Thus, treatments need to be tailored to the individual. Ideally, the physician team and speech–language pathologists will work closely together to optimize each patient’s swallowing function and provide him or her with realistic expectations for the future.

98.7 Roundsmanship

- Although bedside swallowing evaluations may be considered for detecting aspiration, their sensitivity is significantly lower than that of modified barium swallow (MBS) and functional endoscopic evaluation of swallow (FEES), especially in patients with silent aspiration (absence of a spontaneous cough reflex).
- Botulinum toxin injection is a nonsurgical treatment option for relaxing the UES and generally results in significantly improved swallowing function in patients with primary UES dysfunction.
- Because cricopharyngeal muscle dysfunction is believed to be a major mediator in the development of Zenker diverticulum, cricopharyngeal myotomy should be included with any procedure done to address the diverticulum.
- In individuals suspected to have neurogenic dysphagia, flexible endoscopic evaluation of swallow (FEES) is a reasonable screening approach to detect aspiration; however, video-fluoroscopic swallow study is the gold standard because it allows assessment of the oral preparatory phase, reflex initiation, and pharyngeal transit.
- In patients at high risk for dysphagia following therapy for head and neck cancer, a pretreatment swallowing assessment should be considered. A formal evaluation by a speech–language pathologist before oncologic intervention allows time to develop specific compensatory maneuvers and plan rehabilitation.

99 Evaluation and Management of Tracheobronchial Infections and Masses

Christopher R. Gilbert, Lonny Yarmus, and Lee M. Akst

99.1 Introduction

Tracheobronchial masses and infections are rather uncommon within the general population. Unfortunately, few symptoms are specific for these diseases; most present with some combination of cough, dyspnea, wheezing, respiratory failure, and hemoptysis. Because their presentation can be quite similar to those of many other diseases, they are often considered relatively late in the differential diagnosis, which can lead to a delay in diagnosis and treatment. This chapter will focus on the most common etiologies of tracheal masses and infections seen in clinical practice. It will also concentrate on common tracheobronchial infections and tracheal masses that generally require endoscopic evaluation. A more in-depth review of covered topics is available within our reading list at the end of this chapter.

99.2 Tracheal Infections

99.2.1 Etiology, Pathogenesis, and Natural History

Upper respiratory tract infections are quite common and often caused by viruses. They typically present with viral-type prodromes and are frequently self-limited. However, certain tracheal infections, albeit rare, are very important to recognize because they have the potential to be fatal if left untreated.

Bacterial tracheitis (also known as exudative tracheitis) is believed to occur as a complication of viral croup or laryngotracheitis, and therefore its incidence is highest in the fall and winter months. Bacterial tracheitis can present in the adult or pediatric population; however, the adult form is often self-limited, so many people may not seek medical attention. Adults will often present with productive cough and fevers, but because of the larger size of the adult trachea, obstruction is quite rare. Most children will present acutely ill and within a few hours to days experience the onset of an acute “barking” cough, fever, hoarseness, and stridor. Unfortunately, because of the rapidly progressive nature of the disease, many children can develop respiratory distress within hours. There is usually no drooling or dysphagia, which is more common in patients with supraglottitis. The two most common pathogens identified appear to be *Staphylococcus aureus* and *Moraxella catarrhalis*.

99.2.2 Diagnostic Testing

Endoscopic examination remains the mainstay of both the diagnosis and treatment of suspected tracheobronchial infection. We review the role of biopsy versus tracheal aspiration in the situations presented below.

Endoscopic examination will confirm the diagnosis of bacterial tracheitis, revealing marked edema, purulent exudate, mucosal ulceration, pseudo-membrane formation, and mucosal

sloughing within the tracheal lumen, all of which can contribute to airway obstruction. Blood cultures are frequently negative, but tracheal cultures will often identify the pathogen. Examination of the airway is best accomplished within the controlled confines of the operating room and often requires the use of rigid bronchoscopy for the adequate suctioning and removal of pseudo-membranes. The majority of affected children will need mechanical ventilation during the acute phase of the illness, mainly for airway protection, but once the mucosal inflammation has subsided, most are safely extubated and do well.

Radiographic imaging may be helpful in formulating a diagnosis of endobronchial tuberculosis, but 20% of patients with isolated endobronchial tuberculosis have normal findings on chest imaging. It therefore remains important that bronchoscopy and subsequent microbiological analysis be performed for the diagnosis. Varying mucosal or submucosal pathologic changes, including ulcer, granuloma, infiltration, fibroplasia, and stenosis, have been described. Patients with suspected isolated endobronchial tuberculosis require direct biopsy sampling of the endotracheal lesions because noninvasive respiratory sampling tends to be nondiagnostic.

For those patients in whom tracheobronchial fungal infections develop, endoscopic examination is warranted to obtain a diagnosis as well as examine the extent of disease. The limited data available regarding fungal tracheobronchitis provide an incomplete description of the endoscopic presentations; however, a number of case reports are available. There appear to be two common descriptions: (1) intraluminal involvement with circumferential growth and invasion and (2) diffuse plaque-like involvement of the trachea.

99.2.3 Differential Diagnosis

Because of the nonspecific symptoms of cough, fever, and dyspnea, the differential often remains relatively broad. However, the development of stridor and/or hoarseness, especially over a short period of time, should raise concern for bacterial laryngotracheitis. The possibility of tuberculosis exposure in a patient's history raises concern for endobronchial tuberculosis, although some patients have no clear exposure history identified. Endobronchial tuberculosis often has a biphasic age distribution, commonly presenting in young females as well as in the elderly. Immunosuppressed patients will be at increased risk for the development of fungal infection, including laryngotracheitis.

99.2.4 Treatment

The antibiotic selected should provide empiric gram-positive and gram-negative coverage until the Gram stain returns. With the continued rise of methicillin-resistant *S. aureus* (MRSA), most suggest vancomycin until pathogen identification. The duration of antibiotic therapy often ranges from 10 to 14 days.

Fig. 99.1 Endotracheal *Aspergillus* infection. A large fungating mass is seen emanating from the right main stem; culture of this mass grew *Aspergillus*.

The treatment for endobronchial tuberculosis includes the use of standard anti-tuberculosis therapy. Some advocate corticosteroids to decrease tracheobronchial stenosis; however, the data remain largely from case series and retrospective studies. One needs to consider the risk for the systemic advancement of tuberculosis secondary to the use of steroids. In cases of severe tracheobronchial stenosis, more invasive therapeutic interventions are often indicated, including the use of balloon dilation and stent placement. Focal stenosis may be amenable to surgical resection once infection control is achieved.

The long-term sequelae of fungal tracheobronchitis are not well-known because most of the patients appear to die of their underlying illness. Aspergillosis is the most common fungal infection reported (□ Fig. 99.1). Treatment also appears highly individualized; however, antifungal use is reported in most series. Descriptions of survivors have ranged from asymptomatic to severely stenotic.

99.3 Tracheal Masses

99.3.1 Etiology, Pathogenesis, and Natural History

The incidence of tracheal masses in the general population is relatively rare, with some estimates of two cases per every million persons. Presenting symptoms can range from cough and dyspnea to respiratory failure from central airway obstruction. It is quite common for patients with less severe symptoms to be given a misdiagnosis of asthma, bronchitis, or chronic cough before the correct diagnosis. This delay in accurate diagnosis appears most likely related to the nonspecific presentation and rarity of tracheal masses.

99.3.2 Diagnostic Testing

Endoscopic airway evaluation is invaluable for establishing the diagnosis of an endotracheal mass. It is performed via flexible

or rigid bronchoscopy, as well as direct laryngoscopy, depending on the location of the lesion and the preference of the physician. Lesions are inspected, and biopsies can be obtained.

Endobronchial Masses Related to Systemic Diseases

Wegener Granulomatosis

Patients with Wegener granulomatosis (WG) generally test positive for cytoplasmic antineutrophil cytoplasmic autoantibody (c-ANCA); however, up to 20% of patients with airway involvement may be negative for c-ANCA. The results of further diagnostic testing, such as biopsy demonstrating necrotizing vasculitis of small vessels, can help confirm the diagnosis.

Amyloidosis

The diagnosis of amyloidosis requires a tissue biopsy in which characteristic amyloid fibrils stain pink with hematoxylin–eosin as well as demonstrate green birefringence under polarized light microscopy after being stained with Congo red.

Sarcoidosis

Endoscopy in patients with sarcoidosis will often reveal diffuse hyperemia, edema, and less commonly ulceration. Nodules and mass lesions have also been well described. Supraglottic structures may be involved, with subglottic disease much less common. A classic “turban-like thickening” of the larynx can be seen, and most believe this is related to diffuse infiltration and swelling of the supraglottis. A diagnosis of sarcoidosis requires biopsies of affected areas as well as a negative work-up for tuberculosis. These biopsies should identify well-defined noncaseating granulomas without evidence of vasculitis, necrosis, or infection. Pulmonary nodules on chest X-ray or computed tomography (CT) and an elevated angiotensin-converting enzyme (ACE) level may also help in the diagnosis, although these results can be normal in approximately 10% of cases.

Tracheobronchopathia Osteochondroplastica

Endoscopy for tracheobronchopathia osteochondroplastica (TO) is diagnostic with the visualization of innumerable small, hard nodules extending from the subglottic space to the carina. The nodules can cause tracheal narrowing and rigidity if sufficiently large and numerous. One of the distinguishing features of TO is the absence of involvement of the posterior membranous wall.

Nonmalignant and Malignant Tracheal Tumors

Recurrent Respiratory Papillomatosis

The diagnosis of recurrent respiratory papillomatosis (RRP) is suspected with the endoscopic visualization of characteristic hypervascular papillary lesions (□ Fig. 99.2), but the diagnosis is confirmed by pathologic analysis.

Suspected neoplasms within the tracheobronchial tree should be confirmed pathologically. This can be performed via flexible or rigid bronchoscopy, as well as direct laryngoscopy, depending on the location of the lesion and the preference of the physician. Once a diagnosis is obtained and the endoluminal

extent of disease has been assessed, further treatment options can be discussed. Endobronchial ultrasound is a minimally invasive tool that helps identify the degree of airway invasion. A number of studies have identified a strong correlation between endobronchial ultrasound definition of airway invasion and histologic invasion. The 20-MHz radial probe is able to identify distinct layers of the airway wall (□ Fig. 99.3, □ Fig. 99.4, □ Fig. 99.5). The depth of invasion and the delineation between

normal and abnormal tissue are easily identified invasively with the endobronchial ultrasound probe.

Pulmonary function testing can be helpful in identifying central airway obstruction. The typical flat truncation of inspiratory and expiratory limbs is suggestive of a fixed airway obstruction (see □ Fig. 99.4). CT of the chest and neck may also be helpful in identifying tracheal pathology. However, an

endoscopic evaluation during each patient's work-up remains essential.

99.3.3 Differential Diagnosis

The differential diagnosis for tracheobronchial masses is rather broad, although most of the etiologies are quite rare. The most common masses in adults are related to malignant disease, whereas in children the most common masses are nonmalignant in nature (□ Table 99.1 and □ Table 99.2). There are also a number of systemic diseases that can initially present with tracheobronchial masses, or new evidence of tracheobronchial involvement may appear further along in the disease course. We briefly review the more common tracheobronchial masses seen with their initial presentations.

Endobronchial Masses Related to Systemic Diseases

Wegener Granulomatosis

WG is a multisystem disease often affecting adults in the fourth and fifth decades of life. It is pathologically defined by necrotiz-

ing granulomatous vasculitis involving the small vessels, but well-defined granulomas can also be located within the tracheobronchial tree. WG commonly involves three distinct areas: the upper respiratory tract, lower respiratory tract, and kidneys. WG involves the tracheobronchial tree in only 10 to 20% of cases but can present with symptoms such as hoarseness, dyspnea, stridor, and progressive central airway obstruction. However, because central airway obstruction can be a presenting feature, an aggressive evaluation of hoarseness or unexplained dyspnea in patients with known or suspected WG is necessary.

Amyloidosis

Amyloidosis is a multisystem disorder characterized by the deposition of insoluble fibrillar proteins in tissues. It may be idiopathic and primary, or secondary to a systemic disease such as multiple myeloma. Both upper and lower respiratory tract disease can occur. Tracheal and lower respiratory tract amyloidosis is especially common in patients with primary amyloidosis.

The most commonly described pattern in amyloidosis is the presence of multifocal plaques within the tracheal and bron-

chial submucosa without extension beyond the airway wall. More localized disease in the form of masslike tumors may also appear in the trachea or bronchi.

Sarcoidosis

Sarcoidosis is a chronic granulomatous disorder of unknown etiology with the potential to involve virtually any organ system. Although otolaryngologic manifestations may occur in up to 40% of patients with sarcoidosis, primary involvement of the trachea or esophagus occurs in fewer than 1% of cases. The true pathogenesis of sarcoidosis is not well defined, but the primary hypothesis suggests that exaggerated cellular immune responses lead to the injury, disruption, and destruction of affected organs. The disease is often self-limited and relatively benign, except when it causes damage to vital organs such as the heart and lungs.

Tracheobronchopathia Osteochondroplastica

TO remains a rare disease characterized by the presence of nodules of cartilage, bone, or both within the submucosa of the

trachea. It was first described in 1855, and as of 1992, only 350 cases had been reported in the literature.

Nonmalignant Tracheal Tumors

Nonmalignant tracheal tumors are oftentimes small (<2 cm), round, and soft. The term nonmalignant is preferred to benign given that although these tumors may not have metastatic potential, their anatomical location is not benign, and they can cause critical airway obstruction.

Recurrent Respiratory Papillomatosis

The most common nonmalignant tumor of the trachea is squamous cell papilloma, also referred to as recurrent respiratory papillomatosis (RRP). This disease has a bimodal onset with both pediatric and adult forms; the pediatric form is typically more aggressive and more likely to involve the tracheobronchial tree than the adult form, which shows a predilection for isolated laryngeal involvement. The true incidence is unknown, but most believe it ranges between 1.5 and 4.5 per 100,000. It appears to occur most often in patients who are immunocom-

promised, with HIV infection/AIDS the most common primary illness.

RRP is a disease of viral etiology, linked to human papilloma-virus types 6 and 11. Morbidity and mortality are not related to the viral infection itself, but rather to the small risk for malignant transformation, the impact of mass lesions on laryngeal function, and airway obstruction. Presenting symptoms of papillomatosis may include cough and hoarseness, but it may also present with stridor and central airway obstruction. The duration of symptoms before diagnosis may vary because a misdiagnosis of asthma or allergies is common.

Granular Cell Tumors

Granular cell tumors were first described in 1926 and thought to be myogenic in origin, but they have more recently been attributed to a neurogenic origin. These lesions are mainly intraluminal in nature but can also invade locally. Malignant transformation has been reported in up to 2% of cases, with tumors larger than 8 mm carrying the highest risk for transformation.

Chondromas

Chondromas are mesenchymal tumors often described as hard, broad-based, and covered by mucosa. They are often found on the internal aspect of the posterior cricoid lamina, but they have been reported throughout the trachea. Calcification commonly occurs but unfortunately does not help distinguish

benignity. Malignant chondrosarcomas may also calcify, and therefore this type of lesion requires further investigation.

Leiomyomas

Leiomyomas commonly occur in the membranous portion of the trachea and originate in smooth muscle within the tracheal wall. Endoscopically, most appear as smooth, polypoid-type masses.

Hemangiomas

Hemangiomas of the upper airway have been described in both the adult and pediatric populations. Endoscopically, they often appear as blue, smooth, broad-based lesions emanating from the posterolateral aspect of the subglottic area. These lesions are covered by normal respiratory epithelium and may simply regress over a period of observation.

Malignant Tracheal Tumors

The most common tracheal tumors are malignant in nature and may contribute to mortality in either of two distinct manners: asphyxiation from central airway obstruction or locoregional invasion with progression of disease. Unfortunately, most patients remain without a diagnosis and present late. The importance of early diagnosis cannot be overstated because patients presenting with early-stage disease and undergoing surgical resection fare better than those presenting later with more advanced disease. Surgical resection rates for tracheal tumors remain low, with most series in the 10% range. Many patients who have potentially resectable tracheal tumors appear to be treated initially with modalities other than curative surgery for unclear reasons.

Squamous cell carcinoma and adenoid cystic carcinoma appear to be the most common primary malignancies of the trachea, together accounting for over three-quarters of all tracheal carcinomas. Other malignant tumors include mucoepidermoid carcinoma, carcinoid, non-squamous cell bronchogenic carcinoma, melanoma, sarcoma, and lymphoma.

Squamous Cell Carcinoma

Squamous cell carcinoma is the most common tracheal tumor. Unfortunately, it presents with a rather rapid progression and is often not amenable to surgical resection. Men are twice as likely to develop squamous cell carcinoma, with 90% of all cases related to tobacco abuse. Squamous cell carcinomas often demonstrate exophytic growth with ulceration and bleeding. The lateral tracheal wall is often involved. In patients with posterior wall involvement, invasion from an esophageal primary should always be considered.

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma is reported as the second most common malignant tracheal tumor. There appears to be no sex predilection, and the age of patients in reported cases ranges from 30 to 90 years, with the average age in the middle forties. Adenoid cystic carcinoma has been described as a relatively

low-grade malignancy originating from the epithelium of mucosal glands lining the respiratory tract. Microscopically, it appears as small, uniform cells that are arranged in a tubular, sheetlike pattern. Adenoid cystic carcinoma will often arise from the posterolateral distal two-thirds of the trachea.

Lymphoma

The incidence of lymphoma has been increasing. The increase is thought to be related to the population with HIV infection; 75,000 new cases occurred in the year 2008. Approximately 75% of lymphomas presenting in the neck region will have nodal involvement, with the remaining 25% being extranodal.

Metastatic Malignant Tumors

Metastatic implants to the trachea fortunately remain uncommon; however, they have been well reported. The most common tumors reported to metastasize to the trachea include thyroid, esophageal, laryngeal, and lung tumors.

99.3.4 Treatment

The etiology of the mass will dictate the overall management, but patients with large obstructing masses will require relief of central airway obstruction through the use of endoscopic methods or the placement of a tracheostomy. One of the particularly challenging aspects surrounding the management of central airway obstruction is that patients typically present late in their course with a critical airway. The first step in the management of central airway obstruction is to secure a stable airway. Because of the complexity of many of these cases, a multidisciplinary approach to further treatment is recommended.

Although the complete management of central airway obstruction is beyond the scope of this chapter, a brief overview of the authors' general approach is provided. Rigid bronchoscopy remains the procedure of choice because of the ability to achieve immediate airway stabilization while providing oxygenation, ventilation, and diagnostic and therapeutic intervention.

The optimal endobronchial therapy depends on the characteristics of the mass. Three types of airway obstruction have often been described, which are illustrated in □ Fig. 99.5. Extrinsic obstruction and mixed obstruction respond well to endobronchial balloon dilation and stenting, whereas intrinsic disease may respond favorably to direct tumor destruction and excision (laser vaporization, cryotherapy, and/or mechanical débridement). The presence of purely extrinsic disease remains a contraindication to the use of the destructive therapies such as laser and cryotherapy because these damage the airway wall.

Because many patients with obstruction will present late in the disease course (and therefore may not be eligible for tracheal resection), tracheal stents remain a good option. Stents palliate the dyspnea resulting from central airway obstruction and may help liberate patients from the ventilator. The most common types of stents available in the United States are silicone and self-expanding metal stents. Silicone stents come in various sizes and are easy to modify. They are also easy to remove or reposition, but placement can be more difficult and requires the use of rigid bronchoscopy. Metal stents can be placed via

flexible bronchoscopy but are more expensive; in addition, granulation tissue is more likely to develop, which limits removal or repositioning.

Endobronchial Masses Related to Systemic Diseases

Wegener Granulomatosis

The management of tracheobronchial WG can be difficult, and a multidisciplinary approach should be used. Systemic symptoms are often treated with steroids, but more potent immunomodulators may be required. Airway disease may not respond in the same fashion as systemic disease and therefore may need to be treated independently. Endoscopic and/or surgical therapy is indicated in those with central airway obstruction. Direct intralesional treatment with corticosteroids or mitomycin has been reported. Other potential interventions include balloon dilation, stent placement, and resection. Because of high rates of restenosis in the face of active disease, surgical resection should be reserved for cases in which WG has resolved.

Amyloidosis

A diagnosis of amyloidosis should prompt referral to a medical oncologist for systemic evaluation; however, no medical therapy available at this time appears to modify its overall course. For patients with secondary amyloidosis, treatment of the underlying disease appears to delay amyloid deposition and disease progression. Surgical treatment should focus on maintaining airway patency, preserving laryngeal function, and improving voice quality. Complete resection at the cost of function is discouraged because recurrence is common regardless of the extent of excision. Localized laser and microdébrider resection are the modalities most commonly used.

Sarcoidosis

The treatment of sarcoidosis commonly involves the use of systemic corticosteroids, which has been associated with improvement in more than 80% of cases of laryngeal sarcoid. Systemic steroids remain the first-line treatment in all patients, except those with central airway obstruction. If central airway obstruction is severe, airway interventions may be required; these include balloon dilation, endoscopic excision or destruction, and/or stent placement. Urgent tracheostomy may be required for patients with critical airway disease. Direct intralesional treatment with corticosteroids or mitomycin has been reported but will not have an immediate effect.

Nonmalignant Tracheal Tumors

Recurrent Respiratory Papillomatosis

Although current medical and vaccine therapies are the subjects of active investigation, current clinical care is directed at removing the lesions. The treatment of RRP focuses on the surgical débridement of lesions in order to control symptoms. Most advocate early and aggressive intervention for patients presenting with any form of progressive airway obstruction. Laser therapy and débridement for papilloma destruction are the most commonly performed procedures. Other therapeutic

options include photodynamic therapy, with one study showing a small but statistically significant decline in papilloma recurrence. Nonsurgical approaches include the use of antiviral agents such as acyclovir, cidofovir, interferon, and ribavirin. More recent work has demonstrated a significant decrease in papilloma recurrence after the initiation of antireflux therapy, most notably ranitidine, which may have an immune-modulating effect.

Chondromas

Definitive treatment requires surgical resection because of a high incidence of recurrence with endoscopic resection.

Leiomyomas

Tracheal resection is recommended because recurrence and death related to hemorrhage after endoscopic excision have been reported. Although the data are limited, some experts recommend bronchoscopic excision only when a lesion is clearly pedunculated because of the previously mentioned risk for hemorrhage.

Hemangiomas

In patients with symptomatic hemangiomas, surgical resection has traditionally been the treatment of choice. However, recent work suggests that propranolol may replace surgery as a first-line treatment. The data remain retrospective and are derived from small case series, but because of the significant improvements noted and the minimal side effect profile of propranolol, this treatment continues to hold promise. Other options include steroids, interferon, or laser therapy.

Malignant Tracheal Tumors

Treatment for a patient with tracheal cancer remains highly individualized, with little literature available to help guide one's decisions during planning. Unfortunately, there is currently no universally accepted, data-driven staging system for tracheal carcinoma. The prognostic implications of local lymph node involvement also remain unclear. In contrast, evidence of metastatic disease does appear to correlate with worse outcomes. The most important prognostic factors related to survival appear to be the histology of malignancy, along with the ability to achieve a histologically complete resection. Patients with adenoid cystic carcinoma or mucoepidermoid carcinoma appear to do better than those with other malignancies.

Patients undergoing resection appear to do better, and those undergoing complete resection seem to do the best. This is the case not only in patients with local disease but also in those patients with advanced disease who undergo a local resection. Surgical resection remains the procedure of choice for malignant tracheal tumors. Despite this, large series from Europe show that only 10% of patients with tracheal cancer undergo resection, whereas another 40% could have been offered resection. Experts in tracheal resection believe that up to 50% of the trachea can safely be resected without causing significant stress or anastomotic compromise. Thanks to the pioneering research of Hermes Grillo and his colleagues, tracheal resection techni-

ques continue to improve, and the larger centers quote operative mortality rates of around 3%.

Patients with obvious widespread metastatic disease and a large tumor burden should be offered palliative interventions, whereas resection should be considered for those with local disease and no comorbidities. When patients present with locoregional disease, a multidisciplinary approach to their disease and therapeutic options should be used. It is important that these patients undergo evaluation and treatment at large tertiary centers with extensive experience in complex airway management and tracheal resection. This type of centralized care will not only improve patient care but also provide large databases to help promote research within this disease.

Endoscopy is often used as a treatment for patients with central airway obstruction and as a palliative measure for those with unresectable disease. It is also used to evaluate and treat hemoptysis, and to aid in surgical planning. Similarly, radiotherapy can be utilized either as a primary mode of treatment or as adjuvant therapy after resection. High-dose radiation to the chest remains relatively contraindicated because it results in changes and scarring when generally surgical excision would be a viable alternative. Adjuvant radiotherapy appears to increase survival times; this is thought to be related mainly to improved local control of disease. Few data exist regarding systemic chemotherapy in the treatment of tracheal malignancies. Because of the paucity of data, we recommend chemotherapy only for patients in clinical trials who have primary tracheal malignancies.

The outcomes of patients with tracheal malignancies remain poor, with 5-year survival rates in the 10 to 15% range. However, as noted above, observational data sets have found that those undergoing surgical resection of their malignancy appear to have improved outcomes, with some studies quoting 5-year survival rates higher than 50%.

Lymphoma

One obvious exception to the above treatment paradigm is lymphoma within the tracheobronchial tree. Options for both diagnosis and treatment may vary among institutions. There still remains significant debate regarding the proper method of obtaining tissue. Most pathologists prefer excisional biopsies to help diagnose lymphoma and define the particular subtype. Fine-needle aspiration can often provide a diagnosis, but the lack of architecture sometimes makes subtype definition difficult. Lymphoma is generally treated with chemotherapy and radiation; surgery rarely if ever plays a role in the disease. However, the presence of central airway obstruction will often be an indication for airway stabilization until a response to chemotherapy and radiotherapy has begun.

Metastatic Malignant Tumors

Metastatic disease should always be confirmed pathologically if the confirmation will influence future treatment or if there is a question regarding the diagnosis. No specific treatments are available to individualize care; rather, it is recommended to proceed with a general approach to airway obstruction and palliation.

99.4 Roundsmanship

- Cases of bacterial and fungal tracheobronchitis remain relatively rare; however, they can be life-threatening if misdiagnosed.
- Endobronchial tuberculosis remains a worldwide infectious disease problem with the potential to cause recalcitrant tracheobronchial stenosis.
- Nonmalignant tracheal tumors are more common in the pediatric population and are often best treated with surgical resection.
- Surgical resection with curative intent remains the goal in patients who have localized primary tracheal malignancies
- Endoscopic methods remain a mainstay for the treatment of malignant disease during attempts to palliate central airway obstruction.

100 Tracheobronchoscopy and Esophagoscopy

Thomas L. Carroll

100.1 Introduction

Tracheobronchoscopy and esophagoscopy are essential, fundamental tools for the otolaryngologist. They afford the evaluation, management, and surveillance of subglottic, tracheal, bronchial, and esophageal disease and injury. Familiarity with the anatomy of the larynx, hypopharynx, esophagus, and lower airway is paramount for those performing these interventions. A thorough understanding of the available instrumentation, the techniques of use, and the advantages and disadvantages of both rigid and flexible endoscopy are required for the operating surgeon.

100.2 Tracheobronchoscopy

100.2.1 Anatomy

The subglottis begins approximately 5 mm below the upper lip of the true vocal folds. It extends to the inferior border of the cricoid cartilage, where the trachea begins. The cricoid is the only complete ring in the airway. The trachea, with its membranous posterior wall, extends approximately 10 cm (in adults) to the carina, where the right and left main bronchi begin. The main bronchi further divide into lobar bronchi (three on the right, two on the left), and yet again into lobar segmental bronchi (18 in all). The trachea, bronchi, and further diminishing levels of the lower airway are also referred to as generations; the trachea is the zero generation, the main bronchi are the first generation, and so forth. Each of the lobar and lobar segmental bronchi has a specific, anatomically appropriate name (□ Fig. 100.1).

100.2.2 Indications

Indications for tracheobronchoscopy are categorized as either diagnostic or therapeutic. Evaluations for secondary malignancy in head and neck cancer and for stridor with concern for airway stenosis or foreign body aspiration are the most common reasons for an otolaryngologist to perform tracheobronchoscopy. Other reasons to perform this intervention include unexplained hemoptysis, chronic cough, unexplained wheezing or dyspnea, infectious concerns, and imaging findings requiring direct evaluation. These indications often lead to interventions that include bronchoalveolar lavage, transbronchial or intraluminal biopsy, removal of a foreign body, assistance in intubation (endotracheal tube positioned over a flexible bronchoscope), assistance in the placement of a percutaneous tracheotomy tube, and suctioning of inspissated secretions or blood clots.

100.2.3 Equipment

Tracheobronchoscopy can be performed with either rigid or flexible endoscopes; both types have unique roles in the management of tracheobronchial pathology. Although they are used to evaluate the subglottis, trachea, and bronchi, these

pieces of equipment are typically referred to as bronchoscopes. Their inherent advantages and disadvantages in both the operative and office settings must be understood by the operating surgeon to obtain the best possible visualization and most facile completion of the indicated intervention.

Rigid Bronchoscopy

Rigid bronchoscopes are specialized metal tubes available in a variety of lengths and diameters. They are often divided arbitrarily into pediatric and adult sets. They typically range from 3 to 8.5 mm in diameter and increase in length to proportionally accommodate the size of the patient's larynx and trachea (□ Fig. 100.2). The tip of a rigid bronchoscope is beveled to facilitate passage through the oral cavity, larynx, and carina. The wall of the distal end of the scope is perforated to allow ventilation during rigid tracheobronchoscopy (□ Fig. 100.3). Although pediatric and adult models can vary, the proximal end has an adapter for a light source and an anesthesia ventilation circuit. The proximal end also allows the placement of a rigid Hopkins rod telescope of exact length, as well as flexible suction tubing and working instrumentation through an airtight rubber gasket (□ Fig. 100.4). The working instruments are of a precise length so that their tips to exit just beyond the distal end of the bronchoscope. Visualization through the rigid scope occurs when the examiner looks either directly through a glass window at the proximal end or through the eyepiece of an inserted Hopkins rod telescope (with or without a camera/video system attached). The direct view can be somewhat limiting; therefore, a Hopkins rod telescope with a straight or angled lens is used to place the point of visualization at the distal end of the scope, nearest the pathology of interest. Most surgeons attach a video camera to the eyepiece of the Hopkins rod telescope to project the picture of the airway onto a monitor in front of them. Video technology also provides a means to photo document a procedure and work in a more ergonomically comfortable position.

Rigid bronchoscopy is performed exclusively in the operating room and almost exclusively under general anesthesia. The primary advantages of a rigid bronchoscope include a large lumen and the ability to ventilate the patient directly through the scope during an intervention. These two advantages make it possible to remove large foreign bodies, control brisk bleeding for which the passage of a larger-diameter suction is required, debulk airway tumors, and discharge airway stents. Pediatric otolaryngologists and surgeons who remove foreign bodies from the trachea and proximal bronchi almost exclusively use rigid bronchoscopy as a first-line intervention for the aforementioned reasons and have various sizes available as needed. Rigid bronchoscopes have the primary disadvantage of being too stiff, short, and wide to allow access to most second-generation (lobar) and third-generation (lobar segmental) bronchi.

Flexible Tracheobronchoscopy

Flexible bronchoscopes, transnasal esophagoscopes, and flexible laryngoscopes can all be used to evaluate the lower airway.

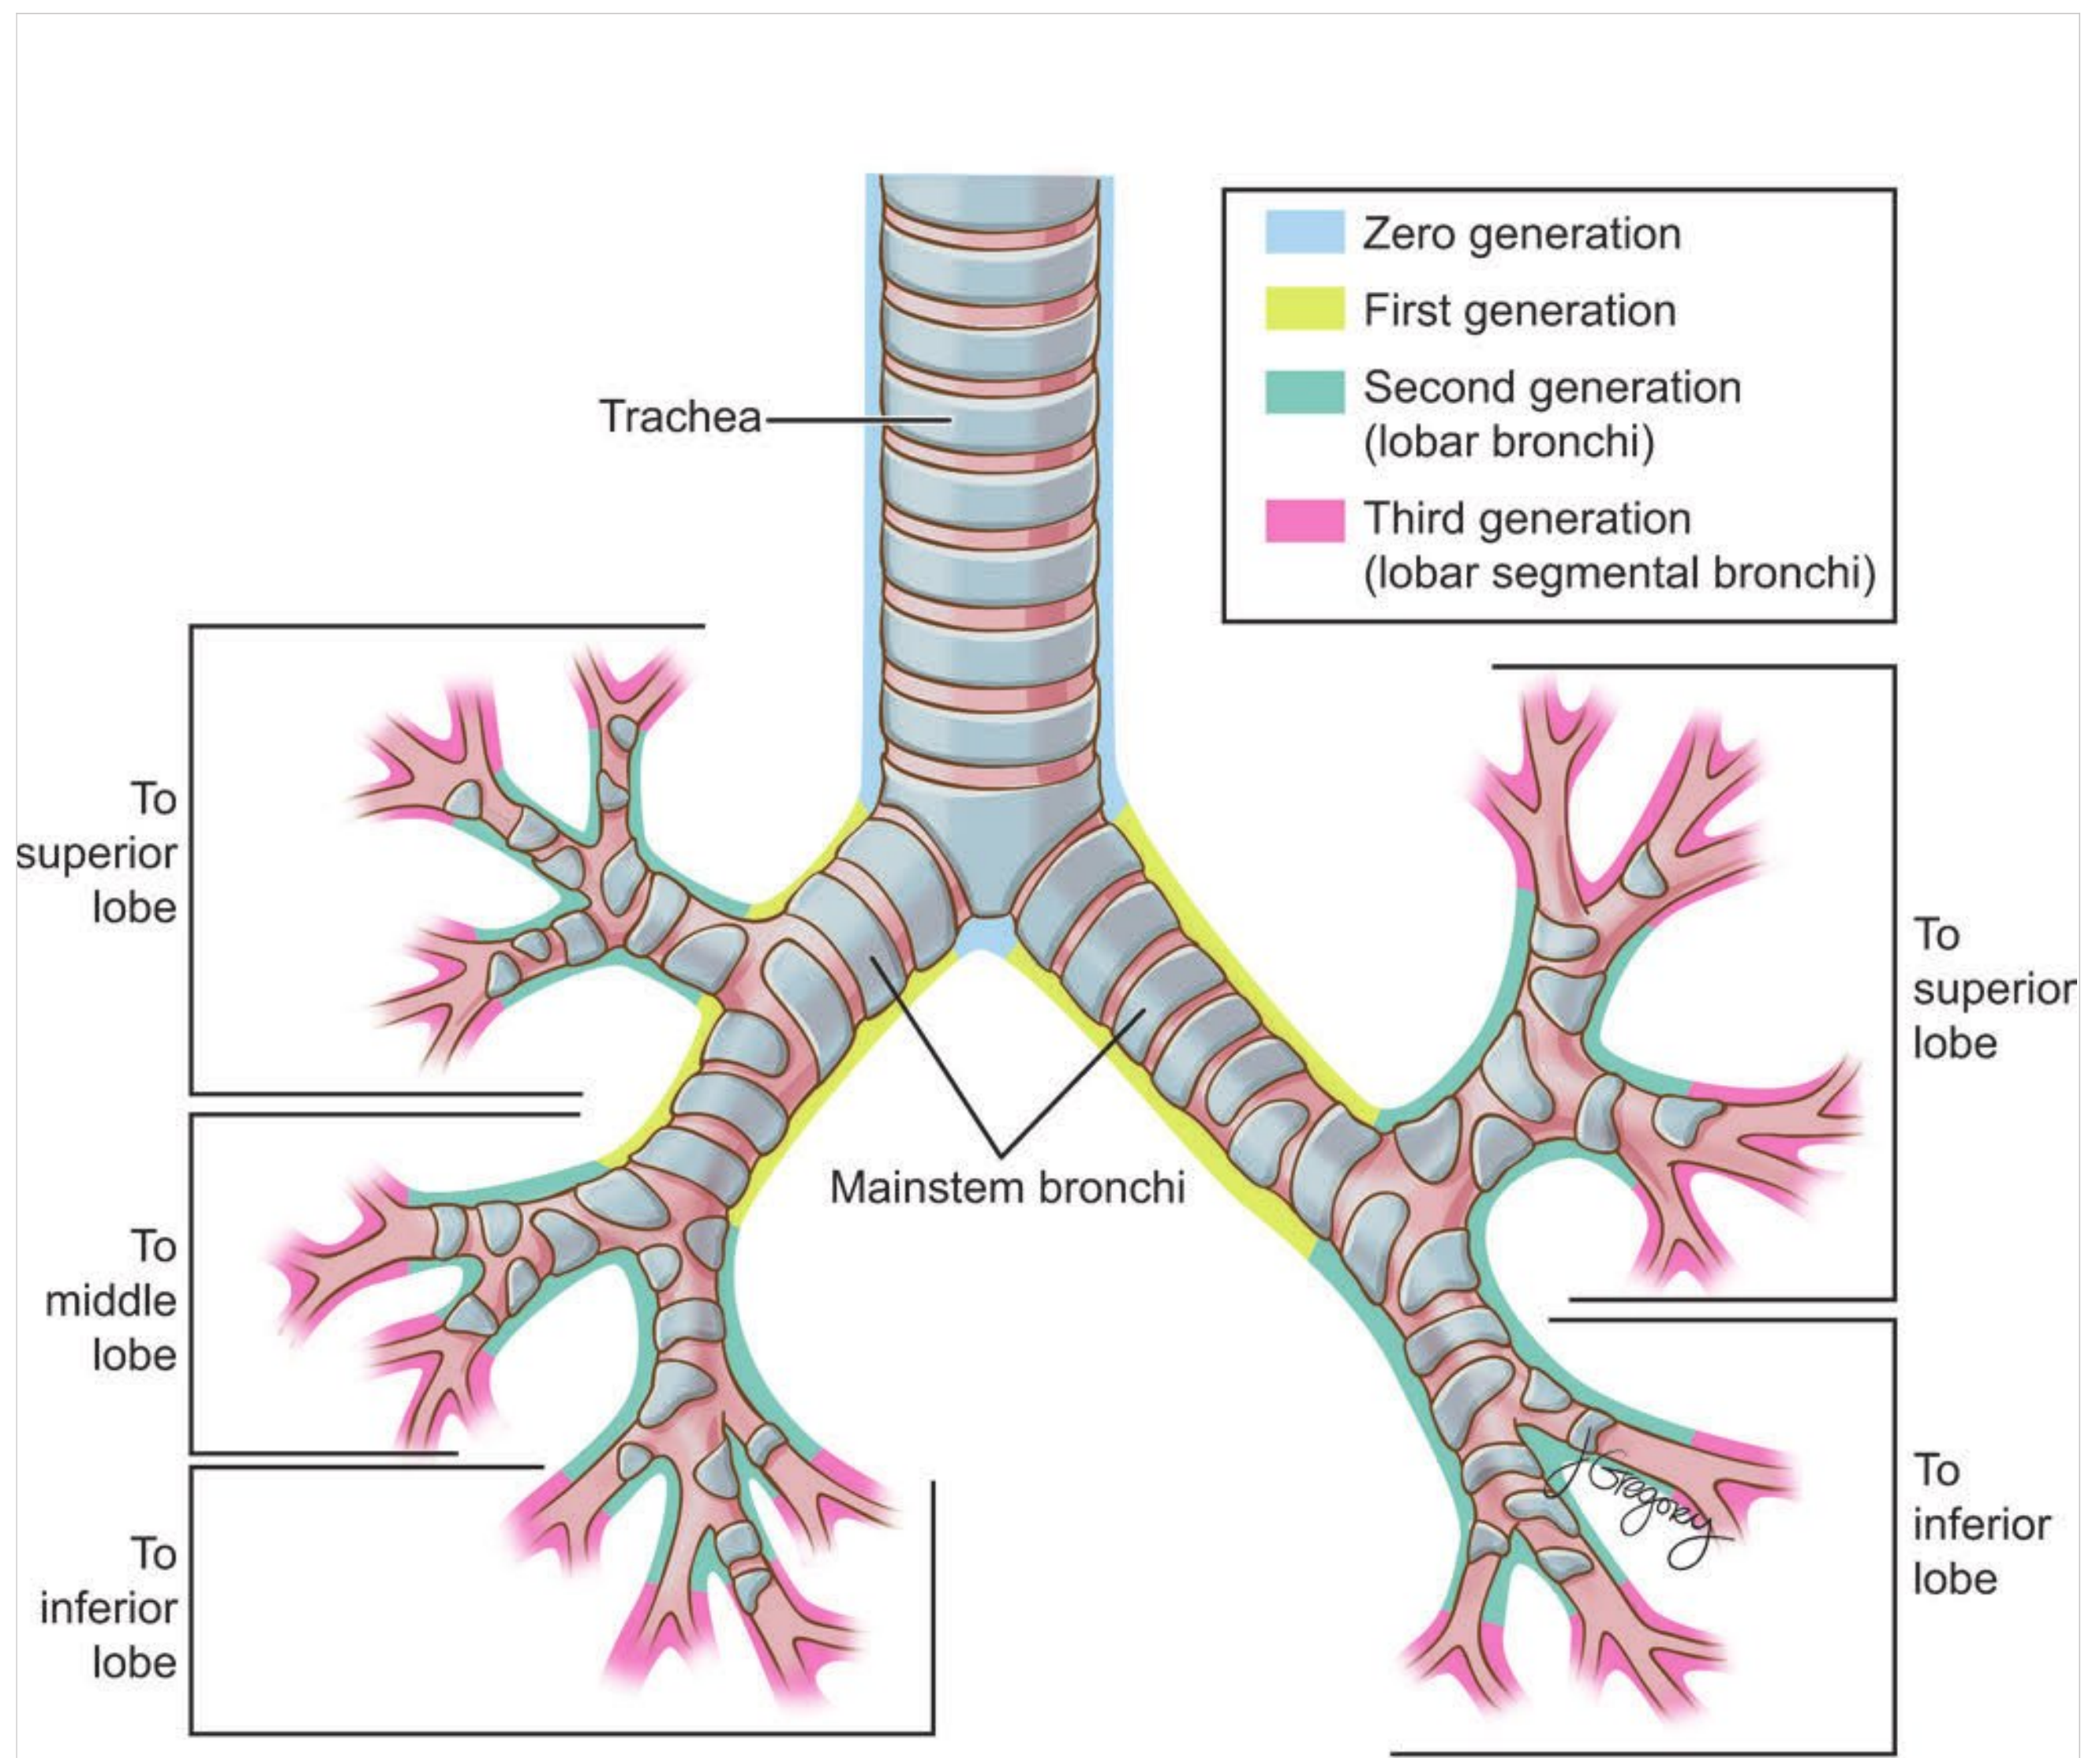

Fig. 100.1 Tracheobronchial tree.

Fig. 100.2 Adult (top) and pediatric (bottom) rigid bronchoscopes.

Fig. 100.3 Ventilation ports at the distal end of a rigid bronchoscope.

Fig. 100.4 Proximal ends of rigid bronchoscopes, with rigid endoscope inserted (top right).

Each has its advantages and limitations; the flexible bronchoscopes and transnasal esophagoscopes are similar. The scopes can vary in length and diameter, but are all comparable in terms of their features. A typical adult flexible laryngoscope is approximately 30 cm in length and 4.1 mm in diameter. The average adult bronchoscope is 60 cm in length and 6 mm in outer diameter, and the average transnasal esophagoscope is 60 cm in length and 5.1 mm in diameter. These lengths and sizes vary among manufacturers, and the scopes for the pediatric population can be as small as 2.2 mm in diameter. The anatomical area being evaluated and the patient's age and ability to tolerate an office-based procedure will typically dictate the length and diameter of the flexible endoscope used, the type and level of anesthesia required, and the location of the procedure. The endoscopes are available with and without working channels that allow suctioning and the passage of small (usually less than 2 mm in diameter) instruments for endoscopic procedures. Commonly used channel instruments include cup forceps, laser fibers, balloons, injection/biopsy needles, and foreign body retrieval tools, such as baskets and graspers.

Flexible endoscopes are available in two forms: fiber-optic and distal chip. Although distal chip technology is becoming more accessible and popular, flexible fiber-optic scopes continue to be commonplace. Fiber-optic bronchoscopes are flexible plastic and metal tubes composed of bundles of glass fibers that transmit light to the scope's distal end and an image directly to a proximal eyepiece. The glass fibers are delicate; if the scope is mishandled, fiber breakage can lead to a patchy image. Alternatively, chip tip digital endoscopes use a charge-coupled device to capture an image. As the image is projected through a lens onto the capacitor array (a two-dimensional photoactive region) of the charge-coupled device, each capacitor accumulates an electric charge proportional to the light intensity at that location. A control circuit ultimately converts the charges of the entire array into a sequence of voltages. In the chip tip scope, these voltages are then sampled, digitized, and projected as a digital video image that can be displayed and recorded. Chip tip digital endoscopes are less delicate than their fiber-optic equivalents. They create clear, crisp images without the pixilation

seen in the images of even the most pristine fiber-optic scopes. Some of the digital processors have the added ability to simulate light filters to more clearly define vascular and neoplastic lesions. Chip tip digital endoscopes are more expensive and require specialized processing devices for visualization of the image (there is no way to directly visualize through a chip tip scope); therefore, they are not as appealing to some clinicians. Both fiber-optic and chip tip endoscopes can be attached to video recording devices with monitors for documentation purposes.

The primary advantage of flexible bronchoscopy is the ability to visualize and intervene in smaller, more distal second- and third-generation bronchi. A flexible scope also provides angles of visualization and larger visual fields that are impossible with a fixed, rigid Hopkins rod. The scope can often be passed, diameter permitting, through the lumen of an endotracheal or tracheotomy tube. The disadvantages of flexible bronchoscopes include the inability to suction at high volume, pass large instruments for intervention, and ventilate through the instrument.

100.2.4 Technique

Rigid Tracheobronchoscopy

In the adult patient, general anesthesia is typically induced, and ventilation proceeds via a face mask. As an alternative, spontaneous ventilation techniques can be used and are often preferred in pediatric cases. The adult patient is placed with the neck flexed and the head extended (sniffing position) to allow better visualization of the larynx. This position may be changed to facilitate access to the trachea and distal bronchi as the case proceeds. The table is turned toward the operating surgeon who takes over mask ventilation temporarily while positioning himself or herself at the head of the bed. The surgeon places an upper dentition mouth guard or protects the upper gingiva with gauze. The dominant hand introduces the rigid bronchoscope into the oral cavity while the nondominant hand opens the mouth and stabilizes the scope. The bevel of the distal bronchoscope should be in the anterior (neutral) position to allow elevation of the base of the tongue and epiglottis as the larynx is visualized directly (□ Fig. 100.5). The bronchoscope should be passed through the vocal folds with the beveled edge rotated 90 degrees from neutral to avoid unnecessary trauma. Locating the glottis can be difficult when this direct method is used. An alternative technique is to use an anesthesiologist's straight or curved blade laryngoscope in the nondominant hand to better expose the endolarynx while placing the bronchoscope between the vocal folds with the dominant hand. Once the bronchoscope is in place, the surgeon removes the laryngoscope blade while visualizing through the bronchoscope to ensure that its position is maintained. It is common to use either method with a Hopkins rod telescope already inserted into the rigid scope for visualization on a video monitor.

After the rigid bronchoscope is safely in the trachea, the anesthesia team can attach the ventilation circuit to its proximal ventilation port, and ventilation can safely proceed. Standard positive-pressure ventilation is not always possible if the bronchoscope must be frequently removed during the case or if the pathology is in the proximal trachea, resulting in a situation in which the ventilation ports on the bronchoscope are proximal

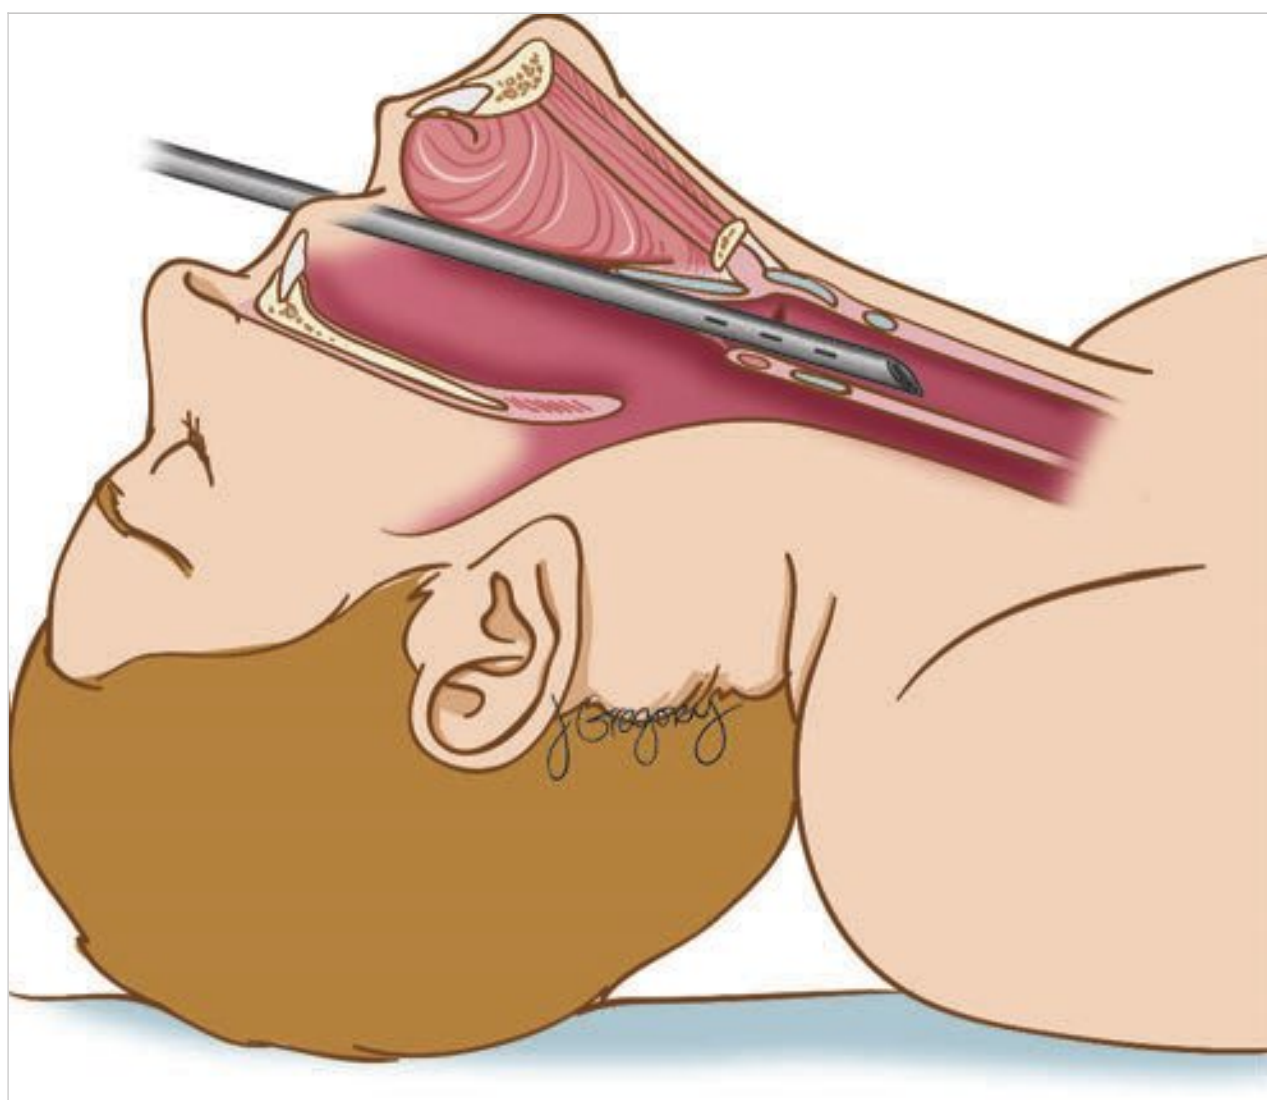

Fig. 100.5 Rigid bronchoscopy is performed by aligning the axis of the oral cavity, glottis, and trachea with head extension and neck flexion.

to the vocal folds. In these instances, a jet ventilation technique can be used via the bronchoscope or, alternatively, via a catheter placed into the airway outside the bronchoscope.

When the main bronchi are evaluated, it is often necessary to manipulate the neck to obtain a better angle for access to the more distal airway. In such a scenario, the head is tilted so that the ear is brought closer to the contralateral shoulder. The rigid bronchoscope has been mostly supplanted by the flexible bronchoscope, but it is still preferred for the retrieval of foreign bodies, especially if the objects are sharp. Because of the hollow lumen and steel structure of the endoscope, a sharp object can be delivered into it, after which both can be removed together so that the sharp object cannot injure tissue or become snagged as it is withdrawn.

Flexible Tracheobronchoscopy

Flexible tracheobronchoscopy can be performed in multiple settings under various levels of anesthesia. It can be successfully accomplished without sedation but with topical local anesthesia in the office setting, under conscious sedation with topical anesthesia in an endoscopy suite, or under general anesthesia via an existing endotracheal tube. A flexible endoscope passed through the nose is easily manipulated during an evaluation of the subglottis, trachea, and main bronchi in the office setting. Office tracheobronchoscopy without sedation is performed with the patient seated upright (□ Fig. 100.6). If the subject does not have a tracheotomy, nebulized 4% plain lidocaine is administered orally. At the same time, the nasal passages are topically decongested and anesthetized. With the surgeon facing the patient, a flexible endoscope is placed through the more patent nasal passage. The larynx is visualized and evaluated for pathology, abnormalities of vocal fold motion, and glottic stenosis. If the larynx remains too sensate for the procedure to proceed, additional 4% lidocaine is applied to the vocal folds through the working channel of the endoscope. For the tracheotomized patient, lidocaine applied via the working channel and

Fig. 100.6 Flexible tracheobronchoscopy can be performed comfortably under topical anesthesia.

the tracheostoma can also be used to anesthetize the larynx and lower airway. In addition, the distal examination can be performed via the tracheotomy. If it is not possible to offer nebulized treatments in the office setting or a scope with a working channel is not available, lidocaine can alternatively be applied by injecting it into the airway percutaneously. This produces a cough, which distributes the medicine. Lidocaine can also be applied transorally with an Abraham cannula. Taking the time to slowly and comfortably topically anesthetize a patient is invaluable for the patient's experience. It also allows the surgeon to survey the anatomy methodically and perform any procedures deemed necessary.

When it is necessary to evaluate the lower airway beyond the main bronchi, sedation is often needed, so the procedure is performed in a monitored endoscopy suite with the patient in the supine position. In addition to the intravenous sedatives given, topical local anesthesia is routinely administered directly to the larynx and trachea to decrease the need for excessive sedation and allow the patient to maintain satisfactory respiration. With the endoscopist at the head of the bed for orientation, the flexible bronchoscopy proceeds. It is imperative to remain aware of the anteroposterior and lateral orientation during flexible tracheobronchoscopy in the awake/office or sedated/endoscopy suite setting. General anesthesia can be administered for flexible bronchoscopy if the patient cannot tolerate the procedure because of anxiety or a severe gag reflex, or if the delicate nature of the procedure requires respiration to be held temporarily.

100.2.5 Risks and Adverse Effects

The most severe complication of rigid tracheobronchoscopy is pneumothorax or pneumomediastinum. If this is suspected, a chest X-ray is obtained after the procedure. Depending on the severity of the intervention, a chest X-ray may also be obtained after flexible bronchoscopy. An unsedated transnasal bronchoscopic procedure may have to be aborted approximately 3% of the time because of a narrow nasal vault, epistaxis, or patient intolerance. Loss of the airway requiring surgical intervention is possible during rigid bronchoscopy, as is the case in any proce-

cedure in which general anesthesia is administered and an endotracheal tube is not placed. This possibility should be considered preoperatively for any patient with potentially obstructing lesions of the oral cavity, larynx, or pharynx or any patient with limited neck mobility. The surgeon should have appropriate instrumentation available for emergent tracheotomy during all airway cases.

100.3 Esophagoscopy

100.3.1 Anatomy

The esophagus is a muscular tube that extends from the hypopharynx to the stomach. It is composed of only four layers, lacking a serosa outside the adventitial layer. The muscular layer, deep to the mucosa and submucosa, is composed of skeletal muscle in the proximal third and smooth muscle in the lower third of the esophagus (the muscular layer of the middle third is mixed). The upper esophageal sphincter (UES) is the tonically contracted proximal margin of the esophagus located approximately 16 cm from the incisors at the level of the sixth cervical vertebra. For all landmarks, an additional 3 cm can be added when they are measured from the nasal sill. The UES is 2 to 4 cm in length and is a functional unit that is composed of the cricopharyngeus muscle as well part of the inferior constrictor, upper esophagus, and the cricoid and arytenoid cartilages. The esophagus length ranges from 20 to 24 cm, extending to the lower esophageal sphincter (LES). The LES is not a true sphincter but a 2- to 4-cm area composed of tonically contracted smooth muscle from both the esophagus and diaphragm; it is both a physiologic and an anatomical entity located approximately 39 cm from the incisors at the level of the 11th thoracic

vertebra adjacent to the cardia of the stomach. The rugae of the stomach meet the smooth wall of the esophagus at the gastroesophageal junction. A location of the gastroesophageal junction more than 2 cm above the diaphragmatic pinch is considered a hiatal hernia. The squamous epithelium of the esophagus meets the gastric columnar epithelium of the stomach at the squamocolumnar junction, also known as the Z-line. This is approximately 40 cm from the incisors and should correlate with the termination of the longitudinal submucosal vessels of the esophagus and gastroesophageal junction. Irregularities of the Z-line can be indicative of esophagitis or possibly Barrett esophagus (squamous metaplasia). Barrett esophagus should be suspected when tongues of what appear to be gastric mucosa migrate proximal to the gastroesophageal junction, infringing on the area of the longitudinal esophageal vessels. The squamocolumnar junction and the gastroesophageal junction, when normal, are found at the same level but are, by definition, different.

Other anatomical areas of interest are the external compressors of the esophageal lumen. Moving distally through the esophagus, they are the aorta (pulsatile, approximately 23 cm from the incisors); the left main bronchus (approximately 27 cm from the incisors); and the diaphragmatic pinch (approximately 38 cm from the incisors; □ Fig. 100.7).

100.3.2 Indications and Patient Selection

Rigid esophagoscopy and flexible esophagoscopy are typically performed for both diagnostic and therapeutic purposes. Esophagoscopy can be used to inspect the lumen of the esophagus

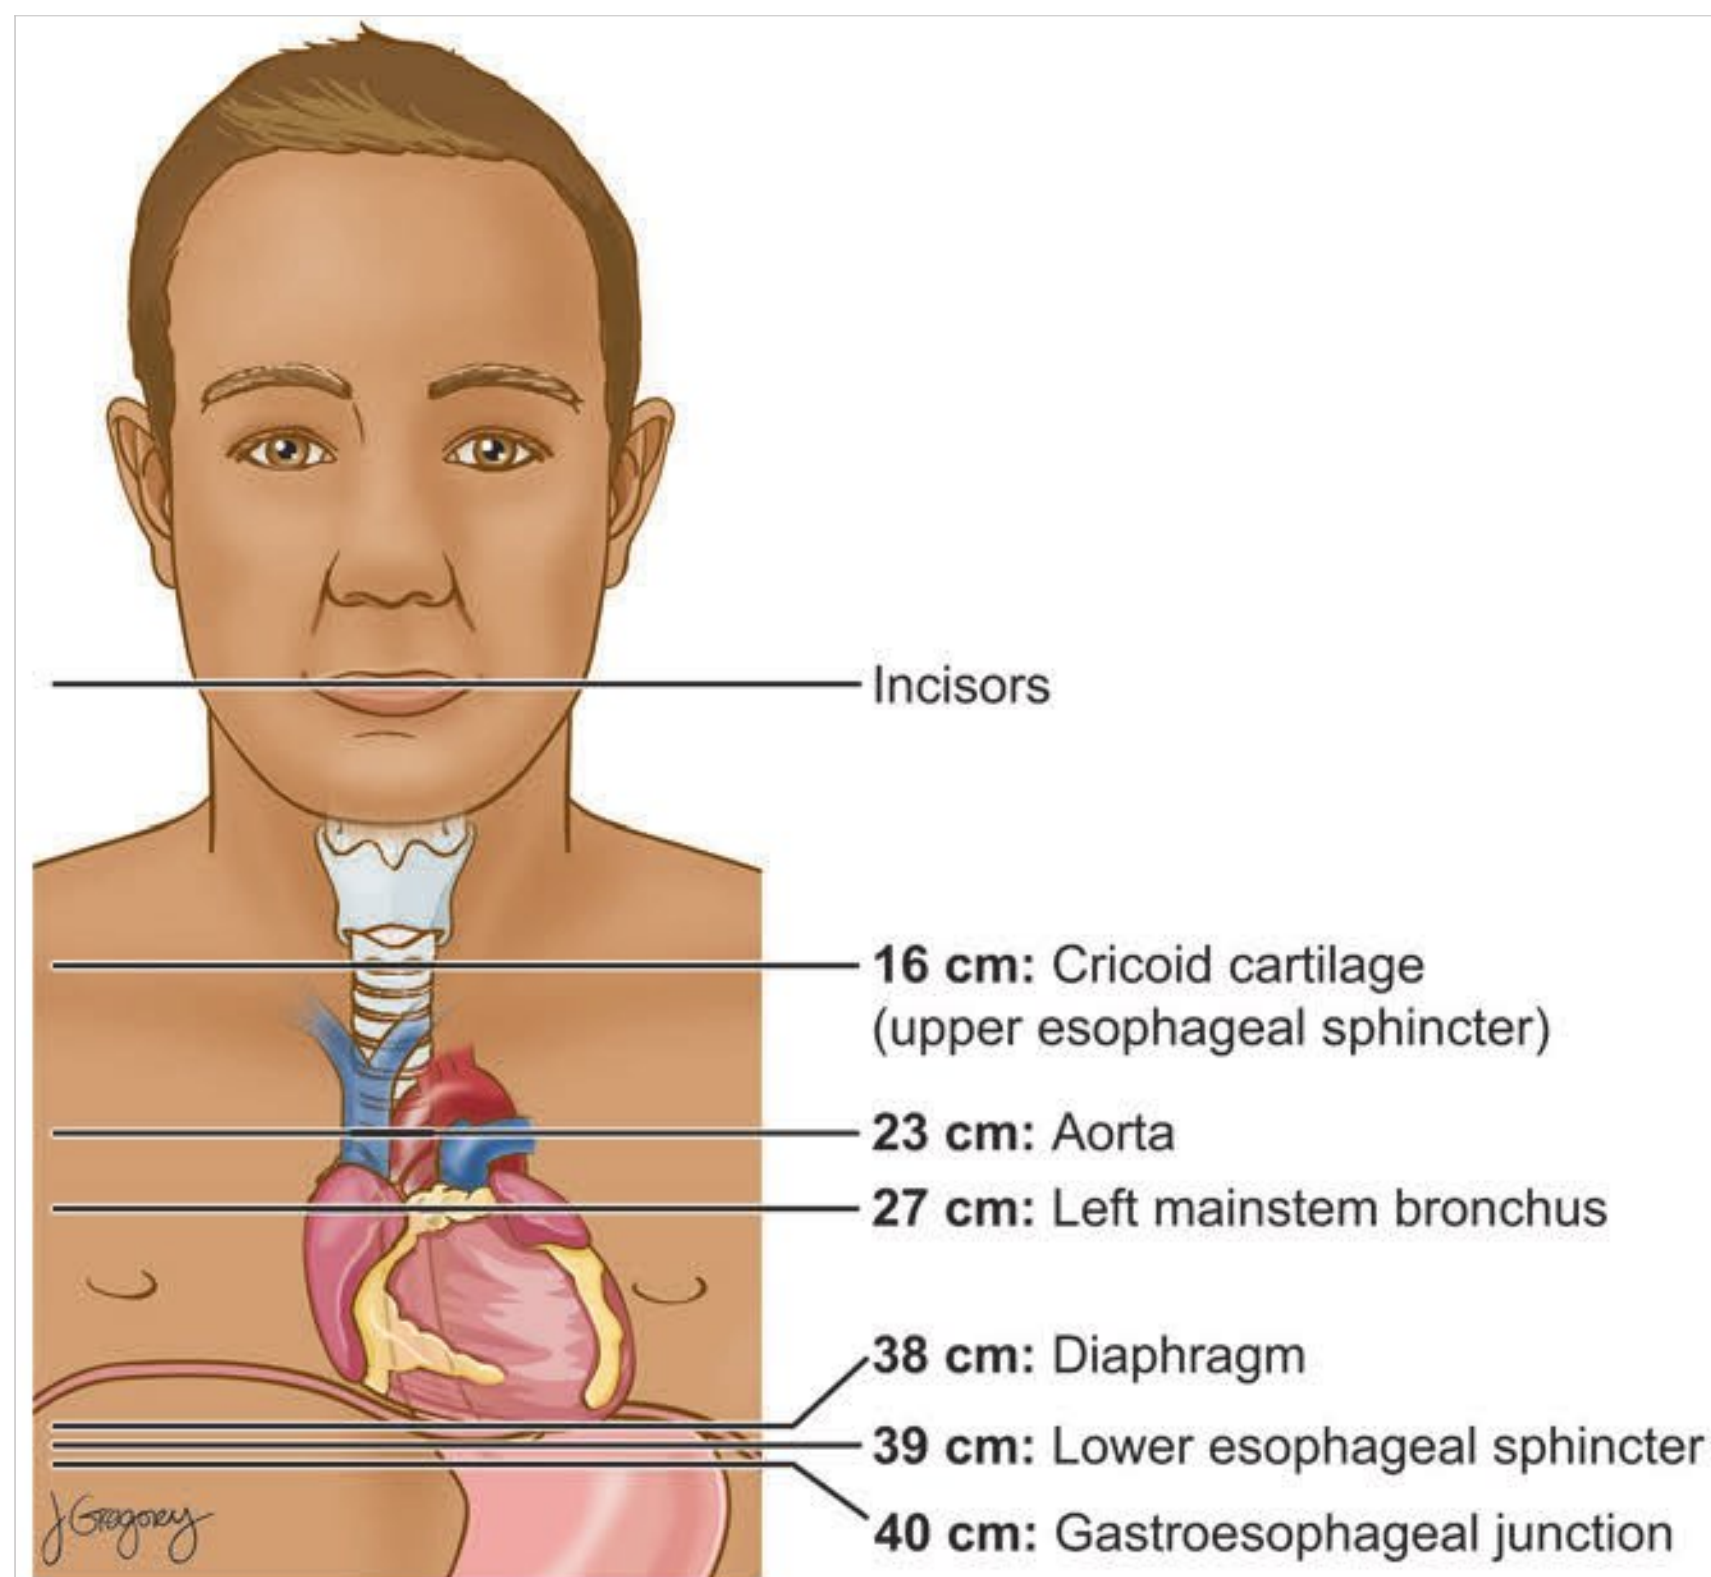

Fig. 100.7 Distances from the incisors to the various landmarks encountered during esophagoscopy.

Fig. 100.8 Rigid esophoscopes.

for pathology including tumor, strictures, foreign bodies, and changes to the mucosal surface caused by infectious or inflammatory conditions. Diagnostic biopsies can be performed as necessary. Esophagoscopy is not an effective tool to evaluate peristalsis because the presence of the scope in the esophagus alters its function. Esophagoscopy is often used to deliver instruments for therapeutic interventions, including balloons for dilation, graspers, laser fibers, and devices for cutting and radio-frequency ablation. Esophagoscopy also aids in the placement of tracheo-esophageal puncture devices after laryngectomy.

Patients are chosen for esophagoscopy based on their history, their response or lack of response to medical therapies, or the results of other diagnostic tests. Radiographic studies such as chest X-ray and barium esophagography may reveal foreign bodies; anatomical abnormalities such as webs, strictures, and diverticula; or evidence of achalasia that warrants visualization or intervention. The indications for esophagoscopy in patients with laryngopharyngeal reflux are ill defined. Recent findings suggest that patients presenting with symptoms of laryngopharyngeal reflux without symptoms of gastroesophageal reflux disease (GERD) may be at an elevated risk for esophageal adenocarcinoma. Thus, the presence of laryngopharyngeal reflux in and of itself may warrant esophagoscopy to rule out Barrett esophagus, erosive esophagitis, or adenocarcinoma. Unexplained esophageal dysphagia, weight loss, hemoptysis, hematemesis, odynophagia, and regurgitation are also indications for esophagoscopy. Patients who have head and neck cancer with esophageal symptoms require esophageal screening to rule out secondary malignancy or alternative pathology.

100.3.3 Equipment

Both rigid and flexible esophoscopes are available and have inherent advantages and limitations. Rigid esophoscopes are employed exclusively in the operating room, whereas flexible esophoscopes can be used both in the operating room and in the office with an unsedated patient.

Fig. 100.9 (a) Transnasal endoscope and (b) flexible gastroscop.

Rigid Esophagoscopy

A rigid esophoscope is a hollow, oval metal tube with a flared, blunt tip and a proximal “keel” for easier manipulation and orientation. It is available in many lengths and diameters (□ Fig. 100.8). Unlike rigid bronchoscopes, rigid esophoscopes typically do not have a separate port for a telescope and do not have a proximal adapter for instrumentation. Light is delivered via a long light carrier that is inserted through a separate, smaller port and emerges near the distal tip. The proximal opening is the only place through which both visualization (with or without a Hopkins rod telescope) and instrumentation occur. Rigid esophagoscopy is superior for evaluating the cervical esophagus because of difficulties of insufflation and visualization in the area of the UES. It is also preferred when larger biopsies or higher-volume suction is needed.

Flexible Esophagoscopy

Flexible esophoscopes are available in two varieties. Transnasal esophoscopes are intended for use in an awake, office setting, whereas flexible gastroscopes are used for sedated, transoral esophagoscopy in the operating room or monitored endoscopy suite. Both types of flexible esophoscope routinely incorporate chip tip digital technology, deliver air and water for visualization, have at least a 2-mm working channel for suction and the insertion of smaller biopsy forceps and intervention devices, and are available in various diameters and lengths. A typical transnasal esophoscope is 4.5 mm in diameter, whereas a gastroscop ranges from 9 to 12 mm in diameter and can deliver larger working instrumentation compared with a transnasal esophoscope. Transnasal esophoscopes have only one control wheel that flexes and extends the scope in one plane, whereas gastroscopes have two control wheels that allow flexion and extension of the tip in two planes perpendicular to each other (□ Fig. 100.9).

Flexible esophagoscopy can be performed without general anesthesia and is not challenged by cervical spine anatomy/limitations. It provides better visualization of the squamocolumnar junction and gastroesophageal junction, and the examiner can visualize the gastroesophageal junction from within the stomach by retroflexing the endoscope. Unsedated office-based transnasal esophagoscopy can avoid the need for sedation and its attendant risks. The patient is also free to return to unrestricted activity after the procedure is complete. It is well

Fig. 100.10 Rigid esophagoscopy is performed with the middle finger of the nondominant hand on the patient's hard palate and the esophagoscope resting on and advanced by the thumb.

tolerated with the application of only topical nasal decongestant and anesthetic. The procedure, not including the time needed for topical anesthesia to take effect, lasts approximately 5 to 10 minutes. Sedated flexible esophagoscopy is usually preferred if numerous biopsies are indicated with a resulting increase in the duration of the procedure. If evaluation of the stomach or upper duodenum is indicated by a patient's history of abdominal pain, nausea, or vomiting, a sedated procedure with the appropriate scope is indicated.

100.3.4 Technique

Rigid Esophagoscopy

Rigid esophagoscopy is performed in the operating room under general endotracheal anesthesia (although monitored anesthesia care and local anesthesia are possible) with the patient supine. One should avoid using a shoulder roll or any other positioning that causes extension of the neck. The patient's upper teeth are protected with a tooth guard. The surgeon stands at the head of the bed and uses the nondominant hand to simultaneously open the mouth, stabilize the scope off the teeth, and advance the scope. The instrument is inserted under direct visualization through the oral cavity in a perpendicular trajectory toward the pharynx. The dominant hand serves only to support the length of the rigid scope and alter the angle of insertion. At the base of the tongue, the contour of the posterior pharyngeal wall is followed, and the esophagoscope is eventually aligned parallel with the esophagus. When the postcricoid area is reached, the larynx is lifted anteriorly to expose the esophageal introitus, which is usually slightly to the left of midline (□ Fig. 100.10). The rigid scope is then advanced to the gastroesophageal junction if there is no obstructing pathology. The mucosal lining is visualized and instrumented as needed as the scope is slowly retracted. A Hopkins rod telescope can be inserted once the scope is in the esophagus for photo documentation and superior visualization.

Flexible Esophagoscopy

Transnasal esophagoscopy is performed with the patient seated in the office examination chair in a comfortable position. Cotton soaked in oxymetazoline and 4% lidocaine is placed in both nares for 10 minutes. If needed, benzocaine spray is applied to the oropharynx, or 2% viscous lidocaine is ingested. The scope is inserted through the more patent nasal passage and the larynx is visualized. While the tip of the scope is positioned just above the postcricoid area on the left, the patient is asked to swallow, and the scope is inserted into the esophagus while simultaneously engaging a small puff of air. With the use of a combination of insufflation, water, and suction, the scope is passed into the stomach and the stomach is insufflated. Retroflexion is performed to visualize the gastroesophageal junction from below. The scope is then pulled back into the esophagus, where the Z-line is visualized. Biopsies are taken from the area of the squamocolumnar junction and gastroesophageal junction if abnormalities are visualized. The mucosa of the entire esophagus is then carefully inspected as the scope is withdrawn. This procedure can be recorded through still images or video.

Sedated esophagoscopy with a flexible scope is performed with the patient in the lateral decubitus position. An oral appliance is inserted between the teeth to direct the flexible endoscope to the midline of the oropharynx. Under direct visualization, the endoscope is inserted past the tongue base and via the piriform sinuses into the esophagus. The examination proceeds as above for the transnasal esophagoscope once the instrument is in the esophagus. If a sedated or general anesthesia esophagoscopy procedure is performed without incident, the patient can be started on clear liquids in the postanesthesia care unit, and eating can proceed later in the day if the patient is otherwise asymptomatic.

100.3.5 Risks and Adverse Effects

Approximately 3% of the time, unsedated transnasal esophagoscopy is aborted because of a narrow nasal vault, patient discomfort, or epistaxis. Esophageal perforation is the most significant complication of esophagoscopy. If the patient has symptoms of chest pain, odynophagia, dyspnea, or tachycardia after the procedure, this must be ruled out. If it is suspected during the procedure, a nasogastric tube can be placed under direct visualization and intravenous antibiotics started. If perforation is suspected in the postanesthesia care unit, a chest X-ray is indicated to evaluate for free air or pneumothorax, and esophagography with a water-soluble contrast material should be performed when the patient is stable. Esophageal perforation can be avoided by never forcing an esophagoscope when it meets resistance and always having clear visualization of the esophageal lumen before advancing the scope.

100.4 Roundsmanship

- Tracheobronchoscopy and esophagoscopy are invaluable tools for the otolaryngologist, serving both diagnostic and therapeutic purposes.
- Patient positioning is the key to successfully completing rigid tracheobronchoscopy and esophagoscopy.

- Instrumentation for both rigid and flexible tracheobronchoscopy and esophagoscopy is available in multiple lengths and diameters, and the appropriate size must be chosen. This is especially important in pediatric and smaller adult patients. Having alternate sizes of rigid bronchoscopes available and ready if need be is paramount in the setting of obstructing airway cases.
- In-office, nonsedated options exist for both tracheobronchoscopy and esophagoscopy, and these techniques are often preferred by both patient and provider.
- Taking the time to topically anesthetize patients so that they are comfortable is invaluable during the performance of unsedated in-office procedures.
- Complications from tracheobronchoscopy and esophagoscopy typically present immediately postoperatively, and the operating surgeon should always be ready to care for a perforation of the trachea or esophageal lumen. The surgeon should have

a low threshold for obtaining a postoperative chest X-ray when performing these procedures.

101 Evaluation of the Rhinosinusitis Patient and Surgical Considerations

Steven David Schaefer

101.1 Introduction

The time-honored rhinologic history and physical examination are the mainstay of the evaluation of a patient presenting for the medical or surgical treatment of sinonasal disease. A third diagnostic element, computed tomography (CT), has emerged as an essential part of furthering our understanding of the extent of sinonasal disease and of surgical planning.

101.2 History

Common clinical complaints are summarized in the Box Clinical Complaints Associated with Rhinosinusitis (p.774), below. Today, our understanding of sinusitis extends beyond an identification of the classic triad of headache, nasal obstruction, and mucopurulent rhinorrhea. We now recognize that shared respiratory epithelium and the anatomical proximity of the sinuses and nasal passages predispose to an inflammatory process incompletely described by the term sinusitis. A more inclusive term is rhinosinusitis. (The two terms are used interchangeably in this text.)

Clinical Complaints Associated with Rhinosinusitis

Major complaints

- Facial pain, pressure
- Facial congestion, fullness
- Nasal obstruction, blockage
- Nasal discharge, purulence; discolored postnasal discharge
- Hyposmia, anosmia
- Purulence in nasal cavity

Minor complaints

- Headache
- Halitosis
- Fatigue
- Dental pain
- Cough
- Ear pain, pressure, fullness

Source: Modified from Lanza DC, Kennedy DW. Adult rhinosinusitis defined. *Otolaryngol Head Neck Surg* 1997;117(3 Pt 2):S1–S7.

In communicating the clinical diagnosis of sinusitis, the temporal aspect of the process is essential to planning treatment. Historically, no good consensus exists for differentiating acute from chronic sinusitis. The American Academy of Otolaryngology-Head and Neck Surgery Task Force resolved these issues by defining acute sinusitis as sinusitis with a duration of less than 4 weeks, subacute sinusitis as that with a duration of 4 to 12

weeks, and chronic sinusitis as that with a duration of longer than 12 weeks (□ Table 101.1). Common symptoms are headache, facial pain and pressure, and mucopurulent rhinorrhea.

Headache is a common symptom of rhinosinusitis as well as of various intracranial and extracranial pathologic processes. The location of the headache, in addition to its character, response to prior treatment, timing, and associated symptoms, should be documented. Headache due to sinus disease is usually localized to the involved sinus and contiguous structures; for example, maxillary sinusitis leads to pain in the upper jaw. Disease within the sphenoid sinus presents more of a diagnostic challenge because the pain is typically referred to the vertex region. In contrast, headache or pain in the occipital region suggests a neuromuscular or intracranial vascular origin. Headache accompanied by cranial nerve findings, such as vertex symptoms with cranial nerve II, III, IV, or V findings, suggests a medical emergency such as cavernous sinus thrombosis. The character of the headache may offer a useful diagnostic clue because sinus pain tends to be more focal, whereas neurovascular headache is associated with other symptoms, such as the “sick headache” of migraine, or may be related to the menstrual cycle. This picture can be particularly confusing if the sinus disease triggers a migraine. A response to decongestants or antibiotics suggesting rhinosinusitis versus a response to specific medications for neurovascular disease should be elicited to help differentiate between these two common conditions. Finally, the history should include the time of day when headache occurs and its relationship to events in the day and accompanying symptoms, such as the visual aura of neurovascular headache.

Facial pain and pressure: The patient usually uses the term facial pain to describe various levels of discomfort over a specific region of the face. This symptom, particularly if accompanied by tenderness, is more specific for rhinosinusitis than is headache. Pressure or a sense of fullness within the sinuses or adjacent region of the nose is a complaint probably reflecting the inability of the obstructed sinus ostium to permit equilibration with the ambient atmosphere.

Mucopurulent rhinorrhea: The presence of anterior or posterior mucopurulent rhinorrhea correlates well with sinonasal disease. As a generalization, this complaint is more often seen in association with other symptoms of sinus disease in acute infections, whereas it may be the sole manifestation of chronic rhinosinusitis. Care should be taken in the history to distinguish between actual infectious rhinorrhea and the clear or white secretions suggestive of allergic rhinitis.

Previous surgical treatment: A knowledge of any previous surgical treatment is very useful in understanding the pathogenesis of current disease and identifying potential pitfalls in revision surgery. This is important because patients have been found to fail surgery for the following reasons: (1) failure of the previous surgery to address the site of disease (e.g., only a Caldwell-Luc procedure performed for combined maxillary and ethmoid sinusitis); (2) incomplete ventilation of a diseased sinus, particularly retention of infected ethmoid cells; (3) inadequate

Table 101.1 Clinical categories of rhinosinusitis (from the 1996 American Academy of Otolaryngology-Head and Neck Surgery Task Force)

	Duration	Strong history	Include in differential	Special notes
Acute	Up to 4 wk	2 major factors OR 1 major factor, 2 minor factors OR Nasal purulence on examination	1 major factor, 2 minor factors	Fever or facial pain does not constitute suggestive history in absence of other nasal symptoms or signs
Subacute	4–12 wk	Same as chronic	Same as chronic	Complete resolution after effective medical therapy
Chronic	12 wk	2 major factors OR 1 major factor, 2 minor factors OR Symptoms or nasal purulence on examination	1 major factor, 2 minor factors	Facial pain does not constitute suggestive history in absence of other nasal symptoms or signs
Recurrent acute	Four episodes per year, each episode last 7–10 days; absence of intervening signs of chronic rhinosinusitis	Same as acute rhinosinusitis		
Acute exacerbations of chronic	Sudden worsening of chronic rhinosinusitis, return to baseline after treatment			

Modified from Lanza DC, Kennedy DW. Adult rhinosinusitis defined. *Otolaryngol Head Neck Surg* 1997;117(3 Pt 2):S1–S7.

postoperative care; (4) lack of identification of confounding disease processes, such as allergic fungal sinusitis with polyps or AERD (aspirin-exacerbated respiratory disease); (5) iatrogenic sinusitis induced by obstruction of a preoperatively normal sinus resulting from postoperative alterations of the outflow tract of the sinus; and (6) idiopathic disease. Knowledge of the previous surgery is also useful in identifying potential pitfalls of revision surgery because the earlier operations may have resulted in dehiscence of the lamina papyracea or skull base with subsequent herniation of orbital or cranial contents into the sinuses. In such patients, the history may range from rather vague indications, such as “some polyps were removed from my nose 10 years ago,” to the rather obvious indication of skull base penetration from a history of “clear fluid drains from my nose since sinus surgery.” The more information the history conveys to the surgeon, the more likely it will be that the surgeon can preoperatively obtain the appropriate tests and consultations to manage these pitfalls (□ Fig. 101.1).

101.2.1 Surgical Considerations

The essential questions to be resolved in considering surgery for a patient are these: Has medical therapy proved inadequate or unlikely to manage the sinonasal disease? Is surgery appropriate and likely to significantly improve the patient’s state of health? Surgery should be reserved for those patients whose disease is refractory to repeated courses of prolonged appropriate antibiotic therapy: one or more broad-spectrum antibiotics for 3 weeks or longer. Surgical indications are further strengthened by increases in the duration, morbidity, severity, or frequency of infection despite good medical treatment. Other considerations are the actual measures being employed to diagnose a sinus infection. Many of the measures or symptoms used to diagnose rhinosinusitis are rather vague or nonspecific, such as

headache. Others—for example, mucopurulent rhinorrhea—are more consistent with acute or chronic sinusitis. A history of polyps does not necessarily indicate the need for surgical treatment. However, polyps refractory to allergic management that are associated with nasal obstruction, with or without exacerbation of asthma, are properly treated by surgery. On the other hand, surgical treatment of asthma and nasal polyposis without consideration of aspirin sensitivity is a missed opportunity to manage aspirin-exacerbated respiratory disease. Finally, the history should be correlated with a physical or radiographic finding before surgery is considered. Significantly, an opacified sinus on imaging without a history of sinusitis or evidence of neoplasm is not alone an indication for surgery.

101.3 Physical Examination

101.3.1 Nasal Endoscopy

The second element of an evaluation for the medical or surgical treatment of sinus disease is careful endoscopic examination of the nose. The concept of using an optical telescope to examine the nose is not new; however, advances in the last three decades in optics and illumination have led to significant supplementation of conventional anterior rhinoscopy with nasal endoscopy. Endoscopy is directed toward confirming the history and documenting evidence of sinonasal disease—in particular, obstruction of the ostia of the sinuses. The office examination should begin with vasoconstriction and, if needed, anesthesia to permit maximal visualization of the nose. The nose should be examined with a rigid 0-degree and/or a 30- or 45-degree telescope. A flexible endoscope is an alternative instrument, but the optics are inferior to those of the rigid endoscope. The first passage of the endoscope should be along the floor of the nose (□ Fig. 101.2).

This first phase of endoscopy permits visualization of the orifice of the nasolacrimal duct (in the inferior meatus), inferolateral nasal wall, eustachian tube orifice, and nasopharynx. The second passage of the endoscope is immediately inferior to the middle turbinate and provides a view of the sphenothmoid recess, middle meatus, and sphenoid ostium. Each of these sites may be variably difficult to examine because of the presence of polyps, degenerated mucous membrane, or pneumatization of the middle turbinate. The last passage of the telescope should be directed toward the frontal recess, thus crossing adjacent to the junction of the middle turbinate and the agger nasi. Coupled with a good history, nasal endoscopy should be regarded as a highly sensitive and specific measure of sinonasal disease. Potential findings include the following.

Polyps

The identification of massive polyposis is not difficult, nor is it solely in the realm of the skilled nasal endoscopist. In contrast, recurrent ethmoiditis due to a small polyp obstructing the ostiomeatal complex can be difficult to diagnose and often goes unrecognized during anterior rhinoscopic examinations.

Fig. 101.3 Zero-degree endoscopic view of the left side of the nose. The inferior turbinate, middle turbinate, inferior aspect of the bulla ethmoidalis, nasopharynx, and a posterior septal deviation are well visualized. BE, inferior aspect of the bulla ethmoidalis; IT, inferior turbinate; MT, middle turbinate; NP, nasopharynx.

Mucopurulent Secretions

When the history is used to direct the examination, the endoscopic documentation of mucopurulent secretions draining from the ostium of the involved sinus is “the gold standard” in making the diagnosis of sinusitis.

Deviated Nasal Septum

The relationship of a partially deviated nasal septum to sinusitis or otitis media has been and remains the subject of much discussion in otolaryngology (□ Fig. 101.3). Less controversial is lateral compression of the middle turbinate by the deviated septum as a cause of recurrent sinusitis. In the absence of sinus

disease, this form of airway obstruction is corrected by septoplasty. In contrast, impaction of the middle turbinate into the lateral nasal wall with sinusitis is treated by septoplasty and surgery of the involved sinus.

Concha Bullosa

Pneumatization of the anterior aspect of the middle turbinate is referred to as a concha bullosa. Many such conchae have little clinical significance. A concha bullosa is significant when such enlargement of the turbinate obstructs the ostiomeatal complex or is the actual site of infection.

Fungal Sinusitis

Two forms of fungal sinusitis may be recognizable on nasal endoscopy: invasive and noninvasive. Probably less frequent in incidence but better known to physicians is invasive fungal sinusitis, which comprises acute fulminant, chronic, and granulomatous forms. Mucormycosis is an acute fulminant invasive fungal sinusitis that is typically seen in compromised patients. This entity is characterized by various degrees of bone and soft-tissue destruction on both endoscopic and CT examination; it is treated with aggressive surgery and systemic antifungal agents. Less known is noninvasive fungal sinusitis, which includes fungal balls and allergic fungal sinusitis. Allergic fungal sinusitis presents with nasal polyps, a green “slimelike” fungal debris within the sinus lumen, and areas of increased density within opacified sinuses on CT and variable bone resorption on scanning. This entity is a localized, extramural immune response to noninvasive dematiaceous fungi (e.g., *Bipolaris*) and is managed by removal of the polyps and fungus, continual aeration and cleaning of the involved sinus, and corticosteroids as needed (□ Fig. 101.4).

Tumors

The diagnosis of benign and malignant tumors of the sinonasal region has been greatly enhanced by the ability of the endo-

Fig. 101.4 Coronal computed tomographic scan of a patient with allergic fungal sinusitis involving the left maxillary sinus. Note area of hyperdensity (arrow) within the maxillary sinus.

scope to magnify, illuminate, and view sites at various angles from the optical axis of the instrument. Often, a history of epistaxis with accompanying evidence of soft- or hard-tissue invasion and the endoscopic identification of a friable, irregular mass within the nose lead to a histopathologic confirmation of carcinoma. More challenging is the diagnosis of a unilateral sinonasal polyp versus inverting papilloma in the patient with a history of multiple “polyp surgeries” and the endoscopic picture of a rather unimpressive mass in the nose. In the case of a sinonasal tumor, the diagnosis can be confirmed by biopsy in the office, whereas for some inverting papillomas, formal surgery is required to obtain sufficient tissue for pathologic examination (□ Fig. 101.5).

Epistaxis

Bleeding from the nose is often due to the erosion of blood vessels supplying the anterior nasal septum. Other common sites of bleeding are along the anterior aspect of the inferior or middle turbinates. Less common is bleeding in the posterior region of the nose or the nasopharynx. All patients with either prolonged or frequently recurrent epistaxis should undergo a complete endoscopic examination to rule out occult neoplasms or vascular malformations. In the postpubertal male, epistaxis may be associated with a benign tumor known as a juvenile nasopharyngeal angiofibroma. This tumor, which most often presents with nasal obstruction and subsequent epistaxis, arises between the basiocciput and basisphenoid. Bleeding from a sinus cavity into the nose should alert the physician to a possible tumor within the sinus and necessitates CT.

101.3.2 General Otolaryngologic Examination

Other aspects of the physical examination include evaluation of the following.

Olfaction

Various methods exist to roughly quantify olfaction, but many of these suffer from a lack of standardization and degradation of the substances causing the odor over time. An excellent alternative is a commercially available smell identification test, which is based on the University of Pennsylvania Smell Identification Test (UPSIT). This test, which uses a normalized “scratch and sniff” measurement of olfaction, is administered within 15 minutes by the patient (Sensonics, Haddon Heights, NJ). Contrary to popular opinion, impaired olfaction is complicated and is often not due to simple obstruction of the nose by a deviated septum or nasal polyps. Many a surgeon and patient have been disappointed after surgery performed to restore olfaction.

Vision

The evaluation of vision is guided by the history. For example, chronic ethmoid or sphenoid sinusitis may first present as alterations in visual acuity or visual fields. Any infectious, inflammatory, or benign or malignant process may first present with compromise of vision and/or an abnormal appearance of the eyes. Although Graves disease or thyroid eye disease is often

Fig. 101.5 (a) Endoscopic intraoperative photograph of inverting papilloma of the right side of the nose. Neurosurgical cottonoid appears in the inferior region of the nose. IP, inverting papilloma; MT, middle turbinate. (b) Coronal magnetic resonance image showing inverting papilloma (arrow) in the same patient as in (a). The contralateral maxillary sinus is opacified because of sinusitis, not tumor. The maxillary sinus on the same side as the tumor is not opacified. MS, maxillary sinus.

considered the most likely cause of unilateral exophthalmos, any mass-occupying process that extends into the orbit may present with this finding (□ Fig. 101.6 and □ Fig. 101.7).

Infections of the face or sinuses (viscerocranium) may spread to the eye and brain (neurocranium). Early infections of the eye limited anteriorly to the periosteum of the orbit or septum orbitale present with edema and erythema of the eyelids. As the infection spreads into the orbit, proptosis develops and extraocular movement declines. Further involvement of the superior

(b) Axial CT scan of another patient with bilateral thyroid eye disease. The optic nerve (arrow) is compressed by extraocular muscles (asterisks).

Fig. 101.7 Axial computed tomographic scan of a malignant tumor (arrowheads) of the right side of the nose invading the ipsilateral orbit. In contrast, the contralateral lamina papyracea is intact. lp, lamina papyracea; T, tumor.

Fig. 101.8 (a) Coronal computed tomographic (CT) scan of a patient after antibiotic treatment for acute sinusitis showing only mild residual thickening of the mucous membrane lining the right maxillary sinus. The uncinate process, ostium of the maxillary sinus (asterisk), anterior ethmoid cells, alveolar recess of the maxillary sinus, and frontal sinus are all normal. ar, alveolar recess of the maxillary sinus; ec, anterior ethmoid cells; FS, frontal sinus; MS, maxillary sinus; up, uncinate process. (b) Sagittal CT scan through the plane of the right frontal recess. An agger nasi cell is extending into the frontal recess of the frontal sinus and slightly narrowing the outflow tract of this sinus. Other structures noted are the sphenoid sinus, ethmoid sinus, middle turbinate, and inferior turbinate. an, agger nasi cell; ES, ethmoid sinus; FS, frontal sinus; it, inferior turbinate; mt, middle turbinate; SS, sphenoid sinus. (c) Axial CT scan through the mid plane of the sphenoid sinus showing the internal carotid arteries, sphenoid sinus ostium (asterisk), nasolacrimal duct, lateral recess of the sphenoid sinus, and deviated nasal septum. ICA, internal carotid arteries; nld, nasolacrimal duct; lr, lateral recess of the sphenoid sinus. (d) Axial CT scan of the same patient as in (a–c) showing normal outflow tract of the frontal sinus. (e) Axial CT scan through the mid body of the left frontal sinus in another patient. This patient has a frontal cell arising within the frontal sinus, which partly contains air (asterisk); the drainage pathway distal to the cell is obstructed. Posteriorly, a suprabullar ethmoid cell extends into the frontal recess. FC, frontal cell; sbc, suprabullar ethmoid cell.

orbital fissure leads to a loss of extraocular movement. Infection or any other process that compromises the optic nerve between the retina and the optic chiasm leads to a Marcus Gunn pupil or afferent pupillary defect. Such a process is detected by moving a flashlight from one eye to the other. Normally, there is both a direct and consensual constriction of the two pupils. In the presence of an afferent pupillary defect, the involved eye minimally constricts during direct illumination with the flashlight, giving the impression of pupillary dilation, while the uninvolved eye constricts. Shining a light in the normal eye causes both pupils to constrict because of an intact pupillary afferent pathway. Another name for such an abnormal finding is positive swinging flashlight test. Visual impairment of the contralateral eye indicates extension of the disease process into the cavernous sinus. As is true in any patient with ophthalmologic symptoms, joint management with an ophthalmologist is required.

Neuropathy

Additional dysfunction of cranial nerves III through VI further localizes potential benign and malignant processes to within the sinuses with or without extension to the cavernous sinus.

101.4 Computed Tomography and Magnetic Resonance Imaging

CT is the third element of the evaluation of a patient with sinusitis and the radiographic sinus examination of choice. From a practical standpoint, coronal CT of the paranasal sinuses may be far more cost-effective than repeated plain films and is far more likely to aid in the patient's treatment. As both computer and X-ray detection technologies evolve, modern CT scanners capture multiple images in an axial plane and reformat the images in axial, coronal, and sagittal projections. With the knowledge that a patient who has a simple upper respiratory infection may have abnormal findings on a CT scan of the sinuses, the timing of imaging has been further refined. The "best practice" today is to perform CT several weeks after the completion of prolonged antibiotic therapy unless the patient's condition warrants immediate intervention (□ Fig. 101.8). Magnetic resonance (MR) imaging is selectively employed to discern the contents of an opacified sinus with or without CT cisternography (□ Fig. 101.9a), which aids in imaging the extension of sinus disease into adjacent structures such as the eye and brain (□ Fig. 101.9b).

Fig. 101.9 (a) Contrast computed tomographic cisternogram showing cerebrospinal fluid (CSF) fistula (arrow) in the roof of the right ethmoid sinus. (b) Magnetic resonance image with a small polyp-like structure in the superior region of the left side of the nose in a patient with intermittent CSF rhinorrhea is found to be an encephalocele (arrow-head).

Reading any form of imaging of the sinus should begin with what is obvious, and sometimes overlooked: first verify that the scans are from the patient of interest, the date of the examination, and the quality of the images. CT is employed in the following situations.

101.4.1 Extension of Disease beyond Sinuses

Infections of the eye or brain may result from either hematogenous or direct extension of sinusitis. CT is important in both evaluating the involvement of other organs and planning treatment, such as drainage of a subperiosteal orbital abscess into the ethmoid cavity via an endoscopic ethmoidectomy. MR imaging may be complementary to better discern the disease process and the extent of disease beyond the sinuses (□ Fig. 101.10).

Fig. 101.10 Iatrogenic brain abscess following sinus surgery (arrow-heads), best demonstrated on sagittal magnetic resonance image.

101.4.2 Problem Diagnosis

Some patients present with a sole complaint indicative of either sinusitis or another disease process. In the absence of physical findings (see Box Physical Findings in Rhinosinusitis (p.780)), CT is helpful in such cases to rule out chronic sinus infection before proceeding with other forms of treatment (e.g., migraine headache or migraine exacerbated by sinusitis). Another problem diagnosis is the so-called silent sinus syndrome. This disorder is characterized by an inward displacement of the roof and the posterior walls of the maxillary sinus. The uncinate process uniformly approximates the medial inferior orbit. The maxillary sinus is opacified on CT scans even though frequently the patient is unaware of any sinus disease. However, as the walls of the sinus collapse inward, the floor of the orbit continues to implode into the sinus, leading to inferior displacement of the globe and subsequent diplopia (□ Fig. 101.11). Double vision may be the first symptoms of this atypical form of sinusitis.

Physical Findings in Rhinosinusitis

- External physical findings
 - Swelling and erythema: maxillary, orbital, and frontal regions
- Findings on anterior rhinoscopy
 - Hyperemia
 - Edema
 - Crusts
 - Purulence
 - Polyps
- Findings on nasal endoscopy
 - Bluish discoloration of turbinates
 - Purulence at sinus ostia
 - Polyps, note size and location
 - Septal deflection: note compromise of sinus ostia
 - Concha bullosa
 - Paradoxical turbinates
- Other abnormalities

Modified from Hadley JA, Schaefer SD. Clinical evaluation of rhinosinusitis: history and physical examination. *Otolaryngol Head Neck Surg* 1997;117(3 Pt 2):S8–S11.

Fig. 101.11 (a) Coronal and (b) axial computed tomographic scans from a patient with silent sinus syndrome. The floor of the right orbit (arrow) is displaced or contracted inferiorly, causing a more inferior location of the globe compared with the normal left orbit. The uncinate process completely approximates the inferior medial right orbit. The coronal image also shows a nasal septum deviated to the right and excessive pneumatization of the anterior aspect of the left middle turbinate, known as a concha bullosa (concha). The axial image shows the loss of the S appearance of the posterior maxillary wall (short arrows), which follows from the inward collapse of the roof and posterior walls of this sinus. (c) The surgical findings in this patient. ES, ethmoid sinus; MT, middle turbinate; orbit, inferomedial wall of orbit.

Fig. 101.12 (a) Coronal computed tomographic (CT) scan, 2-mm slices, of a patient with postoperative cerebral spinal fluid rhinorrhea resulting from injury to the roof of the right ethmoid sinus (arrow). (b) Sagittal CT scan of patient in (a) showing the skull base defect. The site of the injury is typical; instruments can be directed through the skull base as the surgeon progresses to the posterior ethmoid cells.

101.4.3 Recurrent Sinusitis

Because plain films of the sinuses are neither sensitive nor specific for many of the disease processes affecting the paranasal sinuses, CT is employed in patients with multiple episodes of sinusitis and/or nasal polyps. This examination clearly delineates the extent and severity of disease. In contrast, isolated anterior ethmoiditis can easily be unrecognized on a Caldwell radiograph because this film reflects the sum of all the bone and soft-tissue densities within the sinus. In cases of allergic fungal sinusitis, MR imaging is a useful supplement to CT because fungal concretions appear as low signal intensity or signal voids on T2-weighted images.

101.4.4 Recurrent Disease after Surgery

Patients with recurrent sinusitis or polyps after surgery are difficult to evaluate by any modality because of a loss of normal sinonasal architecture and fibrosis. CT is strongly recommended for any such patient in whom postoperative medical therapy fails after a trial of 2 to 3 months or for whom revision surgery is contemplated. If the history or physical examination suggests that the prior procedures may have injured the floor of the anterior cranial fossa or orbit, 1- to 2-mm coronal slices are recommended (□ Fig. 101.12). MR imaging is particularly useful for identifying encephaloceles and mucoceles, which may not be apparent on CT scans (□ Fig. 101.13).

Fig. 101.13 Sagittal T1-weighted magnetic resonance (MR) image showing epidural mucopyocele (arrowheads) arising from the frontal sinus. MR image reveals heterogeneous contents of the mucocele, which would not be discernible on computed tomography.

101.4.5 Surgical Planning

The CT scan provides an essential road map in both planning and performing endoscopic sinus surgery. In the operating room, particular attention should be given to the following: (1) angle or plane of the lateral lamella of the cribriform plate relative to the cribriform plate and the roof of the ethmoid sinus, which may predispose to penetration of the anterior cranial fossa; (2) proximity of the maxillary ostium to the orbital floor; (3) extent of pneumatization of the ethmoid sinus, which can be minimal anteriorly, thereby increasing the risk for penetration of the orbit, or extensive posteriorly, with cells surrounding the optic nerve; (4) number and location of septa relative to the midline of the sinus; (5) location and any dehiscence of the optic nerve or carotid artery within the lateral wall of the sphenoid sinus; (6) anterior–posterior pneumatization of the frontal sinus, which influences access to the sinus through the frontal recess; and (7) extent of residual sinus architecture to aid in the identification of surgical landmarks.

101.4.6 Staging Rhinosinusitis

CT provides an objective measure of the extent of rhinosinusitis. Staging benign sinus disease, much like the staging of neoplasms, has evolved as a means to convey the extent of the

Fig. 101.14 Intraoperative computer-assisted image guidance. Lower right quadrant shows biopsy site of left clival mass. The other three quadrants show localization of the tumor in three projections during surgical removal.

disease process and audit therapeutic outcome. Of the various proposed staging systems, the modified Lund-Mackay system has proved both simple to use and sufficiently precise to satisfy these goals. After appropriate medical treatment, CT scans of all four sinuses are evaluated. Each sinus is assigned a numeric value: 0, no abnormality, 1, partial opacification; or 2, total opacification. The anterior and posterior ethmoid sinuses are separately evaluated and graded. Each ostiomeatal complex is included in the staging and is given a value of 0 for no obstruction and 2 for obstruction. A total score of 0 to 12 for each side is possible, with the higher number reflecting more severe rhinosinusitis.

Regarding intraoperative computer-assisted image guidance, as CT and stand-alone work station computing power increased in the 1990s, digital data from imaging studies were reprocessed and coupled to electromagnetic and infrared detectors to guide surgery within the brain and face, in a process much like that of a GPS (ground-positioning satellite) system (□ Fig. 101.14).

101.5 Roundsmanship

- A complete history and a carefully performed physical examination (including nasal endoscopy) are critical for treating patients presenting with sinus or nasal problems.
- Mucopurulent rhinorrhea is the most consistent symptom of bacterial sinusitis.
- The majority of patients with sinusitis spontaneously improve with minimal physician management. A minority of these patients require antibiotics. When surgery is being considered, the physician should taken into account the length of treatment and the antibiotics previously used. Too frequently, patients are treated for a week or so with one antibiotic, followed by another trial of one or more antibiotics. Once medi-

cal management has failed, the decision to perform surgery should also be based on the imaging findings of refractory sinusitis and the physical findings.

- The preoperative CT scan is a road map to surgery. In those patients who have had prior surgery, imaging should delineate why it failed and forewarn the surgeon of potential pitfalls, such as prior injury or vulnerability to injury of the eye or brain.

102 Anatomy and Physiology of the Nose and Paranasal Sinuses

Steven David Schaefer and Ameet R. Kamat

102.1 Introduction

An understanding of the anatomy and physiology of the nose and paranasal sinuses is essential to optimize the diagnosis and treatment of diseases of these organs. The evolution of computed tomography (CT) and magnetic resonance (MR) imaging, coupled with advances in our understanding of the pathogenesis of upper respiratory tract disease and its treatment, has reawakened otolaryngologists' interest in this heretofore underappreciated organ system. The advent of improved surgical optics and endoscopes requires that the otolaryngologist–head and neck surgeon be thoroughly familiar with the anatomy of the upper respiratory tract. This requirement is reflected in the detailed anatomical citations in this chapter.

102.2 Applied Anatomy

102.2.1 Anatomy of the Nose

As the most prominent facial feature, the nose has been the subject of both Western and Eastern art for millennia. In ancient India, the practice of amputating the nose as a punishment for adultery led to a practical understanding of the external nasal anatomy as surgeons developed forehead and arm flaps to reconstruct the skin and nasal skeleton. The nasal skeleton is a pyramid consisting (superiorly) of paired bones and (inferiorly) of paired upper and lower lateral cartilages. The nasal bones overlap the upper lateral cartilages, which are attached to the internal surface of the bones. The inferior third of the external nose is supported by the semilunar or archlike lower lateral or alar cartilages. The medial crura join together to form the columella, which is connected to the caudal septal cartilage by the membranous septum. The lateral crura provide the structural support to the nasal introitus and abut the upper lateral cartilages to form the limen nasi. The narrowest part of the nasal airway is the internal nasal valve, which is roughly bounded medially by the septum, inferiorly by the nasal floor, laterally by the inferior turbinate, and superiorly the limen nasi. The regulation of inspiratory nasal airflow begins with dilation of the nostrils by the facial muscles; airflow is constricted by the nasal valve and modified by the turbinates and the cartilaginous–bony septum. The inferior, middle, superior, and rarely supreme turbinates are the most prominent appendages of the lateral nasal wall. The inferior, middle, and superior turbinates, or bony conchae, are medial to the outflow tract of the nasolacrimal duct, the outflow tract of the ethmoid, maxillary, and frontal sinuses, and the outflow tract of the posterior ethmoid sinus, respectively (□ Fig. 102.1). The midline septum consists of the anterior quadrilateral cartilage and four bones: the perpendicular plate of the ethmoid posterosuperiorly, the vomer posteriorly, and the crests of the maxilla and palatine bones inferiorly. Posteriorly, the nasal cavity communicates with the nasopharynx via the choanae (□ Fig. 102.2).

The external and internal blood supply to the nose is the carotid artery. The internal carotid artery gives rise via the ophthalmic artery to the anterior and posterior ethmoidal arteries (□ Fig. 102.3). These vessels provide blood to the superior lateral nasal wall and superior septum. The external carotid artery vascularizes the remaining nose. The greater palatine and facial arteries supply the anteroinferior nasal septum and lateral nasal wall. The inferoposterior septum and nasal wall receive their primary blood supply from the sphenopalatine artery, which is one of the five branches of the internal maxillary artery. A confluence of the anterior branches of the internal and external carotid arteries at the anterior nasal septum forms the Kiesselbach plexus or Little area. Given the turbulent airflow across the anterior septum, particularly in the presence of a deviation of the caudal septum, and the abundant blood supply, the Kiesselbach plexus is the principal site of epistaxis. Venous drainage of the nose is primarily via the facial, sphenopalatine, and ophthalmic veins. This rich venous plexus may drain to the intracranial veins, forming the so-called danger triangle, from which infection can ascend from the skin and soft tissue bounded by the nasal root and oral commissures and the nasal cavity to the brain.

102.2.2 Anatomy of the Paranasal Sinuses

The investigation of paranasal sinus anatomy may have begun with the anatomist Galen in the second century AD, although

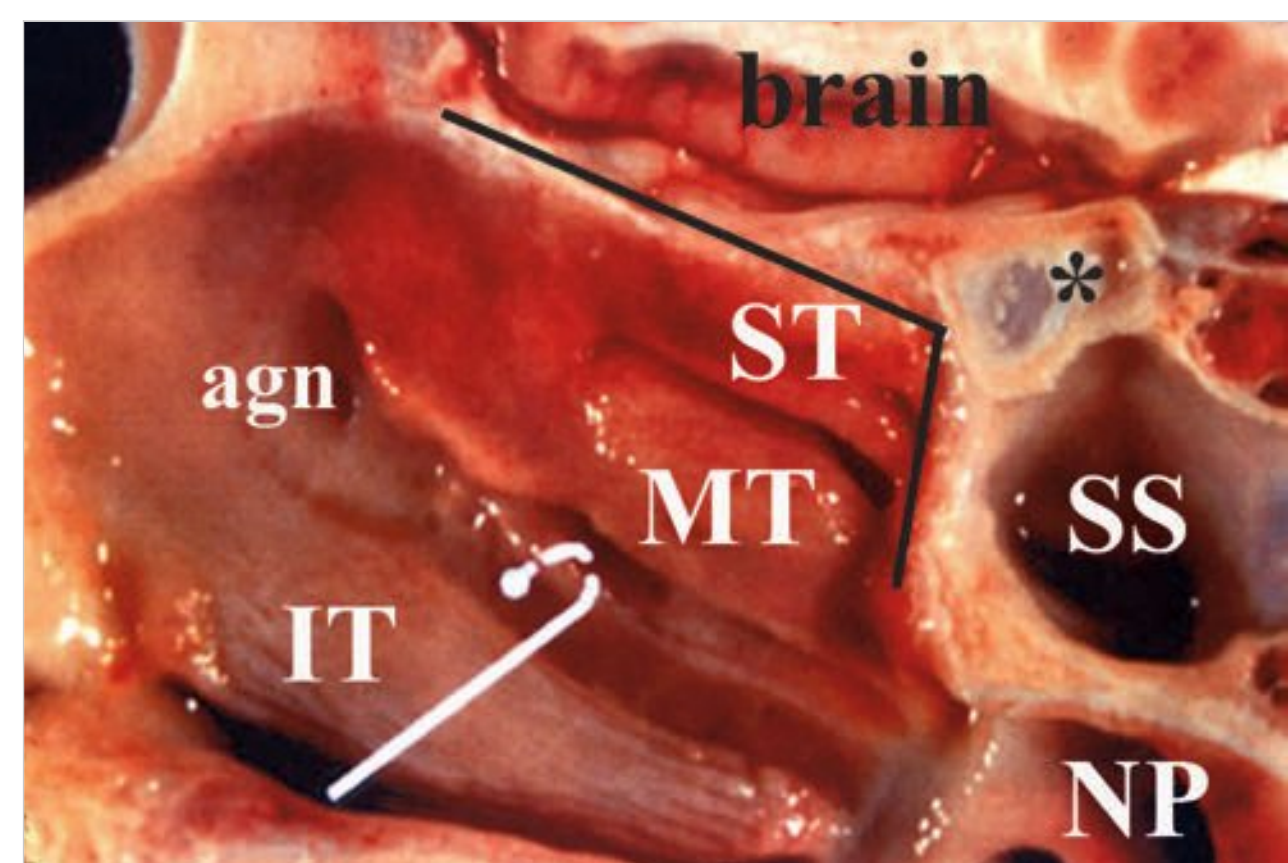

Fig. 102.1 Sagittal cadaver section showing left lateral nasal wall. The black line parallel to the floor of the anterior cranial fossa and the second line parallel to the anterior wall of the sphenoid sinus emphasize the posterior–inferior 15-degree slope of the skull base. During intranasal sinus surgery, the surgeon must adjust the dissection of the ethmoid sinus inferiorly during advancement into the posterior region of the nose. agn, agger nasi; asterisk, extramural ethmoid cell; IT, inferior turbinate; MT, middle turbinate; NP, nasopharynx; SS, sphenoid sinus; ST, superior turbinate.

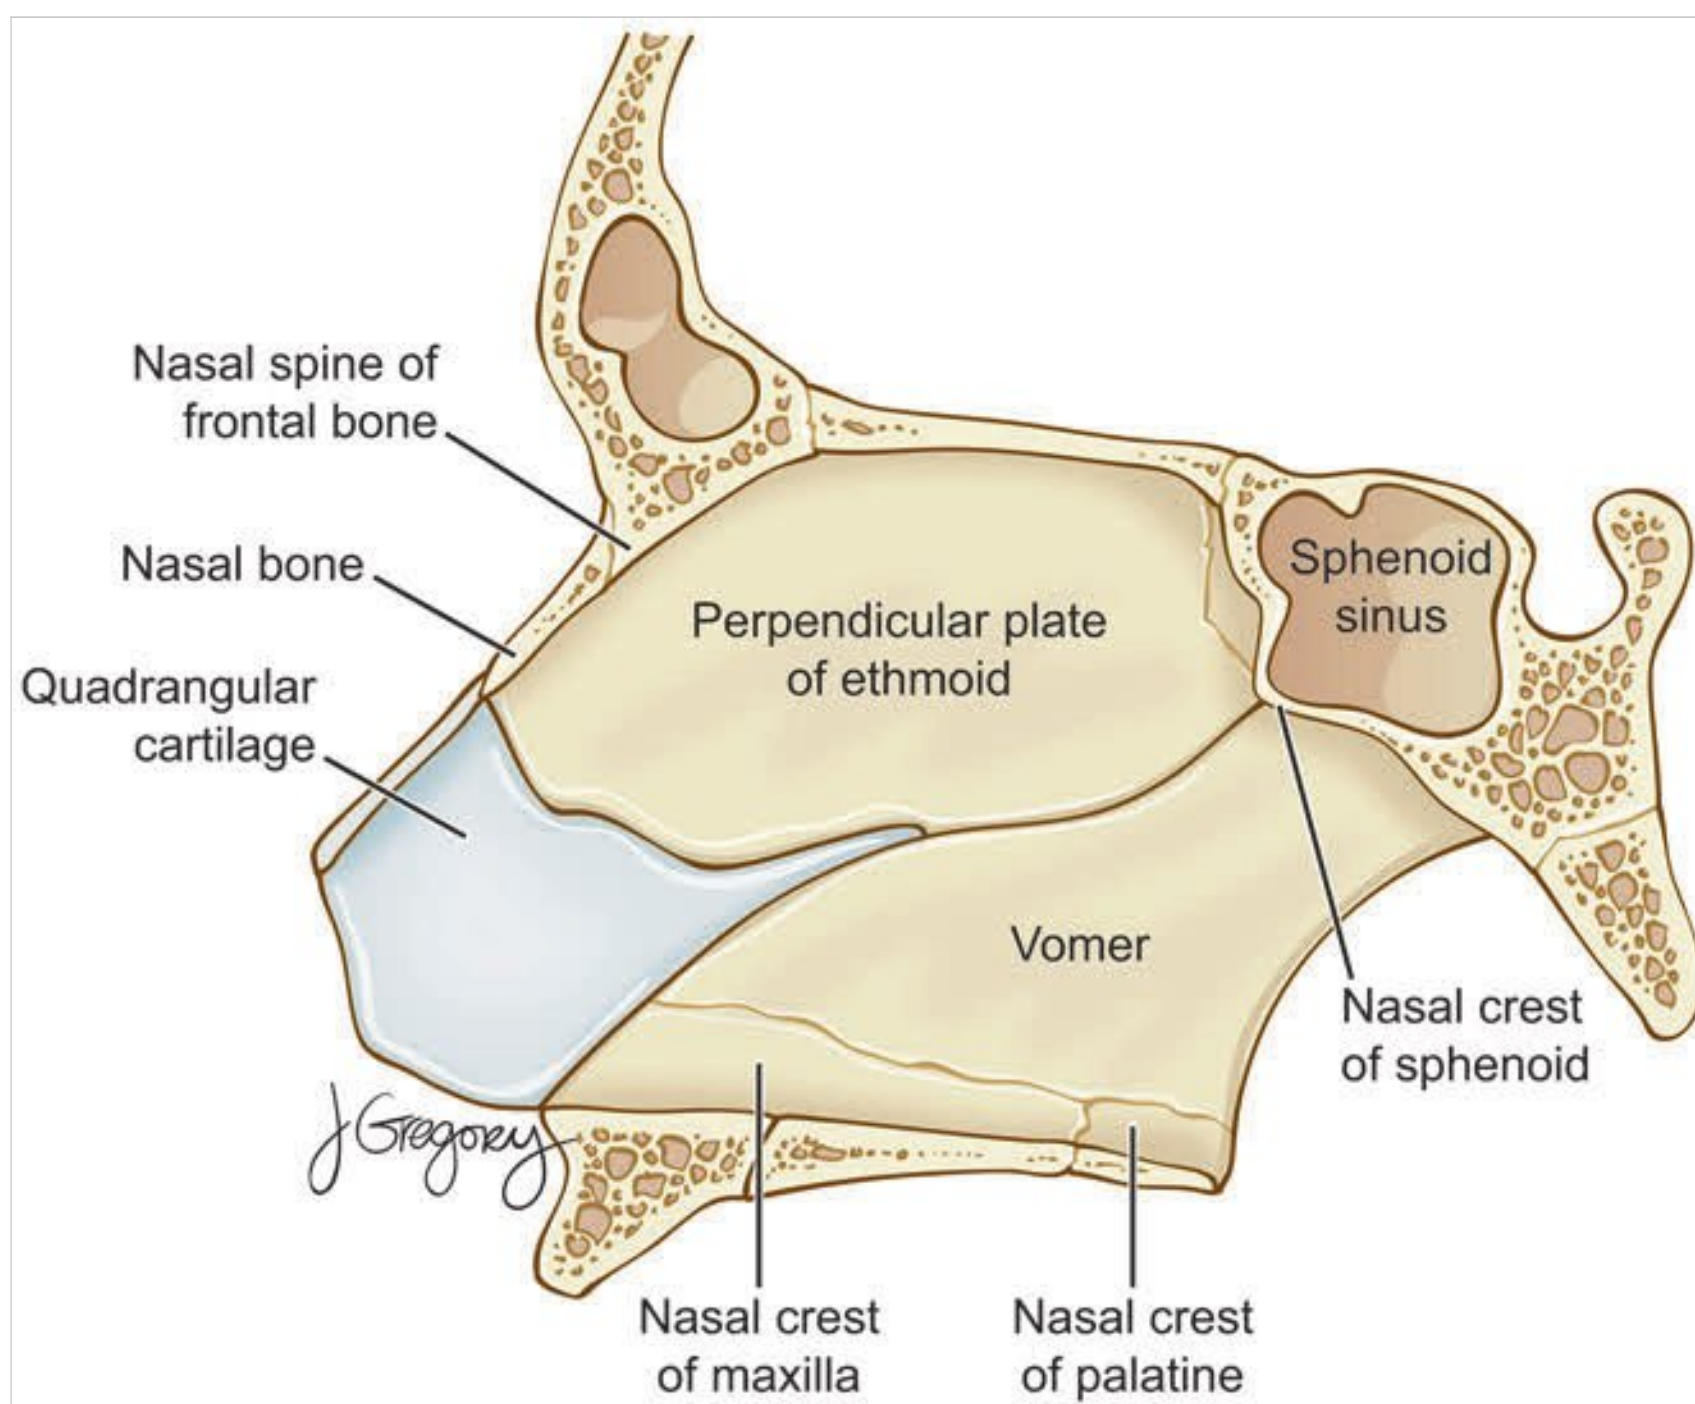

Fig. 102.2 The nasal septum comprises the quadrangular cartilage and the nasal crest of the palatine bone, maxillary crest, vomer, nasal crest of the sphenoid, and perpendicular plate of the ethmoid. The blood supply consists of the anterior and posterior ethmoidal arteries, which are branches of the internal carotid artery via the ophthalmic artery, and the sphenopalatine, sublabial, and greater palatine arteries, which are branches of the external carotid artery.

Fig. 102.3 Axial cadaver section through the sphenoid and maxillary sinuses. In some individuals, posterior ethmoid cells expand into the sphenoid bone. Less commonly, these extramural ethmoid cells (i.e., pneumatizing beyond the ethmoid bone) expose the optic nerve. The extramural cells are referred to as Onodi cells. A, optic nerve; ICA, internal carotid artery; ITF, infratemporal fossa; MS, maxillary sinus; SS, sphenoid sinus.

his writings do not mention the sinuses by name. The depth and nature of descriptions of the sinuses have varied considerably throughout history, usually mentioned within larger works. Notable in this regard were da Vinci's discussions of the maxillary sinus and Berengario da Carpi's initial descriptions of the sphenoid sinus (in the 16th and 17th centuries). In the 17th and 18th centuries, studies began to focus upon the sinuses

themselves. Most of these works, however, were by individuals concerned not with detailed, precise anatomy but with more theoretical questions addressing functional explanations for the existence of these "hollow" spaces in the cranium. Anatomical observations by such individuals were not usually performed for a systematic assessment of structure; rather, they appear to have been used to buttress their particular functional theories. In the late 19th century, the Austrian anatomist Emil Zuckerkandl published the first detailed and systematic anatomical and pathologic description of the paranasal sinuses.

During the preantibiotic era of the early part of the 20th century, anatomical studies focused upon descriptions that could improve procedures for the cannulation or drainage of pathologic sinuses. After treatment, sinus infections were observed often to recur in the same treated sinus, and to spread and infect the other, untreated sinuses. These secondary infections were explained by the close and intimate relationships seen in the anatomy of the paranasal sinuses. The importance of understanding prenatal development as a vehicle to understanding sinus surgery became more fully appreciated. Later, technologic advances saw the development of external and endonasal (intranasal) microscopic and endoscopic sinus procedures. The advent of endoscopes, CT, and other technologies has led to a renaissance in our understanding of the anatomy and physiology of the sinuses.

Ethmoid Sinus

The ethmoid and other paranasal sinuses originate from the primordia of the cartilaginous nasal capsule, and their pneumatization follows from epithelial budding into the bony elements of the cranium, thus establishing a communication network with the nasal cavity throughout life. The prenatal development of the paranasal sinuses begins as an evagination of respiratory mucosal epithelium from the nasal capsule invading two bony

Fig. 102.4 (a) Axial cadaver section through the ethmoid sinus, orbit, and sphenoid sinus. The ethmoid sinus is anatomically divided into an anterior and a posterior ethmoid sinus. The sphenoid sinus is vertically separated into a right and left sinus by the intrasinus septum. In this specimen, the right internal carotid artery is seen as it passes through the cavernous sinus. ant eth, anterior ethmoid sinus; ICA, internal carotid artery; intr sept, intrasinus septum; post eth, posterior ethmoid sinus. (b) Enlargement of (a) showing from above left the ostiomeatal complex. asterisk, hiatus semilunaris; be, anterior aspect of bulla ethmoidalis; eth inf, ethmoid infundibulum; mt, middle turbinate; nld, nasolacrimal duct; up, uncinat process.

elements of the splanchnocranium (i.e., maxillary and ethmoid bones). Once mesenchymal differentiation in the area of the inferior nasal conchae ensues, it has the effect of producing a more prominent fold of the conchae and aids in accentuating the depth of these grooves, or furrows. The developing folds are considered the primitive step for conchal formation, whereas the furrows constitute the future inferior and middle meatus. By the 63rd to 70th day of prenatal development, six major furrows develop along with their corresponding ridges or folds, called the ethmoturbinals (i.e., turbinates arising from the ethmoid). The number of these folds and furrows that persist during fetal development varies. For example, from the seventh month to term, one can find three to five ethmoidal conchae with a corresponding number of intervening meatus, but after birth, because of either fusion or obliteration, only two or three ethmoidal conchae may persist (i.e., middle, superior, or supreme ethmoidal conchae).

The first primary furrow of the lateral nasal wall is located between the first and second ethmoturbinals, sometimes referred to as the first interturbinal furrow. The appearance of the first furrow is also an important developmental stage because its descending anterior region will become the ethmoid infundibulum, while the superiorly ascending region will become the frontal recess (□ Fig. 102.4). The former is an important region into and through which a number of the paranasal sinuses will eventually drain to the nasal cavity. The frontal recess, on the other hand, undergoes further development with the appearance of additional furrows, what Kasper termed pits, which are outgrowths of epithelium that appear as spherically shaped excavations in this region. Pneumatic invasion of the frontal bone originating from one of these pits in the frontal recess results in the development of the frontal sinus.

At birth, the ethmoid sinus consists of anterior and posterior divisions. The ethmoid labyrinth may be visualized consistently by plain film radiography only after the first year post partum and only if the air-filled divisions of the ethmoid sinus are well developed. At the ages of 4 to 8 years, the ethmoid sinus system is 18 to 24 mm in length, 10 to 15 mm in height, and 9 to 13 mm in width. By the 12th year, the ethmoids have reached nearly adult size, with expansion during puberty involving primarily the bones outside the ethmoid capsule.

In the adult, the ethmoid sinus viewed in a transverse section forms a pyramid, with a blunted apex located anteriorly and a wider base located posteriorly. The entire sinus measures 4 to 5 cm anteroposteriorly, 2.5 cm inferosuperiorly, 0.5 cm wide anteriorly, and 1.5 cm posteriorly. Various descriptions of the ethmoid roof, such as fovea and foveolae ethmoidales, have caused considerable confusion over the years. Lateral to the lamina cribrosa of the cribriform plate, the insertion of the middle turbinate, and the lateral lamella of the cribriform plate, numerous ethmoid air cells open superiorly and are closed by the frontal bone. Because the indentations or foveolae (from the Latin, foveolae ethmoidales ossis frontalis, “ethmoid pits of the frontal bone”) are invaginations into the frontal bone, this bone and a portion of the fovea form the roof of the ethmoid sinus (□ Fig. 102.5). The roof of the ethmoid articulates with the lateral lamella of the cribriform plate. The length and orientation of the lateral lamella, the thinnest bone in the entire skull base, determines the depth of the olfactory fossa and relates to the vulnerability to intracranial penetration. The lateral wall of the ethmoid bone is the lamina papyracea (orbital plate), which forms the most constant component.

The actual size of the sinus and the number of cells present vary in each reported series. The ethmoid cells are divided into

Fig. 102.5 Coronal cadaver section through the mid plane of the maxillary sinuses. The superior, middle, and inferior turbinates are well seen, along with the attachment of the middle turbinate to the cribriform plate and roof of the ethmoid sinus. The section also passes through the anterior ethmoid sinus and crista galli. cg, crista galli; cp, cribriform plate; ES, ethmoid sinus; ethm rf, roof of the ethmoid sinus; IT, inferior turbinate; MS, maxillary sinuses; MT, middle turbinate; ST, superior turbinate.

those that are within the ethmoid bone, or intramural, and those that are outside the ethmoid bone, or extramural. The anterior ethmoid cells can be further subdivided based on their location or that of their ostia. However, cells of a given origin frequently invade the territory usually occupied by cells of another origin, and at least some authors favor classification by the location of their ostia.

During development, the attachments of the various bony structures arising from the ethmoid (i.e., conchae, uncinat process) to the lateral wall are formed by one of several ground plates, or basal lamellae. While the lateral attachments of these lamellae end abruptly, their medial aspects project beyond the labyrinth and form prominences that extend into the nasal cavity. The most anterior of the lamellae is the lateral extension of the uncinat process. The second lamella is referred to as the anterior plate of the bulla because its extension into the nasal cavity forms the bulla ethmoidalis, while the third lamella serves as the attachment of the middle turbinate. The third lamella is an important anatomical structure, demarcating the division between the anterior ethmoid cells and the posterior cells and so essentially dictating the drainage patterns of these air cells into the middle and superior meatus, respectively. The third lamella is also clinically significant because it is considered a natural boundary to the spread of infection into the posterior ethmoid, and it is the posterior landmark in anterior ethmoidectomy. The fourth lamella is at the attachment of the superior turbinate, and when a supreme turbinate is also present, a fifth lamella arises lateral to this turbinate.

Among the various classifications proposed, the Ritter nomenclature system conveys most clearly the origin and drainage of the ethmoid cells. In the Ritter classification, the most

anterior cells are the frontal recess cells (range, 0 to 4 cells), which arise from the anterosuperior growth of the ethmoid cells into the frontal bone. These cells may come to rest within the frontal bone by forming the frontal sinus, giving rise to the frontal bullae, bulging into the frontal sinus floor, or forming the supraorbital ethmoid cells as they pneumatize the orbit.

The bullar cells drain into the middle meatus via crescentic ostia that lie superiorly, posteriorly, and parallel to the much larger semilunar cleft in the lateral nasal wall, the entrance of which Zuckerkandl described as the hiatus semilunaris (see □ Fig. 102.4b). The hiatus semilunaris forms the curved groove between the bulla ethmoidalis, which borders it posteriorly, and the uncinat process, a ridge of bone formed by the ramus descendens of the first ethmoturbinal, which borders it anteriorly. The anteroinferior boundary of the hiatus semilunaris is the uncinat (from the Latin *uncinia*, “hook”) process, also a semilunar structure, which has an anterosuperior to posteroinferior sagittal orientation. This structure attaches to the lamina perpendicularis of the palatine bone and the ethmoid processes of the inferior turbinate. The anterior aspect of this attachment to the lateral nasal wall has been called the maxillary line.

Conchal cells are ethmoid air cells that invade the middle conchae, and when these cells are located in the anterior aspect of the conchae, the condition is referred to as a concha bullosa. The concha bullosa cells are clinically important because they can be an isolated source of recurrent ethmoiditis or may obstruct the middle meatus. The middle turbinate, being a medial appendage of the lateral nasal wall, overhangs the bulla ethmoidalis, the hiatus semilunaris, and the uncinat process. On occasion, both the uncinat process and the hiatus semilunaris are not covered by the downward expansion of this 3.5- to 4-cm-long important bony structure. Anteriorly, the middle turbinate is attached superiorly to the cribriform plate, with a 15-degree slope posteroinferiorly so that the posterior tip lies at, or immediately inferior to, the sphenopalatine foramen.

The posterior ethmoid cells (range, 1 to 7 cells), which invade the posterior ethmoid capsule, may also involve the middle turbinate, sphenoid, palatine, and maxillary bones. The posterior cells drain into the superior and, to a lesser degree, the supreme meatus. An important form of extramural extension of the posterior ethmoid cells is the migration of these cells to the medial aspect of the optic nerve within the sphenoid bone. Collectively, these cells are known by various names, including postrema cells. When the cells are superior and inferior to the optic nerve, they are known as Onodi cells. Such cells are clinically important because the optic nerve may be covered by relatively thin bone and vulnerable to injury during dissection posterior to the anterior face of the sphenoid bone. The anterior ethmoidal canal containing the artery and nerve of the same name runs between 2 mm inferior and 4 mm superior to the cribriform plate. The anterior ethmoidal artery originates from the ophthalmic artery to course through the orbital region and passes through the anterior ethmoidal canal onto the anterior cranial fossa to finally enter the nasal cavity. The posterior ethmoidal canal traverses the ethmoid bone at a plane approximately 1.5 mm (range, 0 to 3.1 mm) above the cribriform plate, and it may, like the anterior canal, be partially dehiscence of bone (□ Fig. 102.6).

Maxillary Sinus

The maxillary sinus has been referred to as the antrum of Highmore in honor of the English anatomist Nathaniel Highmore, whose 1651 treatise *Corporis Humani Disquisitio Anatomica* describes and illustrates this sinus. However, the person recognized as the earliest known discoverer of the maxillary sinus is Leonardo da Vinci, who both illustrated and described this sinus in 1489.

Fig. 102.6 Sagittal cadaver section through mid plane of the right ethmoid sinus. Beginning anteriorly, the frontal sinus communicates with the nose through its ostium. Defining the posterior aspect of the frontal recess is the anterior ethmoidal artery. Inferior to this vessel is the bulla ethmoidalis, and approximately 10 mm posterior to the anterior ethmoidal artery is the posterior ethmoidal artery. The anterior ethmoid sinus is separated by the basal lamella of the middle turbinate from the posterior ethmoid sinus, and posterior to this sinus is the sphenoid sinus. The optic nerve passes through the superior aspect of the lateral wall of the sinus. Within the lateral wall of the sphenoid is the bony prominence surrounding the internal carotid artery. Other important structures are the ethmoid infundibulum and uncinat process. aea, anterior ethmoidal artery; bl MT, basal lamella of the middle turbinate; ethm inf, ethmoid infundibulum; fo, frontal sinus ostium; FS, frontal sinus; ICA, internal carotid artery; on, optic nerve; SS, sphenoid sinus; up, uncinat process.

The maxillary sinus, lying within the body of the maxillary bone, is the largest and most constant of all four paranasal sinuses. The maxillary sinus is generally described as shaped like a pyramid. Its anterior wall is the facial surface of the maxilla, where the facial vein and artery run, while the posterior wall is the infratemporal fossa, where the maxillary artery and vein are located. The medial wall constitutes the lateral wall of the nasal cavity, where a number of vascular structures are situated (e.g., branches of the sphenopalatine, the septal branch of the superior labial, and the ethmoidal arteries). The superior wall or roof of this sinus is the floor of the orbit, and the floor of the maxillary sinus is the alveolar process of the maxilla. It becomes evident from its topographic relationship to contiguous structures that infections and tumors of the maxillary sinus can spread in multiple directions, especially to the dentition (see □ Fig. 102.5).

Development of the maxillary sinus begins by the 65th day of gestation, so that it is the first sinus to develop in utero. At birth, the sinus has an average volume of 6 to 8 mL but is fluid-filled, making the interpretation of plain film radiographs difficult. The maxillary sinus then undergoes two periods of rapid growth: one between birth and 3 years, and the other between the ages of 7 and 12 years. Between these two growth periods, at around 4 years of age, the sinus extends laterally past the infraorbital canal. After the second period of rapid growth (□ Table 102.1), subsequent expansion involves pneumatization of the alveolar process of the maxilla. Before growth is completed, the maxillary sinus descends from 4 mm above the floor of the nasal cavity at birth to the same level as the nasal floor at the age of 8 to 9 years, and then a final drop of 4 to 5 mm below this level occurs by adulthood.

In the adult, the maxillary sinus can be roughly described as triangular in shape, measuring 25 mm along the anterior limb of its base, 34 mm in depth, and 33 mm in height. The primary or natural ostium of the maxillary sinus is located in the superior aspect of the medial wall of the sinus, and the sinus drains via its infundibulum into the ethmoid infundibulum and thus the hiatus semilunaris. The natural ostium tends to be elliptical, measuring from 1 to 20 mm in length. In addition, accessory maxillary sinus ostia have been found in 15 to 40% of subjects examined by various authors. These ostia may be located in the ethmoid infundibulum or the membranous region of the medial sinus wall (known as the membranous meatus or fontanel),

Table 102.1 Embryologic patterns of sinus development

Paranasal sinus	Embryologic appearance	Postnatal appearance	Growth spurt interval
Ethmoid sinus	Development begins in third fetal month.	Present at birth	First growth spurt occurs between first and fourth years, second growth spurt between fourth and eighth years.
Maxillary sinus	Development begins by 65th day of gestation.	Present at birth	First growth spurt occurs between birth and 3 years, second growth spurt between 7 and 12 years.
Frontal sinus	Development begins in fourth fetal month.	Detected at 7 to 12 years of age	Adult size is attained by 20 years.
Sphenoid sinus	Development begins in third fetal month.	Detected at 3 to 4 years of age	By seventh year, sinus begins to extend posteriorly toward the sella turcica.

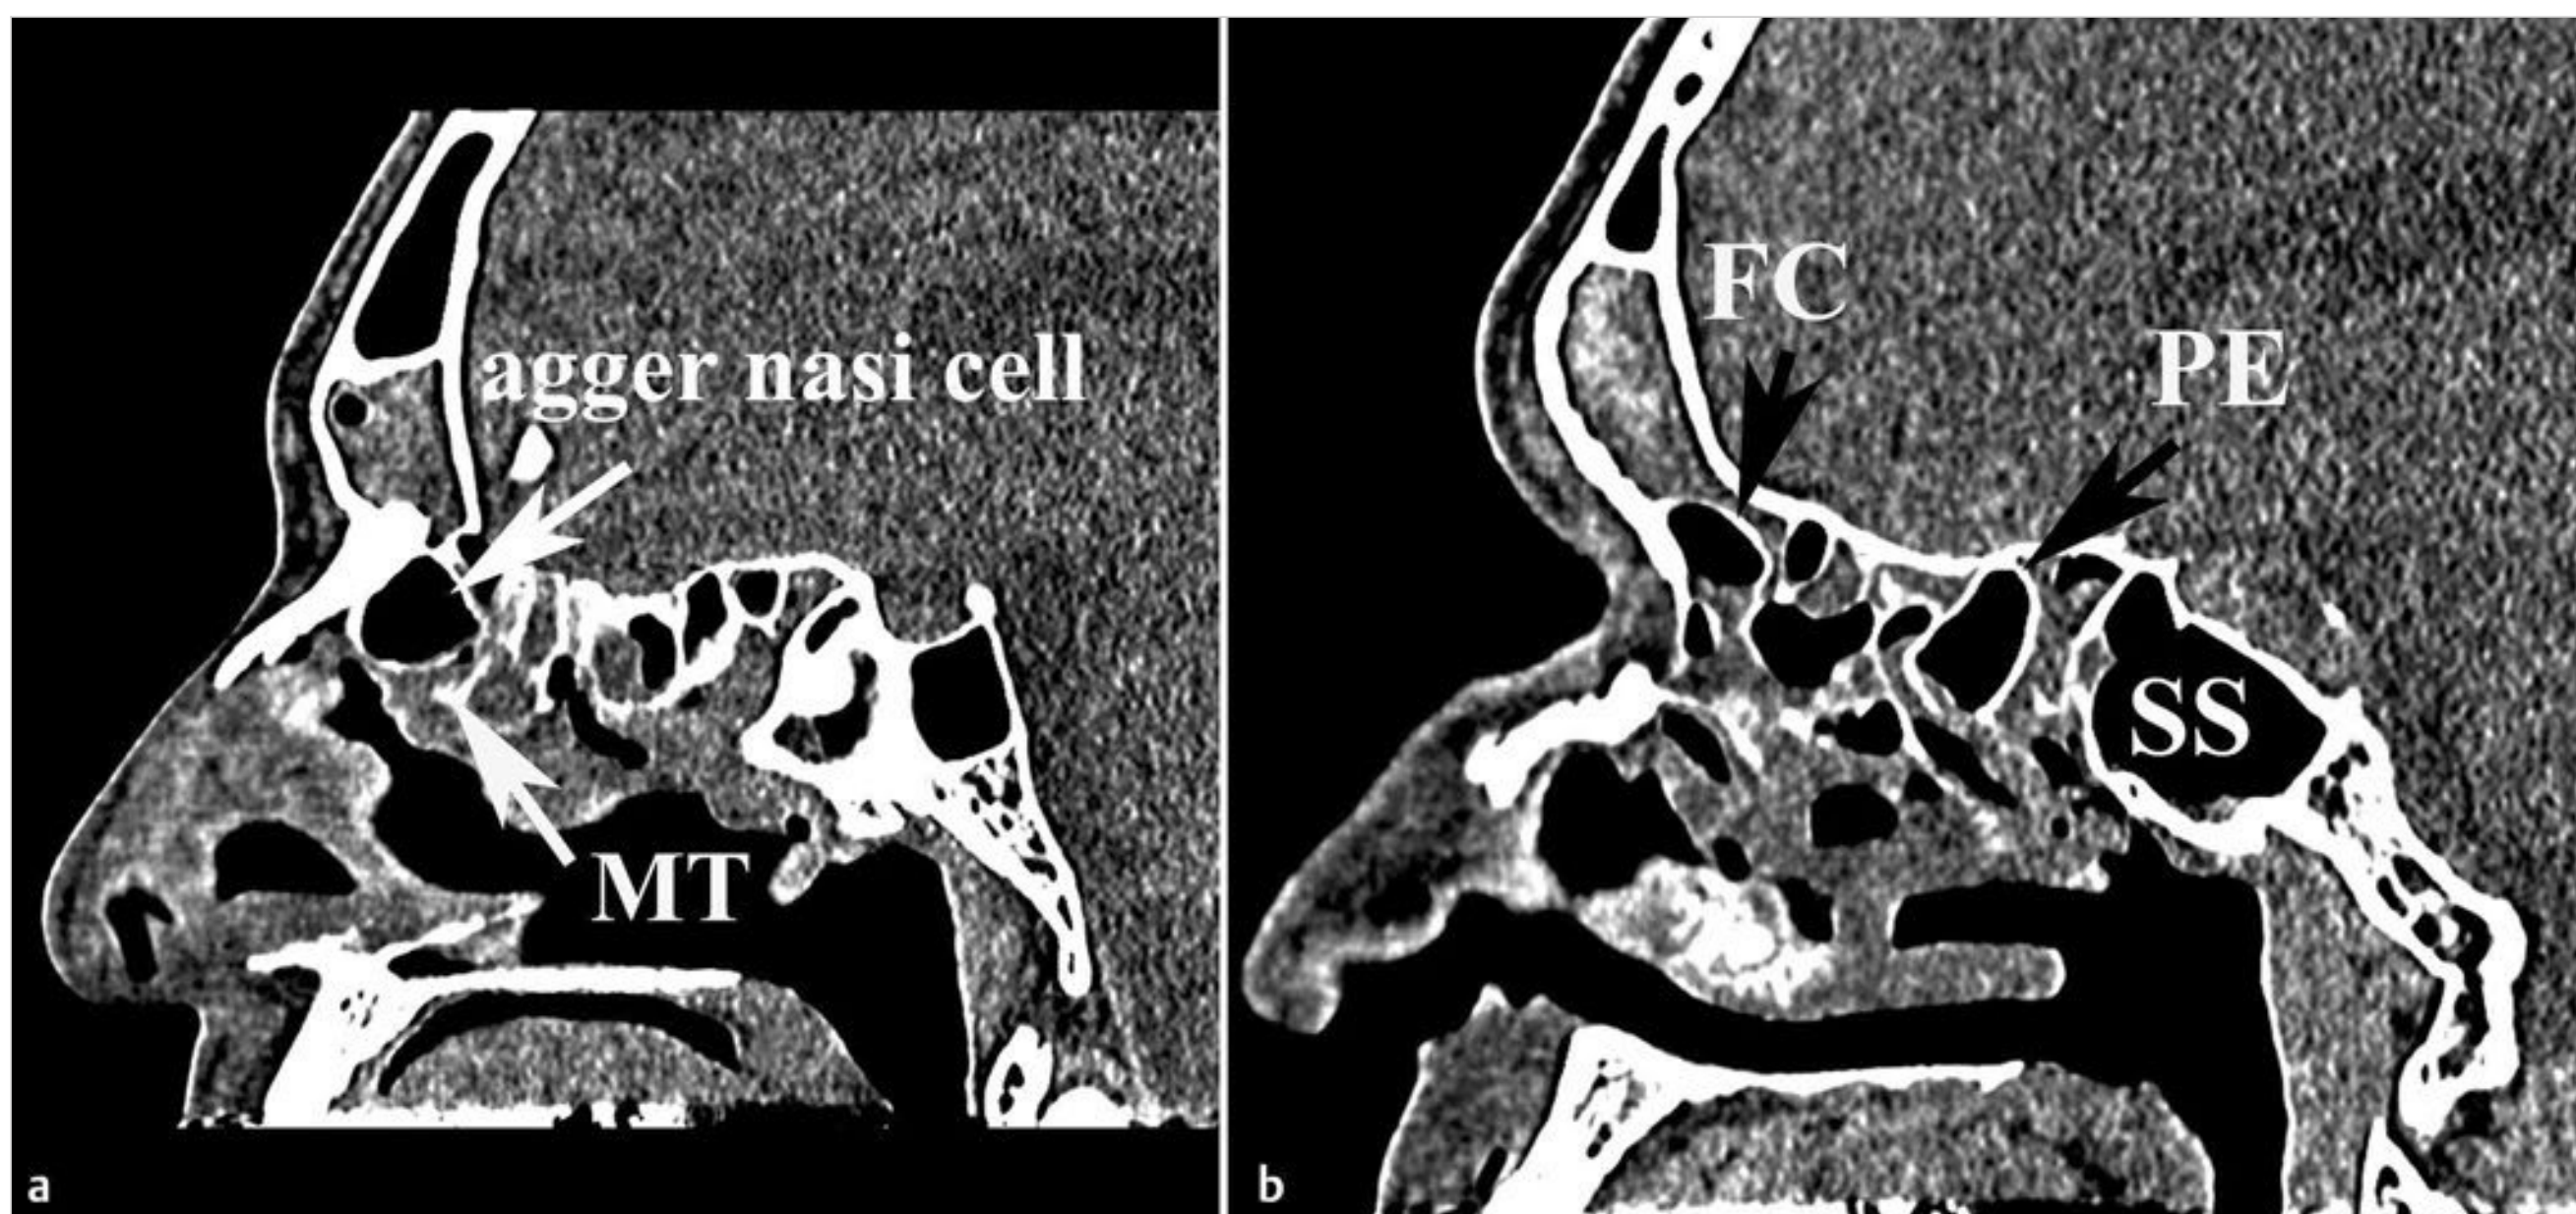

Fig. 102.7 Sagittal computed tomographic (CT) scans through the ethmoid and frontal sinuses. (a) An ethmoid cell is pneumatizing the agger nasi and forming an agger nasi cell, which is one of several cells that populate the frontal recess in this patient. The anterior aspect of the middle turbinate is posterior to this cell and confirms the origin of the cell within the agger and not within more posterior cells, such as lacrimal cells. Note the obstruction of the frontal sinus outflow tract into the nose by the cell. MT, middle turbinate. (b) Sagittal CT scan through the ethmoid sinus, frontal sinus, and sphenoid sinus (SS). The outflow tract of the frontal sinus is occluded by a frontoethmoid or frontal cell. Posterior to this cell is another frontal cell, which is superior to the bulla ethmoidalis; therefore, this cell is referred to as a suprabullar cell. Posterior to the anterior ethmoid cells, there is one large posterior ethmoid cell. Between this cell and the anterior wall of the sphenoid sinus is the sphenothmoid recess. FC, frontal cell; PE, posterior ethmoid cell; SS, sphenoid sinus.

which is inferior to the uncinat process and superior to the insertion of the inferior turbinate.

Frontal Sinus

Volcher Coiter of Holland, a pupil of Fallopius and Eustachius, is said to have been the first to describe the frontal sinus. Interestingly, Berengario da Carpi described the frontal bone region as having “two tables within which there is a notable vacuity so as to not weigh down the body,” but da Vinci, in 1489, may have been the first to recognize its existence and illustrate its morphology.

The development of the frontal sinus is initiated in the fourth fetal month, when the entire nasofrontal area is represented by the frontal recess, and it is the last paranasal sinus to develop. The usually paired frontal sinuses have several possible origins, each of which influences the relationship of this sinus to the lateral nasal wall and its drainage pattern within the middle meatus. In a study of 100 adult specimens and 15 late-term fetuses, Kasper found the most common origin of the frontal sinus to be pits or furrows within the frontal recess, which are considered rudimentary anterior ethmoid cells. The anatomy of this region is challenging because there is neither a clear developmental pattern nor any constancy in the differentiation of the frontal pits. One can have as many as four pits, or there can be a total absence of pit formation. When there is no pit formation, the frontal recess remains a simple blind outgrowth from the middle meatus without configuration of its lateral wall. Which of these pits is variably present and which goes on to become the frontal sinus determine the specific pattern of sinus

drainage. If the most anterior pit (i.e., pit 1) migrates in a ventral direction, it may pneumatize the agger nasi bone, becoming an agger nasi cell, whereas the second most anterior pit (i.e., pit 2) may migrate anterosuperiorly to become the frontal sinus (see Fig. 102.6). Thus, the terms agger nasi (referring to the mound of bone anterior to the insertion of the middle turbinate) and agger nasi cell (referring to the cell that pneumatizes the agger nasi) are not interchangeable because each represents a distinct anatomical entity (Fig. 102.7). Moreover, a markedly pneumatized agger nasi cell can have pathophysiologic consequences in frontal sinus drainage. Another variant of frontal sinus formation can occur if no anterior ethmoid air cells develop in the frontal recess; ethmoid air cell extension from the ethmoid infundibulum then can create a frontal sinus.

At birth, the sinus has little clinical relevance, and it is often indistinguishable from the anterior ethmoid cells. At 3 years of age, the frontal sinus is observed 3.8 mm above the nasion (a craniometric point defined as the junction between the nasal and frontal bones at the midline), and it continues its vertical growth trajectory at an average annual rate of 1.5 mm until the 15th year. Final growth is completed before the 20th year.

The adult frontal sinus, when viewed in a transverse section, has been classically described as pyramidal in shape by Mosher. The base or inferior floor of the pyramid is the orbital nasal portion of the splanchnocranium, the apex extends outward a variable distance over the orbit, the anterior wall is subcutaneous, and the posterior wall is cerebral. The dimensions of the adult frontal sinus have been reported as measuring 28 mm in height, 27 mm in width, and 17 mm in length. This ideal sinus is a representative average, with the actual size and configuration

Fig. 102.8 Composite of computed tomographic scans through the frontal sinus outflow tract. Coronal (upper left), sagittal (upper right), and axial (lower) images are paired—that is, anterior to posterior, medial to lateral, and inferior to superior. When the images are viewed collectively, the obstruction to the right frontal outflow tract is seen to be due to frontal cells, noted best in the upper right sagittal lateral image (arrow). ant, anterior; inf, inferior; lat, lateral; med, medial; post, posterior; sup, superior.

reflecting the origin of the cavity and the superior development into the squama of the frontal bone. At the inferior aspect in the midsagittal plane, the anterior or outer table of the frontal sinus is approximately twice as thick as the posterior or inner table. Historically, the communication of this sinus with the nasal cavity has been described as a distinct nasofrontal duct, although others prefer the term frontal recess. The term nasofrontal duct, which is used to describe the communication of the frontal sinus through the middle meatus with the nasal cavity, is anatomically and developmentally incorrect. To confuse the issue even further, the terms frontal recess, frontal infundibulum, and nasofrontal duct have also been used interchangeably when in reality they represent different anatomical structures. Conceptually, the frontonasal outflow tract has been likened to an hourglass, with the upper portion being the body of the frontal sinus, the neck being the ostium (varying 2 to 10 mm in diameter), and the lower portion beneath the neck being the frontal recess. However, the term frontal recess, introduced by Killian, is based on the prenatal observation of a space that is the continuation of the ascending branch of the first primary interturbinal furrow, with the descending branch becoming the ethmoid infundibulum. The frontal infundibulum was defined by Killian as the superior opening of the frontal sinus drainage tract. A more recent interpretation of this anatomy defines the frontal infundibulum as viewed from within the frontal sinus as the funnel-shaped narrowing toward the frontal ostium. Finally, the nasofrontal duct as defined by Lang is any mucosa-lined bony passage longer than 3 mm. We would question this definition because the outflow tract of the frontal sinus is potentially narrowed by the ethmoid bulla, or the lamella of the bulla, posteriorly and by agger nasi cells anteriorly rather than forming a true duct. In 1939, Van Alyea described the outflow tract of the frontal sinus as the frontal recess, and despite its earlier mean-

ing, this term best describes the area. The developmental variability of the frontal sinus leads to the observed multiple drainage patterns, which can be further complicated by the highly variable pneumatization of the adjacent ethmoid air cells and by the position of the uncinete process (□ Fig. 102.8).

Sphenoid Sinus

In 1521, Giacomo Berengario da Carpi was the first to describe the sphenoid sinuses, but it was Tillaux who suggested that this sinus is part of the other paranasal sinus complex. According to Dixon, the sphenoid sinus is the most variable cuboidally shaped sinus of all the paranasal sinuses. The average adult sinus has six surfaces: the anterior, posterior, superior, inferior, medial, and lateral walls (□ Fig. 102.9). In addition, the sphenoid bone, where this sinus resides, is strategically located in one of the most complex regions in all of human anatomy. The endocranial surface of this bone serves as a seat for endocrine activity; as a conduit for the cranial nerves responsible for vision, ocular movements, nasal mucosal gland stimulation, and nasal sympathetic innervation; and as a conduit for the major vascular supply of the nasal cavity.

Growth of the usually paired sphenoid sinuses is initiated during the third month of intrauterine development. The two sinuses generally develop asymmetrically because usually one sinus encroaches upon and limits the other's growth to a rudimentary size. The vertical bony partition between the two sinuses has been incorrectly termed median septum. Congdon suggested the more appropriate term intersinus septum because the partition is frequently more lateral than medial, and this is the accepted term today. Both complete and partial septation of the sinuses is frequent because no clear pattern has emerged from a number of studies. When the sinus is viewed

Fig. 102.9 Coronal computed tomographic scan through the sphenoid bone. The left sphenoid bone is pneumatized superiorly by an extramural posterior ethmoid cell and inferiorly by the sphenoid sinus. Because the sphenoid sinus does not have a horizontal septum, the appearance of such a structure implies an extension of the ethmoid sinus into the sphenoid bone. p ethm, posterior ethmoid cell; SS, sphenoid sinus.

in a coronal plane, a horizontal partition may be present. In reality, the extramural posterior ethmoid cells have pneumatized the superior aspect of the sphenoid bone, and the sphenoid sinus lies inferior to the “horizontal septation.”

Around the time of birth, the sphenoid sinus is primarily an evagination of the sphenothmoid recess, with essentially no growth until the age of 3 years. It is not until the third year of life that the sphenoid conchae become attached to the presphenoid and the cavity develops into the definitive sphenoid sinus. In the most common developmental type, the postsellar type, the sinus extends posteriorly toward the sella turcica by the age of 7 years. Development may continue into adulthood and involve the basisphenoid, with arrest in pneumatization accounting for the tremendous variations in the sinus size.

The average adult sinus measures 20 mm in height, 23 mm in length, and 17 mm in width. The volume varies from 0.1 to 30 mL, with the average ranging from 5 to 7.5 mL. As the sinus expands, vessels and nerves in the lateral aspect of the body of the sphenoid bone come to lie as indentations in the wall of the sinus. The sphenoid sinus drains by a single ostium into the sphenothmoid recess. This ostium, in the clinical setting, is 2 to 3 mm in diameter and may be either round or elliptical. The sinus depends on mucociliary flow for drainage because the ostium is located typically 10 to 15 mm superior to the floor of the sinus, or 8 mm from the cribriform plate (range, 1 to 15 mm) and 5 mm lateral to the nasal septum. Our own experience suggests that in most cases the ostium is observed inferior rather than superior to the average location and generally lies at a 30-degree angle from the floor of the nose and at the inferior plane of the superior turbinate. The pneumatization of the posterior aspect of the middle turbinate may make visualization of this ostium difficult. Because of the importance of such identification in surgery, various measurements have been reported. Mosher found that the anterior face of the sphenoid sinus averaged 7 cm from the nasal spine at an angle of 30 degrees.

102.3 Physiology

The lining of the nasal vestibule is essentially a continuation of the adjacent facial skin and consists of squamous epithelium with sebaceous and sweat glands and coarse hairs known as vibrissae. Within the nasal cavity, the epithelium transitions from squamous and transitional to respiratory, pseudostratified columnar epithelium (posteriorly) consisting of ciliated (columnar) cells, nonciliated (columnar) cells, goblet cells, and basal cells. This epithelium lies on a basement membrane and a lamina propria. All of the glands, as well as the neural and vascular structures, are found within the lamina propria. The nose and sinuses are cleansed by mucus produced by the goblet cells. Mucociliary clearance is accomplished by cilia that beat at a rate of approximately 1,000 strokes per minute and direct the mucus within the sinuses and nose in a specific pattern (□ Fig. 102.10).

Olfactory epithelium forms the third type of lining in the nose and covers the superior turbinate and adjacent nasal septum. This pseudostratified epithelium contains bipolar neurons that have specific receptors for odorants, so that they are the first-order neurons in a complex pathway for smell via the limbic system, reticular formation, hippocampus, thalamus, hypothalamus, and frontal lobe. Although olfaction is relatively “insensitive” in humans compared with that in many animals, it remains an important sense and an essential requirement for complex taste.

Nasal airflow is regulated by the autonomic nervous system via parasympathetic innervation of the nasal glands through the sphenopalatine ganglion and by vasodilation. The nasal mucous membrane covering the inferior and middle turbinates becomes engorged with blood secondary to vascular control by the sympathetic nervous system. The relative inputs of the two elements of the autonomic nervous system alternate from side to side approximately every 2 to 4 hours. This nasal cycle results in maximal patency or obstruction of one airway. Patients may perceive this normal nasal physiology as an indication of an airway problem. In persons who have other mechanical obstructions of the nose, such as a deviated septum or polyps, cycling of the airway may compound the nasal obstruction. Furthermore, the turbinates will become engorged with blood as an individual turns the head from side to side while sleeping. Pregnant women are particularly sensitive to nasal obstruction due to hormone-induced engorgement of the mucous membranes, with some prone to rhinitis or sinusitis, a condition known as rhinitis of pregnancy.

102.4 Roundsmanship

- The discrete anatomy of the paranasal sinuses is extremely variable. Each sinus develops within certain parameters and shares physical features and relationships with the other sinuses and the nose.
- The ethmoid is the key sinus both anatomically and functionally. The proximity of this sinus to the frontal and maxillary sinuses accounts for the spread of disease from former to the latter, and for obstruction of the outflow tracts of the frontal and maxillary sinuses from ethmoid sinusitis, polyps, or tumors.

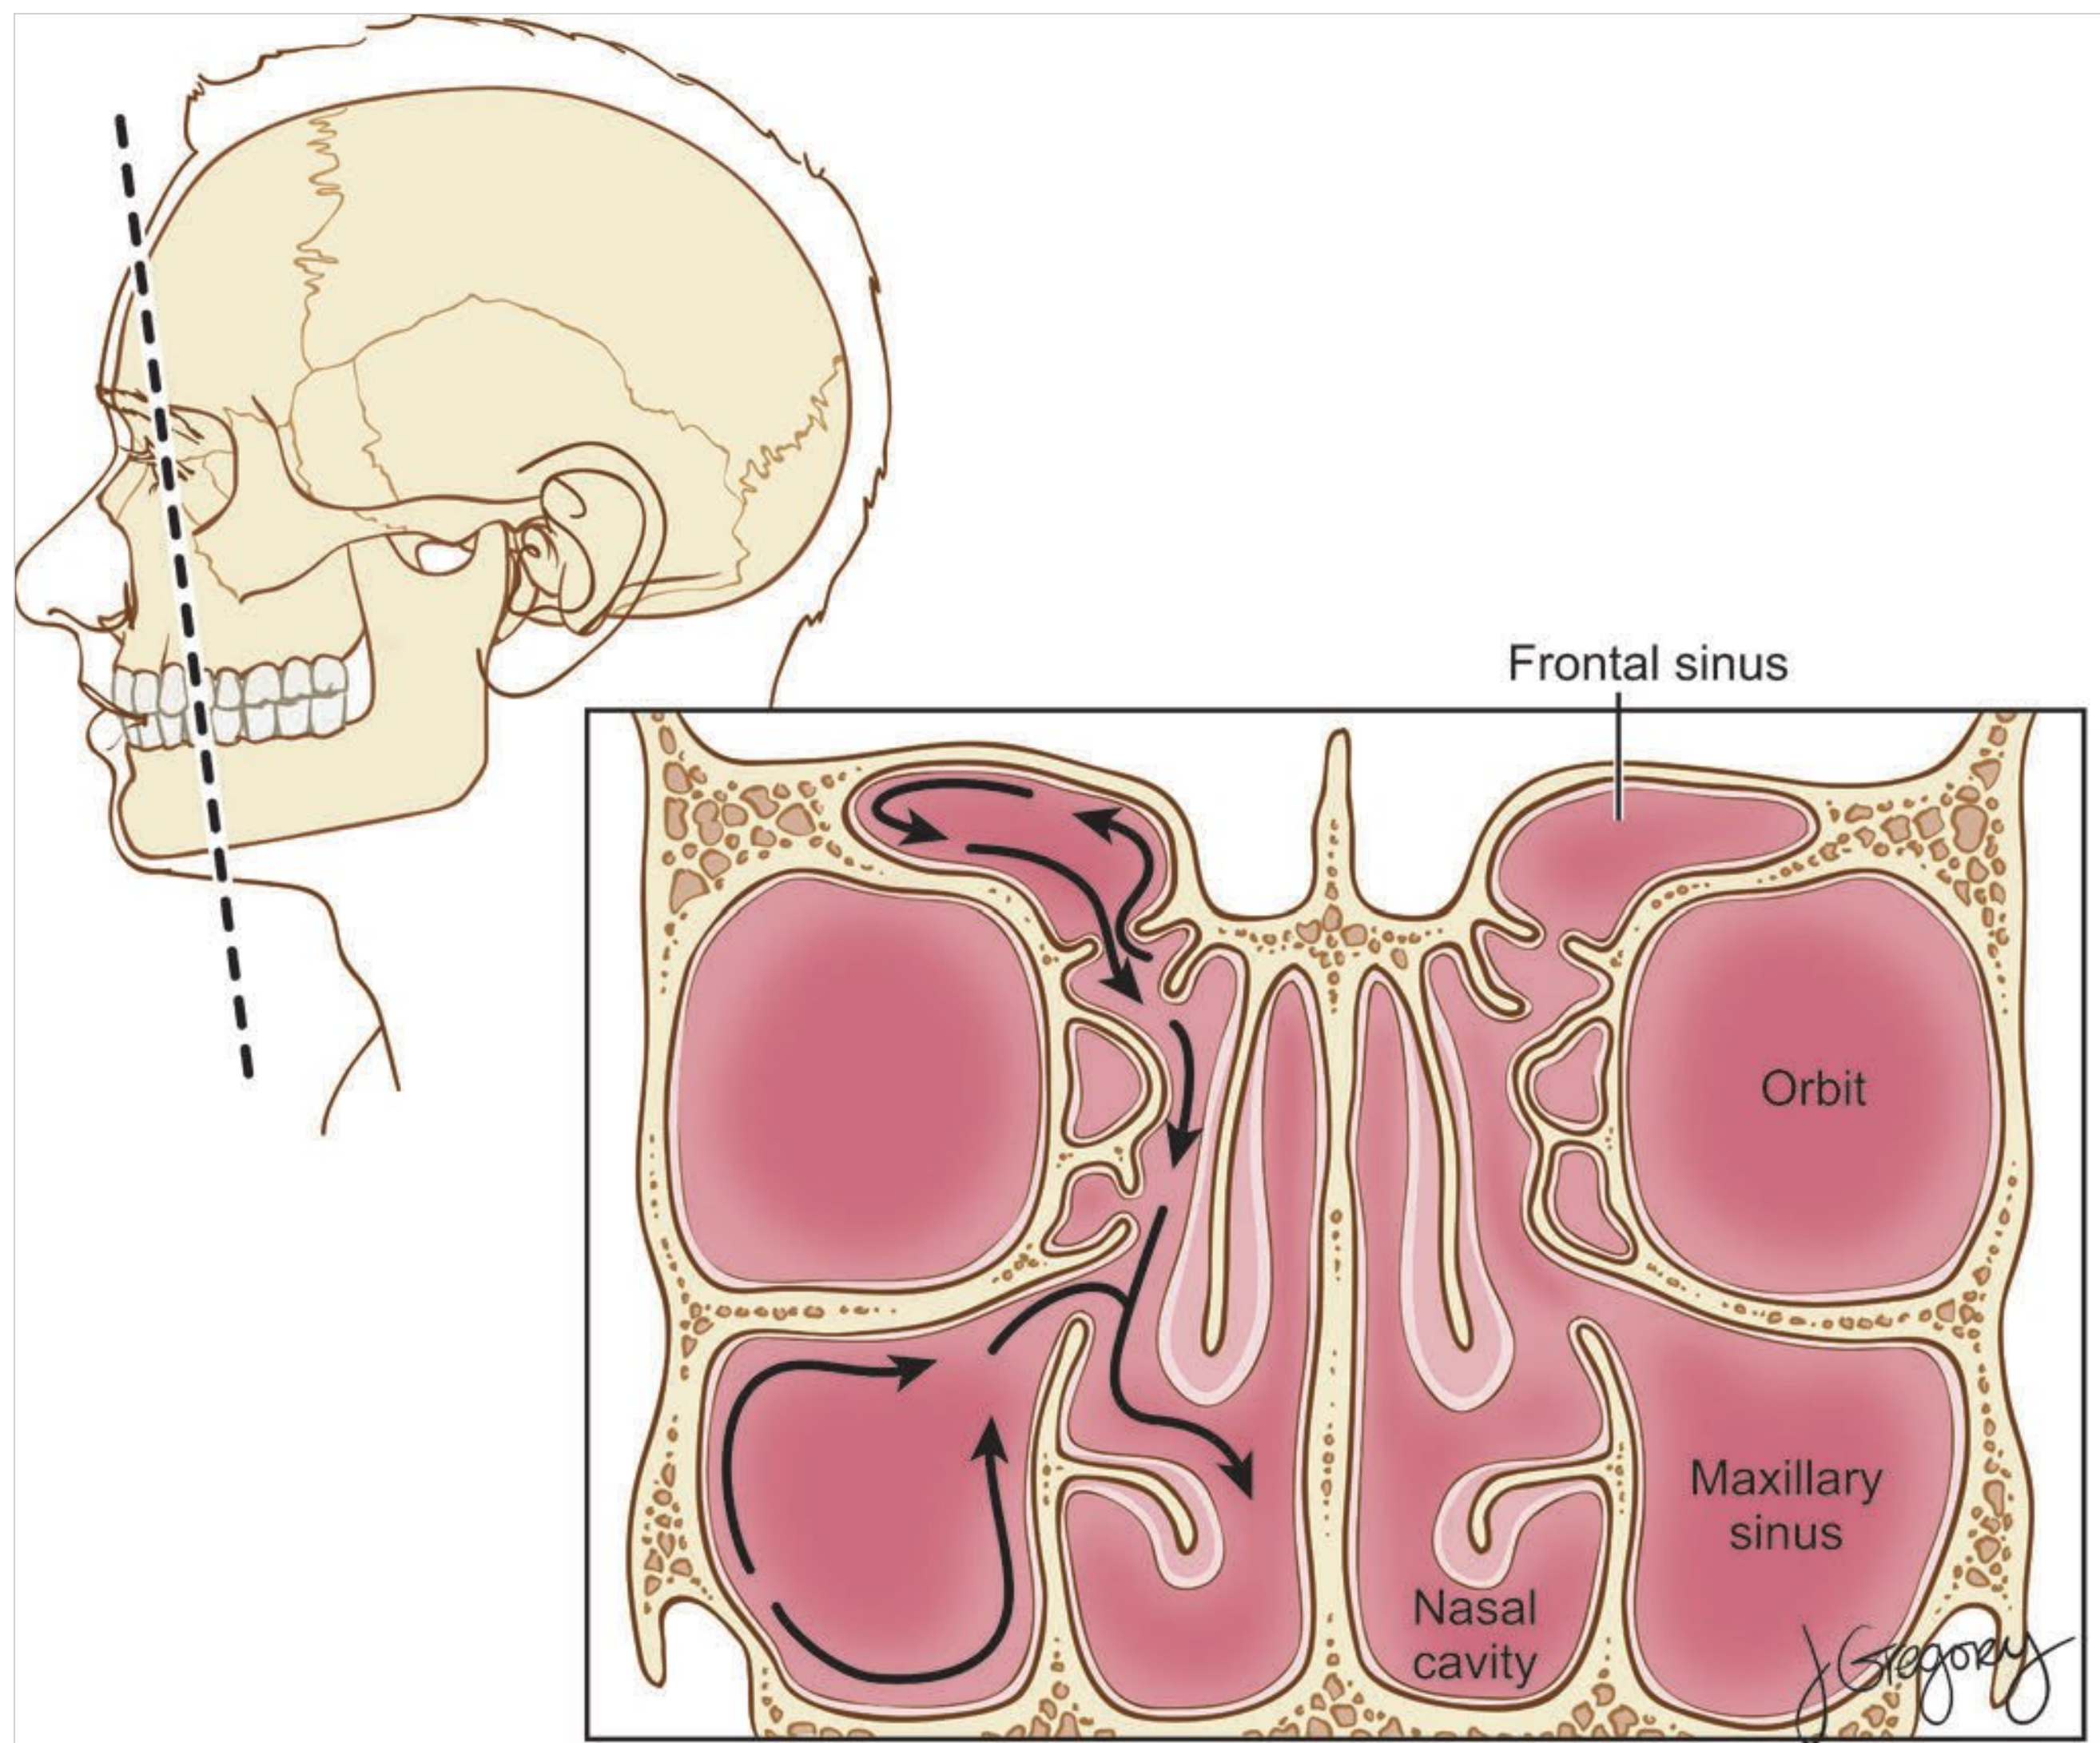

Fig. 102.10 As illustrated, mucous circulation within the paranasal sinuses follows specific pathways leading to egress into the nose.

- The complex embryologic origins of the frontal sinus determine the structure of its outflow tracts and the likelihood of frontal sinusitis.
- The maxillary and ethmoid sinuses are both present at birth, with development of the former beginning in the first trimester and development of the latter in the third trimester.
- Nasal airway patency is regulated by the autonomic nervous system, with airway resistance varying between the sides every 2 to 4 hours. Therefore, patients may complain of nasal airway problems that are simply reflections of normal airway physiology.

103 Nasal Immunity

William R. Reisacher and Emily Z. Stucken

103.1 Introduction

Strategically positioned at the entry point of the respiratory tract, the nasal cavity constantly processes stimuli from the environment. These include particles, such as microbes, chemicals, and proteins, as well as factors related to air quality, such as temperature and humidity. The nasal cavity is forced to decide whether or not a particular stimulus is dangerous to the body, and then take the necessary steps to either neutralize or tolerate it. To perform this function, the nasal cavity possesses an elaborate system of both innate and adaptive immune mechanisms. The innate immune system is the first line of defense and uses both specific and nonspecific mechanisms, whereas the adaptive immune system demonstrates both specificity and memory through the clonal proliferation of T and B lymphocytes. Any errors in these systems, through either a deficient or a hypersensitive response, may produce damage to the respiratory tract and subsequent disease.

103.2 Histology of the Nasal Cavity

The vestibule of the nasal cavity is lined with keratinized, stratified squamous epithelium that is contiguous with the skin of the external nose. At the limen nasi, this squamous epithelium changes first to nonciliated cuboidal or columnar epithelium before transitioning to the respiratory epithelium that lines the remainder of the nasal cavity and paranasal sinuses. This respiratory mucosa is a pseudostratified, ciliated, columnar epithelium made up of three cell types: ciliated cells, goblet cells, and basal cells (□ Fig. 103.1). Ciliated cells are the most prevalent cell type lining the surface epithelium. Each cilium has nine microtubule doublets surrounding two central singlet micro-

Fig. 103.1 Photomicrograph of the nasal respiratory epithelium. b, basal cell; c, ciliated cell; g, goblet cell; lp, lamina propria; m, seromucinous gland.

tubules, in a configuration similar to that of cilia found elsewhere in the body, with dynein arms articulating between the outer microtubules (□ Fig. 103.2). Each ciliated cell contains over 200 cilia, which beat at 10 to 20 cycles per second to power mucociliary clearance. Goblet cells rest on the basement membrane and produce mucus that is expelled from the apical surface. The third cell type that makes up the respiratory epithelium, the basal cell, sits on the basement membrane and serves as a source of regenerating ciliated and goblet cells.

Other cell types found in the nasal cavity include melanocytes and intraepithelial lymphocytes, as well as scattered plasma cells, mast cells, and eosinophils. The intraepithelial lymphocyte population within the nasal cavity is composed strictly of T cells with few, if any, B cells. This likely explains the finding that the majority of lymphomas of the nasal cavity are NK/T-cell lymphomas. Lymphomas of the paranasal sinuses, in contrast, tend to be of B-cell origin.

103.3 Innate Immune System

The most basic features of the innate immune system are the barrier of the nasal respiratory mucosa and mucociliary clearance. Mucus, which is primarily composed of high-molecular-weight, heavily glycosylated macromolecules, sits on a less dense layer of serous fluid produced from seromucinous glands in the underlying lamina propria. The viscous mucinous layer traps inhaled particulate matter, while the serous layer allows the underlying cilia to beat freely and direct mucus-trapped foreign matter toward the nasopharynx to prevent damage to the respiratory tract (□ Fig. 103.3). The efficiency of this system is regulated by the physical properties of mucus, as well as the frequency of the ciliary beat.

In primary ciliary dyskinesia, the microstructure of the cilia are altered because of defects in the dynein arms. As a result,

Fig. 103.2 Cross section of a cilium, demonstrating the arrangement of microtubules and cross-linking proteins.

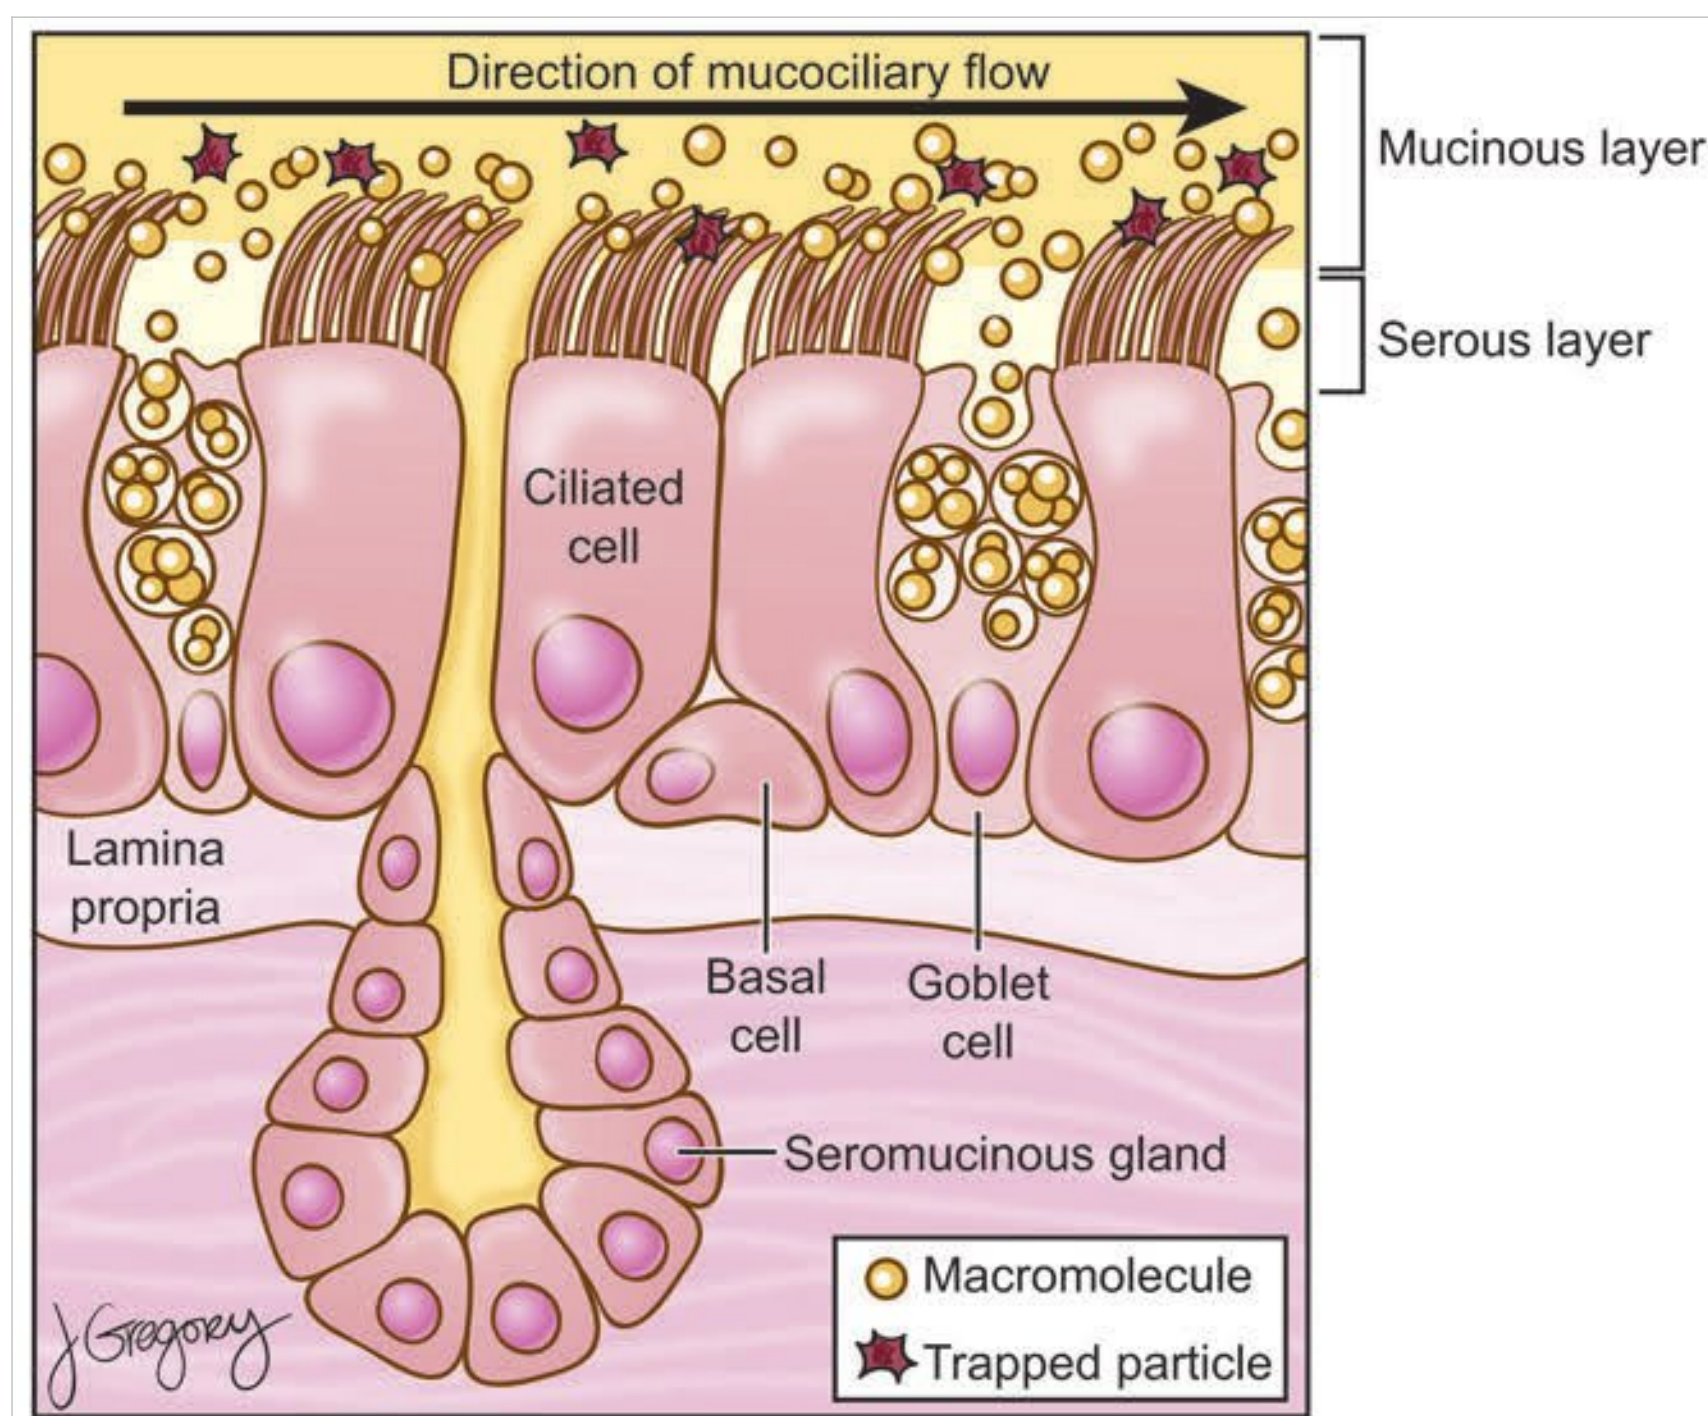

Fig. 103.3 Mucociliary flow carrying trapped particles toward the nasopharynx.

Fig. 103.4 The opsonization of pathogens and foreign debris allows more efficient binding and phagocytosis by activated cells.

mucociliary clearance is impaired. Patients with primary ciliary dyskinesia are susceptible to recurrent episodes of sinusitis, bronchitis, and bronchiectasis as a result of mucociliary stasis. These patients often present with respiratory distress in the neonatal period. They go on to develop chronic cough and rhinitis in early childhood, with recurrent episodes of rhinosinusitis, otitis media, bronchitis, and pneumonia. Male infertility is also common. The triad of recurrent rhinosinusitis, bronchiectasis, and situs inversus is known as Kartagener syndrome. A brush biopsy of the nasal mucosa for ultrastructural analysis can establish the diagnosis of primary ciliary dyskinesia.

Particles on the mucosal surface of the nose are also detected by the surface receptors of macrophages and dendritic cells, which then engulf and internalize them. This function is enhanced by a process known as opsonization, in which the particles are coated with antibodies or complement (□ Fig. 103.4). Opsonization also attracts and activates other inflammatory cells located in the lamina propria, such as lymphocytes, neutrophils, eosinophils, basophils, mast cells, and plasma cells.

Although this is largely a nonspecific process, the structure of certain opsonins allows some specificity, as well. Serum amyloid A is an opsonin secreted by respiratory epithelial cells that binds directly to gram-positive bacteria, and surfactant proteins (SP-A and SP-D) have the ability to bind and agglutinate bacteria, fungi, and allergens, as well as inorganic particles.

Respiratory epithelial cells secrete small, extracellular peptides, such as β -defensin, as well as larger proteins, such as cathelicidin, lysozyme, and lactoferrin; these can inhibit the growth of microbes, have immediate microbicidal activity, or even possess immunomodulatory capabilities. Lysozyme, an enzyme that is also secreted by monocytes and macrophages, is directed against the peptidoglycan cell wall of certain bacteria, such as *Streptococcus* and *Pseudomonas*. The destruction of gram-negative bacteria by lysozyme requires the presence of certain cofactors, such as ascorbic acid, antibody-complement complexes, and lactoferrin, which is an iron-binding protein found in neutrophil granules. The protein psoriasin increases the cell wall

permeability of bacteria such as *Escherichia coli*, and calprotectin has both antibacterial and antifungal activity.

The human body is exposed to viruses on a regular basis, and the respiratory tract is their primary target. The first lines of defense against viruses are nasal air filtration, the mucous barrier, and the secretion of immunostimulatory cytokines and chemokines from epithelial cells, macrophages, and neutrophils. The most important of these chemical messengers are the interferons IFN- α and IFN- β , which upregulate genes that protect cells against viral replication. Current efforts are under way to identify pharmacologic agents that could activate this gene pathway and produce a rapid but nonspecific defense against viruses during epidemics when vaccines are not effective.

Nasal defense against parasitic infections occur primarily through complement proteins involved in opsonization, chemotaxis, cellular activation, and the direct killing of parasites. Other proteins that perform similar functions include collectin and peptidases (C-reactive protein and serum amylase proteins), which may be either secreted or membrane-bound. Another line of defense is the chitinase family—specifically, acid mammalian chitinase (AMCase)—which is a class of genes that are regulated by interleukin-13 (IL-13), a major Th2 cytokine. The products of these genes act upon chitin, which is abundant in parasites, nematodes, insects, and fungi. It is theorized that allergic disease, also dominated by Th2 inflammation, represents an over activation of the evolutionarily beneficial ability to defend against these previously common invaders. Current evidence suggests that AMCase expression is highly associated with recalcitrant chronic rhinosinusitis (CRS).

Another protein of the innate immune system that may cause problems when overactivated is B-cell activating factor (BAFF), a member of the tumor necrosis factor (TNF) family. BAFF is produced in epithelial as well as submucosal cells of the sinonasal tract and regulates B-cell survival, proliferation, and antibody production. Evidence suggests that increased BAFF expression, which is seen in patients who have chronic rhinosinusitis with nasal polyposis (CRSwNP), may enhance immunoglobulin A (IgA) synthesis and eosinophilic inflammation. In addition to BAFF, other cytokines that modulate the B-cell response in patients with CRSwNP include B-cell attracting chemokine-1 (BCA-1) and stromal cell-derived factor-1 α (SDF-1 α).

Toll-like receptors (TLRs) are specific pattern recognition receptor proteins that are present in soluble, transmembrane, or cytosolic forms on macrophages, dendritic cells, or epithelial cells in the respiratory tract. These genetically ancient receptors are able to recognize certain pathogen-associated molecular patterns (PAMPs), such as bacterial lipopeptide, endotoxin, flagellin, double-stranded RNA, and bacterial DNA. By unknown mechanisms, TLRs are able to tolerate normal bacterial flora, but when activated by pathogens, they initiate both innate and adaptive processes. TLR9, one of the 11 known mammalian TLRs, has been studied for its ability to stimulate a Th1 immune response while inhibiting a Th2 response. CpG, a bacterial DNA sequence and TLR9 agonist, has been investigated for use as an adjuvant for hepatitis and cancer vaccines, as well as an immunostimulatory agent for the treatment of allergy, asthma, and CRS.

103.4 Adaptive Immune System

The adaptive immune system in humans is a mechanism by which the body mounts an antigen-specific response to a particular insult. The main components of the adaptive immune system are B and T lymphocytes and the family of immunoglobulins. B cells originate in the bone marrow and are initially coated with surface IgM and IgD. After leaving the bone marrow, they migrate to secondary lymphoid organs and proliferate in response to antigen stimulation and T-cell interactions. When stimulated, B cells mature into immunoglobulin-secreting plasma cells that are antigen-specific. These plasma cells undergo class switching to elude other immunoglobulin classes, including IgA, IgG, and IgE, each of which has a specific immune role. Two immunoglobulin classes, IgA and IgE, perform important functions within the nasal cavity and paranasal sinus environment and deserve special attention.

IgA is the most prevalent immunoglobulin in the nasal cavity. It exists in monomeric and dimeric forms, but the IgA in the nasal cavity and paranasal sinuses is largely in the dimeric form of secretory IgA (SIgA). SIgA is a 390-kDa dimer linked by a J chain and containing a secretory component that allows active passage across the nasal epithelium. The SIgA found in nasal mucus coats bacterial and other antigenic material and prevents it from breaching the nasal mucosa.

The importance of IgA in protecting the nasal mucosa from foreign invaders is demonstrated in patients who lack this immunoglobulin. Selective IgA deficiency is the most common isolated immunoglobulin deficiency, with incidence rates ranging from 1 per 223 to 1 per 1,000 individuals in the United States. In this patient population, IgA-laden B cells lack the capacity to differentiate into IgA-secreting plasma cells. Patients with selective IgA deficiency often have a commensurate increase in IgM levels. Their clinical presentation ranges from asymptomatic to prone to the development of recurrent sinonasal, pulmonary, and gastrointestinal infections. Sinus infections are mainly bacterial in origin. Allergic disease and autoimmune disorders are also more prevalent in this patient population. The management of patients with selective IgA deficiency includes the treatment of acute bacterial infections or the daily administration of prophylactic antibiotics, depending on the severity of symptoms.

The second immunoglobulin that plays a pivotal role in the local immunity of the nasal cavity is IgE. IgE is the main immunoglobulin involved in the allergic response and is important in the pathophysiology of allergic rhinitis. Although IgE-producing plasma cells are not a normal component of the nasal mucosa, an increase in allergen-specific IgE has been found in the nasal turbinate tissue of allergic patients. There is evidence that the IgE permeating the nasal tissues of allergic individuals may be produced locally rather than migrate from distant sources. Several studies have shown that immunoglobulin class switching can occur in the local environment of the nose, and *ex vivo* studies have demonstrated that allergen-induced class switching occurs in isolated nasal turbinate tissues. Investigators have also demonstrated an increase in antigen-specific IgE in patients who have rhinitis with negative results on serum allergy testing. It has been suggested that a local allergic response may be the inciting factor in these patients, who have previously been categorized as having nonallergic rhinitis based on the

results of systemic testing. Further discoveries in this field may lead to an improved understanding and treatment of this patient population.

T cells are the second class of lymphocytes that make up the adaptive immune system. T cells originate in the thymus, where they mature and undergo differentiation. Autoreactive cells are selected for apoptosis before leaving the thymus. Once T cells exit the thymus, they are attracted to lymphoid organs by cellular signaling. When an antigen is encountered, a T cell becomes activated and undergoes clonal expansion with specificity to that antigen. T cells differentiate into one of two lineages: helper T cells, which are positive for CD4, and cytotoxic T cells, which are positive for CD8. CD4+ T helper cells further differentiate into either Th1 cells or Th2 cells, which can be distinguished by differences in their cytokine profiles and functionality. Th1 cells produce IL-2 and IFN- γ , which are involved in cytotoxic inflammatory reactions in response to intracellular pathogens. They participate in delayed-type hypersensitivity reactions, act primarily through cell-mediated interactions and communication through cytokines. Th2 cells produce IL-1, IL-4, IL-5, IL-9, and IL-10, favoring IgE-mediated allergic inflammation and eosinophil production (□ Fig. 103.5). The cytokines produced by each cell type inhibit the activation of the other cell type, thus preventing the activation of conflicting inflammatory pathways.

Differential activation of Th1 and Th2 pathways within the nasal cavity promotes differential expression of rhinologic disease. In chronic rhinosinusitis with nasal polyps (CRSwNP), the local inflammatory environment exhibits a predominance of Th2 cells and the Th2-related cytokines IL-4 and IL-5. This is significantly different from chronic rhinosinusitis without nasal polyps (CRSSNP), which is generally a Th1-driven process. Activation of the Th2 cytokine profile is associated with the influx of eosinophils, which comprise 60 to 90% of the cell population in nasal polyps. The inflammatory products of eosinophils have the capacity to inflict local tissue damage, which has been proposed to account for the inflammatory reactions that occurs in nasal polyposis. The predominance of a Th2- and eosinophilia-mediated reaction also accounts for the association of nasal polyps with allergy and asthma, which are also Th2-driven processes.

103.5 Roundsmanship

- Nasal immunity relies on both innate and adaptive mechanisms.
- Deficiencies, as well as hypersensitivities, of nasal immunity can produce disease.
- Mucociliary clearance moves pathogens and foreign particles toward the nasopharynx.
- Innate defense mechanisms may be antigen-specific, as well as nonspecific.
- Opsonization both attracts and activates other inflammatory cells.
- Chemical messengers are able to activate genes that assist in the body's defense against pathogens.
- B-cell differentiation and IgE production may occur on the local level.

Fig. 103.5 T-cell lineage and pathways of differentiation into Th1 and Th2 helper cells. IFN, interferon; IL, interleukin.

- The balance of Th1 and Th2 cytokines may play a role in certain disease processes, such as nasal polyposis.

104 Olfaction and Taste Disorders

William R. Reisacher and Saral Mehra

104.1 Introduction

The ability to smell and taste plays an important role in our enjoyment of life, as well as our survival in the world. These senses help us identify which foods to eat, as well as alert us about potentially dangerous substances in the environment. The sense of smell is linked to sexual attraction, and certain odors and tastes can evoke powerful emotions and bring back vivid memories many years after the initial experience. For the otolaryngologist, disorders of olfaction and taste are amongst the most difficult to diagnose and treat. Because the perception of flavor represents a complex integration of olfactory and gustatory signals in the orbitofrontal and other areas of the cerebral cortex, disorders of taste and smell are often analyzed together. However, the two systems are quite different in terms of anatomy, physiology, and pathology, and separate discussions are warranted.

104.2 Olfaction Disorders

104.2.1 Applied Anatomy

The pathway for the sensation of smell begins when odorant molecules access the olfactory epithelium via airflow. The olfactory epithelium is composed of a 1- to 2-cm² patch of pseudostratified columnar epithelium on the cribriform plates, segments of the superior and middle turbinates, and superior nasal septum. The olfactory epithelium contains nerve endings of the olfactory sensory neurons of cranial nerve I (and some endings of cranial nerve V, which sense compounds such as menthol, mustard, and capsaicin). Olfactory cells are bipolar sensory neu-

rons within the nasal epithelium that have nonmotile cilia (□ Fig. 104.1). These neurons extend their unmyelinated axons in bundles through the cribriform plates to synapse with cells in the olfactory bulbs. Axons from cells in each bulb coalesce to form the olfactory tract on each side. These tracts then send their signals to a wide number of brain areas, which together are called the primary olfactory cortex. The pattern of receptor stimulation is unique for each particular odorant, and this pattern is reassembled centrally for processing.

A multigene family has recently been identified in humans that encode approximately 500 G-protein-coupled odorant receptors (GPCRs), which are expressed only on the dendrites and axons of olfactory sensory neurons. Although the neurons expressing a particular receptor are randomly distributed in the olfactory epithelium, each projects to a topographic region in the olfactory bulb that is specific to that receptor.

104.2.2 Terminology

A smell disorder can be described as either a quantitative or a qualitative problem. A diminished sense of smell is hyposmia, and a total absence of smell is anosmia. Qualitative disorders, which can collectively be called dysosmias, include parosmia (an altered perception of smell that is usually foul), phantosmia (perception of smell in the absence of a physical stimulus), and agnosmia (the inability to verbally differentiate a smell despite being able to distinguish between odorants).

An etiologic classification system also exists, and clinical olfactory disorders can be transport (conductive), sensory, or neural. Transport loss is a decreased access of odorant molecules to the olfactory epithelium, sensory loss involves damage

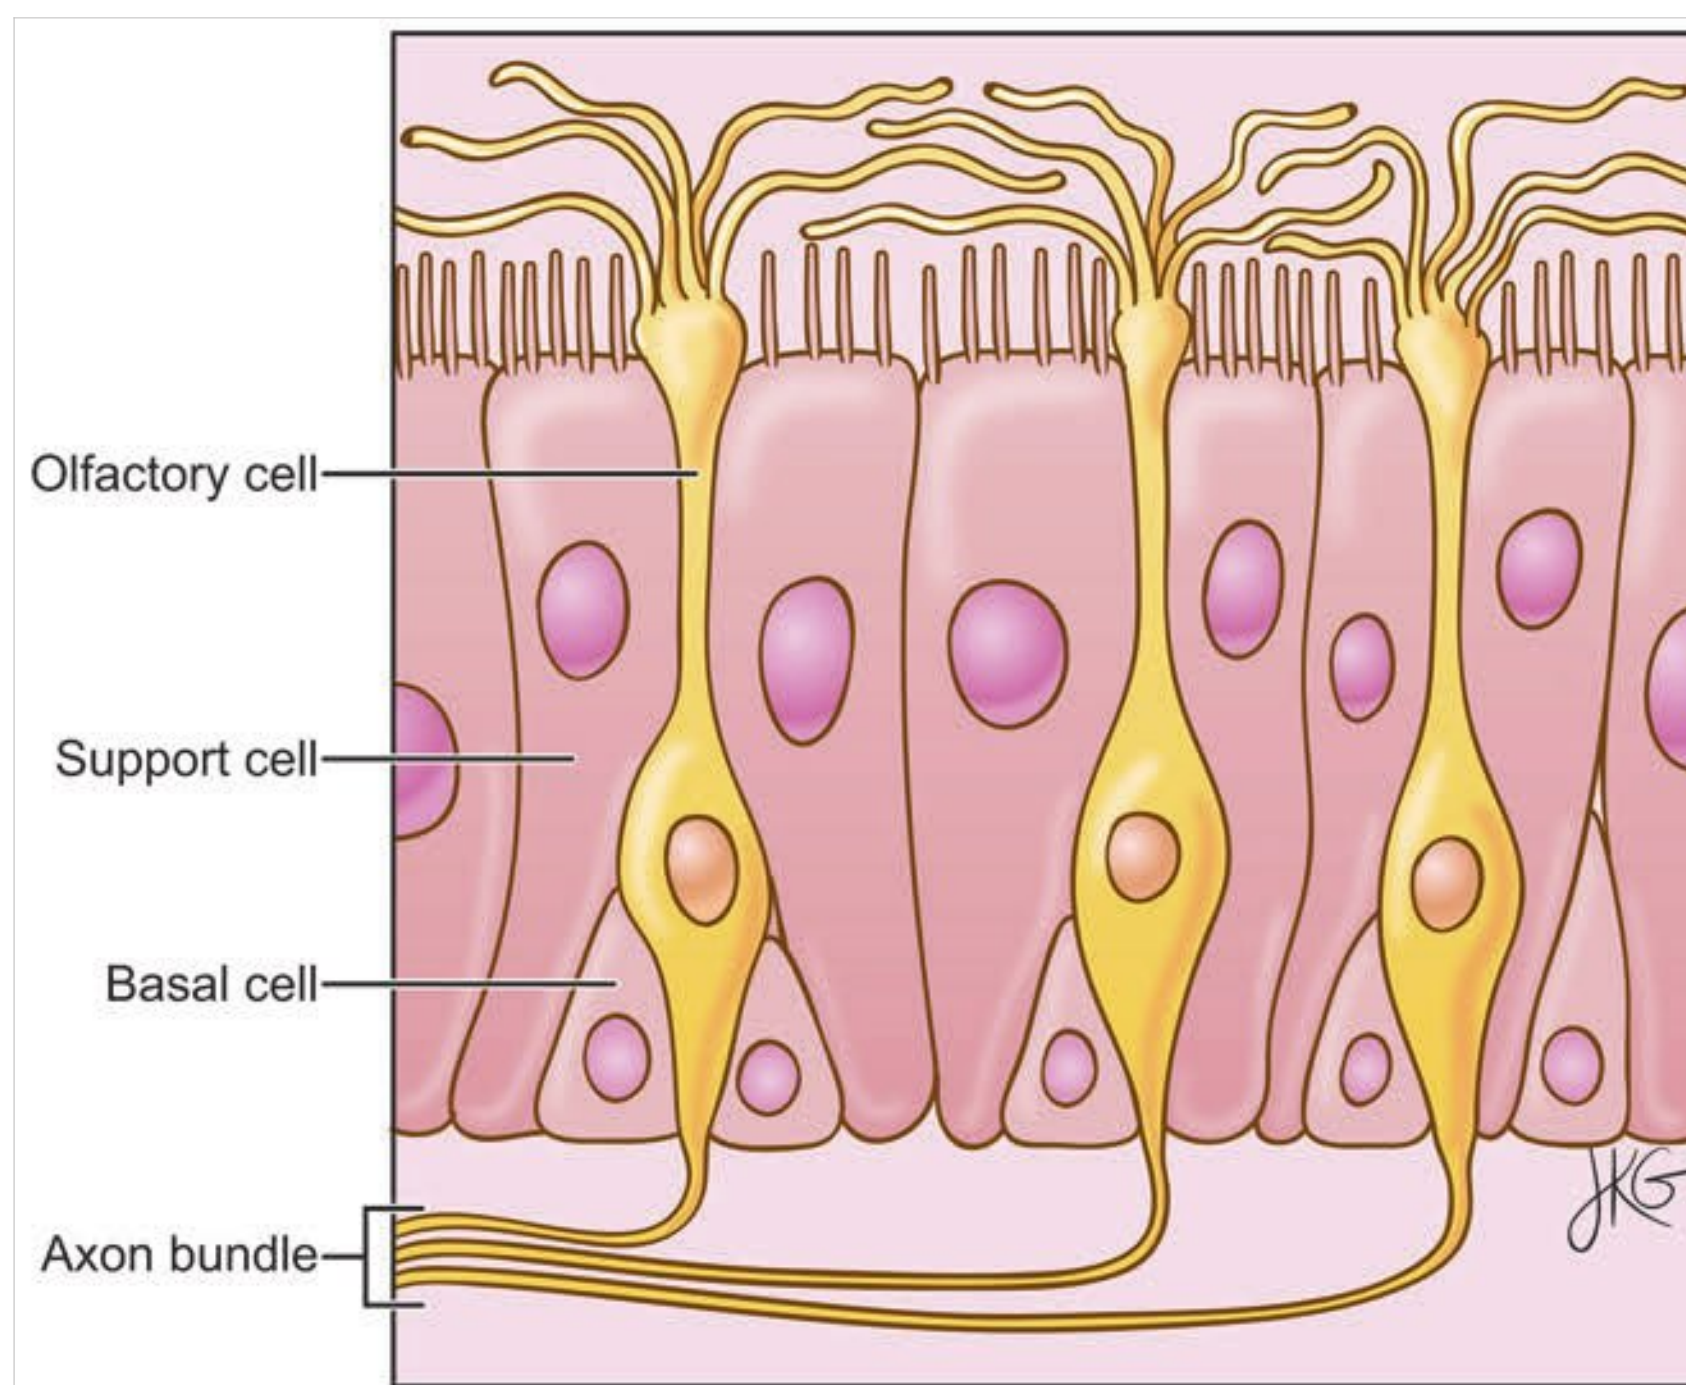

Fig. 104.1 Structure and cellular population of the olfactory epithelium.

to the neuroepithelium, and neural disorders reflect injury to the olfactory bulb and central olfactory pathways.

104.2.3 The Disease Process

Etiology

Loss of smell is usually caused by nasal or sinus disease, upper respiratory tract infection, head trauma, or side effects from a large variety of medications. A comprehensive differential diagnosis for olfaction disturbances is shown in □ Fig. 104.1.

Pathogenesis

The pathogenesis of disorders involving olfaction depends on the etiology. The mechanism of chronic rhinosinusitis (CRS) is likely a mixed transport and sensory problem consisting of obstruction and direct injury to the neuroepithelium, resulting in baseline olfactory sensory neuron death. This mixed loss theory is supported by the finding that a number of patients who have adequate medical or surgical treatment for other sinonasal complaints have persistent osmias. The pathogenesis of olfactory disorders following viral infection is postulated to involve the olfactory receptor cells; however, a central mechanism cannot be completely ruled out. There is also a strong association between olfaction disorders and neurodegenerative diseases such as Parkinson disease and Alzheimer disease. Finally, malingering must be included in the differential diagnosis of smell disorders, and a number of objective tests are designed to detect malingerers.

104.2.4 Medical Evaluation

Presenting Complaints

A thorough patient history will include the timing of the olfactory problem (sudden, gradual, fluctuating); previous incidents of the problem; antecedent events (head trauma, upper respiratory infection); associated symptoms (nasal obstruction, rhinorrhea); the presence of other neurologic deficits, such as memory impairment and motor findings; and a history of nasal surgery.

Physical Examination

The physical examination should include a thorough otologic, upper respiratory, and head and neck evaluation. The nasal examination should include endoscopy evaluating the middle meatus, sphenoid recess, nasopharynx, and olfactory cleft; any anatomical obstructions to airflow, such as polyps, masses, or edematous mucosa, should be noted. In addition, a comprehensive neurologic examination should be conducted that emphasizes the cranial nerves and general sensorimotor function.

Testing

Tests of olfaction disorders are useful in confirming patient complaints, documenting the level of impairment, and evaluating improvement over time. Qualitative olfactory impairment can be tested with a forced-choice verbal identification of odors

Fig. 104.2 Some commonly available tests to assess olfactory function. (a) Sniffin' Sticks. (Courtesy of Burghart Messtechnik, Wedel, Germany). (b) University of Pennsylvania Smell Identification Test (UPSIT). (Courtesy of Sensonics, Haddon Heights, NJ).

such as in the University of Pennsylvania Smell Identification Test (UPSIT), “Sniffin’ Sticks,” and the Connecticut Chemosensory Clinical Research Center Test (□ Fig. 104.2). The UPSIT uses 40 scratch-and-sniff odors; the patient must choose from one of four and identify the odor. This test can also be helpful in identifying malingering. Threshold tests, discrimination tests, and objective tests (e.g., chemosensory event-related potentials, odor-induced changes on electroencephalogram and electro-olfactogram) can also be conducted as indicated. Serum testing for systemic diseases should include blood glucose, thyroid function, erythrocyte sedimentation rate, and liver function. Finally, skull base and/or brain imaging with computed tomography (CT) or magnetic resonance (MR) imaging is indicated as guided by the medical evaluation.

104.2.5 Treatment

Treatment should focus on the etiology and may involve a multidisciplinary team. For patients with a transport smell disorder, medical management of allergies, infections, and inflammation is frequently effective. Surgery may be indicated when polypsis, nasal septal deviation, or CRS results in a transport disorder. However, it is important to remember that CRS may cause direct toxicity to the olfactory nerve, which may result

in persistent olfactory loss even after polyp removal and sinus reventilation.

104.2.6 Prognosis

Although there is no proven effective treatment for a sensorineural olfactory loss, spontaneous recovery and regeneration are common in postviral olfactory disorders and may occur up to 2 years after viral exposure. Similarly, in olfactory dysfunction following head trauma, improvement may occur without intervention because of the regenerative capacity of the olfactory system. One study that tested olfactory function in 66 patients with olfactory dysfunction following head injury found that 36% improved, 45% showed no change, and 18% worsened. Treatment is warranted because patients risk injury from their inability to detect gas leaks, smoke, spoiled foods, and other warning signs of impending danger. Also, quality of life is significantly affected in patients whose enjoyment from tasting foods is diminished, leading to weight loss, malnutrition, impaired immunity, and worsening of medical illness, particularly in the elderly.

104.3 Taste Disorders

104.3.1 Applied Anatomy

The sense of taste occurs when chemicals bind to taste receptors, which are polarized neuroepithelial cells that form columnar, pseudostratified “islands” in the surrounding oral cavity epithelium. Clusters of approximately 50 to 100 taste receptors, known as taste buds, are located at various places within the oral cavity, including the edges of the tongue, anterior and dorsal surfaces of the tongue, soft palate, pharynx, and larynx. On the tongue, taste buds are located within fungiform, foliate, and circumvallate papillae. Fungiform papillae are on the anterior two-thirds of the tongue and can contain up to 15 taste buds. Foliate papillae are located on the posterior and lateral edges of the tongue and typically contain many more taste buds than fungiform papillae. The approximately nine circumvallate

papillae are located on the posterior tongue, separating the anterior tongue from the base of the tongue.

Taste receptor cells share almost all of the properties of neural cells except that they have no axons (□ Fig. 104.3). Sensory information is transmitted to afferent nerve fibers located within the taste buds, which have cell bodies in the sensory ganglia of cranial nerves VII, IX, and X. Fibers from these ganglia project into the central nervous system at the level of the rostral solitary nucleus of the brainstem. Signals then travel via thalamic pathways to the primary opercular and insular taste cortex, as well as the orbitofrontal cortex, cingulate gyrus, and other integrative projection areas. Cranial nerve VII, whose cell bodies are within the geniculate ganglion, transmits taste information through two branches, the chorda tympani and the greater superficial petrosal nerve. Cranial nerve IX, whose cell bodies are in the petrosal ganglion, innervates most of the foliate and circumvallate papillae. Cranial nerve X, whose cell bodies are in the nodose ganglion, innervates taste buds in the pharynx and larynx via the superior laryngeal nerve.

The five basic tastes in humans are sweet, sour, bitter, salty, and umami. Sweet taste encourages the consumption of carbohydrates, which are required for energy. Sour taste is associated with acids, which increase as foods begin to spoil. Likewise, many substances that are poisonous to humans have a bitter taste. Salt intake is necessary for maintaining water balance and blood circulation, and umami, which is the taste of L-glutamate, signals the presence of proteins in food. Certain visual and textural cues can also have an impact on the perception of how food tastes, and many genetic, cultural, and developmental factors contribute to an individual’s attraction to certain foods.

104.3.2 Terminology

A quantitative reduction in gustatory sensitivity is referred to as hypogeusia, whereas the absence of this sense is called ageusia. Certain central nervous system diseases, such as multiple sclerosis, are capable of producing a taste disturbance on half of the tongue, called hemiageusia. A qualitative reduction in gustatory sensitivity is referred to as dysgeusia. An altered perception

Table 104.1 Differential diagnosis of olfactory and taste disorders

Etiology of olfactory disorders	Etiology of taste disorders
Nasal and sinus disease	Oral and perioral infections
Allergic or vasomotor rhinitis	
Chronic sinusitis	Aging
Nasal polyps	
Adenoid hypertrophy	Iatrogenic causes
Following viral upper respiratory infection	Oral appliances
	Dental procedures
Head trauma	Middle ear surgery
Direct injury	Oncologic surgery
Nerve injury	Procedures with lingual compression
Brain injury	Tonsillectomy, oropharyngeal surgery
	Micro-laryngoscopy
Neurodegenerative disease	Endotracheal intubation
Alzheimer disease	
Parkinson disease	Trauma
Multiple sclerosis	Fractures of the skull base or midface
Aging	Neurologic conditions
	Idiopathic mononeuropathy, polyneuropathy (e.g., Bell palsy)
Exposures and nutritional factors	Cerebrovascular disorders, accidents
Medications	Gustatory aura with epilepsy or migraine
Cigarette smoking	Multiple sclerosis
Cocaine abuse (intranasal)	
Toxic chemicals	Systemic disease
Industrial agents	Sjögren syndrome
Vitamin and trace metal deficiency	
Radiation treatment of head and neck	Endocrine disorders
	Adrenocortical insufficiency
Congenital conditions	Diabetes mellitus
Congenital anosmia	Hypothyroidism
Turner syndrome	
Kallmann syndrome	Congenital conditions
	Kallmann syndrome
Neurologic conditions	Turner syndrome
Neoplasm or brain tumor	
Epilepsy (olfactory aura)	Exposures and nutritional factors
Migraine headache (olfactory aura)	Medications
Cerebrovascular accident	Vitamin and trace metal deficiency
Parkinson disease	Malnutrition

Table 104.1 continued

Etiology of olfactory disorders	Etiology of taste disorders
Parkinsonian syndromes	Toxic chemicals and industrial agents
Alzheimer disease	Radiation treatment for head and neck cancer

Systemic lupus erythematosus	
Pregnancy	

of taste without any stimulation is known as parageusia. Dysgeusia and parageusia can be further described depending on the type of taste that is present. The perception of a foul taste may be referred to as cacogeusia, and that of a metallic taste may be called metallogeusia.

104.3.3 Medical Evaluation

Presenting Complaints

The diagnosis of taste disorders begins with a detailed history, starting with a description of the problem. The physician should ask when the problem first was noted and about events that occurred around that time, such as illnesses, radiation treatments, or new medications. The history should also elicit information about recent trauma or surgical procedures, particularly those occurring in the oral cavity or oropharynx.

Physical Examination

During the physical examination, the otolaryngologist should perform a complete head and neck examination, including a thorough assessment of the sinonasal tract with nasal endoscopy. It is important to remember that many complaints of taste disturbance actually stem from olfactory deficits. A careful examination of the oral cavity should be done to assess for oral and perioral infections, as well as for dental carries and gingival disease. Middle ear function should be evaluated with otomicroscopy along with audiography and tympanometry. A full cranial nerve examination should be performed, and any positive findings should prompt a consultation by a neurologist. Because many causes of taste disturbance may be systemic in nature, such as chronic renal failure and liver disease, it is recommended that each patient also have a complete evaluation by his or her primary care physician.

Testing

Testing should focus on identifying the etiology, assessing the patient's function, and determining the impact on the patient's quality of life. Blood testing may be useful to diagnose nutritional deficiencies, such as vitamin D and zinc deficiencies, which can lead to taste disturbance. CT or MR imaging may be obtained to rule out CRS, temporal bone disease, or brain abnormalities. There are a limited number of objective tests to assess taste function, but one of the most common is electro-gustometry (EGM), in which stimulation of the taste buds in various parts of the tongue, either with an electric stimulus or with flavored paper discs, is followed by a measurement of threshold. In general, increased thresholds on both sides of the tongue are associated with peripheral damage to the receptor systems and the tongue by physical or chemical trauma, whereas asymmetric abnormalities are usually associated with peripheral nerve damage or central nervous system causes. Instruments to help assess the impact of disease on quality of life include the Short Form 36 Health Survey (SF-36) and the Beck Depression Inventory.

Differential Diagnosis

Some common medications that may lead to taste disturbances include angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers, diuretics, chemotherapeutic agents, and topical antihistamines. Approximately one-third of adults undergoing tonsillectomy experience taste disturbances 2 weeks after surgery, decreasing to fewer than 10% after 6 months. A comprehensive differential diagnosis for taste disorders appears in □ Table 104.1.

104.3.4 Treatment

The treatment for taste disturbance focuses primarily on identifying the underlying cause. The physician must also keep in mind that the perceived intensity of taste generally diminishes with age, as well as with psychological problems. Oral hygiene must also be discussed, along with the importance of smoking cessation. Acute disturbances in taste are typically transient in nature and require no specific treatment. In 2009, there was a sharp rise in reports of metallogusia after the consumption of pine nuts, which was believed to have occurred after a type of pine nut containing a toxin had entered the human food supply. The condition became known as “pine mouth” and produced symptoms lasting for up to 2 weeks after the ingestion of breads or sweet foods. It has recently been discovered that certain genes control the temperature dependence of sweet taste

receptors, and studies are under way evaluating the utility of hot and cold stimulation in the treatment of sweet dysgeusia.

104.4 Roundsmanship

- The perception of flavor is a complex integration of olfactory and taste stimuli in the cerebral cortex.
- Disorders of smell can be classified as quantitative (hyposmia or anosmia), qualitative (dysosmia), or based on the site of pathology (transport, sensory, or neural).
- The five basic tastes in humans are sweet, sour, bitter, salty, and umami, each of which has a proposed survival or homeostatic function.
- A quantitative reduction in gustatory sensitivity is referred to as hypogeusia or ageusia; a qualitative reduction in gustatory sensitivity is referred to as dysgeusia.
- The possible etiologies of taste and smell disorders are large and varied, and the clinical evaluation must focus on identifying the most likely cause.
- Disorders of smell and taste can be dangerous because they may lead to weight loss, malnutrition, and the inability to sense danger, particularly in the elderly.

105 Benign Nasal Obstruction

Anthony P. Sclafani and Anthony M. Sclafani

105.1 Introduction

Nasal obstruction is a common complaint frequently experienced during a number of normal and pathologic conditions. When chronic, however, nasal obstruction can cause significant morbidity and reduction in quality of life. The physician must determine the specific etiology and direct treatment toward it; however, the etiology may often be multifactorial, and treatment plans should be created that most effectively address these factors.

105.2 Incidence and Prevalence of Disease

All patients have experienced nasal congestion at some point in their lives, but persistent nasal obstruction for more than a month should be evaluated. Symptomatic and persistent nasal obstruction is estimated to affect 20% of the population. Eighty percent or more of individuals in the population have a septal deviation of some degree, and approximately 5% of people have symptomatic nasal obstruction associated with a deviated septum.

105.3 Terminology

The diagnosis and management of nasal obstruction are greatly facilitated by a consideration of structural versus functional nasal obstruction. Nasal obstruction from a fixed, structural cause such as a deviated septum is typically constant and usually of long duration. Obstructive symptoms that are of recent development or that vary over time suggest a pathophysiologic cause and may be more amenable to medical treatment. The term nasal cycle refers to the cyclical alternation of vasocongestion and decongestion naturally occurring in the nose. This cycle is coordinated between the two sides of the nose; the vasoerectile tissue on one side undergoes engorgement while the opposite side shrinks because of diminished blood flow. In most persons, the pattern reverses every 4 to 6 hours. The term laminar airflow refers to the smooth, nonturbulent flow of air through the nasal cavity.

105.4 Applied Anatomy

The nasal cavities are bounded bilaterally by three sets of turbinate bones, the nasal sidewalls, and the alae, and medially by the nasal septum and columella. The caudal end of the nasal bones is termed the piriform aperture. The posterior choanae are the junctions of the two nasal cavities with the nasopharynx. The internal nasal valve is a physiologic area bounded by the inferior turbinate (anterior head), the junction of the upper lateral cartilage (ULC) and lower lateral cartilage (LLC) (the “scroll”), the nasal septum, and the nasal floor. The attachment of the ULC and septum should form an angle of about 10 to 15 degrees (□ Fig. 105.1). The external nasal valve is the rim of the

ala. The inferior turbinate, a separate bone (inferior concha) forming the lower part of the lateral nasal sidewall, is covered by vasoerectile mucosa that responds to both environmental and physiologic stimuli. More superiorly, portions of the ethmoid bone, including the middle turbinate, complete the lateral and superior nasal walls. Medially, the nasal septum is composed of the quadrangular cartilage, which rests upon the maxillary crest, a ridge of bone rising up from the palate. Dorsally, the nasal septum fuses with the ULCs to make up the lower nasal dorsum. Posteriorly, the quadrangular cartilage articulates with the vomer (inferiorly) and perpendicular plate of the ethmoid bone (superiorly). Submucosal blood vessels running in the perichondrium supply nutrients to the septal cartilage. Small areas of the septum are contributed by the palatine and sphenoid bones (□ Fig. 105.2).

105.5 The Disease Process

105.5.1 Etiology

Given the multiple potential causes of nasal obstruction, it is impractical to discuss each in detail here; most are covered more comprehensively elsewhere in this book. Deviated nasal septum may occur congenitally, as a result of birth trauma, or as a result of nasal trauma later in life, but most often it is developmental, becoming evident in adolescence or after puberty. Minor deflections of either the bony or cartilaginous septum are very common, even in relatively asymptomatic patients, but some patients with minor deviations may complain significantly of obstructive symptoms. Likewise, turbinate enlargement can be congenital/developmental, with bulky turbinate bone. More common is mucosal hypertrophy (secondary to chronic rhinitis or sinusitis) with or without bony enlargement. Internal nasal valve dysfunction can be idiopathic or can be related to prior nasal surgery; intercartilaginous incisions and removal of portions of the lateral crura during rhinoplasty can

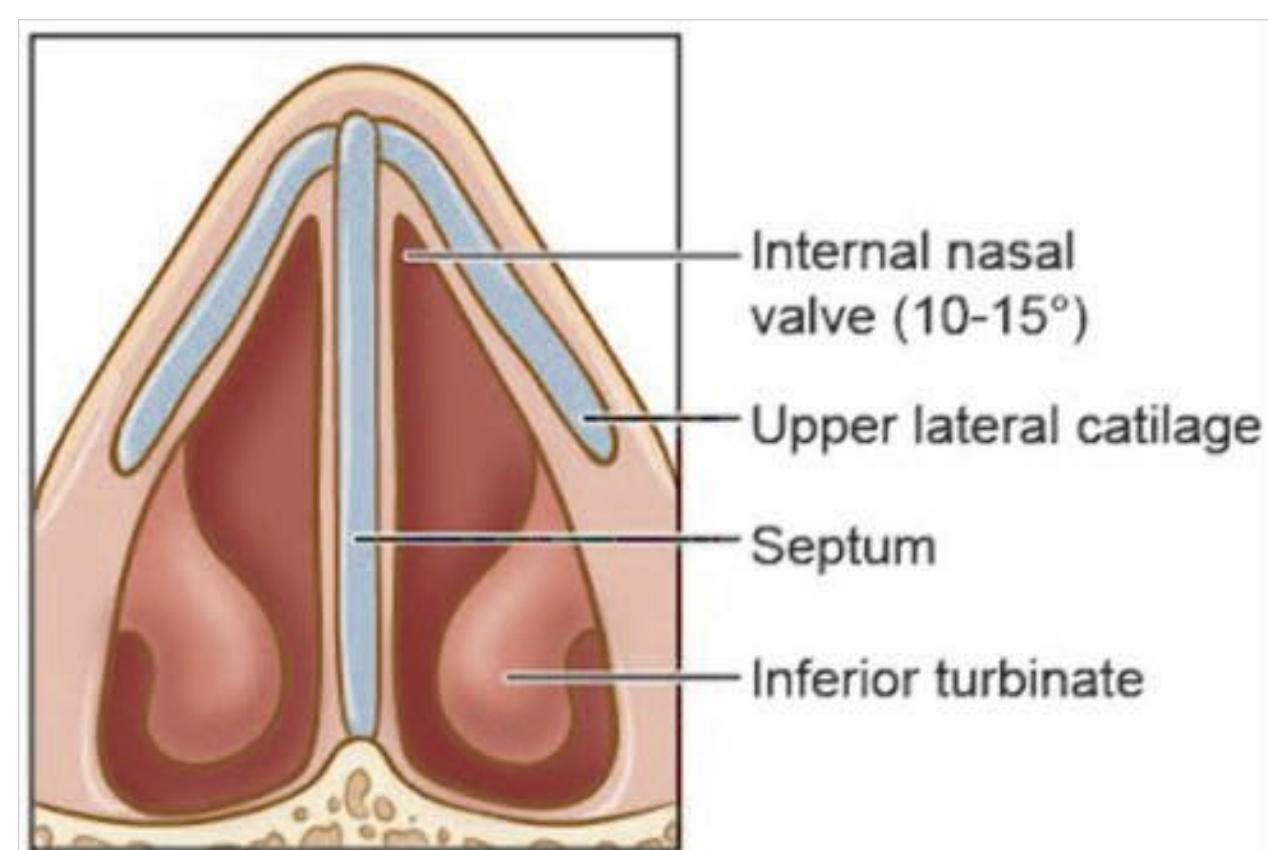

Fig. 105.1 The internal nasal valve is defined by the nasal septum, nasal floor, anterior end of the inferior turbinate, and lateral nasal sidewall. The internal nasal valve angle is roughly 10 to 15 degrees.

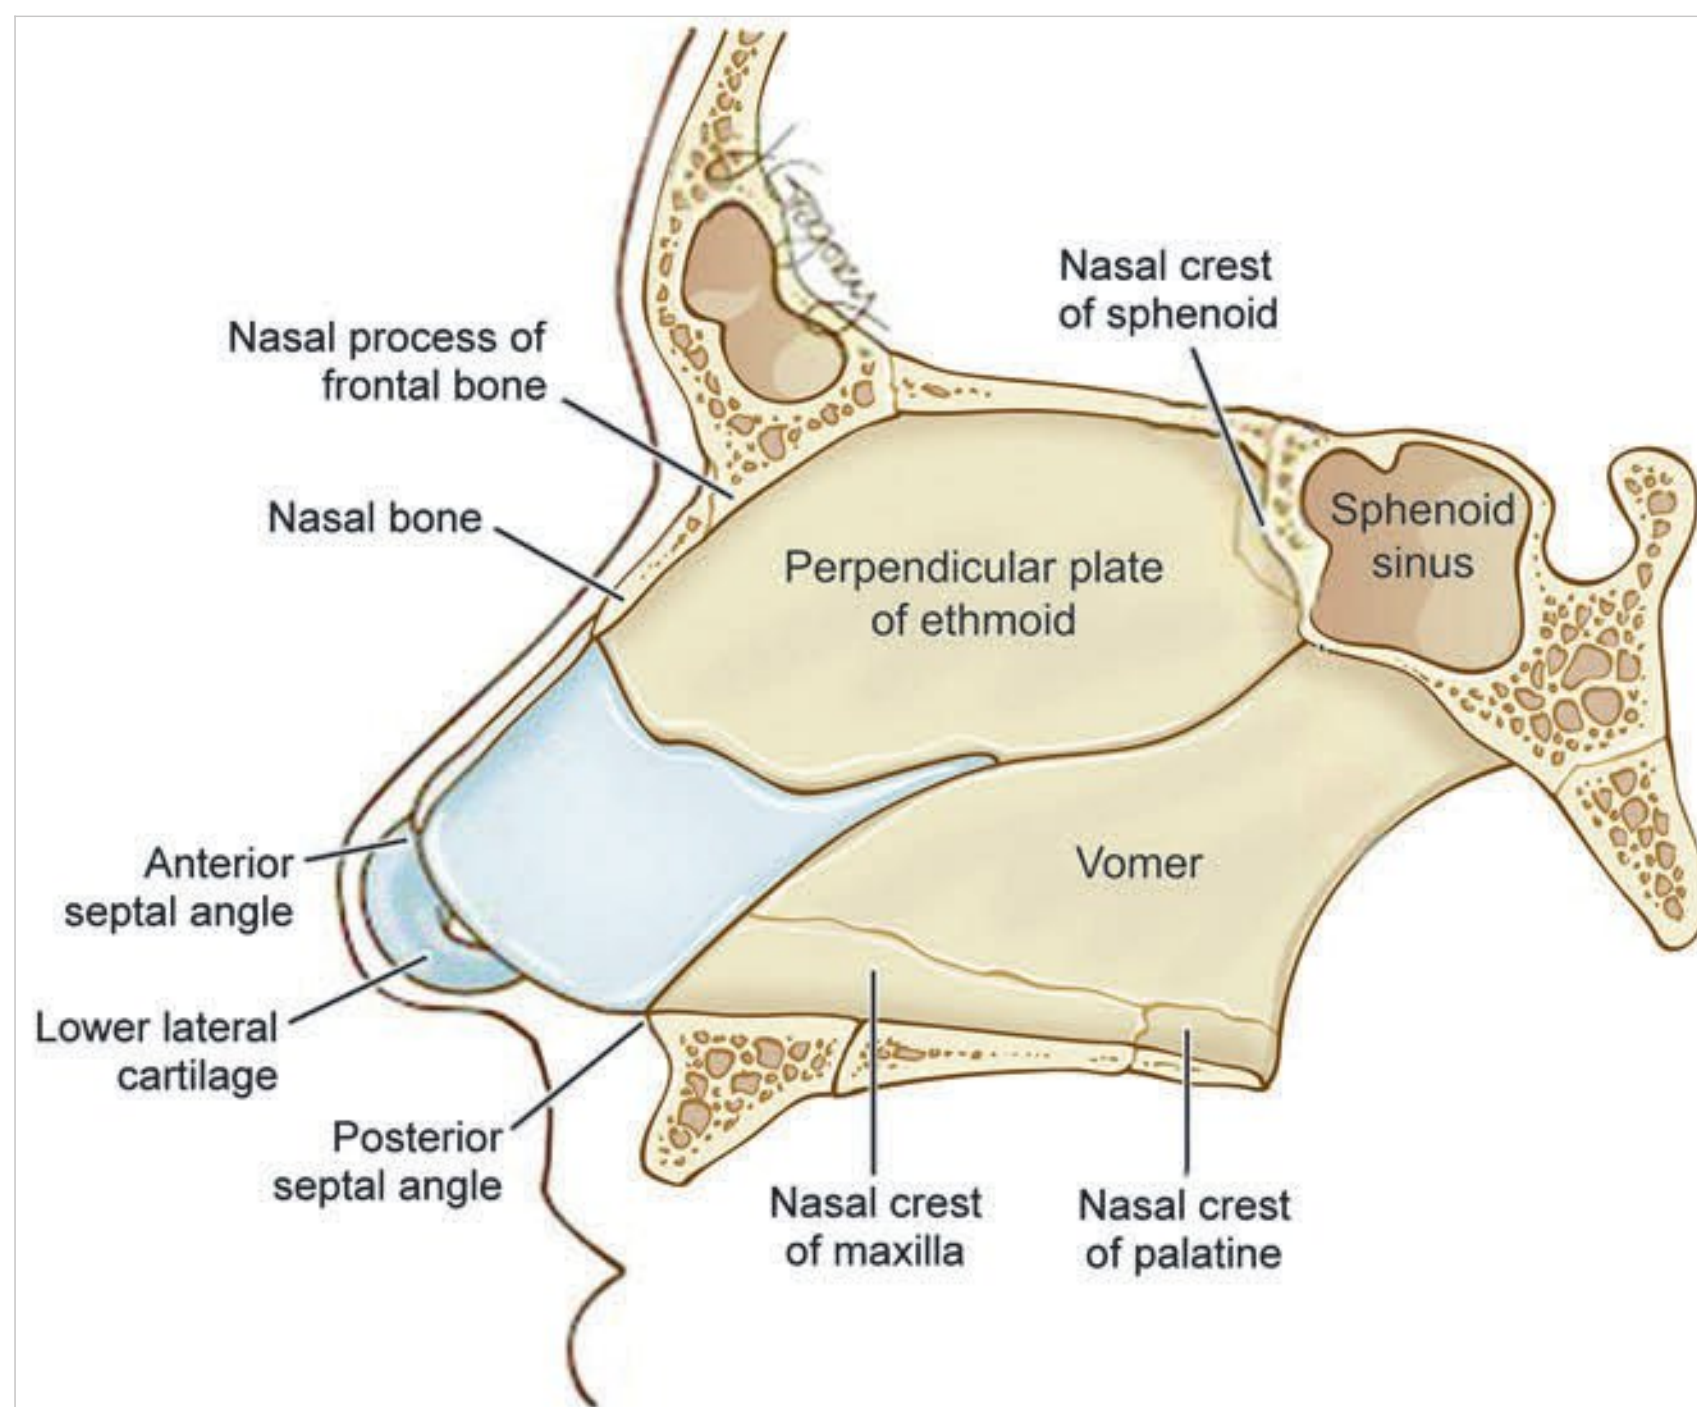

Fig. 105.2 Septal anatomy.

Fig. 105.3 Septal perforation viewed from the patient's left nasal cavity. The anterior end of the left inferior turbinate is seen on the right side of the photo, while the right and middle turbinates can be seen through the septal perforation.

weaken the lateral support of the nasal valve and lead to medial collapse of the valve. Similarly, the ULC can become flail and prone to collapse after dorsal nasal reduction because the fusion of the ULC with the septum may be removed when a cartilaginous dorsal hump is removed, and injudicious rasping of a bony hump may disarticulate the ULC from its attachment to the undersurface of the caudal end of the nasal bone. Septal perforation (□ Fig. 105.3) or excessive removal of the inferior turbinate (“empty nose syndrome”) can also cause subjective symptoms of nasal obstruction associated with turbulent nasal airflow, crusting, and dryness. Prior septal surgery is the most common cause of nasal septal perforation; intranasal use of illicit drugs (e.g., cocaine) is also quite common.

105.5.2 Pathogenesis

Inspired air is directed posteriorly after entering the nasal cavity, passing the area of the internal nasal valve about 15 to 20 mm from the alar margin and then continuing to the nasopharynx. Fifty percent of total airway resistance occurs during the passage of air through the nose. Quiet inspiration is generally laminar in nature, whereas expiration may be more turbulent. Turbulent airflow facilitates air distribution within the nasal cavity, but requires more energy and may lead to a sensation of nasal obstruction. Turbulent airflow occurs in the setting of higher transnasal pressures and faster air speeds; hence, narrow nasal passages will require faster air flow to deliver the same volume of air to the nasopharynx, leading to more turbulent airflow. By Poiseuille's law of the flow of a fluid through a tube,

where in this case P equals the transnasal pressure drop, μ represents the fluid viscosity, L stands for the length of the nasal cavity, Q is the volume flow rate, and r is the radius of the nasal cavity. As the radius decreases, the pressure change across the nasal length increases by the fourth power; therefore, even a moderate reduction of the nasal cavity radius can cause a significant increase in transnasal pressure unless it is compensated for by a large reduction in the rate of airflow. As can be seen, a deviated nasal septum, enlargement of the turbinate, partial inward collapse of the internal nasal valve, significant nasal polyposis, or masses will reduce the nasal airway radius and greatly increase the transnasal pressure differential. This pressure gradient may also cause dynamic inspiratory collapse at the semicollapsible internal nasal valve. Furthermore, airflow velocity necessarily increases as the airway radius decreases in order for the same air volume to be delivered to the nasopharynx. As noted earlier, an increase in flow rate increases the turbulent aspects of airflow, and turbulent airflow further contributes to the sensation of nasal obstruction.

105.5.3 Natural History and Progression

Nasal obstruction, in and of itself, represents an impairment of quality of life. It may lead to chronic mouth breathing, dry mouth, and snoring, but alone it will not cause obstructive sleep apnea. The treatment of other symptoms associated with nasal obstruction, such as epistaxis, chronic rhinorrhea, and sinus infection, is best directed at the underlying cause. Nasal obstruction from a fixed cause, such as a deviated septum, will not progress, but obstruction from a physiologic cause may progressively worsen until the obstruction is chronic and complete unless the root cause is treated. Not uncommonly, the development and progression of a functional cause of nasal obstruction may be associated with a previously tolerated or compensated structural cause: again, the treatment of both causes is reasonable in symptomatic patients.

105.5.4 Potential Disease Complications

Nasal obstruction, if it affects areas of sinus outflow, can increase the likelihood of sinus infection. A severely deviated septum can compromise the nasal cavity in the area of the middle turbinate, causing the latter to remain fairly lateral during development, obstructing the middle meatus and infundibulum. Areas of a severely or sharply angulated deviated septum can become dessicated and therefore points of epistaxis, as can chronically inflamed and hyperemic septal or turbinate mucosa. Nasal obstruction can be associated with chronic mouth breathing and fatigue (especially during strenuous activity), although dry mouth and snoring may be the most prominent symptoms noted by patients; however, as noted above, they will not cause obstructive sleep apnea. Hyposmia may result from severe nasal obstruction because airflow to the olfactory nerve endings in the superior nasal cavity can be compromised by severe nasal obstruction; anosmia, however, is typically not caused by nasal obstruction alone, and other causes of anosmia must be sought.

105.6 Medical Evaluation

The central piece of the medical evaluation for nasal obstruction is the physical examination. Anterior rhinoscopy with a nasal speculum and head mirror/light should be performed both before and after the topical application of a nasal decongestant. The color and degree of congestion of the mucosa, as well as the response to the decongestant, should be noted. Once decongested, the posterior nares are more viewable. However, rigid nasal endoscopy is invaluable in inspecting the posterior nares, middle meatus, and posterior choanae. Flexible endoscopy may be necessary when a severe caudal septal deflection prevents an adequate posterior inspection. Nasal polyps, debris, mucopurulence, and cobblestoning of the mucosa should be noted; any localized or atypical soft-tissue mass should be noted and biopsy considered. The integrity of the entire septum should be ascertained. Crusts of dried mucus or blood should be removed with forceps or suction so that all mucosal surfaces can be inspected; small septal perforations or masses may lurk beneath this debris.

105.6.1 Presenting Complaints

In addition to simple nasal obstruction, patients may also report intermittent headaches, nasal discharge, and/or facial pain and pressure; these symptoms may suggest sinusitis, and radiographic imaging is often necessary to eliminate the possibility of sinusitis. Other symptoms may include chronic mouth breathing, dry throat, snoring, decreased sense of smell, and, in the case of nasal obstruction caused by allergic rhinitis, post-nasal drip and rhinorrhea.

105.6.2 Clinical Findings, Physical Examination

The diagnosis of a deviated septum is relatively straightforward; a portion of the septum deviates significantly from the midline (□ Fig. 105.4). An enlarged turbinate likewise fills a disproportionate amount of the airway and narrows the functional lumen of the nose. Collapse of the internal nasal valve may be suggested by narrowing (especially at the dorsal junction of the ULC and septum), but the diagnosis is made when there is visible and symptomatic inward collapse on inspiration, with a reduction or elimination of symptomatic obstruction when this area is stabilized (not splayed laterally) with a small curet or forceps. The Cottle maneuver manually stabilizes the cheek lateral to the ala (without distracting the ala laterally) in order to prevent internal nasal valve collapse on inspiration; patients with internal nasal valve collapse will note improvement in breathing during the Cottle maneuver. Among the more common causes of nasal obstruction, allergic rhinitis and sinusitis are discussed elsewhere in this book.

A septal disorder, such as perforation or hematoma, can also cause nasal obstruction. A perforation can cause symptoms of nasal obstruction, either by serving as a nidus for mucous crusting or by causing turbulent airflow; it may be obvious on physical examination or may be seen only endoscopically after débridement of the nose. Nasal polyps, although common, cause nasal obstruction only when massive. More commonly, physiologic causes of nasal obstruction include rhinitis of pregnancy (secondary to elevated estrogen levels and generally seen in the

Fig. 105.4 (a) Severe caudal septal deviation seen by anterior rhinoscopy. (b) Low septal deviation encroaching on left inferior turbinate and obstructing the airway. The inferior meatus is seen. IM, inferior meatus; IT, inferior turbinate; S, septum.

third trimester of pregnancy and in the first 6 months post partum); classic rhinitis medicamentosa (rhinitis secondary to the administration of α -adrenergic topical agents); and drug-induced rhinitis (particularly β -blockers, angiotensin-converting enzyme [ACE] inhibitors, and oral contraceptives). Rhinitis of pregnancy and rhinitis medicamentosa generally have a pale, swollen, and “boggy” mucosa (especially the inferior turbinate). Especially in the case of rhinitis medicamentosa, an unusually rapid decongestion may be seen after the application of a decongestant spray.

More uncommonly, inflammatory conditions such as sarcoidosis, systemic lupus erythematosus, and Wegener granulomatosis may cause mucosal edema and nasal obstruction; sarcoidosis, in particular, may present with a pale, “cobblestone” mucosa. Tumors of the nasal cavity are relatively rare, with inverting papilloma the most significant. Arising from the lateral nasal sidewall, inverting papilloma may vary in appearance from polypoid to wartlike and may degenerate to a squamous cell carcinoma. Finally, masses of the nasopharynx or stenosis/atresia of the posterior choanae can cause nasal obstruction, so a complete evaluation of the nose and nasopharynx is mandatory.

105.6.3 Testing

Physical examination of the nose, including nasal and nasopharyngeal endoscopy, is the first step in the evaluation of nasal obstruction. Computed tomography (CT; \square Fig. 105.5) is indicated in the presence of any bony or soft-tissue erosion or mass, or if sinusitis is suspected; contrast-enhanced CT or magnetic resonance imaging is indicated if a malignancy is considered.

Functional testing may include rhinomanometry, acoustic rhinometry, or peak nasal inspiratory flow. Rhinomanometry simultaneously measures air pressure in the nasopharynx and anterior nares, but it is cumbersome and generally limited to research applications. Acoustic rhinometry determines the internal cross-sectional area of the nose by measuring the reflectance of sound waves and can be performed easily in the office setting; it can be useful in evaluating changes in the internal nasal structure, but its accuracy decreases posteriorly in the setting of significant anterior obstruction. Peak nasal inspiratory flow measures the maximal airflow through the nose, but normative data are lacking, hindering its clinical use. If an inflammatory process is suspected, biopsy and serologic testing are performed as indicated.

105.6.4 Differential Diagnosis

The differential diagnosis of nasal obstruction is broad, including common as well as uncommon causes. Principal primary causes of nasal obstruction include deviated nasal septum (congenital, developmental, or traumatic; \square Fig. 105.6), inferior turbinate hypertrophy, and internal nasal valve collapse. Common secondary causes of nasal obstruction include upper respiratory tract infections; sinusitis; rhinitis (allergic or nonallergic); rhinitis medicamentosa; rhinitis of pregnancy; and medications (especially β -blockers, ACE inhibitors, oral contraceptives, and many psychotropic medications). More uncommon causes include septal hematoma or perforation; nasal polyps; choanal atresia/stenosis; nasal foreign bodies; nasopharyngeal masses;

Fig. 105.5 (a) Axial computed tomographic (CT) scan demonstrates deviation of the septum from the midline. The left inferior turbinate fills in much of the void created by the deviation. The maxillary sinus is well aerated and has no evidence of mucosal disease. The zygoma, mandibular condyle, and medial pterygoid and lateral pterygoid processes are also seen in this projection. IT, inferior turbinate; LP, lateral pterygoid; MC, mandibular condyle; MP, medial pterygoid; MS, maxillary sinus; S, septum; Z, zygoma. (b) Coronal CT scan of the same patient further demonstrates the severity of the septal deviation. The inferior turbinate fills much of the space voided by the septal deviation. The middle turbinate is seen, and the ethmoid sinuses and maxillary sinuses are free of disease. The orbital muscles are seen: the superior rectus, lateral rectus, and inferior rectus; the medial rectus is seen just below the superior oblique muscle (not marked). The optic nerve is clearly seen. ES, ethmoid sinuses; IR, inferior rectus; IT, inferior turbinate; IR, lateral rectus; MR, medial rectus; MS, maxillary sinuses; MT, middle turbinate; ON, optic nerve; S, septum; SR, superior rectus.

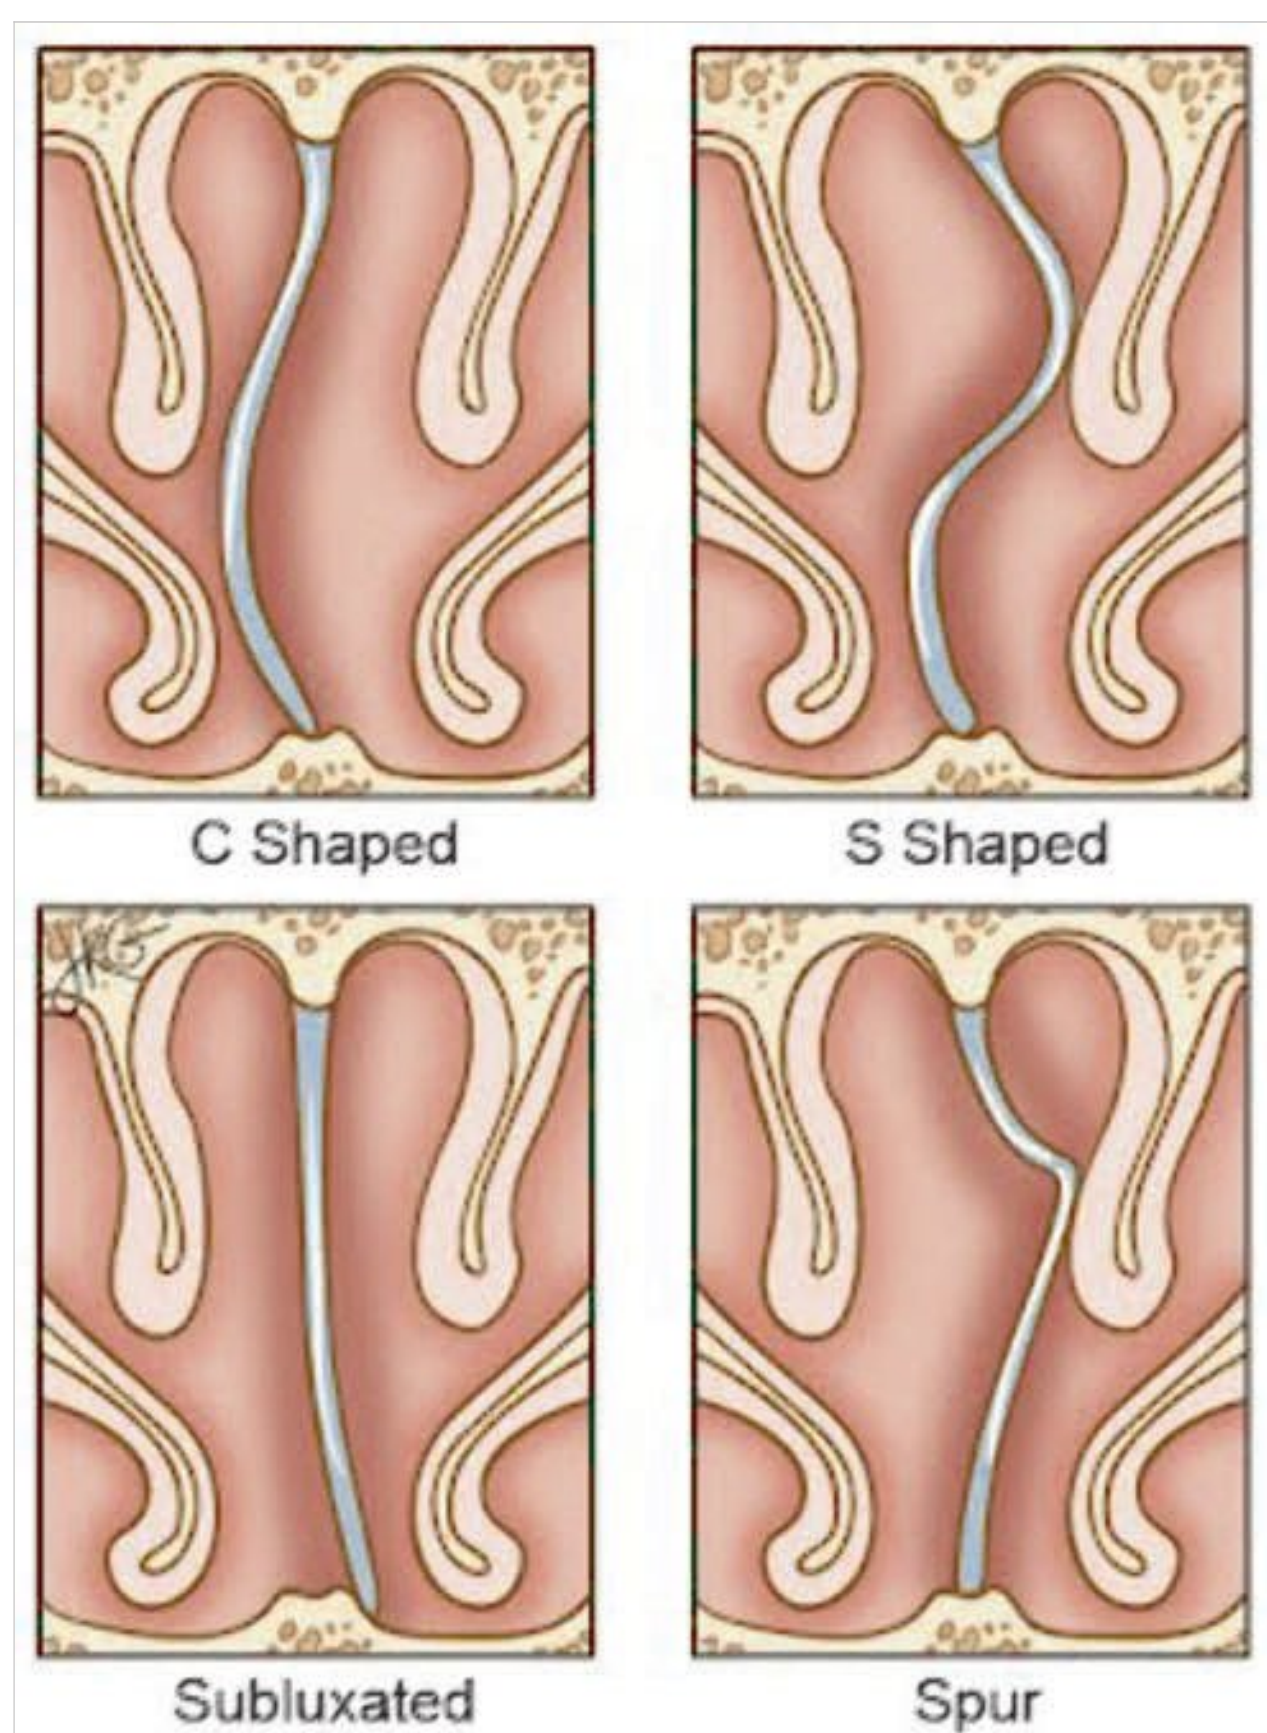

Fig. 105.6 Septal deviations can present in various forms.

inflammatory disorders (Wegener granulomatosis, sarcoidosis, systemic lupus erythematosus); nasal tumors (inverting papilloma, carcinoma); and hypothyroidism.

105.7 Treatment

105.7.1 Medical Treatment

The medical management of nasal obstruction is directed at the underlying cause. In general, nasal obstruction from noninfectious, noninflammatory disorders is treated symptomatically. Nasal saline sprays and rinses, along with topical emollients, may help relieve or reduce symptoms, as well as assist the natural cleansing mechanism of the nose by facilitating the débridement of dried mucus. Topical nasal corticosteroids, in most cases and unless contraindicated, may help relieve primary or reactive mucosal edema, thereby providing a more patent airway. Topically applied nasal steroids typically begin to demonstrate an effect in 7 to 10 days. The most common side effects of intranasal steroids include headache, postnasal drip, and nasal dryness. Patients should be advised to avoid spraying the medication directly toward the septum to avoid chemical irritation of the mucosa and the possibility of a septal perforation. Patients should be counseled to administer the spray with the contralateral hand, aiming toward the ipsilateral medial canthus.

Nasal decongestants may provide some mild temporary relief by reducing the vascular engorgement of (primarily) the

inferior turbinates, but this is generally acceptable to patients only for short-term relief, as in an upper respiratory tract infection or seasonal allergic rhinitis. Directly applied topical decongestants cause a more potent decongestion of the nasal mucosa, but routine use for more than 3 to 4 days may induce a relative resistance to normal, physiologic adrenergic stimuli—hence, the severe rebound congestion associated with rhinitis medicamentosa.

In the case of nasal obstruction caused by septal perforations, most symptoms can be relieved with saline sprays, nasal rinses, and topical emollients. A septal button can be placed through the perforation to reduce symptomatic whistling. Made of soft silicone, this two-piece device is inserted bilaterally and snapped together through the perforation, limiting or eliminating airflow across the perforation.

105.7.2 Surgical Treatment

The four most common reasons for surgical treatment of nasal obstruction are correction of nasal septal deviation, treatment of turbinate hypertrophy, internal nasal valve repair, and repair of septal perforation.

Correction of Deviation of the Nasal Septum

Modern corrective septal surgery can be divided into two basic categories: subtotal septectomy, popularized by Killian, and septoplasty, described by Cottle. The Killian approach is more direct, removing deviated septal cartilage and bone, whereas the Cottle philosophy is predicated upon managing the natural tendency of the cartilage to warp while maximally preserving cartilage. Ultimately, all septal manipulations are performed in a submucoperichondrial and submucoperiosteal plane in order to preserve septal blood supply.

The Killian incision is made parallel and 10 mm posterior to the caudal septum. Before elevating a mucosal flap, it is essential to perform proper hydrodissection of the mucoperichondrium by injecting local anesthetic into both sides of the septum. Correct injection is evidenced by blanching and elevation of the mucosa and represents separation of the mucoperichondrium from the cartilage. The plane is further developed, the ipsilateral mucosal flap is raised over both the cartilaginous and the bony septum, and an incision through the cartilage is made parallel to the mucosal cut; this provides access to the contralateral submucoperichondrial plane, which is similarly elevated. Once both mucosal flaps are elevated, a cartilage cut is made and continued to the bony septum, parallel to (but at least 10 mm below) the dorsal septal edge. The cartilage is freed from its posterior bony attachments to the perpendicular plate of the ethmoid and vomer, and then cut from its attachment to the maxillary crest. Once this outlined segment of cartilage is removed, only a caudal/dorsal L-shaped strut of cartilage remains. It is essential that this L-strut be located at least 10 mm caudally and dorsally to avoid a tip collapse and a saddle nose deformity, respectively. Any deviated portions of posterior septal bone or maxillary crest are then removed with rongeurs or an osteotome, as described in the section on septoplasty (□ Fig. 105.7).

The Killian submucous resection offers simple and quick access to the mid and posterior septum. However, exposure of the caudal portion of the L-strut is very limited, and the elevation

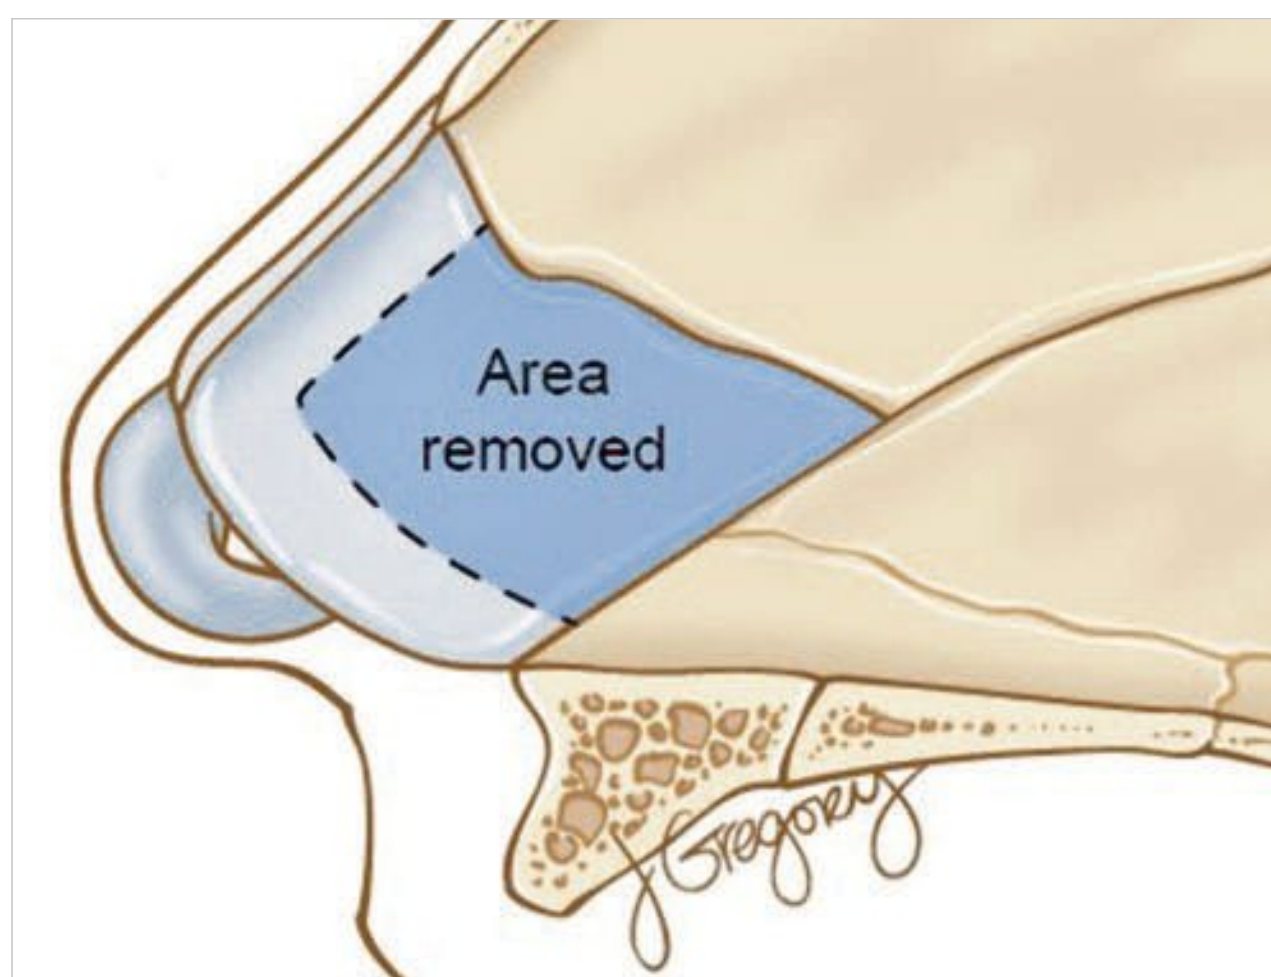

Fig. 105.7 Killian submucous resection of the septum removes maximal amounts (shaded area) of septal cartilage.

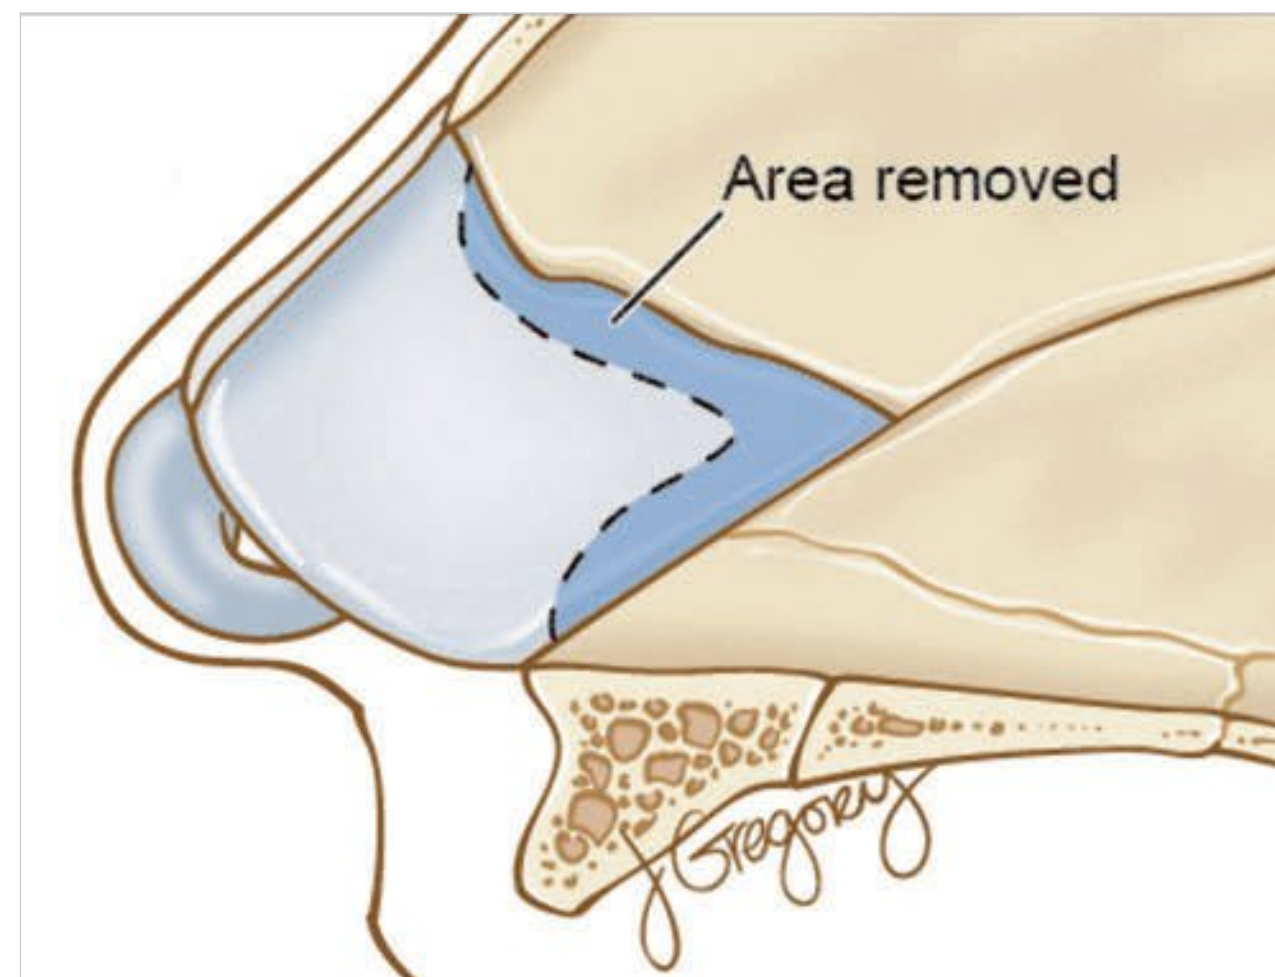

Fig. 105.8 Cottle septoplasty preferentially removes minimal amounts of cartilage to allow the creation of a “swinging door” of quadrangular cartilage.

of bilateral complete septal flaps is necessary. A large potential space for fluid collection (septal hematoma or seroma) is created, and a significant portion of the remaining quadrangular cartilage has been separated from its blood supply, the mucoperichondrium. Deviated portions of cartilage are removed, rather than remodeled, and so deviations of the remaining L-strut are not addressed by the classic submucous resection.

Septoplasty is classically performed through a Cottle hemitransfixion incision, placed at the margin of the caudal septum. An ipsilateral mucosal flap is elevated along the length of the septum, including the maxillary crest. Decussating fibers of periosteum and perichondrium often make this elevation more difficult, and a two-tunnel (one along the inferior septum, one along the medial nasal floor) approach is used, enabling sharp division of the decussating fibers if needed. A “swinging door” of cartilage is created by first removing an inferior strip of cartilage along the length of the maxillary crest, incising cartilage, and dissecting this strip from the contralateral mucoperichondrium. Next, the quadrangular cartilage is disarticulated from the bony septum, allowing elevation of the contralateral mucoperichondrium from the bony septum. A Takahashi forceps is used to remove small fragments of bone to allow free movement of the septal cartilage. Significant bony septal deviations are more carefully removed by first incising the bone superior to the deviation sharply with bone scissors; it should be remembered that the perpendicular plate inserts into the anterior cranial fossa floor, and rough handling of this bone can lead to a cerebrospinal fluid leak. If the remaining quadrangular cartilage (pedicled on its dorsal attachments and on one unelevated mucoperichondrium) can be moved to the midline easily, no further intervention is needed (□ Fig. 105.8). However, in most cases there are still substantial deviations remaining. Along concave areas, a series of partial-thickness cartilage incisions can be made, parallel to the axis around which cartilage warping is desired (□ Fig. 105.9). Significant deviations that still remain may be incised and dissected off the contralateral mucosal flap. Finally, the caudal septum can be dissected from the anterior nasal spine (anterior-most portion of the maxillary crest)

Fig. 105.9 (a–c) Partial-thickness cartilage incisions promote warping away from the cuts around an axis parallel to the cuts and can be used to promote septal cartilage remodeling.

and sutured as necessary to the nasal floor periosteum or through a hole drilled into the maxillary crest.

The main advantage of the Cottle septoplasty is the greater amount of structure preserved and the avoidance of bilateral mucoperichondrial elevation. This makes septal cartilage resorption, saddle nose deformity, and septal hematoma formation less likely. However, cartilage warping can be unpredictable and may leave residual deviations.

Regardless of the specific technique used, once the deviation has been corrected, the mucosal flaps are quilted together with a transseptal 4–0 plain gut running suture and the incision closed with interrupted 4–0 chromic sutures. It is good practice to close mucosal tears with 4–0 plain sutures, and these should always be closed if a tear is located nearby on the contralateral flap. In these cases, or if there is excoriation of the mucosa, soft silicone splints should be placed bilaterally and sutured together with transseptal 2–0 silk sutures. Septal perforations, although uncommon, are most frequently seen after septal surgery. Hemostasis should be excellent at the conclusion of the surgery, and nasal packing is almost always unnecessary

because epistaxis after septal surgery is uncommon (1%). It should be noted that because the growth centers of the nose are located in the inferior quadrangular cartilage, driving the growth of the nose during puberty, septal surgery is generally deferred until age 15 years in girls and 16 years in boys; premature disturbance or destruction of the nasal growth centers can stunt full growth of the nose to adult size.

Treatment of Turbinate Hypertrophy

Multiple treatments of turbinate hypertrophy have been described, but these can be categorized loosely as those that reposition, those that remove bone, and those that treat cartilage. Long-term control of mucosal hypertrophy with depo injections of corticosteroids has been described, but the potential for retrograde injection into orbital vessels, causing blindness, has led to the abandonment of this practice. Mucosal and submucosal cauterization of the turbinates will induce some fibrosis after tissue death, leading to some contracture of the mucosal surfaces. However, with all turbinate therapies, untreated mucosa will undergo additional enlargement if the underlying cause of the hypertrophy is not addressed. Fracturing the turbinate (outfracture) laterally alone can relieve nasal obstruction, but only briefly (3 to 6 months). Total removal of the inferior turbinate, addressing both bone and mucosa, was similarly advocated but subsequently abandoned. Total removal frequently injured the sphenopalatine artery at the posterior end of the turbinate, causing massive epistaxis; in the long term, these patients frequently developed atrophic rhinitis. Patient complaints of nasal obstruction after total turbinectomy are believed to be the result of a lack of mucosal surface area for air humidification and the production of mucus, and this is difficult to treat adequately. Partial turbinectomy, removing the anterior one-third of the turbinate, is highly effective in relieving nasal obstruction caused by turbinate enlargement because this area is the narrowest portion of the nasal airway. After the mucosa in this area has been crushed with a curved hemostat to reduce bleeding, the turbinate bone and mucosa are cut with turbinate scissors along the line of crushed tissue, and the anterior turbinate is removed with Takahashi forceps; the stump of the turbinate is cauterized and the remaining turbinate outfractured. A submucous resection of the turbinate is similar, except that the mucosa is first incised along the free turbinate margin, and a flap of mucosa is elevated from the medial side of the turbinate bone. The turbinate bone, along with the mucosa on the lateral side of the turbinate, is crushed and excised. Following cauterization of the stump, the mucosa flap is redraped over the raw surface. Submucous resection of the turbinate generally is associated with less postoperative crusting than partial turbinectomy. Newer technologies, such as radio-frequency ablation and submucosal powered débridement, also lead to less bleeding, but only submucosal powered débridement has been shown to be associated with lasting results similar to those of partial or submucous resection of the turbinates.

Because the inferior turbinates are covered with vasoerectile tissue, bleeding is the most common complication (5%) of turbinate surgery. Adequate hemostasis should be ensured by the conclusion of surgery, and consideration given to the placement of resorbable gelatin hemostatic sponge material over the cut surfaces of the turbinate; however, as with septal surgery, nasal

packing is rarely needed. Patients should be started early on saline nasal sprays to diminish crusting and promote rapid mucosal healing. In general, after this and most other nasal surgeries, it is good practice to advise patients against nose blowing, head hanging, and strenuous activities for 10 days after surgery to avoid postoperative epistaxis.

Internal Nasal Valve Surgery

As mentioned earlier, the internal nasal valve is formed by the caudal end of the ULC, inferior turbinate, septum, and nasal floor. Narrowing of the cross-sectional area of the airway will increase air speed and the transnasal pressure gradient. Weakness of any wall of the valve area will lead to inward inspiratory collapse. In addition to correcting any septal deformities and/or turbinate enlargement, increasing the nasal valve angle (between the ULC and the septum, normally approximately 10 to 15 degrees) or strengthening the lateral wall of the valve (the ULC, LLC, and their articulation at the “scroll”; see Chapter 53) can reduce or correct impaired inspiratory airflow.

The two main surgical maneuvers in valve repair are spreader and alar batten grafts. Both can be placed through either closed or open rhinoplasty approaches. To create a spreader graft, cartilage is harvested (ideally from the nasal septum or the conchal bowl) and shaped into a rectangular block 2 to 3 mm wide, 12 to 15 mm long, and 3 to 4 mm thick. It is then sutured in a submucosal pocket after the ULC has been divided from the dorsal septum. This will widen the nasal valve cross-sectional area by maintaining the ULC more laterally (□ Fig. 105.10). The alar batten graft is used for more flail caudal ULC and LLCs, including their attachment to each other at the scroll. This area may be weak congenitally because of malposition of the lateral crus or (most commonly) because of lateral crus resection during reduction rhinoplasty. An alar batten graft is tucked into a soft-tissue pocket laterally over the piriform aperture while the medial end is sutured to the dorsal septum (□ Fig. 105.11). The caudal ULC and lateral crus can then be “suspended” by sutures from this more rigid structure, raising the lateral sidewall of the internal valve. Care should be taken to position both grafts precisely so they do not add bulk without adding support. There is generally an excellent “take” of these grafts, and when the procedure is performed properly, they function quite well. However, if not secured properly at its ends, an alar batten graft may add bulk to the valve and cause further inward collapse.

Septal Perforation Repair

The repair of septal perforations uses existing nasal mucosa; therefore, as the size of a perforation increases, the amount of available mucosa is reduced, and ultimately the complete closure rate decreases. A perforation of the septum lacks underlying cartilage as well as mucosa; as a result of both the underlying cause of the perforation and chronic crusting and bleeding at the edge of the perforation, the repair of a septal perforation generally requires the removal of 2 to 3 mm of the rim of the perforation to provide a reasonably healthy tissue edge with which to work.

Perforations smaller than 5 mm in diameter can usually be repaired through an intranasal approach, whereas larger perforations are best repaired through an external rhinoplasty

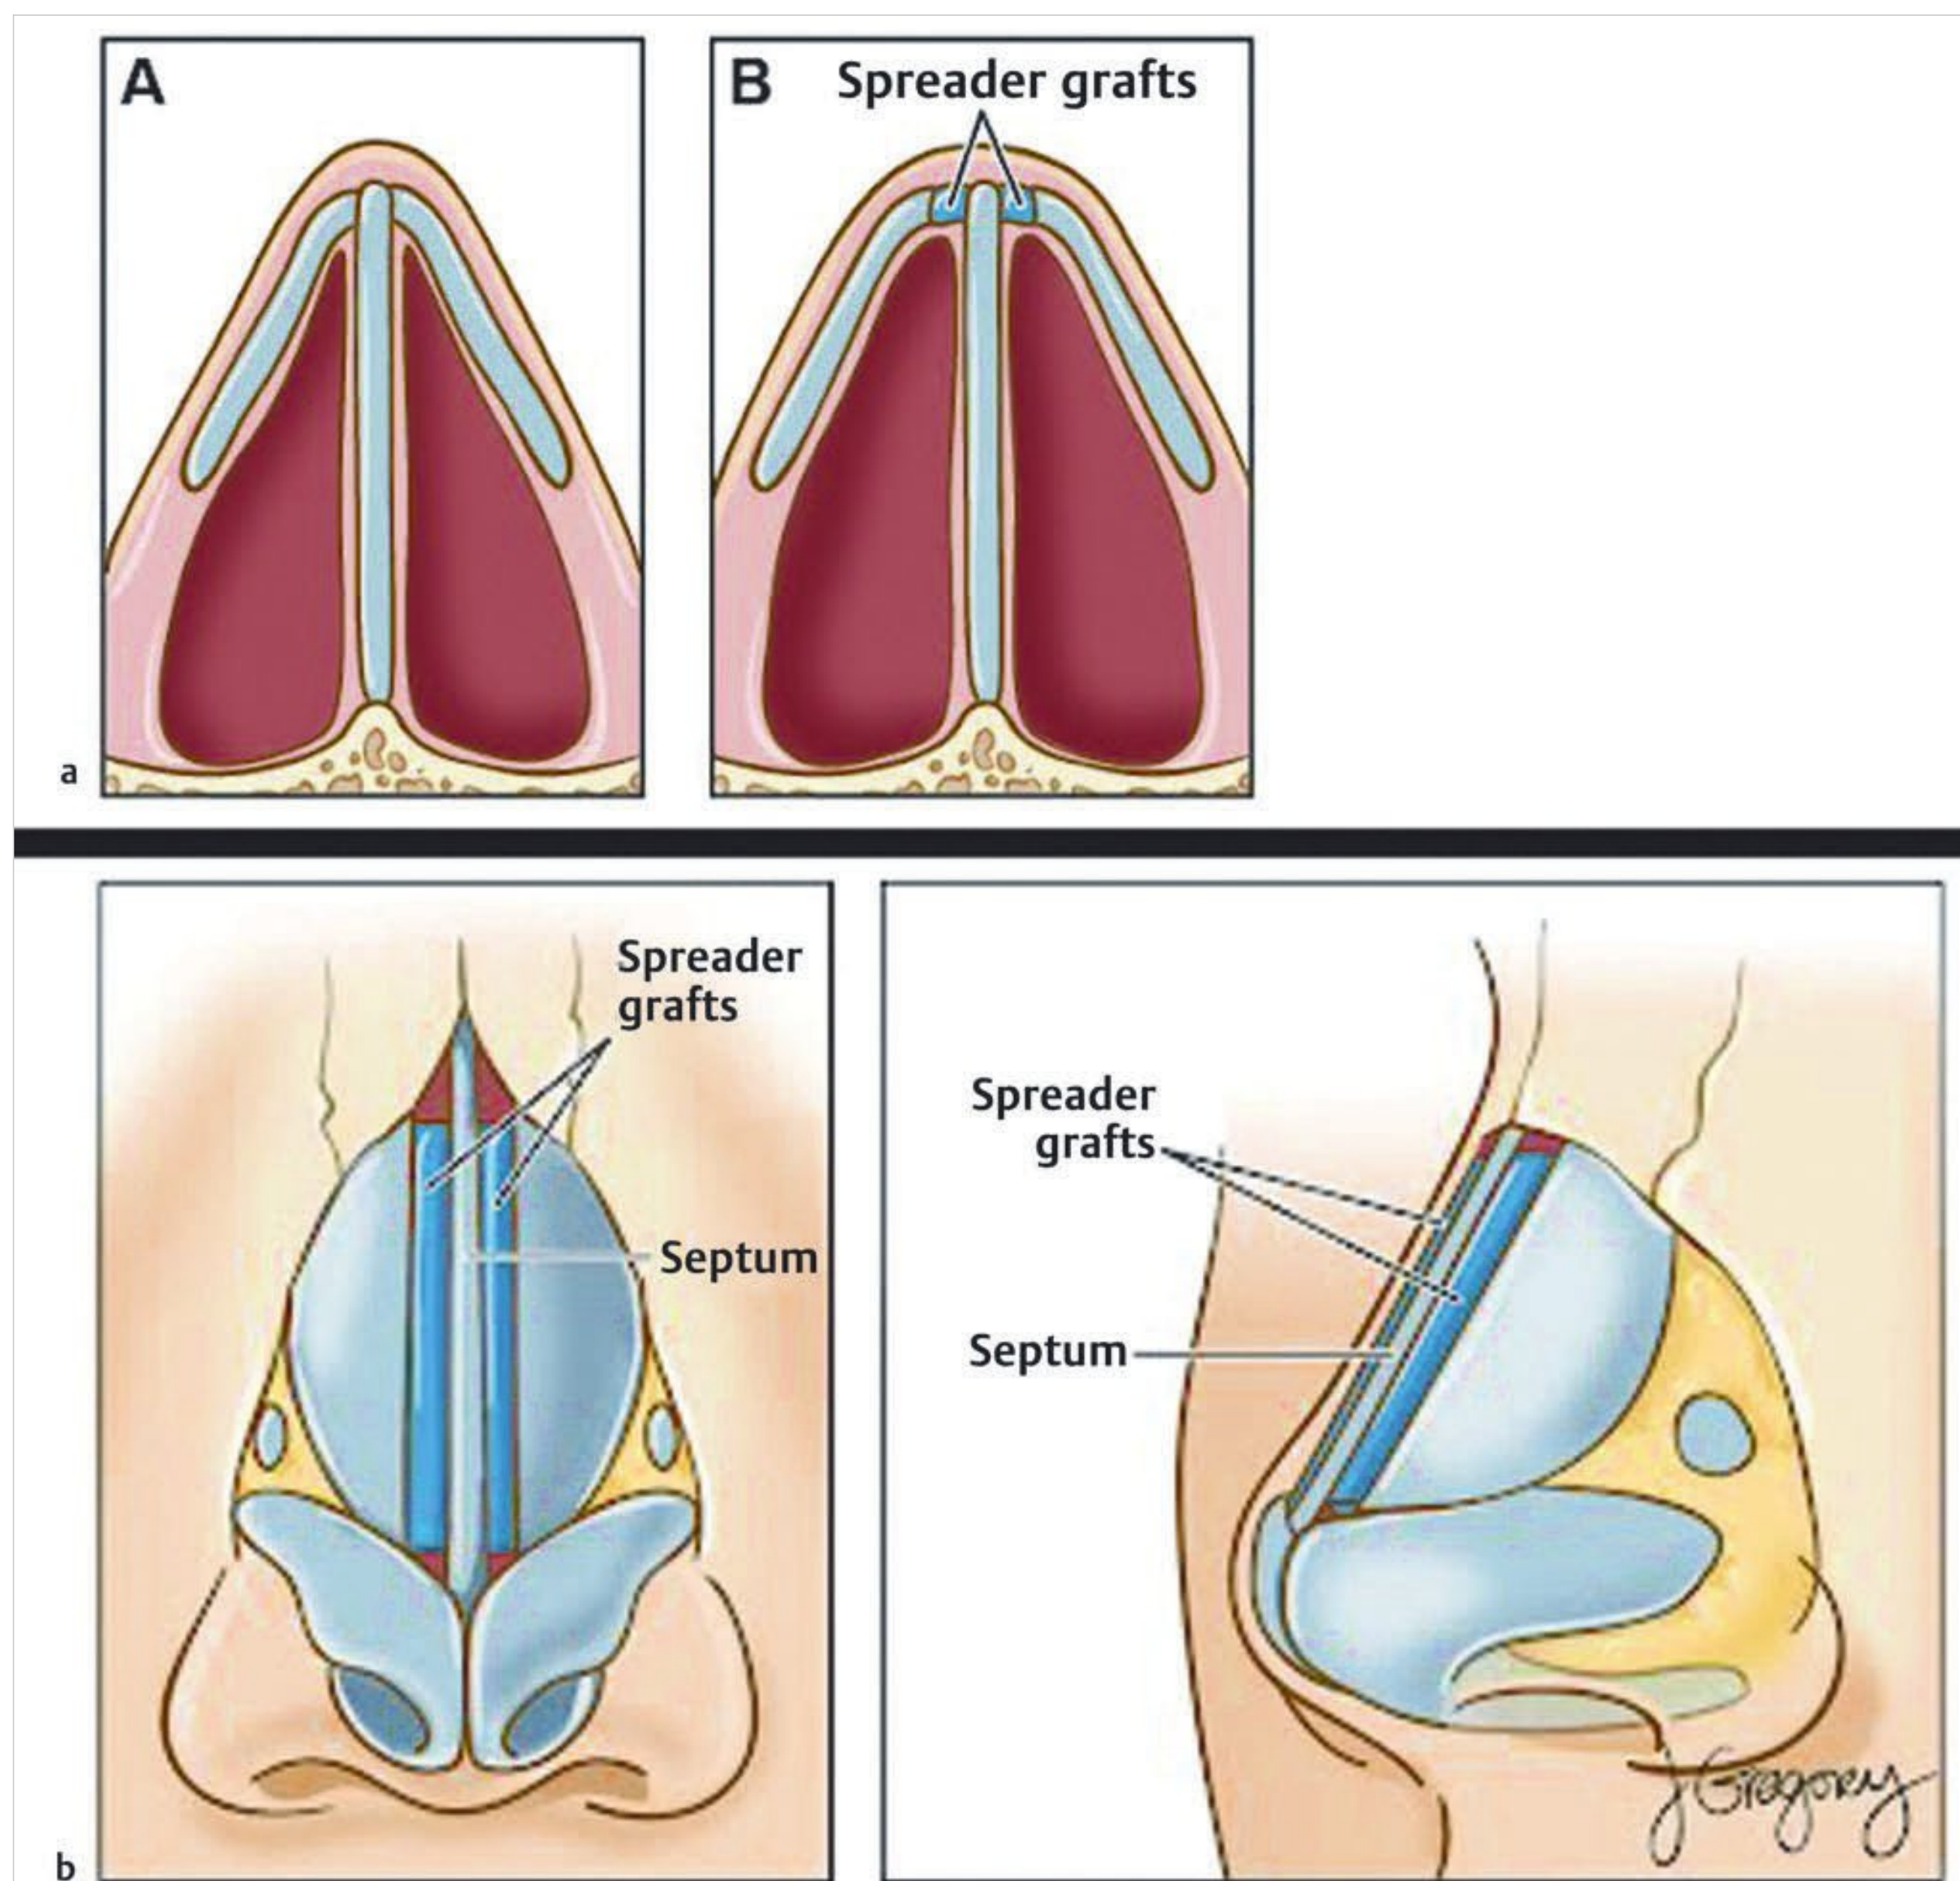

Fig. 105.10 A spreader graft is placed between the upper lateral cartilage and dorsal septum to (a) widen the nasal valve and (b) support the medial upper lateral cartilages.

approach. Regardless of its size, the repair of a septal perforation requires bilateral mucosal flap elevation, advancement/rotation of the mucosal flap edges with suture repair, and placement of an interposition graft of cartilage or soft tissue (temporalis fascia or acellular dermis) between the repaired flaps to serve as a scaffold for full healing. Repaired mucosal flaps are protected with soft silicone splints for 2 to 6 weeks. Perforations smaller than 5 mm can be repaired by first widely elevating the mucosal flaps. Relaxing incisions are made in the flaps in areas where the contralateral flap is intact: superior to the perforation and parallel to the dorsum on one side, posterior to the perforation and perpendicular to the dorsum on the other side. The flaps are then closed in a horizontal fashion on the first side and vertically on the other side, limiting

the overlap of the repairs. The relaxing incisions, with cartilage nourished by intact mucosa on the opposite side, will heal by secondary intention. These repairs are generally (>85%) successful.

Perforations 5 to 25 mm in size can require more extensive surgery. A large, posteriorly based mucosal flap can be elevated from the septum, nasal floor, and lateral sidewall on each side of the nose. A releasing incision is made along the underside of the turbinate origin from the lateral sidewall, allowing free transposition of the flap onto the septum to close the perforation. Denuded bone at the nasal sill occasionally requires coverage with a skin graft. Once the flaps have been used for bilateral perforation repair, the interposition graft is placed, and the mucosal flaps are quilted together with a running plain gut suture.

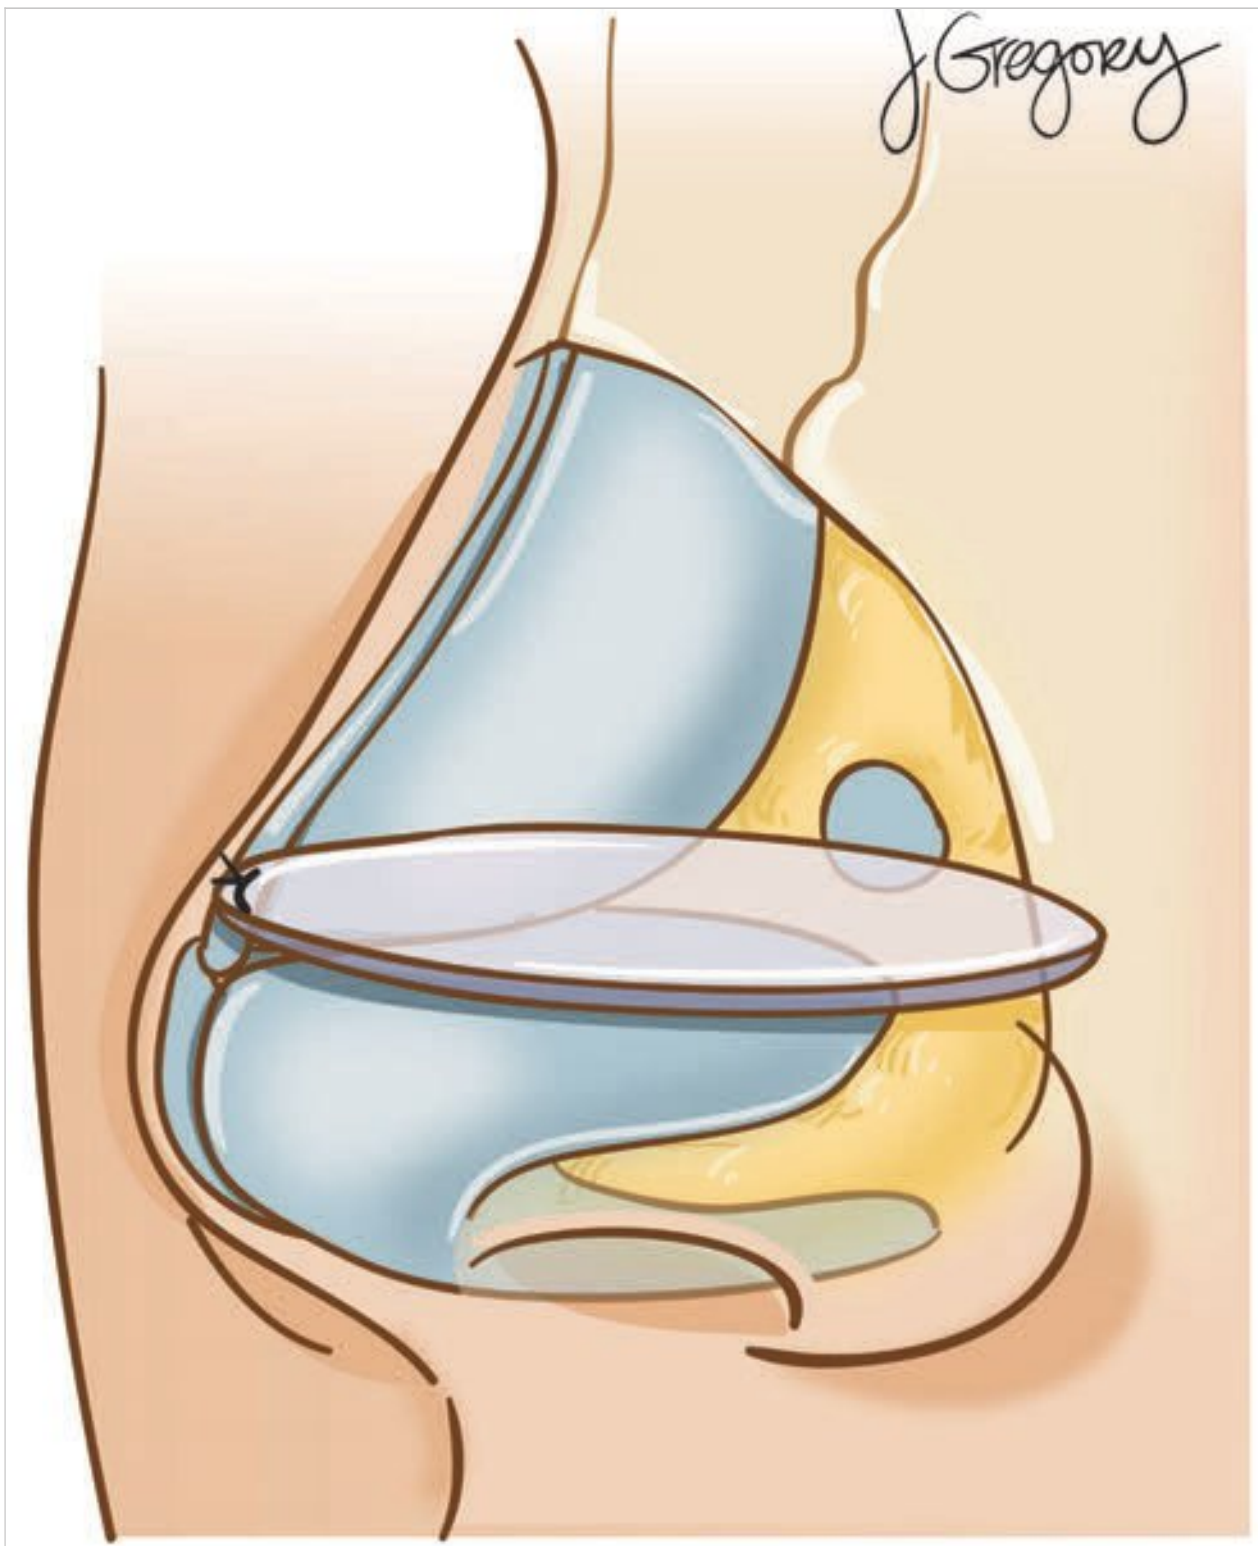

Fig. 105.11 An alar batten graft spans the space between the caudal upper lateral cartilage and cephalic lower lateral cartilage and between the piriform aperture and the dorsal septum to strengthen the internal nasal valve.

Silicone splints are then placed over both sides of the septum, sutured together through the septum, and left in place for 6 weeks. With this technique, perforations of 25 mm or more can be closed successfully in up to 80% of cases.

Caudal septal perforations present a unique problem because it may be impossible to rotate a nasal mucosal flap sufficiently for complete perforation repair. In these cases, a buccal mucosal flap can be raised from the gingivobuccal sulcus and left pedicled near the midline. A temporary fistula is created through the sulcus into the nasal sill medially, and the flap is brought through into the nose. The flap is then sutured to the edges of the perforation. Two to three weeks later, the pedicle can be divided and the fistula closed, but often the pedicle is auto-amputated and the fistula closes spontaneously.

The most likely adverse outcome after septal perforation repair is incomplete closure of the perforation. In general, the success rate for this surgery decreases as the diameter of the

perforation increases. Small perforations can be closed in 85 to 90% of cases, whereas the closure of medium to large perforations may be successful in only 75 to 80% of cases. Care should be taken to avoid destabilization of the caudal and (especially) the dorsal cartilage struts, to avoid the development of a saddle nose deformity. Epistaxis from raw mucosal turbinate edges is generally mild and self-limited.

105.8 Roundsmanship

- Nasal obstruction is a sensation of poor nasal inflow that may or may not directly correlate with the physical examination findings.
- Symptoms of nasal obstruction are increased in situations of turbulent nasal airflow.
- Even small changes of nasal diameter in the areas of airway narrowing can have significant effects on nasal airflow.
- Unless otherwise contraindicated, nonsurgical treatment of nasal obstruction should always be tried before surgery is considered.
- Nasal obstruction may be associated with chronic mouth breathing, dry mouth, and snoring; however, it is not a proximate cause of obstructive sleep apnea.
- The success of septal perforation repair is related to the size of the defect; small perforations are usually closed in 85% of cases, whereas medium to large perforations may be closed in only 75 to 80% of cases.
- Killian submucous resection of the septum classically removes maximal amounts of septal cartilage, leaving only the dorsal and caudal struts; conversely, septoplasty preserves maximal amounts of cartilage and relies in part on the natural tendency of the cartilage to warp away from the side of partial-thickness cartilage incisions.

106 Allergic and Nonallergic Rhinitis

Jennifer S. Collins

106.1 Introduction

Rhinitis has both allergic and nonallergic causes. It is a complex of symptoms characterized by sneezing, runny nose (rhinorrhea), nasal congestion, and nasal itching. Associated symptoms of itchy and watery eyes, itchy ears, sinus pressure, and sleep disturbance may be present. Frequent comorbidities of rhinitis include sinusitis, asthma, eczema, and recurrent otitis media. Mucus in the nose has protective, barrier, and antimicrobial properties; however, too much mucus causes a major disturbance in daily life. The impact and importance of rhinitis are often diminished by practitioners and patients alike, and the symptoms affect almost every aspect of daily activities. Interference with learning, absenteeism from school and work, and disordered sleep create enormous costs to society. A multimodal approach in treatment is often required, including behavioral modifications, antihistamines, topical corticosteroids, and immunotherapy.

106.2 Incidence of Disease

Rhinitis is an exceedingly common global health problem, affecting a quarter of the world's population (approximately 1.6 billion people). Numbers are similar in the United States; approximately 25% of the population suffers from rhinitis. Allergic rhinitis is the most common type; however, cases of nonallergic rhinitis and cases of mixed allergic and nonallergic rhinitis account for approximately 10%–40% of all adult cases. An estimated 17 million individuals are affected by nonallergic rhinitis.

Rhinitis in all forms represents a terrific cost to society. It is one of the top 10 reasons for consultation in primary care clinics in the United States. In the mid 1990s, \$1.8 billion was spent annually on physician visits and medication. Indirect costs to society are equally as great, and in the 1990s there were 811,000 lost work days, 842,000 lost school days, and 4.23 million days of decreased activity.

The incidence of allergic rhinitis varies by sex, age, socioeconomic class, and region. Interestingly, allergic rhinitis was case-reportable in the 19th century. However, over the next 100 years, the incidence of allergic rhinitis rose sharply, and it continues to rise for unknown reasons. Forty percent of children have allergic rhinitis. Boys have the disease more commonly than girls. As we age, for unknown reasons these sexual discrepancies disappear. All races are affected equally. Higher socioeconomic classes often have a higher incidence of disease. The prevalence increases from west to east in Europe. Additionally, English-speaking and industrialized countries have a higher prevalence.

In contrast, nonallergic rhinitis typically presents after the age of 20 years and affects women more than men. We do not see the same differences in prevalence between socioeconomic classes that are seen in allergic rhinitis.

The epidemiology of allergic rhinitis has been the focus of many studies. Factors considered include incidence of child-

hood infection, socioeconomic status, family size, and birth order. The “hygiene hypothesis” proposes that a decrease in the occurrence of childhood infections may be contributing to the increase in allergy. Other studies show evidence of the impact of early antibiotic and acetaminophen use on the increasing development of allergy. Evidence from birth cohorts in Europe is conflicting regarding the impact of socioeconomic status on allergic rhinitis. When Swedish children were followed in the 1950s, a three- to fourfold higher incidence of allergic rhinitis was noted in those with a higher socioeconomic status. Other studies have shown evidence to the contrary. Furthermore, a protective effect of (1) a large family size, (2) being a middle child, (3) maternal exposure to farm work during pregnancy, and (4) rural upbringing has been shown.

Finally, several risk factors for developing allergic rhinitis were identified and include the following: family history of allergic disease, serum immunoglobulin (IgE) level above 100 kU/L before the age of 6 years, being first-born, male sex, tobacco exposure during the first year of life, early use of antibiotics, positive skin testing to allergens, and higher socioeconomic class.

106.3 Classification of Disease

Rhinitis is classified as allergic, nonallergic inflammatory, or nonallergic noninflammatory. Classification is not exclusive, and approximately 34% of individuals have mixed allergic and nonallergic cases (see Box Types of Rhinitis (p. 812)).

Traditionally, allergic rhinitis was classified as seasonal, most commonly caused by aeroallergens and pollens, or perennial, most commonly caused by environmental allergens such as dust mite and cat. This classification posed problems for a number of reasons. Certain allergens vary from year to year, and pollens can last upward of 10 months. Traditional perennial allergens may be in an environment where exposure is intermittent. For example, a patient may be exposed to an animal only at a relative's home.

Types of Rhinitis

- Allergic
 - Seasonal or perennial (chronic), mild intermittent, mild persistent, moderate/severe intermittent, moderate/severe persistent
- Nonallergic inflammatory
 - Occupational, drug-induced, infective, aspirin-sensitive, nonallergic rhinitis with eosinophilia syndrome (NARES), cerebrospinal fluid leak
- Nonallergic noninflammatory
 - Atrophic, emotional, idiopathic, gustatory, hormonal, rhinitis medicamentosa, vasomotor

To account for these issues, the classification of allergic rhinitis was changed to mild intermittent, mild persistent, moderate/

<p>Mild Normal sleep No impairment of daily activities</p> <p>Intermittent < 4 days per week < 4 weeks</p>	<p>Mild Normal sleep No impairment of daily activities</p> <p>Persistent > 4 days per week > 4 weeks</p>	<p>Moderate/Severe Abnormal sleep Impairment of daily activities Troublesome symptoms</p> <p>Intermittent < 4 days per week < 4 weeks</p>	<p>Moderate/Severe Abnormal sleep Impairment of daily activities Troublesome symptoms</p> <p>Persistent > 4 days per week > 4 weeks</p>
--	--	---	---

Fig. 106.1 Classification of rhinitis.

severe intermittent, and moderate/severe persistent, depending on the severity (mild or severe) and duration (intermittent or persistent) of symptoms (□ Fig. 106.1). For symptoms to be mild, there must be normal sleep and no impairment of daily activities.

Nonallergic disease can be either inflammatory or noninflammatory. Inflammatory disease is further divided based on the presence or absence of eosinophilic infiltration as nonallergic rhinitis eosinophilic syndrome (NARES) or occupational/irritant rhinitis. Noninflammatory disease includes atrophic disease, gustatory rhinitis, hormonal rhinitis, rhinitis medicamentosa, and vasomotor rhinitis.

106.4 The Disease Process

106.4.1 Allergic Rhinitis

The etiology of allergic rhinitis is complex, involving genetic and environmental interactions. The expression of allergic disease is autosomal-dominant with incomplete penetrance. Genes located in the major histocompatibility complex (MHC) on chromosome 6 dictate the production of high levels of IgE by B lymphocytes after allergen challenge. The production of IgE facilitates the allergic reaction. The stimulus for turning on the MHC complex is unknown.

The allergic reaction is a complicated chain of events involving the interaction of many cells, chemical mediators, and cellular products. Our knowledge of events comes from *in vitro* studies and studies in which humans are exposed to various allergens, after which nasal washes, nasal biopsies, and analysis for cellular infiltrate are performed.

In general, it begins with antigen processing, including dendritic cells, B lymphocytes, and macrophages. Antigen presentation occurs in the lymph node to type 2 CD4+T helper (CD4+Th2) lymphocytes. Next, B lymphocytes produce allergen-specific IgM and are signaled by the CD4+Th2 lymphocytes to isotype switch to IgE. Allergen-specific IgE binds to its high-affinity IgE receptor, Fc epsilon (FcεR), on mast cells and basophils. A complex of allergen-specific IgE bound to FcεR cross-links the receptors, resulting in the subsequent degranulation of basophilic cells (mast cells and basophils). The degranulation products of mast cells and basophils act in cellular recruitment and the inflammatory stimulation seen in individuals with allergic rhinitis. This intricate and forever-evolving process is discussed in further detail below (□ Fig. 106.2). For complete details, the reader is referred to a textbook of immunology.

Antigen Processing and Presentation

Uptake and allergen processing by the B lymphocytes in the respiratory epithelium begins the process. Specific allergens are loaded into MHC class II and transported to the cell membrane, where they are presented to the CD4+Th2 lymphocytes. Two signals are required to stimulate the B lymphocytes to produce IgM. The first is recognition of the allergen–MHC complex by CD4+Th2 lymphocytes via the T-cell receptor. The second is interaction of the CD40 ligand on the CD4+Th2 lymphocytes and the CD40 receptor on the B lymphocytes. Interaction delivers a critical second signal to the B lymphocytes, triggering the production of allergen-specific IgM. Activation of the CD4+Th2 lymphocyte results in interleukin-4 (IL-4) cytokine secretion. IL-4 has many actions; however, it is critical in inducing isotype switch from IgM to IgE in B lymphocytes. B lymphocytes mature into long-lived plasma cells dedicated to the production of allergen-specific IgE.

Stimulation of basophilic cells: Preformed, circulating, allergen-specific IgE binds to the high-affinity FcεR on basophilic cells, mast cells, and basophils. When free allergen binds to the allergen-specific IgE–FcεR on the cell membrane, cross-linking of these receptors occurs. Cross-linking results in (1) the immediate degranulation of preformed mediators, primarily histamine, within the mast cell or basophil; and (2) activation of phospholipase A2 in the cell membrane (□ Fig. 106.2).

Basophilic cells release multiple chemicals, including exoglycosidases, tumor necrosis factor-α (TNF-α), and the granule-associated products tryptase (only in the mast cells), chymase, peroxidase, and arylsulfatase B, into the epithelium. These chemicals result in increased vascular permeability, vasodilation of the nasal mucosa, and direct stimulation of sensory nerve fibers, causing the acute symptoms of rhinitis: itch, sneeze, rhinorrhea, and nasal congestion. Histamine is the primary mediator of these events, which are referred to as the early-phase response.

Cross-linking of the FcεR also results in the transcription of cytokines and the initiation of arachidonic acid metabolism. Secretion of these cytokines and chemokines amplifies the allergic reaction. The production of vasoactive agents and cytokines, including IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, granulocyte–monocyte colony-stimulating factor (GM-CSF), and TNF-α, promotes chemotaxis, proliferation, IgE production, and activation of a cellular infiltrate in the nasal mucosa, further contributing to the allergic response (see Box Cytokines and Effects in an Allergic Reaction (p.814)). Cellular mixture is a combination of eosinophils, T and B lymphocytes, and mast cells. In particular, IL-5 is

Fig. 106.2 The pathophysiology of allergic rhinitis. FcεR, Fc epsilon receptor; Ig, immunoglobulin; IL, interleukin; MHC, major histocompatibility complex; TCR, T-cell receptor; Th2, type 2 CD4+ T helper lymphocyte.

fundamental to eosinophil proliferation, survival, and chemotaxis in the nasal mucosa. The degranulation of eosinophils releases highly toxic oxygen radicals and proteins that damage the nasal epithelium.

Cytokines and Effects in an Allergic Reaction

- Interleukin-2: activation of T and B cells
- Interleukin-4: autoproliiferation of T cells, activation of B cells, and recruitment of inflammatory cells
- Interleukin-5: recruitment and proliferation of eosinophils
- Interleukin-13: recruitment and proliferation of eosinophils

Arachidonic acid metabolites are potent mediators of the allergic reaction. Cross-linking of FcεR activates phospholipase A₂, releasing arachidonic acid from the cell membrane. Arachidonic acid is metabolized via two separate pathways: (1) the cyclooxygenase pathway to form prostaglandin A₂ and (2) the thromboxane or the lipoxygenase pathway to form leukotrienes (see □ Fig. 106.3). Products of this cascade are responsible for nasal congestion, neutrophilic infiltrate, vasodilation, and cellular chemotaxis.

Fifty percent of individuals with allergic rhinitis will experience a second-phase reaction 2 to 6 hours later, called the late-phase response. We believe that basophils are responsible for the late-phase response because nasal washes from these patients reveal increases in the same mediators involved in the early-phase response, with the exception of prostaglandin D₂, given that basophils do not produce prostaglandin D₂ while they are present in the nasal mucosa after allergen challenge.

Two other important factors contributing to the symptoms of allergic rhinitis are nasal priming and nasal hyperreactivity. Nasal priming occurs with chronic exposure to allergen, resulting in chronic inflammatory changes. Lower and lower thresholds of allergen are required to stimulate rhinitis in these individuals. Additionally, the chronic inflammatory changes result in nasal hyperreactivity, whereby nonspecific irritants, such as strong odors, pollution, and smoke, cause symptoms of rhinitis.

Environmental influences are additional important considerations in the development of allergic rhinitis. Of particular interest is the activation of protease-activated receptors. There are four types of protease-activated receptors; types 2 and 4 are important in allergic disease. These receptors are seven transmembrane G protein coupled receptors widely expressed on many types of cells, including those of the respiratory mucosa. Stimulation of these receptors is irreversible and is accom-

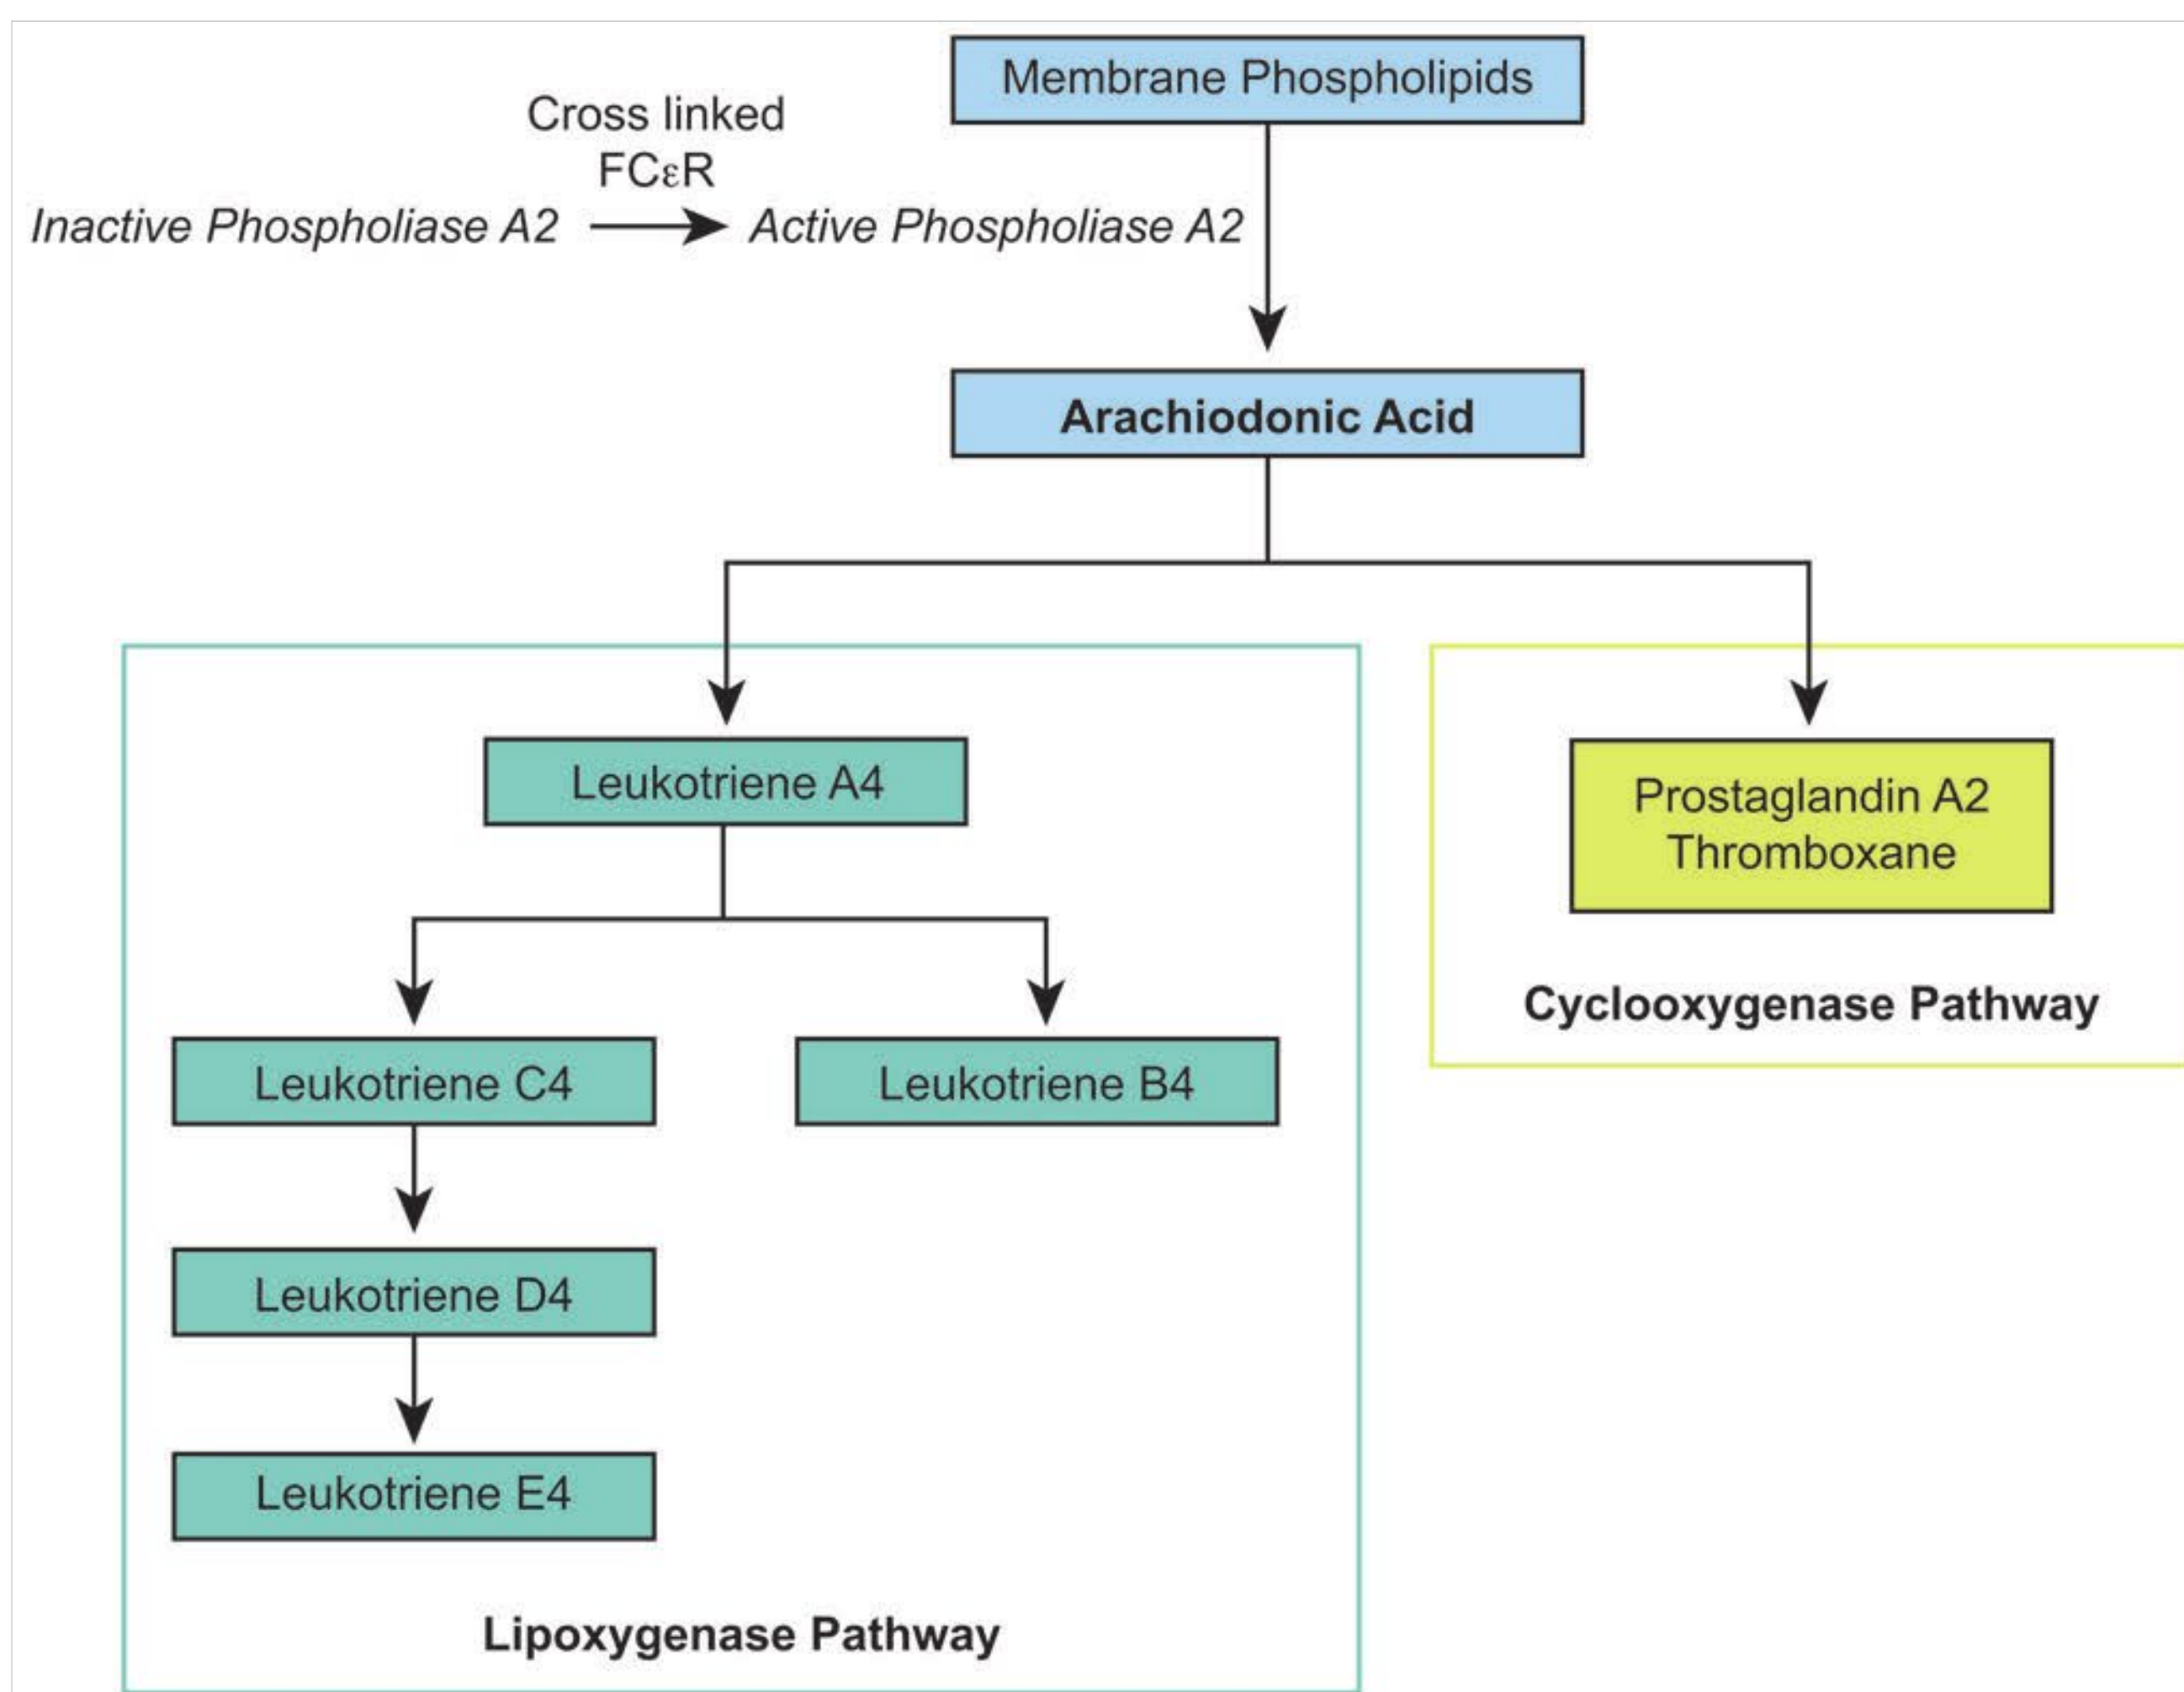

Fig. 106.3 The arachidonic acid cascade. FcεR, Fc epsilon receptor.

plished by endogenous and exogenous serine proteases. Endogenous proteases include tryptase, a degranulation product of mast cells and eosinophils; exogenous proteases include dust mite, *Alternaria*, *Aspergillus*, and cockroach. Stimulation of these receptors results in increased IgE production, angiogenesis, scarring, leukocyte infiltration, and airway hyperresponsiveness. The overall effect of stimulation of these receptors is that environmental allergens are able to penetrate into the mucosal layer. Exposure to exogenous proteases early on may be a risk factor for the development of allergic disease.

106.4.2 Nonallergic Rhinitis

The causes of nonallergic rhinitis are varied and depend on the cause. In general, we know little about its development and/or causes.

Autonomic dysregulation is common to all types of nonallergic rhinitis. Autonomic dysregulation is characterized by an exaggerated or diminished neural response to typical triggers. In normal anatomy, parasympathetic neurons contain acetylcholine, peptide histidine, and vasoactive intestinal peptide. Secretion of these neuropeptides into the nasal epithelium causes vasodilation of capillaries and tissue, resulting in rhinorrhea. In

contrast, sympathetic neurons contain norepinephrine and neuropeptide Y. Secretion of these neuropeptides leads to vasoconstriction, resulting in congestion.

In noninflammatory forms of rhinitis, abnormality of the autonomic nervous system leads to increased rhinorrhea (parasympathetic stimulation) and/or congestion (sympathetic stimulation). Additionally, there is a heightened response to non-specific triggers (environmental irritants), histamine, and cold stimulation of the extremities and nasal mucosa, as well as a decreased response to vasoconstrictive stimuli. For example, patients with gustatory rhinitis have symptoms when they ingest spicy foods. These events result in increased concentrations of intranasal neuropeptides and symptomatology.

Local intranasal allergen-specific IgE was recently identified as playing a potential role in the pathophysiology of nonallergic rhinitis. Despite normal levels of total IgE and negative results of skin prick testing and serum testing for allergic sensitization in some patients with nonallergic rhinitis, intranasal washes from these patients revealed local allergen-specific IgE. Additionally, increased levels of high-affinity FcεR were found in some patients with nonallergic rhinitis. Finally, 50% of these individuals experienced an increase in rhinitis symptoms with dust mite allergen challenge. This suggests that a local allergic

reaction may be causing symptoms not detected by traditional testing methods.

In pregnancy-induced rhinitis, a history of smoking and IgE sensitization to dust mite may play a role, although this is unclear. Some studies suggest that nonallergic rhinitis may precede the development of allergic rhinitis.

106.4.3 Natural History and Progression

The key events that cause rhinitis to start and stop are elusive. Studies that followed college students with allergic rhinitis over 23 years showed a trend decreasing symptoms and disease over time. In contrast, the symptoms of nonallergic rhinitis tend to worsen over time, with the exception of hormone-induced rhinitis. In this case, once thyroid levels are normalized or delivery is induced in women with pregnancy-induced rhinitis, the rhinitis symptoms resolve.

106.4.4 Potential Disease Complications

Psychosocial and medical complications are associated with rhinitis. Embarrassment, social isolation, sleep disturbance, poor school and work performance, and interference with daily activities are significant complications of disease and should be addressed thoroughly. Medical complications include chronic serous otitis media, eustachian tube dysfunction, perforated tympanic membrane, and rhinosinusitis (both acute and chronic).

Importantly, allergic rhinitis is commonly associated with other disease processes, such as asthma, sinusitis, eczema, and recurrent otitis media. Both nonallergic rhinitis and allergic rhinitis of childhood are associated with a two- to fourfold increase in the risk for the development of asthma in children and young adults. Early intervention with immunotherapy in children may prevent the development of asthma.

Nonallergic rhinitis with eosinophilia syndrome (NARES) may be a risk factor for the development of aspirin-exacerbated respiratory disease; however, this relationship is unclear.

Allergic rhinitis and nonallergic rhinitis are associated risk factors for chronic rhinosinusitis. However, we do not know if there is a risk that untreated disease will progress to chronic rhinosinusitis (see Chapter 107 for more details).

106.5 Medical Evaluation

A thorough history is the key to differentiating allergic from nonallergic rhinitis (see Box Highlights of an Allergy History (p.816)). Allergy is the most common cause of rhinitis, and allergic rhinitis should be ruled out before rhinitis with other causes is considered and treated. Important clues in the history that suggest allergic causes are seasonal exacerbations, triggers on exposure to certain substances, and resolution when the exacerbating substance is removed. The onset of nonallergic disease is at a later age, and nasal congestion and postnasal drainage are more prominent in nonallergic rhinitis. Exacerbating factors suggesting autonomic dysregulation are often noted in nonallergic disease, including temperature changes, food, and nonspecific irritants like strong odors and smoke. Hormonal conditions, including hypothyroidism and the changes associ-

ated with pregnancy, may cause nonallergic rhinitis. Pregnancy-induced rhinitis occurs in the second to third trimester, was not present before pregnancy, and resolves within 2 weeks after delivery. Finally, the development of symptoms in association with a new medication may provide an important clue in the history and suggest medication-induced rhinitis (see Box Medications That May Cause Nonallergic Rhinitis (p.816)). Treatment-resistant disease and unilateral symptoms of congestion, pain, and pressure are red flags for a more severe disease process such as cerebrospinal fluid leak or malignancy. The presence of these signs warrants further work-up.

Highlights of an Allergy History

- Establish the main complaint: nasal congestion, pruritus, rhinorrhea, sneezing, decreased sense of smell.
- Establish the duration: Did the symptoms start gradually or acutely? Is there a history of symptoms during childhood? Is there a history of head trauma?
- Establish the frequency of symptoms: intermittent, chronic, seasonal, with known exposures (e.g., at work, school).
- Are the symptoms unilateral or bilateral?
- Are there alleviating or aggravating factors?
- What symptoms are associated? Sleep disturbance, postnasal drip, fever, cough, sinus pressure, tooth pain, loss of smell or hearing?
- How severe are the symptoms? Do they affect daily life, sleep, work, or school activities?
- Is there a history of eczema, asthma, food allergy, or oral allergy?
- Is there a family history of allergic disease?
- Are there exposures in the environment that might be contributing to symptoms (e.g., animals, feathers, mold, leaks, job exposures, tobacco)?
- Which medications have been tried in the past? Have they been tried in combination? Were they being used correctly?

Medications That May Cause Nonallergic Rhinitis

- Analgesics: nonsteroidals, aspirin
- Antihypertensives: angiotensin-converting enzyme inhibitors, amiloride, β -blockers
- Psychotropics: risperidone, chlorpromazine, amitriptyline
- Phosphodiesterase type 5 inhibitors: sildenafil, tadalafil, vardenafil
- Others: cocaine, gabapentin, catecholamines, imidazoles

106.5.1 Presenting Complaints, Clinical Findings, Physical Examination, Testing

Regardless of the cause, patients who have rhinitis present with a symptom complex of nasal congestion, rhinorrhea, nasal pruritus, and/or sneezing. There are many associated symptoms, including sleep disturbance, itchy and watery eyes, ear pain or pressure, diminished or lost sense of smell, postnasal drip, and cough, that are important to describe. Diminished quality of life is a major factor as symptoms of fatigue, depression, and embarrassment are common.

A general head and neck examination should be performed in all patients with rhinitis. Observe for the presence of allergic stigmata: “allergic shiners” (dark circles under the eyes), the “allergic salute” (a transverse supratip crease caused by habitual upward nose wiping), boggy or edematous turbinates and nasal mucosa, nasal polyps, deviated septum, internal nasal valve collapse, and cobblestoning. Nasal endoscopy provides a detailed and complete examination of the nasal cavity. A rigid or flexible endoscope allows the examiner to visualize the middle meatus, eustachian tube, nasal polyps, sphenoidal recess, and posterior choanae, which cannot be visualized during direct observation with a nasal speculum. This is particularly important in the identification of polyps, masses, and adenoid hypertrophy.

Skin prick testing is helpful in providing clues of allergic sensitization. The total serum IgE and allergen-specific IgE levels in the blood provides supportive data for the cause of rhinitis and aid in determining appropriate treatment. The results of these tests may guide treatment toward avoidance and immunotherapy.

Treatment-resistant disease may require radiographic imaging, including sinus X-rays and noncontrast computed tomography (CT) of the sinuses. X-rays are inadequate to quantify sinus disease, and CT is the gold standard.

106.5.2 Differential Diagnosis

The differential diagnosis of rhinitis includes allergic rhinitis, nonallergic rhinitis, rhinitis caused by mechanical factors, granulomatous diseases, defects in cilia, neoplastic diseases, and cerebrospinal fluid rhinorrhea (see Box Differential Diagnosis of Rhinitis (p.817)).

106.6 Treatment

The treatment of allergic rhinitis involves the avoidance of triggers, pharmacotherapy, and immunotherapy. The treatment of nonallergic rhinitis involves avoidance, pharmacotherapy, and surgery (□ Table 106.1 and □ Fig. 106.4; see Box Treatment of Nonallergic Rhinitis (p.817)).

Differential Diagnosis of Rhinitis

- Allergic: intermittent and chronic
- Nonallergic, inflammatory: atrophic, emotional, idiopathic, gustatory, hormonal, rhinitis medicamentosa, vasomotor
- Nonallergic, noninflammatory: occupational, drug-induced (cocaine), aspirin-sensitive, nonallergic rhinitis eosinophilic syndrome (NARES)
- Nasal polyposis
- Mechanical factors: septal deviation, foreign body, choanal atresia, adenoidal hypertrophy, external valve collapse.
- Granulomatous diseases: sarcoidosis, Wegener granulomatosis, malignant midline granuloma
- Defect in ciliary function: primary ciliary dyskinesia
- Neoplastic diseases: malignant or benign
- Cerebrospinal fluid rhinorrhea: traumatic or spontaneous
- Infective: viral, bacterial, fungal, parasitic

Treatment of Nonallergic Rhinitis

- Inflammatory
 - NARES: topical intranasal corticosteroids, decongestants, and antihistamines
 - Irritant/occupational: exposure avoidance, topical intranasal corticosteroids, decongestants, antihistamines
- Drug-induced: exposure avoidance
- Noninflammatory
 - Atrophic: débridement, nasal lavage, topical antibiotic creams
 - Vasomotor: ipratropium bromide, intranasal corticosteroids
 - Hormonal: chromones
 - Rhinitis medicamentosa: weaning regimen overlapped with intranasal corticosteroids

In: Adkinson NF Jr, Bochner BS, Busse WW, Holgate ST, Lemanske RF Jr, Simons FER, eds. Middleton's Allergy: Principles & Practice. 7th ed. Philadelphia, PA: Mosby Elsevier; 2009:973–990.)

The first-line treatment for both allergic and nonallergic rhinitis should focus on the avoidance of any identified triggers. All patients should be counseled on appropriate avoidance techniques. This can be done best by an allergist/immunologist.

In most individuals, pharmacotherapy is required and should be tailored based on symptomatology. Individuals with mild intermittent disease will most likely be managed effectively with one therapy. Others, with more severe disease, will require a multimodal approach. Treatment during pregnancy and nursing requires special attention. Most antihistamines and topical intranasal corticosteroids are pregnancy class C. Of note, diphenhydramine, montelukast, and budesonide for inhalation are pregnancy class B. All medications used in the treatment of rhinitis are secreted into the breast milk, and caution should be used.

Immunotherapy is an important aspect in the treatment of allergic rhinitis. Consideration for the initiation of immunotherapy requires the presence of both symptoms on allergen exposure and allergen-specific IgE. Important factors to be noted before the initiation of therapy include inadequate symptom control with medications, compliance with the medical regimen, cost of the medications, and exposure. Immunotherapy reduces symptoms in approximately 80 to 85% of individuals and has the potential to alter the immune response in a semipermanent way. In general, patients experience symptom relief after 6 months of therapy. Published guidelines on adequate dosing should be followed. The duration of treatment affects efficacy, and studies suggest that a minimum of 3 to 5 years is required to achieve a lasting effect. Individuals on immunotherapy should be monitored yearly for symptom improvement. Importantly, some studies suggest that immunotherapy in children may prevent the progression of airway disease to asthma. Finally, cautious use in certain groups of patients is warranted,

including persons with preexisting autoimmune disease or HIV infection, those on β -blocker therapy, and pregnant women.

Uncontrolled case series have reported on the role of surgical interventions in the treatment of nonallergic rhinitis. Patients who have symptoms that are difficult to treat and who are unresponsive to a multimodal approach of 6 to 12 months of pharmacotherapy should be considered candidates for surgical intervention. Turbinatectomy is beneficial when severe nasal congestion is present. In the past, vidian nerve resection, electrocoagulation of the anterior ethmoidal nerve, and sphenopalatine ganglion block were used; however, none of these techniques has been shown to have long-term benefits. Additionally, some patients experienced persistent pain, which outweighed any benefit of the procedure.

106.7 Roundsmanship

- Rhinitis is a symptom complex characterized by rhinorrhea, sneezing, congestion, and nasal pruritus.
- There are allergic, nonallergic, and mixed causes of rhinitis; rhinitis with nonallergic causes is a diagnosis of exclusion.
- Risk factors for the development of allergic rhinitis are family history of allergic disease, serum IgE level above 100 kU/L before the age of 6 years, being first-born, male sex, tobacco exposure during the first year of life, early use of antibiotics, positive result of skin testing with allergens, and higher socioeconomic class.
- Comorbidities are asthma, eczema, sinusitis, and otitis media.
- Allergic rhinitis is caused by a classic type I IgE-mediated response; nonallergic rhinitis is caused by autonomic dysregulation.
- Treatment is multimodal and includes corticosteroids, antihistamines, and immunotherapy.

107 Medical Management of Acute and Chronic Sinusitis

Jennifer S. Collins

107.1 Introduction

Acute rhinosinusitis (ARS) and chronic rhinosinusitis (CRS) are distinct entities. ARS is an acute infection lasting anywhere up to 12 weeks. In contrast, CRS comprises a spectrum of disease and complex pathophysiology resulting in more than 12 weeks of inflammation of the paranasal passages and nasal mucosa despite medical management. Previously, the treatment of CRS varied depending on the specialty; however, multidisciplinary expert panels put forth guidelines to direct diagnosis and management. The term sinusitis was changed to rhinosinusitis to reflect the involvement of the nasal and paranasal passages. The causes of CRS are varied and often elusive. Differences in allergic sensitization, cellular infiltrates, cytokine expression, and the host response account for the spectrum of disease seen in CRS. The approach to treatment is multidisciplinary and involves medical and surgical modalities.

107.2 Incidence

ARS is the most common health care complaint in the United States, affecting over 1 billion people annually. The cost to society, however, is difficult to estimate because the costs of ARS are often grouped with the costs of CRS. ARS is associated with a significantly decreased quality of life, absence from school and/or work, and increased medication use.

CRS is one of the three most common health care complaints and accounts for 22 million office visits and 500,000 emergency department visits per year in the United States. CRS affects approximately 15 to 30% of the U.S. population, and over \$3.5 bil-

lion is spent annually in its treatment. CRS is subdivided into CRS with nasal polyposis, CRS without nasal polyposis, and allergic fungal sinusitis (AFS). CRS without nasal polyposis is the most common form of the disease, accounting for 60 to 65% of all cases. Cases of CRS without polyposis develop in males and females in equal numbers.

CRS with nasal polyposis accounts for 20 to 35% of all cases. The prevalence of CRS with nasal polyposis is higher in patients who have certain comorbidities, including allergic rhinitis, asthma, aspirin sensitivity, and cystic fibrosis. Aspirin sensitivity is present in 15% of patients with nasal polyps. The late onset of asthma frequently coincides with the development of polyposis in adults. Approximately 40% of patients with cystic fibrosis will have nasal polyps, and any child or adolescent with nasal polyps should be screened for cystic fibrosis. More males are affected than females, and the incidence of polyps increases after the age of 40 years.

AFS accounts for 8 to 12% of all cases of CRS. AFS typically develops in young adults. The mean age of patients at diagnosis is 22 years, and males and females are equally affected. Atopy is a risk factor for disease, and elevated levels of total immunoglobulin E (IgE) are common. There appears to be a geographic distribution of disease, with a higher incidence in more temperate climates.

107.3 Classification of Disease

The classification of rhinosinusitis is based on the duration of illness and the presence or absence of nasal polyps (□ Fig. 107.1). Rhinosinusitis can be acute, recurrent acute, or

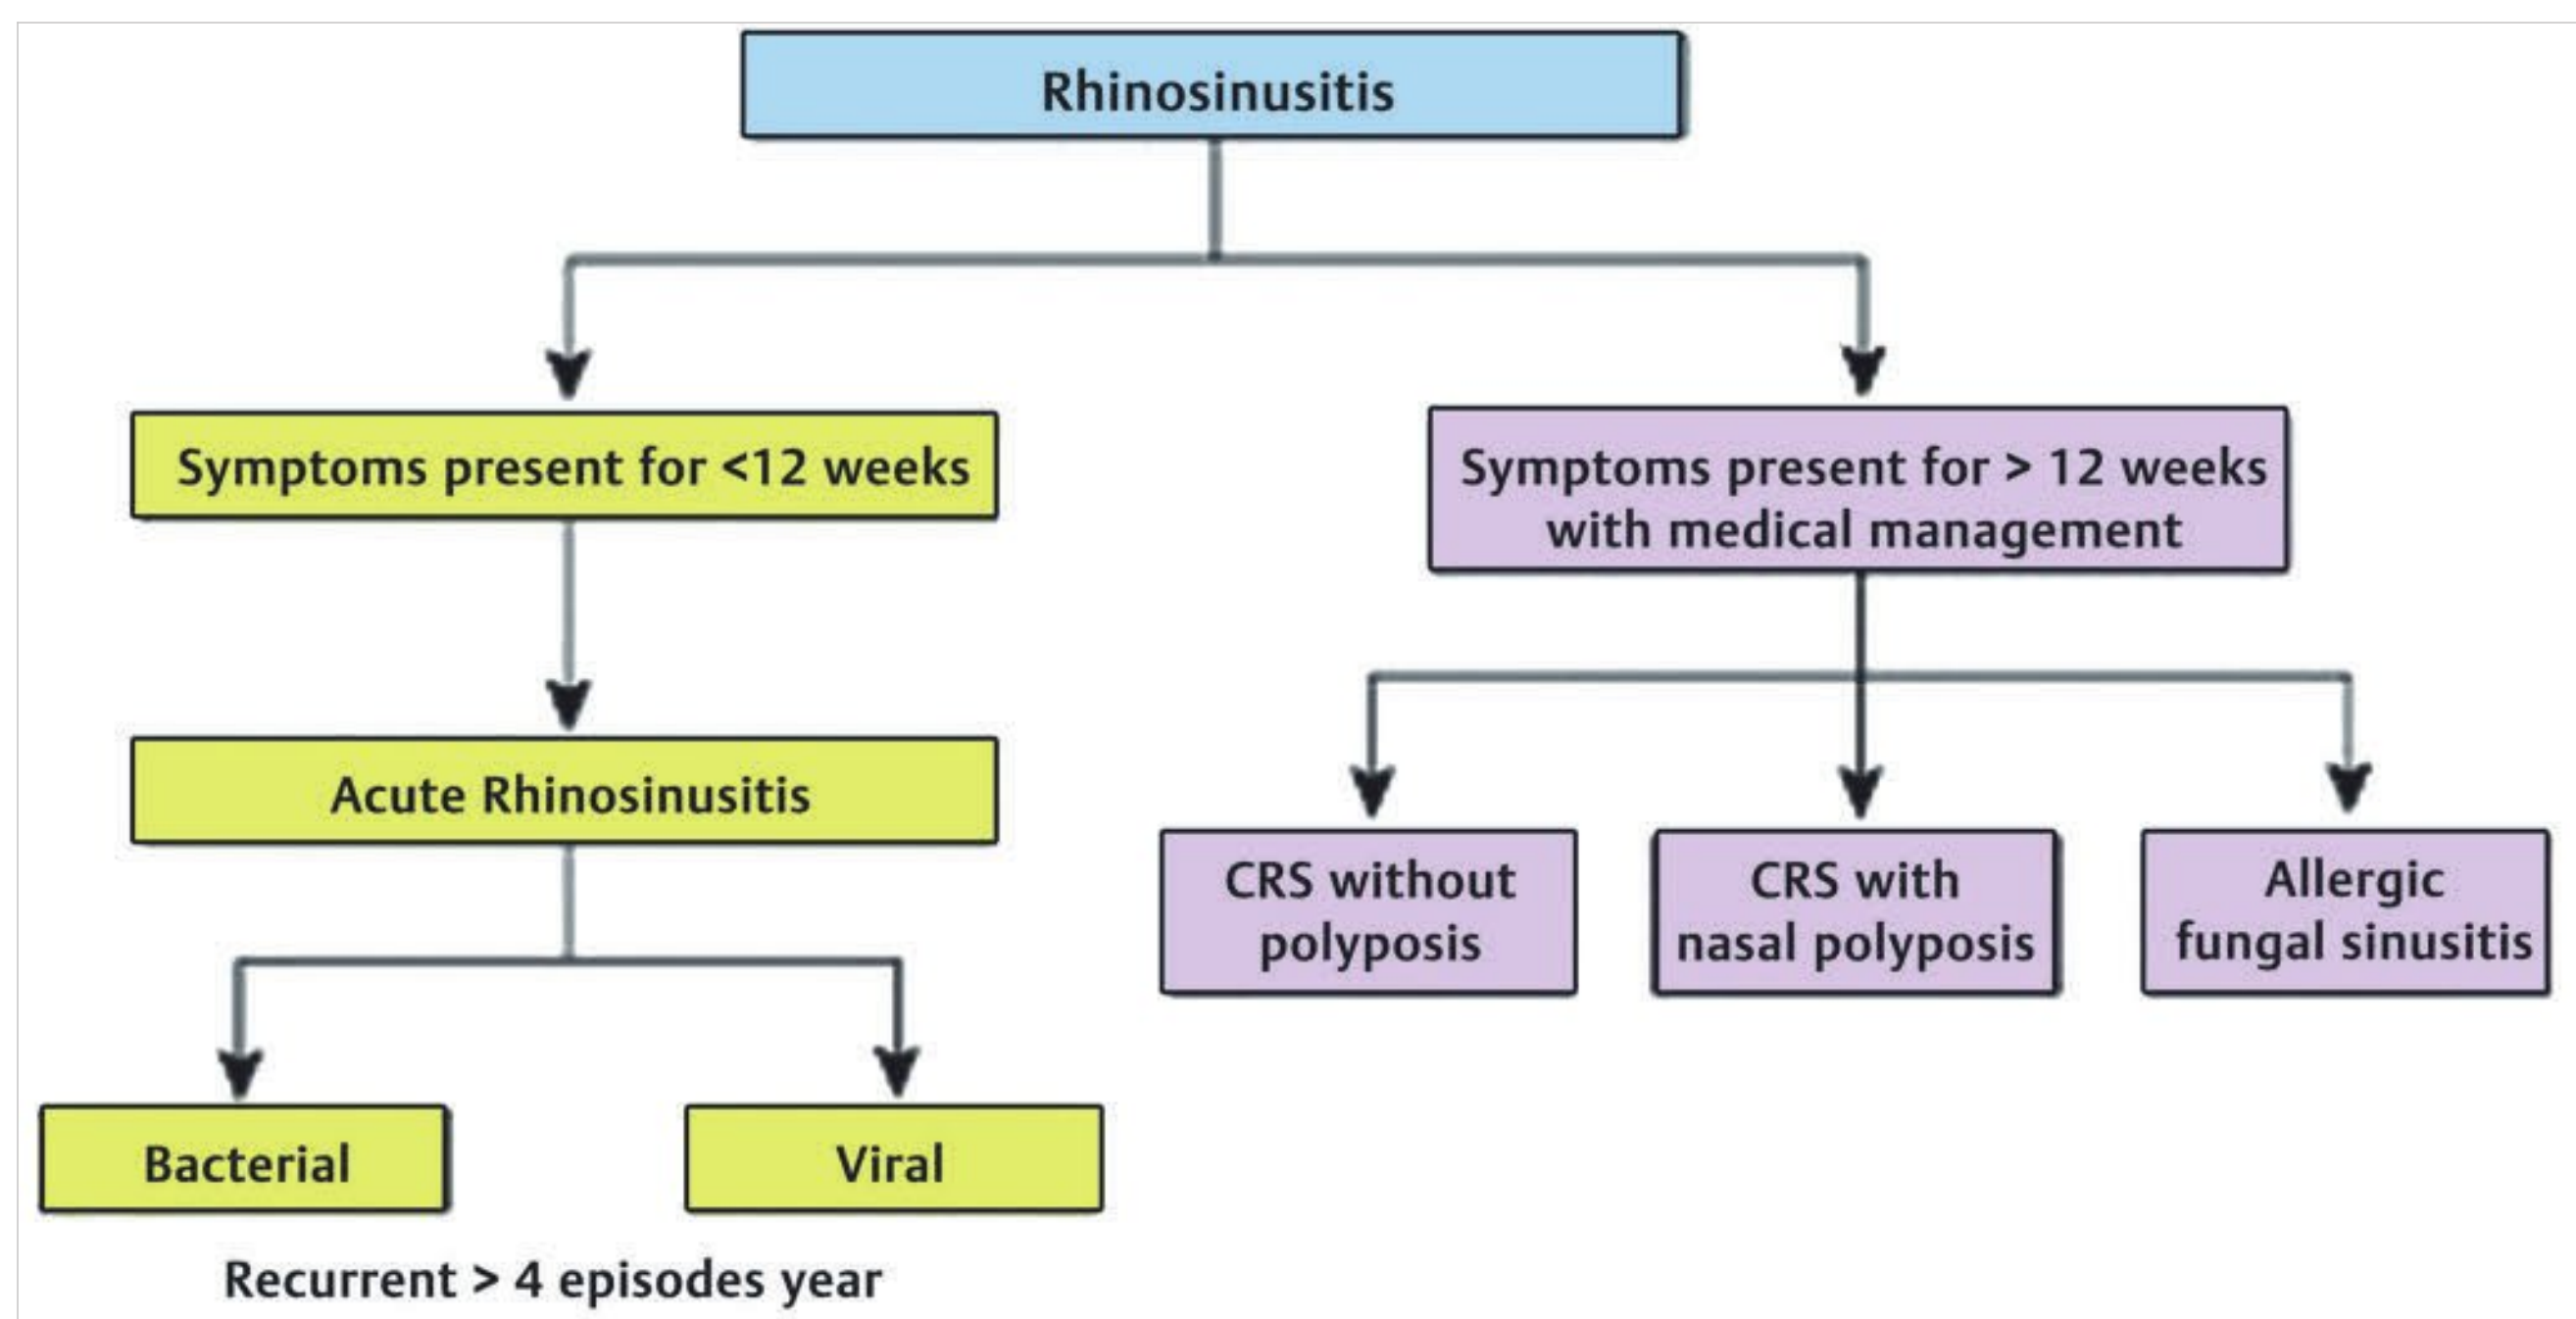

Fig. 107.1 Classification of rhinosinusitis. CRS, chronic rhinosinusitis.

chronic, or it can be an acute exacerbation of chronic disease. Acute sinusitis is sudden in onset, and symptoms can last for up to 12 weeks. Typically, if the symptoms worsen over 5 days or last longer than 10 days, bacterial causes should be suspected. In children, viral infections are more common than bacterial infections. Recurrent rhinosinusitis is characterized by the occurrence of more than four separate episodes in a single year. Individuals are symptom-free between episodes.

CRS is characterized by symptoms lasting longer than 12 weeks despite adequate medical treatment. CRS is further classified by the presence or absence of nasal polyps and by whether criteria consistent with AFS have been met (allergic mucin, fungal hyphae, and IgE-mediated fungal allergy). Patients with AFS are immunocompetent and tend to have allergic rhinitis.

107.4 Applied Anatomy

The exact function of the paranasal sinuses is unknown; however, it is probable that they function to humidify and warm inspired air, lighten the skull, improve vocal resonance, absorb shock to the face or skull, and secrete mucus to assist with air filtration. The paranasal sinuses develop as outpouchings of the nasal mucosa. Narrow ostia connect the sinuses to the nasal cavity. The sinuses are lined with ciliated pseudostratified columnar epithelium with goblet cells. The ostia of the frontal, maxillary, and anterior ethmoid sinuses open into the ostiomeatal complex. The ostiomeatal complex includes the area lateral to the middle meatus and middle turbinate. This unit is important because all sinuses except the sphenoid and posterior ethmoid sinuses drain through it. The posterior ethmoid and sphenoid sinuses open into the superior meatus and sphenoidal recess. Anything that obstructs this unit causes symptoms of facial pain/pressure, congestion and disturbance of normal airflow.

The sinus epithelium is important because it is thinner and less richly supplied with blood vessels and glands than the mucosa of the nasal cavity. Overlying the mucosal layer is a thin layer of mucus infiltrated with cilia, comprising a mucociliary clearance system. The mucociliary clearance system enables the mucosa to remove particulate matter and debris. Particulate matter is trapped in this bilayered system and mobilized by beating cilia that sweep mucus toward the ostia clearing debris. Hair cells in the nasal cavity actively catch particles larger than 15 μm in size. These particles are trapped within the mucosal layer.

107.5 Etiology and Pathophysiology

107.5.1 Acute Rhinosinusitis

The most common cause of acute sinusitis is viral infection. Only 0.2 to 5% of these episodes are further complicated by bacterial infections. The most common viruses causing acute sinusitis are rhinovirus, influenza virus, and parainfluenza virus.

Direct inoculation of the nasal mucosa with virus results in ARS. Viral replication begins immediately, and detectable levels are present within nasal secretions in less than 10 hours.

Symptoms begin approximately 12 hours after inoculation. Virus spreads via direct and systemic methods throughout the paranasal sinuses, causing inflammation. Neutrophils infiltrate the mucosal layer in response to infection, resulting in hypersecretion of glands, increased vascular permeability, and transudation of fluid into the nasal cavity and sinuses. Direct toxic effects of some viruses and/or bacteria on the nasal cilia can disrupt the mucociliary clearance system. Mucosal edema, distortion of the composition of normal mucous secretions, and ciliary dyskinesia result in sinus obstruction.

The most common cause of damaged epithelium is viral infection, which allows the normal respiratory flora to infect the nasal epithelium. This typically occurs 2 to 4 days after the initial viral infection. Normal respiratory flora are typical responsible for infection and include coagulase-negative staphylococci, *Corynebacterium*, and *Staphylococcus aureus*. The most commonly associated bacteria are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Seventy-five percent of cases of bacterial sinusitis are caused by *S. pneumoniae* and *H. influenzae*. Microaerophilic and anaerobic bacteria should be considered in the setting of dental root infection with extension into the maxillary sinus cavity. Importantly, viral infections are not the only cause of damaged epithelium. Allergic disease, mechanical obstruction (e.g., obstruction of the ostiomeatal complex, septal deviation), swimming, odontogenic infections, intranasal cocaine use, impaired mucociliary clearance (e.g., cystic fibrosis, cilia dysfunction), and immunodeficiency should be considered in appropriate patient groups.

107.5.2 Chronic Rhinosinusitis

The etiology of chronic rhinosinusitis remains elusive despite intensive research efforts. In the past, a lack of clear terminology and varied approaches to treatment and study designs contributed to our lack of understanding of these disorders.

We do know that CRS is a heterogeneous group of disorders with different etiologies and pathophysiologies. Complex inflammatory changes occur within the nasal and paranasal mucosa of individuals with CRS. Differences in inflammatory cell infiltrate, type of T-lymphocyte response, and remodeling patterns result in the assorted disease patterns observed. In general, the role of bacterial infection is controversial in CRS both with and without nasal polyposis. Immunodeficiency should be ruled out in patients who have CRS without nasal polyposis. Aspirin intolerance is seen only in CRS with nasal polyposis. IgE and IgG sensitization to fungus and allergic mucin must be present in AFS.

Risk factors for CRS include allergic rhinitis, active tobacco use, immunodeficiency, defects in mucociliary clearance, recurrent viral upper respiratory tract infections, systemic diseases (including Churg-Strauss vasculitis, sarcoidosis, and Wegener granulomatosis), and anatomical abnormalities (\square Table 107.1). Allergic sensitization to dust mites, cockroach, and molds is common in all diseases. This may be in part due to the activation of protease-activated receptors (see Chapter 106 for a full discussion). Importantly, any cause of obstruction (e.g., nasal polyps, granulomatous disease, allergies, mucosal edema) of the ostiomeatal complex can create the sensation of facial pain/pressure, nasal congestion, or disturbance of airflow.

Table 107.1 Risk factors for the development of chronic rhinosinusitis

CRS risk factor	CRS with polyps	CRS without polyps	AFS
Atopy	Common	Common	Common
Immunodeficiency	Rare	Immunodeficiency in 12%	Rare
Environmental irritants	Common	Common	Common
Aspirin intolerance	Common	Rare	Rare

Abbreviations: AFS, acute fungal sinusitis; CRS, chronic rhinosinusitis.

Each disease entity has a distinctive pathophysiology and response to treatment and management, and each is discussed separately below.

Chronic Rhinosinusitis without Nasal Polyposis

CRS without nasal polyposis is the most common form of CRS. Various processes, including allergic, nonallergic, immunologic, and structural abnormalities, contribute to the chronic changes observed in the mucosal layer. Analysis of sinus fluid reveals a neutrophilic infiltrate, as well as low numbers of eosinophils, mast cells, and basophils. Histologic changes within the mucosal lining include thickening of the basement membrane, edema, and hyperplasia of goblet cells, in addition to a submucosal monocytic infiltrate of neutrophils and macrophages.

The cytokine profile in CRS without nasal polyposis is unique. There are elevations in CD4+T helper type 1 (CD4+Th1) lymphocytes and in the lymphocyte-associated cytokines interleukin-1 β (IL-1 β), interferon- γ (IFN- γ), tumor necrosis factor- α (TNF- α), and TGF- β . Elevations in TGF- β result in the characteristic fibrosis seen in CRS without nasal polyposis. This cytokine is noticeably absent in CRS with nasal polyposis.

The role of chronic bacterial infections in CRS without nasal polyposis is debatable. Studies are flawed based on patient selection, culture techniques, and prior use of antibiotics. Recurrent and/or chronic bacterial infections can cause permanent anatomical changes. Additionally, biofilms, which are complex aggregations of bacteria embedded within an extracellular polymeric substance on chronically inflamed surfaces, may be present. These microcommunities of bacteria are difficult to eradicate and may represent a hidden source of chronic infection impenetrable to antibiotics.

Chronic Rhinosinusitis with Nasal Polyposis

CRS with nasal polyposis is the second most common form of CRS. By definition, polyps must be present. Polyps are edematous, semitranslucent masses in the nasal and paranasal cavities that have no pain fibers. There are two types of polyps: ethmoidal and antrochoanal. Ethmoidal polyps are more common, emerge from the ethmoid sinus via the ostiomeatal complex, and are bilateral. In contrast, antrochoanal polyps arise from the maxillary sinus via the middle meatus and are unilateral. Antrochoanal polyps are less likely to be associated with allergic disease. The presence of unilateral polyps is uncommon and should prompt consideration of more severe diseases, including inverted papilloma and nasal tumors.

Epithelial damage with a thickened basement membrane is shown on histologic analysis of polyp tissue. There is an eosinophilic infiltrate, and stromal tissue exhibits fibrosis or edematous changes, decreased blood supply and glands, and the absence of neural tissue. Mature polyps may form pseudocysts with surrounding fibroblasts and inflammatory cells.

The inflammatory infiltrate in the nasal polyps associated with cystic fibrosis and primary ciliary dyskinesia shows important differences. Unlike the eosinophilic infiltrate typically seen in CRS with nasal polyposis, a characteristic lymphocytic and neutrophilic infiltrate is revealed by histology. The presence of this cellular infiltrate in children warrants further screening for disease.

The cellular and cytokine profile of CRS with nasal polyps is in contrast to that of CRS without polyps. It is characterized by activated CD4+Th2 lymphocytes, increased amounts of IL-5, IL-13, and histamine, and the absence of TGF- β . IL-5 and IL-13 are key cytokines in the proliferation and survival of eosinophils. The cellular and cytokine profile suggests an allergic role in the development of nasal polyps.

Although the cause of nasal polyposis remains elusive, it probably represents a heterogeneous disease with varied causes, including allergic and infectious conditions and aspirin sensitivity. Allergic disease most likely plays a role, and up to 60% of patients with polyposis will have atopy. Additionally, IgE is increased locally within polyp tissue. Local IgE production and a type I mediated allergic reaction may have a role in the etiology of polyposis.

A unique subset of adult patients with nasal polyposis will also have aspirin hypersensitivity with aspirin-induced bronchial asthma and/or aspirin-induced rhinitis (aspirin-exacerbated respiratory disease, or Samter triad). In this group of patients, defective inhibition of the cyclo-oxygenase enzyme 1 in the arachidonic acid pathway (see Chapter 106 for full details) leads to the excessive production of leukotrienes. The ingestion of aspirin leads to symptoms of bronchospasm and/or rhinitis 30 minutes to 4 hours later. Symptoms of worsening asthma, nasal polyposis, and rhinitis develop slowly over years despite avoidance of the drug. It is important to recognize and treat this sensitivity because these patients are 10 times more likely to require repeated surgical interventions for polyp management. The diagnosis is made through challenge testing with lysine-aspirin by an allergist/immunologist. Desensitization and long-term aspirin therapy can be effective in treating up to 60% of these patients.

The role of bacterial infections and superantigen activation of T lymphocytes remains controversial. Studies reveal an increased colonization of *S. aureus* in patients with nasal polyps

or aspirin-sensitive asthma versus controls. *S. aureus* produces enterotoxins that act as superantigens, directly activating T lymphocytes, as in atopic dermatitis. Additionally, patients with nasal polyposis have an increased local presence of *S. aureus* enterotoxin-specific IgE. This IgE is not found in the serum, suggesting that a type I mediated allergic reaction to the enterotoxin may occur within the paranasal sinuses, resulting in the formation of nasal polyps.

Allergic Fungal Sinusitis

The pathophysiology of AFS is poorly defined, but it is most likely an infectious and/or allergic process. Presumably, a complex reaction involving both an immediate type I IgE-mediated response and a type III immune complex deposition (fungus-specific IgG and fungus) results in mucosal edema, eosinophilic infiltration, and allergic mucin formation. Supporting evidence includes the presence of fungus-specific IgE and IgG locally and in the serum. Total levels of quantitative IgE are elevated in these patients. Histology of the nasal mucosa reveals eosinophilic infiltrates.

Allergic mucin, present within the sinuses, varies in color and can be anywhere from light tan to dark green, with a thick, peanut butter-like consistency. The function is unknown. Allergic mucin contains degranulated eosinophils, Charcot-Leyden crystals (a by-product of degranulated eosinophils), and fungal hyphae. The identification of fungal hyphae in allergic mucin is problematic, and these are not always identified.

The fungi associated with AFS are ubiquitous in the environment and are in the dematiaceous family. Because of their omnipresence in the environment, exposure does not equate with disease. In children and adults, *Bipolaris* and *Curvularia* are most commonly isolated from the mucin. In adults, *Alternaria* and *Aspergillus* species also play an important role.

107.6 Medical Evaluation

107.6.1 Presenting Complaints

A thorough history is important in the diagnosis of ARS and CRS. Information regarding the nature and duration of symptoms, triggers, alleviating factors, and comorbid conditions (including allergy, asthma, recurrent infections, intranasal drug use, and aspirin sensitivity), as well as previous treatment, imaging, and surgical interventions, should be documented.

Disease is classified based on symptom duration and the presence or absence of nasal polyps and/or allergic mucin. The symptoms of ARS and CRS are similar and divided into major and minor symptoms (□ Table 107.2). Any patient reporting changes in vision, diplopia, severe headache, proptosis, or focal neurologic or meningeal signs requires immediate attention and imaging. Patients with ARS report the acute onset of nasal congestion and obstruction, purulent nasal discharge, maxillary tooth discomfort, and facial pain or pressure that is worse when they bend forward. Symptoms start acutely and can last anywhere up to 12 weeks.

CRS commonly starts with an indolent infection or upper respiratory infection that never resolves. Two of the four hallmark signs of CRS (mucopurulent drainage, nasal obstruction, facial pain/pressure, and decreased sense of smell) must be present in

Table 107.2 Symptoms associated with rhinosinusitis

Major symptoms	Minor symptoms
Facial pain/pressure	Headache
Facial congestion/fullness	Fever
Nasal obstruction/blockage	Halitosis
Nasal discharge/purulence; postnasal drip	Fatigue
Hyposmia/anosmia	Dental pain
	Cough
	Ear pain/pressure/fullness

Source: Adapted from Lanza DC, Kennedy DW. Adult rhinosinusitis defined. *Otolaryngol Head Neck Surg* 1997;117(3 Pt 2):S1–S7.

conjunction with mucosal inflammation for CRS to be considered. Each type of CRS can present characteristically in its own way (see Box Typical Presenting Symptoms of Chronic Rhinosinusitis (p.823)).

Typical Presenting Symptoms of Chronic Rhinosinusitis

- Chronic rhinosinusitis with nasal polyposis: gradual worsening of nasal congestion and facial fullness/pressure; diminished sense of smell
- Chronic rhinosinusitis without nasal polyposis: facial pressure/pain and mucopurulent drainage in association with fatigue and low-grade fever
- Allergic fungal sinusitis: dramatic or progressive presentation of severe nasal congestion, facial asymmetry, and vision changes; thick, “peanut butter-like” discharge from the nose

107.6.2 Physical Examination and Evaluation

An algorithm for the diagnosis and work-up of ARS and CRS is presented in □ Fig. 107.2. In general, a head and neck examination should be done for all patients presenting with these complaints. Observe for signs of facial asymmetry, proptosis, inflamed nasal mucosa, visible polyps, septal deviation, mucopurulent drainage, and lymphadenopathy. Rigid or flexible endoscopy is useful in both ARS and CRS and should be performed if available. The observation of obstruction of the ostiomeatal complex is important.

No radiologic imaging is necessary for ARS. If symptoms persist despite treatment, multiplanar noncontrast sinus computed topography (CT) is the imaging modality of choice to document CRS. Sinus mucosal thickening, sinus ostial obstruction, polyps, and radiographic evidence of sinus opacification are commonly documented in CRS.

The presence of certain diseases warrants further work-up. All children with nasal polyposis should be screened for cystic fibrosis. Patients with recurrent ARS and symptoms of allergic disease and all patients with CRS should undergo an allergy work-up that includes an evaluation for sensitivity to perennial and seasonal allergens and measurement of total IgE. Desensitization should be considered for patients who have CRS with

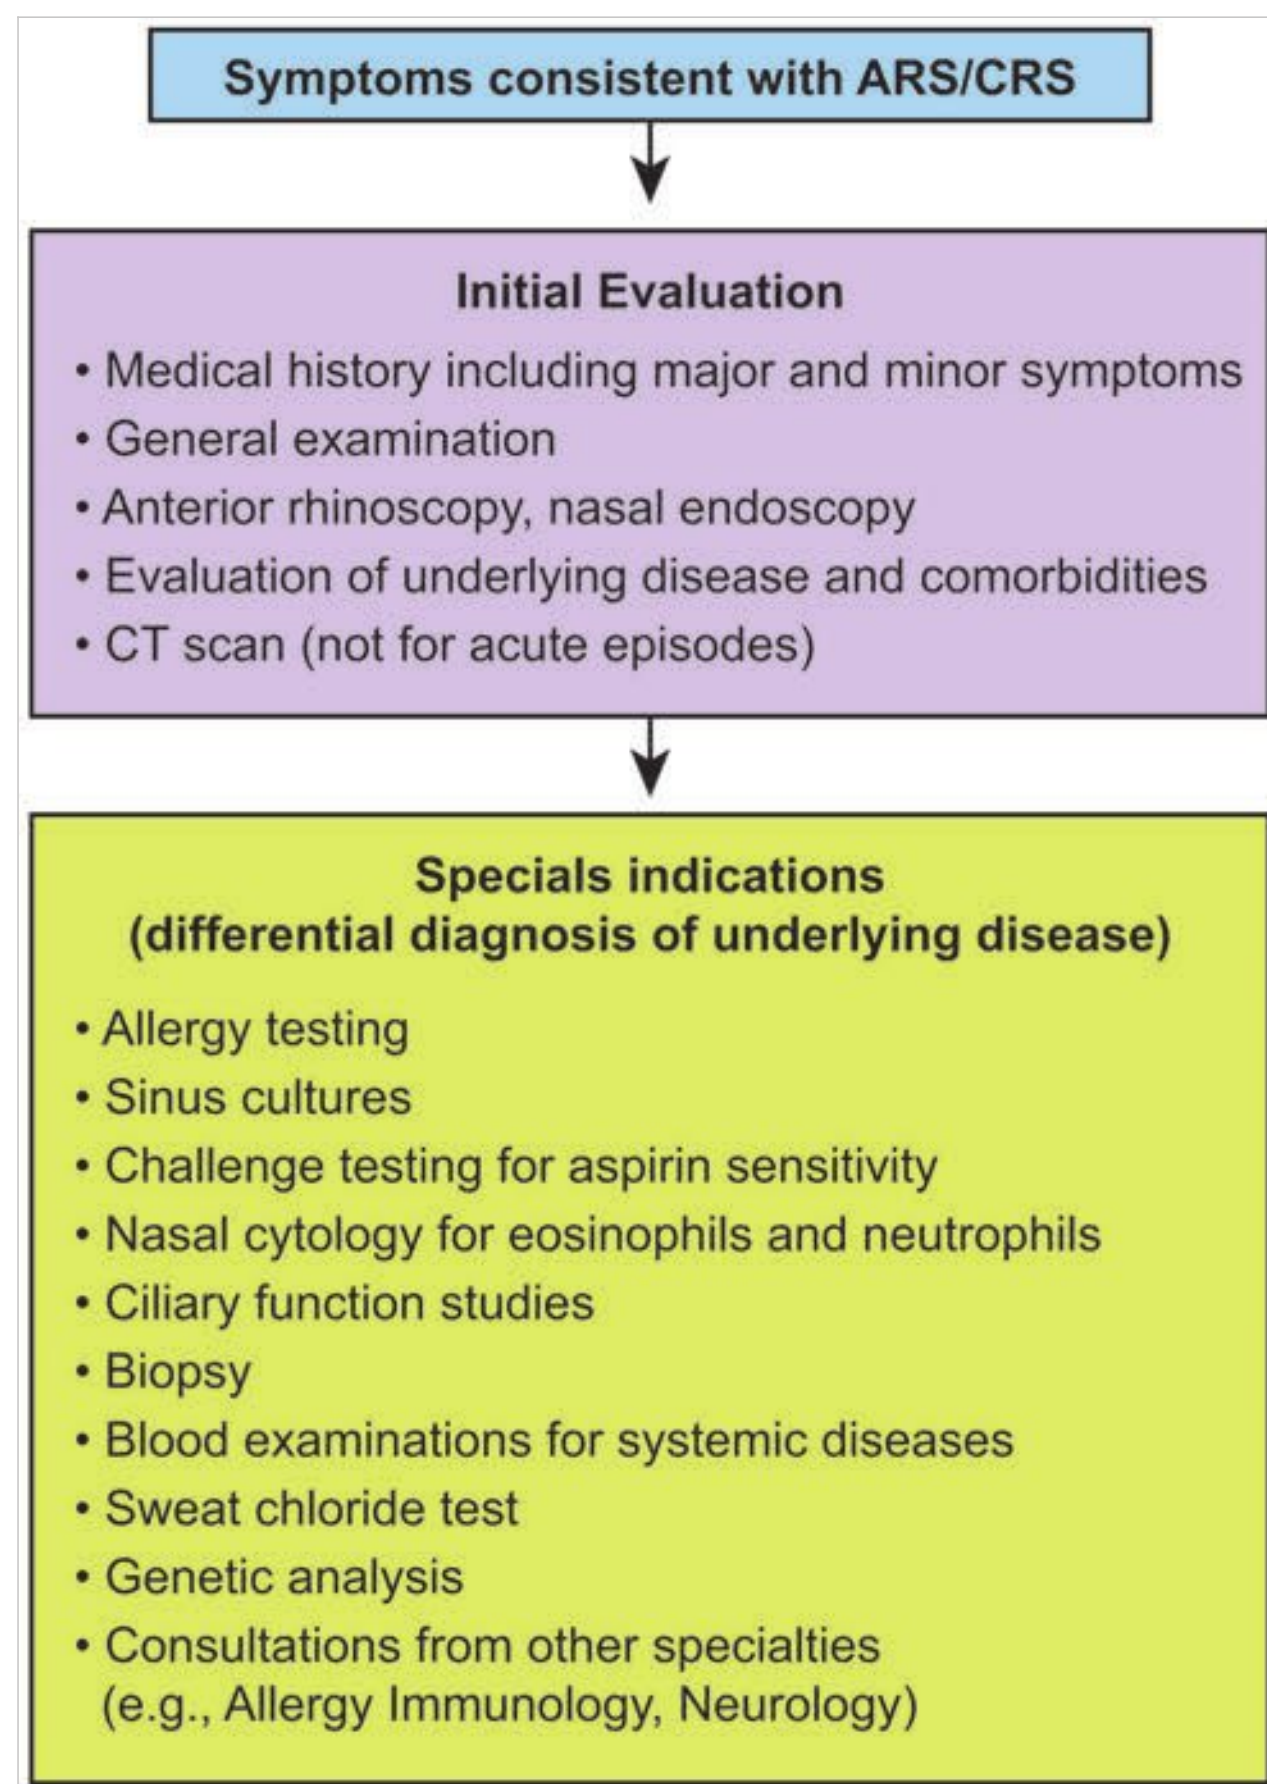

Fig. 107.2 Algorithm for the diagnosis of rhinosinusitis. ARS, acute rhinosinusitis; CRS, chronic rhinosinusitis; CT, computed tomography. Source: Data from Bachert C, Gevaert P, van Cauwengerge P. Nasal polyps and rhinosinusitis. In: Adkinson NF Jr, Bochner BS, Busse WW, Holgate ST, Lemanske RF Jr, Simons FER, eds. *Middleton's Allergy: Principles & Practice*. 7th ed. Philadelphia, PA: Mosby Elsevier; 2009:991–1003.

nasal polyposis and a history of aspirin sensitivity. Finally, patients who have recurrent ARS and CRS without nasal polyposis should be evaluated for possible acquired immunodeficiency (isolated and total hypogammaglobulinemia, selective IgA deficiency, HIV). As advancements are made regarding our knowledge and treatment options for innate immunodeficiencies, including toll-like receptor defects and disorders of complement, defects in these pathways should also be considered. Referral to a specialist in allergy/immunology is indicated for laboratory evaluation, including screening for HIV infection, quantitative immunoglobulins, IgG subclasses, and evidence of immune titers to vaccines.

Nasal swabs provide little or no useful information regarding culprit bacteria and should not be performed. Bacterial cultures via direct sinus puncture or middle meatal endoscopy in patients with CRS can be helpful.

107.6.3 Differential Diagnosis

The differential diagnosis of rhinosinusitis includes allergic and nonallergic rhinitis, atypical migraine headaches, disorders of

olfaction, gastroesophageal reflux, laryngeal reflux, and head and neck tumors.

107.7 Medical Treatment

The goal of medical and surgical treatment is to reduce symptoms and eradicate bacterial and/or fungal infections. Symptom reduction can be achieved with supportive measures of humidified air, saline nasal rinses, and oral decongestants. Monotherapy with intranasal corticosteroids may provide beneficial symptom reduction in ARS and is indicated in combination with other medications in CRS. Maximal treatment of allergic disease should be instituted in appropriate patients (□ Table 107.3).

107.7.1 Acute Rhinosinusitis

The benefits of antibiotic therapy in ARS are controversial, and it should be initiated with care. Cochrane Reviews report a limited role for antibiotics in ARS. In patients who have symptoms for less than 7 days, antibiotic treatment shows a small benefit. When antibiotic therapy is initiated, the first-line treatment against normal respiratory flora should guide the choice. Patients who have fever above 101°F, moderate to severe facial pain, progression of symptoms, or symptoms for longer than 14 days should be treated with antibiotics. Typically, amoxicillin, cephalosporins, and sulfa-based antibiotics are adequate. Macrolide antibiotics may also be used as an alternative.

107.7.2 Chronic Rhinosinusitis

In contrast to ARS, combination therapy with oral or topical corticosteroids and oral antibiotics is recommended for the treatment of CRS with and without nasal polyposis. Treatment with oral corticosteroids is often required. The optimal dosing regimen and treatment duration vary among practitioners.

All patients with CRS should be treated maximally for allergic disease, and immunotherapy should be considered. Identified immunodeficiencies and systemic illnesses contributing to the disease process should be addressed.

Antibiotic choice is guided by drug allergy status, prior use of antibiotics, and culture results. Amoxicillin/clavulanate is the first-line choice in patients without penicillin allergy; in allergic patients, a quinolone antibiotic may be used safely. Clindamycin is an alternative antibiotic for penicillin-allergic patients or for those in whom methicillin-resistant *S. aureus* infection is suspected. Treatment typically is continued for at least 3 weeks to induce remission of symptoms. Multiple courses in combination with surgical intervention are often required.

Patients who have aspirin-sensitive CRS with nasal polyposis may benefit from aspirin desensitization, leukotriene synthesis inhibitors (zileuton), and/or leukotriene antagonists (montelukast), although these are off-label uses. Patients on zileuton should be monitored for evidence of hepatic impairment. Aspirin challenge should be considered in patients with a history of allergy and/or asthma. Other systemic causes of nasal polyposis should be considered and treated.

The treatment of AFS begins with surgery, and medical management follows. Oral corticosteroids are the backbone of

Table 107.3 Medical treatment of acute and chronic sinusitis

Condition	Treatment	
ARS	Antibiotics for 10–14 days	First line: amoxicillin, cephalosporins, trimethoprim/sulfamethoxazole, macrolides Second line: amoxicillin/clavulanate, levofloxacin
	Supportive therapy	Intranasal corticosteroids, nasal decongestants, saline rinses
	Antibiotics for 3 weeks	Amoxicillin/clavulanate, clindamycin
CRS without nasal polyposis	Corticosteroids	Intranasal corticosteroid sprays ± systemic corticosteroids
	Allergy treatment	Maximize medical therapy for allergies Consider immunotherapy
	Supportive therapy	Saline rinses and nasal sprays
	Antibiotics for 3 weeks	Amoxicillin/clavulanate, clindamycin
CRS with nasal polyposis	Corticosteroids	Intranasal corticosteroid sprays Prednisone 40 mg/d for 5 days, then 20 mg for 5 days, then 10 mg for 5 days, then 5 mg for 5 days
	Allergy treatment	Maximize medical therapy for allergies Consider immunotherapy
	Supportive therapy	Saline rinses and nasal sprays
	Leukotriene synthesis inhibitor/leukotriene antagonist	Monteleukast and zileuton
	Allergy treatment	Allergy evaluation and maximal therapy Aspirin challenge and desensitization
	Surgery	Disease-directed sinus surgery
AFS	Corticosteroids	Prednisone 0.5 mg/kg for several weeks, tapered to 10 mg/d; continue taper to lowest dose that maintains remission Intranasal corticosteroid sprays
	Allergy treatment	Immunotherapy
	Antifungals	Oral and topical nasal rinses controversial

Abbreviations: AFS, acute fungal sinusitis; ARS, acute rhinosinusitis; CRS, chronic rhinosinusitis.

maintaining remission in the postsurgical patient. Immunomodulation and suppression of the inflammatory response by the corticosteroids reduces relapses. Dosing guidelines and duration of treatment are unknown and should be based on patient symptom scores.

Immunotherapy may be a powerful treatment tool in AFS. Previously, it was felt that immunotherapy with the inciting fungus might exacerbate disease and should be removed from the treatment regimen. However, three small studies showed that patients receiving immunotherapy for fungus for 3 to 5 years had a reduction in symptom scores, were able to stop oral and topical corticosteroid use, and had decreased relapse rates up to 3 years later. A promising treatment option may be recombinant IgE (omalizumab) therapy. Limited case reports/series suggest decreases in symptom scores and relapse rates.

In the past, oral antifungal therapies for AFS were proposed; however, they have serious side effects, and there is little evidence to support their use. Topical antifungal therapy may add some benefit in reducing symptoms of AFS, but studies are lacking.

107.8 Prognosis

ARS typically responds well to first-line antibiotics. Progression of symptoms or lack of improvement after 7 days of therapy should be considered treatment failure. In these cases, the empiric use of second-line antibiotics (levofloxacin or amoxicillin/clavulanate) is indicated.

Patients should be counseled that CRS is a chronic illness requiring lifelong treatment. The rates of lifelong exacerbations and recurrences of CRS despite maximal therapy are high, particularly in patients with AFS, 10 to 100% of whom experience recurrence.

107.9 Complications

All patients with ARS or CRS may develop complications secondary to a delay in diagnosis, recurrence of disease, or treatment failure. Transient hyposmia or anosmia is typically reversible in cases of virally induced ARS. In rare cases of bacterial ARS,

Table 107.4 Orbital complications of sinusitis

Group	Complication	Description
I	Preseptal cellulitis	Inflammatory edema limited to area anterior to orbital septum, caused by restricted venous drainage; eyelids swollen but not tender, extraocular muscle movement unaffected, no chemosis; proptosis, if present, mild
II	Orbital cellulitis	Pronounced edema of orbital (retroseptal) contents without abscess; chemosis and proptosis, but vision loss rare
III	Subperiosteal abscess	Abscess between bone and periosteum of orbital bone; orbital contents displaced inferolaterally by accumulating pus; chemosis and proptosis; decreased vision or ocular mobility rare
IV	Orbital abscess	Intraorbital collection of pus; severe proptosis, ophthalmoplegia, and vision loss common
V	Cavernous sinus thrombosis	Bilateral ocular signs, fever, headache, photophobia, proptosis, ophthalmoplegia, rapid vision loss, and involvement of cranial nerves III, IV, V ₁ , V ₂ , and VI

abscesses involving the eye, meninges, or brain may ensue. The most common complication of ARS is progression to CRS.

The most worrisome complication of CRS is extension to and/or involvement of the brain via the orbit (□ Table 107.4). Signs of extension into the orbit include proptosis (forward displacement of the eye), gaze restriction, decreased visual acuity, color vision defects, and an afferent pupillary defect. These symptoms in the setting of fever, headache, and cranial nerve palsy suggest the most troublesome complication, the development of cavernous sinus thrombosis.

Alternative complications and concerns of therapy are medication side effects, the emergence of antibiotic resistance, and the development of antibiotic allergy.

107.10 Roundsmanship

- ARS and CRS differ in the duration of illness but have similar symptoms.
- Most cases of ARS are virally induced; patients with symptoms lasting less than 2 weeks do not require antibiotics.
- CRS represents a spectrum of disease depending on the immunologic reaction to environmental allergens and infection.
- CRS is a chronic relapsing and remitting disease.
- CRS is strongly associated with allergic disease.
- The four cardinal signs of CRS are mucopurulent drainage, nasal obstruction, hyposmia/anosmia, and facial pain/pressure; two must be present along with evidence of mucosal inflammation to consider CRS.

- Treatment of ARS rarely requires antibiotics; treatment of CRS requires a multi-modal approach including medical and surgery.
- Signs of proptosis, gaze restriction, decreased visual acuity, color vision defects, and an afferent pupillary defect should alert you the possibility of orbital extension and immediate work up should ensue.

108 Surgical Treatment of Sinusitis

Steven David Schaefer

108.1 Introduction

Over the past century or more, surgical procedures to treat sinusitis and related diseases evolved. The various procedures can be roughly divided into those that entered the affected sinus through face and those that approached the paranasal sinuses through the nose. The former (open) techniques progressed over a century to become well standardized by the 1950s, and although less often employed today, they remain useful in selected patients. The latter (intranasal, referred to as endonasal in Europe) techniques were more problematic in their early development and required modern optical telescopes or endoscopes to visualize and operate on all four sinuses through the nose. The popularization of these less invasive techniques awaited not only the development of surgical endoscopes, but also a convergence of our understanding of sinus anatomy, pathophysiology, and function.

108.2 Open Surgical Techniques

108.2.1 Maxillary Sinus

Before the popularization of endoscopic intranasal sinus surgery, the Caldwell-Luc operation was the most common procedure for the treatment of maxillary sinus disease. This procedure was indicated to treat chronic infection refractory to medical treatment, cysts or polyps within the maxillary sinus, dental fistulas, and fractures of the maxilla; it was also used for decompression or removal of the floor of the orbit in the treatment of thyroid eye disease and biopsy of neoplasm. The procedure consists of two elements: fenestration of the canine fossa and creation of the nasal antral window (antroostomy). The procedure begins with an incision beneath the upper lip in the gingivobuccal sulcus above the roots of the teeth. The soft tissue over the maxilla is elevated in the subperiosteal plane to expose and preserve the infraorbital nerve. The anterior wall of the maxillary sinus is opened (fenestrated) with various types of

surgical burs, bone-cutting forceps, or osteotomes (□ Fig. 108.1). Cysts, polyps, tumors, or diseased mucous membrane is then removed through the fenestration. Next, an approximately 1 x 2-cm rectangle of bone beneath the inferior turbinate is removed to create a nasoantral window. The procedure is completed with reapproximation of the soft tissue over the anterior maxillary sinus wall with suture.

108.2.2 Frontal Sinus

Chronic frontal sinusitis and polyps, mucoceles, and tumors within the frontal sinus have been addressed with multiple approaches to the frontal sinus (□ Fig. 108.2). Perhaps the first form of frontal sinus surgery was trephination, a fenestration of the anterior wall of the sinus through a skin incision over the brow. Because in the preantibiotic era the treatment of osteomyelitis often required the débridement of infected bone, the next procedure in the evolution of the treatment of infections within the frontal sinus was the Riedel operation. In 1898, Riedel described ablation of the frontal sinus by removal of its anterior wall and floor (□ Fig. 108.3). This permitted wide access through the forehead skin but left a significant cosmetic deformity. Killian modified the Riedel procedure in 1904 by preserving a 10-mm-wide bridge of bone at the supraorbital rim, which resulted in less disfiguration than the Riedel operation. In the same year, Hoffman described opening the anterior wall of the frontal sinus while preserving its blood supply via the periosteum of the frontal bone, a procedure later termed osteoplastic frontal sinusotomy. In 1914, Lothrop described a combined intranasal and external procedure that resulted in removal of the floor of the entire frontal sinus, as well as removal of the adjacent nasal septum and intra-frontal sinus septum. This procedure would await the advent of the surgical microscope and endoscopes to be repopularized as an intranasal frontal sinus drainage procedure. Using an external approach to remove the cells of the ethmoid sinus and the middle turbinate, Lynch in 1920 described removal of the floor of the frontal sinus. Over

Fig. 108.1 Caldwell-Luc procedure. (a) Buccal-gingival incision to expose the anterior face of the maxilla. (b) The anterior face of the maxillary sinus is exposed, and a surgical chisel is used to create an opening into the maxillary sinus. (c) A generous fenestration allows adequate exposure for the removal of mucosa of the right maxillary sinus.

Fig. 108.2 Progression of frontal sinus surgical procedures during the past century. In the early 1900s, ablation, or removal of the anterior, the posterior, or both walls of the frontal sinus, was the most common procedure for the treatment of chronic frontal sinusitis. Trephination was a common form of surgical treatment since the time of the ancient Egyptians. In 1904, Hoffman introduced the osteoplastic frontal sinusotomy, which consisted of opening and replacing the anterior wall of the frontal sinus as a means to access this sinus for treatment. The procedure would later be reintroduced in the 1950s, and for many years it served as the most frequent form of frontal sinusotomy. In 1914, Howard Lothrop proposed draining the frontal sinus into the nose by removing the entire floor of this sinus and the adjacent nasal septum. Beginning in the 1980s, a series of intranasal microscopic and endoscopic frontal sinusotomies was popularized in Europe and later in the United States.

Fig. 108.3 Patient several days after removal of the anterior wall of frontal sinus, or ablation procedure of Riedel, for osteomyelitis of the frontal bone.

the next 60 years, several unsuccessful modifications to the procedure were made in order to avoid collapse of the soft tissue of the adjacent orbit into the drainage pathway into the nose. Although variations of the above procedures are still occasionally used, the next major advance in frontal sinus surgery was to combine the osteoplastic frontal sinusotomy with obliteration of the frontal sinus with fat, as described by Goodale and Montgomery in the 1950s. The procedure uses Hoffman's exposure of the frontal sinus via a vascularized anterior frontal sinus bone–periosteal flap to carefully remove all normal and diseased mucous membrane within the sinus, repair fractures, or remove tumors (□ Fig. 108.4). The sinus is then obliterated with abdominal fat, which remains partially viable for many years. When performed correctly, this operation has consistently yielded the best long-term results and has been referred to as the gold standard in frontal sinus surgery. However, the advent of optical endoscopes and various intranasal frontal sinus procedures has significantly reduced the use of the osteoplastic frontal sinusotomy.

108.3 Intranasal (Endonasal) Techniques

In the United States, Harris Mosher was an early proponent of intranasal sinus surgery. His anatomical studies of the ethmoid and sphenoid sinuses formed the basis for intranasal ethmoidectomy and sphenoidotomy. Others, such as Howard Lothrop, reported draining the frontal sinus into the nose via

Fig. 108.4 Osteoplastic frontal sinusotomy via a coronal forehead skin incision, as viewed by the surgeon at the head of the table. The outer periosteum (white arrow), or pericranium, of the frontal bone remains intact, with the anterior wall of the frontal sinus serving as its blood supply. Thus, the procedure is referred to as an osteoplastic frontal sinusotomy. The osteotomy, or incision into the anterior wall of the frontal sinus, is outlined (black arrows), and the anterior wall is incised with fine-cutting burs or saws.

the combination of intranasal removal of the floor of this sinus and an external opening through the brow, or sinusotomy (□ Fig. 108.5). Because these are difficult procedures to perform with only a headlight and potentially more dangerous than the open approaches, early proponents would later question the wisdom of such surgery. By 1929, Mosher described intranasal ethmoidectomy as “one of the easiest operations with which to kill a patient.” Over the next 40 years, relatively few surgeons used intranasal approaches to the sinuses. However, by the early 1980s, Wigand in Germany and Messerklinger in Austria had modified existing intranasal sinus procedures so that they could be performed safely, although not necessarily easily, with the use of endoscopes. Wigand used a headlight and an endoscope to begin his surgery with resection of the middle turbinate to gain exposure to the posterior ethmoid cells and face of the sphenoid sinus. Next, he cannulated the sphenoid sinus ostium, removed the anterior wall of the sphenoid sinus, and performed a total ethmoidectomy. This approach permitted surgery to be performed with the illumination and magnification of endoscopes while the ethmoidectomy was begun posteriorly and the retrograde dissection of the ethmoid cells was directed away from the skull base. Given the statements of Mosher and others, surgeons were well aware of the risk for intracranial injuries during intranasal sinus surgery.

In contrast to this procedure, Messerklinger and Stammberger used their studies of the physiology of the sinuses to apply the optical telescope to modify the anterior ethmoidectomy of Halle. This procedure has the advantage of selectively limiting surgery to the pathologic sinuses. In an anterior-to-posterior approach, the surgery begins with anterior ethmoidectomy and is extended posteriorly depending on the diseased sinuses. The

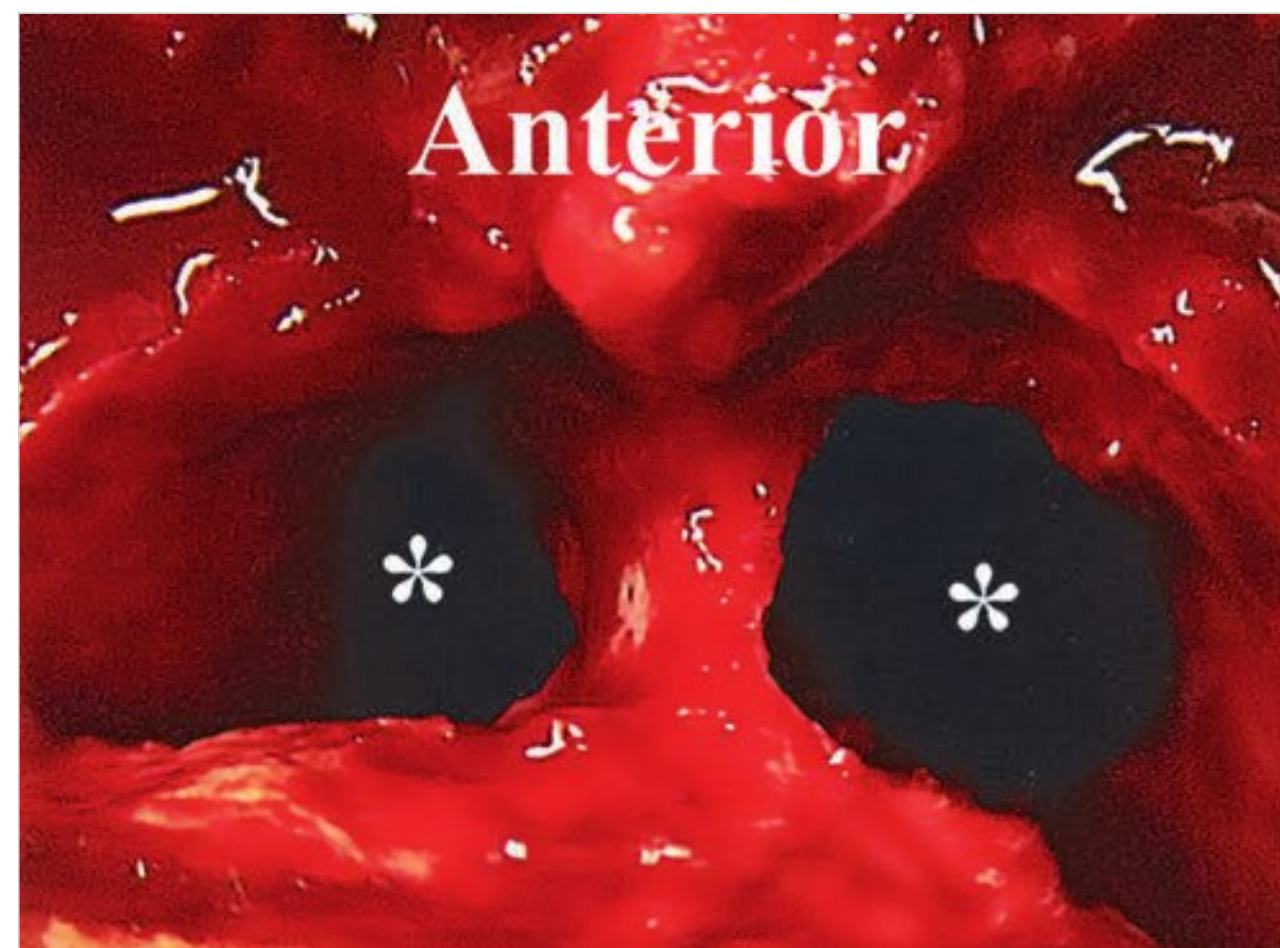

Fig. 108.5 Transfrontal drainage via an osteoplastic frontal sinusotomy into the nose. This so-called marsupialization of the frontal sinus into the nose shares the elements essential to the Lothrop or type III frontal sinusotomy. That is, the floor of the frontal sinus, the intrasinus septum, and the adjacent nasal septum are removed to create a maximal sinusotomy (asterisks).

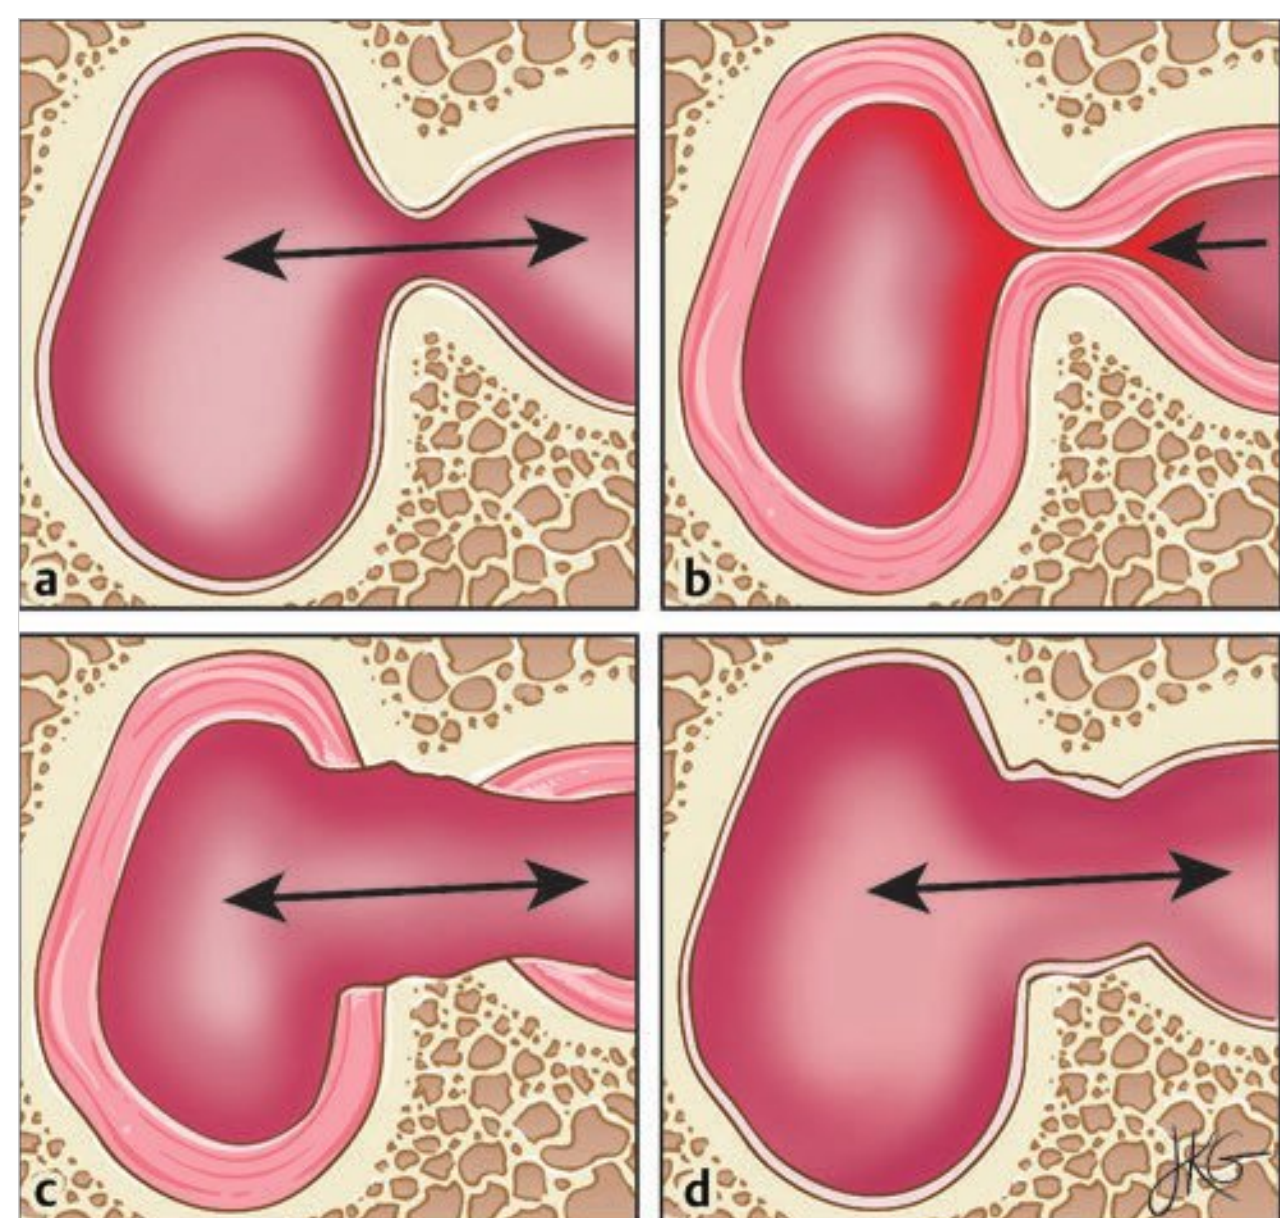

Fig. 108.6 Normal sinus function can be restored following surgical removal of an obstruction to normal ventilation of the sinuses. (a) Normal egress of mucus and ventilation of air into a sinus. (b) With obstruction of this pathway, the mucous membrane becomes hypertrophic, and sinusitis then develops as a result of stasis of secretions within the sinus. (c) The selective removal of the obstructing site by enlarging the ostium of a sinus restores normal ventilation and mucociliary flow. (d) Resolution of the mucous membrane hypertrophy and return of normal sinus function.

disadvantage of such a technique is the anterograde dissection of the ethmoid cells and potential penetration of the skull base.

Building upon the concepts of Messerklinger, Wigand, and Stammberger, Kennedy offered the concept of “functional endoscopic surgery” (□ Fig. 108.6). Such surgery recognizes the

Fig. 108.7 (a) Cadaver section showing removal of the inferior two-thirds of the ethmoid cells and unciniate process (outlined by white lines) in the anterior-to-posterior approach during a combined approach to endoscopic intranasal ethmoidectomy. FR, frontal recess; SER, sphenothmoid recess; SS, sphenoid sinus. (b) Sagittal cadaver section shows the retrograde, or posterior-to-anterior, approach to complete the removal of the remaining superior ethmoid cells. Removal of the superior unciniate process is shown in blue. FR, frontal recess; SER, sphenothmoid recess; SS, sphenoid sinus.

principle of the “potential for reestablishing sinus drainage and mucosal recovery” through correction of the obstructing sinus ostium or isthmus, and removal of devitalized mucous membrane or bone. The goals of the aforementioned surgeons for the treatment of extensive sinusitis or polyposis over time became the same, and differed only in regard to such elements as preservation of the middle turbinate and dissection of the ethmoid labyrinth. The combination of these approaches seeks to bring together the salient features of the anterior-to-posterior and posterior-to-anterior approaches, while observing the concept of functional endoscopic sinus surgery (FESS; □ Fig. 108.7).

The basic elements of modern intranasal sinus surgery incorporate a disease- and anatomy-oriented surgical approach, preserving sinus anatomy and using anatomical relationships to

conform to fundamental surgical principles. A disease-oriented, or functional, approach to sinus surgery assumes that in many patients, chronic sinusitis develops from medically irreversible obstruction of the outflow tract of the sinuses. Such obstruction occurs at the narrowest point of communication of a sinus with the nasal cavity, often the infundibulum or ostium of the involved sinus. Surgery is directed toward removing such restrictions to reestablish normal mucociliary flow.

The first step is exposure of the contents of the lateral nasal wall—that is, the maxillary and ethmoid sinuses. A 0-degree endoscope is used to identify and remove the unciniate process (□ Fig. 108.8). Complete uncinectomy is necessary to begin the anterior-to-posterior exenteration of the inferior ethmoid cells. This permits visualization of the more lateral ethmoid cells and the lamina papyracea. The lamina papyracea should be regarded as a landmark and is exposed through exenteration of the ethmoid cells. The complete removal of the unciniate process should expose the natural ostium of the maxillary sinus (□ Fig. 108.9). If the ostium cannot be discerned, the unciniate process or polyps are obstructing visualization and should be removed. If the ostium appears normal and there is no intrinsic maxillary sinus disease, it is left intact. If the ostium is small or stenotic, it is inferiorly or posteriorly enlarged with either a débrider or forceps. Disease within the sinus is removed with angulated double-spoon or giraffe forceps.

Next, the inferoanterior wall of the bulla ethmoidalis, or second basal lamella, is removed with microcuret, forceps, or more recently surgical débrider. If disease is limited to the anterior ethmoid sinus, individual cells are exenterated to the basal lamella of the middle turbinate (□ Fig. 108.10). The superior–anterior ethmoid cells are then removed in retrograde fashion with microcuret, débrider, or forceps under 30- or 45-degree endoscope visualization. If disease involves the entire ethmoid sinus, the exenteration continues posteriorly to the face of the sphenoid sinus. When indicated by disease, the anterior wall of the sphenoid is removed. Although the sphenoid sinus can be entered medial or lateral to the middle turbinate, we prefer identifying the ostium just inferior to the superior turbinate. The sinusotomy is enlarged with bone-cutting forceps. With the use of a 30- or 45-degree endoscope to visualize the skull base, the residual superior ethmoid cells are exenterated in a posterior-to-anterior or retrograde dissection. Superior cells are removed by grasping or curetting in a pulling motion rather than by directing instruments toward the skull base (□ Fig. 108.11). This motion, as previously noted, reflects translation of the wisdom of Mosher into modern surgical technique to permit safe intranasal sinus surgery. In the absence of frontal sinusitis, the anterior boundary of the procedure is the ethmoid infundibulum.

In the presence of frontal sinusitis, the location of the obstruction to the outflow tract of the frontal sinus and the presence of intrinsic disease or anatomical variations determine the type of opening or sinusotomy performed. These variations in intranasal frontal sinus surgery are classified as types I, IIa, IIb, and III frontal sinusotomy (Draf types I through III) procedures. The complexity of these procedures results from the developmental competition of the unciniate process and ethmoid cells extending into frontal recess to form the outflow tract of the sinus. A type I sinusotomy removes the anterior ethmoid cells obstructing the outflow tract of the frontal sinus within the frontal recess. The frontal recess is defined as a space bounded

Fig. 108.8 (a) Coronal computed tomographic scan shows relevant landmarks near the right ostiomeatal complex. asterisk, uncinata process; es, ethmoid air cell; im, inferior meatus; it, inferior turbinate; ms, maxillary sinus; mt, middle turbinate; s, septum. (b) Intraoperative view of the right middle turbinate (held medially by the curved probe, exposing the uncinata process). The uncinata process forms the anterior and medial boundaries of the ostiomeatal complex and must be completely removed to fully visualize the natural ostium of the maxillary sinus, the lateral ethmoid cells, and the frontal recess cells. up, uncinata process.

anteriorly by the pneumatization of the lacrimal bone, posteriorly by the anterior ethmoidal artery, medially by the middle turbinate, and laterally by the lateral nasal wall. A type IIa frontal sinusotomy includes removal of the frontal recess cells and the floor of the frontal sinus bordered by the middle turbinate and lateral nasal wall. The type IIb sinusotomy differs from the type IIa procedure in that it involves total removal of the floor of the sinus. The type III sinusotomy is the most extensive procedure and has three elements: removal of the adjacent superior nasal septum, removal of the entire floor of the frontal sinus, and removal of the intra-frontal sinus septum (□ Fig. 108.12). The resulting sinusotomy permits maximal drainage of this sinus into the nose. This procedure is also known as the modified Lothrop procedure because it encompasses the elements of the original surgery described in 1914. In recent years, the type III sinusotomy has been increasingly employed for the removal of benign frontal sinus tumors and as a portal to the anterior cranial fossa for the resection of skull base tumors.

108.4 Complications

The most serious complications in sinus surgery involve the orbit and cranium. Both types of complications may be minimized, but not necessarily completely avoided, by careful preoperative evaluation of the patient and the patient's imaging, and by meticulous surgical technique. The preoperative evaluation should include any history of prior sinus surgeries. In such cases, one should inquire about the postoperative course. Surprisingly, patients may not volunteer that after surgery they developed a fever and stiff neck and were admitted to the hospital for intravenous antibiotics, or they may wonder why they had clear fluid dripping from their nose. In both examples, the integrity of the anterior cranial fossa floor was breached. The following should be identified on preoperative imaging: (1) The depth of the olfactory fossa and the plane of the lateral lamella of the cribriform plate. The lateral boundary of the olfactory

fossa is the lateral lamella of the cribriform plate. The deeper the olfactory fossa, the more vertical the lateral lamella becomes. As the lateral lamella becomes more vertical, the likelihood of bony dehiscence of the lamella increases, as does the risk for intracranial injury. (2) The vertical height of the maxillary sinus relative to the vertical height of the ethmoid sinus (□ Fig. 108.13). In most individuals, the ratio of the vertical height of the ethmoid to the vertical height of the maxillary sinus is 1:2. As that ratio declines to less than 1:2, the “vertically shorter” ethmoid sinus results in less vertical volume or space. Consequently, the working distance within the ethmoid sinus between the floor and the roof is reduced, and the incidence of intracranial injury increases. (3) Bony dehiscence of the carotid artery and optic nerve within the sphenoid sinus. As the sphenoid sinus pneumatizes into the sphenoid bone, there may be little or no bone surrounding the medial borders of both the internal carotid artery and the optic nerve. (4) Expansion of the posterior ethmoid cells into the sphenoid bone. As extramural ethmoid cells pneumatize the sphenoid bone, they present significant surgical hazards. First, these cells may expose the medial surface of the optic nerve, forming what is referred to as an Onodi cell. When this variation is present, the optic nerve will appear as a tubular structure coursing through the lateral wall of the Onodi cell and therefore should be avoided. Extramural ethmoid cells may also expand into the central portion of the sphenoid bone, giving the appearance on coronal computed tomographic (CT) scans of a horizontal septum dividing the sphenoid into a superior and an inferior sinus. At sphenoidotomy, surgeons may erroneously believe that they are within the sphenoid sinus, which is inferior to the extramural ethmoid cell. (5) The posterior–inferior slope of the anterior cranial fossa floor. As a generalization, the anterior cranial fossa floor slopes 15 degrees posteroinferiorly. However, sagittal CT scans reveal that some individuals have either a nearly horizontal floor or an inferior expansion into the roof of the ethmoid sinus. (6) The position and presence of bony dehiscence of the anterior and

Fig. 108.12 (a) Type I intranasal frontal sinusotomy. This procedure consists of removing the anterior ethmoid cells within the frontal recess that are obstructing the outflow tract of the frontal sinus. Note that the floor of the frontal sinus is not altered in this procedure. asterisks, ethmoid sinus; FS, frontal sinus; LT, lower turbinate; MT, middle turbinate; MS, maxillary sinus; ST, superior turbinate. (b) Type IIa frontal sinusotomy. Unlike in a type I frontal sinusotomy, the floor of the frontal sinus between the lamina papyracea and the middle turbinate is removed. (c) The elements of a type III frontal sinusotomy are removal of the entire floor of both frontal sinuses; the intrasinus septum, which divides the frontal sinus into a left and a right cavity; and the upper nasal septum. (d) Coronal computed tomographic (CT) scan of patient with bilateral frontal sinusitis (1) secondary to extension of ethmoid cells (2), also described previously as frontal cells, into the floor of the frontal sinus. These ethmoid cells literally balloon into the floor of the frontal sinus and are visible because of the contrast between the mucus in the frontal and ethmoid sinuses (1) and the air within the ethmoid or frontal cells (3). (e) Intraoperative CT reconstruction using computer-assisted image-guided surgery. In this image, the end of a probe placed within the right frontal sinus is identified at the convergence of the vertical and horizontal lines. To restore drainage of the frontal sinus, the floor of the sinus (1) is removed, as are the intrasinus septum (2) and the upper nasal septum (3).

Fig. 108.13 Coronal computed tomographic scan illustrating the vertical relationship of the ethmoid and maxillary sinuses to each other. The potential for intracranial injury increases in those individuals with a relatively “short” vertical height of the ethmoid sinus (a) compared with the height of the maxillary sinus (b).

posterior ethmoidal arteries. As the ethmoid cells expand into the ethmoid bone during fetal and early postnatal development, these vessels are skeletonized, becoming more vulnerable to injury during surgery. (7) Bony dehiscence of the lamina papyracea. The bony integrity of the lamina varies between individuals, and the lack of an intact lamina makes the orbit more vulnerable to surgical injury. Such injuries are even more likely when surgical débriders are used because the periorbita, orbital fat, and muscles can be aspirated into the débrider.

At surgery, several routine precautions or practices should be employed, including the following: (1) Minimizing intraoperative hemorrhage. Increased intraoperative bleeding increases the risk for complications. Reducing hemorrhage begins several minutes before the actual surgery with the appropriate use of vasoconstrictive agents and the infiltration of all surgical sites with a combination vasoconstrictive–anesthetic agent, such as 1% lidocaine with 1:100,000 epinephrine. (2) Avoiding myopic surgery. In using endoscopes, the novice surgeon tends to place the optic too close to site of surgery and in doing so loses perspective and anatomical awareness of important landmarks. The endoscope is best kept at a slight distance from the point of surgery and brought closer to the site of interest as more magnification is required. (3) Avoiding directing instruments into the skull base. As discussed previously in the section on intranasal ethmoidectomy, as surgery proceeds anteriorly to posteriorly within the nose, instruments must be rotated inferiorly rather than advanced superiorly. This observation is the basis for combining an anterior-to-posterior approach for removal of the majority of the ethmoid cells with a posterior-to-anterior (retrograde) dissection of the remaining superior ethmoid labyrinth. In the latter element of the procedure, instruments are directed away from rather than into the skull base. (4) Controlling bleeding to maintain visualization. Too often, the surgeon may attempt to continue surgery when bleeding obscures the surgical field. In such cases, the nose should be packed with cottonoids and the sites of bleeding cauterized. If bleeding is still problematic, pack that side of the nose and work on the

other side. If this fails, discontinuing surgery is the wisest course.

Intracranial injury is uncommon and variable, and it requires immediate attention. Because the roof of the ethmoid sinus is the floor of the anterior cranial fossa, a violation of this bone is likely to cause cerebrospinal fluid rhinorrhea. Although many methods of repairing such defects have been described, we strongly recommend the placement of fat through the defect and into the subarachnoid space. One continuous piece of fat should be used, with approximately three-quarters of the fat placed intracranially and one-quarter within the nose. This “dumbbell”-shaped fat graft should immediately stop the rhinorrhea. A second graft of either mucous membrane or an alloplastic material may be placed intranasally to approximate roof of the ethmoid and held in place with tissue glue and/or absorbable packing. Postoperatively, the patient should be instructed to avoid for several weeks nose blowing and any other activity that increases intracranial pressure. Perioperative antibiotics at the time of injury are appropriate, whereas the sustained postoperative use of antibiotics should be based on the likelihood of overt wound contamination and the virulence of the sinusitis. Following such injuries, most patients do well provided there is no residual intracranial communication. In contrast, the worst outcomes follow vascular injuries; subarachnoid hemorrhage causes intense vasoconstriction of the cerebral vasculature, and even when the site of hemorrhage is controlled, the patient may have a poor outcome.

Orbital injuries vary from hemorrhage to direct trauma to the eye, extraocular muscles, or optic nerve. Hemorrhage may result from a transected ethmoidal artery bleeding into the orbit or injury to the orbital vasculature. Because the orbit is a closed space bounded anteriorly by its periosteum (septum orbitale) and the condensations of this fibrous tissue (the medial and lateral canthal tendons) that fix the septum to the bony orbit, hemorrhage rapidly compromises vision. Increasing pressure within the orbit and eye requires immediate attention and consultation with ophthalmology. As a first step, all packing within the nose should be removed. If ophthalmologic help is not immediately available, a lateral canthotomy and transection of the lateral canthal tendon at its insertion on the orbital rim should be performed. This procedure permits the eyeball to be displaced anteriorly, resulting in additional volume within the orbit and lower pressure. If intraorbital bleeding continues, then the orbit should be explored. Injuries to the extraocular muscles, eye, or optic nerve should all be treated in consultation with an ophthalmologist.

108.5 Roundsmanship

- Frontal sinus surgery has evolved over the past century along two different approaches: drainage of the sinus into the nose and obliteration or ablation of the sinus. In the past 20 years, intranasal endoscopic approaches to the frontal sinus have reduced, but not eliminated, the need for external procedures.
- Intranasal sinus surgery is common today, but historically it was uncommonly used in the United States because of the potentially high complication rate. With the advent of surgical endoscopes to enhance illumination and visualization of the nose and sinuses, and improved techniques.

- FESS (functional endoscopic sinus surgery) is a concept, not a procedure, such as ethmoidectomy. The concept is based on the potential recovery of hypertrophic or chronically infected sinus mucous membrane following the restoration of normal sinus aeration and mucociliary transport.

109 Tumors of the Nose and Paranasal Sinuses

Ameet R. Kamat and Steven David Schaefer

109.1 Introduction

Benign and malignant tumors of the nose and sinuses arise from the uniquely ectoderm-derived epithelium known as schneiderian epithelium, in recognition of the contributions of Victor Conrad Schneider to our understanding of this organ system. Schneiderian epithelium arises from the primitive nasal sacs that invaginate to form the nasal placodes and, subsequently, the nose and sinuses. In contrast, the laryngobronchial tree forms from endoderm or foregut-derived epithelium. Within the lining the nose and sinuses, mucoserous glands form by an interaction between the ectoderm and mesoderm. This complex embryogenesis gives rise to two types of neoplasia: that resulting from metaplastic epithelium, forming squamous cell tumors, and that originating from mucoserous epithelium.

109.2 Incidence of Disease

A recent Danish review of the various sinus and nasal cavity tumors detailed their frequency (□ Table 109.1).

109.3 The Disease Process

109.3.1 Etiology and Pathogenesis

Generally, benign and malignant tumors of the sinus and nasal cavities share many initial symptoms, depending on their origin, anatomical site, and rate of growth. Tumors arising within the nose or involving its lateral wall can present early with epistaxis or nasal airway obstruction. Aside from the benign, much more common inflammatory nasal polyps, papillomas arise from the nasal and rarely from the sinus mucous membrane. Because these neoplastic growths develop from the schneiderian mucous membrane, arising nearly uniformly from either the lateral nasal wall or septum, appear either fungiform or sessile, and have a variable behavior, they are also designated schneiderian papillomas. Histologically, the papillomas appear

either papillary and exophytic, or exhibit an inverting epithelial growth into the underlying stroma. This variant of schneiderian papillomas, also commonly referred to as an inverting papilloma, is more frequently associated with the lateral nasal wall and sinuses. On nasal endoscopy, papillomas are significantly more solid than inflammatory polyps and have irregular surfaces.

109.3.2 Natural History and Progression

Relatively few schneiderian papillomas arise directly from the sinus cavities; rather, they extend into the sinuses. Patients may develop proptosis or diplopia as the papilloma continues to grow, expands into the bony orbit, and compresses, without infiltrating, the orbital periosteum or periorbita. Fewer than 5% of schneiderian papillomas are associated with squamous cell carcinomas. It remains unclear if such carcinomas arise within anaplastic changes in existing papillomas, occupy a cavity that had preexisting papillomas, or begin within foci of carcinoma in existing papillomas. Whatever the origin of these epithelial carcinomas, their clinical course rapidly departs from that of a mass obstructing the sinus or nasal cavities; they have the potential to cause epistaxis and directly extend into adjacent structures, invading the orbit, brain, facial soft tissues, muscles, and nerves.

Progressive invasion leads to impaired vision, trigeminal nerve sensory and motor changes, and potentially altered mentation as the tumors invade the brain; regional and distant metastasis may also occur.

109.4 Medical Evaluation

109.4.1 Imaging

Computed tomography (CT) and magnetic resonance (MR) imaging are complementary examinations to evaluate both benign and malignant tumors of the nasal and sinus cavities (□ Fig. 109.1 and □ Fig. 109.2). CT remains the diagnostic test of choice for defining changes within the facial skeleton as tumors erode or invade bone. The rate of growth of a tumor may be inferred from the radiographic findings. As slowly growing tumors compress bone, the bone is remodeled and forms a thin shell around the tumor. Although this finding may suggest benign disease, a slowly growing malignant tumor may have a similar radiographic appearance. More typically, malignant tumors grow rapidly and destroy bone as they invade the facial skeleton. MR imaging better delineates tumors and dramatically reveals differences within the density of soft tissue. CT may show only an opacified sinus, whereas MR imaging reveals the whole range of possible reasons for the opacification. During tumor evaluation, the outflow tract of the sinus may be obstructed by the neoplasm and the sinus cavity filled with mucus. MR imaging can define the extent of disease and allow treatment planning. At the skull base, CT and MR imaging are

Table 109.1 Distribution of sinus and nasal cavity tumors

Tumor type	Percentage of cases
Squamous cell carcinoma	55%
Adenocarcinoma	28.5%
Adenoid cystic carcinoma	5%
Undifferentiated carcinoma	4.5%
Mucoepidermoid carcinoma	2.5%
Transitional cell carcinoma	1.7%
Small cell carcinoma	1.2%
Carcinoma, not otherwise specified	0.8%

Fig. 109.1 (a) Coronal computed tomographic (CT) scan of a patient with esthesioneuroblastoma of the right ethmoid sinus (arrow). (b) Coronal magnetic resonance image. Superior to the arrow, the image shows the intracranial extent of tumor, which is much less obvious on the CT scan.

Fig. 109.2 (a) Positron emission tomography (PET)-computed tomography (CT) of a 55-year-old woman with adenoid cystic carcinoma arising in the right maxillary sinus and extending through the ipsilateral orbit to the dura of the right middle fossa. On the left, axial CT scans through the mid plane of the tumor (arrow) show excessive erosion of bone. At the upper right, PET-CT shows moderate uptake of the glucose tagged isotope, known as avidity and quantified by the standard uptake value (SUV), reflecting metabolic activity of the tumor. At the lower right, PET-CT shows tumor only at the primary site. (b) Axial contrast-enhanced fat-suppressed T1 magnetic resonance (MR) image of the same patient at the mid plane of the right maxillary sinus emphasizes the soft-tissue elements of the tumor and its invasion of surrounding structures. With this MR imaging protocol, the tumor signal is best separated from the surrounding tissue, permitting maximal identification of neoplasia. (c) Intraoperative photograph of patient showing craniofacial resection of tumor. Arrow indicates resection of the roof of the right ethmoid sinus, which forms part of the floor of the right anterior cranial fossa. A pericranial flap, which is derived from the superficial periosteum of the frontal bone and adjacent soft tissue, is routinely used to reconstruct the floor of the anterior cranial fossa. PF, pericranial flap.

complementary, showing bone, dural, and brain involvement. Recently, positron emission tomography (PET) has been combined with CT to investigate unknown primary neoplasms, differentiate infection from benign or malignant disease, stage known tumors by searching for regional and distant metastasis, and monitor patients after treatment for potential residual or recurrent disease.

109.4.2 Differential Diagnosis

A second group of nonepidermoid epithelial neoplasms arise from either the surface epithelium or any structure within its ducts. These tumors comprise salivary and nonsalivary histologic types. Examples of the former are benign neoplasms such as pleomorphic adenomas and oncocytomas and malignant

tumors such as adenoid cystic, mucoepidermoid, acinic cell, and ductal carcinomas. Nonsalivary neoplasms include various types of adenocarcinomas, olfactory neuroblastomas, and adenosquamous carcinomas. Another malignant neoplasm originates within the melanocytes normally present within the mucosa and submucosa of the nasal and sinus cavities. The development of these mucosal melanomas is often heralded by epistaxis; they appear as black–brown pigmented lesions and may initially seem to be confined to an isolated site. However, distant metastasis is frequently later evident, and 5-year survival is rare. Olfactory neuroblastomas, also known as esthesioneuroblastomas, are derived from olfactory epithelium. These malignant tumors often present with epistaxis and nasal obstruction, and they may be confined to the nose or involve the anterior or middle cranial fossa (see □ Fig. 109.1).

109.5 Disease Staging

Sinus tumors are staged with the TNM (tumor node metastasis) classification and are grouped into maxillary sinus tumors and tumors involving the ethmoid sinuses and nasal cavity.

A T1 lesion of the maxillary sinus is limited to the mucosa of the sinus itself, with no bony involvement. T2 lesions include those with bony involvement of the hard palate and/or middle meatus, without extension to the posterior wall of the sinus or pterygoid plates. A tumor that involves the posterior wall of the sinus, subcutaneous tissues, floor or medial wall of the orbit, pterygoid fossa, or ethmoid sinuses is considered a T3 lesion. A tumor with any invasion of the anterior orbit, skin of the cheek, pterygoid plates, infratemporal fossa, cribriform plate, or sphenoid or frontal sinuses is classified as a T4a tumor. T4b lesions may invade the orbital apex, dura, brain, or middle fossa; involve any cranial nerve other than cranial nerve V₂; or extend to the nasopharynx or clivus.

Ethmoid sinus and nasal cavity cancers are graded similarly, with some differences based on anatomy. T1 lesions are restricted to one subsite (nasal cavity: vestibule, floor, lateral wall, septum; ethmoid sinus: left or right), with or without bony invasion. T2 tumors involve two subsites in a single region or extend into an adjacent region within the nasoethmoid complex, regardless of bony invasion. T3 cancers extend to the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate. T4a tumors can invade the anterior orbital compartment, skin of the nose or cheek, pterygoid plates, or sphenoid or frontal sinuses or can have minimal extension into the anterior fossa. T4b lesions, similar to T4b lesions of the maxillary sinus, may invade the orbital apex, dura, brain, middle fossa, cranial nerves other than the maxillary division of the trigeminal nerve, or the nasopharynx or clivus.

The grading of nodal involvement is the same for both areas. Involvement of a single, ipsilateral node smaller than 3 cm is considered N1 disease. N2a nodal disease indicates involvement of a single, ipsilateral node 3 to 6 cm in size. N2b disease is involvement of bilateral or contralateral nodes smaller than 6 cm, while N2c disease is involvement of at least one lymph node larger than 6 cm.

Staging is done uniformly for both maxillary sinus and nasoethmoid malignancy. T1 lesions without nodal or distant metastasis are stage I, and similarly, T2 lesions without nodal involvement or metastasis are considered stage II disease. Stage

III includes any T3 lesion without nodal or distant metastasis and any T1–T3 lesion with N1 neck disease. Stage IVa includes any T4a lesion or any T1–T3 lesion with N2 nodal involvement, and stage IVb indicates any T4b lesion. Any distant metastasis must be stage IVc disease.

109.6 Surgical Treatment

Given the greater prevalence of maxillary sinus carcinomas than of other paranasal sinus carcinomas, it is understandable that treatment for the past century or more has focused on this sinus. Early attempts to remove the maxilla surgically proved difficult, and surgery was later combined with (and in some cases replaced by) radiation therapy. Because of the propensity of ethmoid, frontal, and sphenoid carcinomas to involve the eyes and cranial cavity and the relative rarity of these tumors, the concept of craniofacial surgery and multidisciplinary therapy has been developed. More recently, the experience gained from endoscopic intranasal sinus surgery has made it possible to perform less invasive surgery in carefully selected patients. Radiation and chemotherapy are often now applied pre- or postoperatively to permit the possibility of preserving important organs, such as the eyes, and improving patient survival. In this chapter, a range of oncologic procedures are presented.

109.6.1 Maxillectomy

This procedure, an en bloc resection of the maxilla, is used primarily for the surgical treatment of malignant tumors arising within or substantially involving the maxillary sinus. In its classic form, a lateral facial skin–muscle flap is developed immediately superficial to the maxilla and adjacent facial skeleton. The most common flap uses a Weber-Fergusson incision, which begins lateral to the orbit, runs horizontally immediately beneath the ipsilateral eyelid, and then progresses inferiorly in the nasofacial crease and around the nasal ala to the upper lip philtrum (□ Fig. 109.3). The upper lip is then divided by the incision, which is further carried into the labial and gingival–buccal sulcus. After exposure of the maxilla, osteotomies are made through the malar eminence to transect the zygoma and frontal bone. The orbital floor and its rim are incised and form the superior aspect of the resection unless the eye or skull is compromised by tumor. The hard palate is divided in the midline (with preservation of the soft palate), and the ethmoid sinus is separated from the maxilla. The final osteotomy is transection of the pterygoid plates, which are included in the surgical resection.

Medial Maxillectomy

As the next step in the evolution of surgery for maxillary sinus neoplasm, medial maxillectomy has advanced significantly in the past 40 years. As initially described, a Weber-Fergusson incision was used to expose the maxilla, and the medial maxillary sinus and lateral nasal wall were removed for low-grade malignancies and benign neoplasms of this site (□ Fig. 109.4). The next modification of maxillectomy was exposure of the maxilla in selected tumors via midface degloving, which involves separating the facial soft tissue overlying the maxilla through circum-malar, gingivolabial, and gingivobuccal incisions. The soft

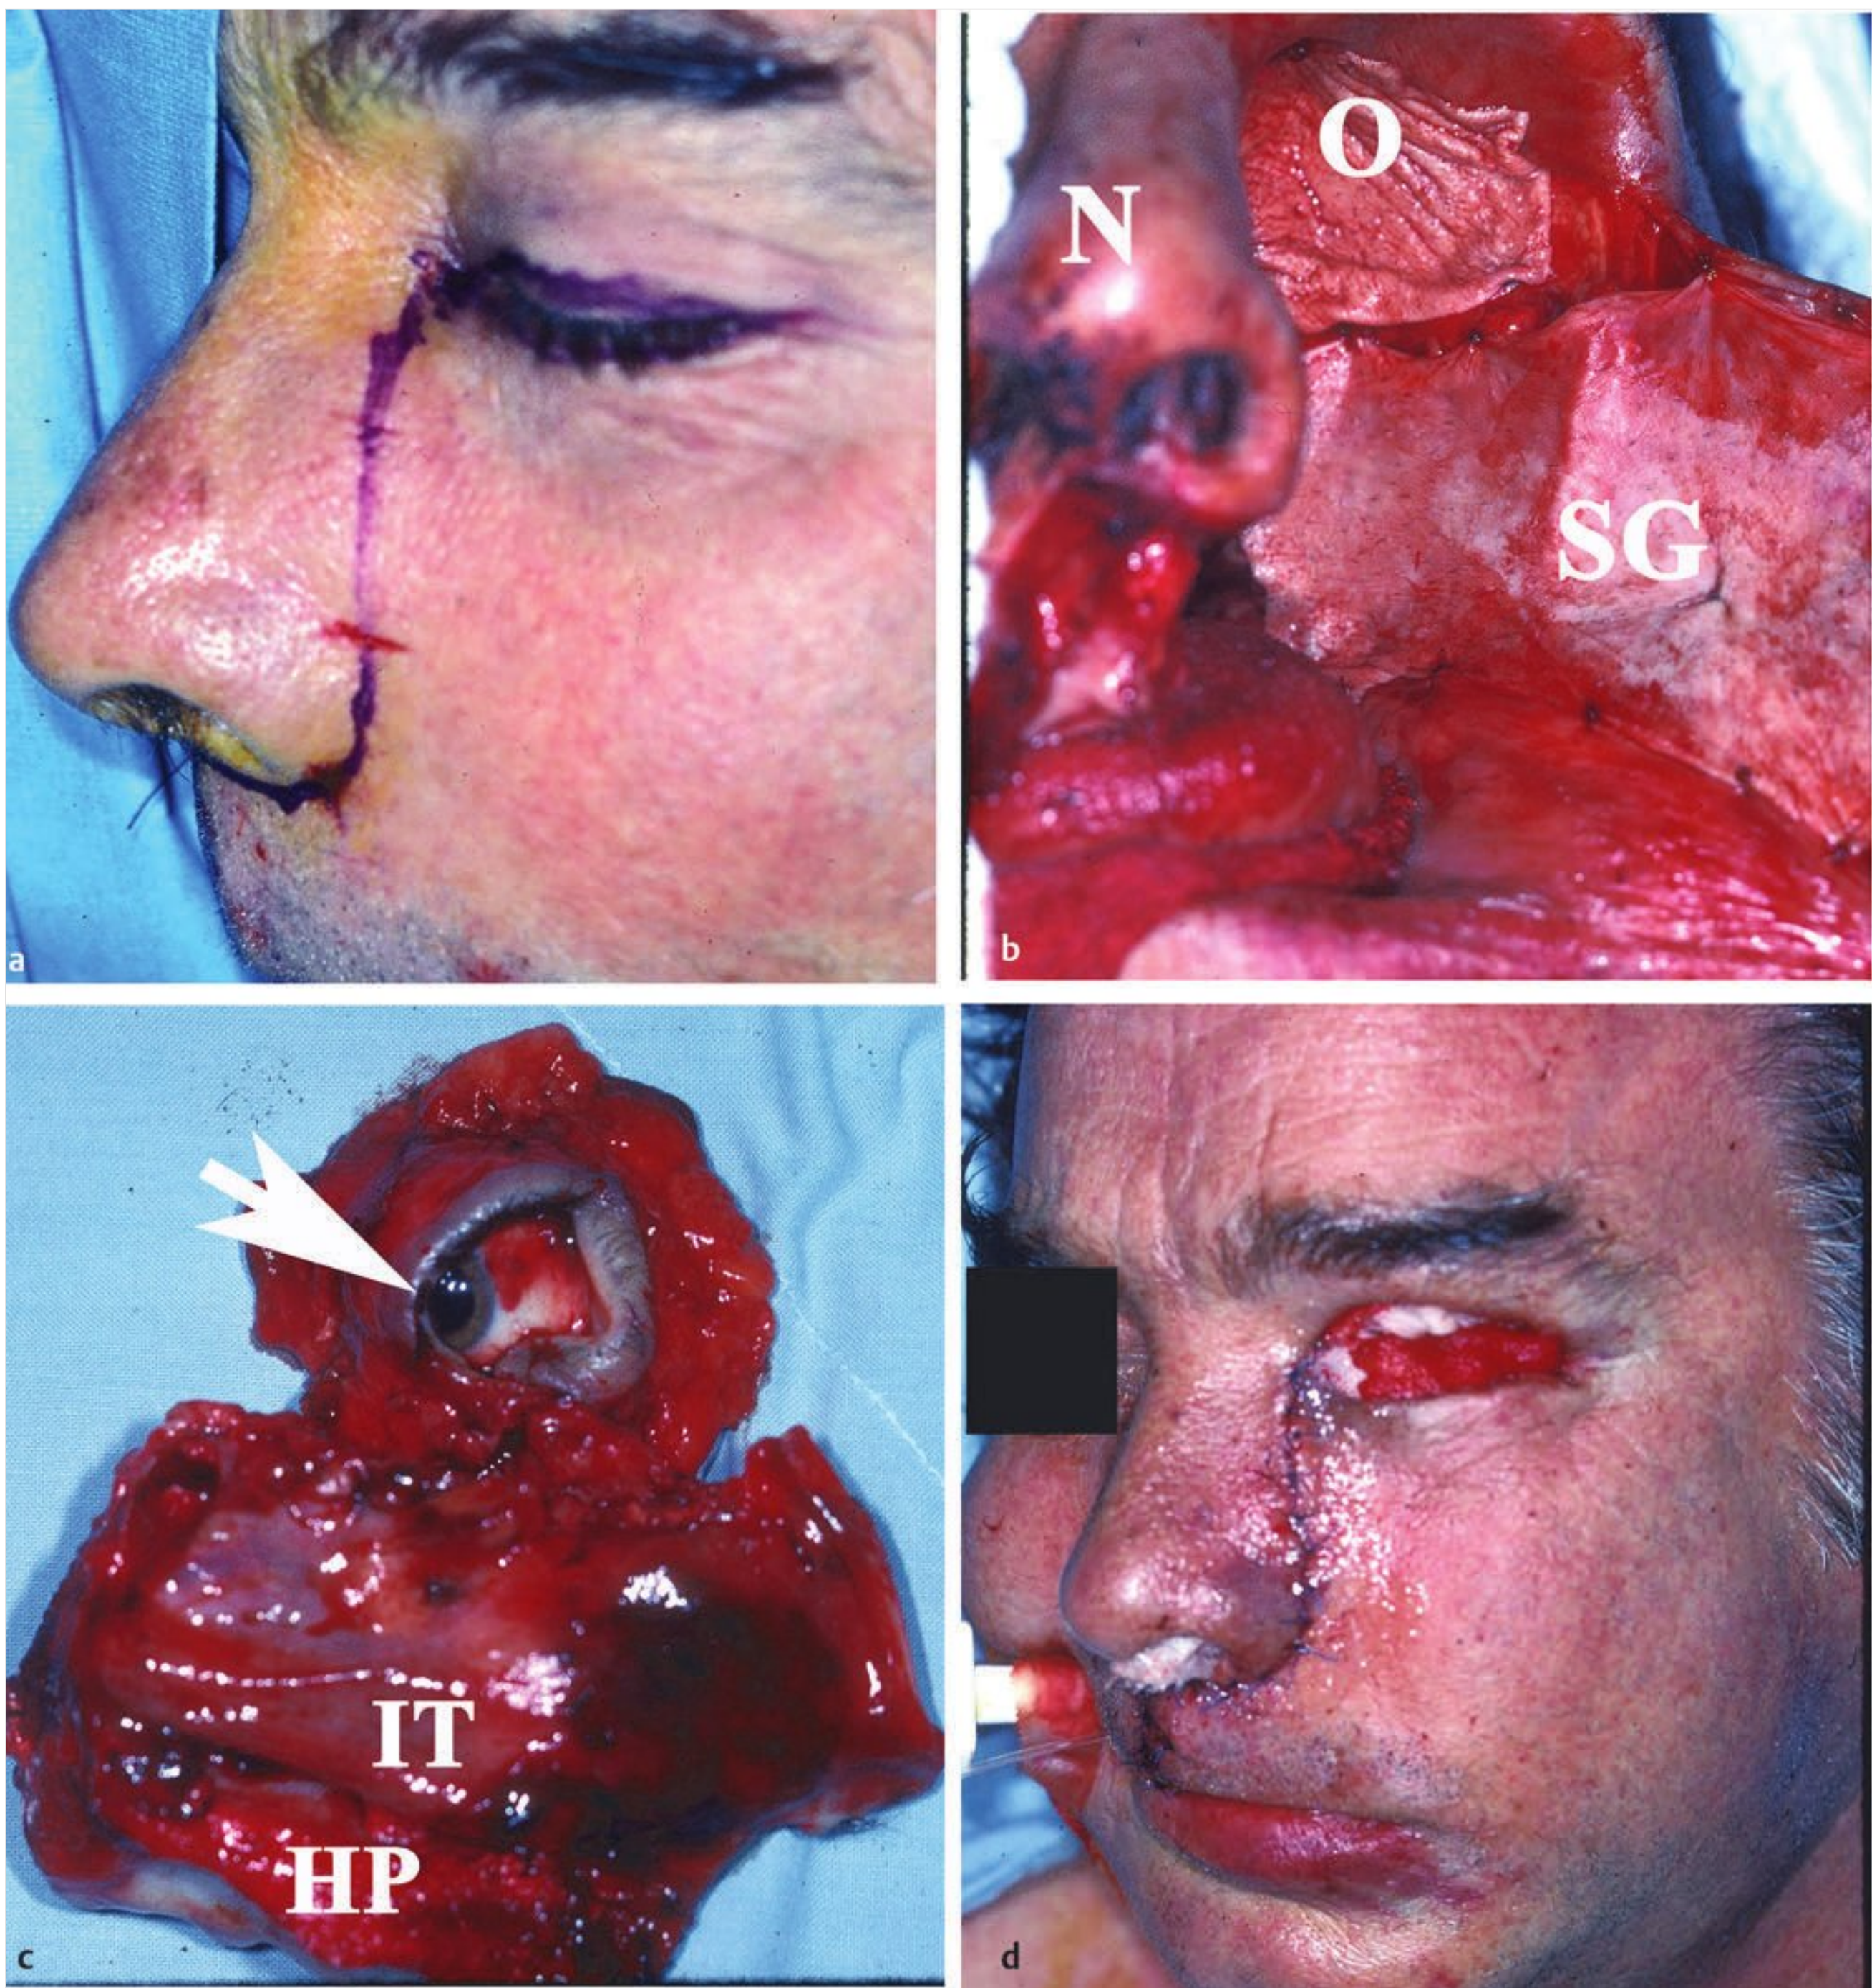

Fig. 109.3 (a) A Weber-Fergusson incision is outlined on this patient, who is undergoing radical maxillectomy with orbital exenteration for squamous cell carcinoma of the left maxillary sinus involving the orbit. The eyelid incision in this patient is on the upper lid for oncologic reasons; typically, the incision runs just below the lashes of the lower eyelid. (b) Intraoperative photograph of the patient in (a) showing exposure of the maxillary and orbital cavities after removal of the sinus tumor and left eye. N, nose; O, orbital cavity with split-thickness skin graft lining the cavity; SG, skin graft surfacing facial flap used to expose the maxilla via the Weber-Fergusson incision. (d) Intraoperative photo showing closure of wound and packing in left orbit supporting the skin graft lining the cavity.

Fig. 109.4 An external approach to a right medial maxillectomy through a nasofacial crease incision provides good exposure of the medial wall of the maxillary sinus.

tissues of the midface are elevated and the maxilla is accessed from a sublabial direction.

Endoscopic Medial Maxillectomy

This is the most recent procedure in the century-long evolution of maxillectomy. Like open approaches to the lateral nasal wall and medial maxillary sinus, this modification includes a complete resection of this site. Because the nasolacrimal duct is transected during the procedure, placing a stent in the duct into the nose or dacryorhinocystostomy is recommended to prevent epiphora. In general, endoscopic medial maxillectomy serves most patients well. However, the limitations of the procedure are poor exposure of the anterior wall of the maxillary sinus and a lack of sufficient experience by most surgeons.

109.6.2 Craniofacial Resection

Multiple surgical approaches are now available for the resection of benign and malignant tumors involving the face and neurocranium. Most paranasal sinus tumors are approached via some form of frontal craniotomy to expose the anterior cranial fossa floor. The standard bifrontal craniotomy provides the best exposure of the tumor but may involve the greatest degree of frontal lobe retraction and therefore the slowest postoperative recovery for the patient (see □ Fig. 109.2). Tumor removal depends on the degree of dural and frontal lobe infiltration, the health of the patient, and the ability to reconstruct the surgical defect. As a generalization, the floor of the anterior cranial fossa is reconstructed with a pericranial flap or free flaps, and forehead defects are repaired with various forms of bone grafts. Radiation therapy is used in most centers, with or without chemotherapy, depending on the type and extent of tumor.

Preoperative radiation and chemotherapy may permit organ-sparing surgery; some esthesioneuroblastomas or squamous cell carcinomas that approximate the optic nerve may be selectively managed by induction chemotherapy and radiation, allowing preservation of the nerve. In contrast, adenoid cystic carcinomas are resistant to chemotherapy and radiation and require aggressive surgical resection.

109.6.3 Endoscopic Skull Base Resection

Building upon the surgical skills acquired from extensive endoscopic sinus surgery, more surgeons are using intranasal endoscopic approaches to remove benign and relatively low-grade malignant neoplasms, such as esthesioneuroblastomas. The ability to successfully and oncologically remove such tumors depends on the following: (1) the surgeon's experience in endoscopic medial maxillectomy and the other approaches used for tumor removal; (2) the surgeon's experience in the repair of cerebrospinal fluid fistulas and encephaloceles, necessary to gain the skills needed for intranasal reconstruction of the skull base; (3) the surgeon's experience in orbital and optic nerve surgery; and (4) the extent of the tumor. When these conditions are met, the surgeon must seek to remove the entire tumor, but the means by which this is achieved may differ from those used in external surgery. For example, a large, bulky tumor with relatively little invasion of the anterior skull base over the nose and septum prevents easy exposure of the normal tissue margins. If the center of the tumor is removed, so that the mass collapses upon itself, then each margin can be identified and the tumor completely resected. The next obstacle the surgeon must overcome is "watertight" reconstruction of the dura. With small dural defects, such reconstruction with fascia or allografts is relatively easy. After complete removal of the skull base, reconstruction is problematic and remains a barrier to a more universal application of the endoscopic approach. However, there is little question that a properly performed and oncologically sound endoscopic resection is preferred by patients (□ Fig. 109.5).

109.7 Prognosis

The object of tumor staging is to relate the clinical findings to the prognosis and to manage treatment based on that prognosis. Approximately 5% of all human neoplasms occur in the head and neck, and 5% of these are within the nose and sinuses. Neoplasms are more common in the maxillary than in the ethmoid sinuses, and frontal neoplasms and sphenoid neoplasms each constitute only 4 to 5% of sinus malignancies. The prognosis worsens as the neoplasm extends beyond the nasal or sinus cavity, invades vital structures, involves regional lymphatics, or metastasizes to distant sites. In the maxillary sinus, the Öhngren line, an imaginary line drawn from the medial canthus to the angle of the mandible, is a useful means to predict prognosis and is significant in tumor staging; maxillary sinus cancers superior to this line (suprastructure neoplasms) can invade the orbit and spread posteriorly into the infratemporal and pterygopalatine fossae. Such neoplasms carry a much worse prognosis than do infrastructure malignancies (inferior to the Öhngren line; □ Fig. 109.6).

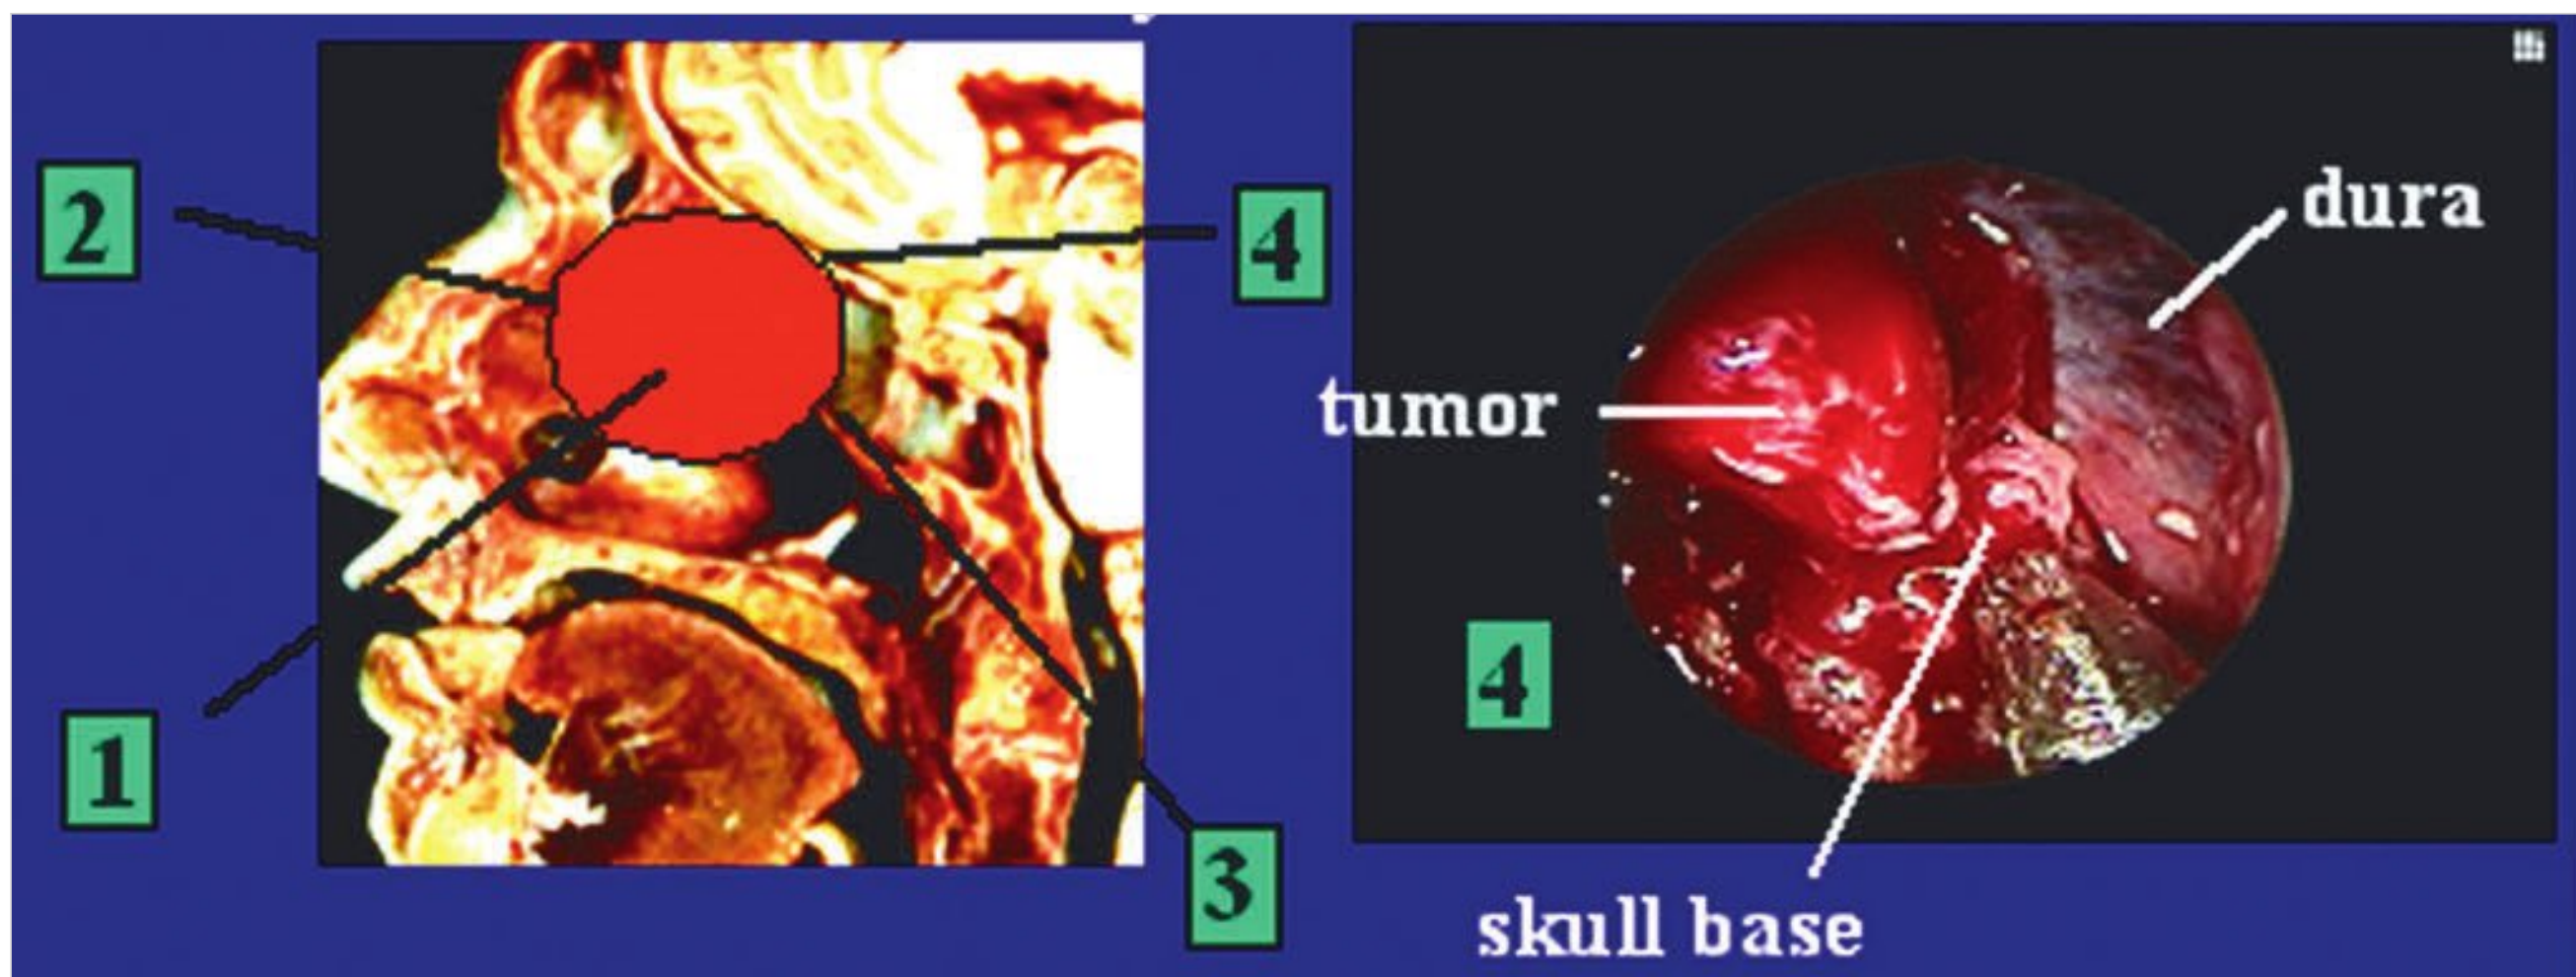

Fig. 109.5 Endoscopic resection of an inverting papilloma invading the skull base. On the left, each step of the resection is outlined. Step 1: The tumor is debulked to permit visualization of the margins. Step 2: The anterior margin of the resection is cleared of tumor and frozen section sent for pathologic examination. Step 3: The posterior or most distal margin is defined and resected. Step 4: Resection of the skull is performed. This is the most critical aspect of the surgery and requires maximal exposure. The endoscopic view of the resection and the dura is seen on the right.

Fig. 109.6 An untreated squamous cell carcinoma of the right maxillary sinus illustrates the natural history of this disease.

109.8 Roundsmanship

- Tumors of the nose arise from the uniquely ectoderm-derived epithelium known as schneiderian epithelium.
- Inverting papillomas are a variant of schneiderian papillomas, arising from an inversion of epithelial growth into the underlying stroma. They most frequently are found within the lateral nasal wall and sinuses. Squamous cell carcinomas are associated with inverting papillomas, but their etiology is unclear.
- Epistaxis and nasal airway obstruction must be evaluated by nasal endoscopy. All patients with such symptoms of more than 4 weeks' duration should be assumed to have a nasal/sinus tumor until it is proven otherwise by nasal endoscopy.
- Computed tomography and magnetic resonance imaging are complementary modalities that should both be employed in evaluating nasal, sinus, and skull base tumors.
- The surgical treatment of sinus/nasal tumors has progressed over the past century toward intranasal endoscopic approaches. Whatever approach is used, complete resection of the tumor is mandatory, and all surgeons must have the ability to use intranasal and external approaches as indicated.

110 Surgical Techniques for the Anterior Skull Base

David Henry Hiltzik and Homere Al Moutran

110.1 Comprehensive Anterior Skull Base Anatomy and Pathology

The subspecialty of cranial base surgery requires a large amount of resources, knowledge, training, and multispecialty collaboration. The anatomical, pathologic, and surgical complexity of the cranial base requires a multidisciplinary approach comprising a dedicated group of professionals. An understanding of neurosurgery, head and neck surgery, medical and radiation oncology, ophthalmology, anesthesia, and especially pathology is critical in the treatment of cranial base neoplasms and diseases. In this chapter, the pathology, surgical approaches, and complications of the anterior fossa will be described and discussed.

110.1.1 Pertinent Anatomy

The anterior cranial base provides support for the frontal lobes of the brain and the grooves for the olfactory nerve. The paranasal sinuses, specifically the frontal and ethmoid sinuses, along with the orbital roofs, are the focal points of the anterior skull base anatomy. The posterior wall of the frontal sinus is the anteriormost limit of the anterior skull base. The ethmoid bone and sinuses, including the cribriform plate, fovea ethmoidalis, and orbital roofs, comprise the floor, along with the planum sphenoidale (□ Fig. 110.1).

Superiorly, the olfactory apparatus lies in the cribriform plate (i.e., the foramina of the anterior cranial base that allow sinus access to the central nervous system). The keel-like crista galli divides the cribriform plate in the midline and is the area where the dura is most adherent. Its position just posterior to the foramen caecum marks the origin of the sagittal sinus. This foramen can be a source of bleeding during anterior craniofacial surgery if not appropriately ligated during exposure. The fovea ethmoidalis makes the greatest contribution to the central anterior floor (see □ Fig. 110.1).

However, the dura is more adherent to the cribriform than to the fovea because of the penetration of the olfactory filaments through the cribriform plate into the superior nasal vault. Despite this fact, the fovea is still the area most susceptible to iatrogenic cerebrospinal fluid (CSF) leak, particularly during endoscopic sinus surgery. Both the anterior and posterior ethmoid arteries and their adjoining vessels help identify the floor of the anterior cranial base. The optic nerve lies in the optic canal approximately 5 mm posterior to the posterior ethmoid artery (□ Fig. 110.2). It sits immediately lateral to the planum sphenoidale, which demarcates the posteriormost border of the anterior skull base. The lamina papyracea, a rather permeable structure that may allow penetration into the orbit, comprises the lateral edge of the ethmoid sinuses. While the periosteum is a barrier to tumor spread, the thin fascial layer that surrounds the orbital fat contributes greatly to orbital integrity, thereby allowing an additional level of resection.

The predominant blood supply of the ethmoids and anterior skull base is derived from both the internal and external carotid artery systems, through the internal maxillary artery and the anterior and posterior ethmoidal arteries, respectively. Similarly, the venous drainage is through the nasal veins, which drain into the jugular system, and the ethmoidal veins, which drain into the cavernous sinus. The sensory nerve supply is through the trigeminal nerve divisions V₁ and V₂.

110.1.2 Tumors of the Anterior Skull Base: Types, Incidence, and Progression

Cranial base tumors, as an aggregate, are relatively rare with varied pathologies. Anterior skull base tumors are largely epithelial, olfactory, or salivary in origin. There is also a large set of tumors that metastasize to the skull base. Sinonasal tumors that involve the anterior cranial base are those that extend superiorly through the skull at the ethmoid roof, cribriform plate, or

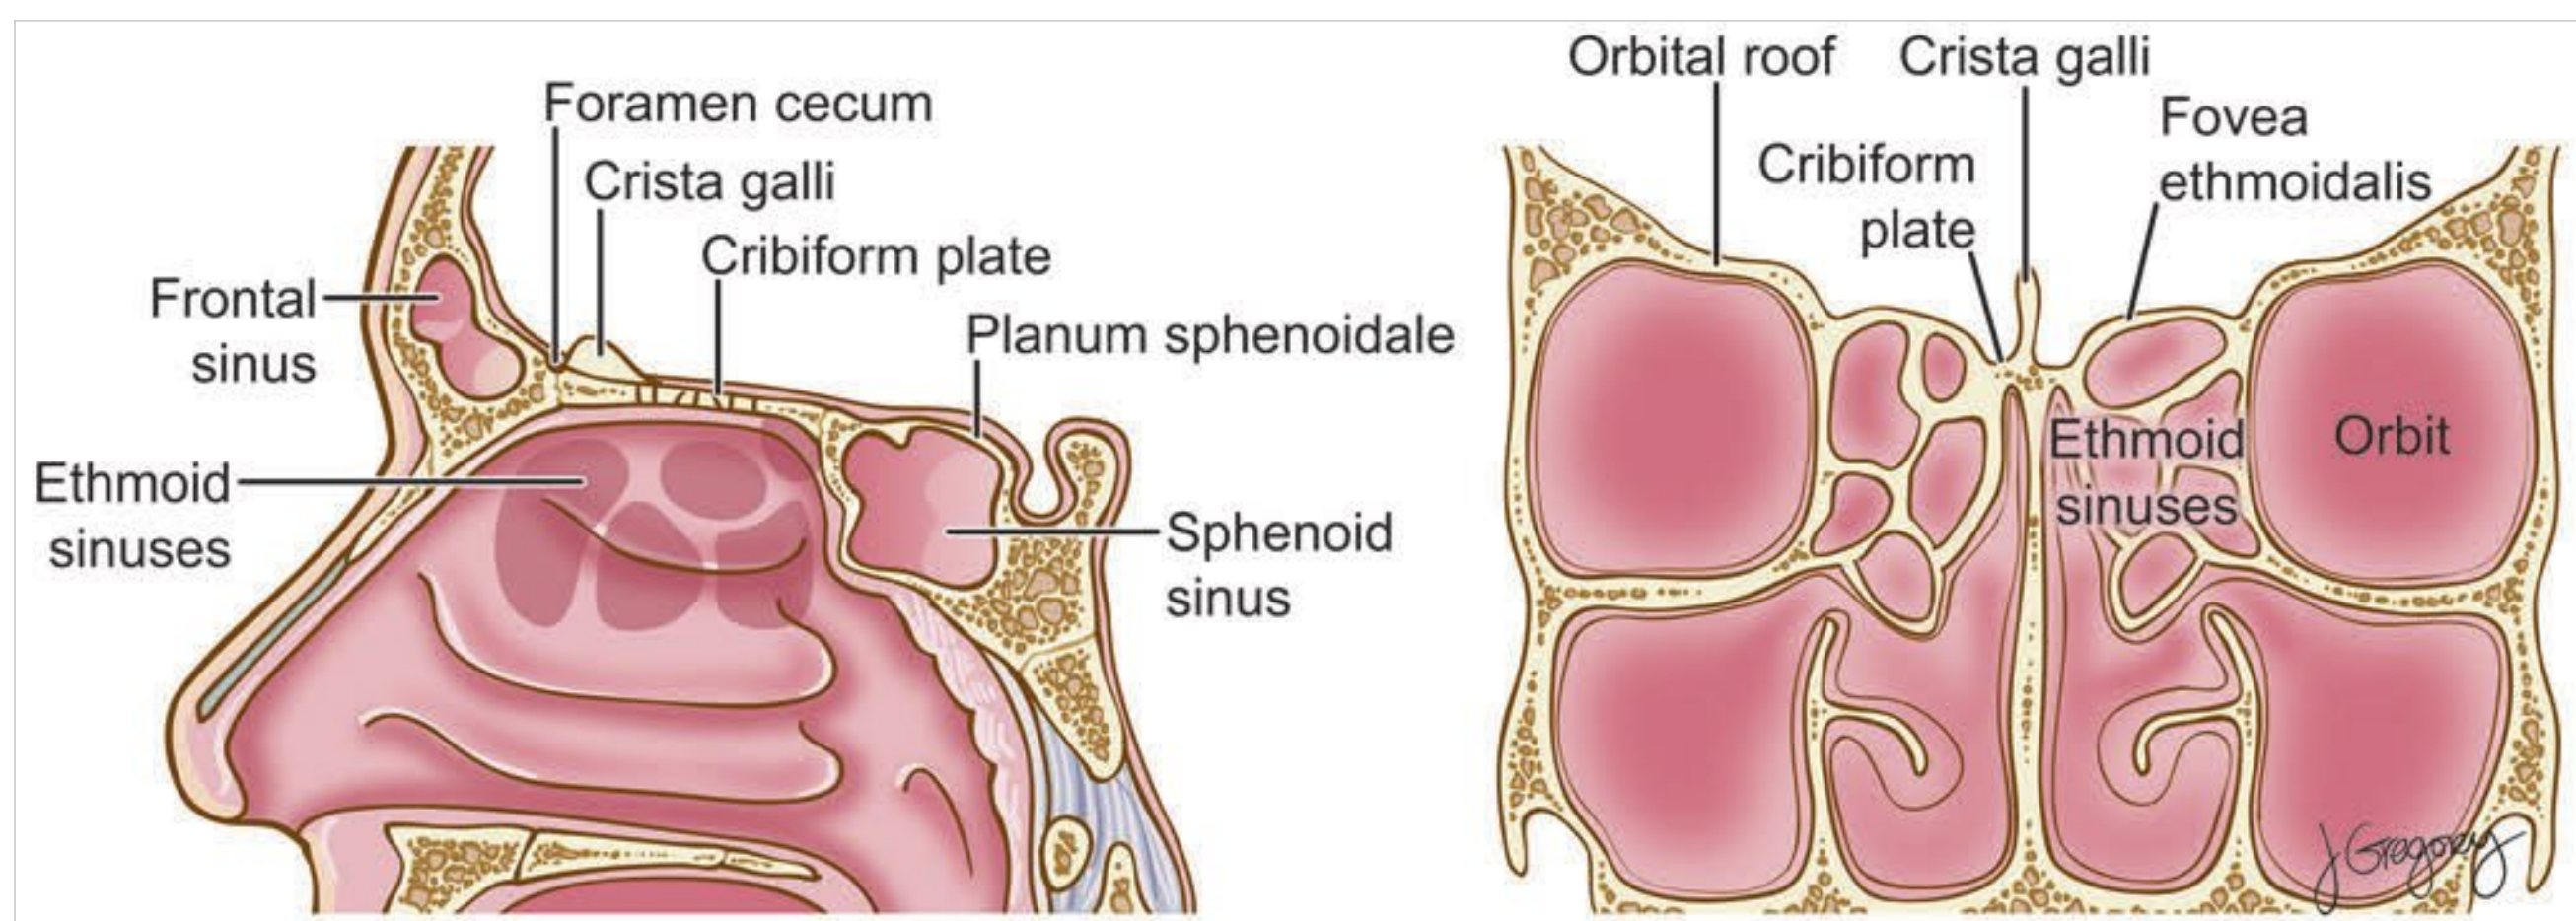

Fig. 110.1 Sagittal and coronal cuts that demonstrate the anterior skull base. Note the distinction between the fovea ethmoidalis and the cribriform plate.

Fig. 110.2 The relationship of the anterior and posterior ethmoid arteries and the optic nerve is shown relative to the ethmoid and sphenoid sinuses.

planum sphenoidale, or posteriorly through the posterior wall of the frontal sinus. Benign processes, such as angiofibromas, inverted papillomas, chondromas, and encephaloceles/mucoceles, as well as malignant processes that are prevalent in these anatomical locations require surgical intervention.

Malignant tumors of sinonasal origin are of endodermal, mesodermal, and epidermal derivation; they include squamous cell carcinoma, esthesioneuroblastoma (olfactory neuroblastoma), sarcoma, adenoid cystic carcinoma, mucoepidermoid carcinoma, melanoma, lymphoma, hemangiopericytoma, malignant giant cell tumor, basal cell carcinoma, and metastatic malignancies. The most common tumor pathologies vary from study to study and from region to region in the world. Squamous cell carcinomas, sarcomas, esthesioneuroblastomas, adenoid cystic carcinomas, and adenocarcinomas are most prevalent in the Americas. In European studies, however, intestinal-type adenocarcinomas (rare in American studies) predominate, and in Brazil skin tumors top the list.

Paranasal tumors are generally locally invasive, with little involvement of the regional lymph nodes (8%) or metastases. Numerous classification systems have been attempted, including the Kadish stage, TNM (tumor node metastasis) system, and international system, but none has significant prognostic value. Overall, the 5-year disease-free survival rate is 50%; adenocarcinoma has a better prognosis than squamous cell carcinoma. Although much has been written about the technical details of the surgeries, few studies have made a great impact with regard to prognosis and long-term results. The international collaborative study group that included 1,307 patients collected from 17 institutions concluded that the histology of the primary tumor, the status of the surgical margins, and intracranial involvement are significant predictors of recurrence-free and disease-specific survival. Other significant factors found in

smaller studies include tumor grade, orbital involvement, and sphenoid sinus involvement. It is critical to recognize that tumor histology coupled with the potential for complete resection, rather than the TNM staging system, is by far the most important criterion affecting cure.

110.2 Preoperative Evaluation

110.2.1 Presentation, Signs, and Symptoms

A common or “standard” presentation for cranial base tumors does not exist because these lesions are asymptomatic until they compromise neighboring structures. Therefore, they are frequently found at advanced stages. The presenting symptoms usually depend on the size and location of the tumor in the skull base and on the related structures. Also, a percentage of tumors are identified incidentally on computed tomography (CT) or magnetic resonance (MR) imaging performed as a result of a generalized, nonfocal complaint of headache.

The anterior skull base and involved paranasal sinuses are closely related to the orbit and to the cribriform plate. If the tumor is predominantly in the nasal cavity, then nasal congestion, epistaxis, anosmia, and unilateral otitis media (effusion) are some of the possible initial symptoms. Tumors of the anterior skull base often produce orbital signs resulting from mass or destructive effects, such as visual disturbances in the form of diplopia or orbital displacement in the form of proptosis, as well as epiphora and visual loss. Because of the close vicinity of the cribriform plate, alterations of taste and smell are possible. Neurologic findings become apparent when tumors erode into the pterygomaxillary space, epidural space, or brain tissue itself

Fig. 110.3 (a) Coronal (soft-tissue window) and (b) sagittal (bone window) computed tomographic scans of a large sinonasal malignancy with mild erosion of the right skull base and invasion into both orbits.

and can manifest as headaches, cranial neuropathies, and even frontal lobe symptoms, such as alterations in personality. Visual changes demonstrate involvement of cranial nerves II, III, IV, or VI or of the orbit. Pain and a variety of dysesthesias result from involvement of trigeminal nerve divisions V_1 and V_2 , especially the supratrochlear, supraorbital, and infraorbital nerves. This is particularly true of adenoid cystic cancers, which have the potential for substantial perineural spread with minimal tumor mass formation.

110.2.2 Radiology

CT, positron emission tomography (PET) coupled with CT (PET-CT), and MR imaging are the mainstays of the preoperative evaluation other than direct biopsy. All lesions of the cranial base require both CT and MR imaging for diagnosis and treatment. Usually PET-CT coupled with MR imaging is employed. CT provides an in-depth understanding of the craniofacial skeleton and its bony relationship to these lesions, whereas MR imaging provides a detailed soft-tissue description. Axial and coronal CT scans are required, along with both soft-tissue and bone algorithms (□ Fig. 110.3). MR imaging generally includes axial, coronal, and sagittal images obtained from both T1 with and without contrast and T2 series (□ Fig. 110.4).

These MR imaging techniques differentiate various tissue types on the basis of signal response. MR angiography can also be of valuable clinical use. A synthesis of both modalities allows a detailed characterization of the tumor with regard to differential diagnosis and of its extent and resectability with regard to preoperative planning. This information is extremely valuable considering the common deficiency in receiving a tissue diagnosis before surgery as a result of the locations of many skull base tumors. Because of the clarity of tumor location and tissue characteristics provided by CT and MR imaging, a narrow range of histologic types can be defined and treated accordingly.

PET has become increasingly valuable in the evaluation of cranial base tumors. It plays a significant role with regard to initial metastatic work-up as well as postoperative surveillance. Preoperatively, it contributes to the staging of cranial base lesions and the detection of metastases, which may result in a change of treatment plan. Postoperatively, these scans are important in differentiating between postoperative tissue fibrosis and previously undetected tumor. The development of fusion PET-CT allows the simultaneous acquisition of anatomical and metabolic data. This technology makes possible the early detection of tumor recurrence, guides endoscopic biopsies, and assists in the selection of an overall treatment plan.

110.3 Surgical Techniques

In 1954, Smith first described anterior craniofacial resection for a tumor arising in the frontal sinus. Ketcham subsequently published the first series of cases and established the first indications, morbidity issues, and outcomes of this type of surgery. Later on, Tessier and Derome improved the technique and introduced modifications to the first approach described.

Since then, anterior craniofacial surgery has been improved by multiple variations and refinements, especially with the revolution of endoscopic technology. Numerous variations and approaches have been described in the literature, as follows:

- Transcranial
 - Standard bifrontal craniotomy
 - Extended frontal craniotomy
 - Frontotemporal craniotomy
- Transfacial/transnasal
 - Endonasal (endoscopic, microscopic)
 - Midfacial degloving
 - Lateral rhinotomy (Lynch approach)

Fig. 110.4 Magnetic resonance (MR) image of the same patient depicted in the computed tomographic scan in □ Fig. 110.3. These (a) anterior and (b) more posterior coronal MR imaging sections demonstrate the dura and orbital contents more clearly, along with the postobstructive sinusitis in the maxillary sinus on the left.

Of note, transcranial and transfacial approaches are often integrated to resect a single tumor.

110.3.1 Open Approach to the Anterior Skull Base

For most anterior craniofacial approaches, the patient should be placed in a supine position. The head usually is rested on a horseshoe-shaped holder but can be fixed with a Mayfield-type pinning system.

The transcranial approach is preferred in most cases in light of its excellent visualization and its ability to provide broad access to the entire anterior skull base laterally from orbit to orbit and anteriorly to posteriorly from the fovea and cribriform to the planum sphenoidale (□ Fig. 110.5). This approach allows a complete, often en bloc resection with minimal aesthetic and functional deficit. The transfacial approaches often leave scarring on the face and offer little added access to the sinonasal cavity and anterior fossa. With the transcranial subfrontal approach, the transfacial approaches are largely used if there is lateral extension of the tumor into the orbit, lateral maxillary sinus, and infratemporal fossa.

Mobilizing soft tissues from the coronal (frontoparietal) suture to the superior orbital rims anteriorly and all the way to the zygomatic arch laterally usually necessitates a bicoronal incision regardless of the tumor location. The scalp elevation can be done in the subperiosteal or subgaleal plane, depending on the surgeon's preference, where a pericranial flap can still be harvested from the cutaneous flap at the end of the surgery (□ Fig. 110.6).

Dissection is done deep to the temporoparietal fascia flap to the level of the temporalis fat pad, where the deep temporalis fascia is duplicated. At this point, the fat pad is entered and the

superficial layer of the deep temporalis fascia is elevated with the skin flap protecting the forehead branches of the facial nerve.

The traditional bifrontal craniotomy begins a few centimeters above the supraorbital rims (see □ Fig. 110.6). Stopping at this level can result in retraction of the frontal lobes to access the planum sphenoidale and more posterior structures. For an improved visualization of the tumor, facilitating its total removal and decreasing, although not eliminating, the morbidity due to brain retraction, the frontal bar (also called sub-basal or extended frontal) approach is favored. Various other craniotomies are also described to accomplish the goal of minimal brain retraction. They involve additional osteotomies that enable removal of the supraorbital rims and nasion en bloc.

This approach exposes the whole area from the rhinion anteriorly to the sella posteriorly and the orbits on the sides. The size of the frontal bone and the amount of the orbital rims included in the flap are determined by the amount of exposure that will be needed.

The supraorbital neurovascular structures are dissected carefully out of the bony foramina, thereby preserving sensation to the forehead and blood supply to an eventually needed pericranial flap. Following craniotomy, dural elevation can extend posteriorly to the tuberculum sellae, falciform ligaments over the optic nerves, and lesser wings of the sphenoid bone.

For unilateral tumors that extend into an adjacent orbit or the cavernous sinus, a frontotemporal craniotomy with orbitozygomatic osteotomy allows a better access to the superior orbital fissure. The open approaches can also be used in conjunction with the transfacial approaches, including midfacial degloving and lateral rhinotomy. For reasons of cosmesis and functional preservation, the subfrontal approach is preferred when an “open approach” is needed.

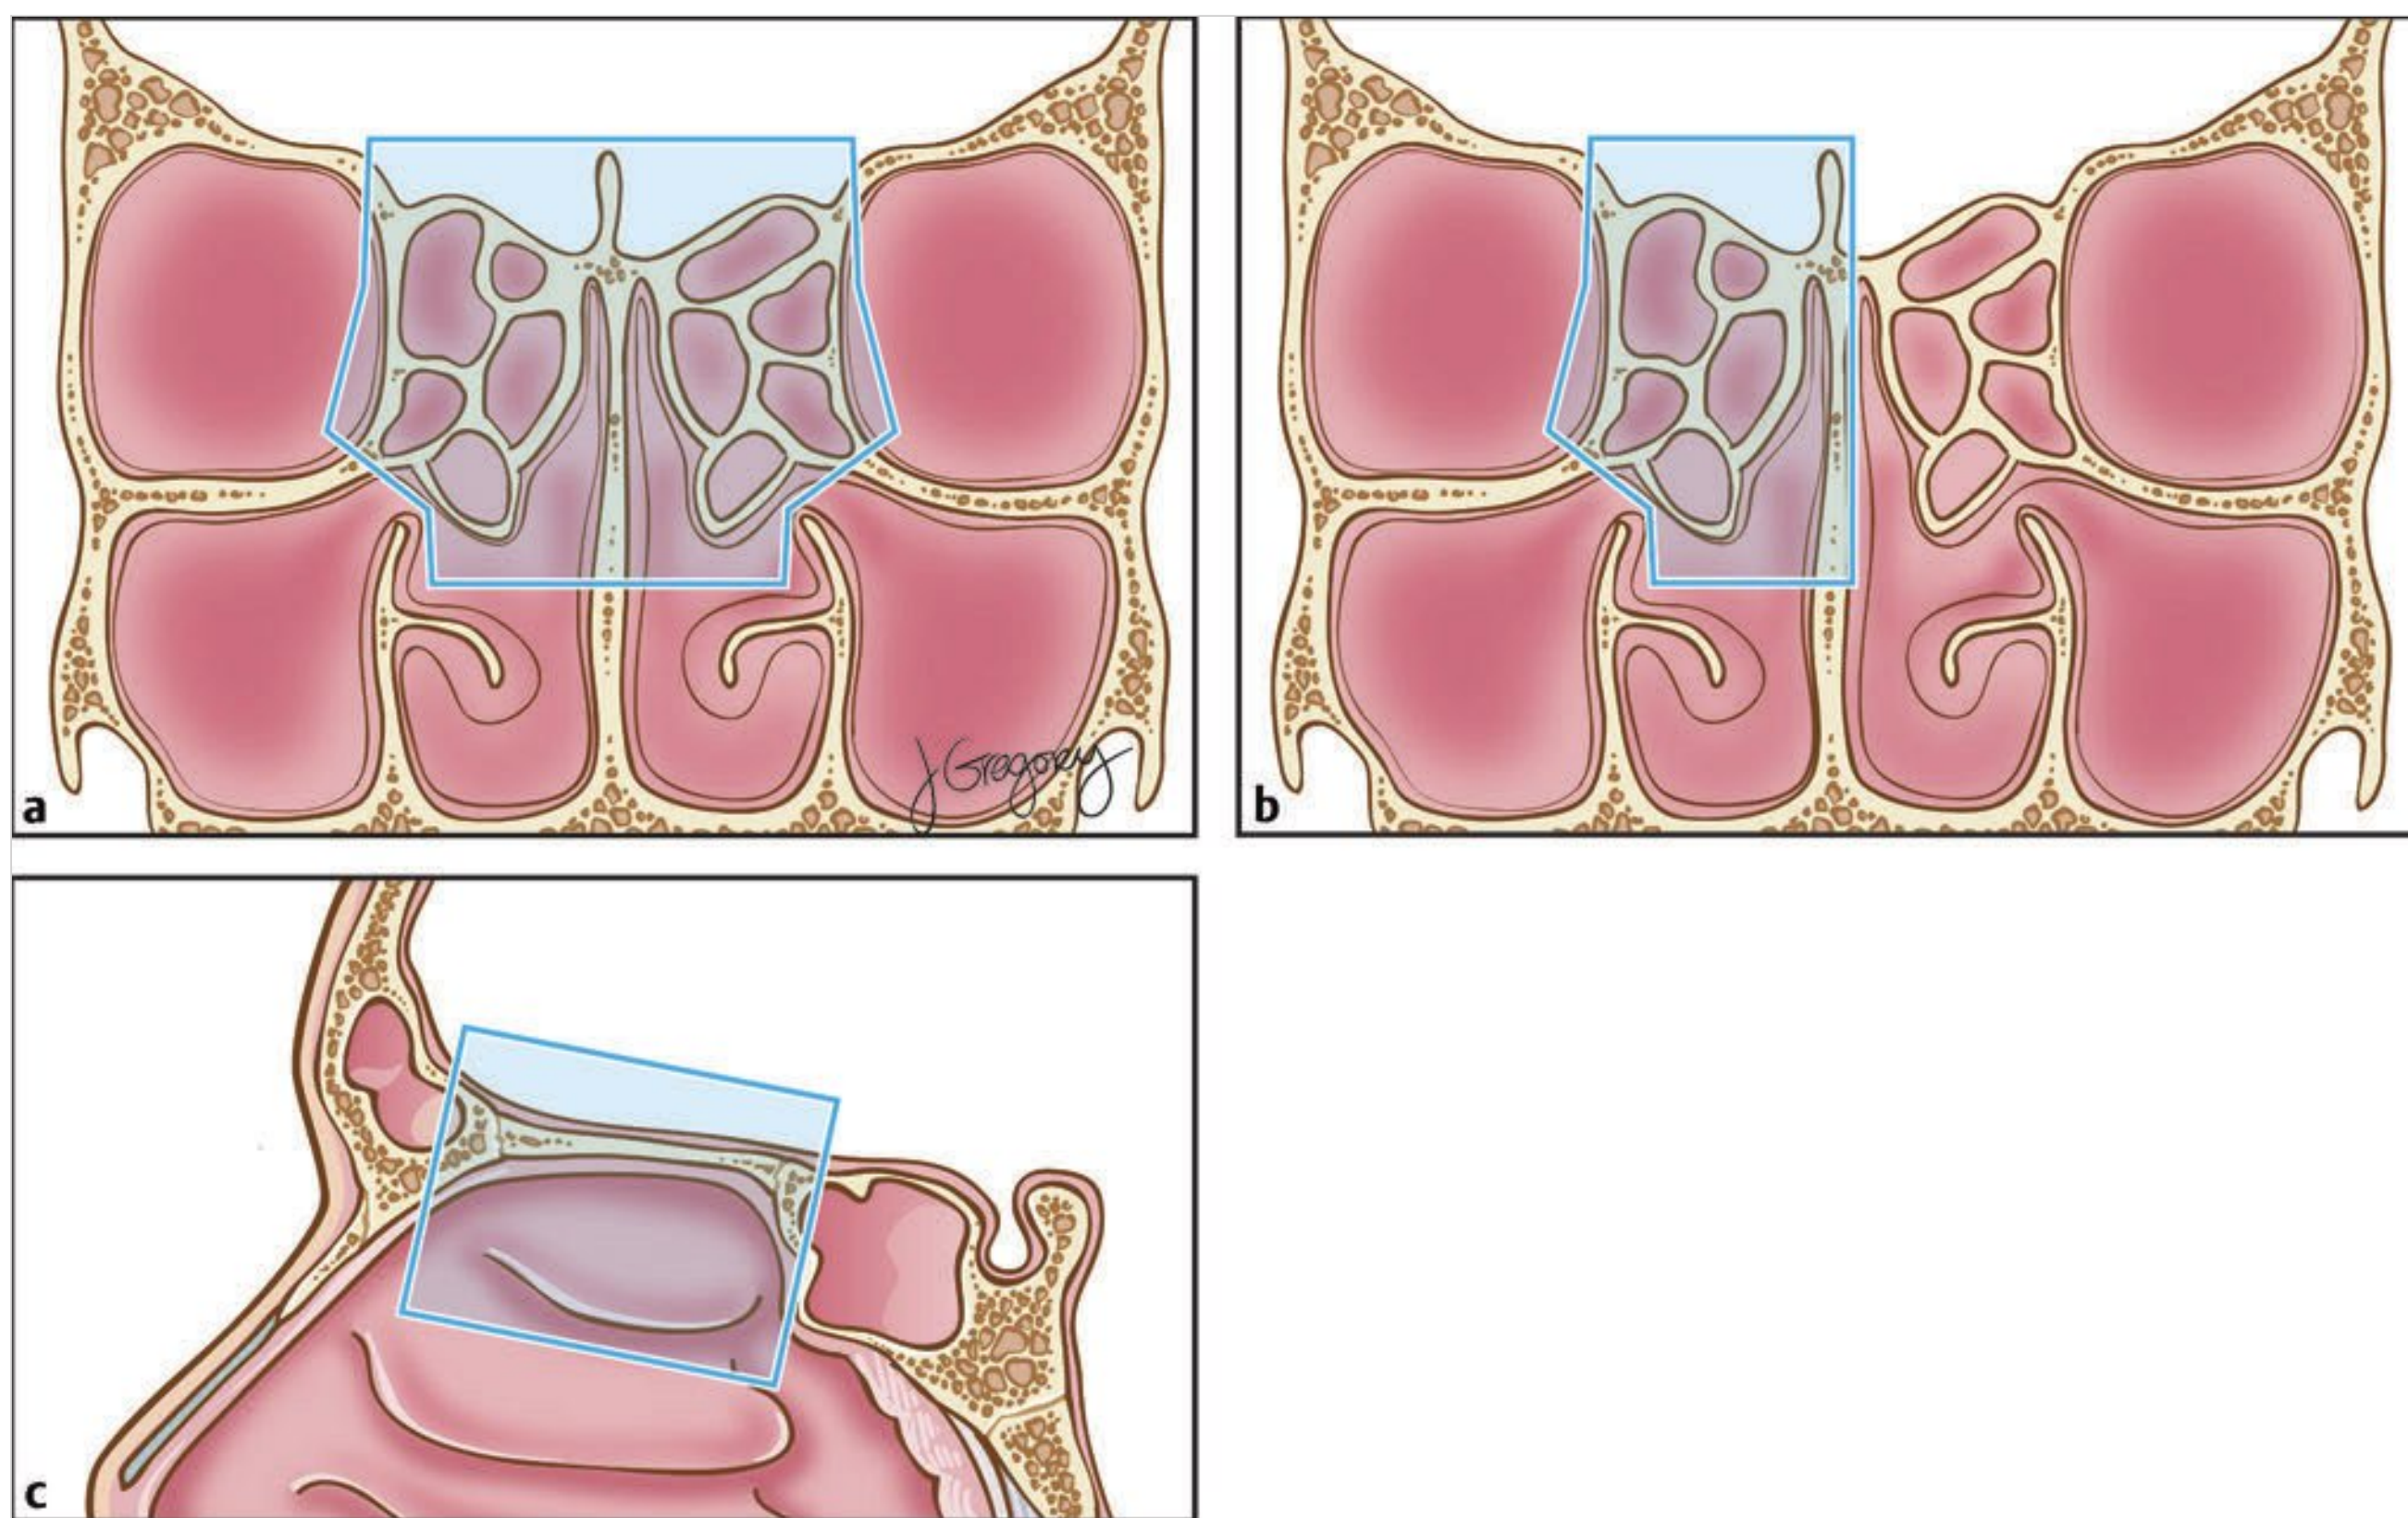

Fig. 110.5 Schematic depicting the desired extent of resection for (a) bilateral and (b) unilateral anterior (c) craniofacial resection.

The approaches from above allow the resection of larger tumors involving dura or brain with complete vascular control and the ability to achieve an en bloc resection with negative margins. The entire sinonasal cavity can be well visualized and accessed, allowing complete exenteration of the ethmoid, maxillary, frontal, and sphenoid sinuses, if necessary, as well as the nasal floor with minimal morbidity.

Once the resection is performed, the skull base must be reconstructed to prevent communication between the sinus and intracranial cavity. If a CSF leak is created, then a watertight seal must be achieved. The pericranial flap is the mainstay of anterior fossa reconstruction in the open approaches. A temporoparietal flap or temporalis muscle flap, as well as fascia lata or a variety of biomaterials, can also be used. Exenteration of the frontal sinus and obliteration of the frontal recess are important components in the closure of these cases to prevent pneumocephalus in the short term and mucocele formation in the long term. The nasal cavity is often packed, and nasal trumpets are placed to avoid pneumocephalus, as well.

110.3.2 Endoscopic Endonasal Approach to the Anterior Skull Base

Technologic advancements in the form of intraoperative navigation and instrumentation plus the acquisition of endoscopic skills and expertise through a better understanding of the anatomy of the skull base “from below” over the last 15 years have brought a true paradigm shift in skull base surgery.

Endoscopic skull base surgery comprises a series of approaches or “corridors” through the sinonasal passages, with the maximum of lateral extension obtained between the two medial orbital walls at the middle of the cribriform plate (mean distance, 25 to 33 mm), while the mean distance between the anterior and posterior ethmoidal arteries at the level of the lamina papyracea is 16 mm. Therefore, the endoscopic endonasal route can be considered a minimally invasive technique for approaching an area limited by the sella posteriorly, orbits laterally, and frontal recess at the junction of the crista galli anteriorly.

The endoscopic approach to the anterior skull base is performed with a “four-handed” technique in which two surgeons use a transethmoid and a transcribriiform approach. This dissection extends from the posterior wall of the frontal sinus to the planum sphenoidale. At the beginning of the case, the patient is positioned with the navigation apparatus and thoroughly decongested. The approach is initiated by resecting the attachment of the anterior portion of the nasal septum to the cranial base after the middle turbinates have been removed. A total ethmoidectomy along with an endoscopic modified Lothrop procedure (wide opening of the frontal recesses with a drilling out of the frontal sinus floor and intersinus septum) is then performed. After wide exposure and visualization of the floor of the entire anterior fossa have been attained, the fovea ethmoidalis and cribriform plate are removed bilaterally. The limits of this module are both laminae papyraceae laterally, the frontal sinus anteriorly, and the transition with the planum sphenoidale posteriorly. Although the cribriform exposure damages olfaction, it is likely that olfaction has already been compro-

110.4 Complications of Cranial Base Surgery

Cranial base surgery poses serious surgical challenges that are reflected in the relatively high rate of postoperative complications. These tumors involve critical structures, so that wide and extensive access is required in both open and endoscopic approaches, often leaving extensive and challenging defects. Because of an average complication rate of 30 to 50%, proper preoperative planning with regard to approach and reconstruction must be performed. Potential risk factors for complications must also be assessed, including patient demographics and comorbidities, prior surgical and radiation treatment, the extent of anatomical involvement of the lesion, and the biology of the tumor type. Although the surgical mortality of these procedures is less than 4%, central nervous system, wound, and systemic medical complications occur in up to 40% of patients. The majority of complications are related to CSF leak, meningitis, and wound infection. Postoperative emergencies specific to any intracranial procedure include cerebral edema, thrombosis, pseudoaneurysm, air embolism, and postoperative seizures.

In most large studies of the complications of skull base surgery for malignant tumors, postoperative wound infections have been reported to occur in up to 20% of cases. These include superficial wound infections, osteomyelitis, intracranial abscess, and bone flap failures. Medical comorbidities and prior radiation therapy have been shown to be predictive factors.

Cranial nerve and orbital complications are of concern in both the intraoperative and the postoperative period and are therefore often predicted based on tumor location and type of approach. Neurophysiologic monitoring understandably plays a crucial role in cranial base surgery. Any orbital involvement or resection of the surrounding structures can produce diplopia and visual disturbances. Epiphora can occur secondary to lacrimal duct complications and an insufficient dacryocystorhinostomy. Deficits of cranial nerves III, IV, and VI are most common in resections involving the cavernous sinus; combined paralysis is therefore called cavernous sinus syndrome. Total ophthalmoplegia and diplopia can be expected in these circumstances, along with conjunctival injection and edema.

CSF leaks, along with wound infections, account for over half of all postoperative complications after cranial base surgery. They occur in 2 to 20% of cases and can often be predicted by radiology showing tumor involvement of the dura, brain, middle ear, and eustachian tube. Prior radiation therapy, dural invasion, and brain involvement are significant predisposing factors. CSF leaks can be categorized as low-flow or high-flow leaks. They are detected by the history and the clinical and radiologic examination. Depending on the surgical site, patients may present with clear rhinorrhea or otorrhea at rest or on exertion, which is often associated with a salty taste and a halo sign (a dark ring surrounding a more lightly stained center) on the patient's dressings or sheets. A collected fluid sample can be assayed for β_2 -transferrin, a protein found only in CSF, perilymph, and vitreous humor. If this is not feasible and the location of the leak cannot be determined, MR imaging or, more commonly, CT cisternography can be performed; CT before and after an intrathecal injection of a radiopaque dye can identify the leak location. Patients can also present with pneumocephalus and, in

Fig. 110.6 (a) The bicornal incision is marked. The hair is not shaved and is completely preserved after the surgery. (b) The scalp flap is elevated, with the pericranium preserved in the scalp for later use in reconstruction of the skull base. (c) The frontal bone flap is removed.

mised by the disease in question. Once the entire bony floor of the anterior fossa is removed, the dural and intracranial portion of the tumor can be resected with negative margins. Reconstruction of the skull base is performed, preferably with local vascularized tissue. If vascular tissue is unavailable, avascular dermal grafts are employed. In simple terms, the “endoscopic approach” can accomplish the same resection as the “open approach,” except that is done from below the skull base instead of above it and with fewer incisions.

Fig. 110.7 Computed tomographic scan of a large pneumocephalus secondary to a postoperative communication between the nasal cavity and intracranial space.

the worst case, a life-threatening tension pneumocephalus (□ Fig. 110.7).

High-flow leaks are most often treated urgently by direct surgical closure with nonvascularized tissue such as fat or fascia, alloplastic materials, or a combination of both along with a tissue sealant. These leaks can be addressed by either open or endoscopic approaches. Low-flow leaks can often be resolved by lumbar drain or, if necessary, ventricular or lumbar shunt placement in intractable situations. Excessive drainage must be avoided to prevent pneumocephalus.

Meningitis is the most undesirable complication of cranial base surgery. The risk for meningitis increases in the presence of a CSF leak, especially in anterior skull base surgery, when the intradural space is directly exposed to the paranasal sinuses.

Meningitis usually presents with fever, headache, nausea, vomiting, and mental status changes. There should be a low threshold for initiating a work-up in the clinical setting of any of these symptoms. CT of the head is performed to rule out increased intracranial pressure and dilated ventricles. A lumbar puncture then allows analysis of the CSF for color, protein, glucose, red blood cells, and white blood cells, and a Gram stain is performed. Postoperatively, meningitis is usually aseptic or of bacterial origin; a viral origin is unlikely. Aseptic meningitis usually results from meningeal irritation by surgical intervention, blood, or breakdown products. Bacterial meningitis, which is more common, is devastating and often the result of large defects that are at risk for CSF leaks. Once meningitis is diagnosed,

treatment with intravenous antibiotics and close monitoring of the CSF leak is initiated.

Cranial base surgery is a complicated and demanding subspecialty with a high risk for complications as well as the potential for great rewards. Patients requiring an anterior craniofacial resection must undergo a thorough work-up with a detailed history, physical examination, and radiologic studies, including CT, MR imaging, and PET. Presurgical planning is crucial and necessitates a multidisciplinary team. The surgical approach depends on a multitude of factors, and close postoperative follow-up is essential to avoid serious complications.

110.5 Roundsmanship

- Skull base surgery requires a multidisciplinary approach across a broad range of subspecialties, with the participation of a head and neck surgeon, neurosurgeon, oncologist, radiologist, and pathologist.
- CT, MR imaging, and PET-CT are all necessary in the evaluation of anterior fossa tumors.
- The surgical approach to the anterior fossa depends on the pathologic type and stage of the tumor, the patient's anatomy, and the surgeon's skill set.
- The complications of skull base surgery can be devastating and must be avoided with the exercise of surgical judgment and close postoperative monitoring.

111 Anatomy and Embryology of the Ear

Christopher J. Linstrom

111.1 Introduction

An understanding of any pathologic process is based upon a thorough knowledge of the normal, including normal development. This is especially true for all structures of the head and neck, and most importantly for the ear. It is impossible to completely understand the basis for much otologic and neurotologic disease without a firm grounding in the embryology and anatomy of the ear.

111.2 Ear Development: The Short of It

Humans are vertebrates, and the auditory system in all vertebrates has the following similar structures (□ Fig. 111.1):

1. A sound-directing appendage, the auricle.
2. A connection between the external sound source and the outer surface of a sound-conducting membrane. Sound pressure (force per unit area) is slightly diminished as sound travels through this junction and must be reamplified.
3. A sound reamplification system. Most, but not all, vertebrates have three ossicles: two long levers (malleus and incus) articulating with a small receiver (stapes).
4. An air pressure-to-fluid compression sound wave transformation system (cochlea). Reamplified sound passing through the stapes sets up a series of waveforms that are carried through a closed fluid space (perilymph). Shearing forces change the resting volume and shape of the endolymph.
5. A fluid wave-to-electrical depolarization transformation system (cochlea). Fluid waves deforming the resting position of the inner and outer hair cells depolarize them, thus transforming the envelope of analogue sound into an electrical representation of sound that is carried along cranial nerve VIII to the brainstem, midbrain, and cortex, where sound is recognized centrally (Broca speech area).

The human ear develops from three tissue sources:

1. The otocyst (□ Fig. 111.2) will form the membranous (cochlear and vestibular) labyrinth. Mesenchyme around the otocyst forms cartilaginous rests, which then ossify to become the endochondral bone of the otic capsule, the densest of the human bones. The petrous portion of the temporal bone is so named because of the dense otic capsule within it.
2. Branchial arches 1 and 2, together with the first pharyngeal pouch, will form all of the structures of the external auditory canal and middle ear except the footplate of the stapes (□ Fig. 111.3). The first pharyngeal pouch develops into the pharyngotympanic (eustachian) tube and middle ear cavity. The middle ear cleft develops around the cartilage of the first and second branchial arches to give rise to the ossicles (□ Fig. 111.4).
3. The six mesodermal hillocks from branchial arches 1 and 2 develop to form the auricle. The superficial mesoderm of branchial arches 1 and 2 gives rise to six preauricular cartilaginous hillocks arranged around the dorsal part of the first branchial cleft. These auricular hillocks (□ Fig. 111.5, □ Fig. 111.6, □ Fig. 111.2) grow and mature to give rise to the

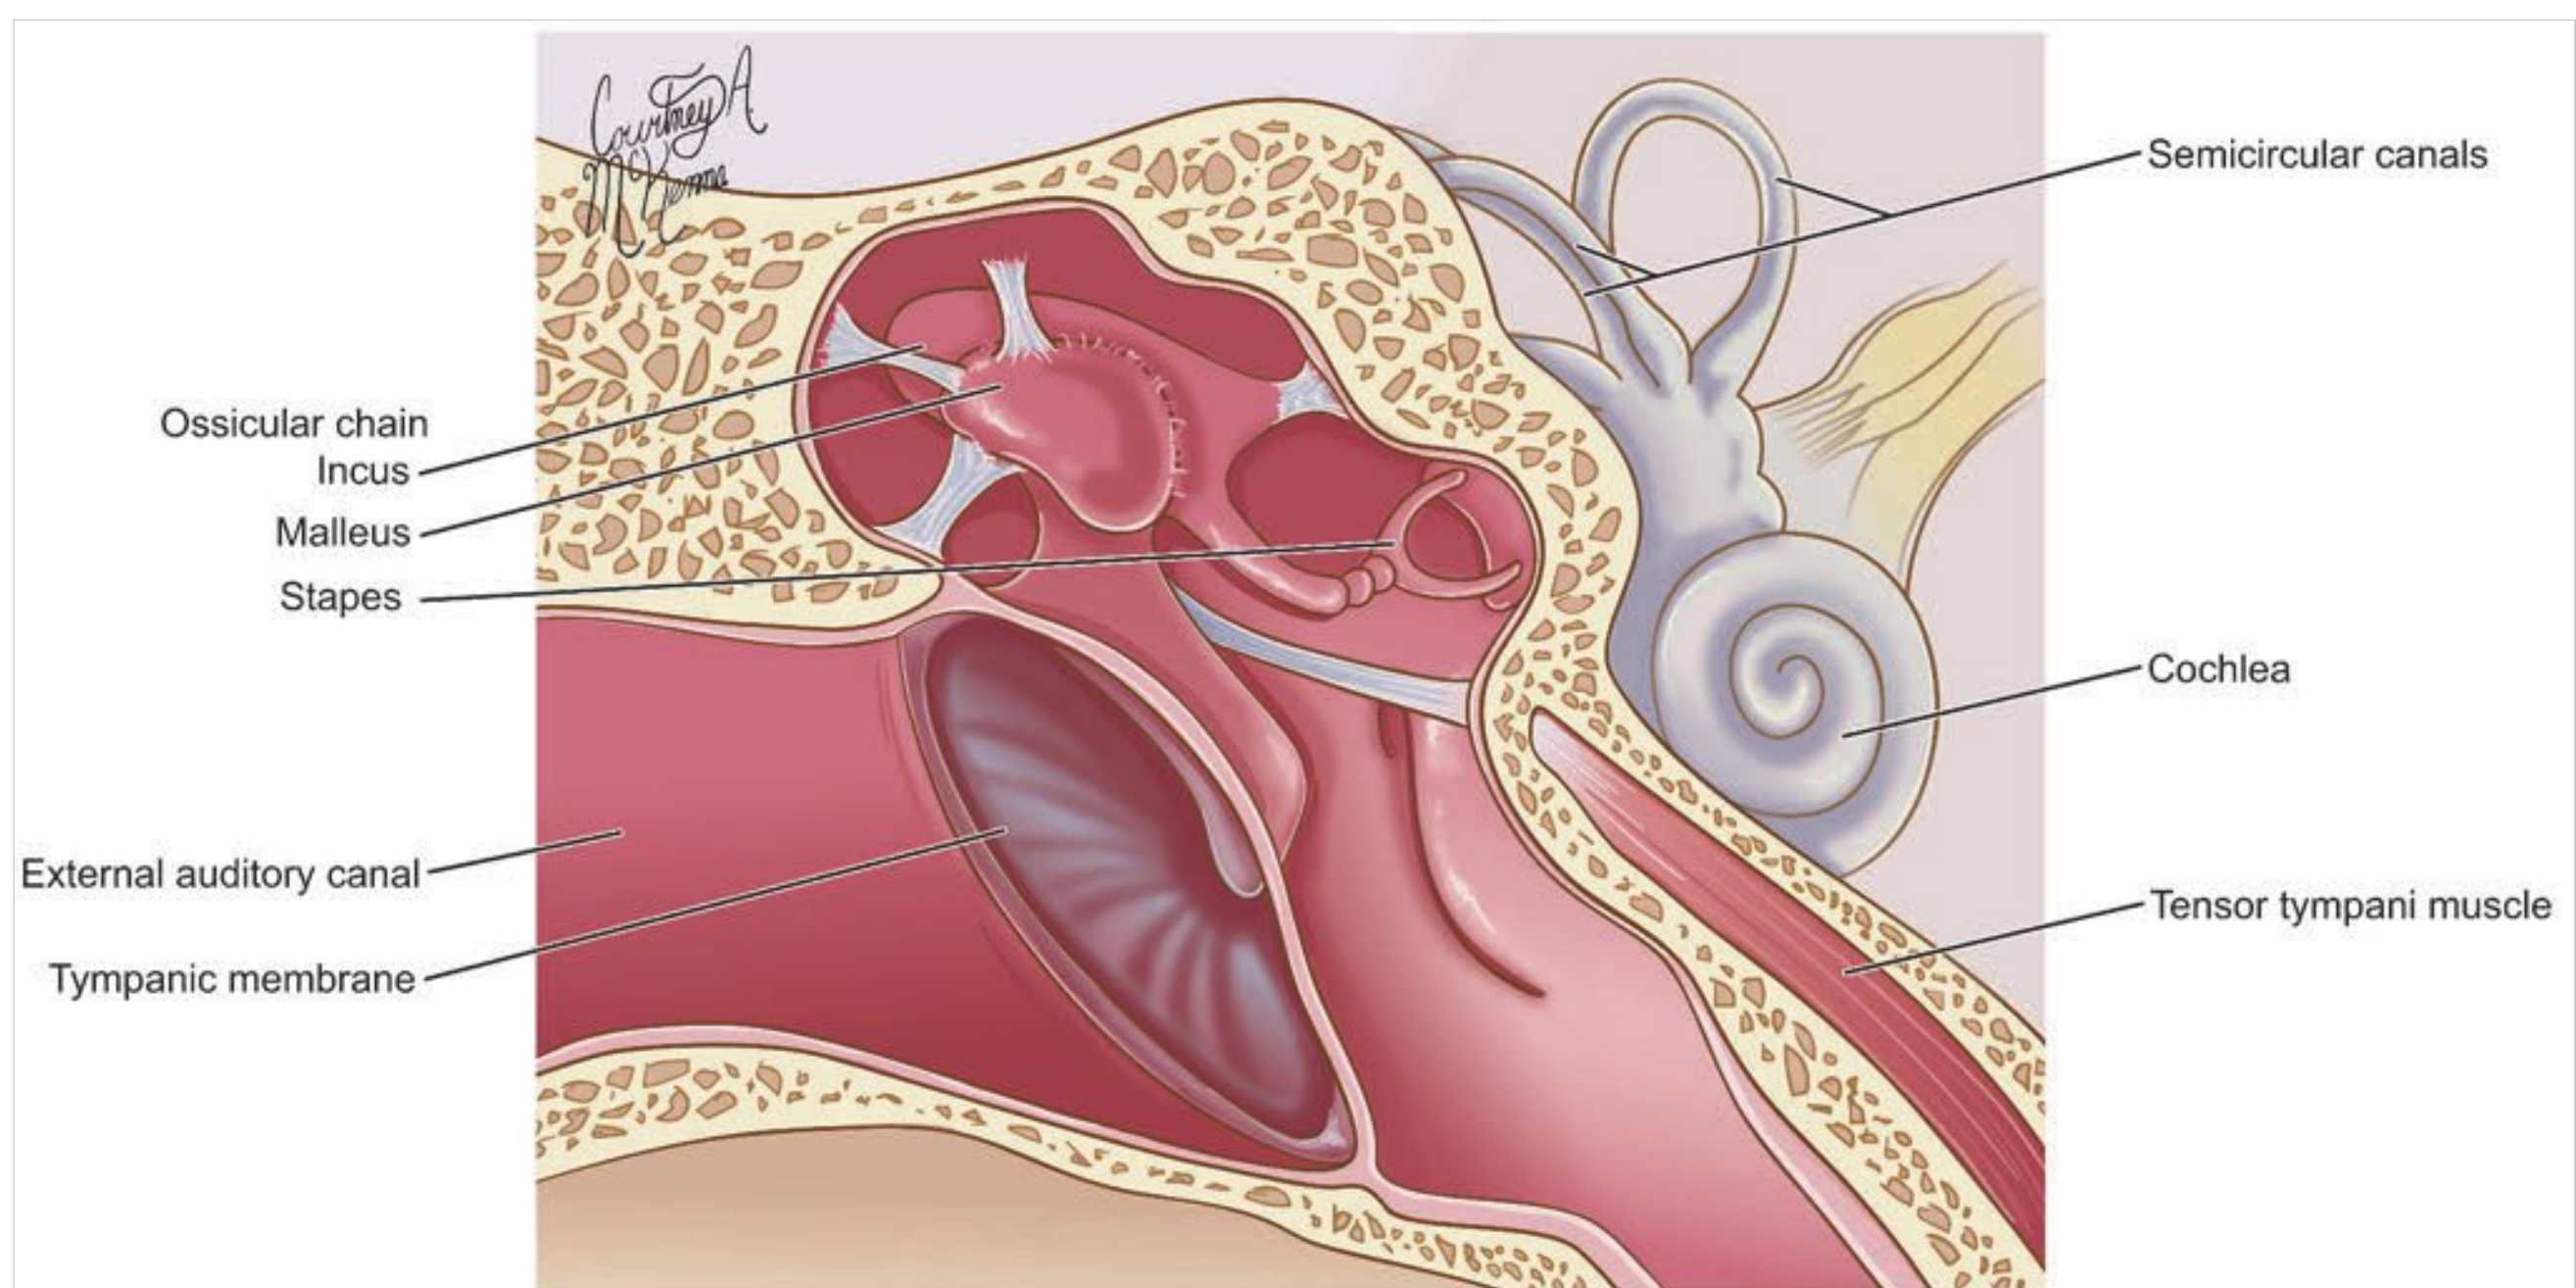

Fig. 111.1 Coronal view of a right ear showing the external auditory canal, tympanic membrane, middle ear space with the ossicular chain, tensor tympani muscle, and structures of the inner ear.

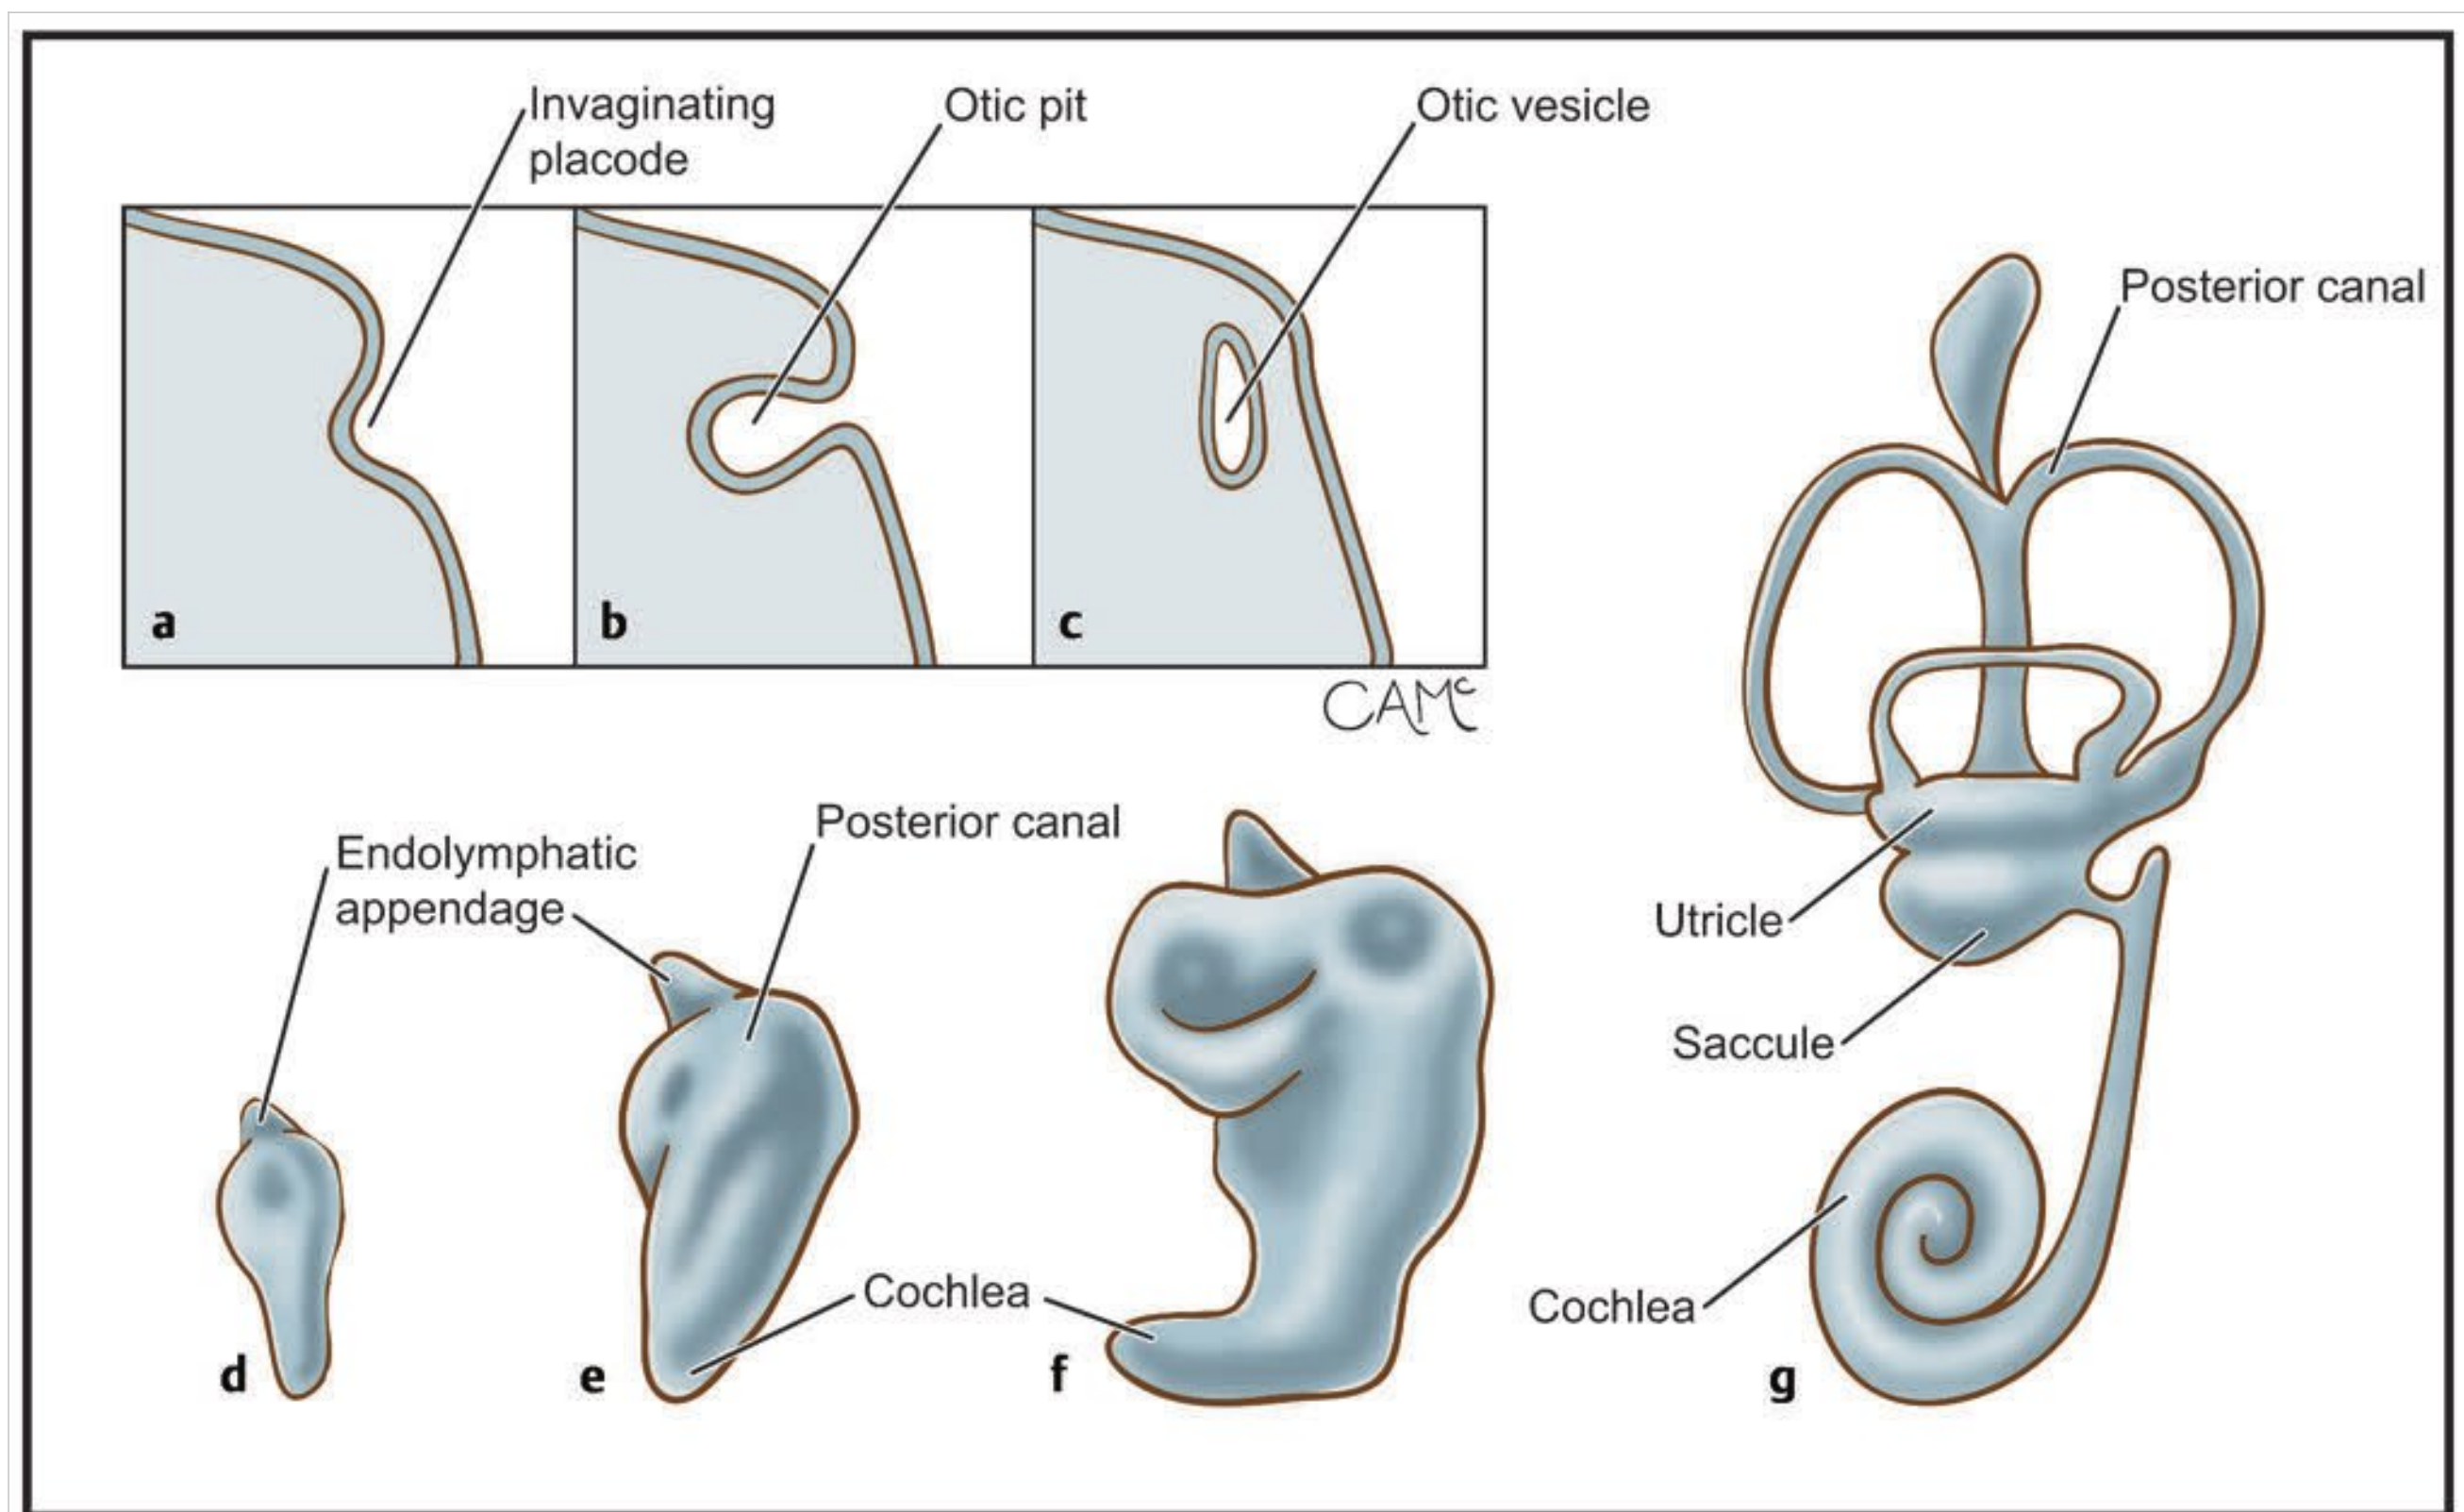

Fig. 111.2 (a–g) Schematic showing development of the membranous vestibular and cochlear labyrinths from the otic pit/vesicle.

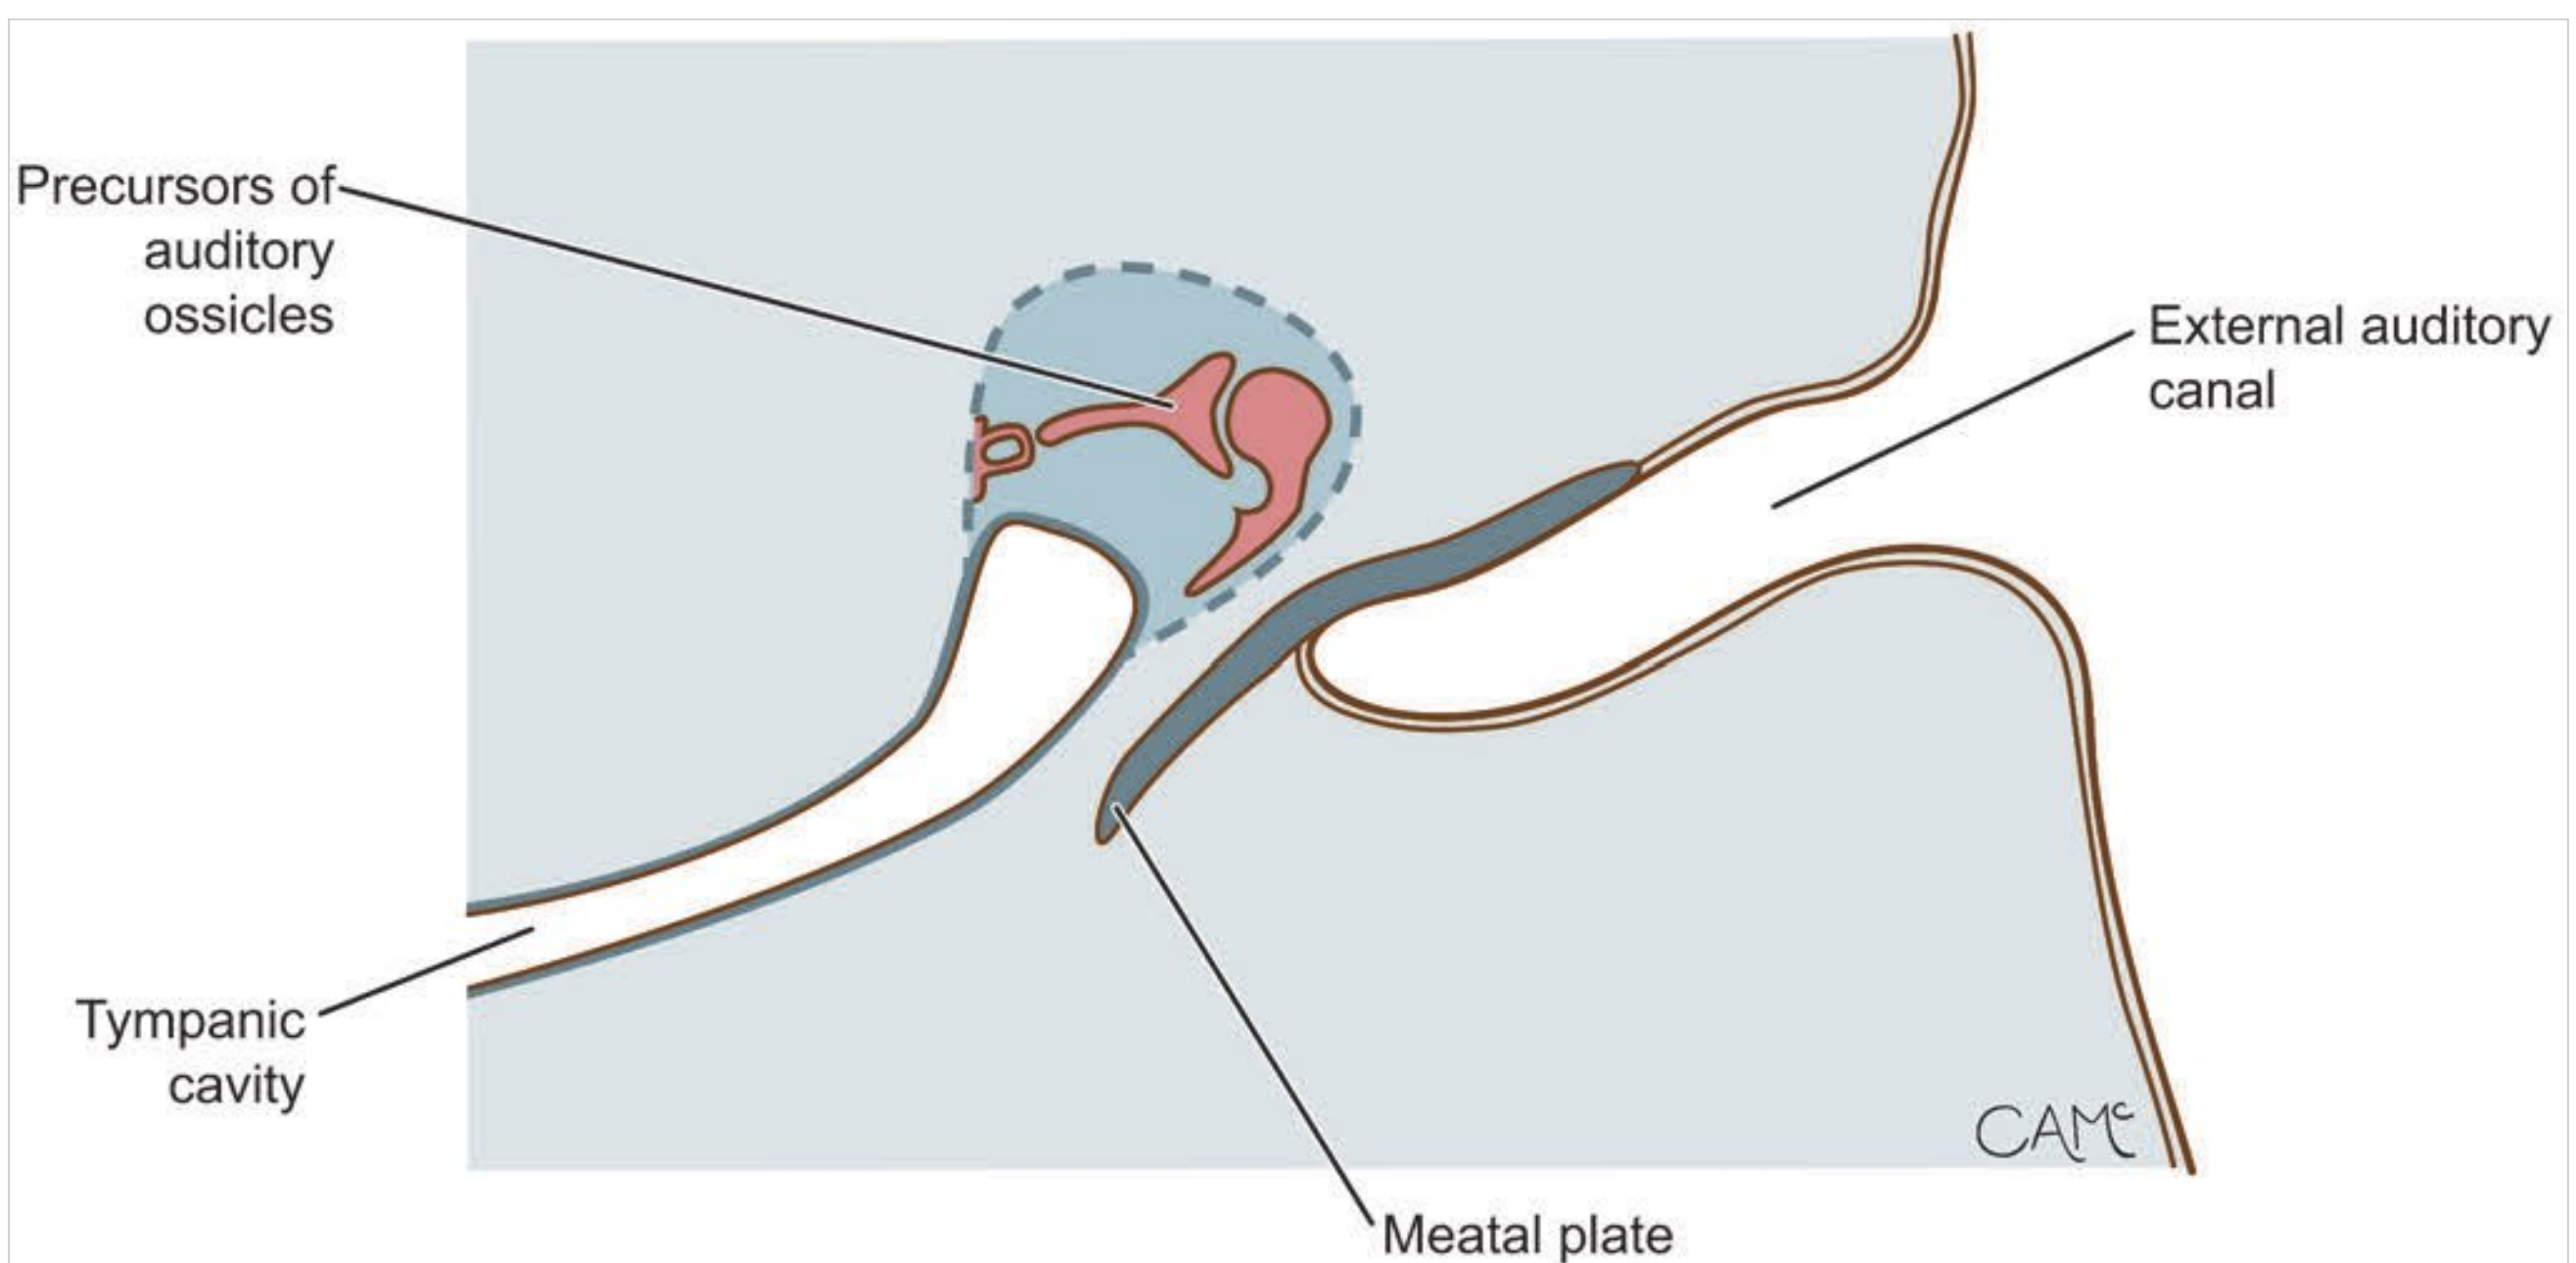

Fig. 111.3 Coronal view of a left ear. Branchial arches 1 and 2 give rise to the first branchial cleft, which invaginates and meets the first pharyngeal pouch to form the external auditory canal, tympanic membrane, and middle ear cleft.

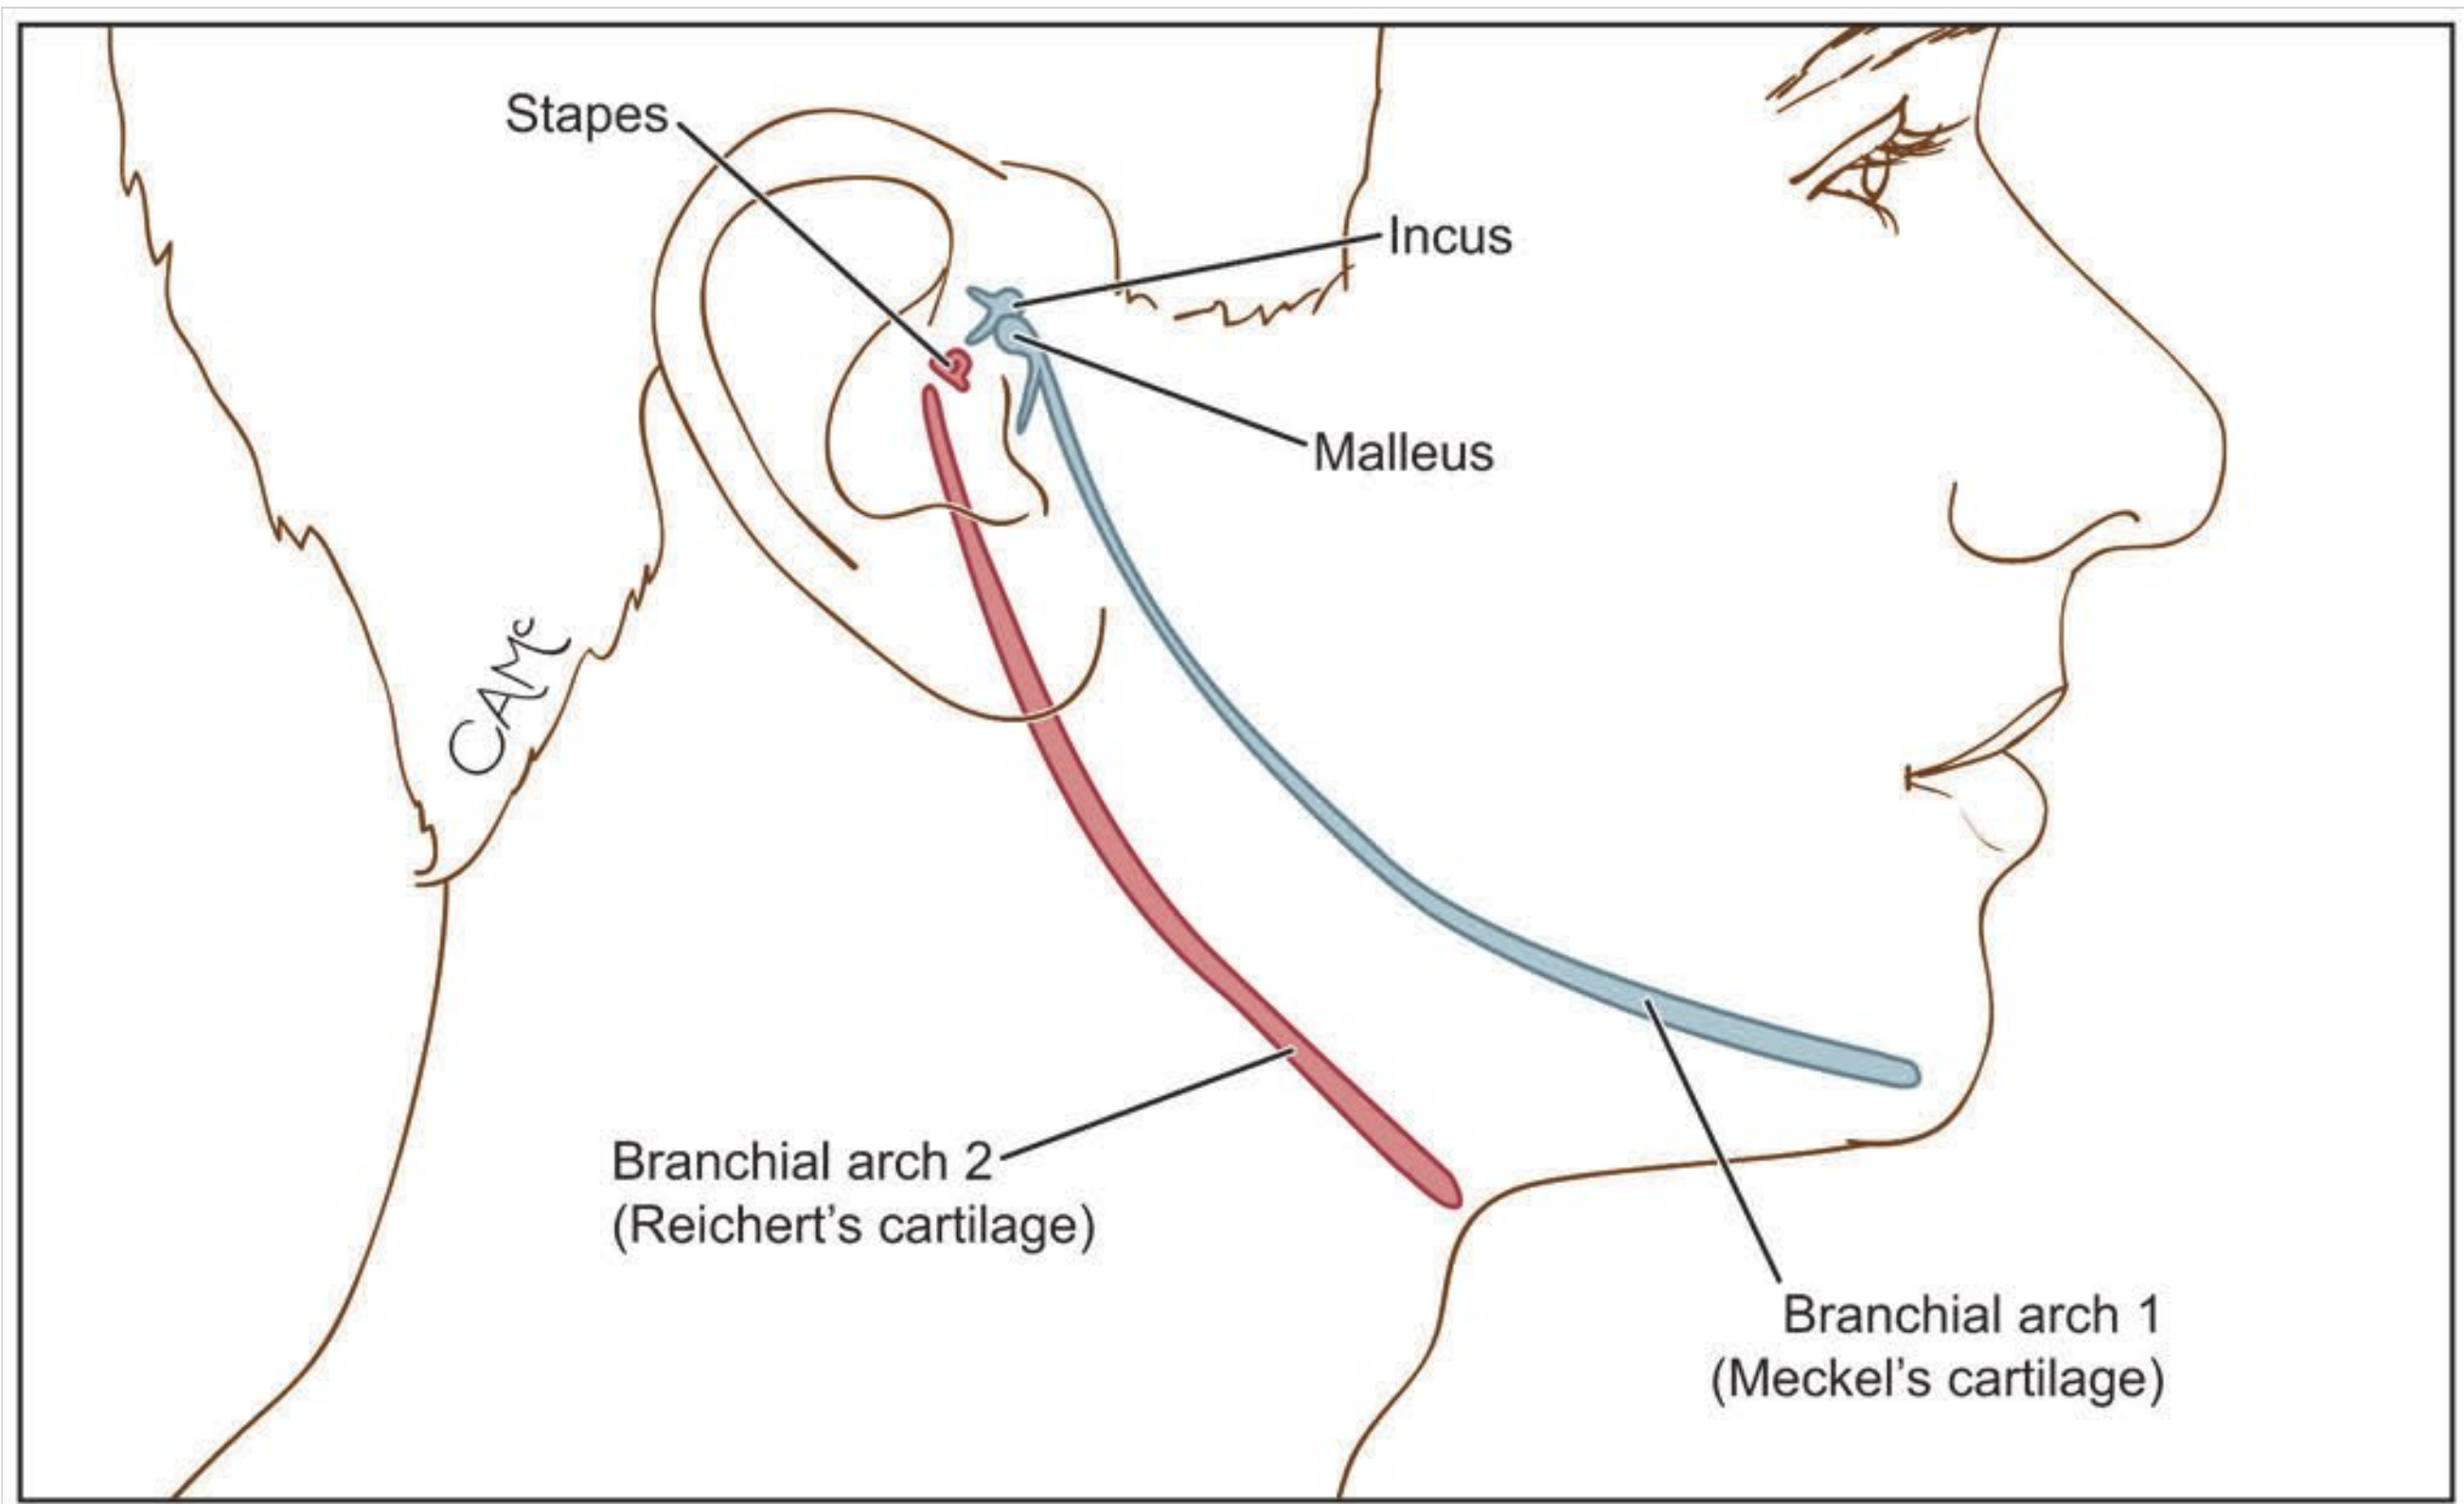

Fig. 111.4 Derivatives of the cartilage of branchial arch 1 (Meckel cartilage) and branchial arch 2 (Reichert cartilage).

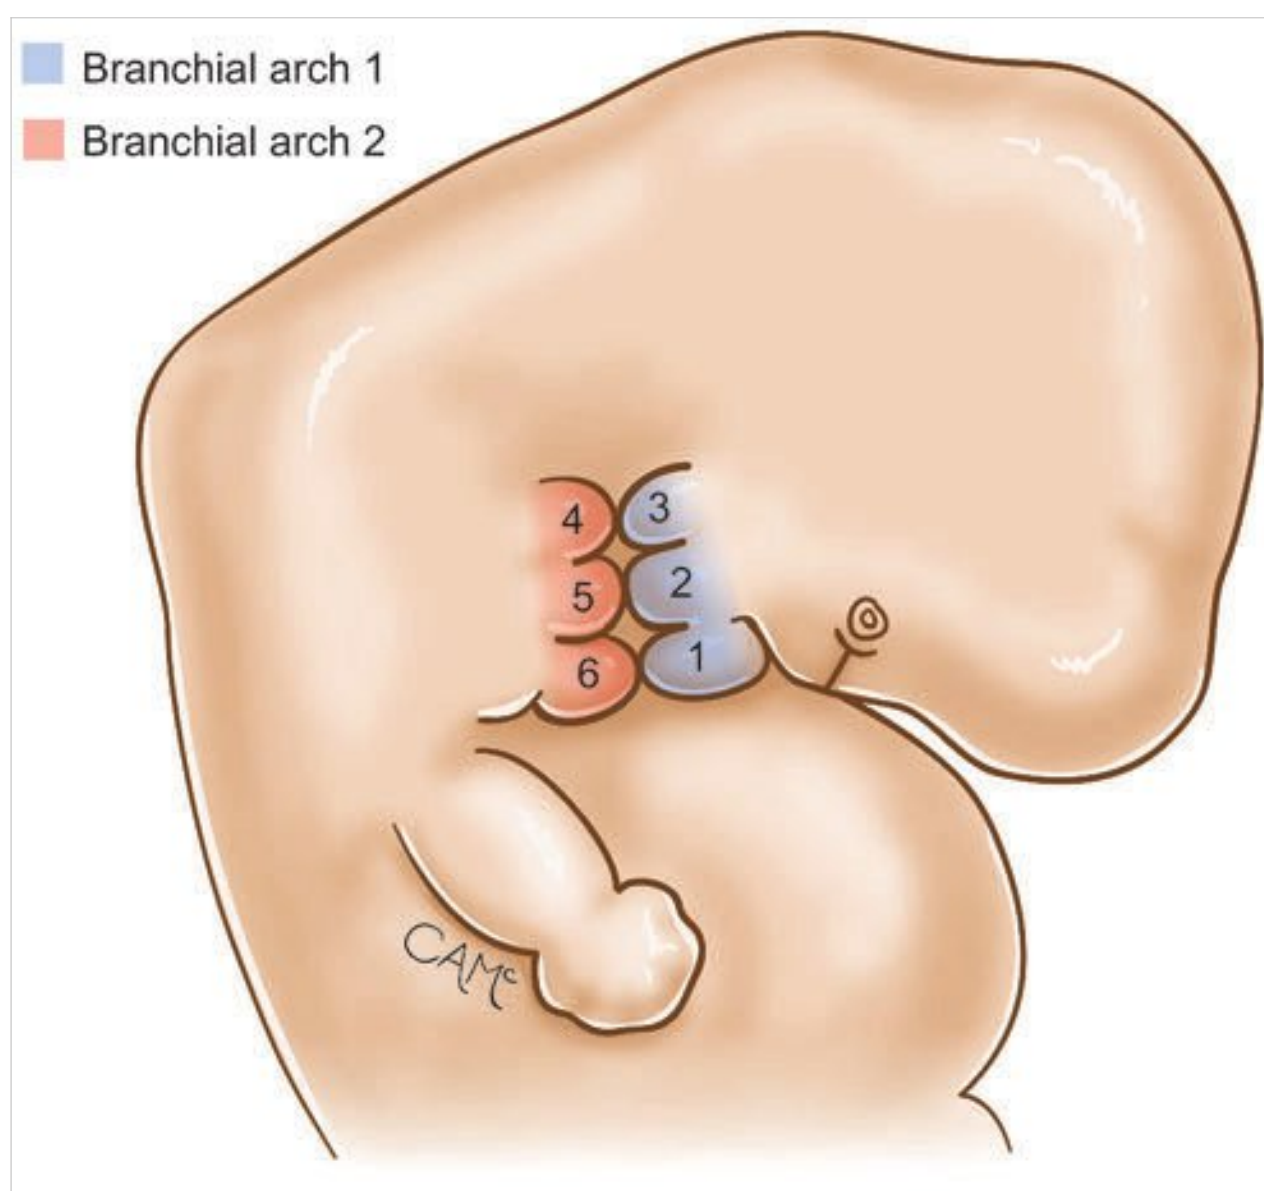

Fig. 111.5 Branchial arches 1 and 2 give rise to the six preauricular cartilaginous hillocks that will form the auricle.

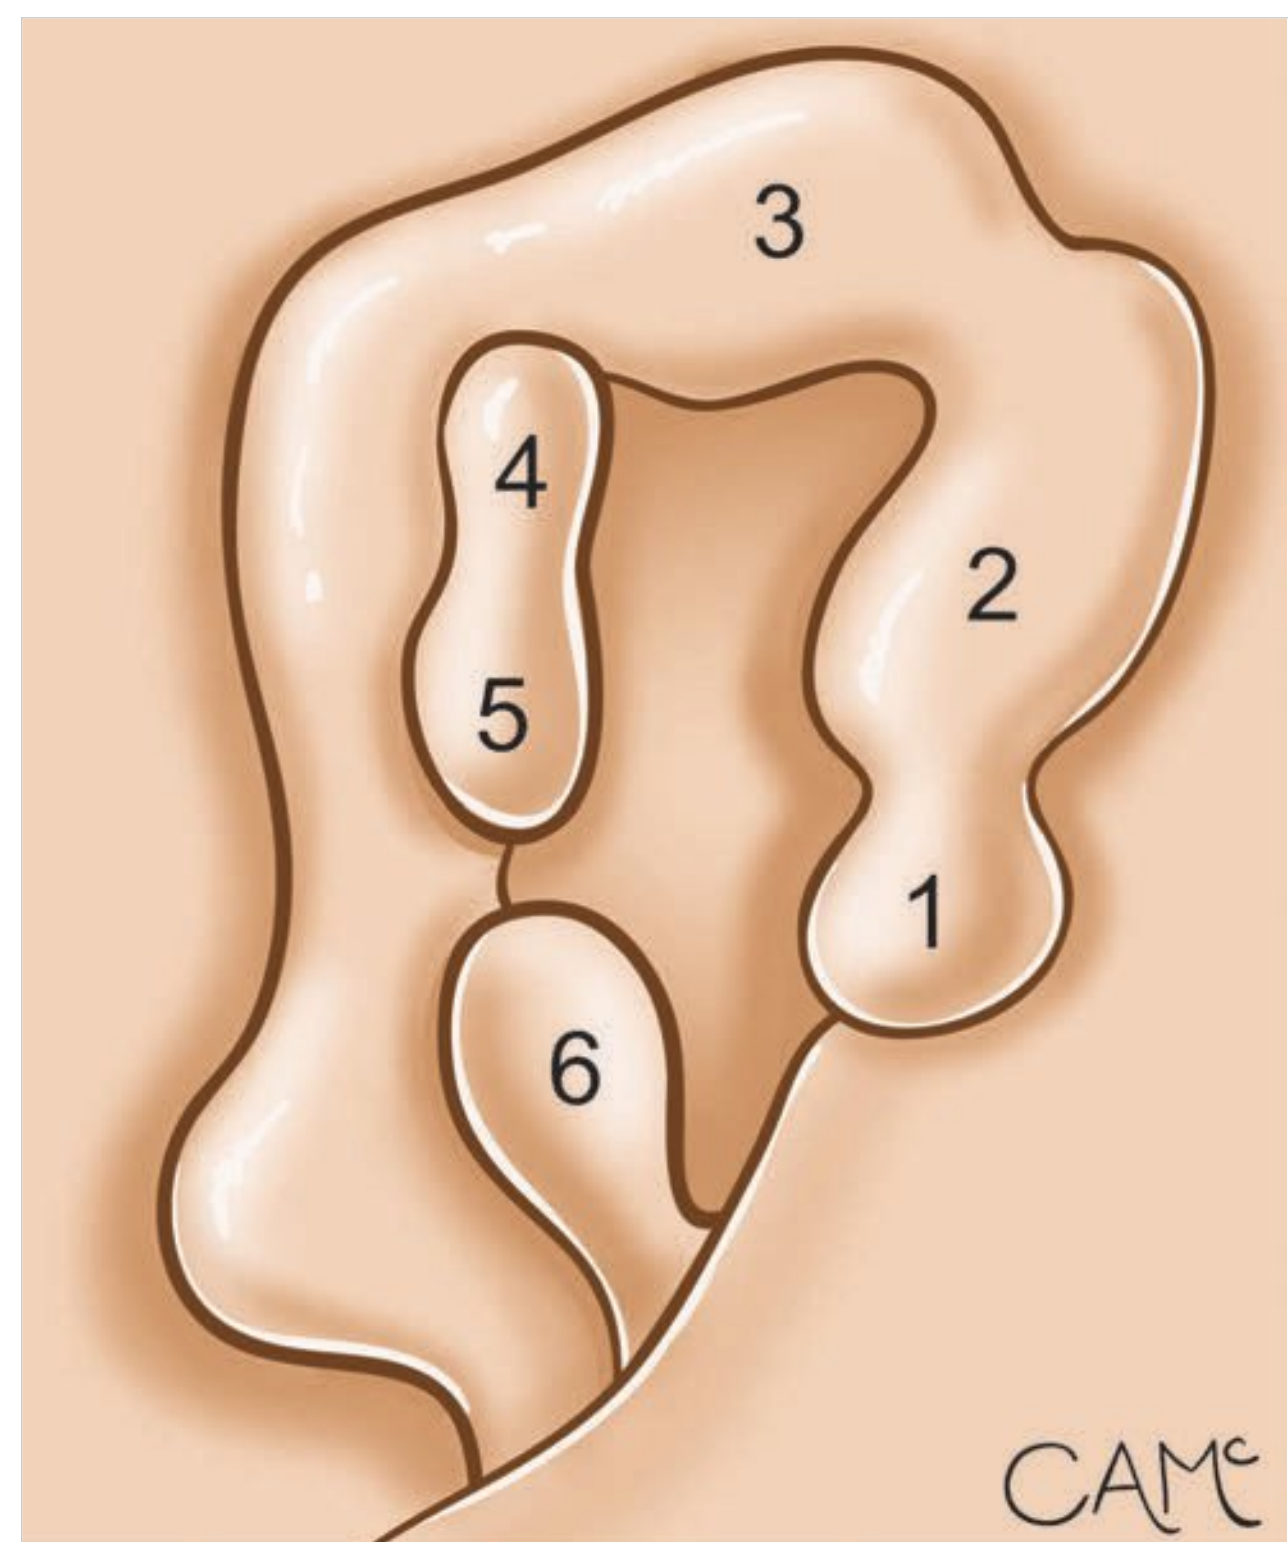

Fig. 111.6 Further development of the six preauricular hillocks into the cartilaginous skeleton of the auricle.

tragus (hillock 1), anterior helix (hillock 2), remainder of the helix (hillock 3), superior part of the antihelix (hillock 4), inferior part of the antihelix (hillock 5), and the antitragus and lobule (hillock 6). The outer and middle ear should be thought of as one developmental “unit.” The inner ear develops simultaneously, but as a separate entity.

111.2.1 Early Embryonic and Fetal Life

The primordium of the inner ear appears in early embryonic life as a collection of plaque-like ectodermal cells on the cephalic end of the embryo next to the open neural tube of the rhombencephalon. This plaque, the otic placode (see □ Fig. 111.2), migrates medially into the surrounding mesenchyme and pinches off to form a pit, the otic vesicle. The otic vesicle continues to migrate medially toward the acoustic ganglion of the developing brain, from which it will derive its innervation. It migrates to lie near the first and second branchial arches. The five branchial arches in the human embryo (1, 2, 3, 4, and 6; 5 is rudimentary) are separated from one another by clefts (outside) and pouches (inside). Each arch has a mesodermal core, is covered with surface ectoderm, and is in close proximity to a pharyngeal pouch with its endodermal lining. Each branchial arch thus has all three structural subunits of development. The mesodermal center develops into the cartilage of the arch: the Meckel cartilage in branchial arch 1 and the Reichert cartilage in branchial arch 2. Each arch will have an arterial supply that involutes and is replaced by a named artery, a corresponding vein, and a nerve. The artery and nerve of branchial arch 1 are the external maxillary artery and the mandibular division of

the trigeminal nerve (V_3); the arterial supply and nervous supply of branchial arch 2 are the facial artery and nerve, respectively.

As the tubotympanic recess of pharyngeal pouch 1 migrates laterally through mesenchyme, it forms the eustachian tube and middle ear cleft. Its endodermal lining envelops the ossicles and will ultimately invest them with respiratory epithelium (pseudostratified columnar epithelium containing supporting cells and mucus-producing goblet cells). Meanwhile, the cleft between branchial arches 1 and 2 (first arch cleft) migrates medially to meet pharyngeal pouch 1. A “sandwich” of these three tissue layer derivatives will form the tympanic membrane: ectoderm (squamous epithelium) laterally, mesenchyme (fibrous middle layer of the tympanic membrane) centrally, and endoderm (respiratory epithelium) medially.

111.3 Ear Development: The Long of It

111.3.1 The Inner Ear

By the first month after conception, the otic placode (ectoderm; see □ Fig. 111.2) has formed in the region of the rhombencephalon. This deepens and migrates medially to form the otic pit, subsequently separating from the surface and becoming the otic vesicle. This is lined by ectoderm (and will be innervated by neural crest cells derived from the neural crest of the rhombencephalon, the acousticofacial ganglion) and is termed the otocyst. Two regions of each otocyst soon become recognizable: a dorsal or utricular portion (□ Fig. 111.8), from which the endolymphatic duct arises, and a ventral or saccular portion. The otic vesicle then begins to divide into three basic subunits (see □ Fig. 111.2 and □ Fig. 111.8; □ Fig. 111.9, □ Fig. 111.10, □ Fig. 111.11).

Fig. 111.7 Derivatives of the six preauricular hillocks in the normal human auricle.

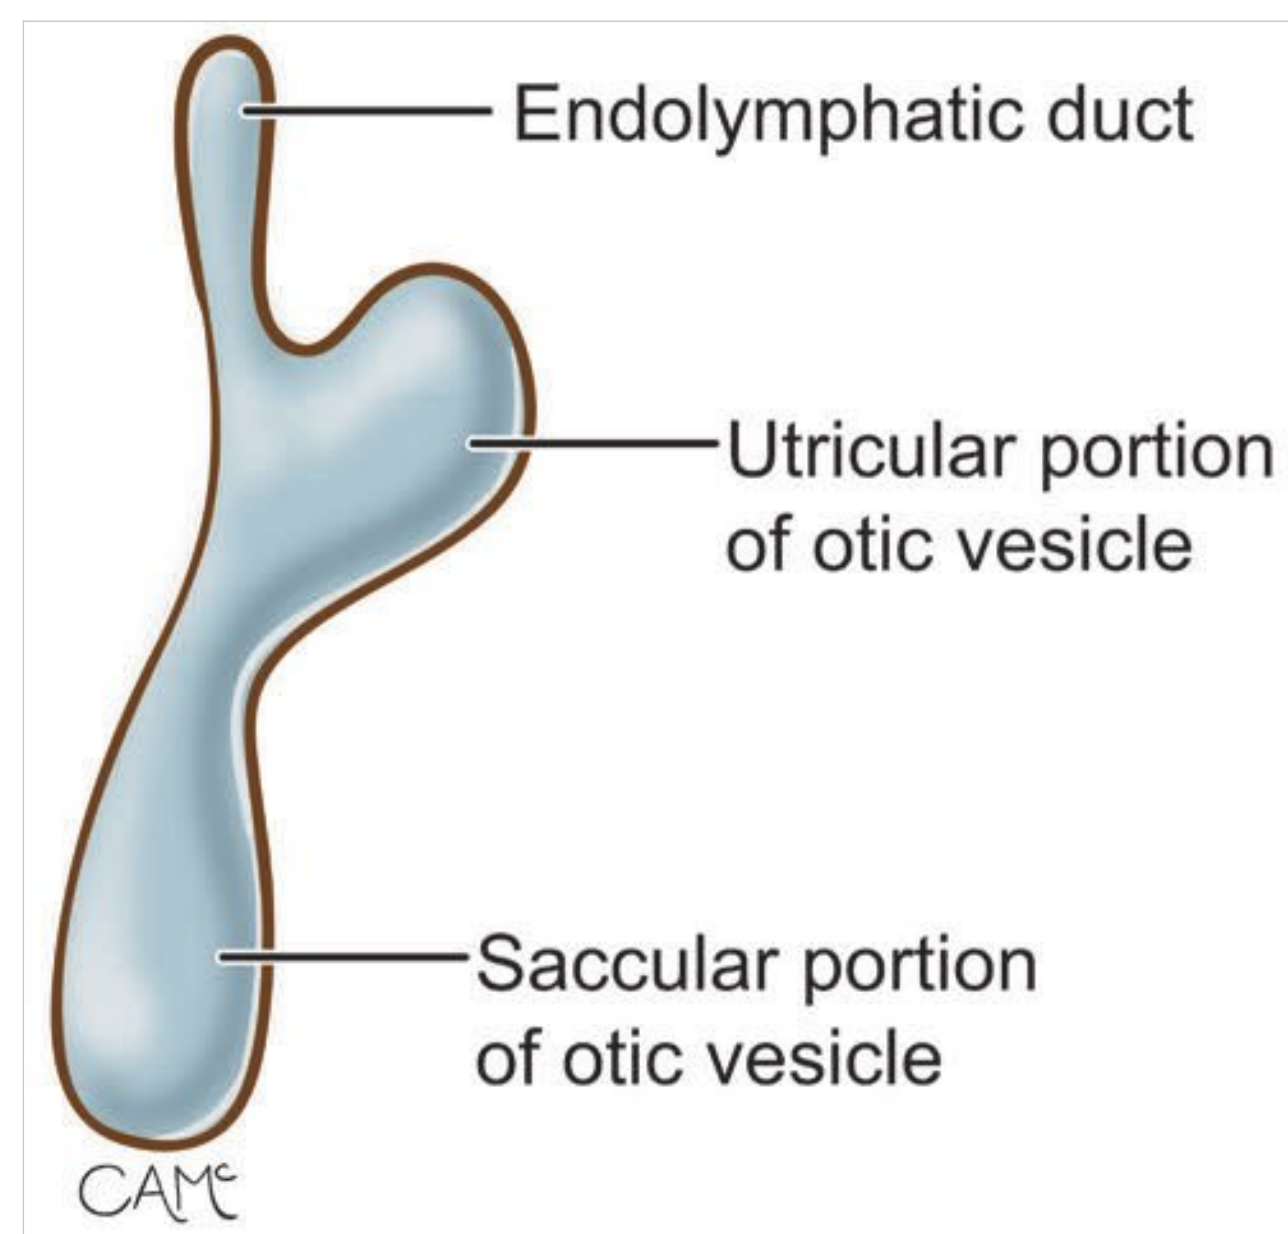

Fig. 111.8 The otocyst differentiates into a dorsal (utricular) portion, which also gives rise to the endolymphatic duct, and a ventral (saccular) portion.

1. First fold → endolymphatic sac.
2. Second fold → pars superior or vestibular section (phylogenetically older) → semicircular canals and utricle.
3. Third fold → pars inferior or cochlear section (phylogenetically newer) → cochlea, including the footplate of the stapes and saccule.

The second and third folds are connected by a constricted area called the utriculosaccular duct, leading from the pars superior (vestibular) to the pars inferior (cochlear) to the endolymphatic duct and sac. The saccule is separated from the cochlea by a deep constriction, termed the ductus reuniens. The membranous labyrinth is formed by the end of the seventh embryonic week.

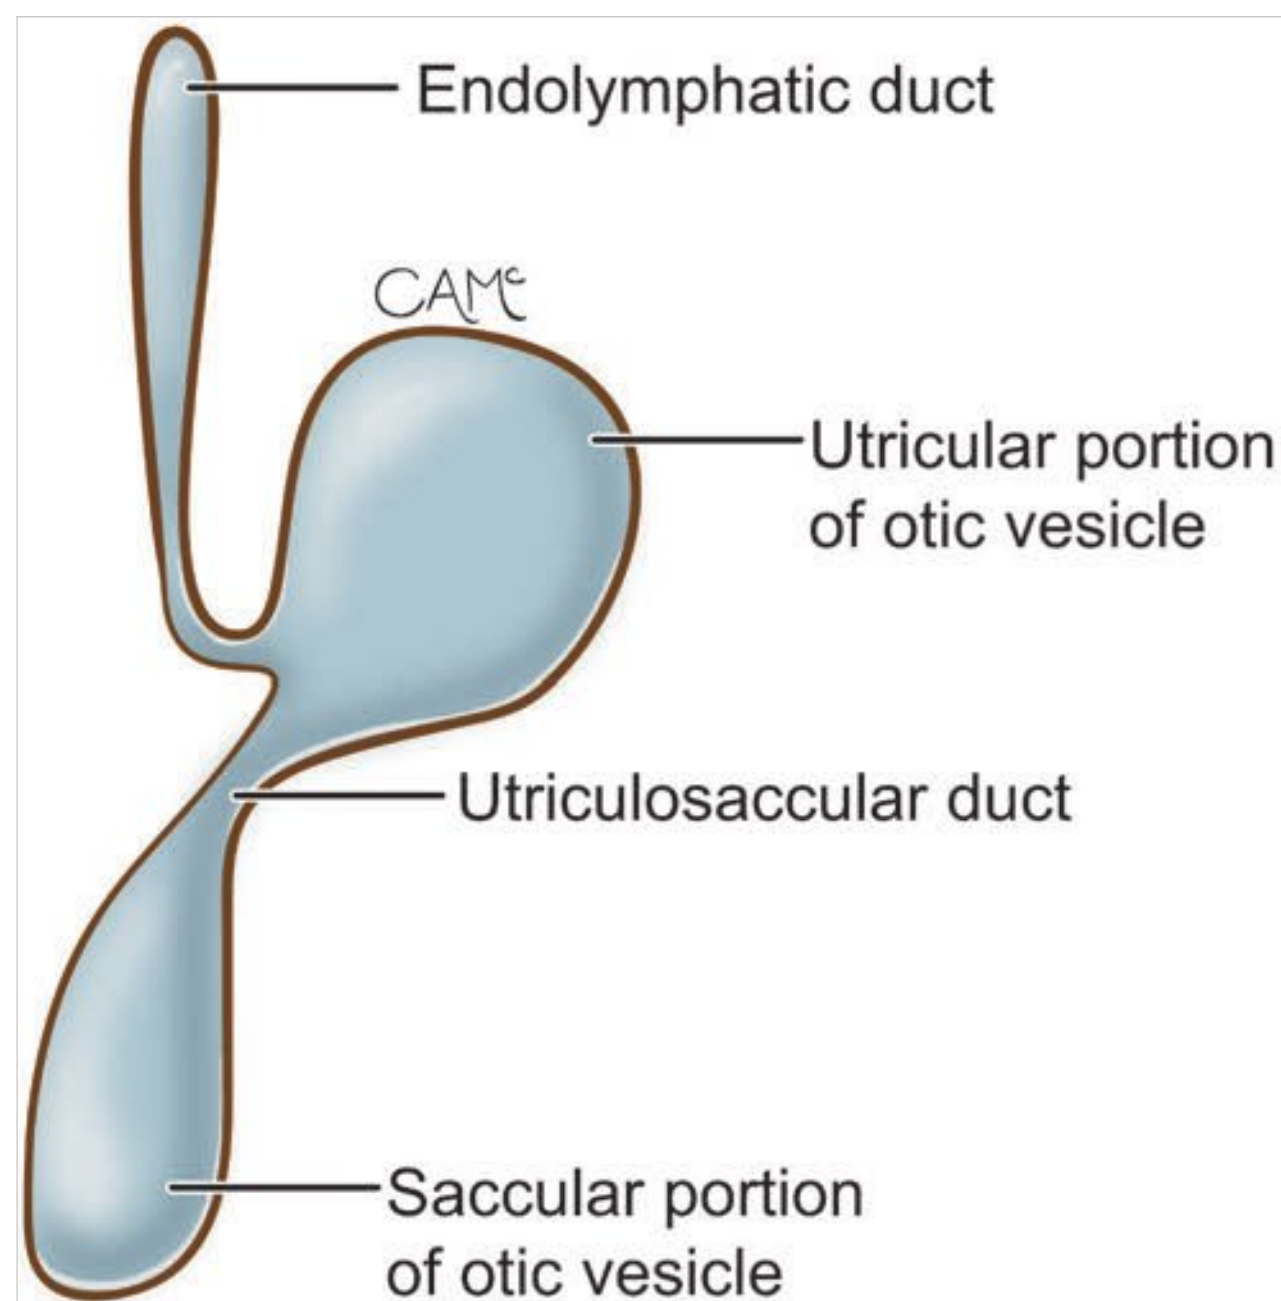

Fig. 111.9 Derivatives of the pars superior are the vestibular labyrinth, utricle, and endolymphatic sac. Derivatives of the pars inferior are the saccule, cochlea, and medial portion of the stapes footplate.

111.3.2 The Semicircular Canals, Utricle, and Saccule

Three flat, disclike diverticula grow out from the utricular portion (from the pars superior), and soon the central portions of the walls of these diverticula fuse and then disappear (see □ Fig. 111.2, □ Fig. 111.8, □ Fig. 111.9, □ Fig. 111.10, □ Fig. 111.11). The peripheral, unfused portions of the diverticula become the semicircular ducts, which are attached to the utricle and enclosed within the semicircular canals of the labyrinth. The three semicircular canals develop ampullated ends, all of which will eventually lie near the facial nerve, oriented roughly in the x, y, and z planes; each ampullated end contains a cupula comprising a gelatinous layer with both supporting and neuroepithelial cells, stereocilia, and kinocilia. The semicircular canals detect angular acceleration when the endolymph moves toward or away from the kinocilia, which serve as a reference. The saccule and utricle develop into gravity-sensing organs with a gelatinous otolithic membrane, upon which microscopic calcium carbonate crystals (otoconia) lie. These have mass and are affected by gravity. The innervation is from below the supporting and neuroepithelial cells. The superior portion of the vestibular ganglion innervates the cristae ampullares of the lateral and superior semicircular canals and the macula of the utricle. The inferior portion of the vestibular ganglion innervates the crista ampullaris of the posterior semicircular ampulla and the macula of the saccule.

111.3.3 The Cochlea

From the ventral (saccular) portion of the otocyst, a tubular diverticulum, the cochlear duct, grows and coils like a snail in two and three-quarter turns to form the cochlea. As the membranous labyrinth enlarges, vacuoles appear in the cartilaginous otic capsule and soon coalesce to form the perilymphatic space. The membranous labyrinth is now suspended in a fluid, the perilymph, within the perilymphatic space. The perilymphatic space related to the cochlear duct develops into two divisions: the scala tympani and the scala vestibuli. The cochlear duct is seen in the adult as the scala media. The scala tympani and scala vestibuli communicate at the helicotrema; the scala media is

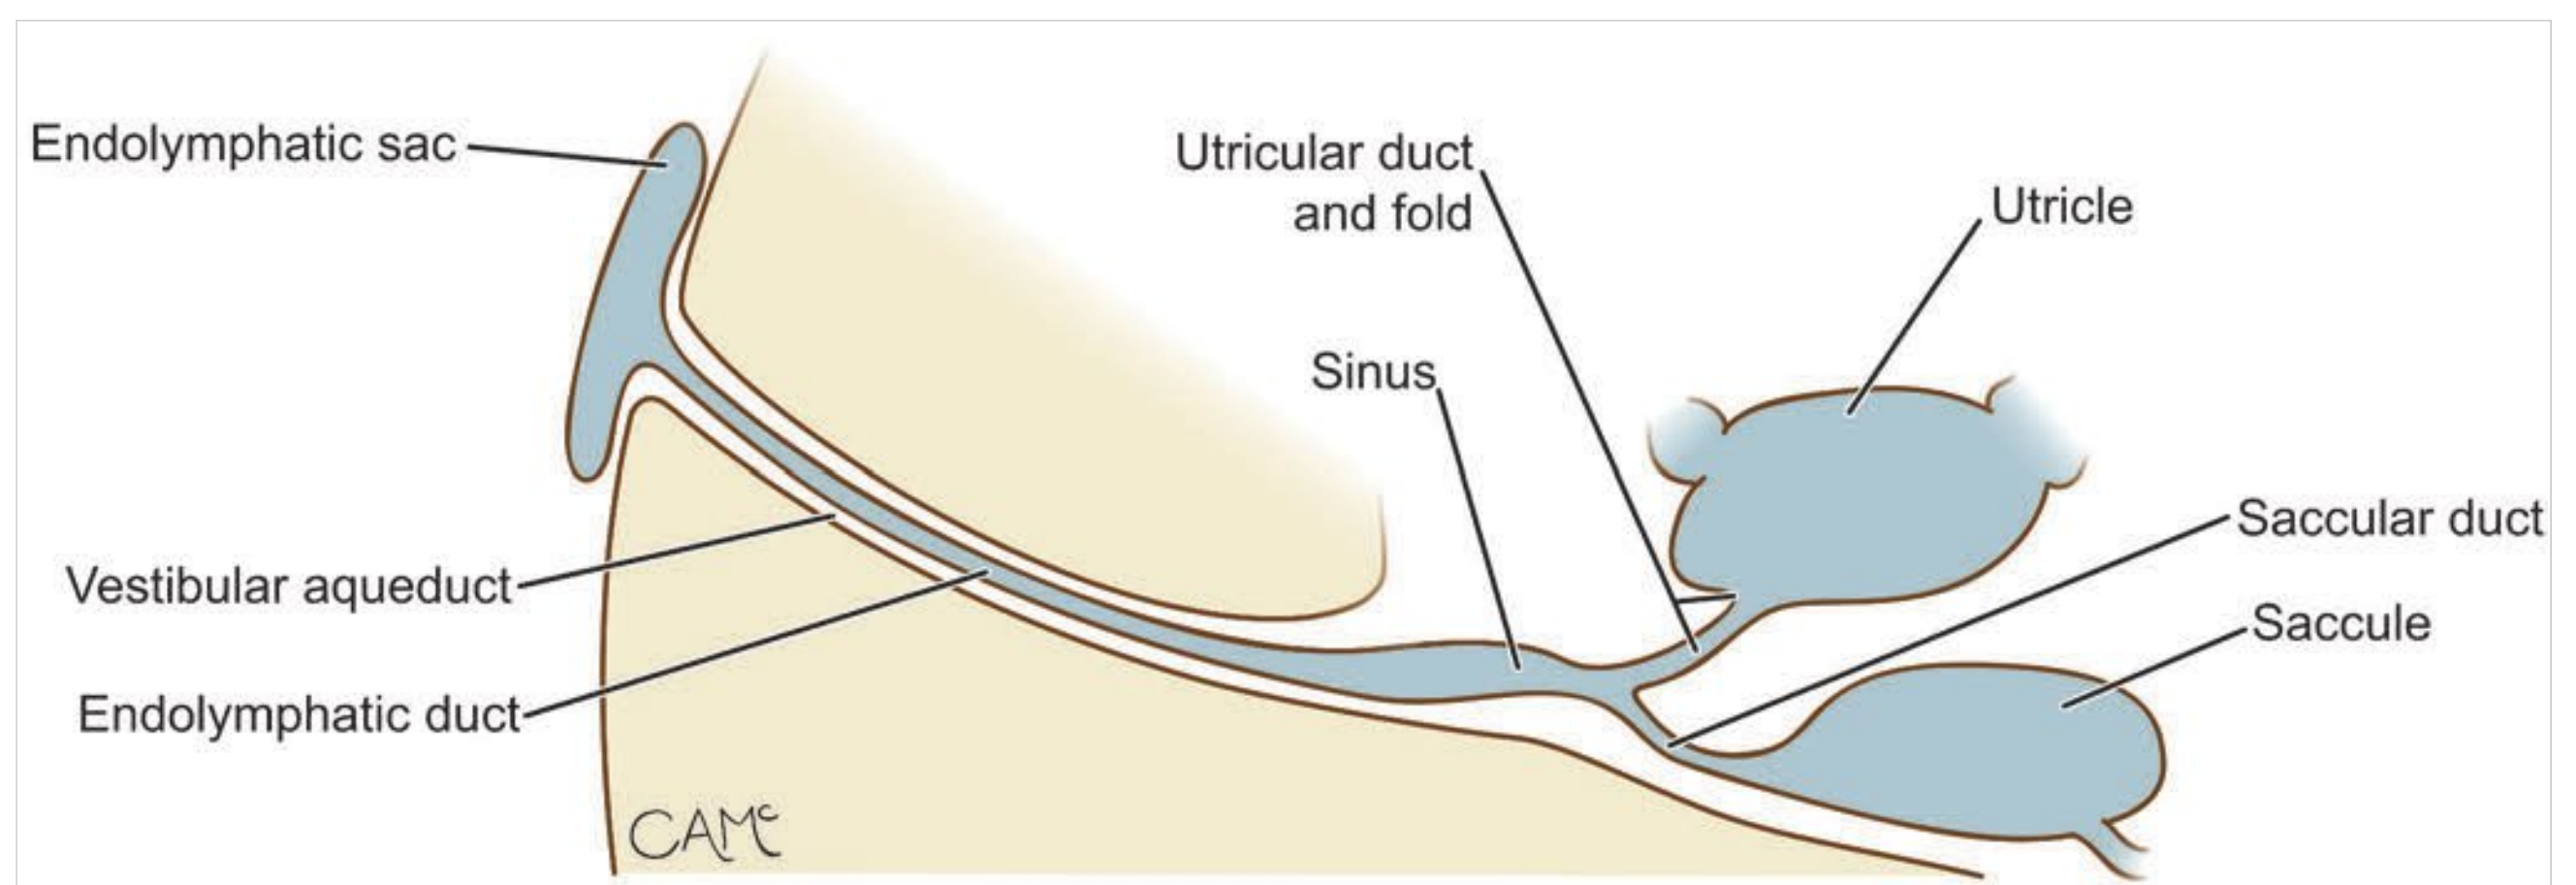

Fig. 111.10 Further development leads to distinct utricular, saccular, and endolymphatic sac formation.

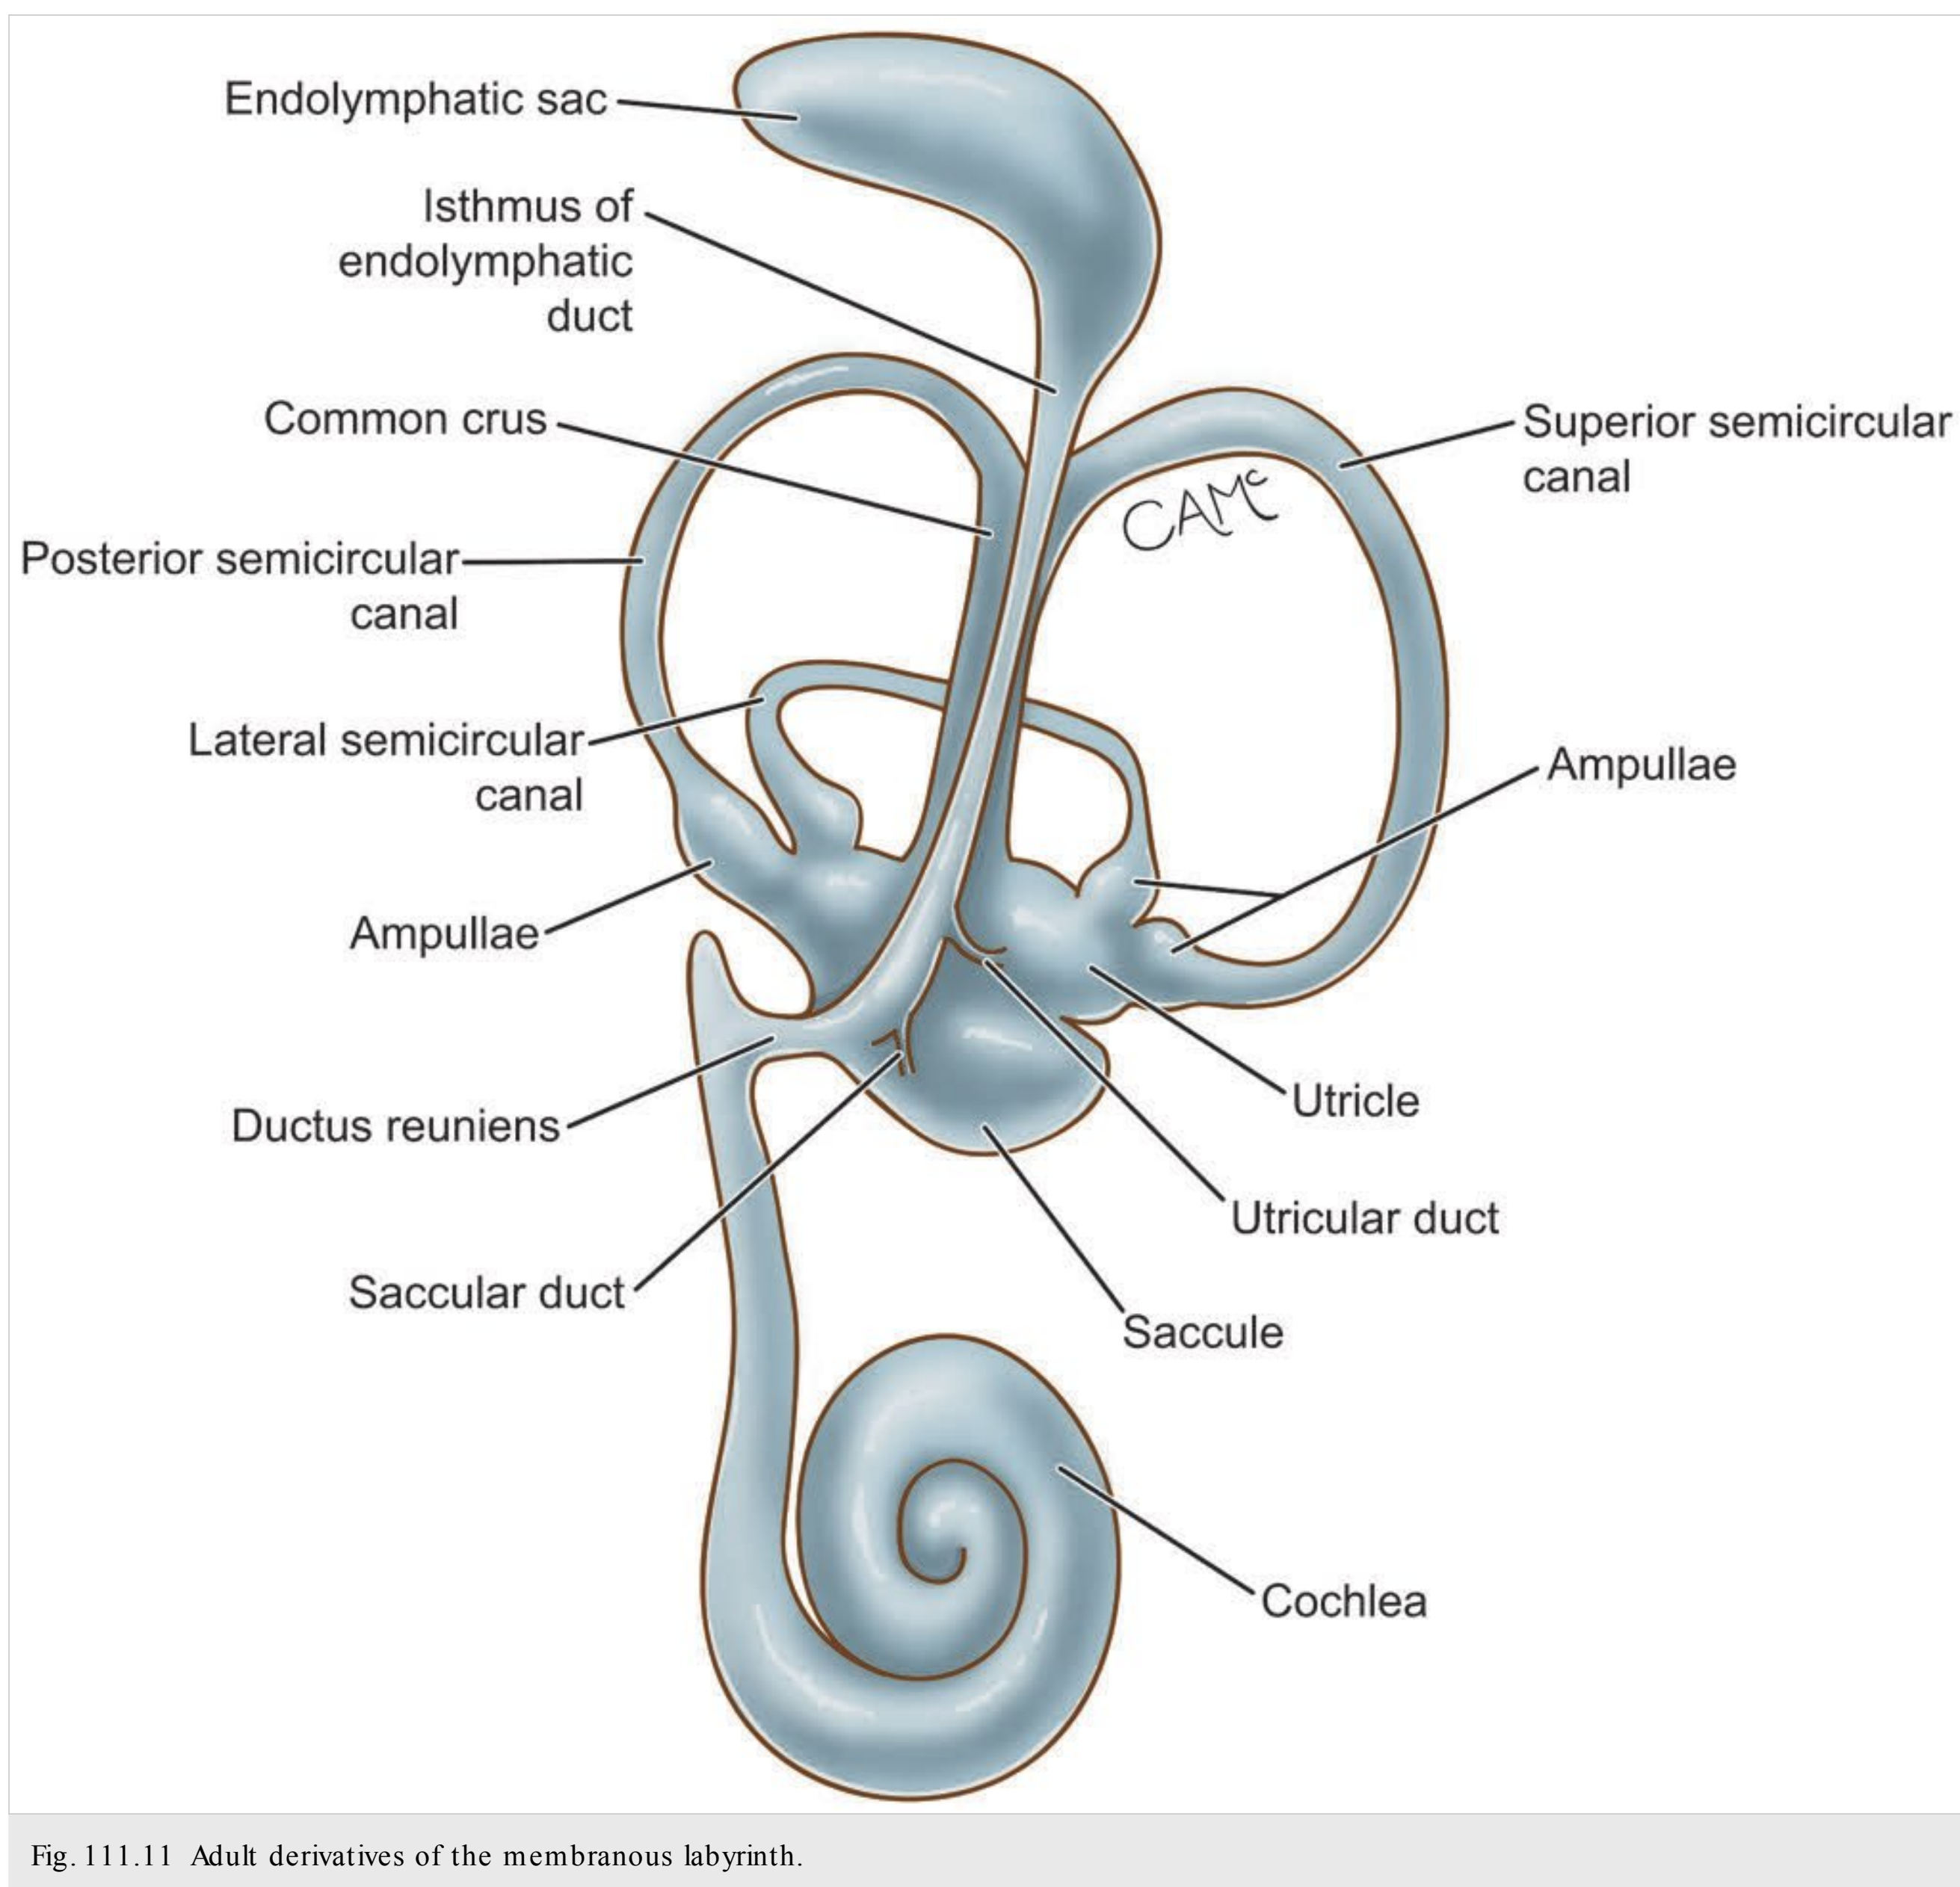

Fig. 111.11 Adult derivatives of the membranous labyrinth.

always separate. Within the cochlear duct (scala media), the connection of the cochlea with the saccule (pars inferior) becomes constricted to form the narrow ductus reuniens (see □ Fig. 111.11).

The organ of Corti differentiates from cells in the wall of the cochlear duct. Ganglion cells of cranial nerve VIII migrate along the turns of the cochlea and form the spiral ganglion, which innervates the organ of Corti. Within the organ of Corti, the epithelial cells differentiate into two columnar ridges, the inner ridge and the outer ridge, which elaborate the tectorial membrane. The inner ridge, called the spiral lamina, becomes the anatomical anchoring point for the organ of Corti. The spiral lamina, together with the helical bony nerve canal, is called the modiolus. The cartilaginous otic capsule ossifies from cartilaginous rests to form the bony (osseous) labyrinth of the inner ear.

The membranous labyrinth attains its adult size in the fetus. The surrounding otic capsule mesenchyme first chondrifies, then ossifies from approximately 14 to 16 ossification centers. Enchondral ossification takes place in all areas of the petromastoid temporal bone except in those areas with endosteal or periosteal surfaces (e.g., fissula ante fenestram). Therefore, three bony layers are histologically present within the temporal bones: the endosteal, enchondral, and periosteal layers.

111.3.4 The Middle Ear and Ossicles

The dorsal end of the first branchial arch cartilage (pars dorsalis of the Meckel cartilage) is closely related to the developing ear and becomes ossified to form the first two bones of the middle ear, the malleus and the incus (see □ Fig. 111.4). The intermedi-

Table 111.1 Auricular derivatives of the hillocks of His

4	Antihelix (superior part)
5	Antihelix (inferior part)
6	Antitragus and lobule

ate portion of the cartilage regresses and forms the anterior malleolar ligament. The trigeminal nerve (cranial nerve V) is the nerve of the first arch. Its derived and innervated muscles include the tensor tympani and the tensor veli palatini, and the anterior belly of the digastric muscle.

The dorsal end of the second arch cartilage (pars dorsalis of the Reichert cartilage) ossifies to form the stapes (all except the footplate) and the styloid process of the temporal bone. The facial nerve (cranial nerve VII) is the nerve of the second branchial arch, and its derived and innervated muscles include the muscles of facial expression, stapedius muscle, and posterior belly of the digastric muscle.

The primitive pharynx is wide cranially and narrows caudally as it joins the esophagus. Pairs of pharyngeal pouches lined by endoderm develop in a craniocaudal sequence between the branchial arches. The first pharyngeal pouch thus lies between the first and second branchial arches. The first pharyngeal pouch expands into an elongated tubotympanic recess and envelops the structures of the middle ear cleft, creating an investiture of respiratory epithelium over all of the structures within the middle ear. The expanded distal portion of this recess contacts the first branchial groove (primordium of the external acoustic meatus) and later contributes to the formation of the tympanic membrane. During the late fetal period, the tympanic cavity gives rise to the mastoid antrum. The tubotympanic recess invaginates and pneumatizes the mesenchyme posterior to the ossicles, forming the aditus ad antrum and the antrum. Even in very poorly pneumatized temporal bones, the antral air cells are almost always found because their formation is an early developmental event. Further mastoid pneumatization occurs during childhood and depends upon normal eustachian tube function. The epithelial lining of the middle ear induces erosion of the surrounding mastoid bone; this is at least in part due to the fact that the partial pressure of air within the middle ear, aditus ad antrum, and antrum is greater than the resting pressure of bone marrow.

111.3.5 The External Ear

The external acoustic meatus develops from the dorsal end of the first branchial groove. The ectodermal cells at the bottom of this funnel-shaped tube proliferate and extend inward as a solid

epithelial plate, the meatal plug. By the early part of month 7 of gestation, the central cells of this plug degenerate, thereby forming a cavity that becomes the inner part of the external acoustic meatus. The early tympanic membrane is composed of the ectoderm of the first branchial membrane, which separates the first branchial groove and the first pharyngeal pouch. The middle layer of mesenchyme of the first and second branchial arches persists between these two as the fibrous layer of the tympanic membrane.

The auricle develops from the superficial mesoderm of branchial arches 1 and 2, which give rise to the six preauricular cartilaginous hillocks arranged around the dorsal part of the first branchial cleft. The preauricular hillocks grow and mature to form the auricle (□ Table 111.1; see □ Fig. 111.5, □ Fig. 111.6, □ Fig. 111.7).

The parts of the auricle derived from the first branchial arch are supplied by the mandibular branch of the trigeminal nerve; those derived from the second branchial arch are supplied by cutaneous branches of the cervical plexus, especially the lesser occipital and great auricular nerves. The facial nerve has few cutaneous branches, but some fibers contribute to the sensory innervation of the skin in the mastoid region and auricle.

111.4 Roundsmanship

- The external and middle ear clefts should be thought of as linked developmental entities.
- Any end organ innervated by the central nervous system develops from ectoderm. The development of the inner ear should be thought of as an event that occurs simultaneously with but separately from the development of the external and middle ear clefts.
- The external auditory canal develops from the first branchial cleft.
- The cartilaginous anlage of the first branchial arch is the Meckel cartilage, which gives rise to the malleus and incus.
- The middle ear, the eustachian tube, and its adnexa develop from the first pharyngeal pouch.
- The cartilaginous anlage of the second branchial arch is the Reichert cartilage, which gives rise to the stapes (except the footplate) and the styloid process.
- The auricle (pinna) develops from six auricular hillocks of cartilage, three each from branchial arches 1 and 2.

112 Auditory Function and Dysfunction

Mila Quinn, Miriam I. Redleaf, and Christopher J. Linstrom

112.1 Introduction

The auditory system has several major distinctions from the vestibular system. The auditory system depends upon a physical interface with the environment: that is, sound vibrations must have open access to entry points into the primary receptive organ, the cochlea. Unlike in the vestibular system, there is no central compensation for unilateral auditory loss. Unlike vestibular sensations, auditory sensations are usually forefront in the conscious mind and are extensively manipulated for the pleasure they bring. The effects of untreated bilateral loss of auditory function are devastating, interrupting the acquisition of information, social contact, and personal growth.

112.2 Transmission of Sound Waves

The anatomical structure that allows the propagation of sound waves is in theory simple. The external auditory canal must have an air-filled lumen—an unobstructed air passage—to allow sound to arrive at the tympanic membrane. Additionally, each external canal has a resonant frequency that amplifies sound in the range of 3 to 4 kHz, much like a narrow-mouthed bottle. Structurally, the external auditory canal is lined with skin containing normal appendages as well as ceruminous glands. The medial portion of the canal is bony, whereas the lateral portion is cartilaginous. The physiologic purpose of the external auditory canal is to direct sound toward the tympanic membrane. However, many factors, both congenital and acquired, can cause canal occlusion.

The most common adult otologic complaint is cerumen impaction associated with secondary conductive hearing loss. Other causes of canal occlusion in adults include chronic ear canal dermatitis (i.e., chronic otitis externa), chronic infection, trauma, osteomata, and exostoses. In children, canal occlusion is most often caused by cerumen. Clearing the external ear of cerumen and/or other debris in most cases immediately improves hearing, usually to the level of the preoccluded state.

112.3 Congenital Auricular Atresia/Microtia

Congenital auricular atresia with microtia occurs rarely (approximately 1 in 1,000 live births), and the incidence varies by race. Congenital canal atresia typically presents very early in life. Despite the desire of parents and referring physicians for early intervention, only otoacoustic emissions testing of the normal ear is appropriate at this time. If the results of otoacoustic emissions testing are normal in the unaffected ear, it is highly likely that this ear will hear well and that the child will develop speech normally; however, if the results are abnormal or unobtainable, an auditory brainstem reflex test (ABR), either with sedation or under general anesthesia, is required to document the level of audition. In cases of bilateral congenital auricular atresia,

otoacoustic emissions testing is not possible, and an ABR with bone stimuli is required. Imaging studies, such as computed tomography (CT) of the temporal bones, add nothing to the immediate diagnostic needs of the child, expose the patient to approximately 50 times the radiation dose of a chest X-ray, and should be performed only before a surgical intervention. The banded bone-anchored hearing aid (BAHA) or baby BAHA is FDA-approved in the United States for children ages 6 months and older. Thus, there is time for both adequate diagnostic testing and therapeutic intervention, even in a child who has bilateral congenital auricular atresia with microtia.

The rare indication for CT before planned surgical correction of congenital auricular atresia (usually no sooner than the end of the child's sixth or seventh year) is to rule out cholesteatoma. This may hasten the time course of intervention but is usually not the only deciding factor. Surgery is generally not performed until the child is old enough to cooperate with postoperative care of the ear.

An older child without amplification may have speech delay or speech inaccuracies as a consequence of bilateral auricular conductive hearing loss. Again, emphasis should be placed on thorough audiometric testing of each ear and age-appropriate audiometric intervention, either with an air-level hearing aid, if possible, or with a vibrotactile hearing aid such as the banded BAHA. The insertion of the flange fixture for the BAHA is FDA-approved in the United States after the fifth birthday. If the child is very small, surgical intervention may be delayed until the skull is large and thick enough to accommodate a 3- or 4-mm flange fixture, usually after the sixth or seventh year. Unlike in adults, the insertion of a BAHA in children should be staged, with a 6-month period allowed for osseointegration of the flange fixture before the abutment is attached and the surrounding soft tissue is thinned.

Adult patients with partial stenosis of the external auditory canal may complain vigorously about itching in and drainage from the canal, and they may present with a history of recurrent ear infections accompanied by hearing loss. Physical examination of an adult will reveal the stenotic canal, and the skin may be visibly inflamed. If indicated, CT of the temporal bones demonstrates the extent of bony narrowing of the external ear, anatomy of the middle ear, integrity of the ossicular chain, anatomy of the otic capsule, and intratemporal course of the facial nerve.

Both medical treatment and surgery of the stenotic or atretic canal are difficult but not impossible. Inflamed and thickened canal skin can occasionally be treated successfully with topical steroids, antifungals, and antibiotics. Definitive treatment often involves excision of the occluding skin, canalplasty (widening of the bony canal), and placement of a thin split-thickness free skin graft to resurface the bony canal. The external auditory canal must be carefully packed to support the new grafts and treated with meticulous care during the healing period (approximately 6 weeks).

In pediatric cases of canal atresia, the treatment is more problematic. The atretic soft tissue and the calvaria adjacent to the external auditory canal, the atretic plate, span the site where the external canal would normally be located. The

ossicles are often malformed; the malleus and incus are typically fused and attached to the bone of the tympanic ring, and there is no tympanic membrane. The facial nerve may run through the middle ear space in an expectedly abnormal course. Because of the lack of height of the tympanic ring, the distance from the glenoid fossa to the middle cranial fossa may be too small to accommodate a neocanal with an adequate lumen. The lack of adequate height forces the neocanal to be located more posterosuperiorly, and the canal may not line up perfectly with the reconstructed tympanic membrane. Reconstruction of an atretic external auditory canal in children is successful only with perfect surgical technique and meticulous postoperative care. This is not an operation for the occasional or inexperienced otologist. The parents must be told that at least some form of postoperative stenosis is likely to occur, even if the initial meatus is widely patent, and that revisions are commonly necessary. A molded ear plug taken at the time of the initial surgery or revision and used during sleep may help to keep the reconstructed canal patent. Meticulous and frequent care is always required. Even if the conductive hearing loss is not improved to the level of soft speech (30 dB), the presence of a patent external auditory canal may allow placement of an air-level hearing aid.

Another successful option for hearing rehabilitation may be the placement of a bone conduction hearing aid. This can be a bone-anchored hearing aid (BAHA) in adults 18 years of age or older or in children older than 5 years, a dentally fixed conduction device in adults 18 years of age or older (SoundBite; Sonitus Medical, San Mateo, CA), or a traditional head-banded bone conduction hearing aid in children (e.g., the banded BAHA). Each device is a vibrotactile stimulator of the cranium and cochlea. The flange fixture (screw) of the BAHA undergoes osseointegration with the cranium behind the stenotic canal. The dental appliance is attached to the subjacent maxillary molars, and the traditional bone conduction aid vibrates against the adjacent cranium via the scalp. The vibratory signal propagates through the entire cranium, stimulating the ipsilateral cochlea. These devices usually eliminate a significant portion of the conductive hearing loss (i.e., only the neurosensory reserve of the cochlea is important in the preoperative evaluation). Because the BAHA is a percutaneous device, the skin over and adjacent to the flange fixture must be pierced and thinned.

112.4 Ossicular Amplification of Sound Vibrations

The next physiologic step in the auditory system is amplification of the sound waves. Transmission of sound waves to the inner ear is accomplished by the tympanic membrane, ossicles, and oval window footplate. The auricle helps to locate sound in the vertical plane. The external canal has its own resonance, which amplifies the 3- to 4-kHz range. Physiologically, the major factors that amplify incoming sound waves are the ratio of the area of the tympanic membrane to the area of the oval window footplate, and the lever action of the ossicles (□ Fig. 112.1).

The sound pressure (pressure = force/area) at ear level is naturally amplified 20-fold by the ratio of the tympanic membrane area to the footplate area, and the lever action of the native unobstructed ossicles increases the sound pressure by 1.3. Together, these increase the signal of the sound vibrations by

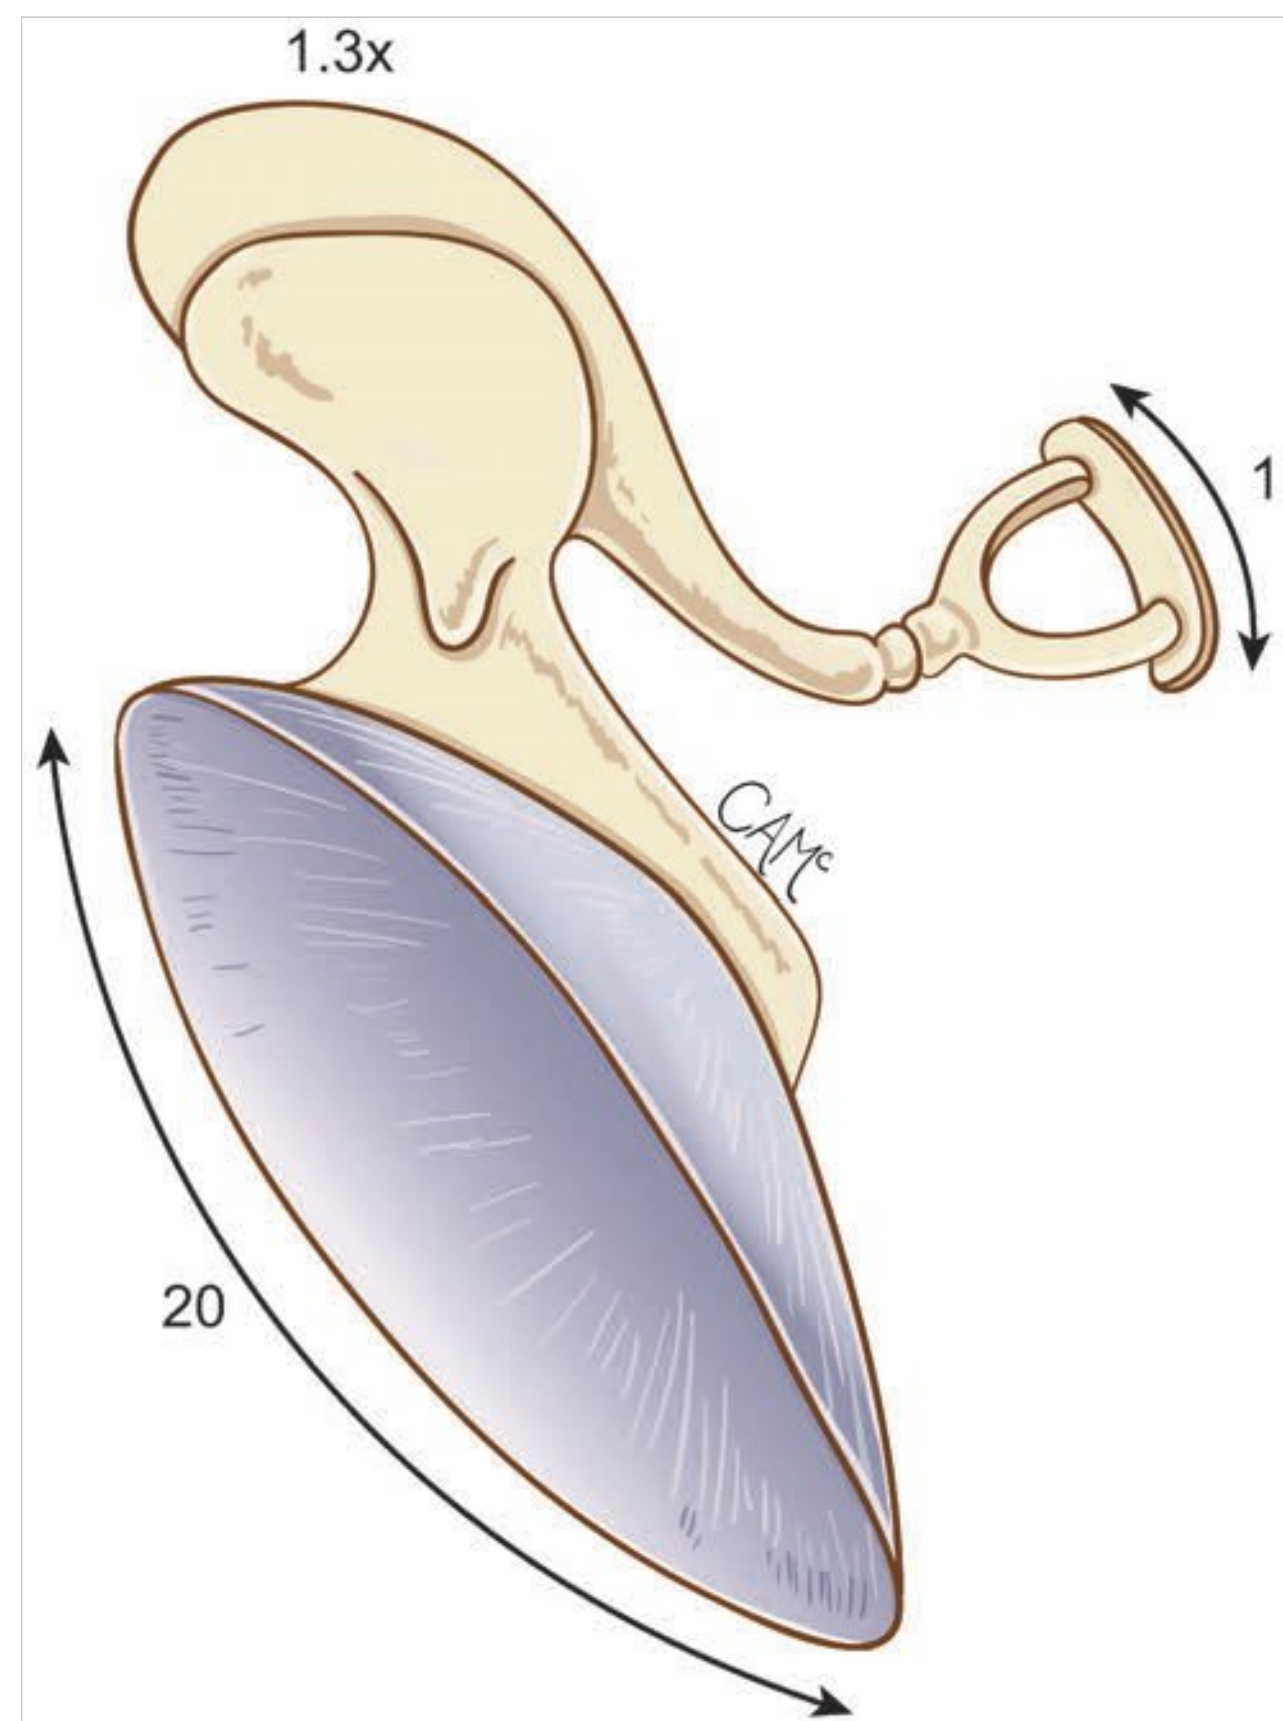

Fig. 112.1 Schematic of the ratio of tympanic membrane size to oval window size (power = force/area = 20), and the lever action of the ossicles (1.3). The sum of these two actions increases the power (power = force/area) of footplate displacement 26 times, which is a net gain of 28 dB in amplitude.

28 dB from the lateral surface of the tympanic membrane to the undersurface of the stapes footplate.

Any pathology that interrupts sound wave amplification to the tympanic membrane and/or ossicles, or impedes ossicular vibration, may cause a mechanical (conductive) hearing loss; middle ear fluid, tympanic membrane perforation, tympanosclerosis, tympanic membrane retraction, ossicular erosion, malleus fixation, and otosclerosis are common middle ear pathologies. This set of problems represents reversible otologic disease. Common problems of the tympanic membrane and/or ossicles can be treated surgically.

Within the middle ear, the most common pathology that impedes ossicular vibration is fluid from otitis media, either the purulence of acute otitis media or the serous effusion of chronic otitis media. Children may not notice or care about their hearing loss, but adults are more apt to notice the change in hearing and will seek medical attention. In addition to the physical and audiometric examinations, CT of the temporal bone may reveal chronic mastoiditis, dehiscence of the tegmen, and/or encephalocele formation. Eustachian tube dysfunction may lead to chronic middle ear and mastoid hypoventilation, and chronic infection may develop. Attempts have been made to correct eustachian tube dysfunction with medical or surgical intervention. These techniques include nasal steroids and other medica-

tions, almost all of which are ineffective. Surgical approaches include partial resection of the cartilaginous meatus in the nasopharyngeal fossa of Rosenmüller and balloon tuboplasty. These are technically difficult to perform with insufficient proof of universal benefit, and they are not part of standard practice. The discipline of surgical manipulation of the eustachian tube is developing. For adults and children, the standard treatment for middle ear fluid is the pressure equalization tube.

Problems of the tympanic membrane and ossicular chain tend to be acquired rather than congenital in both adults and children. In children, congenital ossicular malformations are usually found in combination with canal atresia and tend to consist of misshapen or fused ossicles that are fixed laterally to the atretic plate. Correcting any ossicular problem is secondary to the atresia repair.

If the external auditory canal is patent, the otoscopic examination will help determine the size and location of a tympanic membrane perforation, but an intact tympanic membrane is a natural barrier to full visualization of the middle ear. An audiogram is absolutely required and should demonstrate a conductive or mixed hearing loss in the setting of tympanic membrane or middle ear pathology. A well-performed CT of the temporal bones with thin cuts (1-mm slices) and edge enhancement will usually reveal fenestral otosclerosis or ossicular discontinuity

when these are present. Chronic inflammation may obscure the ossicular chain. It is important that the CT be performed and the results reviewed by an experienced radiologist. CT is the imaging modality of choice when superior canal dehiscence, malleus fixation, or wide cochlear aqueduct is suspected to be the cause of conductive hearing loss (□ Fig. 112.2). It is important to bear in mind that tympanosclerosis is hyalinized scar tissue and not ordinarily calcified. Its characteristic signal on CT is that of a dense shadow, not of calcified tissue.

Conductive hearing loss can be treated medically with a hearing aid in patients of any age, or with a bone conduction aid, as previously described. Surgical interventions for tympanic membrane and ossicular pathology should be well-known to otolaryngologists. Tympanic membrane perforations may be grafted, the ossicular chain may be reconstructed, a stapes prosthesis may be placed, or a BAHA may be inserted.

112.5 Fluid-Filled Spaces of the Cochlea

At the stapes footplate, sound waves are transformed from vibration of the ossicles to undulation of the perilymph in the scala vestibuli. The neuroepithelium of the cochlea is located in

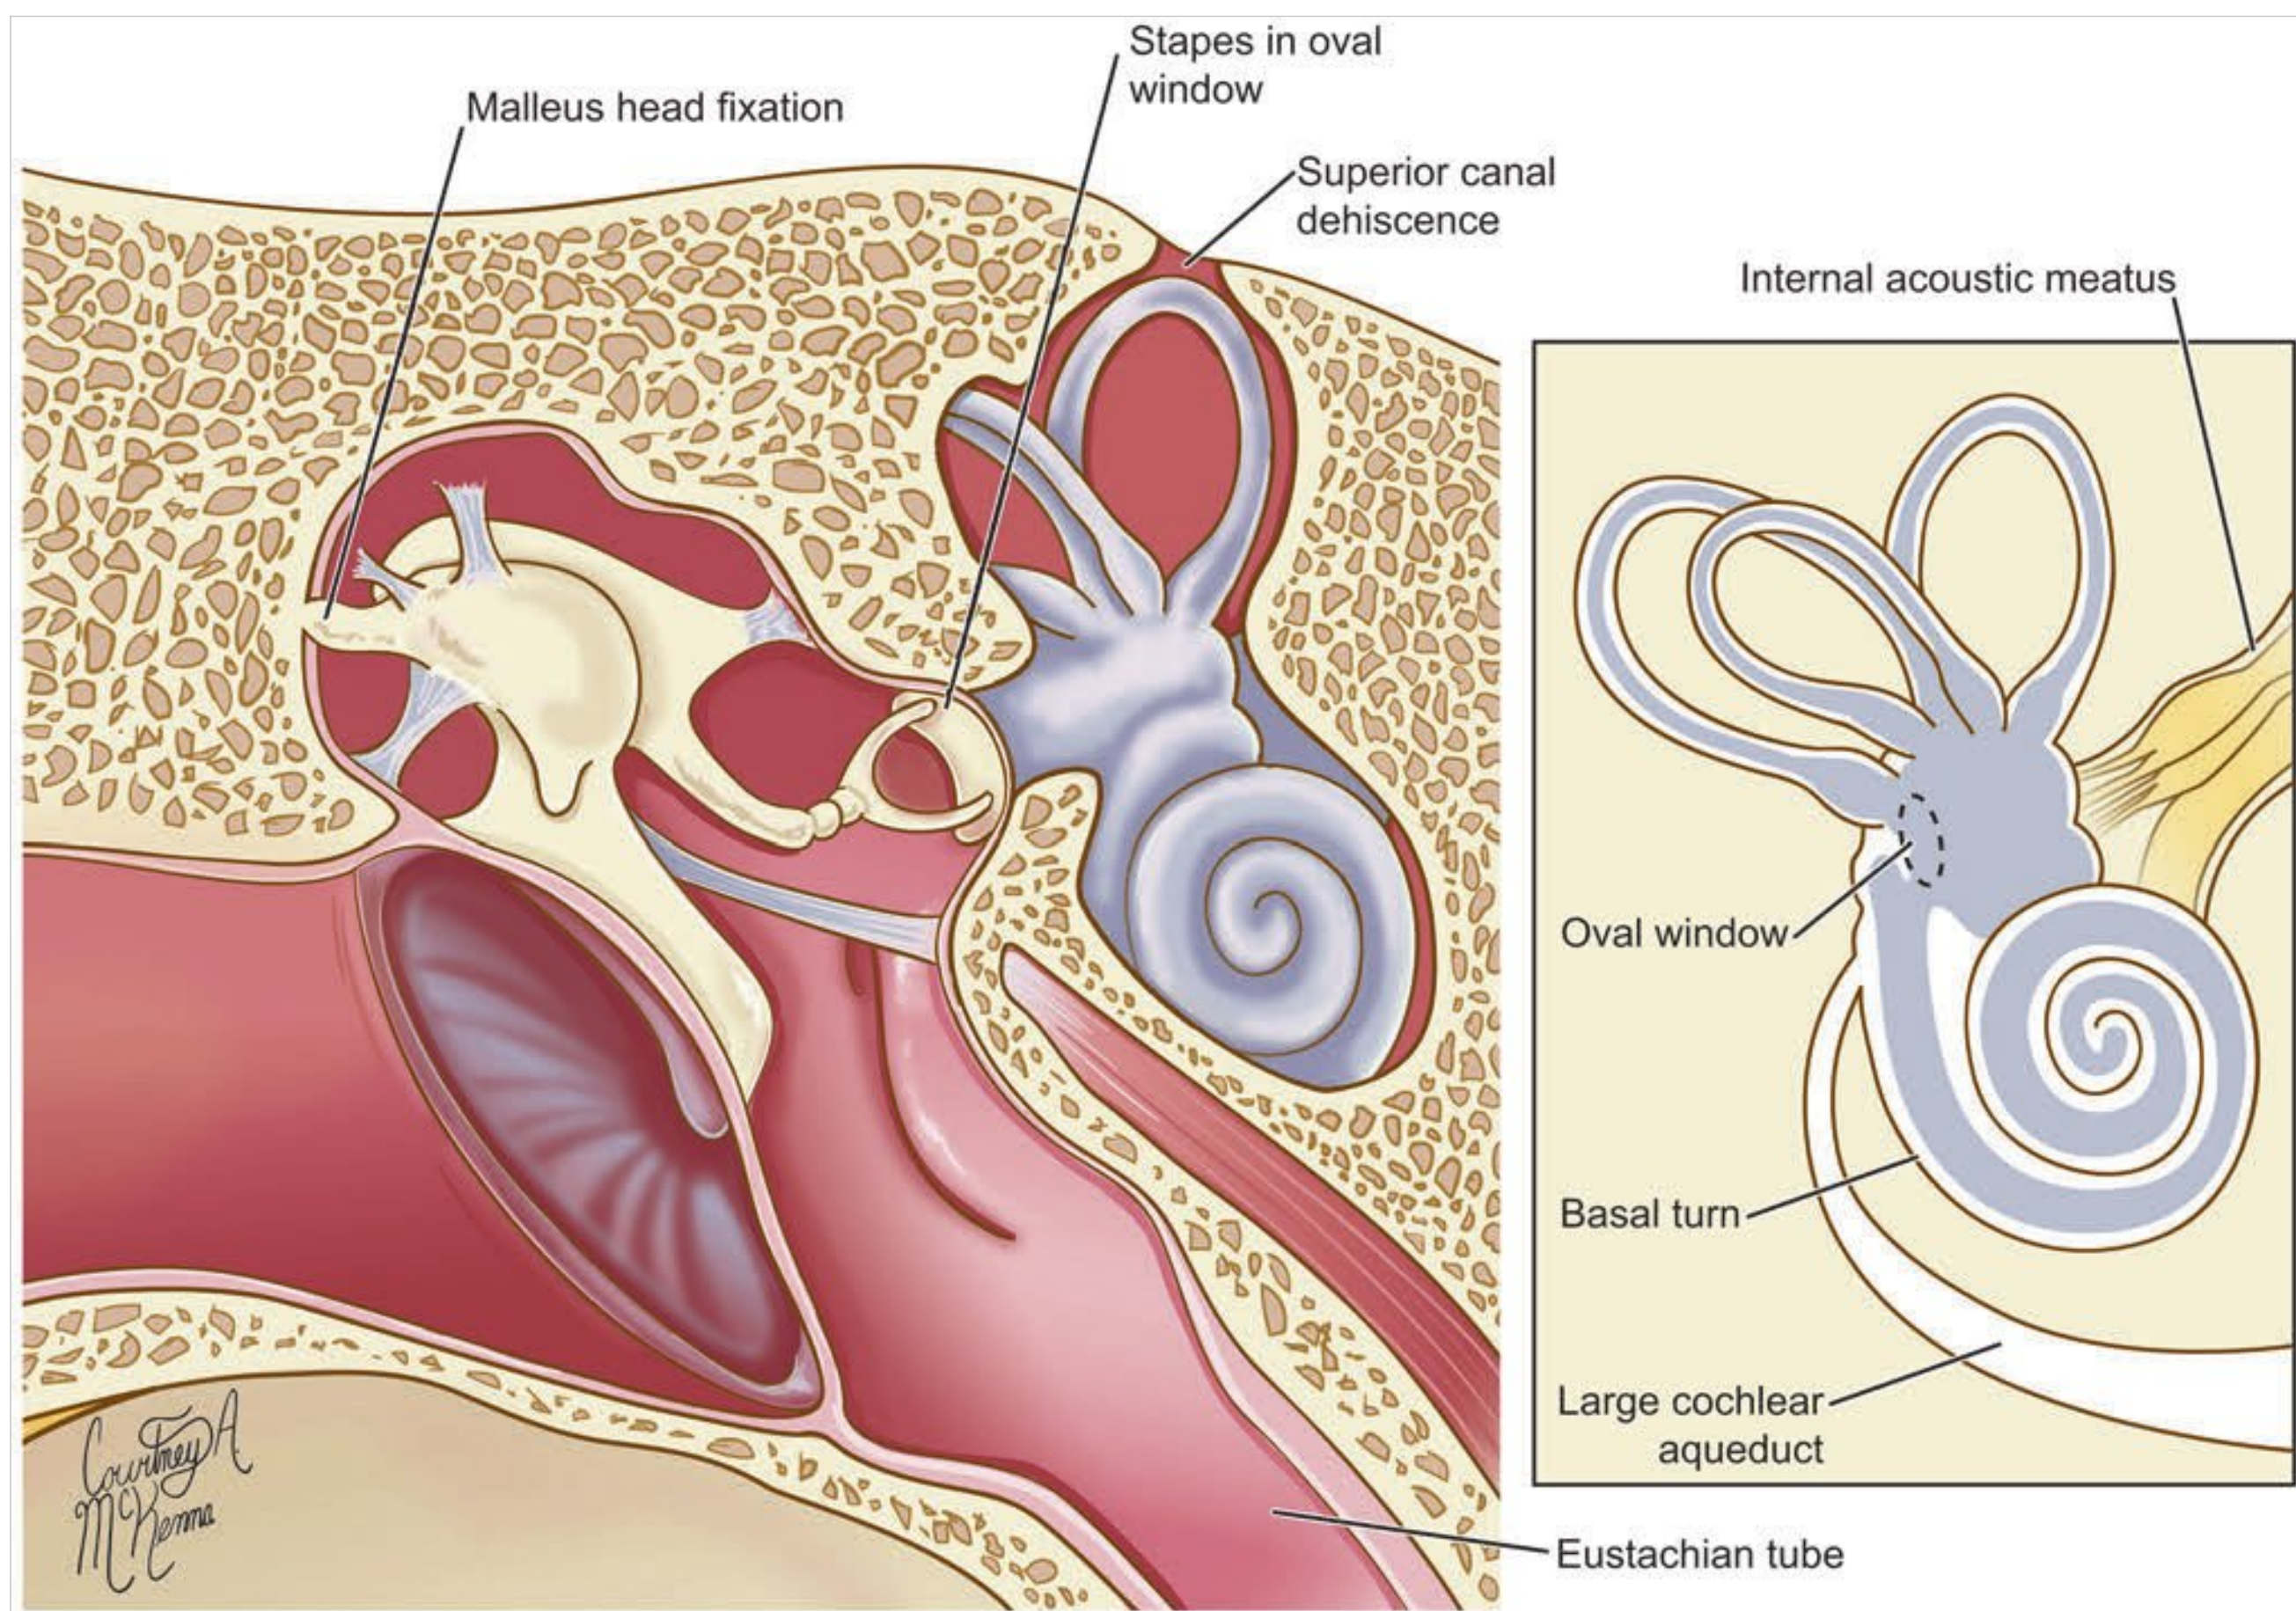

Fig. 112.2 Coronal view of the otic capsule and ossicles demonstrating causes of conductive hearing loss, which are easily identified on a computed tomographic scan: superior canal dehiscence, malleus fixation, and large cochlear aqueduct. The large cochlear aqueduct is in a different coronal plane and is superimposed upon this image.

Fig. 112.3 The cochlea as an uncoiled tube. Oval window vibration causes the perilymph of the scala vestibuli to vibrate, propagating sound waves in fluid around the helicotrema to the scala tympani and round window. The neuroepithelium in the scala media (cochlear duct) is tonotopically arranged, with the highest frequencies represented near the oval window and the lowest frequencies at the helicotrema.

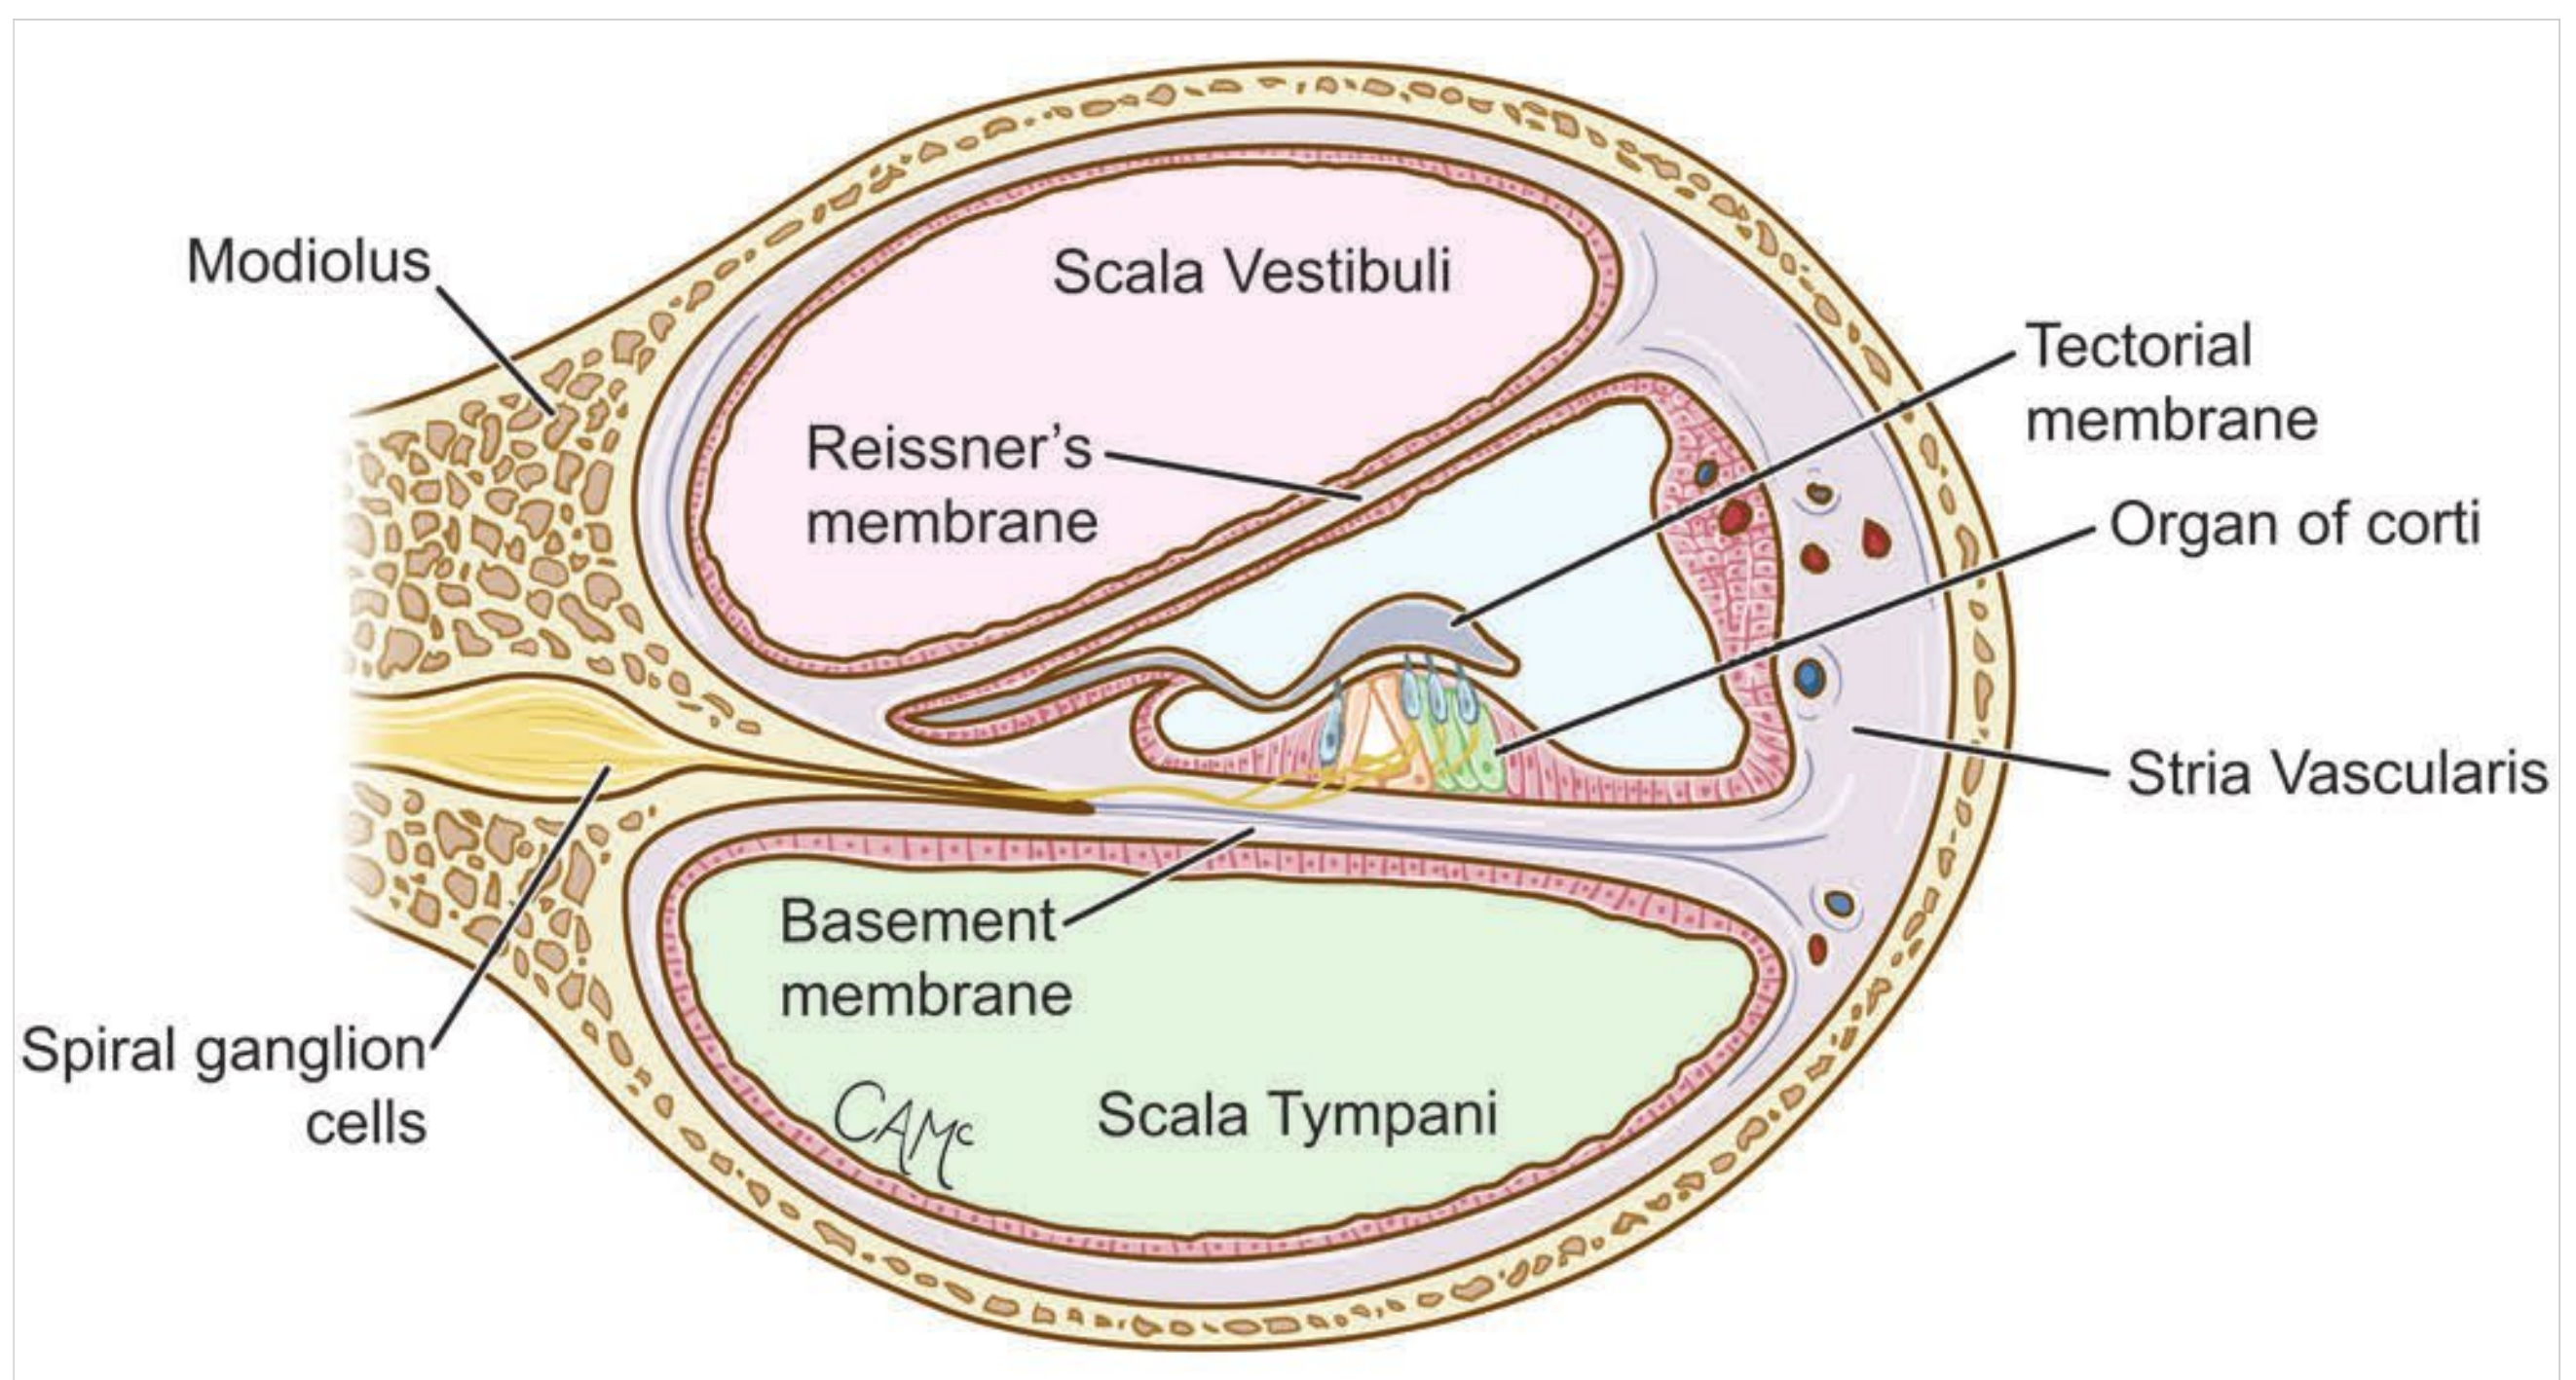

Fig. 112.4 Displacement of the scala media basement membrane by the perilymph of the scala tympani occurs tonotopically and changes the rate of firing of hair cells in the organ of Corti. Afferent signals are transmitted by the nerve fibers of the spiral ganglion cells.

the endolymph of the scala media, a closed tube surrounded by a continuous cushion of perilymph (□ Fig. 112.3). At the same temperature, fluid is neither compressible nor distensible. Sound pressure at the medial surface of the stapes footplate is transmitted throughout the entirety of the perilymphatic space via the helicotrema. Vibration of the stapes footplate at the scala vestibuli is propagated to the tip of the cochlea, the helicotrema, and travels back down the length of the cochlea in the scala tympani to be “relieved” at the round window membrane. Anatomically, the neuroepithelium near the oval window—the base of the cochlea—is most stimulated by high-frequency sounds, whereas the area near the helicotrema is most stimulated by low-frequency sounds.

Neuroepithelial afferent signals depend on two broad conditions: the endolymphatic potential and the undulating displacement of the scala media basement membrane by the perilymph. The differential ion concentrations of the perilymph (low K^+ , high Na^+) and endolymph (high K^+ , low Na^+) are maintained by sodium–potassium pumps in the stria vascularis (□ Fig. 112.4). The net outcome is an 80-mV positive charge in the endolymphatic spaces, which is necessary for neuroepithelial function. Physiologically, two mechanisms appear to focus the undulations of the perilymph to narrow the area of stimulation of the neuroepithelium. The lumen shape and tissue dynamics of the perilymph of the scala tympani displace the basement membrane of the scala media at frequency-

specific locations. And, as will be seen later, there is modulation of the afferent neural signal via efferents and via the outer hair cells.

Pathologic conditions are those that interfere with the composition of the endolymph and the undulation of the perilymph. These conditions are for the most part acquired, not congenital. Otosclerosis of the cochlear otic capsule causes atrophy of the subjacent stria vascularis, disrupts the endolymphatic potential, and causes a concomitant sensorineural hearing loss. The undulating perilymphatic wave is disrupted by many disease processes. Labyrinthitis or meningitis can cause the scalae to fill with new bone (labyrinthitis ossificans). Formation of a “third window”—an opening into the cochlea in addition to the oval and round windows—may cause a conductive hearing loss. This is seen in superior or posterior canal dehiscence. Meniere disease, or endolymphatic hydrops, classically causes unprovoked episodes of aural fullness and pressure, tinnitus, and acute hearing loss, followed by minutes to hours of vertigo. With repeated attacks, there may be slowly progressive hearing loss, which may be related to the distortion and dilation of the scala media.

The primary complaint in all of these conditions is hearing loss. The otologic examination is usually normal. On tuning fork examination, the Weber test may be abnormal; the Rinne test is usually normal. A standard audiogram is required to assess the side and type of hearing loss. Asymmetries of sensorineural hearing are never normal, regardless of the putative diagnosis, and must be further evaluated with an appropriate retrocochlear test: contrast-enhanced magnetic resonance (MR) imaging or CT with contrast. Vestibular evoked myographic potential (VEMP) testing, described extensively in Chapter 113, may help diagnose superior canal dehiscence syndrome. CT can be helpful because it can demonstrate fenestral and/or cochlear otosclerosis, and it usually is quite helpful in identifying ossification of the scalae and canal dehiscence. If superior canal dehiscence syndrome is suspected, then CT should be performed in an orientation orthogonal to the superior semicircular canal.

Treatment for these conditions includes hearing aids. It is important to note that in Meniere disease, the patient’s narrowed dynamic range may result in hyperacusis and/or recruitment, causing the amplified signal to become painful and/or distorted; amplification clipping essential, so that the amplified signal from the hearing aid will not cause discomfort. Similarly, in semicircular canal dehiscence syndrome, amplification may cause dizziness (Tullio phenomenon). These potential problems must be considered by the dispensing audiologist.

Sensorineural hearing loss due to scala tympani ossification and far-advanced otosclerosis can be compensated by cochlear implantation. The conductive hearing loss of superior canal dehiscence can be arrested or sometimes improved with canal occlusion via a middle cranial fossa approach, but this is a technically difficult operation. The hearing loss of Meniere disease may be arrested or sometimes improved by endolymphatic sac decompression and/or shunting, an operation whose efficacy remains controversial because the perceived improvements may be due to the natural unpredictable fluctuations of Meniere disease or a placebo effect.

112.6 Neuroepithelium of the Organ of Corti

The cochlea, seen schematically in □ Fig. 112.5, is 35 mm long in most people and is coiled in two and one-half turns. The scala media contains the primary auditory organ, the organ of Corti (see □ Fig. 112.5), whose function is to transduce the mechanical displacement of the perilymph wave into neurotransmitter firing. The organ of Corti is a complex collection of neuroepithelium consisting of inner and outer hair cells, as well as essential supporting cells (□ Fig. 112.6).

The inner hair cells synapse with afferent fibers of the auditory nerve, while the outer hair cells synapse with efferent fibers from the same nerve. The organ is elongated, running the entire length of the scala media. The composition of the endolymph creates a positive potential relative to the perilymph. Within the tunnel of Corti (the space between the inner and outer hair cells), a different electrolyte composition creates yet another functionally distinct space. The tips of the inner and outer hair cells have stereocilia, which extend into the tectorial membrane. When the basement membrane undulates, these stereocilia are sheared one direction, then another, altering the firing rates of the hair cells.

The sensory information from the hair cells travels medially into the osseous spiral lamina toward the neurologic center of the cochlea, the modiolus (see □ Fig. 112.5). Type 1 and type 2 spiral ganglion cells are the primary sensory afferent cell bodies for the auditory nerve.

Many pathologic conditions affect the function of the organ of Corti. The congenital disorders that cause organ of Corti malformations and dysfunction are numerous. The types of congenital malformations of the otic capsule associated with varying degrees of membranous labyrinth dysgenesis and organ of Corti malformation are shown in □ Fig. 112.7. Most of these malformations are visible with the resolution available on fine-cut CT. However, in most congenital forms of hearing loss, the CT scan appears normal, and in recent years evaluation has relied more heavily on genetic studies. The current classification system for congenital hearing loss is the dfna/dfnb/dfnx and mito system. In this classification, dfn denotes nonsyndromic hereditary deafness, a indicates an autosomal-dominant mode of inheritance, b indicates autosomal-recessive inheritance, x denotes X-linked inheritance, and mito indicates mitochondrial inheritance. The most common form of nonsyndromic sensorineural hearing loss identified at present is malformation of the connexin genes, which encode gap junction proteins between cell membranes and may be responsible for maintaining the sodium–potassium gradients essential for neuroepithelial function.

The types of congenital hearing losses that are associated with other disorders or syndromes are diverse. For example, a widened vestibular aqueduct and enlarged endolymphatic sac can be associated with Pendred syndrome (thyroid goiter/hypothyroidism and bilateral congenital sensorineural hearing loss). Many of the craniofacial syndromes, such as Apert syndrome (acrocephalosyndactyly), Crouzon syndrome (craniosynostosis, low-set ears, exophthalmos, hypertelorism, hypoplastic mandible, often with patent ductus arteriosus and coarctation of the

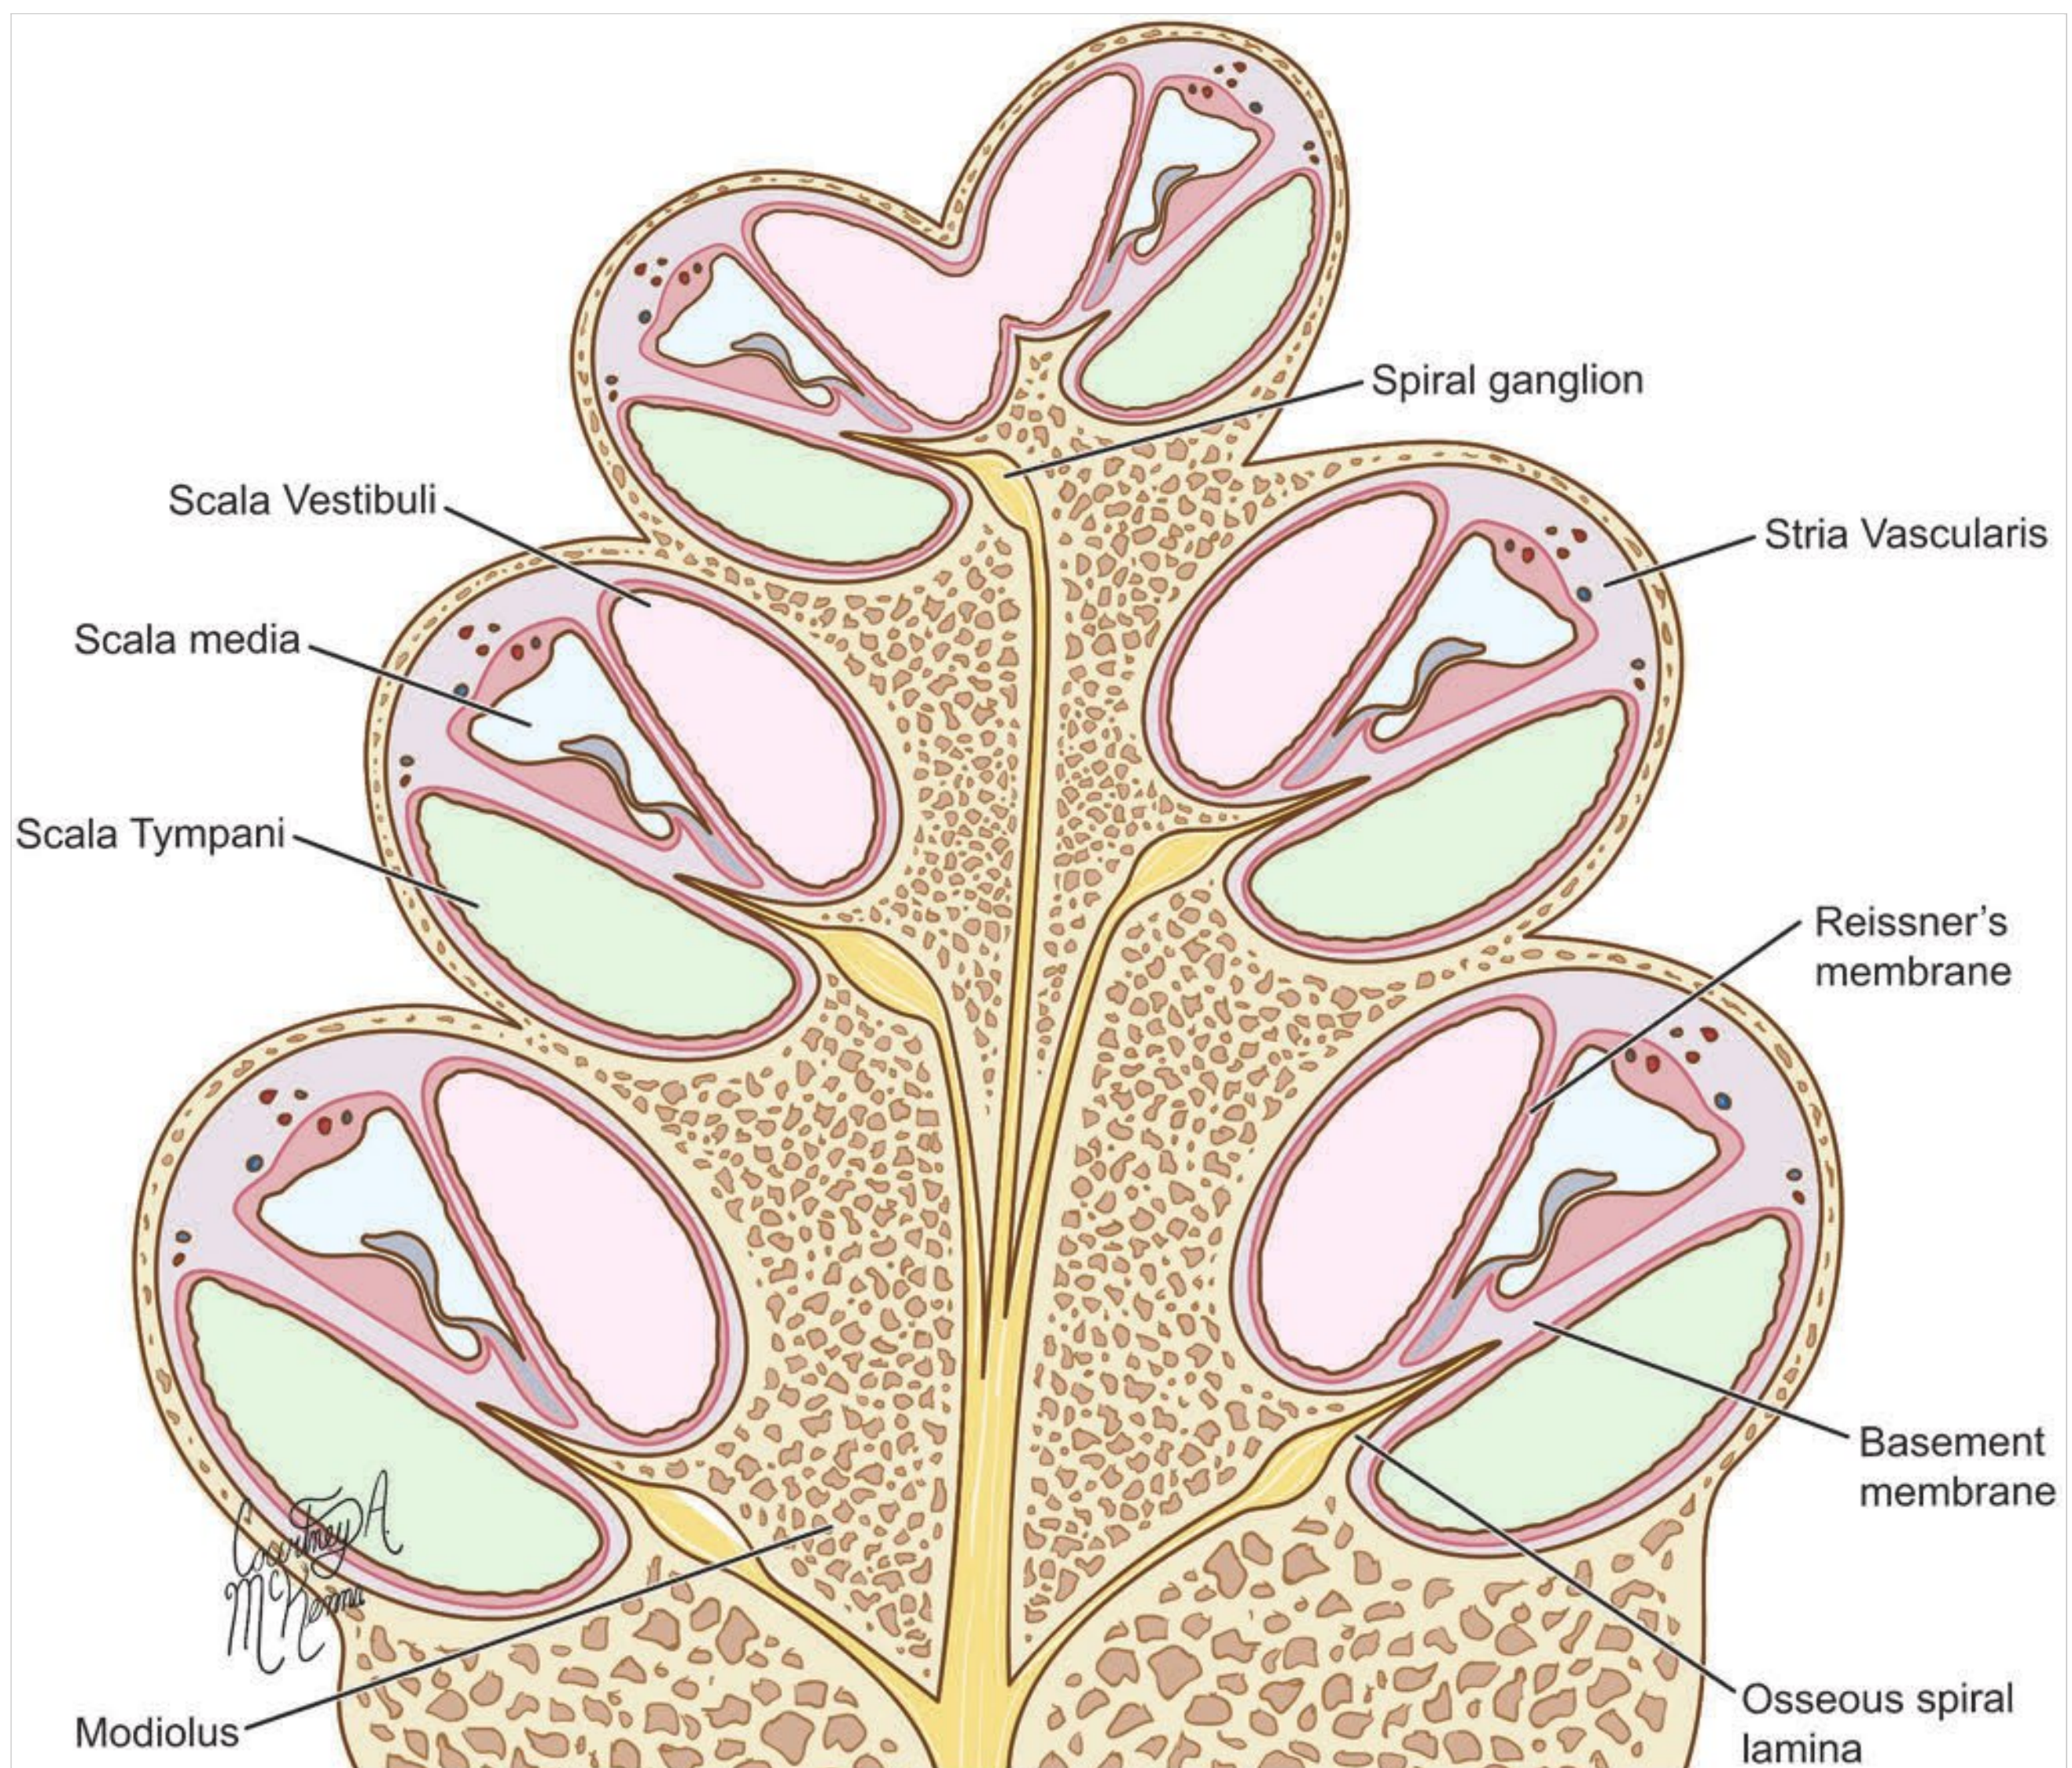

Fig. 112.5 The scalae of the cochlea, coiled 2.5 times in successively smaller turns. The scala media (cochlear duct) with the organ of Corti is seen, along with the scala vestibuli and scala tympani, osseous spiral lamina, stria vascularis, modiolus with spiral ganglion cells, and auditory nerve.

aorta), and Waardenburg syndrome (iris pigment abnormality, white forelock or white hair on other areas of the body, hypertelorism), are apparent on first examination. It is standard to look for disorders of thyroid and kidney function during the routine laboratory testing of children with sensorineural hearing loss, and to check for Usher syndrome (retinitis pigmentosa) by referral to an ophthalmologist for an examination of the retina and possibly an electroretinogram. An electrocardiogram is required to rule out Jervell syndrome and Lange-Nielsen syndrome, in which a mutation of genes coding for potassium channels may cause prolongation of the QT interval, in addition to sensorineural hearing loss. It remains unclear how these congenital structural malformations and gene defects impair hair cell signaling at the cellular level. Repair at the cellular level is not possible at this time.

The infant is often identified because he or she has failed a newborn hearing screening examination and is referred for further testing. An older child will be given the benefit of the doubt for about 12 months. If the child does not say “mama” or “dada” by then, patience and denial of the problem are exhausted, and parents want a swift diagnosis. The hearing screen can be performed with otoacoustic emissions testing, which measures cochlear events, or with an ABR, which is a more involved test of both the peripheral and central auditory system. The ABR is an early-latency evoked response in that the waveforms elicited occur within a few milliseconds of the stimulus. In most cases, the child will eventually be referred for otologic evaluation, which involves a gestational and family history, physical examination, age-appropriate audiometric confirmatory testing, imaging, laboratory testing, and genetic counsel-

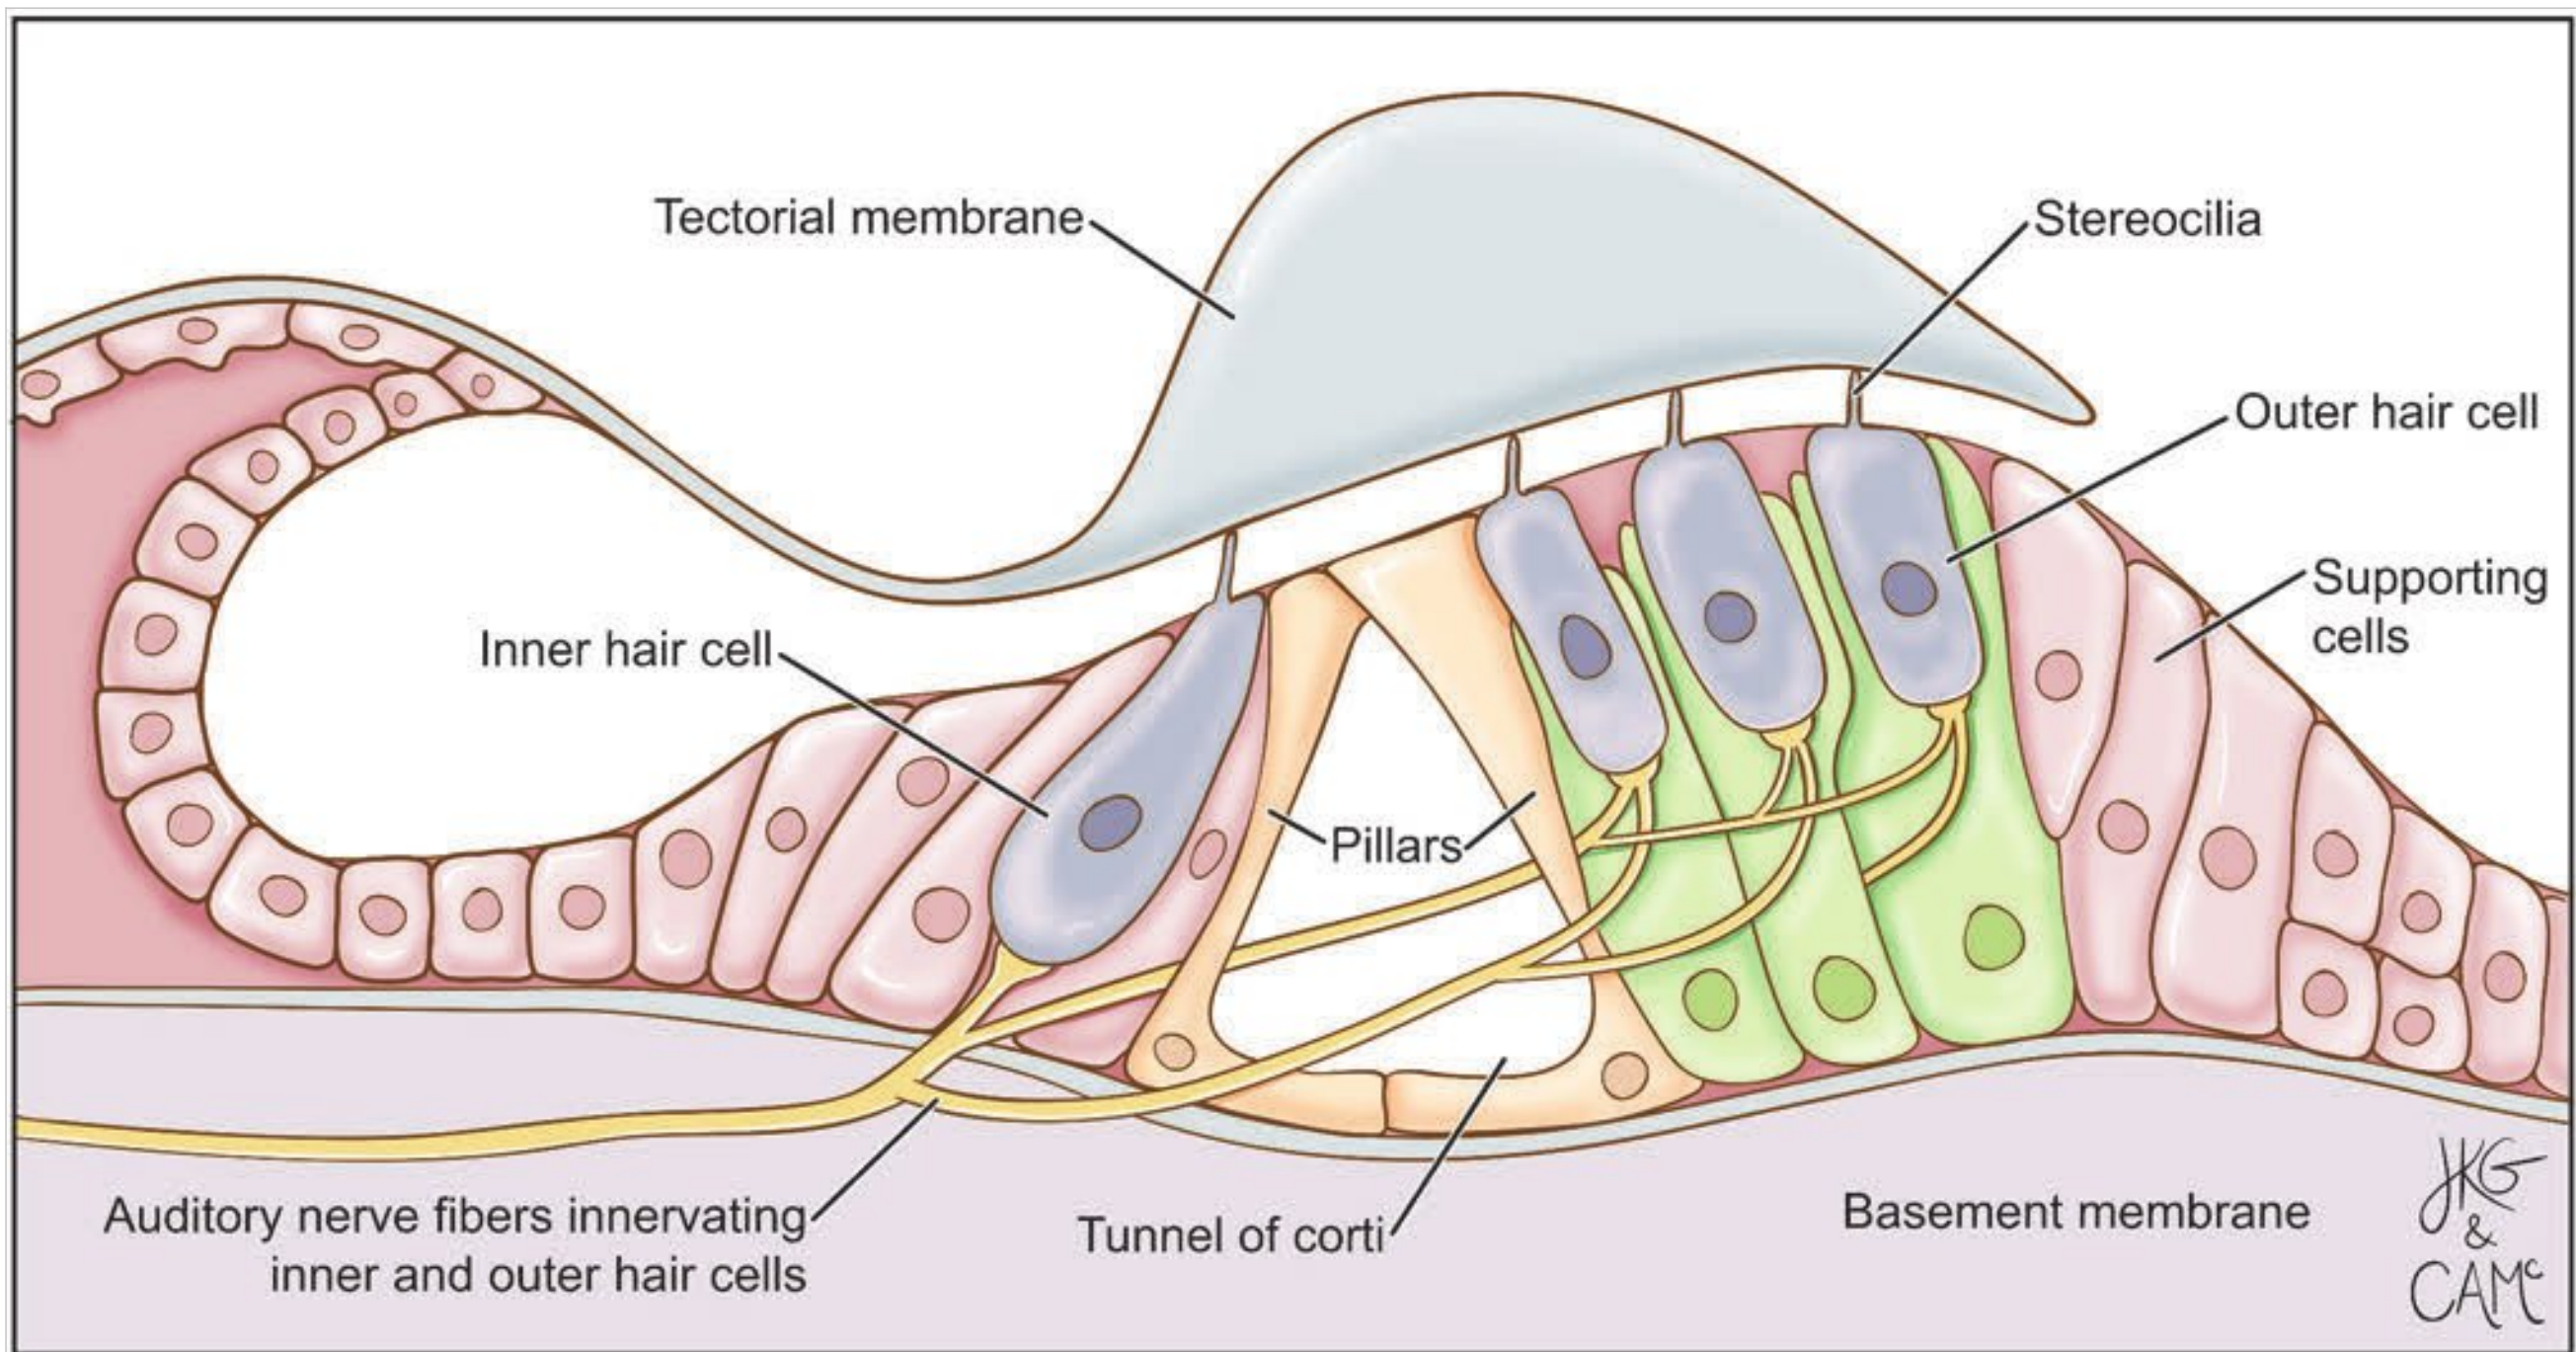

Fig. 112.6 Structure of the organ of Corti, showing the inner and outer hair cells, tunnel of Corti, and supporting cells. Shearing of the hair cell stereocilia modulates firing rates.

ing. It is important not to jump to diagnostic or therapeutic conclusions on the first visit. Even if severe or profound hearing loss is suspected, it is initially very difficult for parents to understand and accept this in their child. In many cases, a brief trial of amplification and repeated testing may be performed to help parents to understand the severity of the problem. Above all, the physician must be empathetic and absolutely sure that the audiometric evaluation has been performed thoroughly and properly before making any significant recommendations, such as cochlear implantation.

Acquired hearing loss in adults is quite common. The most common type is presbycusis, which is the down-sloping high-frequency hearing loss of aging. The actual mechanism remains unclear, as does prevention. Noise exposure and exposure to ototoxic medications have long been known to cause sensorineural hearing loss. Otosclerosis may cause conductive or mixed hearing loss. Autoimmune hearing loss, or autoimmune inner ear disease, ordinarily follows a pattern of a downward fluctuation and inexorable diminution of hearing. It is usually bilateral, but the hearing loss may be sequential (i.e., one ear may lose hearing and then the other after a delay of 6 to 12 months). The pattern of fluctuation is very important in making the diagnosis. Many batteries of serologic testing are available, much as for any rheumatologic disease. These should be done to help support or refute the diagnosis of autoimmune inner ear disease.

The causation of hearing loss in adults often remains uncertain. The audiogram describes the pattern of loss, not the reason for the loss. Otoacoustic emissions, which reflect outer hair cell function, are usually absent. CT of the temporal bone is usually normal. MR imaging of the brain with contrast, with particular attention to the internal auditory canal, is usually normal. The patient is often left with the diagnosis of “sensorineural hearing loss” but not a reason for the loss. It should be a comfort for the patient that a thorough diagnostic evaluation will definitively exclude a retrocochlear tumor as a cause of the hearing loss.

By far the most frustrating form of acquired hearing loss is “sudden deafness,” or sudden idiopathic sensorineural hearing loss, which occurs unilaterally over a period of minutes or hours (by definition, a 30-dB interaural difference in three adjacent frequencies over a period of no more than 3 days) and for which no real etiology is identified. Sudden idiopathic sensorineural hearing loss is thought to be a cochlear event. Because nobody dies of this condition, there is no event-related histopathology to define the cause. Oral or intratympanic steroids are currently the treatment of choice and may reverse the hearing loss if given in a timely fashion and in large enough quantities. There is no place for antiviral medication in the treatment of sudden idiopathic sensorineural hearing loss.

The treatment of sensorineural hearing loss in children and adults is amplification. Hearing aids are tried first, even in children with profound sensorineural loss. Parents are instructed on how to watch for any benefit from hearing aid use, such as startling to noises, recognizing and mimicking environmental sounds, and beginning to phonate. Adults who start using hearing aids can be tested behaviorally and can describe for themselves how amplification may be helping. If the hearing aids are of limited benefit, evaluation for cochlear implantation can be initiated.

112.7 Auditory Nerve and Central Pathways

The cell bodies for the auditory nerve are the spiral ganglion cells in the modiolus of the cochlea. These become the auditory nerve and travel in the internal auditory canal to synapse in the ipsilateral cochlear nucleus. From there, ipsilateral and contralateral projections travel to higher centers, merging with input from the contralateral auditory nerve (□ Fig. 112.8).

Rarely, there is congenital absence of the auditory nerve. This is suspected during newborn auditory screening and is usually accompanied by a malformation of the otic capsule on CT. The internal auditory canal can be narrow. MR imaging can help in identifying how many nerves are present in the internal auditory canal. If only one nerve is identified, and if the face has normal function, the nerve is assumed to be the facial nerve. An electrical ABR, in which an electrode is placed trans-tympanically into the promontory to stimulate the spiral ganglion cells, can help determine if there is a functioning cochlear nerve. The presence of a wave v on an electrical ABR indicates function of the auditory nerve and would support cochlear implantation, if the bilateral hearing level is appropriately diminished.

Another pediatric diagnosis in hearing loss is central auditory neuropathy; the best-understood example of this is the presence of central hemosiderin deposits (kernicterus) in newborns with high postpartum bilirubin levels. Central auditory neuropathy is also diagnosed functionally in patients with auditory neuropathy (auditory dyssynchrony). These patients have poor sensorineural function. Although otoacoustic emissions may be present, the ABR is abnormal and often absent, indicating a disconnect between the cochlea and the eighth cranial nerve. Although these patients may not be the very best candidates, cochlear implantation is indicated because amplification is of very little benefit, if any.

Pathologic conditions of the auditory nerve in adults cause sensorineural hearing loss that is characterized by disproportionately low speech discrimination scores. The most common acquired benign pathology of the auditory nerve is a vestibular schwannoma (or acoustic neuroma), which grows from either the superior or inferior vestibular nerve and impairs auditory function by direct compression of the auditory nerve. The auditory nerve also may be implicated in presbycusis.

Any neurologic condition that occurs spatially in areas of central auditory pathways can affect hearing. Multiple sclerosis can cause sensorineural hearing loss, as can other central autoimmune diseases, such as polyarteritis nodosa. Central auditory processing testing can identify central presbycusis. Any intracranial space-occupying lesion can affect hearing.

The diagnosis of hearing loss is properly made by an audiogram. An unexpectedly low speech discrimination score and normal otoacoustic emissions, a test of outer hair cell function, suggest problems in the auditory nerve or centrally. Central auditory processing tests, such as auditory discrimination tests, temporal processing and pattern discrimination tests, and dichotic speech tests, can help distinguish peripheral dysfunction from central dysfunction. After these functional tests are

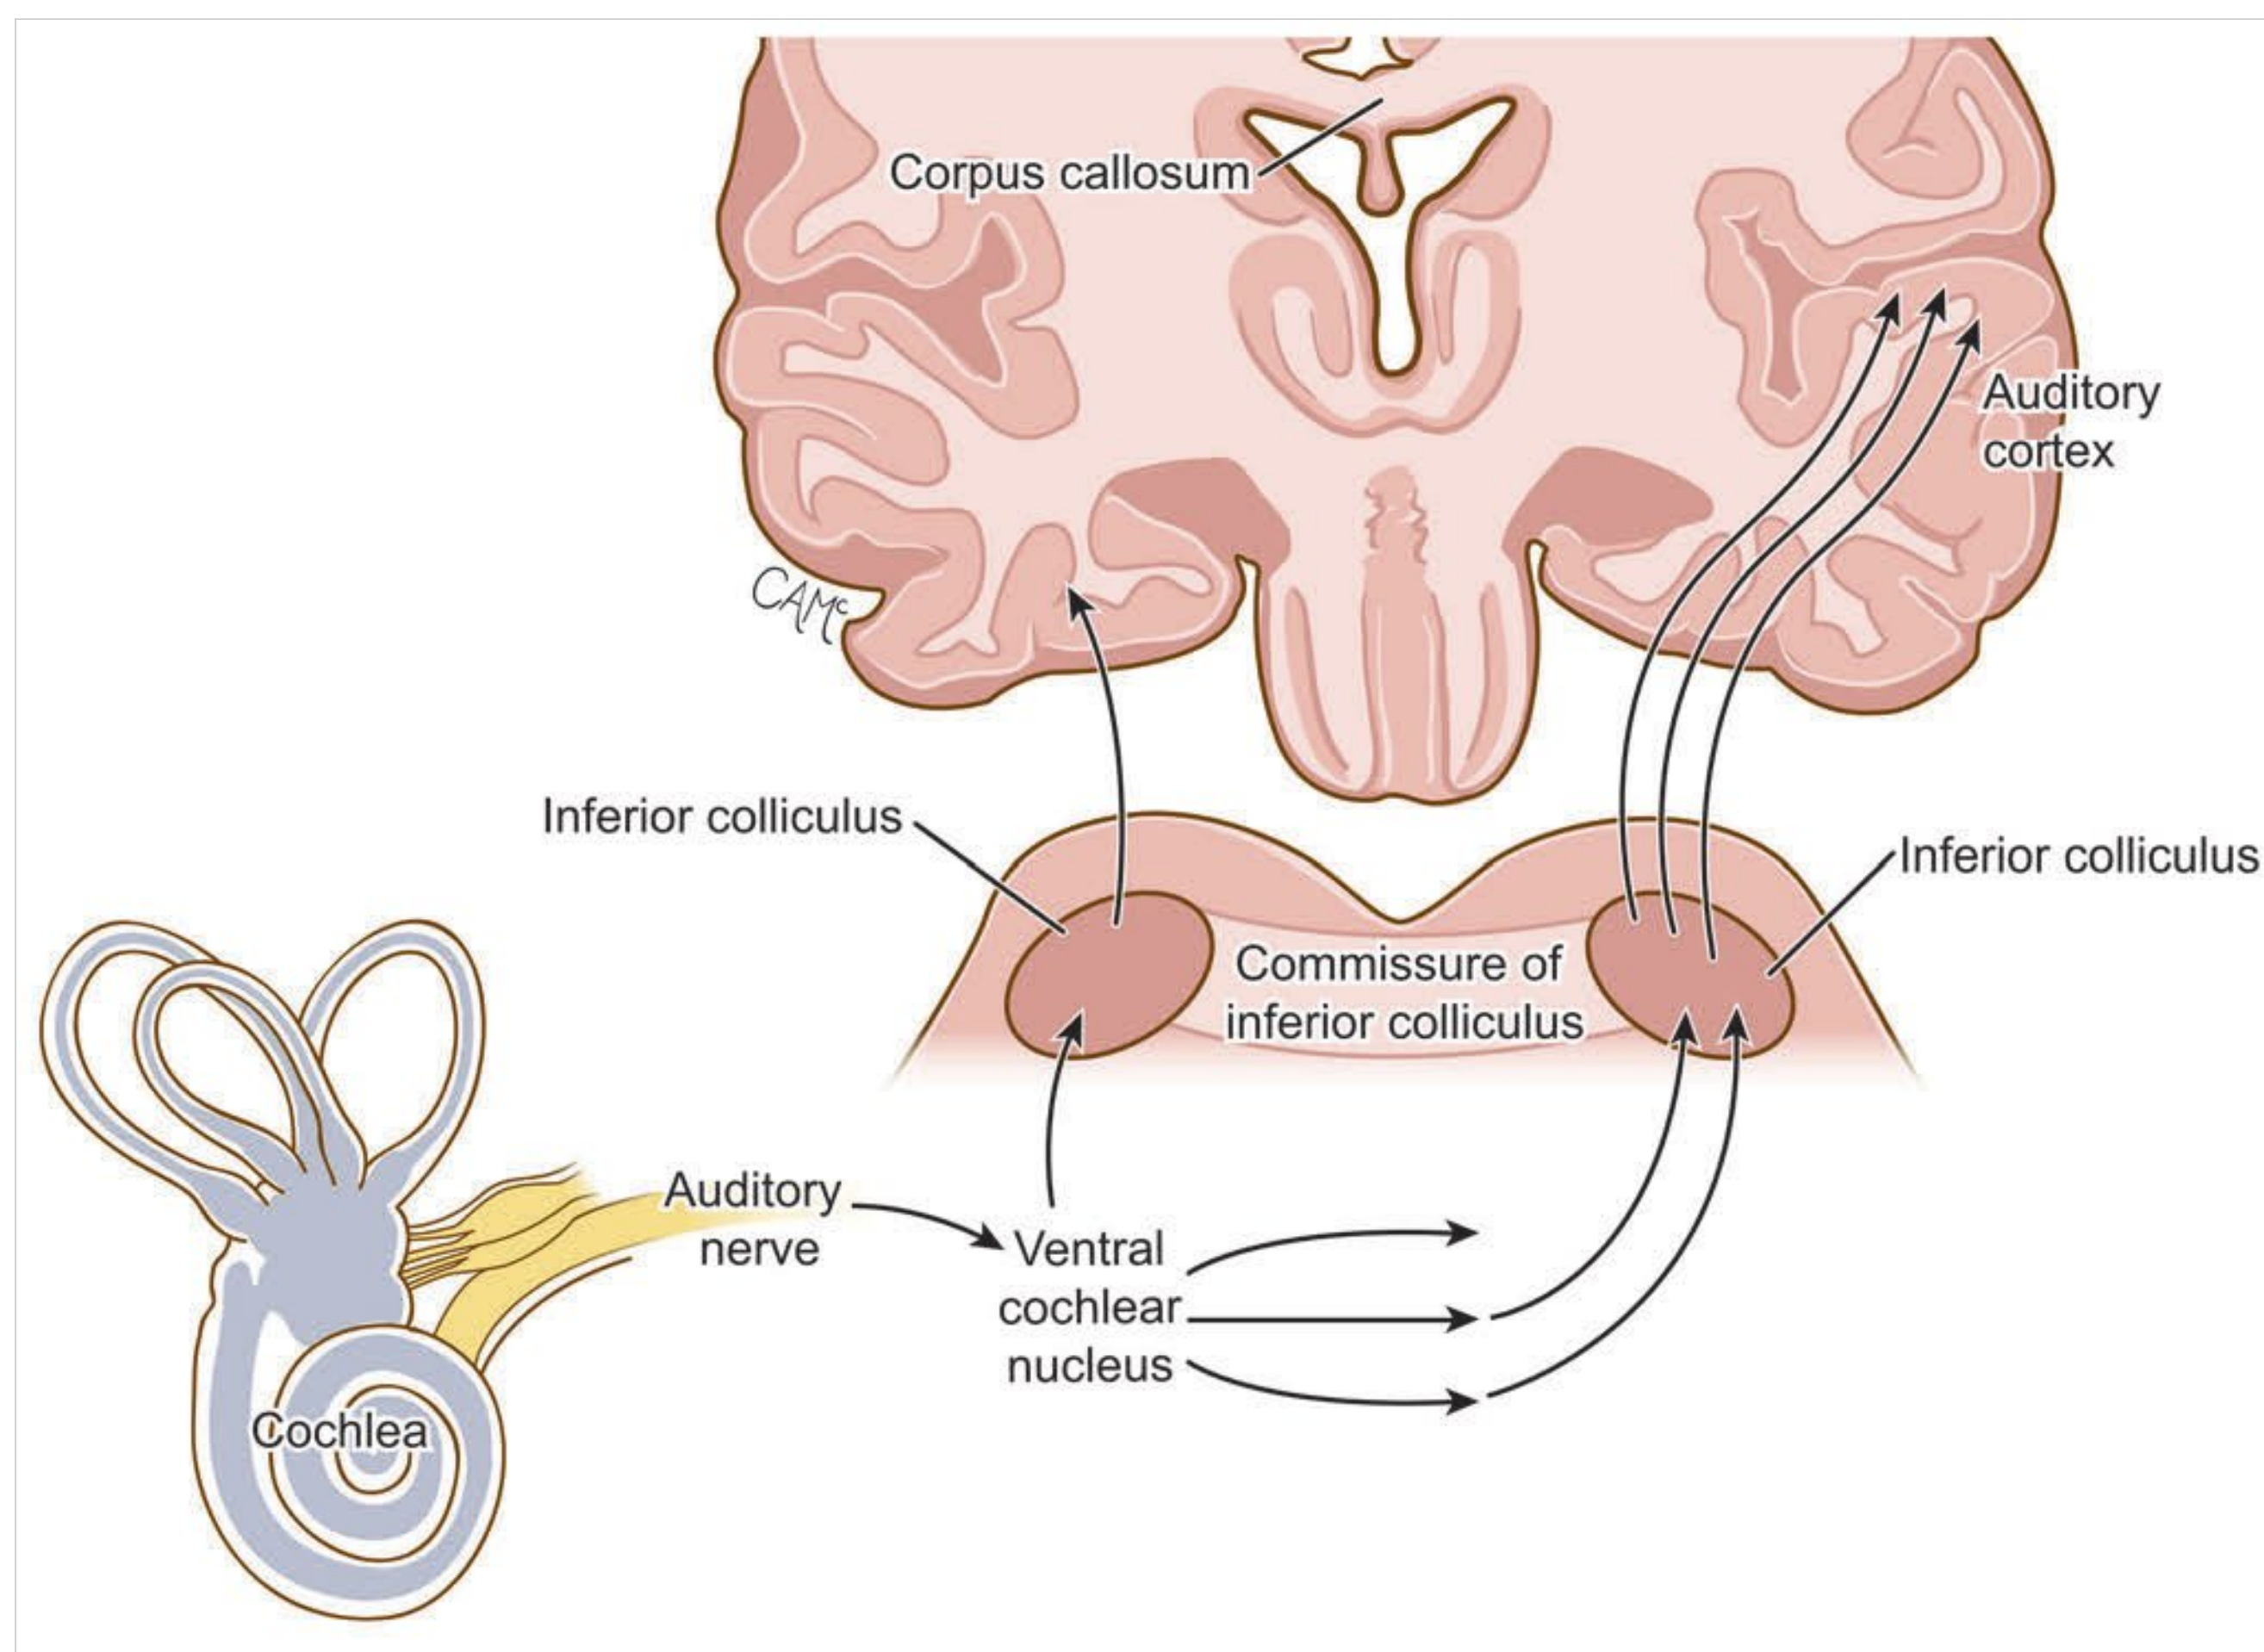

Fig. 112.8 Central projections of the auditory nerve.

obtained, MR imaging of the brain and internal auditory canals with and without gadolinium is imperative. When a neurologic disease is suspected, a neurology consult is appropriate. Any disease process that may be identified should be treated appropriately.

The treatment of sensorineural hearing loss, whether of cochlear or retrocochlear etiology, is amplification. Cochlear implantation is an appropriate treatment modality for those people who cannot be helped with hearing aids. At one time, the replacement of cochlear function with a cochlear implant was considered inappropriate treatment for central sensorineural hearing loss, but opinion on this has changed. These patients comprehend speech better with a cochlear implant than with a hearing aid. The patients must be instructed, however, that the possible improvement after cochlear implantation will be limited by the underlying pathology. Specifically, their speech understanding (especially in noise) may not be as good as that of traditional users of cochlear implants. Hearing retraining programs are now available for adults with decreased central auditory processing, although improvements in central auditory processing disorder tests after retraining have not been established. Perhaps the appropriate metric to quantify improvement has not yet been found.

112.8 Disease-Specific Diagnostic Testing

It is sometimes helpful to reconsider mechanisms of hearing loss and to survey the tests that help clarify each situation. The most common cause of hearing loss is middle ear fluid. This is diagnosed by visualization of the tympanic membrane and insufflation with a pneumatic otoscope. The tympanogram in the setting of middle ear fluid is usually, but not always, flat. Myringotomy may reveal middle ear fluid even in patients with normal otoscopy and peaked tympanogram tracings. Finally, CT can identify fluid in the middle ear and mastoid, especially in the case of chronic mastoiditis.

Conductive hearing loss is diagnosed by tuning fork testing and audiography. The Weber and Rinne tests show characteristic findings, with the Weber test lateralizing to the affected ear. Air conduction may be less than bone conduction in the affected ear, while air conduction is greater than bone conduction in the normal ear. The audiogram usually shows an air–bone gap. However, bone thresholds may be unreliable, especially if there are bilaterally reduced thresholds and if there is difficulty in masking out one side. Very rarely, what is interpreted by the

audiologist as a sensorineural loss may in fact be a conductive loss. Because crucial hearing-related advice and decisions are based upon audiometric testing, the audiologist must be well trained and experienced. Self-administered hearing tests are notoriously unreliable and should not be used. CT at thin slice intervals and with edge enhancement may be helpful in defining the cause of conductive hearing loss. It can show soft tissue in the middle ear space, ossicular erosion, otosclerosis, malleus fixation, a large cochlear aqueduct, and dehiscence of the superior or posterior semicircular canal.

Sensorineural hearing loss should be suspected in anyone with nonpulsatile tinnitus, whether or not the individual is aware of any hearing loss. The Weber and Rinne tests can identify asymmetric hearing loss because air conduction will exceed bone conduction bilaterally, and the Weber test will lateralize to the unaffected side. These tests yield information about the physics of audition but not about the level of audition. Professionally performed audiography is required to demonstrate sensorineural loss. Speech discrimination scores that are lower than pure tone thresholds may indicate dysfunction of the auditory nerve or central hearing loss. The presence of recruitment with tuning fork testing is diagnostic of cochlear losses. Normal otoacoustic emissions, which reflect outer hair cell integrity and function, suggest retrocochlear rather than cochlear losses. In cases of asymmetric sensorineural hearing loss, MR imaging of the internal auditory canals with gadolinium contrast should be obtained to rule out a cerebellopontine angle or an internal auditory canal mass.

The presence of a “third window” should be suspected in adults with no history of otitis who have unilateral conductive hearing loss documented on an audiogram. Vestibular evoked myographic potential (VEMP) testing shows a lower threshold in the affected ear. CT may identify the site of otic capsule dehiscence.

112.9 Roundsmanship

- Physiologically, the major factors that amplify incoming sound waves are the ratio of the area of the tympanic membrane to that of the oval window footplate, and the lever action of the ossicles.
- The neuroepithelium near the oval window (basal turn of the cochlea) is most stimulated by high-frequency sounds, whereas the area near the helicotrema is most stimulated by low-frequency sounds.
- Neuroepithelial afferent signals from the cochlea depend on two broad conditions: the endolymphatic potential and the undulating displacement of the scala media basement membrane by the perilymph.
- Type 1 and type 2 spiral ganglion cells are the primary sensory afferent cell bodies for the auditory nerve.
- From the cochlear nucleus, ipsilateral and contralateral projections travel to higher centers of the brain and merge with input from the contralateral auditory nerve.
- The most common cause of hearing loss is middle ear fluid. This is diagnosed by visualization of the tympanic membrane and insufflation with a pneumatic otoscope.
- The most common cause of acquired hearing loss in adults is presbycusis.
- Sensorineural hearing loss should be suspected in anyone with nonpulsatile tinnitus, whether or not the individual is aware of any hearing loss.
- Pathologic conditions of the auditory nerve in adults cause sensorineural hearing loss, which is characterized by disproportionately low speech discrimination scores.
- The treatment of sensorineural hearing loss, whether of cochlear or retrocochlear etiology, is amplification.

113 Equilibrium Function and Dysfunction

Mila Quinn, Miriam I. Redleaf, and Christopher J. Linstrom

113.1 Introduction

A normally functioning vestibular system calls no attention to itself. When everything is working well, individuals are unaware of balance, much as they are unaware of a normally functioning heart. A normally functioning system can be manipulated to bring casual pleasure, such as rolling down a snow-covered hill, going on “fun rides,” or watching a large-screen IMAX movie. Other than these entertainments, most people rarely think about spinning or balance. In contrast, any dysfunction of the vestibular system is acutely noted by most individuals, who are unable to ignore their symptoms. They usually cannot tell which side is malfunctioning, or what activities elicit their unsteadiness; however, they are usually intensely bothered by their imbalance and demand comfort and relief. It only complicates the picture that any medication or illness can be associated with imbalance and that imbalance occurs in 100% of the population. The goal of this chapter is to guide the general otolaryngologist toward a diagnosis and treatment plan for patients with vestibular complaints. It is unreasonable to expect that the otolaryngologist will cure every patient. The role of the medical professional is to diagnose the end organ that is the likely cause of the problem and to offer reasonable treatment.

This chapter provides an outline of the functional components of the vestibular system. For each functional component, the anatomy, physiology, dysfunction, diagnostic tests, and treatment options are surveyed.

113.2 Orientation of the Peripheral and Central Vestibular Systems

The peripheral vestibular system consists of a bony capsule surrounding membranous canals that are floating in perilymph and filled with endolymph. This fluid in turn bathes the five functional neuroepithelium end organs: the three ampullae of the semicircular canals and the two maculae of the utricle and saccule (□ Fig. 113.1). The electrolyte composition of the endolymph and perilymph differs because of the actions of sodium–potassium pumps. Stimulation of the neuroepithelium causes changes in the discharge rates of the type 1 and type 2 hair cells that make up the maculae and ampullae. These vestibular hair cells synapse with the bipolar neuronal cells of the Scarpa ganglion, the cell bodies of the two vestibular nerves. Impulses

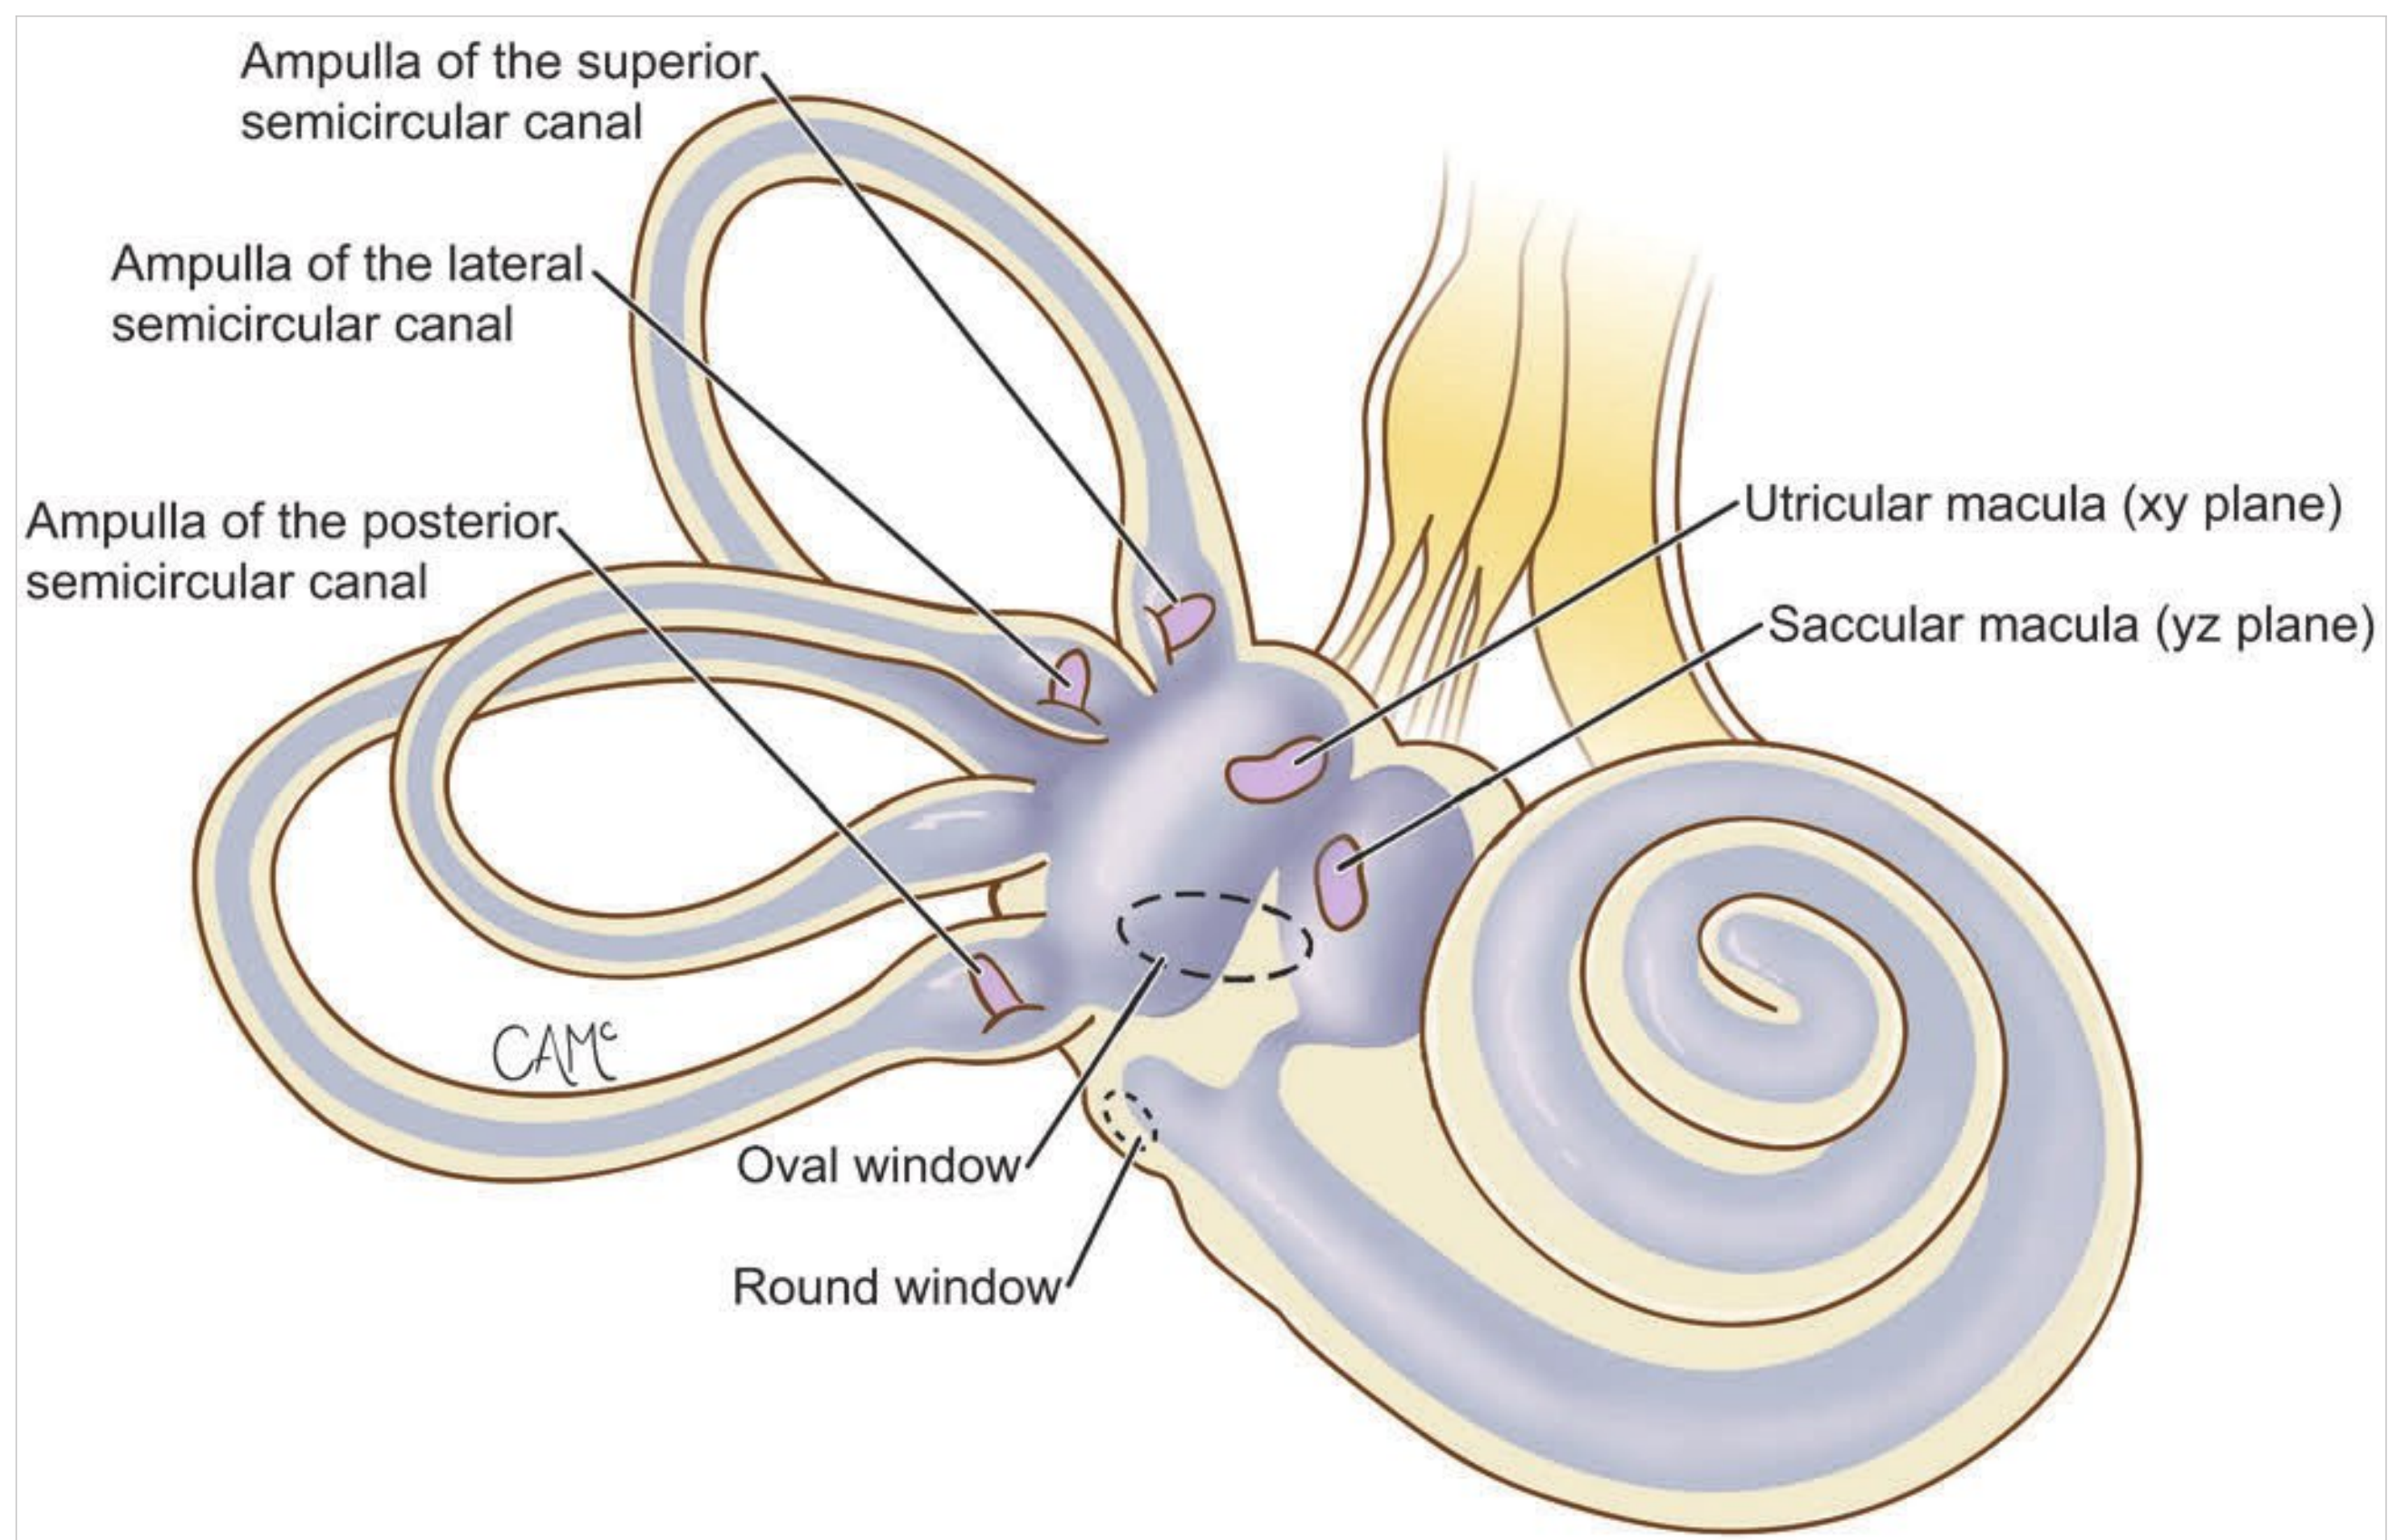

Fig. 113.1 Drawing of the peripheral vestibular system, illustrating the otic capsule, ampullae of the semicircular canals, maculae of the utricle and saccule, and inferior and superior vestibular nerves.

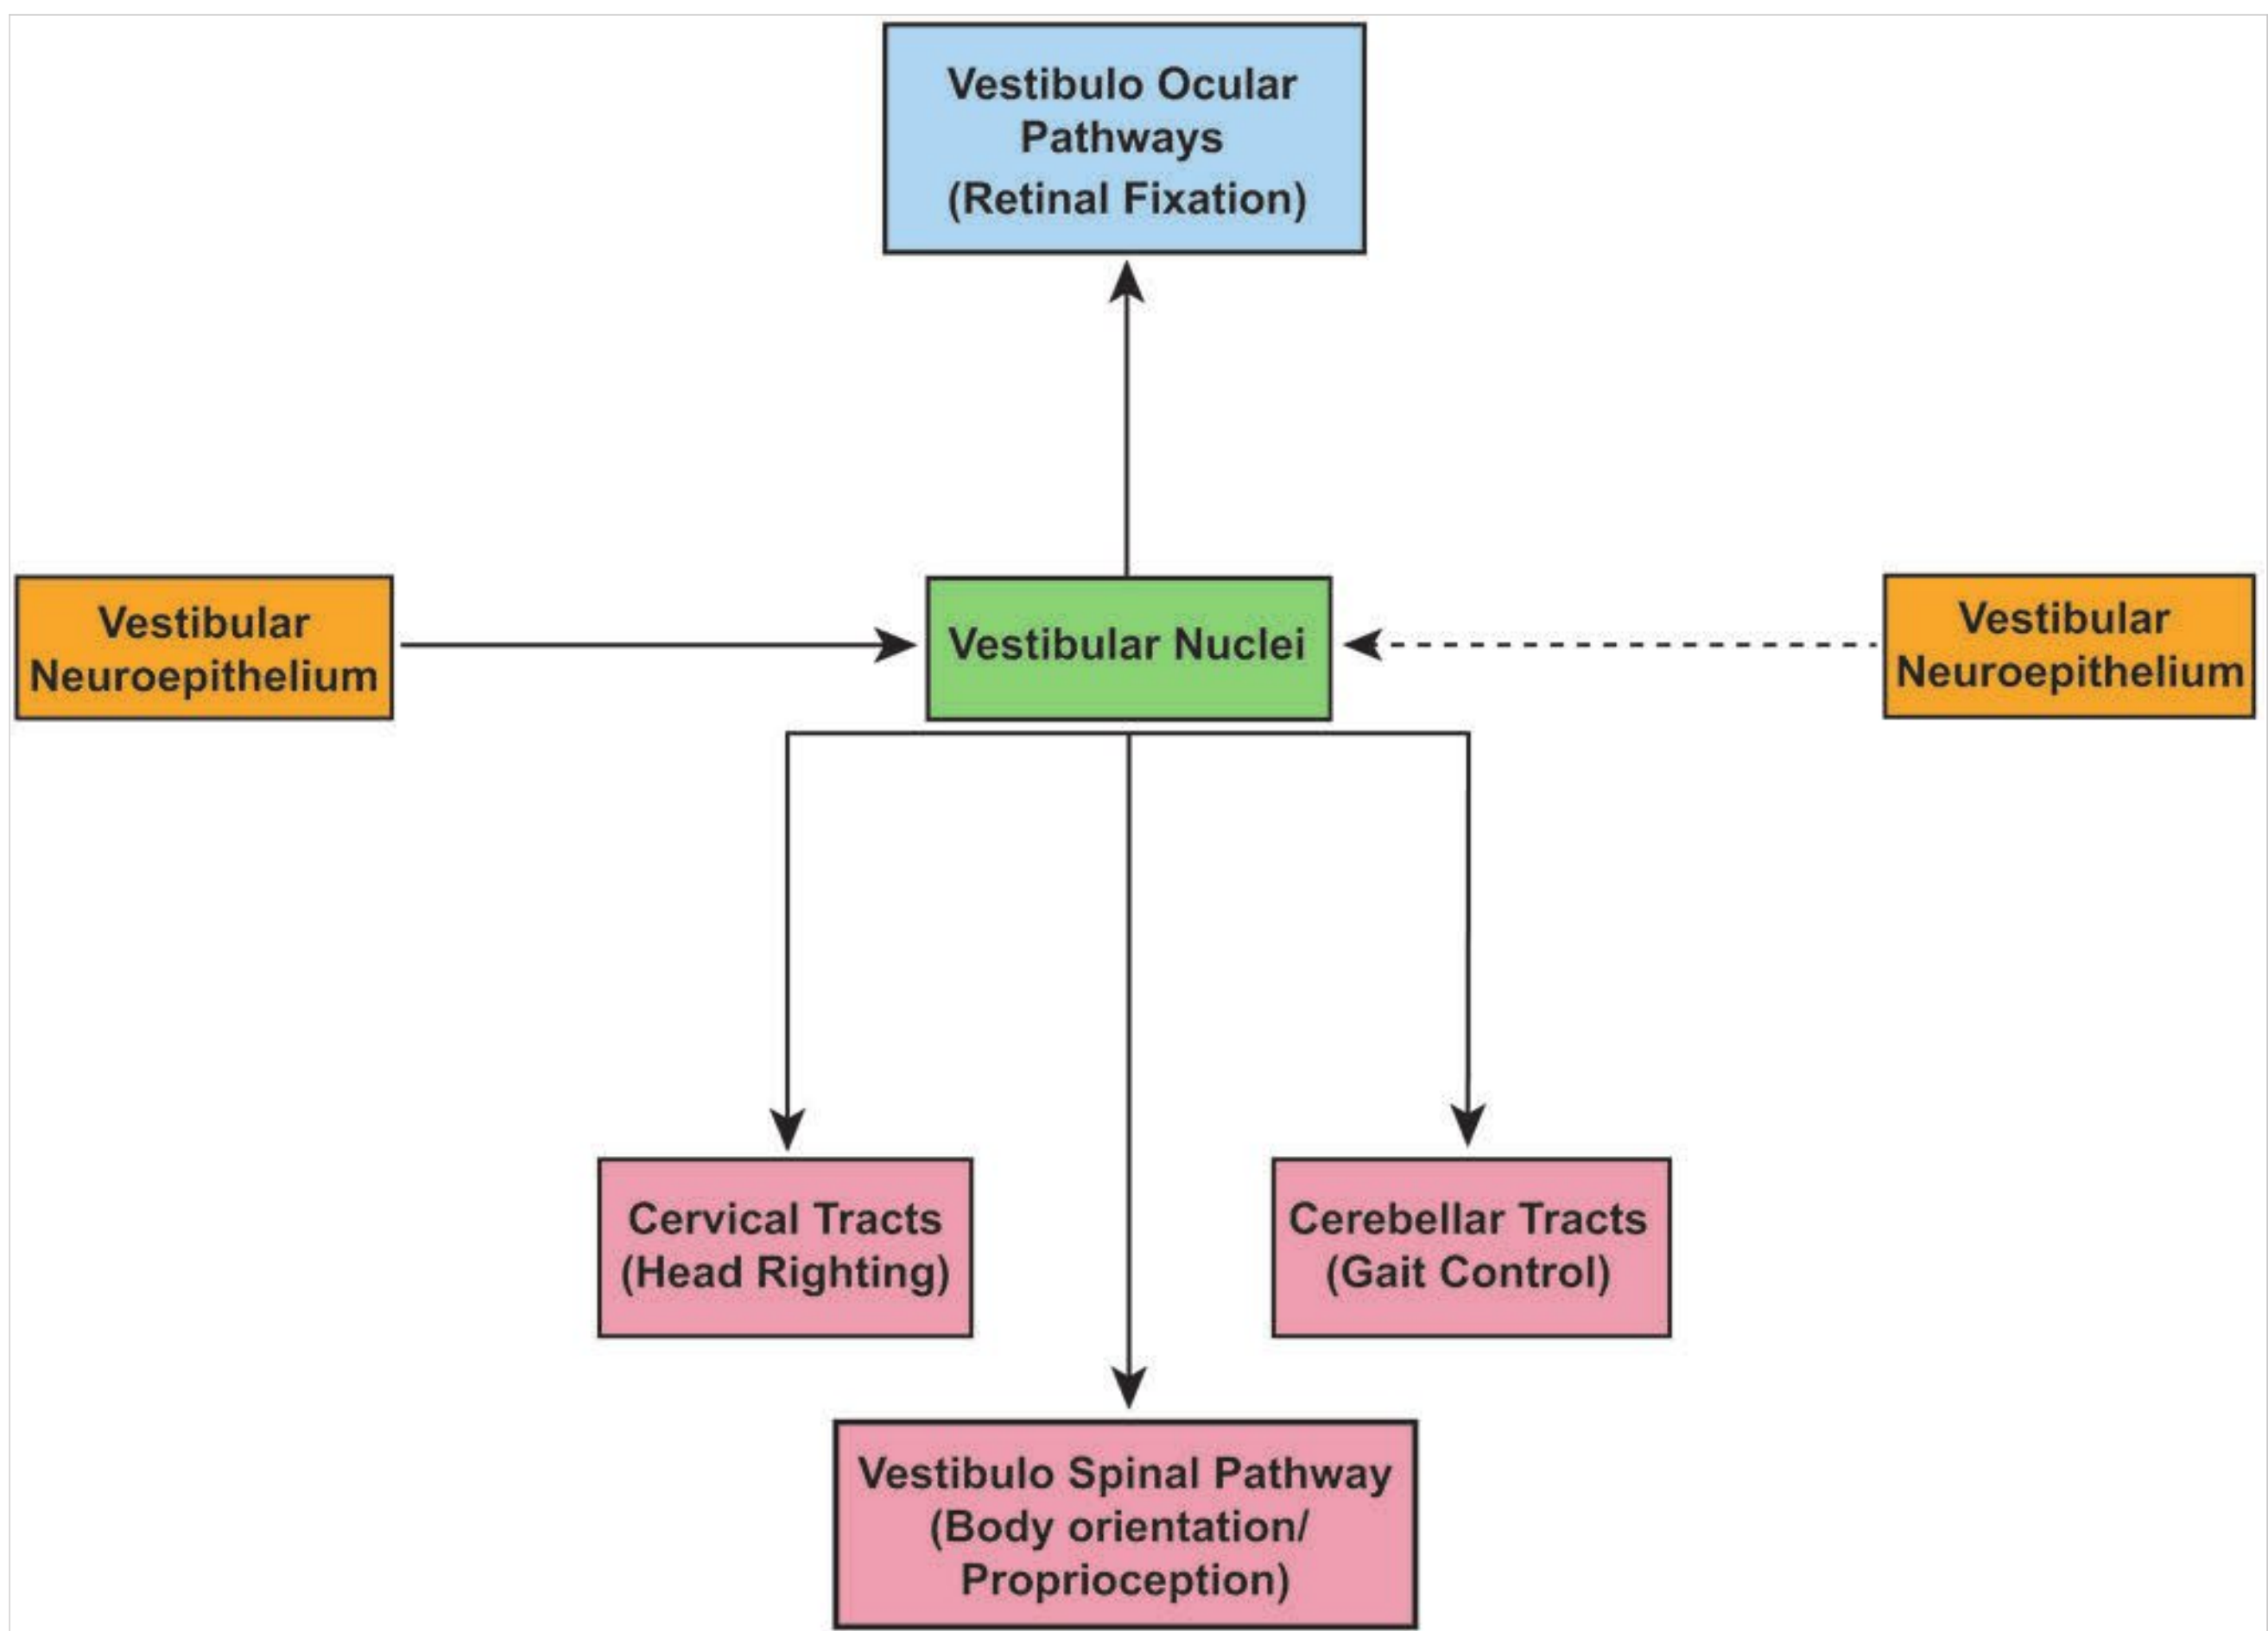

Fig. 113.2 Schematic of the vestibular nerves and their central connections to the cerebellar, ocular, cervical, and proprioceptive systems.

from the five loci of neuroepithelium continue centrally to form elaborate connections to the ocular nuclei, cerebellum, proprioceptive tracts, and cervical nuclei (□ Fig. 113.2). The peripheral vestibular system is enclosed in a continuous bony capsule that has only one opening—the vestibular aqueduct connecting the vestibule to the posterior cranial fossa. Only two structures adjacent to a nonpathologic vestibular capsule can affect equilibrium: (1) The air of the middle ear space is adjacent to the lateral semicircular canal, and changes in air temperature can cause the sensation of motion, and (2) motion at the stapes footplate can also cause the sensation of motion. Some individuals are so sensitive to alterations in footplate dynamics that any dysfunction of the eustachian tube ventilation causes dizziness.

113.3 Bony Anatomy and Physiology of the Peripheral Vestibular System

The bony otic capsule encloses the semicircular canals and the vestibule. The resulting capsule is the only endochondral bone in the body, and it cannot repair itself if fractured. Instead, fibrous tissue forms in the fracture line, but this repair usually

cannot preserve function. By the time of birth, the otic capsule has attained adult size and is completely formed of endochondral bone.

Any of the three perpendicular semicircular canals can undergo erosion, which uncovers the perilymph and exposes the endolymph within the membranous canal to pressure changes, causing disequilibrium (□ Fig. 113.3). This is termed semicircular canal dehiscence. Erosion of the lateral semicircular canal by cholesteatoma causes imbalance with Valsalva maneuver, with finger pressure in the ear canal, or with loud noises. The superior semicircular canal can be uncovered by middle cranial fossa erosion, resulting in the array of symptoms seen in this dehiscence syndrome: general unsteadiness, autophonia, unsteadiness caused by loud noises (Tullio phenomenon), conductive hearing loss, and occasional hyperacusis. Less commonly, the posterior semicircular canal can become dehiscent as a consequence of cholesteatoma, a prominent jugular bulb, or a cerebellar plate in a hypoaerated temporal bone.

The diagnosis of dehiscence in any of the semicircular canals can be established with fine-cut computed tomography (CT) of the temporal bone. Dehiscence of the lateral semicircular canal can be seen on axial or coronal CT. Dehiscence of the posterior semicircular canal is well seen on the Poschl projection, which consists of sections parallel to the superior semicircular canal.

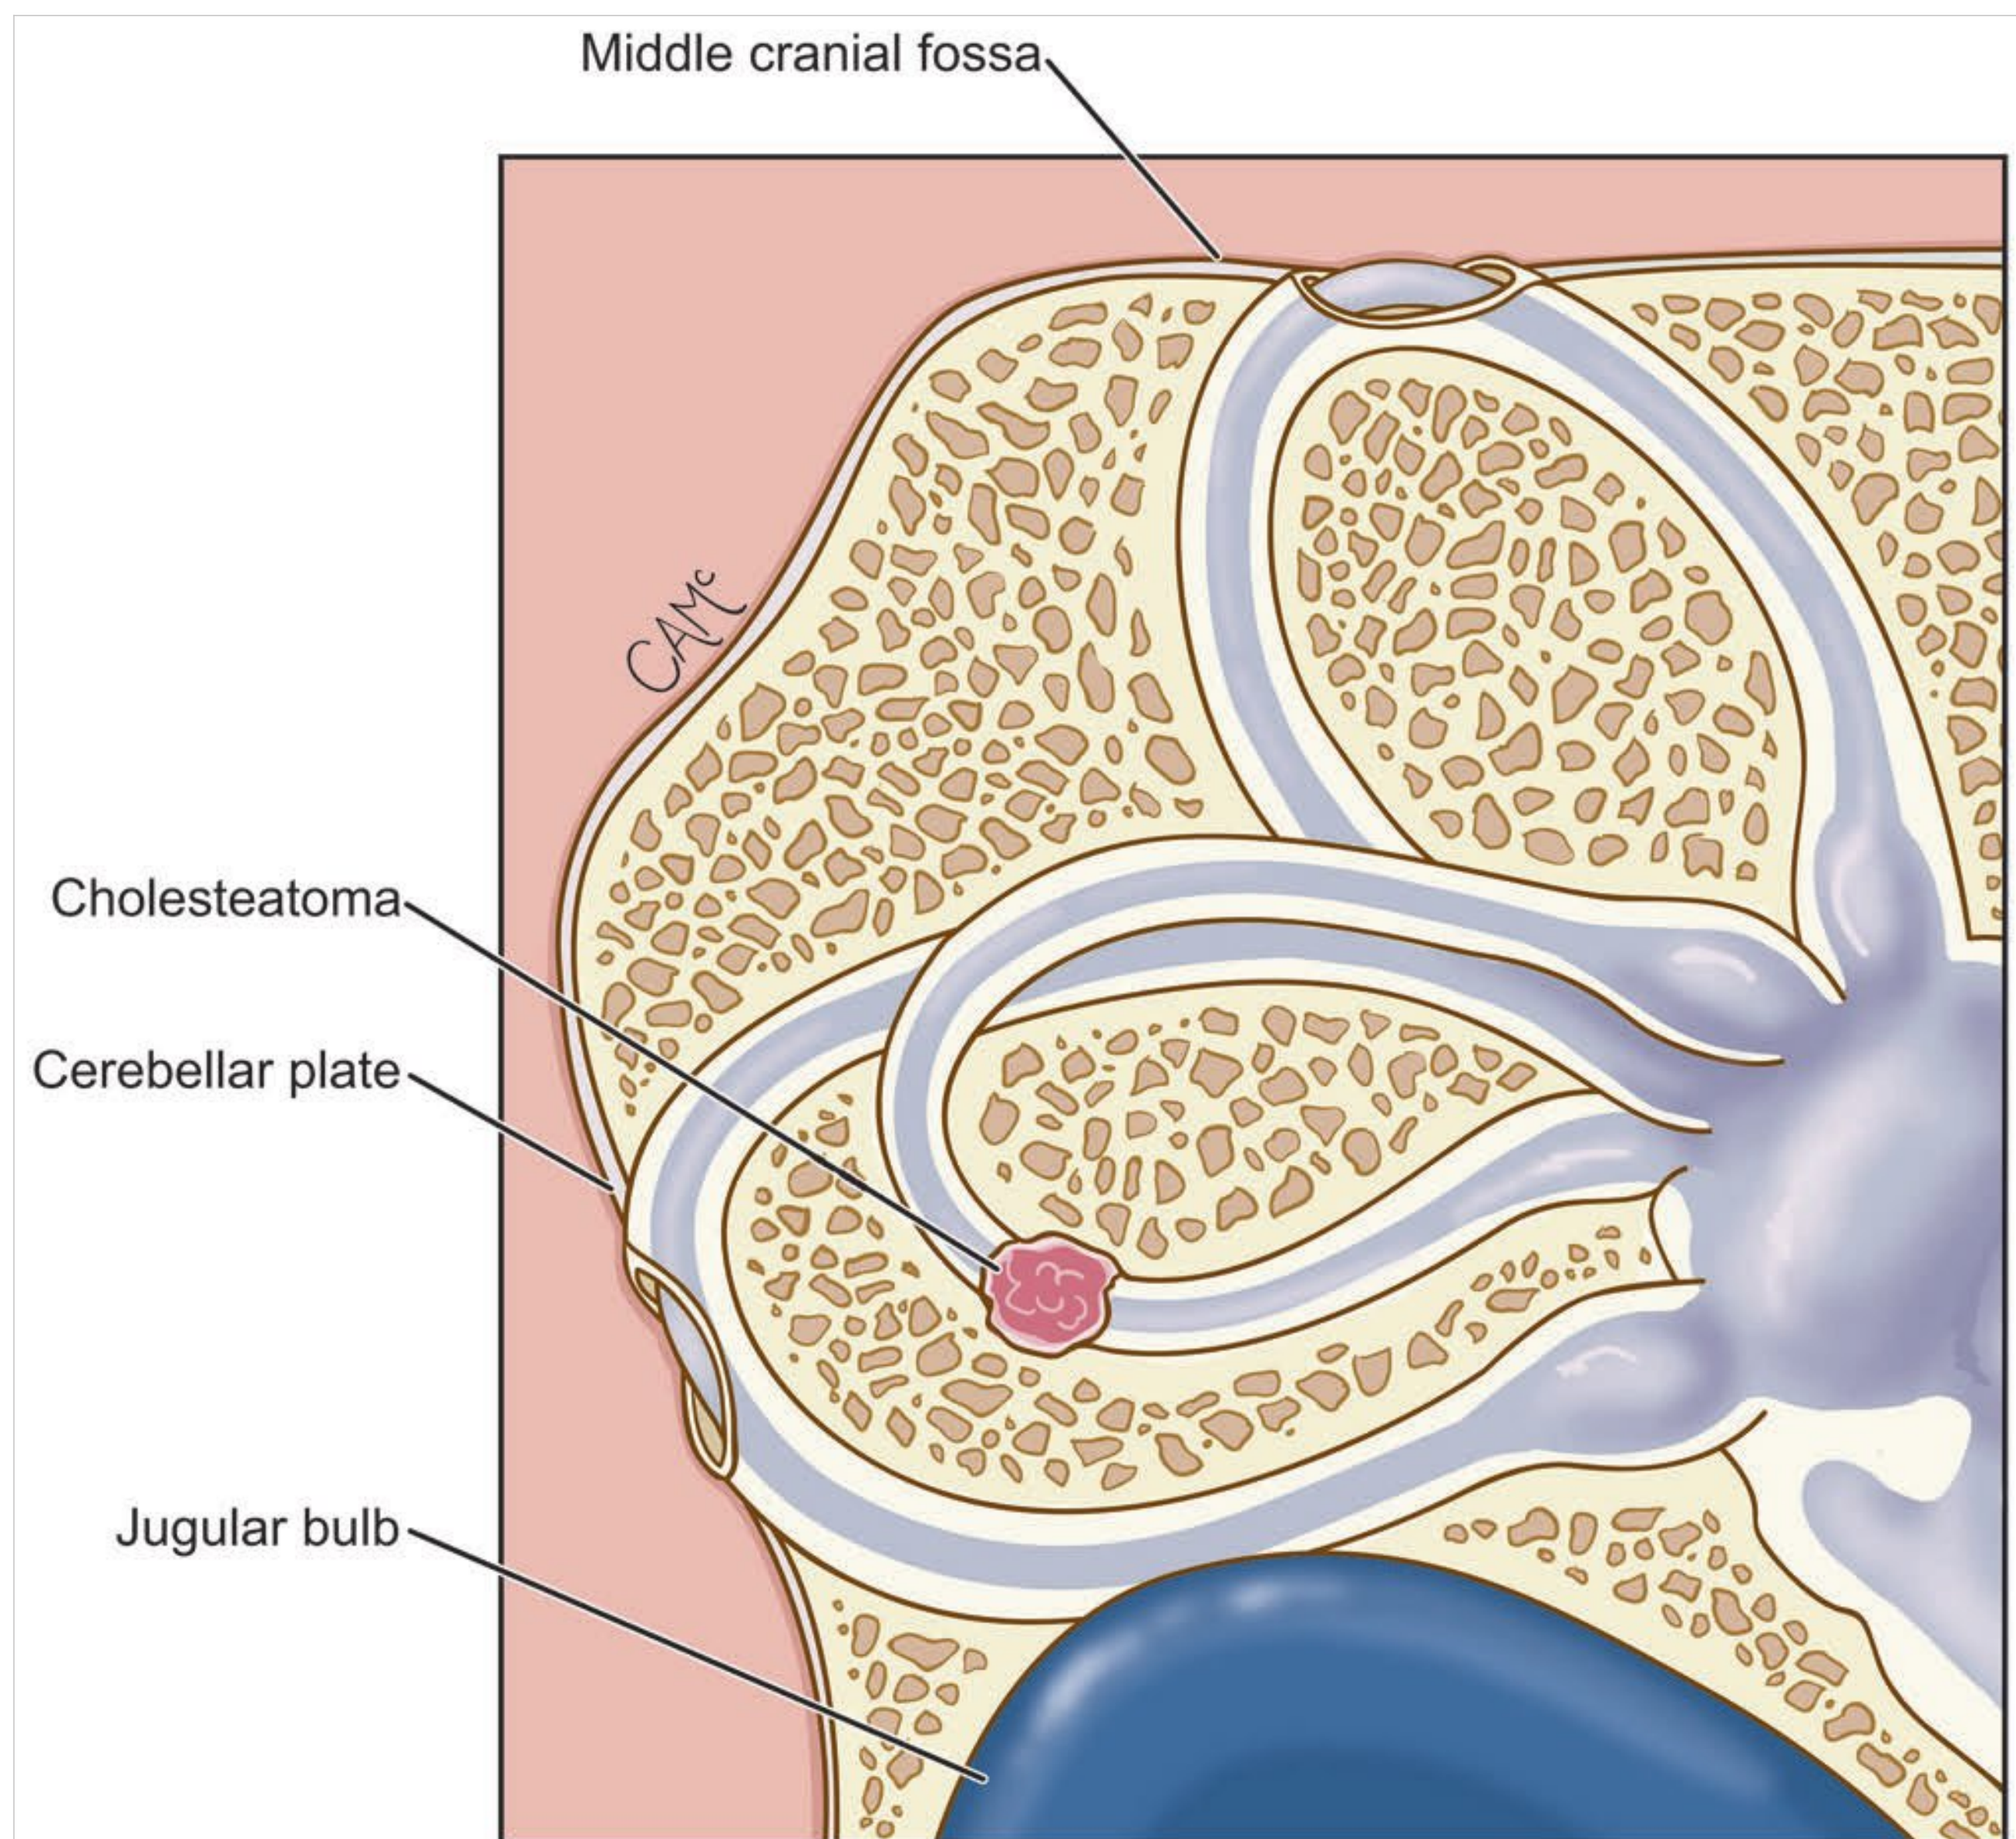

Fig. 113.3 Erosion of the superior, lateral, and posterior semicircular canals. Superior canal dehiscence from erosion of the middle cranial fossa dura, lateral canal dehiscence from cholesteatoma, and posterior canal dehiscence from the jugular bulb or cerebellar plate.

Erosion of the lateral semicircular canal can be established with a fistula test, in which a reliable seal is made between an insufflating ear canal speculum and the skin of the external canal. Positive pressure is applied without a leak, so that the tympanic membrane is compressed toward the promontory. This in turn compresses the exposed lateral semicircular canal periosteum. In lateral canal dehiscence, any positive pressure will cause the eyes to deviate away from the insufflated ear (Hennebert sign).

Vestibular evoked myogenic potentials (VEMPs), also called balance evoked myogenic potentials (BEMPs), are illustrated in □ Fig. 113.4. The physiology of the response is based on a primitive pathway in which the saccule, normally a vestibular organ, functions as a mixed auditory and vestibular organ. When noise is introduced into the ear canal, and ultimately to the stapes footplate, the auditory impulse stimulates central pathways for proprioception and spatial orientation. The VEMP response

therefore is the involuntary motion of the extraocular muscles or involuntary relaxation of a tensed sternocleidomastoid muscle when noise is introduced unilaterally into an ear canal. The decibel threshold for the causing this muscular response is usually roughly equivalent in each ear. However, in the superior canal dehiscence syndrome, the decibel threshold in the affected ear is reduced relative to that in the unaffected ear.

The treatment for canal dehiscence is surgical. Cholesteatomas that erode the lateral or posterior semicircular canals put hearing at risk and will deafen the patient if left untreated. These must be meticulously removed under microscopic magnification and the canal immediately patched with appropriate materials, such as fascia or periosteum. In a large dehiscence, the lumen of the canal can be obliterated with bone paste or bone cement, with every effort made not to tear the membranous canal. Superior canal dehiscence from erosion of the middle cranial

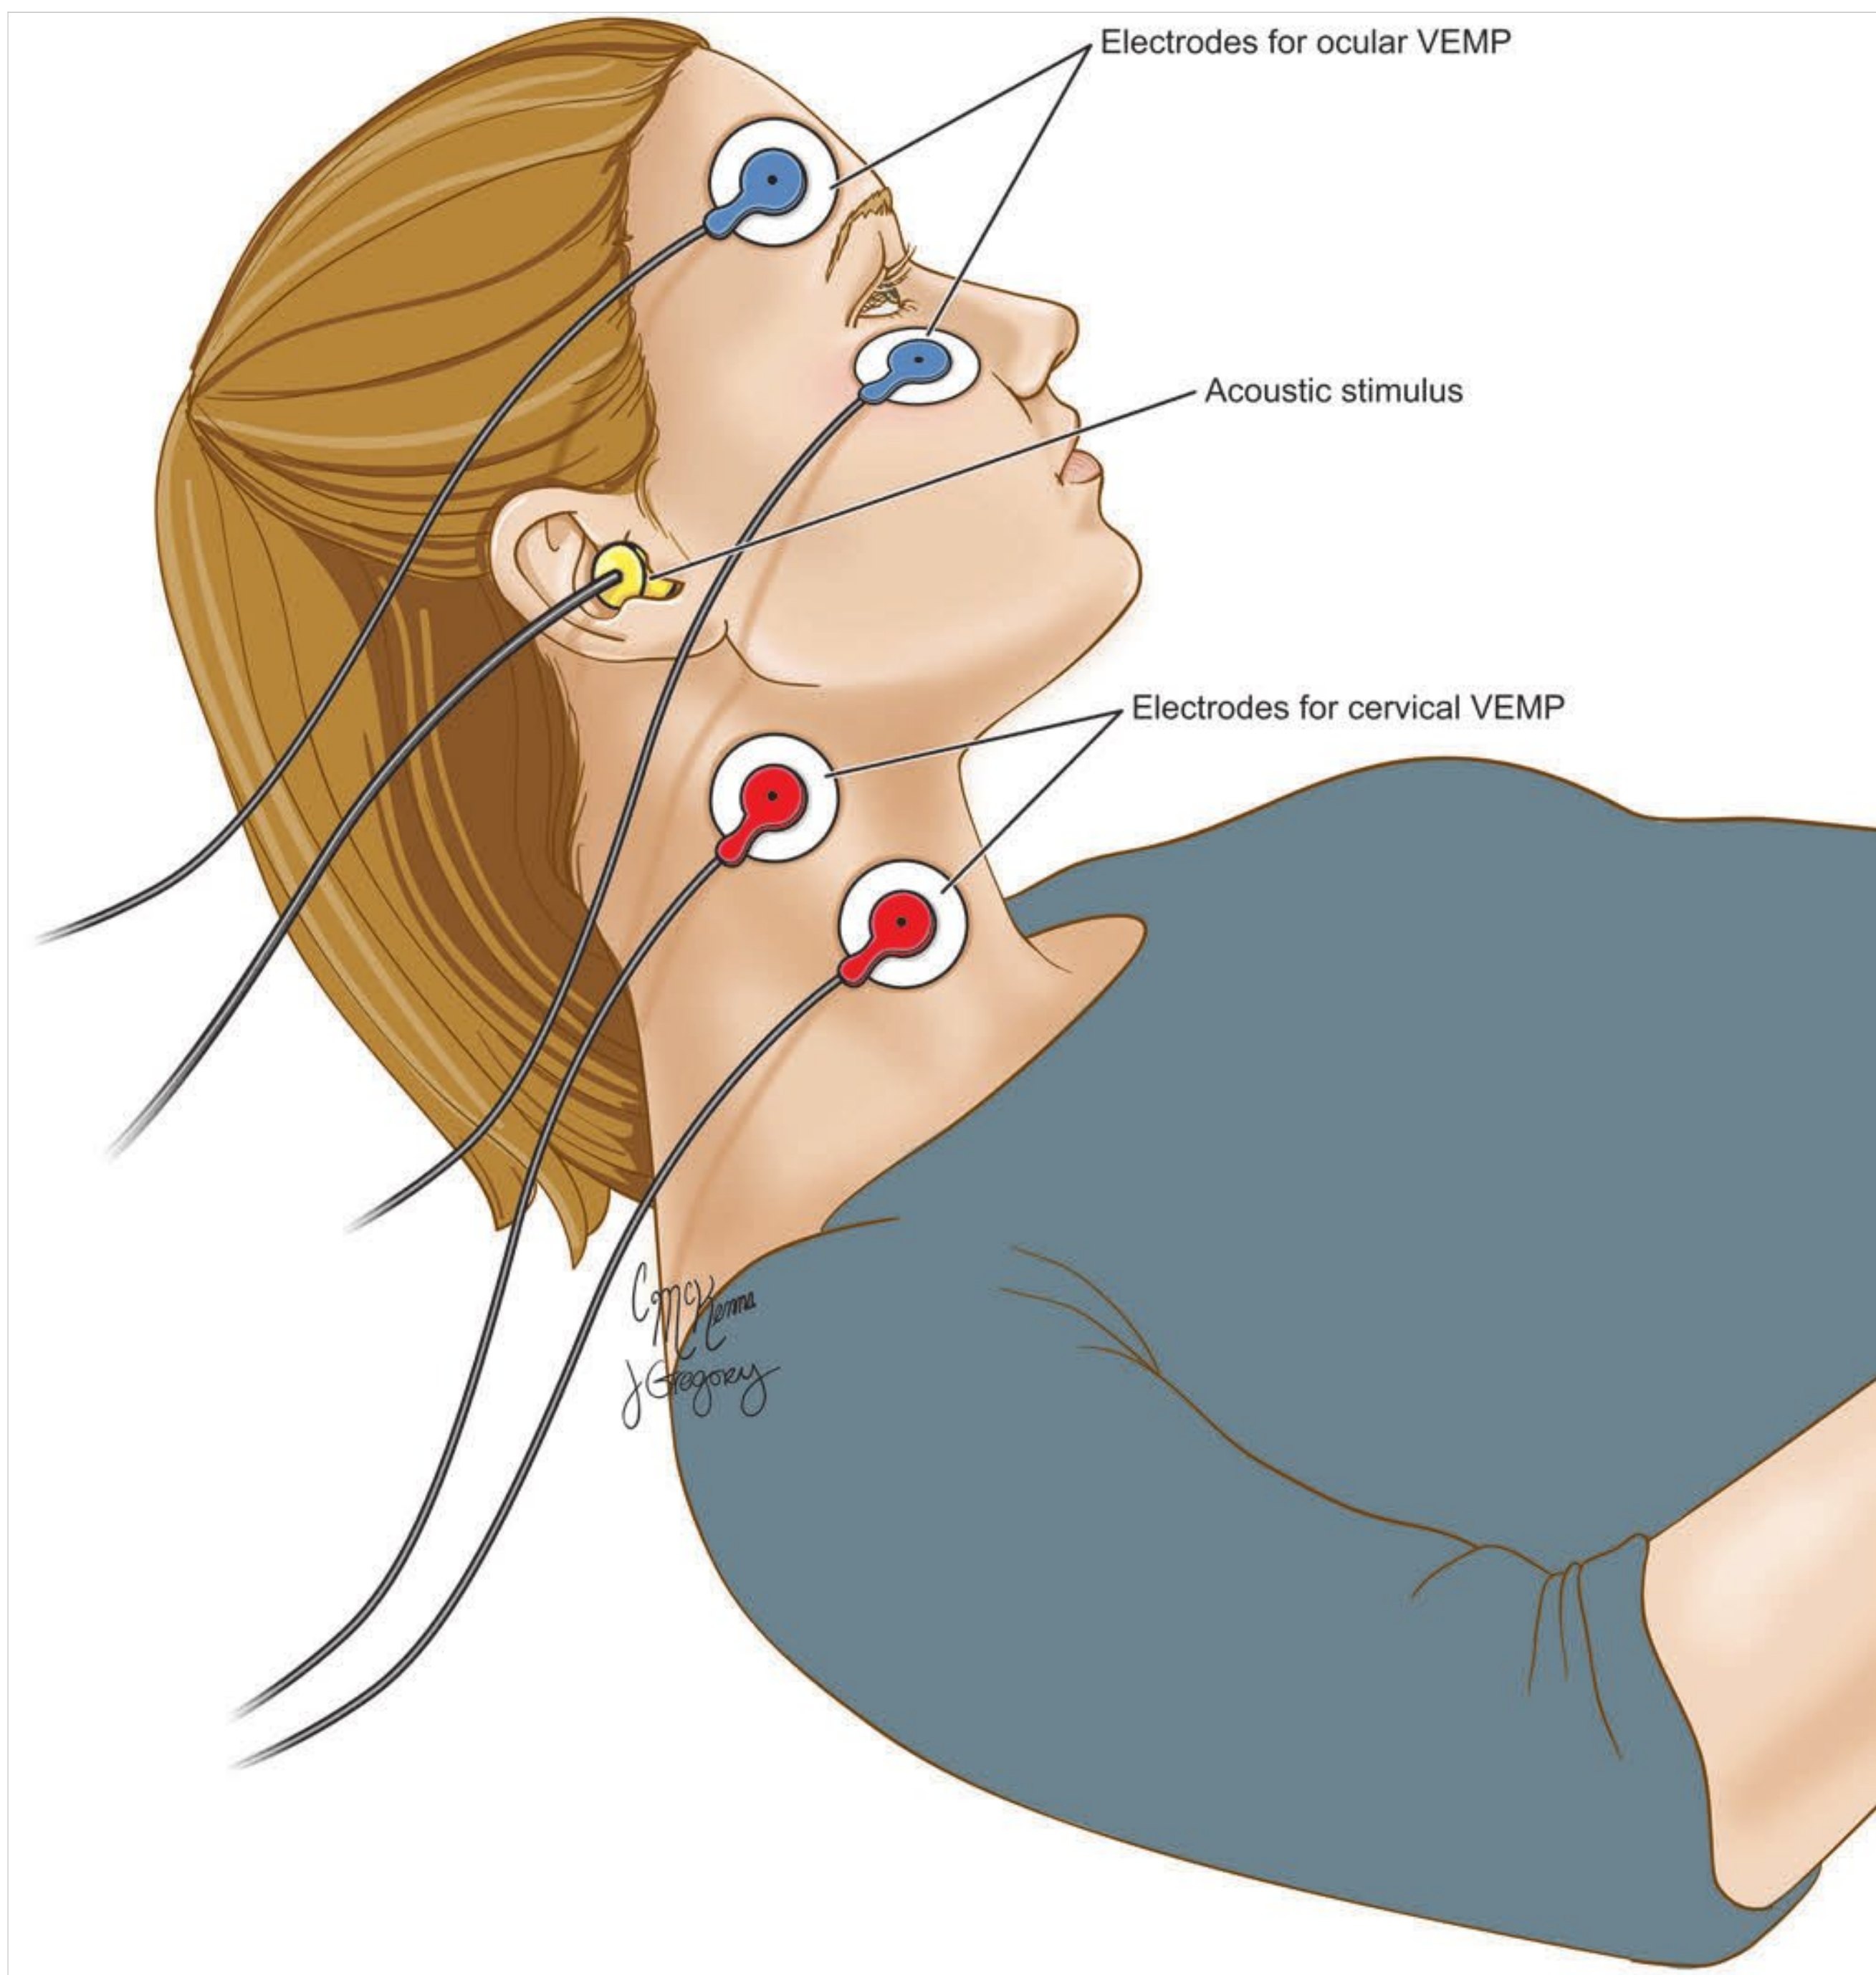

Fig. 113.4 Positioning of electrodes, of acoustic stimulation, and of the patient for VEMP testing. VEMP, vestibular evoked myogenic potential.

fossa dura carries less risk for inner ear fistula and sensorineural hearing loss. Instead, the discomfort from conductive hearing loss and dizziness must be weighed against the morbidity of a middle cranial fossa approach to canal plugging.

113.4 Membranous Endolymphatic Canals

The membranous vestibular labyrinth is enclosed by the bony vestibular capsule (□ Fig. 113.5). The membranous labyrinth is

filled with endolymph, in which the ratio of potassium to sodium is higher than in perilymph. Because of the difference between the ratios of K^+ to Na^+ in the two fluids, endolymph has a net positive charge of 89 mV compared with perilymph. The membranous canals are continuous with the scala media of the cochlea via the ductus reuniens, and continuous with the endolymphatic sac on the cerebellar plate via the vestibular aqueduct. The connection between the vestibular aqueduct and the posterior cranial fossa, although porous, is not directly open. Any breach of the membranous labyrinth causes marked

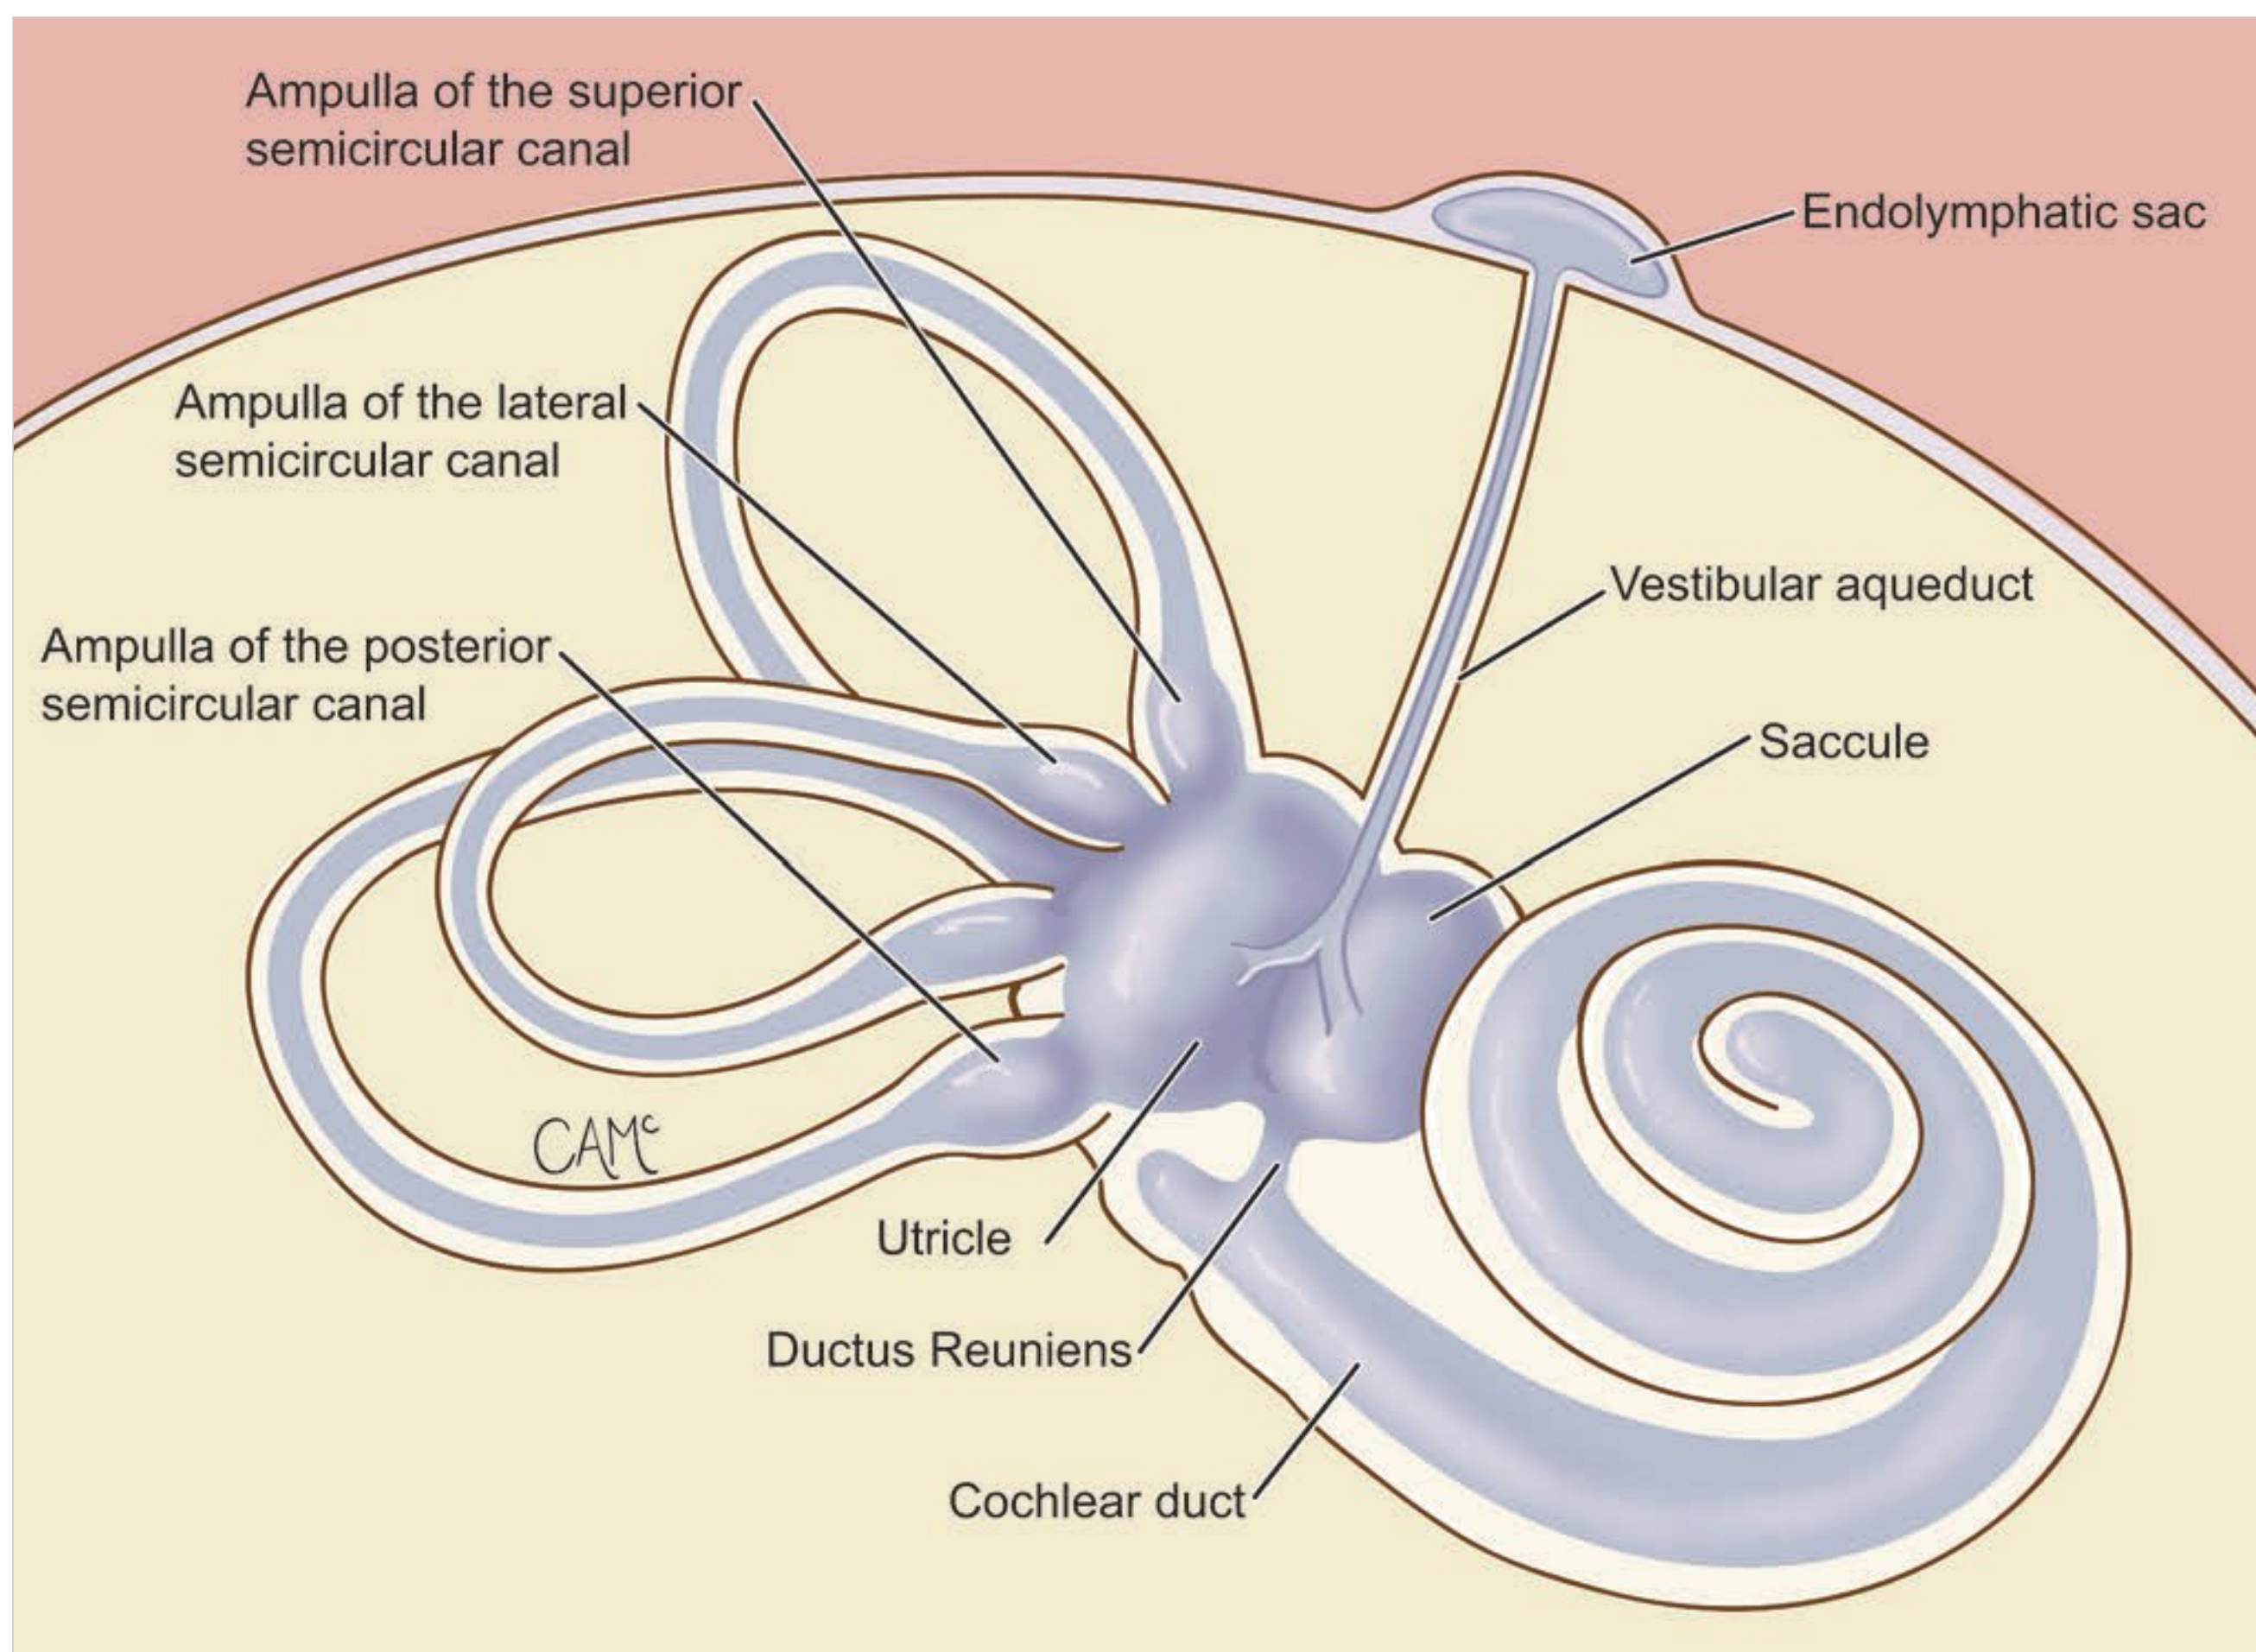

Fig. 113.5 Membranous canals within the bony otic capsule.

vestibular symptoms and may be the basis for the disabling vertiginous episodes that occur in Meniere disease.

Most balance disturbances related to the endolymphatic canals are not caused by actual rupture of the membranous canal. Instead, exposure of the perilymph to direct pressure or leakage of perilymph usually causes imbalance. As previously mentioned, dehiscence of the semicircular canals causes imbalance when pressure changes are introduced to the exposed periosteum of the canal. Additionally, imbalance can be caused by leakage of perilymphatic fluid. Leakage is usually from the vestibule via the oval window, fissula ante fenestram, or fossula post fenestram, but sometimes from the scala tympani of the cochlea via the round window niche, or from the ampullated end of the posterior semicircular canal via the Hyrtl fissure (□ Fig. 113.6). The fissula, fossula, and Hyrtl fissure are congenital fissures filled with soft tissue that are present in all temporal bones, but they usually are not porous.

Diagnostic tools to distinguish perilymph exposure, perilymph leak, and Meniere disease are varied. The eyes deviate away from the affected ear with positive pressure and toward the affected ear with negative pressure. This is the Hennebert sign.

When this maneuver seems unambiguous, leak can be confirmed by direct observation of the round and oval window niches. Rarely, a sample of clear fluid from these sites can

confirm the presence of β_2 -transferrin. Semicircular canal dehiscence has previously been described and can be identified with VEMP testing and Poschl views on temporal bone CT.

Meniere disease has a typical and reliable set of symptoms, in which recurrent episodes of unilateral ear pressure, tinnitus, and hearing loss are accompanied by disabling vertigo. The episodes last for hours, but not days, and audiometric testing confirms a low-frequency sensorineural hearing loss that is worst during the acute spell and gradually returns to a new baseline afterward. The pathophysiology of the disease is thought to be increased fluid pressure in the endolymphatic canals, causing dilation of the membranous canals. The abnormal physiology of Meniere disease can be detected by electrocochleography, which shows the ratio of the summation and action potentials in response to an auditory stimulus to be abnormally large (SP/AP > 0.50; □ Fig. 113.7). It would be reassuring to assert that electrocochleography is the gold standard for establishing Meniere disease in a dizzy patient, but the changes seen on electrocochleography are unreliable, and the test is uncomfortable for most patients and difficult to organize.

Treatment for exposure of the membranous labyrinth or leakage of perilymph is surgical. Fistulas are approached via middle ear exploration with the placement of fat, fascia, or areolar tissue into the most likely sites of leak. Canal resurfacing with fascia or periosteum and canal plugging with bone paste

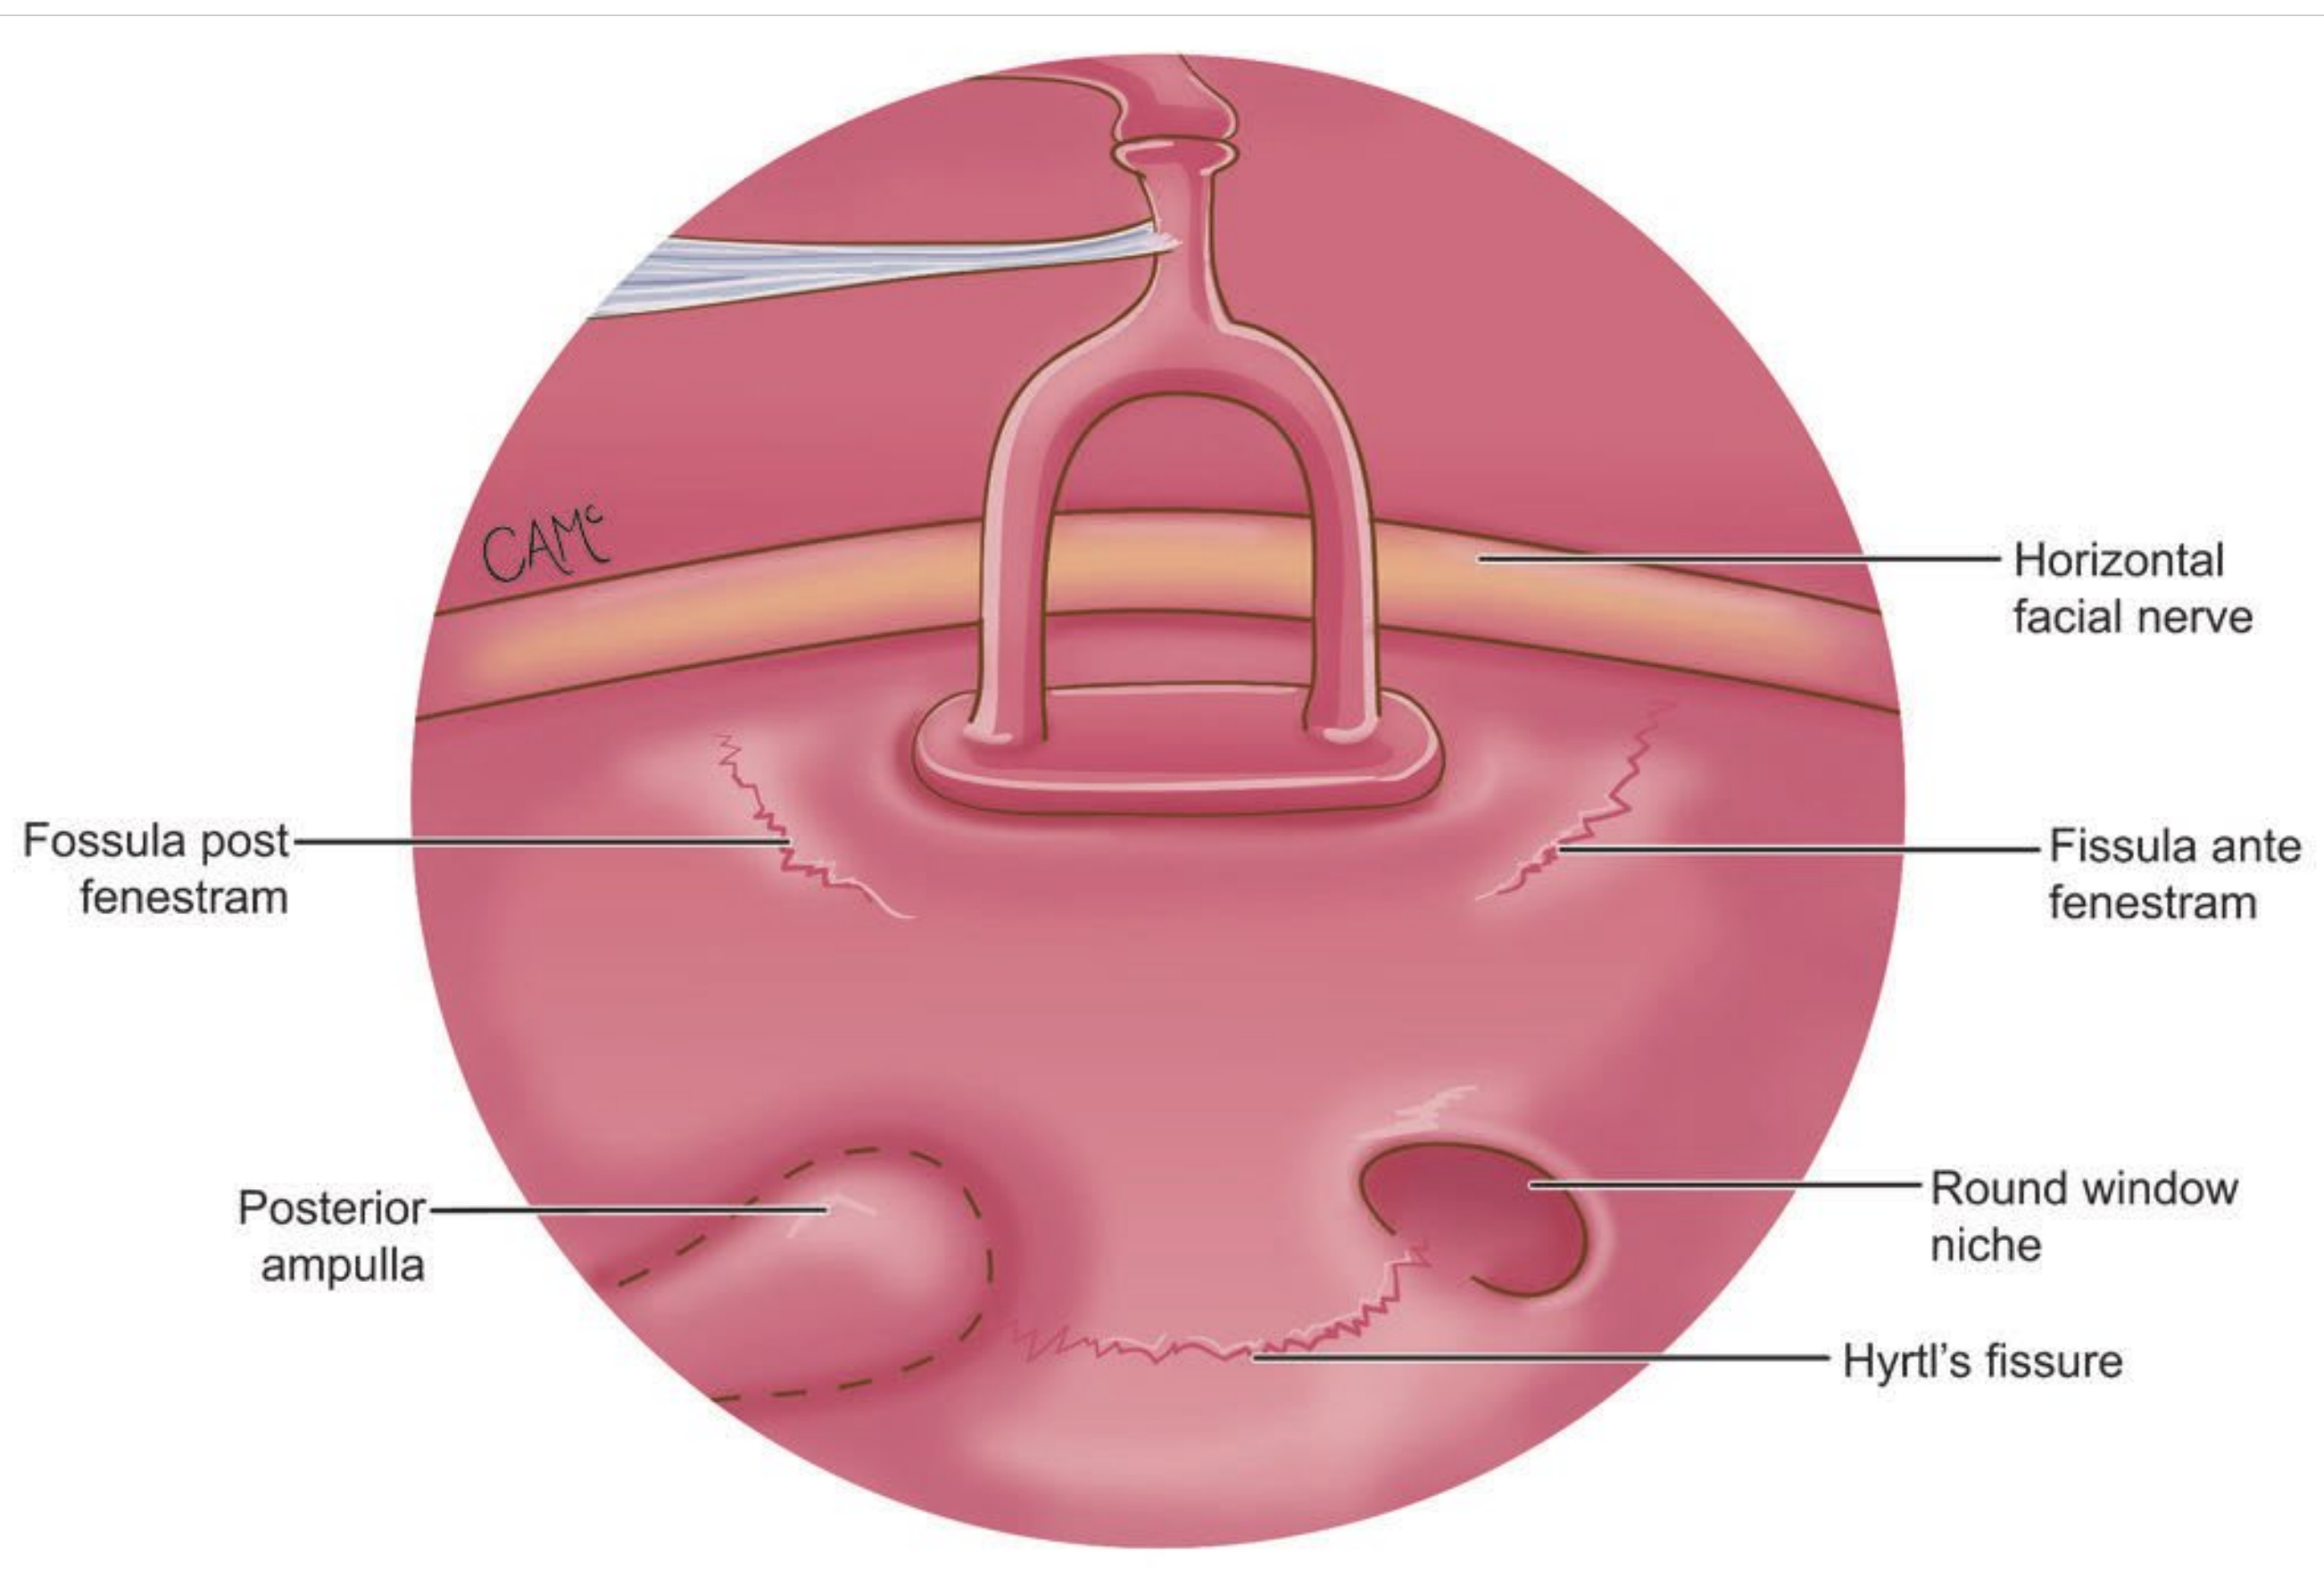

Fig. 113.6 Sites of perilymph leakage: the fissula ante fenestram, fossula post fenestram, scala tympani via the round window niche, and ampullated end of the posterior semicircular canal via the Hyrtl fissure.

as well as bone cement have previously been described. Treatments for Meniere disease range from stress reduction to craniotomy with vestibular nerve section. Because Meniere disease is very responsive to increases in psychological stress, simple information about the disease and what to expect, and referral for psychological techniques of stress reduction, are enough to manage the disease in some patients. The next tier of treatments involves salt restriction and daily diuretics. Some patients benefit from the placement of a pressure equalization tube in the affected ear, and some benefit from tube placement followed by the application of positive pressure for 5 minutes several times per day (the Meniett machine). Decompression of the endolymphatic sac can bring relief for some patients, although this may be a placebo effect. Destructive interventions are intratympanic instillations of gentamicin, sacculotomy, labyrinthectomy, and intracranial vestibular nerve section. Although gentamicin is considered a selective vestibulotoxin, it often causes incidental sensorineural hearing loss, and the patient must be cautioned of this risk.

113.5 Neuroepithelium

The peripheral sensory organs for balance are the ampullae of the lateral semicircular canals and the maculae of the utricle and saccule. The canals are perpendicular to one another, although they are all tilted up at an angle of 30 degrees from

the horizontal. Therefore, the horizontal semicircular canal is 30 off the horizontal plane, and the two other canals are perpendicular to that plane. The semicircular canals detect angular motions and turns. When the head moves, the endolymph moves relative to the ampulla of the canal, and that deflection of the crista of the ampulla causes an increase or decrease in the baseline firing rate of the type 1 and type 2 vestibular hair cells (□ Fig. 113.8). The presence of cold or warm water in the ear canal changes the temperature of the middle ear space, cooling or warming the endolymph of the lateral semicircular canal and causing that ampulla to deflect away from the vestibule or toward the vestibule.

The utricle is located on the ceiling of the vestibule, directly inferior and medial to the horizontal facial nerve as it courses over the oval window niche. The utricle is basically in the x-y plane. The saccule is located on the anterior medial wall of the vestibule, just anterior and medial to the anterior lip of the oval window. The saccule is basically in the y-z plane. These two organs detect linear acceleration and falling. The sensory neuroepithelium of the utricle and that of the saccule are the maculae, in which the type 1 and type 2 hair cells are oriented toward a central striola; their baseline firing rates are modified by acceleration.

Disorders of the neuroepithelium are twofold; those resulting from abnormal stimulation of the neuroepithelium or those caused by death or hypofunction of the neuroepithelium.

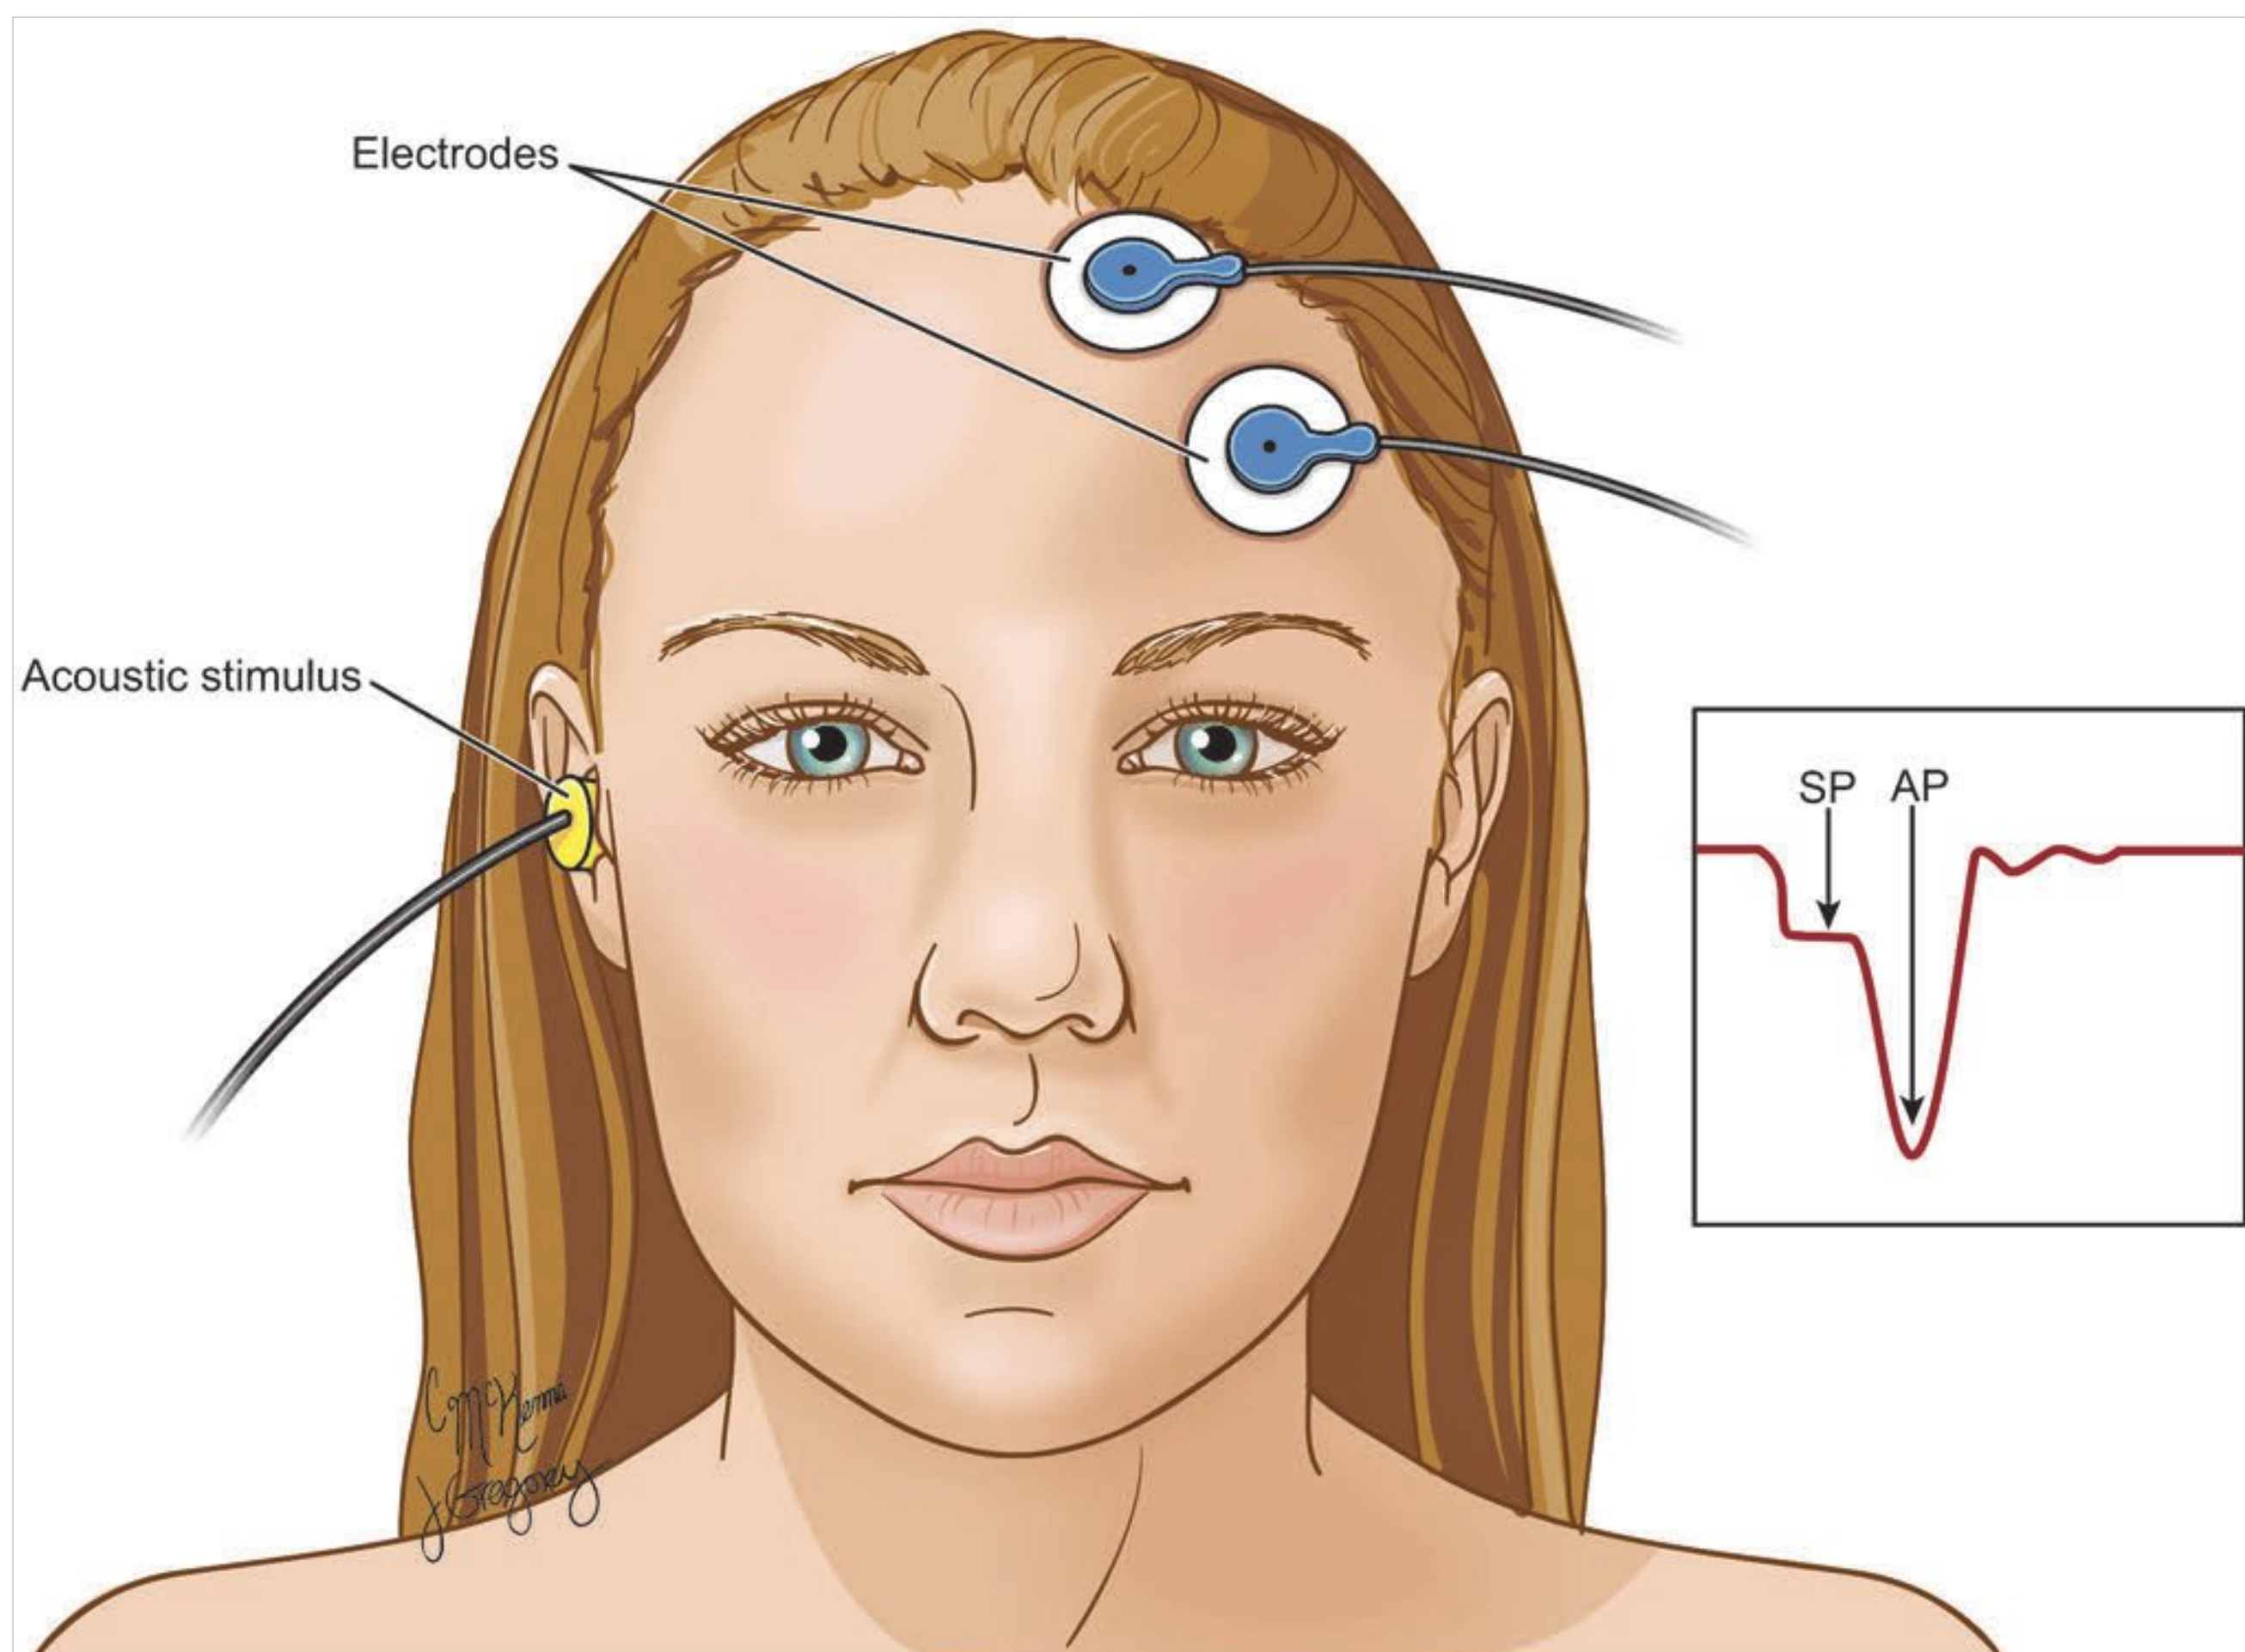

Fig. 113.7 Electrocochleography technique. Acoustic stimuli can be introduced via the canal or transtympanically. An electrical response within the first 2.0 milliseconds consists of the summation potential and action potential. SP, summation potential; AP, action potential.

Benign paroxysmal positional vertigo (BPPV) is caused by nonphysiologic stimulation of the ampullae by otoliths, which are loose neuroepithelial components composed of calcium carbonate around a matrix protein. In this disorder, which tends to occur most often in the posterior semicircular canal, normal head motions cause abnormal stimulation of the posterior canal neuroepithelium with an exaggerated central response that patients find unpleasant. BPPV is diagnosed by Dix-Hallpike testing (□ Fig. 113.9), in which the patient is positioned with the head turned and hanging so that the aberrant otoliths of the posterior semicircular canal cause maximal stimulation and nystagmus. The characteristic result is a rotatory and lateral nystagmus that beats toward the ground when the subject's head is hanging backward with the problem ear down. The nystagmus begins a second or two after the provocative position is assumed, grows in intensity, and then abates. Sitting up reverses the direction of the nystagmus. Each subsequent cycle of stimulation is shorter and less intense. BPPV is by far the most common reason for referral to an otolaryngologist's office for imbalance.

Other disorders of the neuroepithelium result from death of the type 1 and type 2 hair cells. Ototoxins, usually intravenous antibiotics given for life-threatening infections, cause generalized nonresponsiveness of the ampullae and maculae to stimu-

lation. Caloric testing elicits reduced or no symptoms and nystagmus. The patient cannot fix any visual target on the retina while the head is moving (oscillopsia), resulting in an inability to read signs or recognize faces while walking.

Labyrinthitis (infection or inflammation of the perilymph or endolymph) causes hair cell death and nonfunction. This would be identified by a reduced response on caloric testing or by enhancement in one labyrinth on magnetic resonance (MR) imaging with and without gadolinium. A key feature of true labyrinthitis is that the intraotic inflammation and infection are devastating to vestibular and auditory function, and the patient becomes quite ill, with roaring tinnitus in the affected ear. In the long term, unilateral peripheral vestibular loss would be expected, with completely absent caloric responses and robust horizontal nystagmus toward the unaffected ear when vibration is applied to the mastoid of the affected side.

Loss of utricle function can be identified by the ocular counter-torsion test, in which the subject sits with the head upright. The examiner picks a landmark on the subject's iris and then tilts one ear up, looking for physiologic righting of the iris—an ocular counter-torsion. If this does not occur, if the iris tilts with the head without compensation, hypofunction of the superior utricle is indicated.

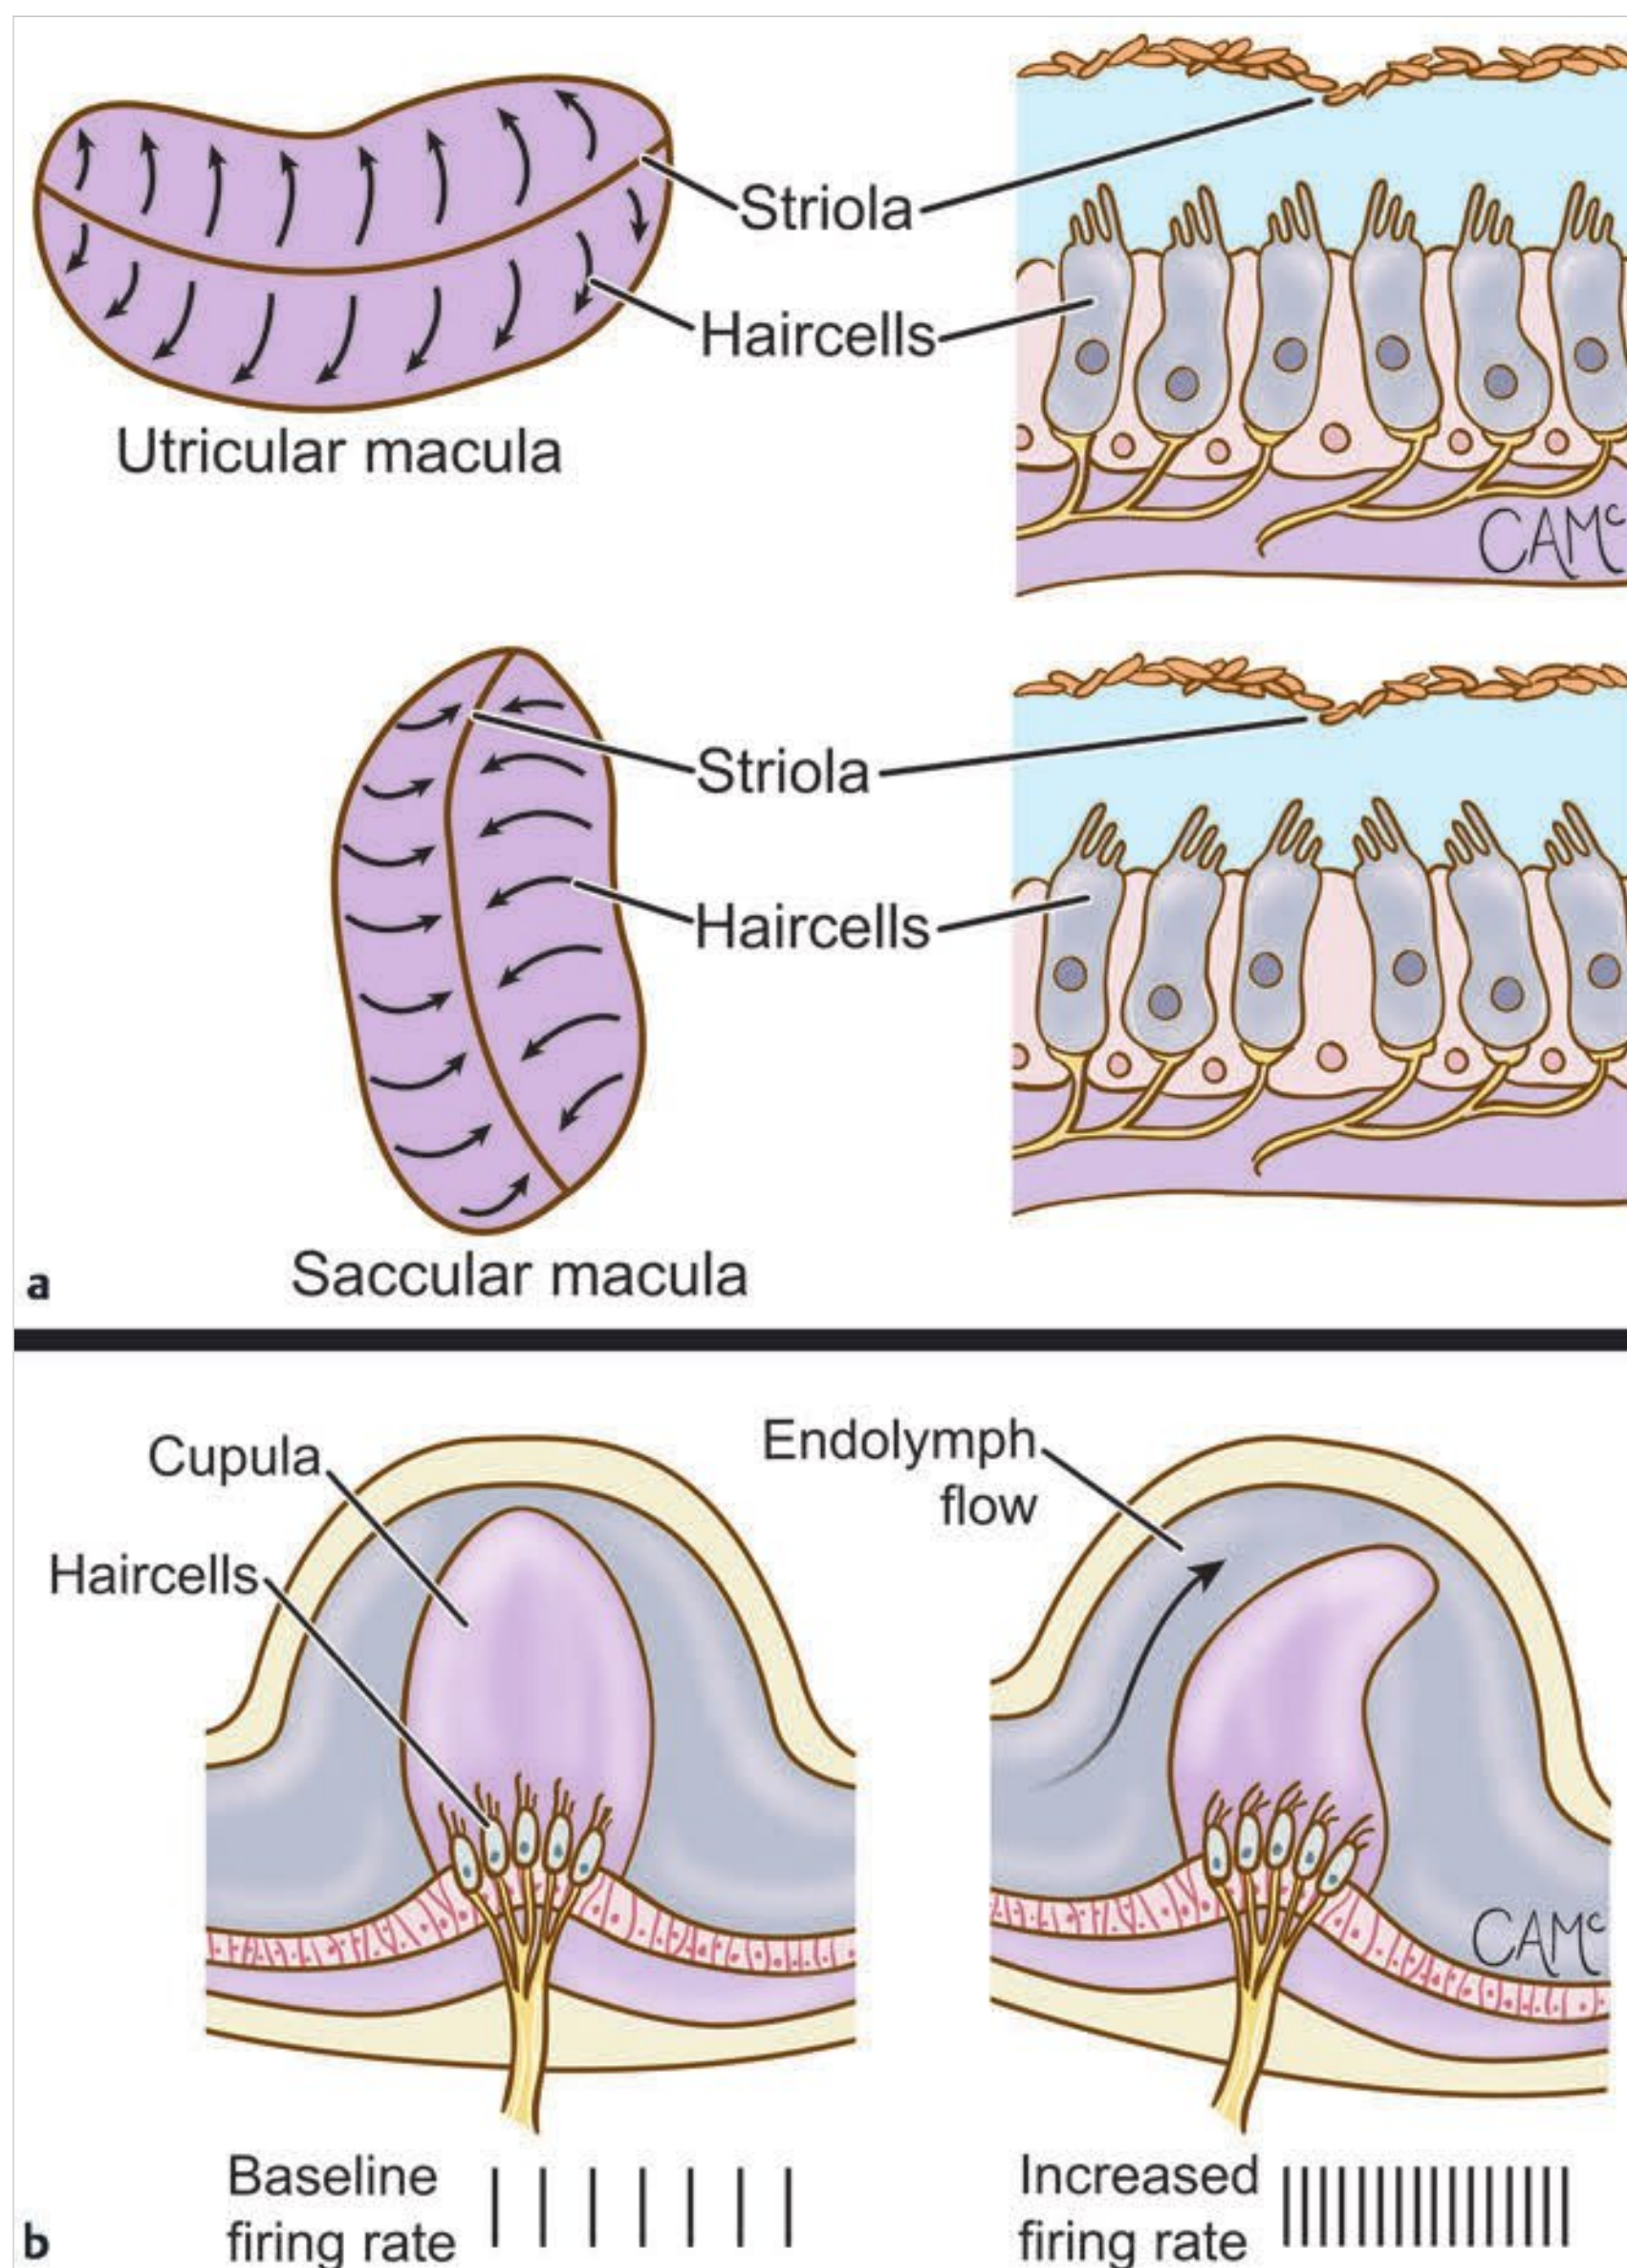

Fig. 113.8 (a) Maculae and (b) ampullae: orientation of type 1 and type 2 hair cells and the response of firing rates to hair cell deflection.

A common and perhaps more serious malfunction of the neuroepithelium is alcohol intoxication. As ingested alcohol diffuses into the endolymph, the endolymph rises, giving the subject a sensation of motion. A characteristic nystagmus follows. Although this condition requires no treatment except time, it is probably responsible for more deaths, in motor vehicle accidents, than any other form of dizziness.

The treatment for loss of neuroepithelial function consists of supportive care in the short term and physical therapy in the long term. There is no method of restoring the lost function, and in the acute phase of unequal vestibular inputs from the two ears, a vestibular suppressant and medical leave are the best that can be offered. In the long term, when vertigo has given way to general unsteadiness, physical therapy can help the patient regain some balance, independence, and confidence.

The treatment for BPPV, on the other hand, can intervene at the site of the problem and show good results. The treatments for BPPV range from interventions during a single office visit to surgical obliteration of the malfunctioning semicircular canal.

The particle repositioning (Epley) maneuver can allow the loose otoliths to fall into the vestibule, where they become asymptomatic. Habituation exercises can retrain the central vestibular system to ignore the aberrant information from the affected ear. In patients with long-term BPPV, the posterior semicircular canal can be obliterated, or the cingulate nerve can be sectioned in an infracochlear approach.

113.6 Vestibular Nerves

The five islands of vestibular neuroepithelium transmit their varying discharge information to the superior and inferior vestibular nerves, which are afferent (sensory) nerves. The macula of the utricle and ampullae of the superior and lateral semicircular canals synapse with the superior vestibular nerve, while the macula of the saccule and ampulla of the posterior semicircular canal synapse with the inferior vestibular nerve. The portion of the inferior vestibular nerve that travels from the

Fig. 113.9 Dix-Hallpike testing: position of the left posterior semicircular canal in the left head-hanging position. The canal is positioned to cause maximal stimulation and pooling of the otoconia away from the ampulla. In the Epley maneuver, the canal is then rotated 270 degrees to allow the otoconia to pour into the vestibule. The canal is pictured in mid rotation as the otoconia begin to fall into the vestibule.

ampulla of the posterior semicircular canal is called the cingulate nerve. The nerve cell bodies for the bipolar primary axons of the vestibular nerves are located in the internal auditory canal, forming the Scarpa ganglion. From the internal auditory canal, the nerves progress across the cerebellopontine angle to enter the brainstem.

Isolated dysfunction of any of these nerves can occur. The reasons are usually hard to identify. Isolated neuronitis occurs secondary to autoimmune disease, presumed viral infection, idiopathic inflammation, and neoplasms along the nerve route. The symptoms are nonspecific and usually consist of generalized unsteadiness and spinning without ear symptoms or position sensitivity. A coordination of tests can help identify which vestibular nerve is hypofunctioning; absent caloric responses identify superior vestibular nerve malfunction because lateral canal stimulation is ineffective. Increased VEMP thresholds identify inferior vestibular nerve malfunction because the saccule requires more auditory stimulation to elicit the primitive auditory–vestibular response. Normal hearing (by an audiogram and/or otoacoustic emission testing) helps to exclude labyrinthitis as a possible cause of dizziness because the hearing in the putative ear should be affected as well as balance in labyrinthitis.

If the hearing is symmetrical and unchanged, the diagnosis of vestibular neuritis (aka vestibular neuronitis) may be supported by a reduced bithermal caloric response on one side or abnormal results of symmetry, phase and gain testing on the Harmonic Rotation Chair test. Of these examinations, the bithermal caloric test on the Visual Electronystagmogram (VNG) done with infrared goggles or on the Electronystagmogram (ENG) performed with transdermal electrodes is both localizing (what place within the inner ear?) and lateralizing (which side?).

Like the treatment for neuroepithelial loss, previously described, the treatment for vestibular nerve hypofunction

consists of supportive care in the acute phase and physical therapy in the long term.

113.7 Central Pathways

The many and complex central connections for the afferent vestibular impulses are diagrammed in Fig. 113.3. The central downstream cross-connections for the afferent vestibular information appear to coordinate two major systems. The information from the two peripheral vestibular organs is coordinated so that a stimulus of the canals of one ear is interpreted along with an equal and opposite counterstimulus of the canals of the contralateral ear. Far more complex than this coordination, however, is the constant repositioning and reassessment of the orientation of the ocular globe, the head on the neck, and the entire body along its vertical axis. The central connections for the vestibular system therefore interpret the differing afferent information from each ear and instruct the rest of the body—eyes, neck, and posture—to adjust.

Any central disease can cause malfunction of the coordination of the vestibular input and therefore can cause imbalance. Multiple sclerosis, cerebral vascular events, cerebral inflammatory diseases, and migraine can all cause vestibular dysfunction. On testing in these cases, the audiogram tends to be symmetric and uninformative. Simple cerebellar testing—finger to nose, repetitive motions, Romberg test—may identify problems in cerebellar function. The caloric responses are normal in each ear. However, the head thrust test, in which the clinician rotates the subject's head quickly to the side, may reveal that the eyes do not stay fixed on their target but instead show a compensatory saccade after the thrust is complete. Similarly, oculokinetic tests may find that the eyes do not track normally. Many other findings on electronystagmography (ENG) are indicative of

Fig. 113.10 Posturography measures the subject's maintenance of vertical body orientation in progressively more difficult conditions. The visual background is fixed or sways. The platform on which the subject stands is flat or wobbles. The subject's eyes may be open or closed.

nonspecific central disease: nystagmus, which does not depend upon position and which is not suppressed; the inability to track a sinusoidal motion; and the inability to perform saccades.

Posturography (□ Fig. 113.10) tests the input and integration of the peripheral vestibular system, eyes, and proprioceptive tracts. These may be quite abnormal in central disease. Posturography is also a good tool for identifying malingerers, who tend to sway and almost fall during the easiest conditions but will manage to keep their balance during the more challenging conditions to avoid hurting themselves.

If central disease is suspected, MR imaging of the brain and internal auditory canals with and without gadolinium can be performed.

Migraine-equivalent vertigo may be the diagnosis for many patients who simply defy classification. Pathognomonic symptoms are the conversion of migraine headaches into vertiginous episodes that have the same temporal patterns and the same

triggers. For example, a 40-year-old woman has experienced migraines at the same time as her menstrual cycle for years. Then suddenly the migraines stop, and she instead experiences vertiginous episodes at the same time of the month and for the same number of days. These patients respond well to preventive measures and to topiramate or verapamil. However, many patients who most likely have this syndrome do not fit easily into this pattern of symptoms. Patients who experience episodes of imbalance with no audiologic findings, and with normal ENG and normal MR imaging findings, may warrant a closely monitored trial of verapamil.

113.8 Directed Diagnostic Inquiries

The diagnosis and treatment of patients with dizziness is not a science derived from first principles. Instead, it is a struggle through inexact histories, contradictory tests, the patient's despair, and the clinician's frustration at not being able to help. A further complicating feature is that people who report several episodes or days or years of dizziness often have additional episodes of dizziness resulting from a new cause. For example, people with Meniere disease may have recurrent episodes of BPPV. The key to managing the stresses of the clinic visit and subsequently to devise a reasonable treatment plan is to try to keep the many diagnostic possibilities in mind.

The history can give significant clues. Effort should be made to obtain a concise and specific answer to one key question: Did this dizziness start one day and has it continued since then, or does it come in episodes? The answer to this question is usually very difficult to elicit because most people cannot verbally distinguish between a constant symptom of varying intensity, like BPPV or an ototoxic effect, and a symptom that started years ago but is episodic. Patients prefer to describe how uncomfortable they are and will have to be redirected until this key question is answered. Although most referrals to the otolaryngologist's office for imbalance are ultimately for BPPV, the majority of patients with pathognomonic nystagmus on Dix-Hallpike testing do not give a history of vertigo after position change.

Because most dizziness is BPPV, the most important feature of the physical examination is the extent to which the dizzy patient unconsciously guards against head motion during the interview. A look at the tympanic membrane usually does not add any information. A special feature of the physical examination is insufflation with a pneumatic speculum to look for eye deviation toward the contralateral ear in cases of perilymphatic fistula.

An audiogram must be performed to look for unilateral otologic loss and for Meniere disease. Patients with unilateral losses often are unaware of them. Otoacoustic emissions establish cochlear function and can help distinguish labyrinthitis from neuronitis.

Office tests for vestibular function include the Dix-Hallpike test, ocular countertorsion test, head thrust, and vibration test. These maneuvers look for BPPV, utricular failure, central dysfunction, and unilateral peripheral vestibular loss, respectively.

VEMP testing can help identify superior canal dehiscence if the threshold is lower in the affected ear, or unilateral inferior

vestibular nerve dysfunction if the threshold is higher. ENG can distinguish central from peripheral dysfunction, and caloric testing can help identify superior vestibular nerve hypofunction. Electrocochleography is not helpful practically, but theoretically it can help identify Meniere disease. Rotatory chair testing can help identify unilateral vestibular loss.

Posturography gives an overall view of visual and proprioceptive balance integration. CT identifies canal dehiscence, and MR imaging looks for inflammation of the vestibular labyrinth and nerves and for central disease.

113.9 Roundsmanship

- When the head moves, the endolymph moves relative to the ampulla of the canal, deflecting the crista of the ampulla and causing an increase or decrease of the baseline firing rate of the type 1 and type 2 vestibular hair cells.
- The macula of the utricle and the ampullae of the superior and lateral semicircular canals synapse with the superior vestibular nerve, while the macula of the saccule and the ampulla of the posterior semicircular canal synapse with the inferior vestibular nerve.
- Leakage or exposure of the perilymph to direct pressure, or any breach of the membranous labyrinth, causes marked vestibular symptoms.
- It is very helpful to obtain from the patient a specific answer to the question, Did this dizziness start one day and has it continued since then, or does it come in episodes?
- The most important feature of the physical examination is the extent to which the dizzy patient unconsciously guards against head motion during the interview because most dizziness is benign paroxysmal positional vertigo.
- In lateral canal dehiscence, any positive pressure will cause the eyes to deviate away from the insufflated ear (Hennebert sign).
- Any of the three mutually perpendicular semicircular canals can undergo erosion, which uncovers the perilymph, exposes the endolymph within the membranous canal to pressure changes, and can cause disequilibrium.
- The diagnosis of canal dehiscence in any of the semicircular canals can be established with fine-cut CT of the temporal bone.
- Benign paroxysmal positional vertigo is caused by nonphysiologic stimulation of the ampullae by loose neuroepithelial components termed otoliths.

- The abnormal physiology of Meniere disease can be detected by electrocochleography, in which the summation and action potentials in response to an auditory stimulus show an abnormally large ratio ($SP/AP > 0.50$).
- Electroneurography can distinguish central from peripheral dysfunction, and caloric testing can help identify superior vestibular nerve hypofunction.
- Posturography tests the input and integration of the peripheral vestibular system, eyes, and proprioceptive tracts.
- The treatments for benign paroxysmal positional vertigo range from interventions during a single office visit to surgical obliteration of the malfunctioning semicircular canal.
- The treatment for loss of neuroepithelial or vestibular nerve function consists of supportive care in the short term and physical therapy in the long term.

114 Diagnostic Audiology

Shlomo Silman and Carol A. Silverman

114.1 Introduction

This chapter provides an overview of tuning fork tests; behavioral hearing tests, including pure-tone threshold tests, masking, and speech audiometry; physiologic measures of auditory function, including tympanometry, acoustic reflex threshold and acoustic reflex adaptation testing, and otoacoustic emissions testing; auditory evoked potentials testing, including electrocochleography, auditory brainstem response testing, and auditory steady-state testing; testing for the identification of functional hearing loss; hearing screening; pediatric audiologic assessment; and vestibular testing, including electronystagmography, videonystagmography, sinusoidal harmonic acceleration, computerized dynamic platform posturography, and vestibular evoked myogenic potential testing. Understanding the interpretations of these audiologic tests will assist the otolaryngologist in the diagnosis and management of hearing and vestibular disorders.

114.2 Tuning Fork Tests

Tuning forks have two tines that, when struck against an object, produce a tone close to a pure tone at a specific frequency (with some lower-intensity overtones [harmonics]). The most commonly employed tuning fork is the 512-Hz tuning fork. The 1024- and 2048-Hz tuning forks generally provide supplemental information. The 256-Hz tuning fork can produce vibrotactile sensations that the patient may mistake for sound, so this tuning fork is infrequently used. The most useful tuning fork tests are the Weber and Rinne tests.

With the Weber tuning fork test, the tuning fork base is placed on the midline of the forehead, and the patient is asked on which side the sound is louder. If the sound is equally loud in both ears or heard in the center of the head, the absence of lateralization is consistent with symmetric hearing loss or symmetric, normal hearing sensitivity. Lateralization indicates: (1) conductive hearing loss in the ear to which the sound lateralized; (2) sensorineural hearing loss in the ear opposite the ear to which the sound lateralized; or (3) asymmetric sensorineural hearing loss that is worse in the ear opposite the ear to which the tone is lateralized. Sound will lateralize to the ear with conductive hearing loss because of one of the following: (1) an occlusion effect that traps sound pressure generated in the external ear canal with vibration of the ear canal walls; (2) a reduced middle ear resonant frequency with a mass-loaded ear (as in ossicular discontinuity or some cases of middle ear effusion with more viscous fluid); or (3) a phase advance with a stiffening pathology (e.g., ossicular fixation or some cases of middle ear effusion with less viscous fluid) that creates a tight coupling between the footplate and oval window, resulting in a more direct path to the inner ear.

In the Rinne tuning fork test, bone-conduction (BC) hearing is compared with air-conduction (AC) hearing. The base of a vibrating tuning fork is held firmly against the mastoid process for about 2 seconds; the tuning fork then is held vertically with

the tips of the tines located at about 1 to 2 cm lateral to the entrance of the ear canal. If hearing by AC produces a louder sensation than hearing by BC, the result is consistent with normal hearing sensitivity or sensorineural hearing loss; this result is termed a positive Rinne ($AC > BC$). If hearing by BC produces a louder sensation than hearing by AC, then the result is consistent with conductive hearing impairment; this result is termed a negative Rinne ($BC > AC$). If the loudness sensation by BC is equal to that by AC, the result is classified as an equivalent Rinne ($AC = BC$), consistent with normal hearing sensitivity or a mild conductive hearing loss. A study of the accuracy of the Rinne test on 100 ears with various conductive pathologies (with masking of the contralateral, nontest ear) revealed that the minimum air–bone gap for the Rinne tuning fork test to meet a 75% correct detection criterion is 55 to 60 dB at 512 Hz and larger at 1024 Hz; trial performance of the Rinne test with the 2048-Hz tuning fork fails to meet even a 50% (chance) correct detection criterion even for the largest air–bone gaps. Thus, the Rinne tuning fork test is not useful in the detection of minimal air–bone gaps or conductive pathologies producing high-frequency hearing losses.

114.3 Behavioral Hearing Tests

114.3.1 Classification of Type and Magnitude of Hearing Loss Based on the Pure-Tone Audiogram

Hearing sensitivity conventionally is assessed at the pure-tone octave frequencies of 250, 500, 1000, 2000, 4000, and 8000 Hz. Pure-tone AC threshold testing is done with earphones placed over the pinnae of the outer ears or with insert earphones worn in the ear canals. BC threshold testing is performed with a bone vibrator/oscillator placed on the mastoid process of the temporal bone. The outcome of threshold testing is recorded on an audiogram (□ Fig. 114.1), which displays test frequency along the x-axis and intensity along the y-axis. A threshold that is better than 0 dB HL (decibels hearing level; e.g., -5 dB HL) indicates hearing sensitivity that is better by 5 dB than the hearing sensitivity of a young adult without hearing or ear problems.

When BC testing is performed, the threshold results furnish information about the sensorineural mechanism. Auditory signals delivered through an earphone worn over the pinna or an insert receiver in the ear canal pass through the ear canal into the middle ear and cochlea, where the sound is transduced into a neural impulse that then travels through the auditory nerve and cochlear nuclei (and through the rest of the auditory brainstem to the auditory cortex). Thus, an AC threshold reflects integrity of both the sensorineural and conductive mechanisms. An elevated AC threshold therefore indicates a hearing problem in the conductive and/or sensorineural mechanism. The difference in decibels between the AC and the BC thresholds is referred to as the air–bone gap (ABG), which yields information on the status of the conductive mechanism.

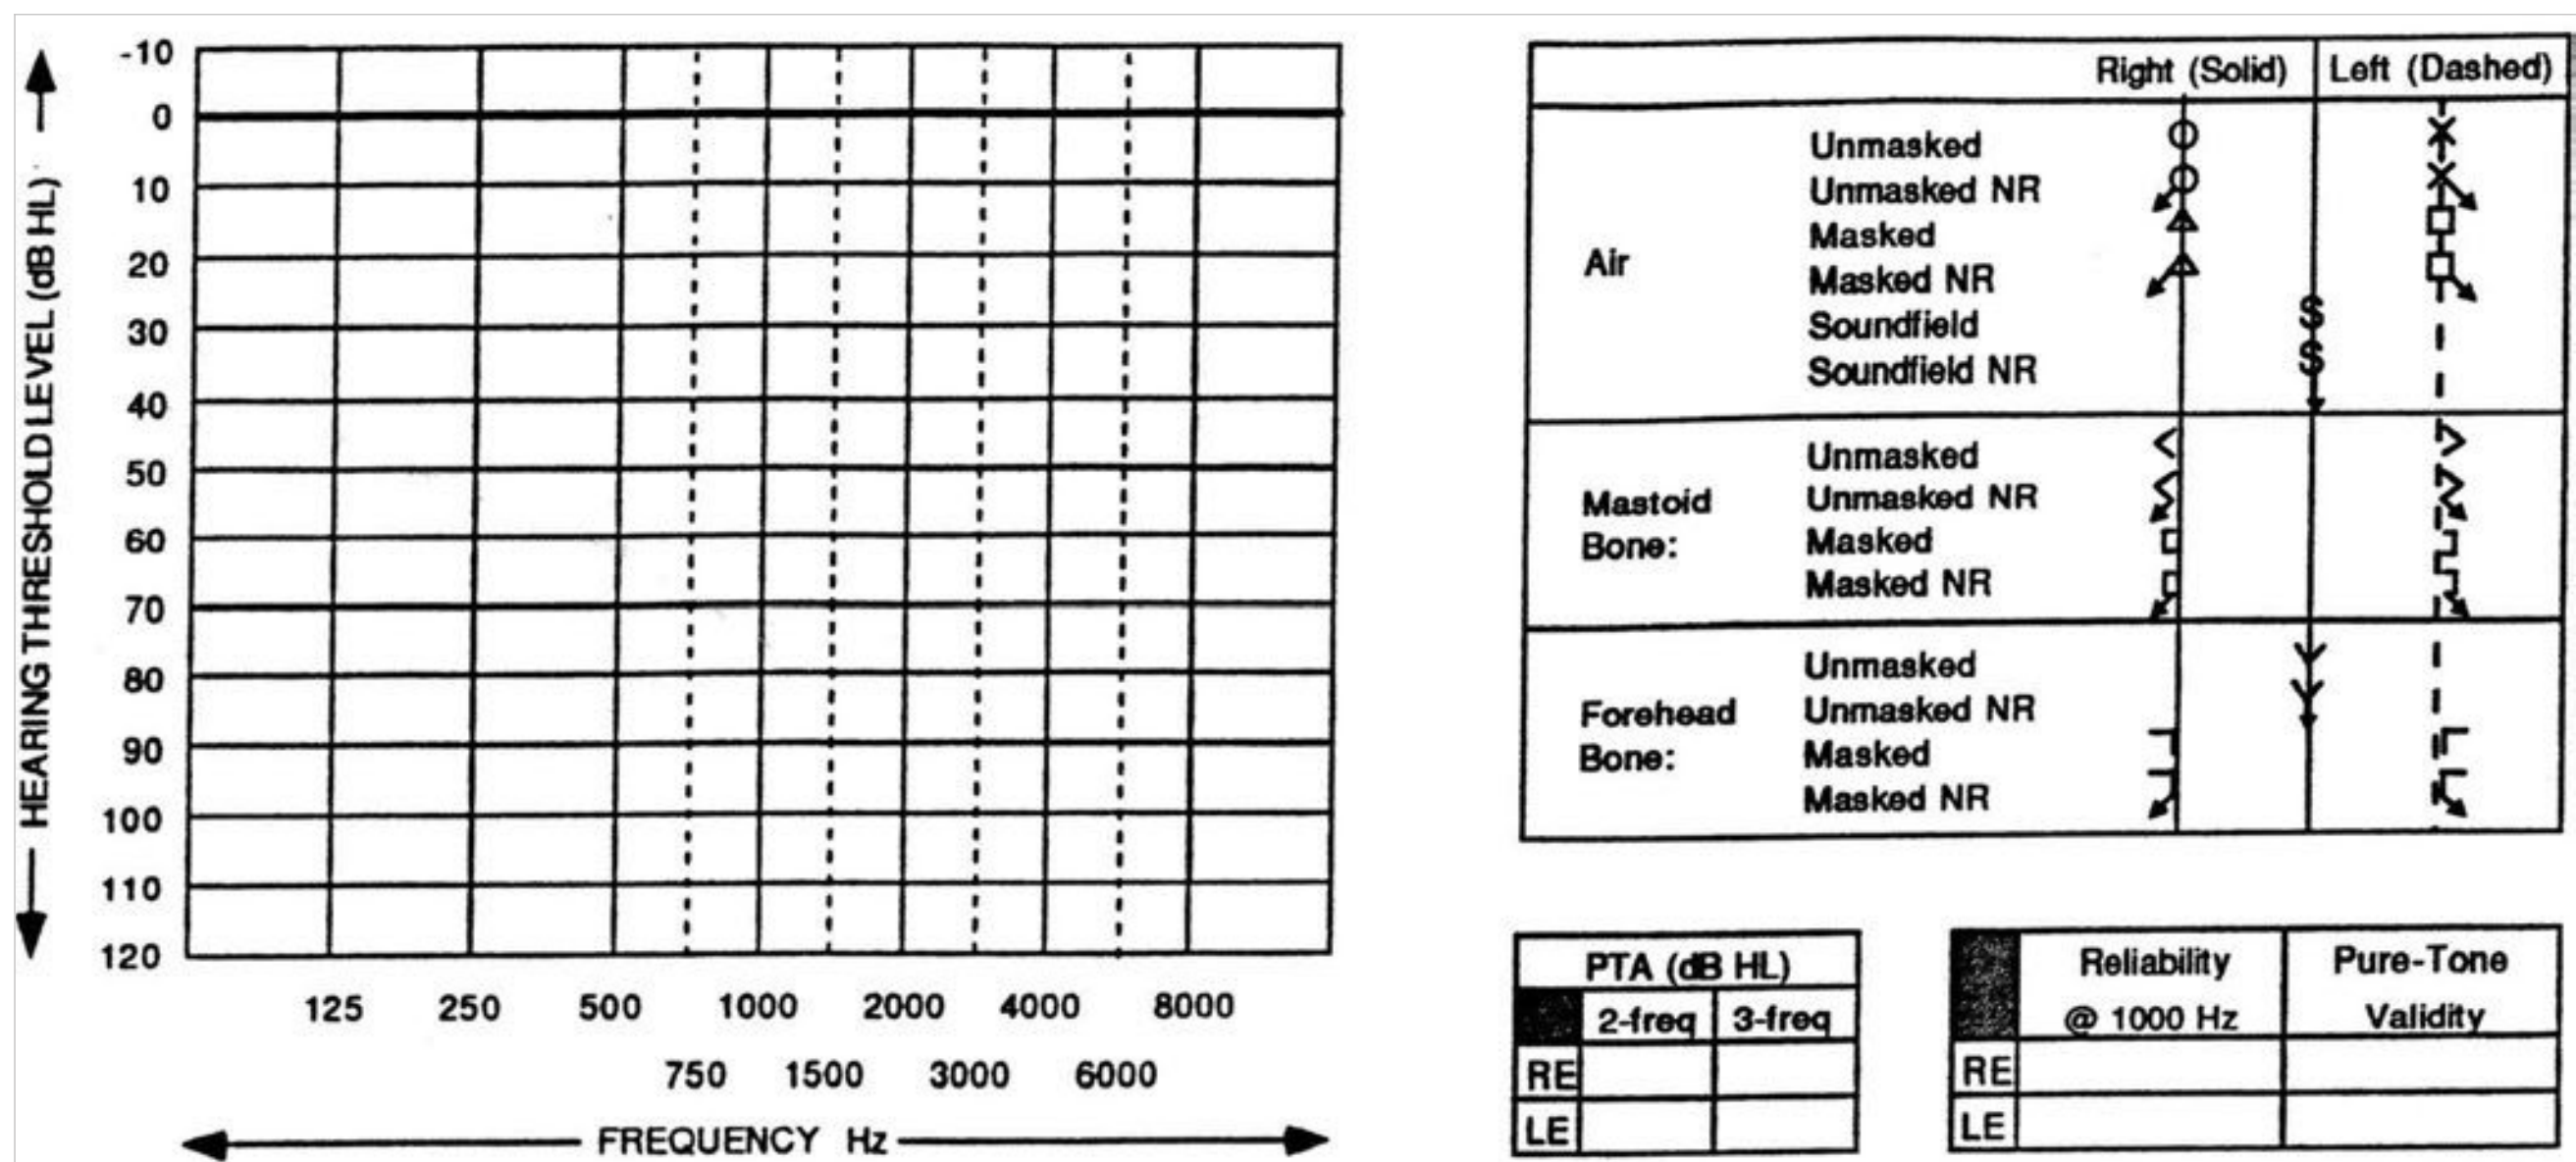

Fig. 114.1 Audiogram template. Intensity is shown on the ordinate, and frequency is shown on the abscissa. Thresholds are reported based on the use of a 5-dB-intensity step size. The legend shows the symbol used for recording pure-tone air conduction and bone conduction thresholds for each ear, and in the sound field. IE, left ear; NR, no response; PTA, pure-tone average; RE, right ear.

The upper limit of the normal range of BC thresholds is 15 dB HL, although some clinicians consider 25 dB HL to be the upper limit. The upper limit of the normal range of AC thresholds is 25 dB HL in adults. With conductive hearing impairment, the BC threshold is within normal limits but the AC threshold is elevated beyond the normal limit, yielding a significant (>10 dB) ABG. With sensorineural hearing impairment, the AC and BC thresholds both are elevated beyond the normal limits and are approximately equal, without significant ABGs. Mixed hearing impairment (hearing impairment affecting both the conductive and sensorineural mechanisms) is characterized by AC and BC thresholds that are elevated beyond the upper limit of normal and AC thresholds worse than BC thresholds, yielding significant ABGs. A medically significant conductive mechanism problem can be present without a hearing impairment per se, as significant ABGs can be present although neither the AC nor BC threshold exceeds the upper limit of normal (normal hearing sensitivity with significant ABGs). A mixed hearing loss is present only when elevated AC and BC thresholds and a significant ABG are present at the same frequency. Various types of hearing loss are shown in Fig. 114.2. Common causes of conductive and sensorineural hearing loss are shown in Table 114.1.

The magnitude of the hearing impairment is specified based on the pure-tone average (PTA), which usually is a 3-frequency average of the AC thresholds for 500 Hz, 1000 Hz, and 2000 Hz, but also can be a 4-frequency average (e.g., 500, 1000, 2000, and 3000 Hz or 500, 1000, 2000, and 4000 Hz). The Committee on Hearing and Equilibrium of the American Academy of Otolaryngology—Head and Neck Surgery has adopted the use of a 4-frequency PTA (based on 500, 1000, 2000, and 3000 Hz) for the evaluation of Meniere disease, vestibular schwannoma, and conductive hearing loss. In their guidelines for the evaluation of conductive hearing loss, they also specify the use of this 4-frequency average for reporting ABGs.

Table 114.2 shows a classification of the degree of hearing loss based on the PTAs over the so-called speech frequencies (500, 1000, and 2000 Hz); the classification ranges from normal to profound. Note that the classification of the degree of hearing loss is similar for children and adults except that the upper limit of normal hearing sensitivity is 15 dB HL for children and 25 dB HL for adults; consequently, the range from 16 to 25 dB HL is classified as slight hearing loss in children. This table also shows the impact of the various degrees of hearing loss on speech understanding without amplification, given that soft conversational speech is approximately 35 dB HL, conversational speech is approximately 45 to 50 dB HL, and loud conversational speech is approximately 65 dB HL. Table 114.2 also shows the predicted impact of various degrees of hearing loss on speech and language when early intervention is not provided. Persons with a normal PTA but with hearing impairment in the high frequencies may experience difficulty hearing conversations in noisy, group, or reverberant situations, even when the high-frequency impairment is mild. The effect of a unilateral hearing loss is less adverse than that of a bilateral hearing loss, but it becomes more pronounced in more competitive listening situations.

Frequency-specific threshold data based on a behavioral audiologic evaluation often can be obtained from infants having a cognitive age as young as 6 months. In an infant with a cognitive age younger than 6 months, behavioral observation audiometry is limited as it can help rule out only moderate or worse hearing impairment in at least one ear.

Pure-Tone Configuration

The pure-tone audiogram can be classified not only in terms of the type and degree of hearing loss, but also in terms of its audiometric configuration. Fig. 114.3 illustrates some common audiometric configurations, such as flat, sloping, rising,

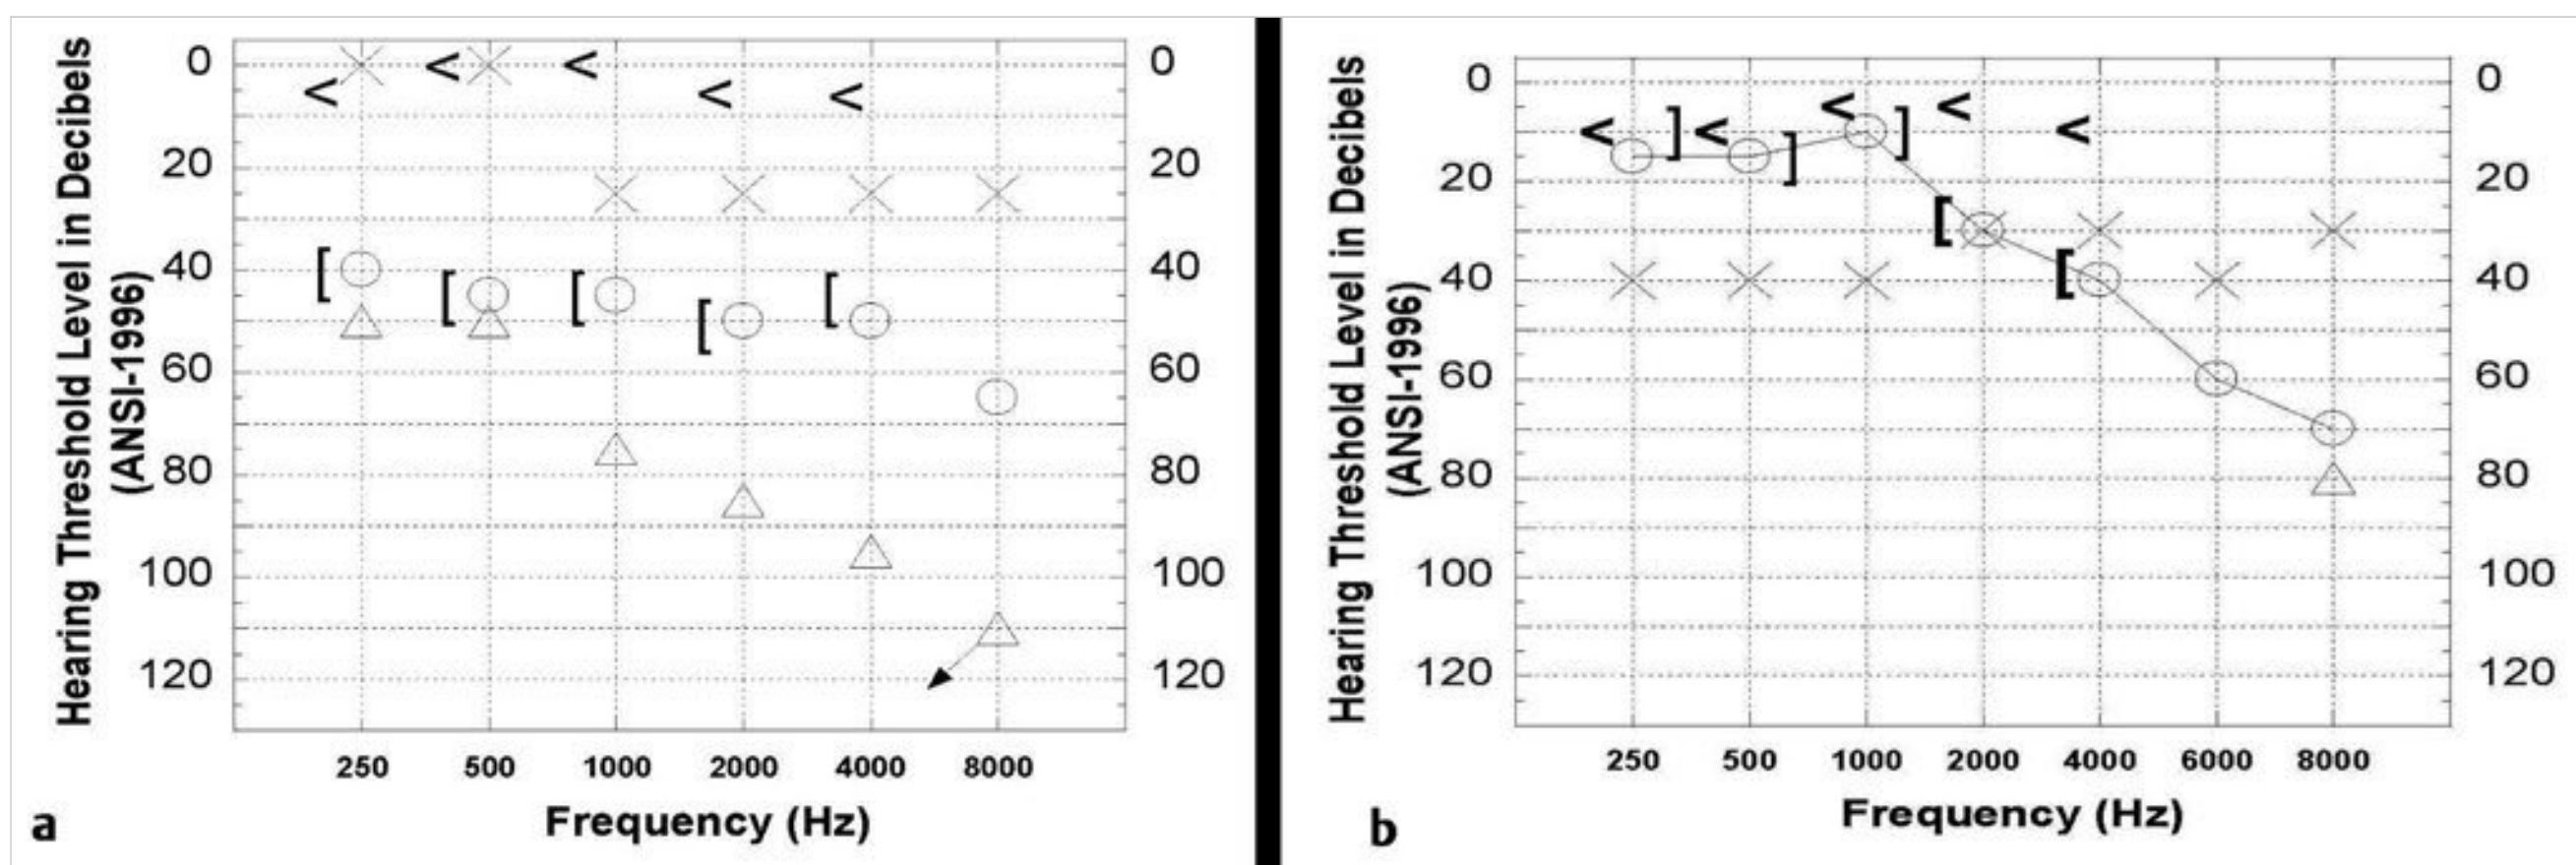

Fig. 114.2 (a) In the right ear at the low frequencies, the masked (true) right bone conduction (BC) thresholds are beyond the normal limits and the masked (true) air conduction (AC) thresholds are also beyond the normal limits without significant air–bone gaps (ABGs), consistent with the presence of sensorineural hearing loss at these frequencies; in the right ear at the higher frequencies above 500 Hz, the masked (true) right BC thresholds beyond the normal limits and the masked (true) right AC thresholds beyond the normal limits, with significant ABGs (30 to 50 dB), are consistent with the presence of a mixed hearing loss at these frequencies. In the left ear at the low frequencies, the unmasked BC thresholds represent the cochlear reserve of the left ear (although the symbol indicates BC vibrator placement on the right mastoid); the masked (true) BC thresholds for the right ear are elevated, so the unmasked BC thresholds must represent the BC hearing for the left ear. The unmasked BC thresholds (representing left BC hearing) and the left AC thresholds both are within normal limits without significant ABGs, so they are consistent with normal hearing sensitivity at these low frequencies. In the left ear at frequencies above 500 Hz, the unmasked BC thresholds (representing left BC hearing) and left AC thresholds remain within normal limits, but significant ABGs are present (20 to 25 dB), consistent with normal hearing sensitivity with significant ABGs at these frequencies. (b) In the left ear at the low–mid frequencies through 1000 Hz, the left masked (true) BC thresholds are within normal limits but the left AC thresholds are elevated beyond the normal limits with significant ABGs (30 to 35 dB), consistent with conductive hearing impairment at those frequencies; at frequencies above 1000 Hz, the unmasked BC thresholds (representing left BC hearing) remain within normal limits and the left AC thresholds remain beyond the normal limits with significant ABGs (20 to 25 dB), also consistent with conductive hearing impairment at these frequencies in the left ear. In the right ear at low–mid frequencies through 1000 Hz, the unmasked BC thresholds, representing right BC hearing, and the AC thresholds are within normal limits, consistent with normal hearing sensitivity at those frequencies; above 1000 Hz, the right masked (true) BC thresholds and right AC thresholds are elevated beyond normal limits without significant ABGs, consistent with a sensorineural hearing loss at those frequencies. ANSI, American National Standards Institute.

trough, high-frequency, low-frequency, inverted scoop or trough, fragmentary or corner, notched, and peak. The audiometric configuration may be suggestive of an etiology but usually is not pathognomonic. A flat audiometric configuration is seen, for example, with late-stage Meniere disease. Sloping audiometric configurations are commonly seen in presbycusis. Ears with relatively early-stage Meniere disease often show a rising audiometric configuration. Some individuals with congenital hearing loss have a trough audiometric configuration, whereas individuals with an inverted scoop or inverted trough audiometric configuration have a hereditary hearing loss. Some cases of hereditary hearing loss produce a fragmentary or corner audiogram. Occupational hearing loss often initially produces a hearing loss with a notch centered at frequencies within 3000 to 6000 Hz. Some patients with Meniere disease display a 2000-Hz peak audiogram whereby the pure-tone thresholds are within normal limits at 2000 Hz but then increase as frequency increases above and decreases below the peak frequency.

Audiometric configuration also is affected by the type of conductive hearing impairment. An audiogram with a stiffness tilt refers to an audiometric configuration for a stiffening conductive lesion in which the conductive hearing loss preferentially affects low frequencies, whereas one with a mass tilt refers to an audiometric configuration for a mass conductive lesion (e.g., ossicular discontinuity) in which the conductive hearing loss

affects the high frequencies more than the low frequencies. A Carhart notch refers to an audiometric configuration often seen in patients with otosclerosis whereby the BC threshold is poorer at 2000 Hz than at the adjacent frequencies because of loss of ossicular resonance. Some cases of middle ear effusion and chronic ear disease show a peak audiogram whereby the AC threshold peaks at 2000 Hz; this finding suggests the presence of a stiffness effect at the low frequencies that disappears at 2000 Hz, together with a mass effect that begins to be observed above 2000 Hz.

Ototoxic Monitoring with Standard Pure-Tone Audiometry

Ototoxic (cochleotoxic and/or vestibulotoxic) effects may be observed in patients receiving aminoglycoside antibiotics (e.g., kanamycin and amikacin), loop diuretics (e.g., ethacrynic acid and furosemide), cancer agents (e.g., cisplatin and carboplatin), or high doses of aspirin and antimalarials (e.g., quinine). Often, these effects are permanent, although they may be temporary and reversible. Patients receiving ototoxic drugs should have audiologic monitoring. A commonly employed protocol established by the American Speech-Language-Hearing Association (ASHA) is to obtain a baseline audiogram before or within 72 hours after the first dose of an aminoglycoside, and within 1 week before or within 24 hours after the first dose of a chemo-

Conductive	Sensorineural: cochlear	Sensorineural: eighth nerve or cochlear nuclei
Aural atresia	Noise-induced hearing loss	Vestibular schwannoma
Eustachian tube dysfunction	Ototoxicity	Auditory neuropathy spectrum disorder
Otitis media	Meniere disease (endolymphatic hydrops)	Some cases of vascular loop syndrome
Cholesteatoma	Presbycusis	Presbycusis
Temporal bone trauma/fracture affecting the outer ear and/or middle ear	Temporal bone trauma/fracture affecting the cochlea	Temporal bone trauma/fracture affecting the auditory nerve and/or cochlear nuclei
Otosclerosis	Otosyphilis	Otosyphilis
Glomus tumor within the middle ear space (occasionally mixed hearing loss when the tumor invades the cochlea)	Meningitis	Meningitis
Exostoses and osteomas that are large enough to close off the ear canal	HIV/AIDS	HIV/AIDS
External otitis with swelling of the ear canal sufficient to close off the ear canal	Other infections affecting newborns (Rh incompatibility, cytomegalovirus infection, rubella, toxoplasmosis)	Other infections affecting newborns (Rh incompatibility, cytomegalovirus infection, rubella, toxoplasmosis)
Hereditary (genetic)	Hereditary (genetic)	Hereditary (genetic)
Tympanosclerosis	Perilymph fistula (can also be mixed hearing loss)	
Ossicular chain discontinuity	Idiopathic sudden sensorineural hearing loss	
Larger tympanic membrane perforations	Diabetes mellitus	
	Autoimmune inner ear disease	
	Superior semicircular canal dehiscence syndrome (air–bone gaps are considered to be artifactual)	

therapeutic agent. In responsive patients, the AC thresholds should be done over the range of 250 through 8000 Hz. The ASHA protocol specifies weekly monitoring for aminoglycoside antibiotics and monitoring within 24 hours of each dose of a platinum derivative. A change in hearing sensitivity, calculated with reference to the baseline results, is a worsening of threshold by at least 20 dB at any one frequency or by at least 10 dB at any two frequencies, or a loss of response at three consecutive test frequencies at which responses previously could be recorded. Any change needs to be confirmed at a retest within 24 hours. If any change is significant, then acoustic admittance and BC threshold testing needs to be done to rule out changes due to a conductive component. With unresponsive patients, physiologic measures such as otoacoustic emissions testing and auditory brainstem response testing should be used for audiologic monitoring of patients receiving ototoxic drugs.

Extended High-Frequency Audiometry

Extended high-frequency pure-tone AC testing involves obtaining thresholds above 8000 Hz—that is, at 9000, 10,000, 11,200, 12,500, 14,000, 16,000, 18,000, and 20,000 Hz. Ultra-high-frequency audiometry has been used to monitor ototoxic hearing changes because many ototoxic drugs (e.g., cisplatin) may affect the ultra-high frequencies before affecting the traditional audiometric frequency range (250 through 8000 Hz). Various rapid protocol threshold test procedures involving extended

high-frequency audiometry frequently have been employed to identify the so-called sensitive range of ototoxicity (SRO). A significant limitation of extended high-frequency audiometry is that the threshold increases with frequency, and also with age. Thus, a baseline threshold may be beyond the output limits of the audiometer, precluding the possibility of seeing ototoxic changes at that frequency, particularly in older adults.

114.3.2 Speech Audiometry

The procedure for measuring the speech recognition threshold (SRT) involves having the patient repeat spondaic words spoken with equal stress on each of the two syllables. The SRT is the lowest intensity at which the patient can correctly repeat the speech stimuli with 50% accuracy. Agreement between the SRT and PTA is determined by measuring the decibel difference between these measures. When the audiometric configuration is flat within the speech frequencies (i.e., not more than a 5-dB difference between two adjacent octave frequencies in the 500-through 2000-Hz range), the comparison is made between the SRT and 3-frequency PTA. Similarly, with sloping or rising audiometric configurations, whereby more than a 5-dB difference exists between two adjacent octave frequencies in the 500 through 2000 Hz range, the comparison is made between the SRT and the 2-frequency PTA based on the best two AC thresholds among 500, 1000, and 2000 Hz. Agreement, as indicated by a small decibel difference between the SRT and PTA, substanti-

Table 114.2 Pure-tone average, degree of hearing loss, impact of hearing loss on speech, and impact of hearing loss on speech and language

Pure-tone average (dB HL)	Degree of hearing loss	Impact on hearing and speech (without amplification)	Impact on speech and language without intervention
0–15	Normal	None	None
16–25 (children)	Slight	May have hearing difficulty in the classroom	May have slight articulation, language, and educational problems
16–25 (adults)	Normal	None or minimal when listening to conversation in competitive situations	None
26–40	Mild	May have difficulty understanding faint speech, speech at a distance, or speech in competitive situations	Adults: none Children: more likely to show some articulation, language, and educational problems
41–55	Moderate	Difficulty generally experienced hearing conversational speech at 3 to 6 feet, as well as difficulty hearing faint or distant speech or speech in competitive situations	Adults: usually none Children: effects of hearing loss on articulation, voice quality, language, and educational achievement more pronounced than for mild hearing loss
56–70	Moderate to severe/severe	Usually difficulty hearing loud as well as conversational speech, faint or distant speech, or speech in competitive situations	Adults: deterioration in speech may occur Children: increasingly adverse effects of hearing loss on articulation, voice quality, and educational achievement
71–90	Severe	May hear some loud sounds near the ear; difficulty hearing loud and conversational speech as well as faint or distant speech, or speech in competitive situations	Adults: usually deterioration in articulation and voice quality Children: in addition to adverse effects on articulation, voice quality, language, and educational achievement, speech and language generally do not develop spontaneously
91+	Profound	Will not hear faint or distant speech, conversation in quiet surroundings at 3 to 6 feet, loud speech, or speech at 1 foot from the ear	Adults: more pronounced adverse effects on articulation and voice quality Children: increasingly adverse effects on articulation, voice quality, language, and educational achievement; speech and language generally do not develop spontaneously; benefit substantially more limited for hearing aids than for cochlear implants

Abbreviation: dB HL, decibels hearing level.

ates the validity of the AC thresholds for a given ear. If technical factors can be ruled out, an SRT significantly better (>12 dB) than the PTA may indicate the presence of functional (nonorganic) hearing impairment. If the SRT is significantly worse (>12 dB) than the PTA, the difference is usually attributable to language factors.

Supra-threshold speech recognition performance (speech discrimination) is obtained for each ear under the earphones to determine how well a person can understand speech at an intensity that is well beyond the SRT. The material used for suprathreshold speech recognition testing ranges from nonsense syllables to words to sentences, but most commonly involves monosyllabic words. The speech recognition score for a given ear generally is reported as the percentage of items correctly repeated by the patient when the speech is presented at

a level that is at about 25 to 40 decibels sensation level (SL: dB above the SRT). A high speech recognition score in a person with a hearing loss suggests that a patient will obtain significant benefit from amplification. Frequently, a patient who is fitted with a hearing aid also receives speech recognition testing in noise in sound field (stimuli delivered through a loud speaker rather than through an earphone) to determine how well a patient will function with a hearing aid in noisy situations.

A statistical approach has been applied to analysis of the speech recognition scores as the 95% confidence limits have been established for each percentage word recognition score. These 95% critical differences limits can be used to compare word recognition performance between ears, assuming most importantly that the pure-tone thresholds are essentially equivalent for the two ears and that recorded materials are used. If

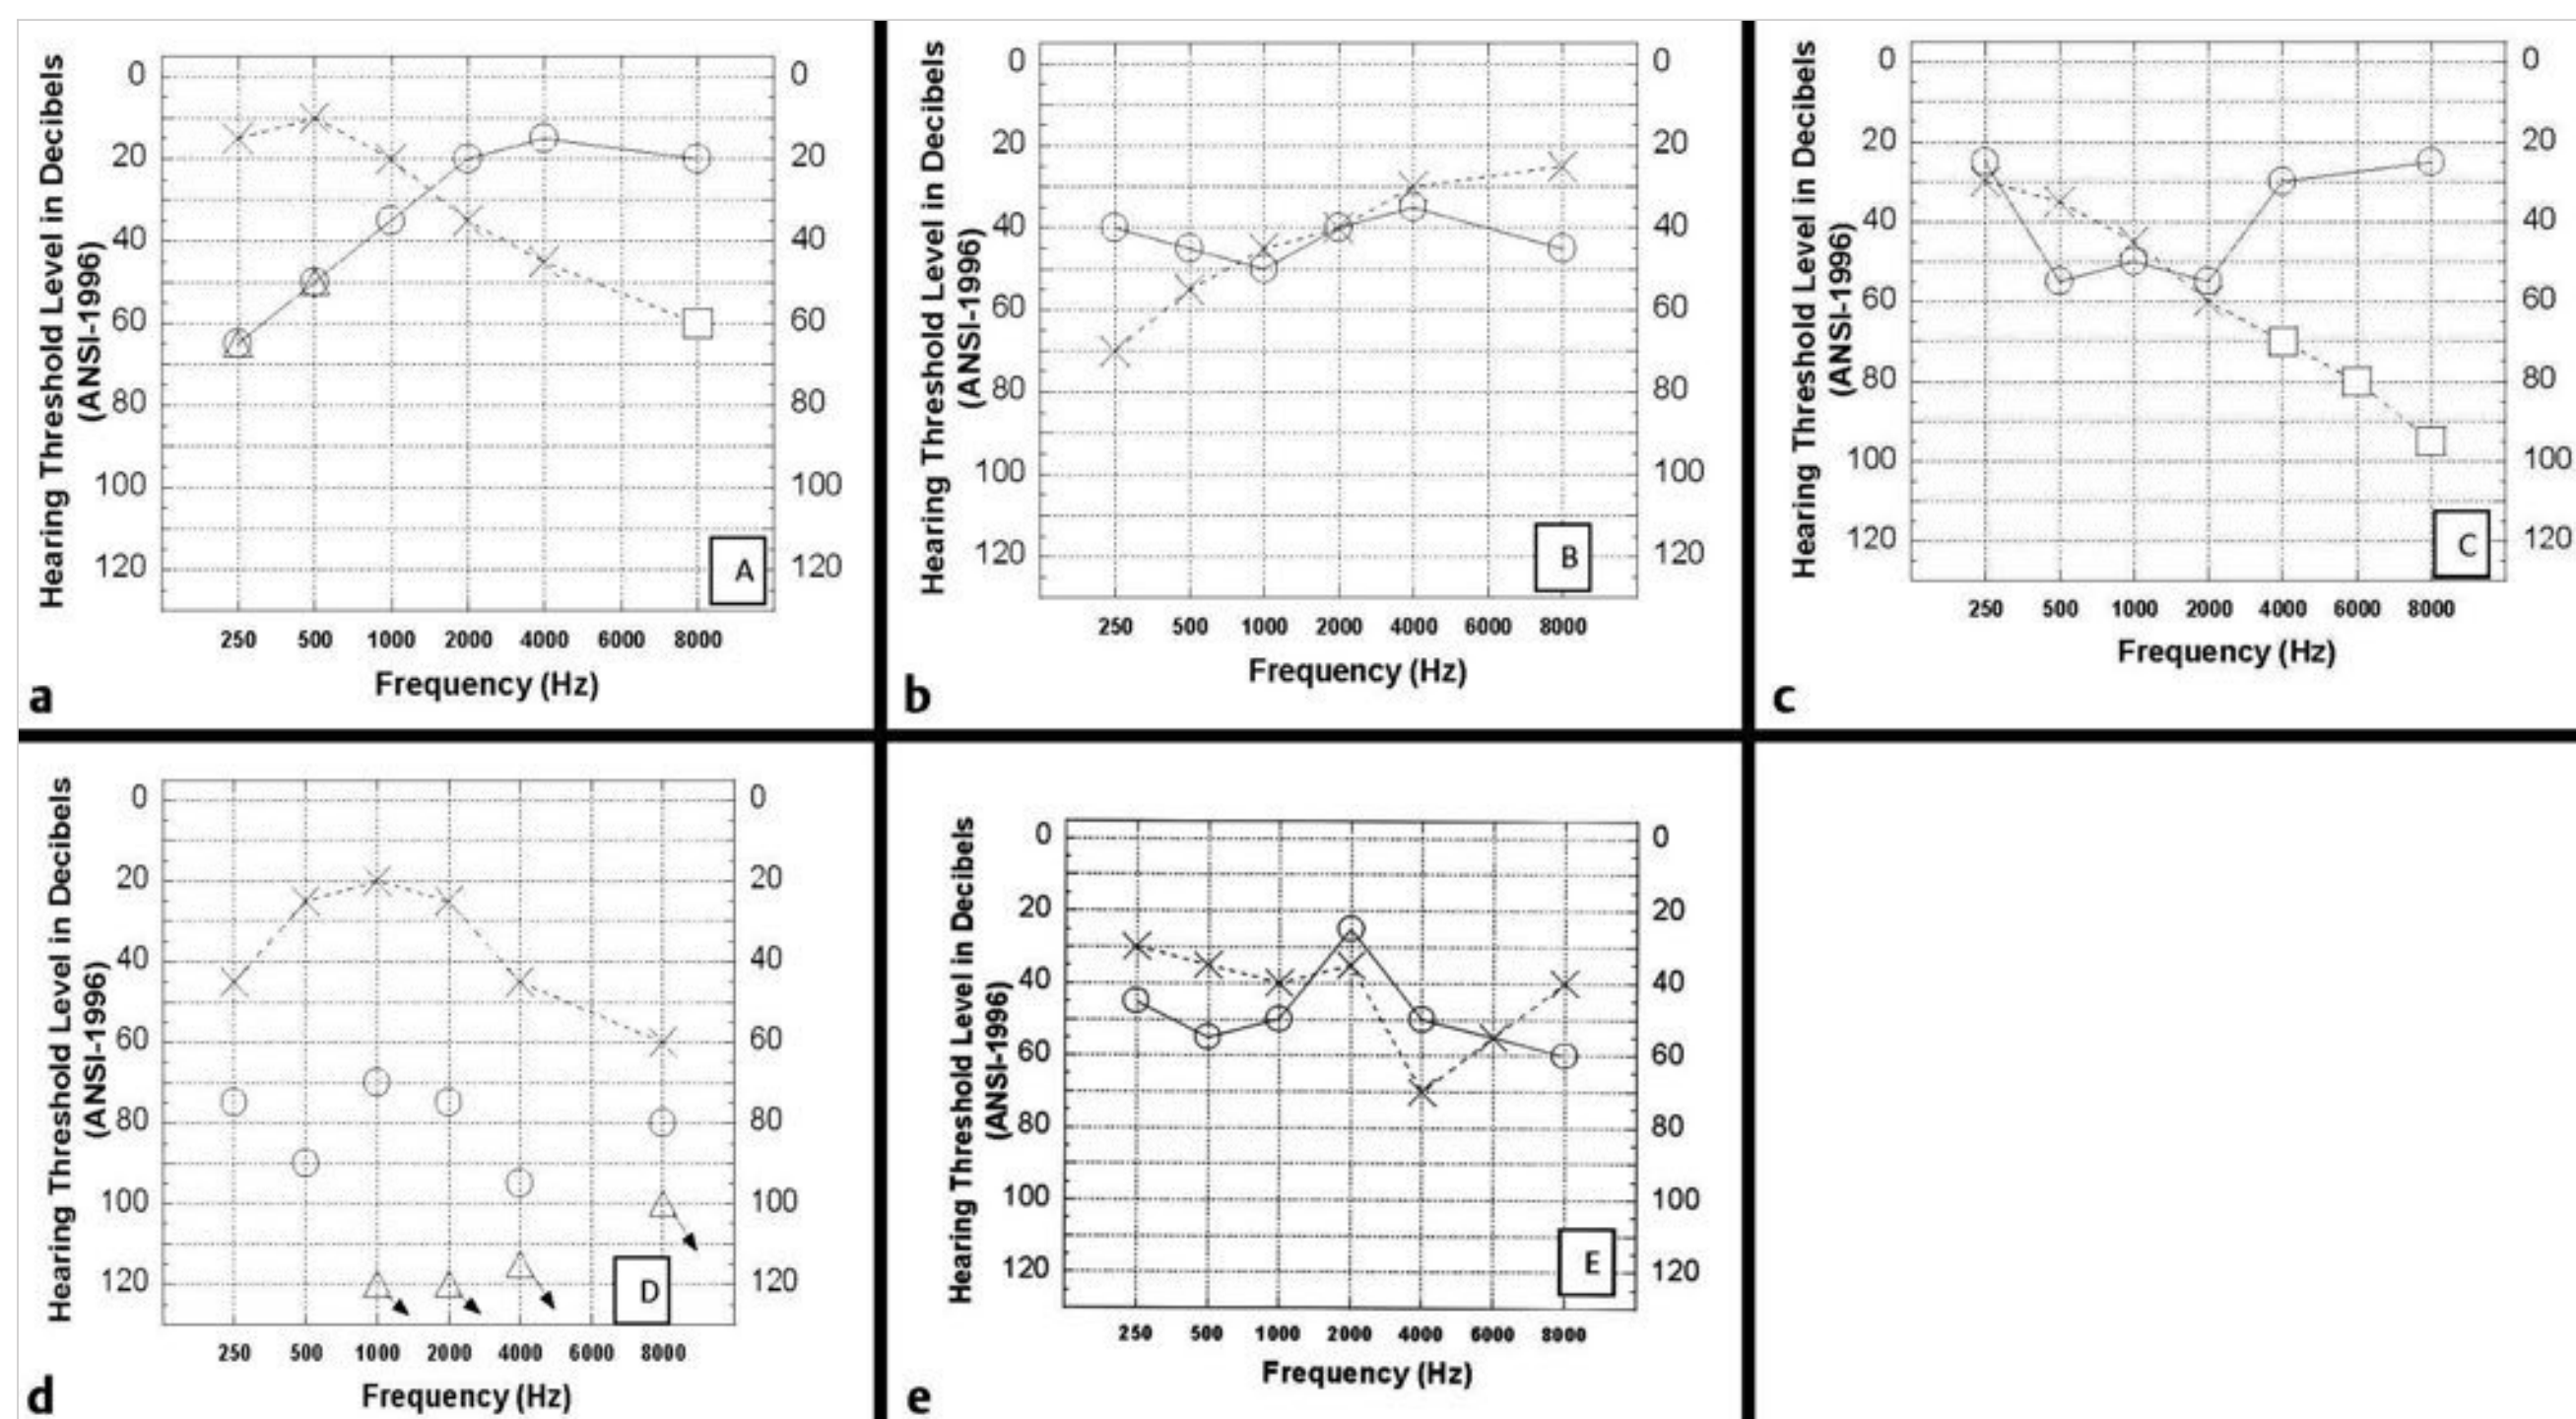

Fig. 114.3 Various audiometric configurations. (a) A high-frequency hearing loss audiometric configuration refers to a hearing loss present only at high frequencies (left ear). A low-frequency hearing loss audiometric configuration refers to a hearing loss present only at low frequencies (right ear). (b) With a flat audiometric configuration, the pure-tone thresholds generally are roughly equivalent (within about ± 20 dB) across the frequency range (right ear). With a rising configuration, the pure-tone thresholds improve as the frequency increases (left ear). (c) With a sloping audiometric configuration, the pure-tone thresholds worsen as the frequency increases (left ear). With a trough (also called saucer) audiometric configuration, the pure-tone thresholds are worse in the mid frequencies than in the low or high frequencies (right ear). (d) An inverted scoop or inverted trough audiogram has a configuration that is the opposite of that for the trough or saucer audiogram, with pure-tone thresholds worse in the low and high frequencies than in the mid frequencies (left ear). A fragmentary or corner audiogram refers to an audiogram with hearing thresholds present only for the low frequencies near the output of the audiometer (right ear). (e) A notched audiometric configuration is indicative of hearing loss within a restricted frequency range that recovers above and below the notch frequencies (left ear). A peak audiogram refers to an audiogram with pure-tone thresholds that are normal at a single or restricted range of frequencies but are consistent with hearing loss at frequencies above or below the peak frequency (right ear). ANSI, American National Standards Institute.

the score for one ear falls significantly outside this range, it can be concluded that word recognition performance is significantly poorer for one ear than for the other ear. Such a finding may suggest a retrocochlear pathology, but the utility of such a finding is somewhat limited, given that vestibular schwannomas are likely to be associated with asymmetric audiometric configurations. The 95% confidence limits may be more useful for comparing speech recognition performance in a given ear at a past test session with performance at a current test session, provided that the pure-tone results have remained stable over time.

The sizes of the 95% confidence intervals are narrower for scores at the extreme ends of the range (i.e., close to 0% or 100%) and for longer word lists, and are wider for scores in the middle of the range and for shorter word lists. These 95% confidence intervals have been widely employed in audiology. For example, they have been used to determine which hearing aid or hearing-aid electroacoustic characteristic produces a significant improvement in the word recognition score or to determine whether aural rehabilitation produces a significant benefit in communicative efficiency.

An individual with normal hearing sensitivity who presents with deficits in auditory processing, such as diffi-

culty understanding speech in background noise, distractibility or difficulty attending to speech, auditory memory problems, or difficulty in auditory discrimination, may have a central auditory disorder. A battery of sensitized speech tests (e.g., filtered speech, speech in noise, rapid speech) and electrophysiologic measures has been employed to detect central auditory disorder in individuals with normal hearing sensitivity and auditory-processing deficits.

114.3.3 Masking

Clinical masking of the nontest ear (NTE) during audiologic assessment often is necessary to prevent the NTE from participating in the assessment of the test ear (TE). In some situations, sound presented to the test ear is heard by the nontest ear, yielding a false impression of the hearing sensitivity of the test ear.

An understanding of the concepts of interaural attenuation, crossover, and cross-hearing is required to understand when masking is required to block out participation of the NTE. Interaural attenuation refers to the loss in intensity of a sound as it travels from the TE to the NTE by BC. A sound presented by AC loses approximately 40 dB as it travels from the TE to the NTE.

Hence, the interaural attenuation for AC sounds is approximately 40 dB. The interaural attenuation largely reflects the difference in impedance between air and the skull, resulting in rejection of energy when AC sound penetrates and sets the skull bones and the cochleae into vibration; little loss of intensity then occurs as the sound travels by BC through the skull bones to the cochleae of both ears. If a tone is presented to the right ear at 70 dB HL by AC (through the earphone), then it is estimated to arrive at the cochlea of the left ear at 30 dB HL. Thus, the crossover level of that 70-dB HL tone presented to the TE is 30 dB HL. Cross-hearing occurs if the BC threshold of the NTE is sufficient to hear the crossover level (i.e., is 30 dB HL or better in this example). If cross-hearing occurs, then the unmasked AC threshold for the TE represents the hearing sensitivity of the NTE rather than that of the TE; masking of the NTE is required to establish the true AC threshold of the TE. A general rule for AC masking, based on this interaural attenuation for AC, is to mask whenever the threshold of the TE minus 40 dB equals or exceeds the BC threshold (or AC threshold since the AC threshold sometimes is slightly better than the BC threshold). The need to obtain a masked AC threshold should be based on comparison of the AC threshold for the TE with the AC threshold for the NTE. For example, if the right ear AC threshold is 20 dB HL and the left ear AC threshold is 70 dB HL, then the masked left ear AC threshold needs to be obtained with masking noise in the right ear. The masked AC threshold can be equivalent to the unmasked AC threshold or up to about 60 or 65 dB poorer than the BC threshold of the TE because the largest possible ABG is approximately 60 to 65 dB.

The results of several studies suggest that the interaural attenuation for insert earphones is significantly greater than that for traditional supra-aural earphones. Thus, we suggest the following rule when insert earphones are used: If the depth of the insert earphone insertion is deep, then consider the interaural attenuation to be 65 dB at 250 and 500 Hz, and 55 dB at the higher frequencies; if the depth of the insert earphone insertion is shallow, then use interaural attenuation values that are 5 dB lower than those for deep insertion.

The interaural attenuation for BC sounds is essentially 0 dB, which means that sounds delivered through the bone oscillator travel by BC to the cochleae of both ears, essentially with no loss in intensity. If a tone is presented to the right ear at 70 dB HL by BC (through the bone oscillator), then it is estimated to arrive at the cochlea of the left ear at 70 dB HL (70 dB HL – 0 dB interaural attenuation). Because the interaural attenuation for BC is approximately 0 dB, the unmasked BC threshold represents the better cochlea, regardless of whether the bone vibrator is placed on the right or left mastoid process of the temporal bone. Thus, the unmasked BC threshold is needed for only one ear, and the obtained BC threshold represents the cochlear integrity of the better ear. The ABG should be examined in each ear to determine the need for obtaining a masked BC threshold whereby the true BC threshold for the TE is obtained by using a bone vibrator on the mastoid process of the TE while masking noise is presented by AC through an earphone on the NTE. If the ABG in a given ear exceeds 10 dB, then the masked BC threshold should be obtained.

Consider an example in which the unmasked BC threshold is 30 dB HL, the right AC is 30 dB HL, and the left ear is 40 dB HL. In this example, the left BC threshold must be 30 dB HL (it

cannot be any better than the unmasked BC threshold, and it cannot be poorer than the AC threshold of that ear). In the left ear, the best the BC threshold can be is 30 dB HL, and the worst it can be is 40 dB HL (equivalent to the right AC threshold). Thus, masking is unnecessary in this situation as we can consider the BC threshold to be 30 dB HL, bilaterally. Consider another example in which the unmasked BC threshold is 30 dB HL, but the right and left AC thresholds are 50 dB HL. In this example, the ABG is 20 dB, bilaterally, so masked BC thresholds need to be obtained for both ears. The clinician obtains the masked BC threshold first for the right ear, putting masking noise in the left ear, and obtains a right masked BC threshold of 45 dB HL. This shift would obviate the need for obtaining the masked BC threshold for the left ear, which can be assumed to be 30 dB HL (the unmasked BC threshold), which has to represent the BC threshold for at least one ear. If, however, the right masked BC threshold did not change significantly from 30 dB HL, then the left masked BC threshold would need to be obtained because it could be 30, 35, 40, 45, or 50 dB HL.

The situation for masking during speech audiometry is similar to the situation for pure-tone testing except that the speech level in the TE is compared against each BC threshold (and AC threshold to be conservative) at all frequencies. Masking should be employed whenever the speech level in the TE exceeds any AC or BC of the NTE by 40 dB or more.

Masking cannot always be achieved because in some situations the masking noise in the NTE will cross over and reach the BC threshold of the TE, thereby resulting in cross-hearing of the noise by the TE. In such a situation, the masking noise in the NTE has confounded threshold measurement in the TE. This is termed a masking dilemma. The audiometric configuration that is most likely to be associated with a masking dilemma is maximal bilateral ABGs. For example, let us consider the situation in which the unmasked BC threshold is 10 dB HL and the unmasked AC threshold is 60 dB HL. In this example, when a masked BC threshold is obtained for one of the ears, say the right ear, a relatively high starting level of masking noise needs to be introduced into the left ear because the AC threshold is relatively high there. It is possible that the noise crosses from the NTE to the TE with an interaural attenuation of 40 dB (the noise is presented by AC) and may reach the BC threshold of 10 dB in the TE, thereby elevating the BC threshold in the TE.

□ Fig. 114.4 shows the unmasked and masked pure-tone and speech results in a patient with an asymmetric hearing loss.

114.4 Physiologic Measures of Auditory Function

114.4.1 Acoustic Admittance Testing

A tympanogram is a graph of the admittance (Y) of the middle ear as a function of the air pressure introduced into the ear canal through a probe inserted into the ear canal. The variation in air pressure generally is in the range of about +200 to –300 decapascals (daPa). A probe tone is introduced through a speaker in the probe assembly; some of the energy is admitted into the middle ear through the tympanic membrane, and some of the energy is rejected at the tympanic membrane. The microphone in the probe assembly picks up the

TEST EAR	MODE	250 Hz	500 Hz	1000 Hz	2000 Hz	4000 Hz	8000 Hz
Right (noise in L)	AC						
	BC

Word Recog. Score (%)	100		35	40			76	30	95	75

Fig. 114.4 The unmasked and masked pure-tone and speech results in a patient with an asymmetric hearing loss. Note that the unmasked air conduction (AC) thresholds for the right ear range between 0 and 15 dB HL, consistent with normal hearing sensitivity. The unmasked AC thresholds for the left ear, ranging between 50 and 60 dB HL, are 40 to 50 dB poorer than the AC thresholds for the right ear; because the interaural attenuation for AC is 40 dB, subtracting 40 dB from the unmasked AC thresholds of the left ear indicates that the right ear may be cross-hearing the tones presented to the left ear; therefore, masking noise was presented to the right ear while the AC thresholds were reestablished in the left ear to obtain the true masked AC thresholds for the left ear. The levels of masking noise are shown in the table below (test ear left, noise in R), mode AC, and the masked left AC thresholds (see box symbols) are shown at levels between 60 and 80 dB HL. Note that the unmasked bone conduction (BC) thresholds were obtained with the bone vibrator placed on the left ear; these thresholds, between 0 and 15 dB HL, reflect the integrity of the cochlea on the right side because the interaural attenuation of BC is 0 dB, and the ear with the better cochlea is the right ear. To determine the masked true left ear BC thresholds, masking noise was presented to the right ear while the BC thresholds were reestablished in the left ear. The levels of masking noise are shown in the table below (test ear left, noise in R), mode BC, and the masked left BC thresholds (see bracket symbols) are shown at levels that are between more than 40 dB HL at 250 Hz (output limit for BC is 40 dB at that frequency) and 70 dB HL at 4000 Hz. Thus, this patient has a flat sensorineural hearing loss in the left ear of moderately severe degree. The speech table shows that the speech recognition threshold (SRT) is 5 dB HL in the right ear, consistent with the normal-hearing pure-tone threshold levels in that ear; the unmasked SRT in the left ear is 50 dB HL. Because the interaural attenuation for speech AC stimuli is about 40 dB, and because some of the right AC and BC thresholds are 10 dB HL or better, the right ear may be cross-hearing the speech stimuli presented to the left ear, so the left masked, true SRT needs to be reestablished while masking noise is presented in the right ear. The masked left SRT is 65 dB HL, consistent with the masked left pure-tone AC thresholds. As the speech table shows, word recognition testing was done at 35 dB SL re: SRT in the right ear (so the presentation level was the SRT level of 5 plus 35 dB, which equals 40 dB HL) and at 30 dB SL re: SRT in the left ear (so the presentation level was the SRT level of 65 plus 30 dB, which equals 95 dB HL). With a word-presentation level of 40 dB in the right ear, the crossover level into the left ear is 0 dB HL, so cross-hearing by the left ear is not possible, and masking noise in the left ear was not needed while the word recognition score was obtained for the right ear, which was 100%. But with a word-presentation level of 95 dB HL in the left ear, the crossover level is 95 dB - 40 dB = 55 dB HL, resulting in cross-hearing in the right ear. Thus, masking noise was needed in the right ear (75 dB HL of masking was used) while the word recognition score was obtained for the left ear, which was 76% ANSI, American National Standards Institute; dB HL, decibels hearing level; dB SL, decibels sensation level; LE, left ear; RE, right ear.

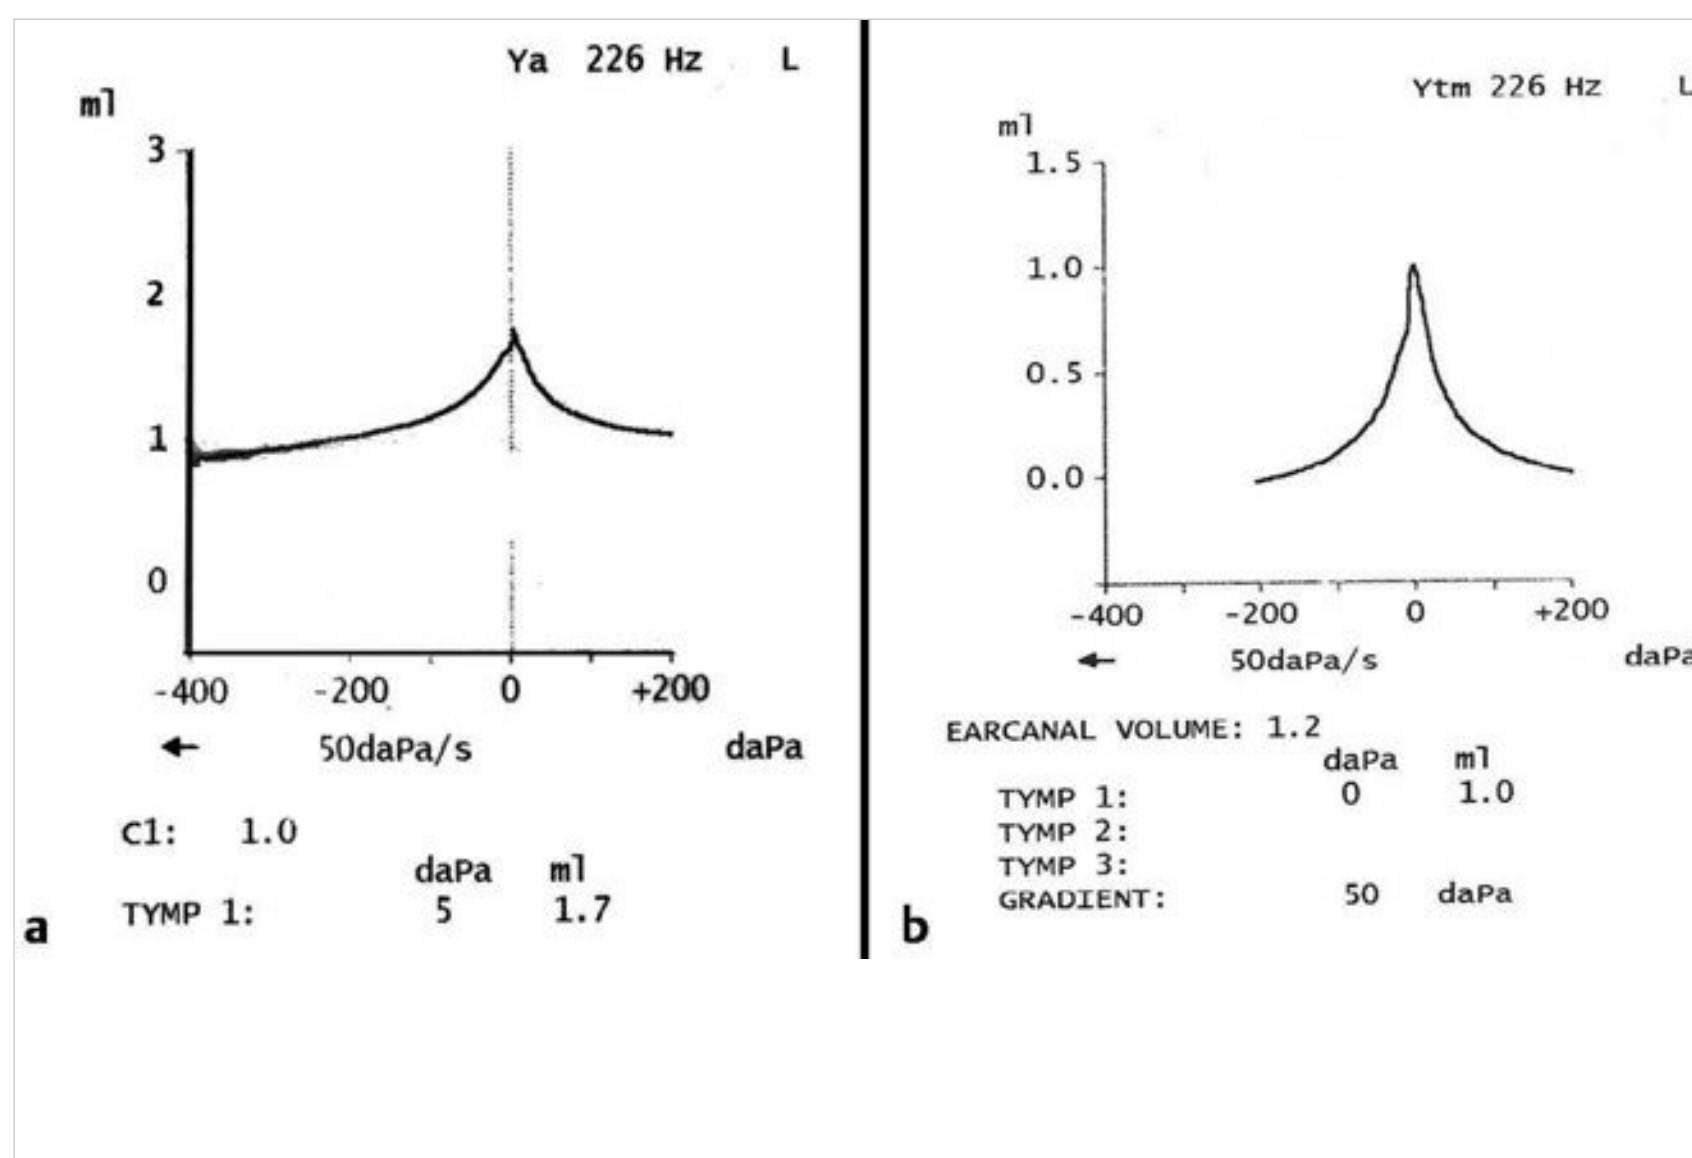

Fig. 114.5 (a) A tympanogram obtained in the baseline-off mode. (b) A tympanogram obtained in the baseline-on mode. The tympanometric peak pressure (TPP) is 5 daPa in (a) and is 0 daPa in (b). Note that in the tympanogram in (a), the ear canal volume (V_{ec}) can be read by looking at the ordinate value associated with an air pressure of +200 daPa and also by reading the C1 value (1.0) below the tympanogram. The value of 1.7 ml represents the combined admittance of the outer and middle ear, so the peak-compensated static-acoustic admittance is obtained by subtracting the C1 value (1.0) from the ml value at the TPP (1.7) to yield 0.7 mmho. In the tympanogram in (b), the V_{ec} cannot be read from the tympanogram curve; the value is displayed below the tympanogram as 1.2 cc. The peak-compensated static-acoustic admittance is the value (1.0 mmho) on the ordinate associated with the TPP; it also is displayed below the tympanogram.

rejected energy and transmits it to a device that measures its admittance in millimhos (mmho). The admittance of the middle ear provides information regarding the presence of any stiffening (e.g., otosclerosis) or loosening (e.g., mass lesion such as ossicular discontinuity) in the middle ear.

Tympanometric Peak Pressure

The peak of the tympanogram occurs when the ear canal air pressure against the lateral side of the tympanic membrane from the probe assembly inserted in the ear canal equals the air pressure exerted laterally from the middle ear against the medial side of the tympanic membrane. The air pressure at which this occurs is referred to as the tympanometric peak pressure (TPP), measured in decapascals. The TPP also represents the ear canal air pressure at which the admittance of acoustic energy into the middle ear from the ear canal is maximal (□ Fig. 114.5). Although it correlates closely with middle ear pressure, the TPP is not an exact measurement of the pressure in the middle ear. In patients older than 12 years of age, the TPP is considered to be within normal limits if it is greater than -50 daPa. A TPP that is equal to or more negative than this cutoff reflects eustachian tube dysfunction in that ear, with or without middle ear effusion; the TPP is obliterated (beyond the negative limit of the air pressure range employed by the device) when the fluid level in the middle ear in cases of middle ear effusion is sufficient to reach the ossicles.

Peak-Compensated Static-Acoustic Admittance and Equivalent Ear Canal Volume

The peak-compensated static-acoustic admittance (in millimhos) is obtained from the tympanogram. When the tympanogram is run at “baseline on” (□ Fig. 114.5b), the device will exclude the admittance from an extreme ear canal air pressure such as +200 or -300 daPa, which grossly represents the admittance of the ear canal (termed the equivalent ear canal volume in cubic centimeters), from the tympanogram. So, the tails of the tympanogram generally will be at about 0 mmho, and the

peak-compensated static-acoustic admittance, in mmho, which can be read from the ordinate at the peak height of the tympanogram, essentially is the admittance of the middle ear. For the 226-Hz probe tone, $1 \text{ mmho} = 1 \text{ cm}^3$. If the tympanogram is run at “baseline off” (□ Fig. 114.5a), then the admittance at the TPP represents the combined admittance of the outer ear and middle ear, and the clinician must subtract the displayed equivalent ear canal volume from this combined admittance of the outer ear and middle ear to derive the peak-compensated static-acoustic admittance.

A normal range for peak-compensated static-acoustic admittance is approximately 0.35 to 1.30 mmho. A peak-compensated static-acoustic admittance that is significantly reduced (<0.35 mmho) is consistent with the presence of a stiffening middle ear disorder. A peak-compensated static-acoustic admittance that is significantly increased (>1.30 mmho) is consistent with the presence of ossicular discontinuity or a stiffening middle ear pathology in conjunction with a flaccid tympanic membrane (or healed tympanic membrane perforation) when significant ABGs are present. Because of the considerable overlap in peak-compensated static-acoustic admittance between normal and pathologic ears, this parameter should be interpreted in conjunction with the audiometric and other acoustic admittance findings. An abnormally large value of the equivalent ear canal volume (V_{ec}), above 2.5 cm^3 in adults or above 2.0 cm^3 in children, is consistent with the presence of tympanic membrane perforation or a patent tympanostomy tube. In such cases, the tympanogram will appear to be flat because the TPP will be absent. If the V_{ec} in a patient with a known tympanostomy tube is significantly below 2.5 cm^3 in an adult or significantly below 2.0 cm^3 in a child, then the finding may be suggestive of a blocked tympanostomy tube; in such cases, if the blockage is limited to the tympanostomy tube, a TPP will be seen, probably within normal limits.

The shape of the tympanogram traditionally has been classified as type A, type A_D , type A_s , or type B (□ Fig. 114.6). Type A, with a normal TPP and normal peak amplitude, is interpreted as consistent with normal middle ear function. Type A_D , with a greater than normal peak amplitude or a peak in which the

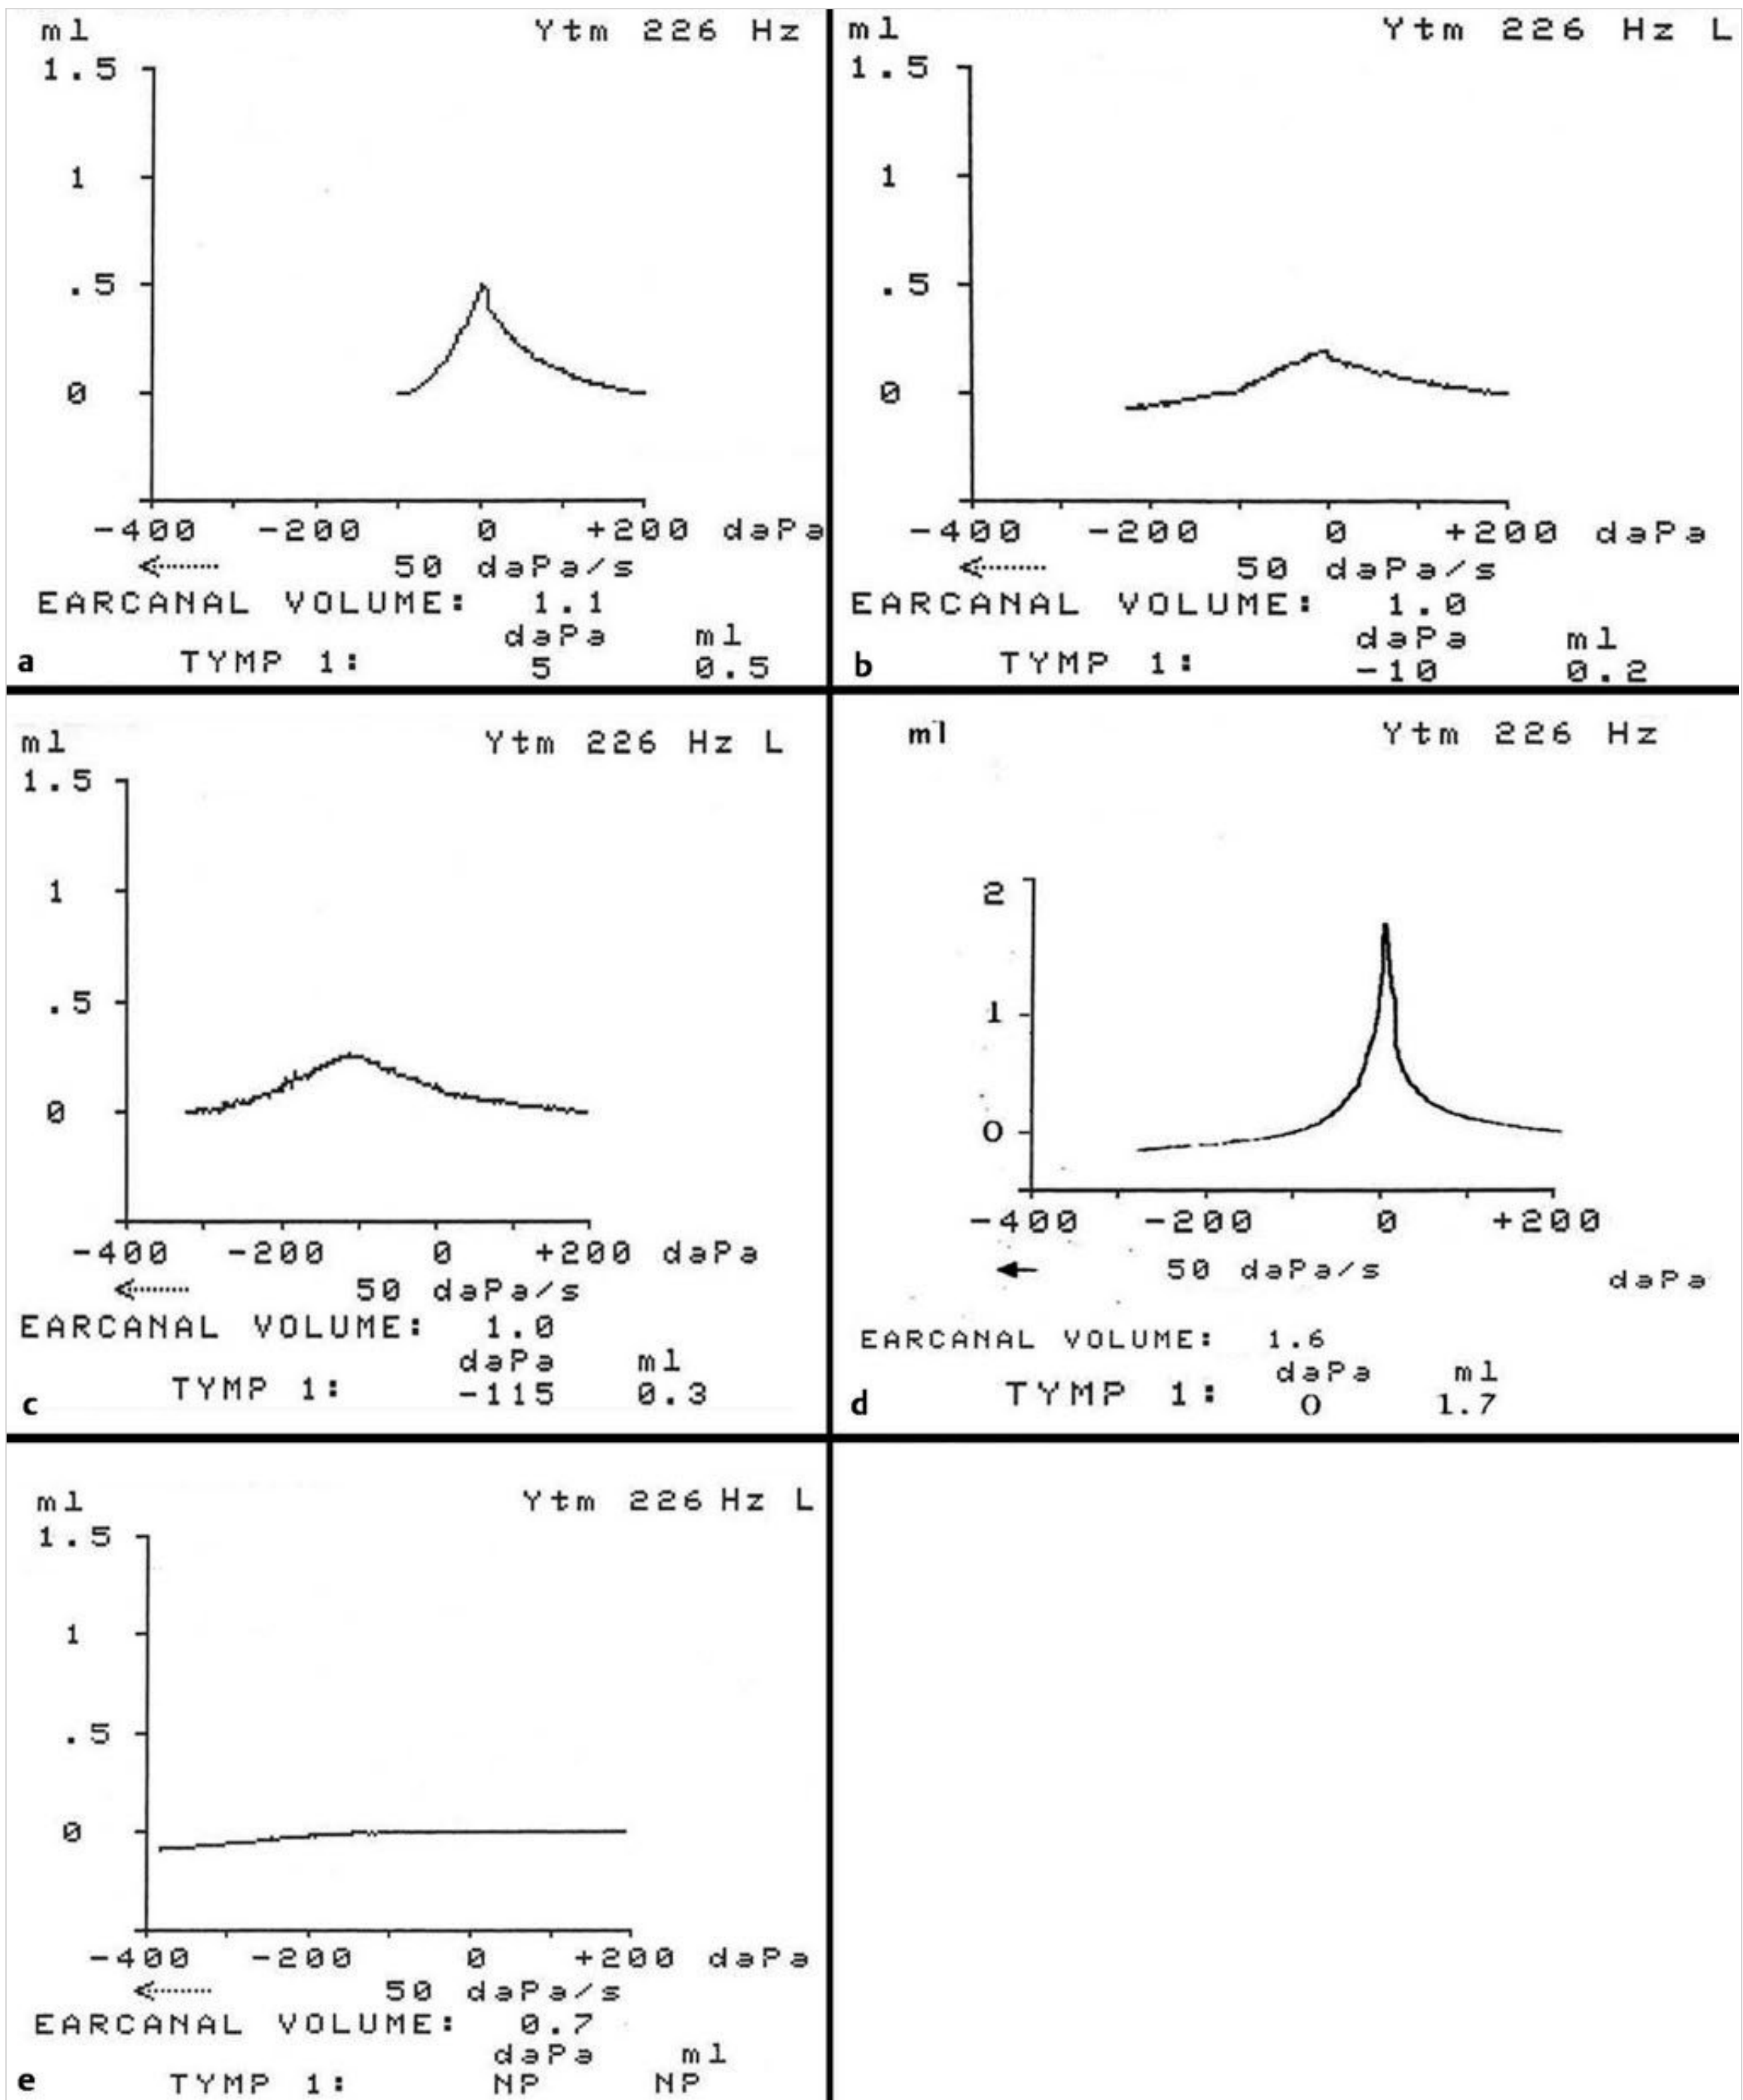

Fig. 114.6 The various admittance tympanogram (baseline on) types for the 226-Hz probe tone. (a) Type A tympanogram with a normal tympanometric peak pressure (TPP) of 5 daPa and a normal peak-compensated static-acoustic admittance of 0.5 mmho. (b) Type A_s tympanogram with a normal TPP (-10 daPa) but a reduced peak-compensated static-acoustic admittance (0.2 mmho). (c) Type C tympanogram with a significantly negative TPP (-115 daPa). (d) Type A_D tympanogram with an abnormally increased peak-compensated static-acoustic admittance (1.7 mmho). (e) Type B tympanogram is flat, with an absent TPP.

right and left slopes do not meet, is consistent with increased admittance of sound energy in the middle ear, which can occur with ossicular discontinuity. Type A_s, characterized by a peak amplitude that is reduced and a normal TPP, has been interpreted as consistent with a stiffening middle ear pathology, such as ossicular fixation. Type C, with a significantly negative TPP, has been interpreted as consistent with eustachian tube dysfunction. Type B is consistent with an associated pathology that produces greatly increased stiffness, such as middle ear effusion, or a condition such as tympanic membrane perforation, in which the admittance in the middle ear does not vary with air pressure. However, we believe it is more useful to interpret TPP and peak-compensated static-acoustic admittance first separately and then together, rather than to interpret just the shape of the tympanogram. If these tympanogram classifications are used, then the peak amplitude should be considered normal if the peak-compensated static-acoustic admittance is within the normal range; similarly, the peak amplitude should be considered reduced if the peak-compensated static-acoustic admittance is below the normal range, and it should be considered increased if the peak-compensated static-acoustic admittance is beyond the normal range. Type C should not be interpreted as consistent with the absence of middle ear effusion. Also, because many stiffening and mass lesions may have peak-compensated static-acoustic admittance values within the normal range, many of these stiffening and mass lesions yield a normal type A tympanogram.

High-Frequency Tympanometry in Older Children and Adults

As mentioned in the previous section, significantly high peak-compensated static-acoustic admittance values can be seen in ears with ossicular discontinuity and in ears with otosclerosis in conjunction with either a flaccid tympanic membrane or a healed tympanic membrane perforation. However, these pathologies also can yield peak-compensated static-acoustic admittance values within the normal range. When peak-compensated static-acoustic admittance exceeds 0.75 mmho and the audiogram shows significant ABGs, consistent with the presence of middle ear pathology, high-frequency tympanometry performed with the 678-Hz probe tone may help differentiate between ossicular discontinuity and ossicular fixation with either a flaccid tympanic membrane or a healed tympanic membrane perforation.

In order to perform high-frequency tympanometry with the 678-Hz probe tone, the major components of admittance—susceptance and conductance—have to be examined. Acoustic susceptance comprises stiffness susceptance and mass susceptance. The former represents the acceptance of sound energy into stiffness; the latter represents the acceptance of sound energy into mass. Conductance represents the acceptance of sound energy into resistance. With the 226-Hz probe tone, the admittance (Y) tympanogram is obtained. With the 678-Hz probe tone, tympanograms for the susceptance component of admittance (symbol is B) and for the conductance component of admittance (symbol is G) are obtained. The susceptance and conductance tympanograms for this probe tone frequency have certain characteristics for ears with ossicular discontinuity that differ from the characteristics for ears with ossicular fixation in

Fig. 114.7 High-frequency tympanometry (660-Hz probe tone) for an ear with ossicular discontinuity and for an ear with otosclerosis in conjunction with a flaccid tympanic membrane or a healed tympanic membrane. The susceptance (B) and conductance (G) tympanograms are shown for each ear. Both of these ears had abnormally large peak-compensated static-acoustic admittance values on the admittance tympanogram for the low-frequency probe tone (not shown here). (A) and (B) show the B and G tympanograms for the ear with ossicular discontinuity. The findings are consistent with ossicular discontinuity as more than 3 extrema (positive and negative peaks) are seen for G and more than 5 extrema are seen for B. (C) and (D) show the B and G tympanograms, respectively, for an ear with otosclerosis and a flaccid tympanic membrane. This ear shows 3 extrema for the B tympanogram and 3 extrema for the G tympanogram, and the number of extrema does not exceed normal limits, so ossicular discontinuity is not present. (Used with permission from Silman S, Silverman CA. *Auditory Diagnosis: Principles and Applications*. San Diego, CA: Singular Publishing; 1997.)

conjunction with either a flaccid tympanic membrane or a healed tympanic membrane perforation.

□ Fig. 114.7 illustrates high-frequency tympanograms (678-Hz probe tone) for an ear with ossicular discontinuity and for an ear with otosclerosis in conjunction with a flaccid tympanic membrane or a healed tympanic membrane. Note the multiple

positive and negative peaks (called extrema) for both the B and G tympanograms in the case of the ear with ossicular discontinuity. More than 5 peaks are present for both the B and G tympanograms, consistent with the presence of a mass-loaded middle ear system, which has shifted the resonance frequency of the middle ear downward from the normal of around 900 Hz. In contrast, note that only three extrema are seen in the B and G tympanograms in the ear with otosclerosis and a flaccid tympanic membrane or a healed tympanic membrane perforation. The criteria for abnormal high-frequency (678-Hz probe tone) tympanometric findings are as follows: (1) more than 5 extrema for the B tympanogram; or (2) more than 3 extrema for the G tympanogram; or (c) the air pressure interval between the outermost extremum for a tympanogram with 5 extrema (either B or G) exceeds 100 daPa, or the air pressure interval for the outermost extremum for a tympanogram with 3 extrema (either B or G) exceeds 75 daPa. The air pressure interval between the outermost extremum in the ear with ossicular discontinuity with a flaccid tympanic membrane or a healed tympanic membrane perforation is less than 75 daPa for both the G and B tympanograms; this finding, along with the number of extrema not exceeding 3 for both the B and G tympanograms, is consistent with the absence of ossicular discontinuity and points to ossicular fixation with a flaccid tympanic membrane or a healed tympanic membrane perforation.

114.4.2 Acoustic Reflex Threshold and Decay

The acoustic reflex primarily involves contraction of the stapedius muscle in response to a sufficiently intense sound. The stapedius muscle originates from the pyramidal eminence on the posterior wall of the tympanic cavity of the middle ear, and its tendon inserts onto the neck of the stapes. Activation of the acoustic reflex decreases the volume of the middle ear as contraction causes medial movement of the ossicles and tympanic membrane medially. The decreased volume leads to increased stiffness, resulting in the rejection of sound energy (decreased admittance of sound in the middle ear).

The acoustic reflex is bilateral, even for acoustic signals presented to only one ear. Therefore, the change in acoustic admittance elicited by a sound can be monitored either in the ear receiving the intense auditory signal (ipsilateral acoustic reflex threshold testing) or in the opposite ear (contralateral acoustic reflex threshold testing). Ipsilateral acoustic reflex threshold (ART) testing involves, like tympanometry, insertion of a probe assembly into one ear. An intense activator (e.g., at 500, 1000, and/or 2000 Hz) is presented through the speaker of the probe assembly into the ear canal. The clinician adjusts the air pressure to match the TPP through one of the tubes of the probe assembly. A constant probe tone (typically 226 Hz) at about 85 dB SPL also is introduced into the ear canal through the probe assembly. A microphone in the probe assembly measures the dB SPL in the ear canal, and the acoustic admittance device converts that reading into acoustic admittance. If the acoustic reflex does not occur, then no change in dB SPL or acoustic admittance occurs. If the acoustic reflex is elicited by a sufficiently intense activator, the dB SPL and acoustic admittance will increase because of the effect of the acoustic reflex on the middle ear volume and admittance. Contralateral ART testing is similar

to ipsilateral ART testing, except that the activator is presented through an insert in the ear canal opposite to the one that has the probe assembly. The intensity of the activator is increased in one ear until a deflection is observed in the contralateral ear with the probe assembly. The ARTs generally are reported for each ear for each activator (conventionally 500, 1000, and 2000 Hz) for the ipsilateral and/or contralateral mode of testing. The ART is labeled for the ear that receives the activator. Therefore, for contralateral ART testing, if the probe assembly is in the right ear, the activator is in the left ear, and the recorded ART is the left contralateral ART because the activating sound in the left ear triggered the acoustic reflex.

The ART represents the lowest sound intensity that yields a detectable decrease in acoustic admittance on the readout of the acoustic admittance device when the device is set to display the acoustic admittance as a function of time lapsing from presentation of the sound.

The ARTs are affected by conductive pathology, significant sensorineural hearing impairment attributed to cochlear causes, and disorders of the acoustic reflex arc, which affect cranial nerve VIII (cochleovestibular nerve), the cochlear nuclei of the auditory brainstem, the superior olivary complex of the auditory brainstem, the motor nucleus of cranial nerve VII (facial nerve), or cranial nerve VII, which innervates the stapedius muscle. The acoustic reflex pattern can be predicted by considering whether the pathology affects the afferent acoustic reflex arc and/or the efferent acoustic reflex arc. In the case of the acoustic reflex, the afferent (sensory) arc involves sound transmission through the outer ear, middle ear, cochlea, cochleovestibular nerve, cochlear nuclei, and superior olivary complex. The efferent (motor) arc involves the motor nucleus of the facial nerve, facial nerve, stapedius, and stapes.

A cochlear hearing loss of approximately 50 dB or more is sufficient to affect the ART by elevating it or making it absent. Cochlear hearing losses involve the afferent arc, so, for example, if the hearing loss is in the right ear, then the right contralateral ART and right ipsilateral ART will be affected because right contralateral and right ipsilateral acoustic reflex testing involve activator presentation to the right ear, which then carries the auditory information through the right cochleovestibular nerve to the superior olivary complex. The effect is frequency specific, so the ART is affected at activator frequencies with significant cochlear hearing loss. Vestibular schwannomas also involve the afferent arc in a similar manner to cochlear hearing losses, except that the effect on the ART is more pronounced than that of cochlear hearing losses and the frequency effect is unpredictable. The Silman and Gelfand 90th percentiles, when applied to the contralateral ARTs, can enable differentiation between cochlear and retrocochlear lesions and can enable the detection of retrocochlear pathology when the hearing sensitivity is normal and ABGs are not present. The 90th percentiles establish the cutoffs for the effect of cochlear pathologies of varying magnitudes and normal hearing sensitivity. Therefore, if the ART is elevated beyond the 90th percentile (and ABGs are absent), then the finding may be consistent with retrocochlear pathology. The 90th percentiles cannot be applied when the cochlear hearing loss reaches a magnitude of 80 dB HL or more.

A facial nerve lesion that is medial to the origin of the nerve to the stapedius muscle can affect the ART by affecting the efferent arc. Therefore, if the lesion affects the right facial nerve

medial to the branch to the stapedius, then the left contralateral ART and right ipsilateral ART will be affected (elevated or absent) at one or more frequencies; left contralateral ART testing involves the affected efferent arc on the right side, and right ipsilateral ART testing involves the affected efferent (as well as afferent) arc on the right side.

A conductive pathology has dual effects. The afferent arc is affected because sound transmission through the middle ear is affected by the ABG. The efferent arc is affected because the pathology prevents acoustic reflex contraction in the ear with the conductive pathology at all activator frequencies. In the case of a right middle ear effusion, the right contralateral ART will be elevated or absent at a given activator frequency according to the magnitude of the ABG at that frequency, which affects the afferent arc; the activator is in the ear with the ABG (afferent arc), and the probe assembly is in the normal ear in which the acoustic reflex is monitored (efferent arc is intact). With left contralateral ART testing, the activator is in the normal left ear (afferent arc), but the probe is in the ear with the conductive pathology; the conductive pathology in the left ear prevents the acoustic reflex from contracting, so the efferent arc is affected and the left contralateral acoustic reflexes will be absent at all activating frequencies. The right ipsilateral ART will be absent for all activators because the efferent arc is impaired by the conductive pathology in that ear, which prevents the acoustic reflex from contracting. The left ipsilateral ART will be present at expected levels as both the activator and probe are in the normal ear. ARTs are more sensitive to conductive pathology than any other acoustic admittance measure. With bilateral conductive pathology, right and left contralateral and ipsilateral ARTs all will be absent at all activator frequencies because all ART testing will involve insertion of the probe in an ear with a conductive lesion that affects the efferent arc, so that acoustic reflex contraction cannot occur. Eustachian tube dysfunction without middle ear effusion generally is too mild to affect the ARTs unless the dysfunction is severe (extremely negative TPP). Recall that ART testing is done at TPP, which generally overcomes the effect of the negative TPP.

114.4.3 Acoustic Reflex Adaptation

Acoustic reflex adaptation (ARA) or decay represents the decrease in magnitude of the acoustic reflex over time during the presentation of an acoustic stimulus over a period of about 10 seconds. Like ART testing, ARA testing can be performed in the ipsilateral or contralateral mode with the probe tone frequency at 226 Hz and activating stimuli at 500 and 1000 Hz. The activating stimuli are presented at 10 dB SLre: ART. Thus, ARA may not be accomplished if the ART is absent or elevated near the output of the acoustic admittance device. If the magnitude of the acoustic reflex decays by 50% or more over a period of 10 seconds, then the ARA is recorded as positive, possibly consistent with retrocochlear pathology. Differentiation between a retrocochlear lesion affecting the afferent arc and a facial nerve lesion (medial to the branch to the stapedius) affecting the efferent arc can be made based on the comparison of ipsilateral and contralateral ARA findings for each ear, similar to the comparisons between the ipsilateral and contralateral ARTs.

The sensitivity and false-positive rate for the differential diagnosis of retrocochlear pathology based on combined contralateral

ART testing using the Silman and Gelfand 90th percentiles and ARA testing are 83% and 10% respectively.

114.4.4 Otoacoustic Emissions

Otoacoustic emissions (OAEs), low-level sounds generated in the cochlea of the inner ear, can be detected with a sensitive, low-noise microphone placed within the external auditory meatus. They represent a by-product of normal auditory physiologic processes involving the interaction between the outer hair cells and the traveling wave along the basal membrane. Spontaneous otoacoustic emissions (SOAEs) occur in the absence of sound stimulation. They are generated at specific sites along the basal membrane of the cochlea and produce two waves traveling in opposite directions. The wave traveling toward the apical end of the basal membrane dissipates; however, the wave traveling backward in the basal direction stimulates the ossicles of the middle ear and tympanic membrane, generating sound in the external ear canal. SOAEs have little clinical applicability because they are absent in approximately 30% of individuals with normal hearing.

Transient otoacoustic emissions (TOAEs) and distortion product otoacoustic emissions (DPOAEs) are evoked otoacoustic emissions because sound stimulation is necessary for their generation. With TOAEs, a cochlear echo is generated by an outgoing wave; this represents a reflection of the traveling wave along the basal membrane that is produced at a point of irregularity along the basal membrane. The outer hair cells enhance the reflected wave in a nonlinear manner, so damage to these hair cells adversely affects the OAEs. The latency of the so-called cochlear echo is roughly 3 to 10 milliseconds, representing the travel time through the ear to the point on the basal membrane where the reflected wave is generated and then the travel time for the wave to be propagated back outward. This mechanism involving irregularities of the basal membrane and the reflected traveling wave also underlies DPOAEs. With DPOAEs, two short-duration pure-tone signals of different frequencies are simultaneously presented into the ear canal. Because of outer hair cell nonlinearities, intermodulation distortion products are produced, resulting in emissions at frequencies that represent certain sums and differences of the stimulating frequencies. The intermodulation distortion product occurring at the frequency representing $2f_1 - f_2$ usually is the one measured and reported in DPOAE testing because this intermodulation distortion product is the largest of the intermodulation distortion products.

Transient Otoacoustic Emissions

□ Fig. 114.8 shows a tracing for TOAEs in an adult ear with normal hearing sensitivity and normal middle ear function. Suggested criteria for a pass result on TOAEs are as follows: (1) signal-to-noise ratio of at least 6 dB for at least four of the following frequencies (1000 Hz, 2000 Hz, 3000 Hz, 4000 Hz, and 6000 Hz); (2) 70% or greater stability of the stimulus peak dB SPL; and (3) overall waveform reproducibility of at least 70%. Studies show that when the average pure-tone thresholds across the entire audiometric frequency range do not exceed 20 dB HL, the probability of passing TOAE testing exceeds 90%. For average pure-tone thresholds between 20 and 40 dB HL, the

Fig. 114.8 A transient otoacoustic emissions (TOAEs) recording in a normal ear. Section A represents the waveform (intensity over time) of the click stimulus. Section B shows the frequency spectrum (intensity as a function of frequency) for the click stimulus, which has a peak sound pressure level (SPL) of 78.5 dB in this example. Section C shows a 93% stability of the stimulus peak dB SPL during this recording. Section D shows a 32.3-dB SPL noise level measured in the ear canal during the recording; with a noise level for rejection of sweeps set to 47.3 dB, only one sweep was rejected (see NOISY XN), which is extremely low. The lower part of the figure (section E) shows the amplitudes of the section A and section B TOAE waveforms over a 20-ms period. The mean amplitude of the section A and section B averages of the response waveform (A&B MEAN) is 16.1 dB SPL (section F). The A-B difference (A-B DIFF) is -0.9 dB, indicating that the noise level in the ear canal is very low. The amplitude of the response (16.1 dB SPL) is shown below this, with a waveform reproducibility (WAVE REPRO) of 98%. Also shown are the reproducibility and signal-to-noise ratios for each of five frequency bands centered at 1000, 2000, 3000, 4000, and 5000 Hz. Here, the signal-to-noise ratios greatly exceed 6 dB at 1000, 2000, 3000, and 4000 Hz. Section G shows the frequency analysis of the noise (light shaded area) compared with the frequency analysis of the TOAEs (dark shaded area).

probability of passing TOAE testing declines as the hearing loss increases, from over 90% at 20 dB HL to approximately 50% at 30 dB HL and approximately 8% at 40 dB HL. Thus, a pass result of the TOAE may not rule out slight to mild hearing loss up to about 40 dB HL. TOAEs are obliterated with conductive pathology for ABGs of at least 20 to 25 dB. They also are obliterated with a substantially negative TPP less than or equal to -200 daPa, even when ABGs are not present. Approximately 80% of patients with retrocochlear pathologies fail OAEs testing; one reason for this, in the case of vestibular schwannomas, is involvement of the cochlear artery.

Distortion Product Otoacoustic Emissions

□ Fig. 114.9 shows a tracing for DPOAEs in an adult ear with normal hearing sensitivity and normal middle ear function.

Various clinics employ different pass criteria for the DPOAEs. We suggest that the criterion for a pass result on the DPOAEs be a signal-to-noise ratio of at least 6 dB at 1000, 2000, 3000, and 4000 Hz; the presence of a signal-to-noise ratio of at least 6 dB at 1500, 5000, and 6000 Hz as well as at the other frequencies strengthens a pass finding.

Studies show that when the average pure-tone thresholds across the entire audiometric frequency range do not exceed 20 dB HL, the probability of passing DPOAE testing exceeds 90% similar to the probability of passing TOAE testing. For average pure-tone thresholds between 20 and 25 dB HL, the probability of passing DPOAE testing declines to about 60% at 25 dB HL. For average pure-tone thresholds between 25 and 40 dB HL, the probability of passing DPOAE testing declines further to 12% at 40 dB HL (for traditional high-level-stimulus intensities). The probability of passing DPOAE testing with average pure-tone

Fig. 114.9 A distortion product otoacoustic emissions (DPOAEs) recording. The f_2/f_1 ratio, shown at the top of the recording, is 1.221. The intensities for f_1 and f_2 , also shown at the top of the recording, are 65 dB SPL and 55 dB SPL, respectively. The “Ear canal response” shows the frequency spectrum of the noise in the ear canal before testing is initiated. The DP-gram is a frequency spectrum. The light and dark shaded areas in the DP-gram show the frequency spectrum of the noise levels during testing. The open circles show the intensity of the emissions at each frequency, usually f_2 , as shown here. The SPL values for the emissions should be compared against the SPL values of the noise to determine the signal-to-noise ratio. In this example, the SPL values for the emissions are substantially more than 6 dB greater than the noise levels across the frequency range. The graph labeled “noise distribution” shows the amplitude distribution of the noise floor.

thresholds equivalent to 50 dB HL is about 5%. Thus, a pass result on DPOAE testing may not rule out slight to borderline moderate hearing loss up to about 40 to 45 dB HL. Like TOAEs, DPOAEs are obliterated with conductive pathology for ABGs of at least 20 to 25 dB and with a substantially negative TPP less than or equal to -200 daPa (even when ABGs are not present).

114.5 Auditory Evoked Potentials

Auditory evoked potentials represent changes in the electroencephalogram (EEG) during auditory stimulation. Recording electrodes, usually placed on the scalp, detect the electrical activity from the brain. Recordings of auditory evoked potentials show the response waveform (amplitude of the electrical activity elicited by the sound stimulation over time [latency]). Because the voltage of the background EEG with electrophysiologic noise is much larger than the voltage of the potential elicited by sound stimulation, averaging of responses to numerous signal presentations, amplification of the response, response filtering, and other procedures are employed to enhance the

evoked potential and reduce the background EEG and noise. The auditory evoked potential tests that have the greatest application for otolaryngologists include electrocochleography (ECoChG), auditory brainstem response (ABR) testing, and auditory steady-state response (ASSR) testing.

114.5.1 Electrocochleography

The evoked potentials that are typically recorded and interpreted in ECoChG include the summing potential (SP) and the action potential (AP). The SP is a direct current potential that represents the extracellular activity of the hair cells within the organ of Corti of the cochlea. Its amplitude is on the scale of microvolts (μ V), ranging from about a fraction of a microvolt up to about 1μ V in a normal ear, for extratympanic placement. Slightly larger amplitudes are obtained with transtympanic placement. The AP is an alternating-polarity potential that represents the synchronous firing of the thousands of fibers of the auditory nerve for a short-duration stimulus such as a click. Its amplitude also is on the scale of microvolts, typically about 2.0

Fig. 114.10 An electrocochleographic recording for a normal ear. The amplitude is $0.03 \mu\text{V}$ (measured from the base) for the summating potential and $0.25 \mu\text{V}$ (measured from the base) for the action potential. Thus, the amplitude ratio is $0.03 \mu\text{V}/0.25 \mu\text{V}$, which equals 0.1 or 10%, which is non-significant for Meniere disease. AP, action potential; SP, summating potential.

μV , but can be as large as about $5 \mu\text{V}$. Its latency ranges from about 1.3 to 1.7 milliseconds (roughly around 2.0 milliseconds); the latency of the SP, which precedes the AP, is slightly less than that of the AP.

ECochG can be performed with the transtympanic or extratympanic placement of the active (noninverting) electrode. The former involves insertion of a needle electrode through the tympanic membrane onto the promontory of the cochlea and generally is done under local anesthesia. It is more invasive than ECochG recorded with extratympanic electrodes. Extratympanic placement can involve placement of an electrode at the tympanic membrane or more laterally in the ear canal. The TIPtrode (Etymotic Research, Elk Grove Village, IL) extratympanic electrode is a gold foil–wrapped inserted earphone with a foam tip that is placed near, but not at, the tympanic membrane. Regardless of the approach, a ground electrode is placed on the forehead, and the reference (inverting) electrode is usually placed on the contralateral earlobe. The amplitudes of the ECochG potentials decrease as the electrode placement becomes more lateral; thus, they are larger for transtympanic than for extratympanic electrode placement. The stimulus usually is a high-intensity click at approximately 80 to 95 dB nHL.

□ Fig. 114.10 shows an ECochG recording. Note that the SP precedes the AP. ECochG typically has been employed in patients suspected of having endolymphatic hydrops. In such cases, the SP/AP amplitude ratio is calculated for each ear, and an elevated SP/AP ratio (due to elevation of the SP) is considered consistent with endolymphatic hydrops; an enlarged ratio also is seen in perilymphatic fistula and some cases of superior semicircular canal dehiscence. The specific SP/AP ratio that is the cutoff for normalcy should be determined by each clinic; generally, this ratio ranges from about 0.35 to 0.5. The results of several investigations reveal a lack of sensitivity of the SP/AP

ratio (25 to 55%) for Meniere disease, regardless of the disease classification as definite versus less than definite. Study findings also reveal that the sensitivity of this ratio is lower if ECochG is performed when no vertigo is present than if it is performed when vertigo is present. Some have suggested that the sensitivity of the SP/AP ratio is enhanced with transtympanic electrodes, but this is not universally accepted.

114.5.2 Auditory Brainstem Response Testing

Neurodiagnostic Auditory Brainstem Response

ABR (brainstem auditory evoked potentials [BAEPs] or brainstem auditory evoked responses [BAERs]) waveforms include a series of peaks (□ Fig. 114.11) and generally occur within about 10 milliseconds after stimulus onset. Wave I is generated at the distal part of the auditory nerve and represents the status of the cochlea. Wave II is generated at the proximal part of the auditory nerve (junction of the auditory nerve with the auditory brainstem). Wave III is generated mainly by the ipsilateral cochlear nucleus and may receive a small contribution from the eighth nerve fibers entering the cochlear nuclei. Wave IV is probably generated mainly by the midline brainstem structures (e.g., superior olivary complex, trapezoid bodies, and acoustic stria). The origin of the positive component of wave V primarily is the contralateral lateral lemniscus (side opposite the side of stimulation). Although waves I and II have single generator sites, the later waves have multiple generator sites. The multiplicity of generator sites for the later waves makes it difficult to localize the lesion to a specific generator site. The major waves that are evaluated diagnostically are waves I, III, and V. The mean latencies in normal individuals at moderately high to high intensities are roughly 1.5 milliseconds for wave I, 3.5 milliseconds for wave III, and 5.5 milliseconds for wave V. The absolute peak latencies decline with maturation in infants. Wave I achieves adult latency values at about 3 months of age, and wave V achieves adult values at about 1.5 to 3 years of age. The interwave interval (IWI), also called the interpeak latency, represents the difference in absolute latency between two waves, such as the I to III IWI, III to V IWI, and I to V IWI. The I to III IWI, approximately a little more than 2.0 milliseconds, traditionally was thought to represent the travel time through the auditory nerve and caudal auditory brainstem; the III to V IWI, approximately a little less than 2.0 milliseconds, traditionally was thought to represent the travel time through the rostral auditory brainstem to the level of the lateral lemniscus; and the I to V IWI, approximately 4.0 milliseconds in normal individuals, traditionally was thought to reflect travel time from the distal auditory nerve to the lateral lemniscus. The I to V IWI also has been referred to as the central conduction time or brainstem transmission time, although peripheral pathology and stimulus parameters do slightly affect the interpeak latency. Because peak latencies shorten with maturation, the I to V IWI does not achieve adult values until about 3 years of age.

Another important measure for the evaluation of the neurodiagnostic ABR is the interaural latency difference of wave V (ILD V); this is the difference between the latencies of wave V in the two ears. The ILD in normal ears typically does not exceed

Fig. 114.11 Auditory brainstem response recordings in an individual with a right acoustic tumor. (a) Tracings from a normal ear and (b) tracings from an ear with a 3-cm acoustic tumor of the cerebellopontine angle. In both ears, the top tracings are the contralateral recordings (test and retest), and the bottom tracings are the ipsilateral recordings (test and retest). In (a), the absolute peak latencies are as follows: 1.40 milliseconds for wave I (amplitude of 0.37 μ V), 3.48 milliseconds for wave III, and 5.72 milliseconds for wave V (amplitude of 0.21 μ V). Thus, the I to III interwave interval (IWI) is 2.08 milliseconds, the III to V IWI is 2.24 milliseconds, and the I to V IWI is 4.32 milliseconds. All absolute peak latencies and IWIs are within normal limits for this ear. In (b), only wave I is present at 1.76 milliseconds (amplitude of 0.18 μ V). Although wave I is within normal limits, the large tumor has obliterated the later waves. Such tumors do not affect wave I because wave I is generated on the auditory nerve distal to the auditory brainstem.

0.3 to 0.4 milliseconds. The peak amplitude, largest for wave V and smallest for wave I, generally does not exceed 1 μ V. The amplitude parameter is not as sensitive to retrocochlear pathology as the IWI or ILD V. Wave V is the most robust wave, and it generally is the only wave seen at threshold. Wave I is the first wave to disappear with stimulus intensity reduction.

The electrode montage typically involves placement of the active (noninverting) electrode on the vertex of the skull or upper forehead, reference (inverting) electrode on the medial earlobe of the ear receiving auditory stimulation, and the ground (common) electrode. Stimuli typically include clicks for neurodiagnostic ABRs and tone bursts for the estimation of behavioral thresholds from the ABR. The transducer can be earphones or a bone vibrator.

The effect of cochlear pathology is to prolong the peak latencies. As the magnitude of the hearing loss increases, the probability of an absent wave I also increases, which in turn results in a decrease in the probability of obtaining the I to V IWI. Cochlear hearing loss is not associated with prolongation in the I to V IWI. Some clinicians obtain a latency-intensity function for wave V in which the wave V latency is shown on the ordinate and the stimulus intensity on the abscissa of a graph. In normal individuals, the slope of this function is downward because the wave V latency decreases as intensity increases. In persons with cochlear hearing loss, the slope becomes steeper than what is seen in individuals with normal hearing or in individuals with conductive hearing loss. Thus, at the lower intensities, the wave V latency is prolonged in comparison with that in individuals with normal hearing, but at the highest intensity levels, it

becomes equivalent to or nearly equivalent to that seen in individuals with normal hearing. Similar findings are obtained when the magnitude of a flat cochlear hearing loss reaches or exceeds about 60 dB HL, except that the wave V latency at the highest intensities does not approach that seen in individuals with normal hearing. With steeply sloping high-frequency cochlear hearing impairment, the function may be shifted significantly to the right of that of individuals with normal hearing, and the wave V latency value may plateau at a significantly prolonged value (i.e., not show further decline with continued increases in stimulus intensity).

With a conductive hearing impairment, the I to V IWI, if wave I is present, is not prolonged. The wave V latency-intensity function is shifted to the right of the function seen in individuals with normal hearing, and the degree of shift correlates with the magnitude of the ABG.

The effect of an eighth nerve retrocochlear pathology such as a vestibular schwannoma or meningioma is to prolong the I to V IWI, and especially the I to III IWI; the cutoff value depends on the clinic normative data, but this value usually approximates 2.3 to 2.4 milliseconds. The III to V IWI usually is unaffected by this kind of lesion unless the lesion is affecting the auditory brainstem because of its large size; the cutoff value depends on the clinic normative data, but this value usually approximates 2.1 milliseconds. The I to V IWI will be prolonged if either the I to III or the III to V IWI or both are prolonged. Although the cutoff value for the I to V IWI should depend on the clinic normative data, this value is approximately 4.3 to 4.4 milliseconds. The sensitivity and false-positive rate of the I to

III/I to V IWI are approximately 90% and less than 10% respectively. ABR testing is the audiologic measure within the audiologist's armamentarium that has the greatest sensitivity with respect to eighth nerve and auditory brainstem tumors. Nonetheless, the sensitivity of ABR to eighth nerve tumors is markedly reduced when tumor size is below 1 cm. If wave I is absent, then the interaural wave V is a useful diagnostic indicator of retrocochlear pathology, except if the pathology is bilateral. With bilateral prolongations of wave V latency, when the I to V IWI is absent because of an absent wave I, the wave V latency should be compared with the normative data, and the patient should be considered to be at risk for retrocochlear pathology if the latency is prolonged beyond 2 to 3 standard deviations above the mean. With some eighth nerve tumors that are large enough to displace the auditory brainstem, the ABR is obliterated in the affected ear, but a contralateral effect on the ABR latencies is seen in the unaffected ear. The III to V IWI traditionally has been considered as an indicator of pathology in the high auditory brainstem, but eighth nerve tumors also can affect the III to V IWI, and high auditory brainstem lesions can be associated with absence of the later waves, preventing measurement of an IWI. Correction factors that increase latency cutoff values for increasing hearing loss should not be employed because they lead to increased false-negative rates.

Although reported in one case study, the use of a high stimulus repetition rate should not be considered as a sensitized ABR measure for the detection of eighth nerve pathology.

Bone Auditory Brainstem Response

ABR threshold testing with BC stimulation, employing click or tone bursts, has been used to estimate the cochlear reserve, particularly in infants and children and individuals with aural atresia. Although peak latencies for BC ABRs are prolonged in comparison with those for AC ABRs in adults (the reverse is true in infants), the ABR thresholds are essentially similar for AC and BC in individuals with normal hearing. Careful calibration of the BC stimuli is essential. Because of output limitations with the BC transducer compared with the AC transducer, maximum BC presentation levels are at about 50 to 60 dB HL. Masking of the contralateral ear is always required when a BC ABR test is done because the BC stimulation is arriving at both ears at the same intensity. The ABG can be grossly estimated by comparing the BC ABR threshold with the AC ABR threshold.

114.5.3 Auditory Steady-State Response

The ASSR is the latest auditory evoked potential technology developed to estimate behavioral audiometric thresholds beyond the capability of the ABR, which is limited when individuals with hearing loss over 80 dB HL are tested. ASSR testing commonly employs amplitude-modulated stimuli because (1) the auditory nervous system is very responsive to amplitude modulation and (2) amplitude modulation greatly reduces the spectral splash of the stimulus so that high ASSR thresholds are valid estimates of the behavioral thresholds. The ASSR printout shows a threshold audiogram (□ Fig. 114.12). The ASSR thresholds generally are within 5 to 10 dB of the behavioral thresholds.

In addition to the fact that ASSR testing can quantify hearing losses up to 120 dB HL (ABR testing is difficult with hearing loss

greater than 80 dB HL), a statistical algorithm is employed by ASSR devices for objective detection of the threshold in a standard manner, whereas threshold identification in ABR testing (with diagnostic devices) generally involves the subjective judgment of the clinician. Another advantage of ASSR testing is that multiple stimulus frequencies in both ears can be tested simultaneously. The major limitation of ASSR testing is its lack of sensitivity to mild hearing loss. However, OAEs and/or ABR is sensitive to mild hearing loss.

114.6 Testing for Functional Hearing Loss

The presence of discrepant findings within an audiologic evaluation or between audiologic evaluations that cannot be attributed to a known organic cause is referred to as functional hearing loss. Other terms, such as nonorganic hearing loss and malingering, have been used; the former term is inaccurate because a functional overlay often occurs in individuals with an organic hearing loss, and the latter term implies conscious deception by the patient. Functional hearing loss is more prevalent in workers in industrial settings who file compensation claims for hearing impairment caused by occupational noise exposure, veterans who file compensation for service-connected hearing loss, and children who are experiencing unexplained academic difficulties.

114.6.1 Functional Indicators within the Routine Audiologic Evaluation

Several measures within the basic audiologic examination can provide indications of the possible presence of functional hearing loss. Pure-tone AC threshold testing routinely involves a retest threshold at 1000 Hz in both ears. Such test-retest reliability normally is within ± 5 dB. Test-retest reliability of ± 15 dB or more is seen in approximately 10% of patients with functional hearing loss. Lack of test-retest reliability is not pathognomonic for functional hearing loss.

In individuals with an asymmetric hearing loss, the absence of a shadow curve in the AC configuration whereby the difference in unmasked AC thresholds exceeds 85 dB also is suggestive of functional hearing loss because interaural attenuation values for AC signals are not this large.

The presence of a significant discrepancy or disagreement between the SRT and the PTA, with the SRT significantly better than the PTA, can be indicative of functional hearing loss when other factors (e.g., instrumentation, lack of understanding of instructions, language familiarity) are ruled out. Speech stimuli are louder than pure-tone stimuli, so a patient using a mental yardstick to respond to stimuli will respond to speech stimuli at lower levels than pure-tone stimuli. The sensitivity of this measure for functional hearing loss is approximately 60 to 70% and may be higher in children because of their naïveté.

The pure-tone or speech Stenger can be performed when the interaural difference in unmasked AC thresholds (or SRTs in the case of a speech Stenger) is at least 40 dB. It is based on the Stenger principle: when two tones are presented bilaterally at the same frequency, the tone is heard only in the ear receiving

Fig. 114.12 Auditory steady-state response (ASSR) recording for a 15-month old girl. (a,b) ASSR thresholds are shown for both ears. (c,d) Estimated behavioral pure-tone thresholds are shown for both ears. At 500 Hz, the ASSR results suggest a severe hearing loss at best and a profound hearing loss at worst, bilaterally; at the higher frequencies, the results suggest a profound hearing loss bilaterally.

the tone at a higher threshold. For example, if the AC threshold is 20 dB HL in the right ear and is 60 dB HL in the left ear, then presentation of a tone at 30 dB HL to the right ear but at 85 dB HL in the left ear results in a sensation level of 10 dB in the right ear and 25 dB in the left ear; thus, the tone is heard only in the poorer, left ear. A patient with functional hearing loss, hearing the tone only in the poorer ear, may make the conscious decision not to respond to the tone in the poorer ear. By keeping the tone at a constant 10 dB SL re: threshold in the better ear and then raising the intensity of the tone in the poorer ear until the patient stops responding (or the admitted threshold is obtained), the threshold of the poorer ear can be estimated to be 15 dB better than the level at which the patient stopped responding. A similar procedure is followed for a speech Stenger, except that spondaic words rather than pure-tone stimuli are presented.

Some clinicians posit the presence of functional hearing loss based on subjective behavioral signs, such as intense lip

reading, exaggerated attempts to hear, and unfamiliarity with amplification if the patient wears amplification. These behavioral signs are not diagnostic of functional hearing loss because many persons with organic hearing loss demonstrate these behaviors. The presence of these behaviors should serve to alert the clinician to the possibility of a functional hearing loss on objective audiologic measures.

114.6.2 Physiologic and Electrophysiologic Measures

ARTs cannot occur at levels equivalent to, or below, the admitted behavior thresholds because acoustic reflexes are elicited by intense acoustic stimulation. In fact, functional hearing loss should be suspected even if the ARTs are elicited at 10 dB SL re: admitted pure-tone thresholds. Electrophysiologic threshold testing with ABR or ASSR can enable objective estimation of the pure-tone thresholds in each ear. Otoacoustic emissions testing

can be helpful in supporting the auditory evoked potential findings, particularly when OAEs are present.

114.7 Hearing Screening

The US Preventive Services Task Force recommends hearing screening in all newborns. The task force has identified the following indicators of risk for permanent, bilateral, congenital hearing loss: stay in the neonatal intensive care unit for 2 or more days, family history of hereditary childhood sensorineural hearing loss, craniofacial abnormalities, and congenital syndromes and infections known to be associated with hearing loss. It recommends the use of a one- or two-step validated protocol, such as OAEs testing with ABR testing done if OAEs testing is failed. Newborns failing hearing screening should receive audiologic and medical follow-up after discharge and before 3 months of age so that early intervention services can be implemented.

The Committee on Practice and Ambulatory Medicine and the Section on Otolaryngology-Head and Neck Surgery upheld prior recommendations of the American Academy of Pediatrics for newborn hearing screening and periodic hearing screening throughout childhood until 21 years of age. The committee further recommended that any child with one or more risk factors for hearing loss should receive hearing screening appropriate for developmental age with at least one comprehensive audiologic evaluation by 2 to 2.5 years of age. All children with fail results on hearing screening should undergo comprehensive audiologic follow-up. Hearing screening should be performed upon parental expression of concern regarding the child's hearing status. The committee also recommends referral for follow-up by an otolaryngologist and pediatric audiologist when factors such as developmental and behavioral delay and problems may affect the validity of routine hearing screening. When hearing loss is documented, follow-up with the implementation of early intervention should involve the specialties of otolaryngology, audiology, speech-language pathology, and genetics.

The guidelines promulgated by the American Speech-Language-Hearing Association for pure-tone hearing screening in children between 3 years of age and third grade are as follows: pure-tone AC screening at 1000, 2000, and 4000 Hz if acoustic admittance testing is part of the identification protocol and also at 500 Hz (provided ambient noise levels do not exceed permissible levels) if acoustic admittance screening is not part of the identification protocol. The screening level is 20 dB HL at all frequencies. A child must pass all frequencies in both ears to pass the hearing screen; any other result is a fail result. All screening failures must be rescreened within 2 weeks, preferably within the same test session after removal and repositioning of the earphones and reinstruction. A child with pure-tone hearing screening failure should be referred for an audiologic evaluation.

A very diverse range of protocols has been used for hearing screening in the elderly, in whom the prevalence of sensorineural hearing loss is high. A commonly employed approach to hearing screening in the elderly involves the AudioScope (Welch Allyn, Skaneateles Falls, NY), a hand-held otoscope that also can be used for pure-tone AC hearing screening at 500, 1000, 2000, and/or 4000 Hz at the level of 20, 25, and/or 40 dB

HL. The highest sensitivity (over 90%), with good specificity (about 70 to 80%), is achieved with 2000 Hz at 40 dB HL. Some studies suggest that individuals who fail pure-tone hearing screening at this level are more likely to go for audiologic follow-up than individuals who fail at lower levels. Another approach to geriatric hearing screening is the 10-item screening version of the Hearing Handicap Inventory for the Elderly (HHIE), which is a self-administered questionnaire that was developed to examine the effects of hearing impairment on social and emotional adjustment. A score of at least 10 (scale of 0, associated with no handicap, to 40, associated with maximum handicap) suggests that the individual perceives that he or she has a hearing handicap and should be referred for audiologic rehabilitative follow-up. Some protocols for hearing screening in the elderly employ both approaches.

114.8 Behavioral Audiologic Testing in the Pediatric Population

Generally, by 6 months, infants begin to localize to sound by turning their head. The use of visual reinforcement audiometry (VRA) in children who are developmentally between 6 months and 2.5 years of age is based on the emergence of this auditory developmental milestone. With VRA, auditory stimuli are presented through a loudspeaker in a sound-treated audiometric booth. A toy that lights up (sometimes it also makes noise) on top of the speaker usually resides within a smoked plastic enclosure and does not become active (illuminated with or without noise) until the audiologist presses the control button. A limitation of VRA in sound field is that the thresholds represent the hearing sensitivity only for the better ear, so VRA usually fails to detect a unilateral hearing loss. Pure-tone AC testing through earphones (traditional or insert earphones) may be employed in VRA in many children within this range who are developmentally older (perhaps about 1 year of age or more). Conditioning would be accomplished in a manner similar to that for auditory stimulus presentation through a speaker. The use of traditional or insert earphones in VRA allows an ear-specific assessment.

Play audiometry generally is performed in children who are developmentally between 2.5 and 4 years of age. Traditional or insert earphones are used for AC testing, allowing ear-specific assessment, and the bone vibrator is used for BC testing. If only one audiologist is doing the hearing testing, a screening audiometer is used, the earphones are placed on the table, and a tone at a moderately intense level is presented; the audiologist then guides the child to perform a task such as throwing a block into a box. Any behavioral task can be employed, such as building a pyramid, stacking rings on a peg, or even clapping or slapping the audiologist's hand. SRT testing often can be accomplished by using a smaller set of spondaic words that are intended for young children or by using spondaic words for which there are picture or toy representations. Supra-threshold SRT may be accomplished by using word lists with vocabularies developed specifically for the assessment of young children.

Hearing testing in older children usually can be accomplished with conventional audiometry involving hand-raising responses to sound presentations.

114.9 Vestibular Testing

The basic vestibular test battery includes videonystagmography (VNG), which has largely replaced electronystagmography (based on recordings of the corneoretinal potential), sinusoidal harmonic acceleration (SHA) testing, computerized dynamic platform posturography (CDPP) testing, and vestibular evoked myogenic potential (VEMP) testing. Both VNG and SHA testing are based on the vestibulo-ocular reflex (VOR).

The cristae ampullares, the sensory receptors of the ampullae of the semicircular canals in the vestibular labyrinth, detect angular acceleration (head turns in the horizontal and/or vertical planes). The right and left horizontal semicircular canals detect angular acceleration in the horizontal plane. Detection of angular acceleration in the vertical planes is accomplished by pairing of the left posterior semicircular canal and right anterior semicircular canal, which are in parallel planes, and by pairing of the right posterior canal and left anterior semicircular canal. When an individual is standing so that the head is upright, the electrical activities generated by the cristae ampullares of the right and left horizontal (lateral) semicircular canals are equal. With head turn to the right (right angular acceleration), the endolymph within the membranous labyrinth of both horizontal canals lags the head turn because of inertia, and its movement is in the opposite direction (leftward). Because the location of the utricle is medial to each of the horizontal canals, the endolymph in the right horizontal canal moves toward the right utricle (utriclepetal) and the endolymph in the left horizontal canal moves away from the left utricle (utriclefugal). Utriclepetal stimulation will result in bending of the kinocilia of the hair cells in the crista ampullaris of the right horizontal semicircular canal toward the utricle in the right labyrinth, resulting in increased electrical discharge from that canal; additionally, the utriclefugal stimulation will result in bending of the kinocilia of the hair cells of the left horizontal semicircular canal away from the utricle in the left labyrinth, resulting in decreased electrical discharge from that canal. Therefore, the right vestibular nerve is excited, whereas the left vestibular nerve is inhibited. The increased electrical activity from the right vestibular nerve is transmitted to the right vestibular nuclei and then through several neurons to lateral rectus extraocular muscle of the left eyeball and to the medial rectus extraocular muscle of the right eyeball. The activation of these muscles moves the eyes slowly to the left. This slow eye movement to the left is facilitated by inhibition of the left vestibular nerve. This chain of events describes the VOR, the purpose of which is to maintain visual fixation on an object through compensatory eye movements when the head turns.

At the end of the VOR, when the slow eye movement deviates from the midline to a critical extent, a central process is triggered that moves the eyes quickly to the right to return the eyes to midline. This fast movement is a saccade. The combination of the slow-phase eye movement in one direction (away from the head movement) followed by a fast-phase saccade in the direction opposite that of the slow-phase eye movement is termed nystagmus, which is said to beat in the direction of the fast phase (saccade). Thus, head turn to the right yields slow eye movement to the left, which, if the deviation is great enough, triggers a saccade to the right, yielding right-beating nystagmus. The slow-phase velocity (SPV) is the physiologic component of

eye movement, and the saccade is the corrective phase of the eye movement. In normal individuals, the amplitude of the VOR is greatest in a dark environment and least in a light environment.

Each of the three semicircular canals in each labyrinth responds best to head rotation in its plane. In this way, the semicircular canals translate head rotation direction in the three-dimensional space.

Nystagmus can be induced in a normal person when warm or cool water or air is injected into an ear canal. The injection of warm water into the right ear canal causes the endolymph in the right horizontal semicircular canal to expand and rise, thereby moving in a utriculopetal direction. Thus, the electrical discharge from the right horizontal semicircular canal is increased relative to the electrical discharge from the left horizontal semicircular canal. Ultimately, the left lateral rectus and right medial rectus muscles are activated, so the slow phase is to the left and the fast phase is to the right, consistent with right-beating nystagmus. The injection of cool water into the right ear canal causes the endolymph in the right horizontal semicircular canal to contract, become denser and falling, thereby moving in an utriclefugal direction. Thus, the electrical discharge from the right horizontal semicircular canal is decreased relative to the electrical discharge from the left horizontal semicircular canal. Because the asymmetry in electrical discharge from the right and left canals favors the left side, ultimately the right lateral rectus muscle and the left medial rectus muscle are activated, so both eyeballs are pulled slowly to the right. When the slow eye movement to the right exceeds a certain point, a central process is triggered that moves the eyes quickly to the left to return the eyes to midline. Thus, the injection of cool water in the right ear yields slow eye movement to the right, and then a fast phase to the left, yielding left-beating nystagmus.

Note that in the vestibular system, a peripheral disorder is one that affects the vestibular labyrinth and/or the vestibular nerve. The vestibular nuclei are considered to be part of the central vestibular system. A left peripheral vestibular lesion reduces the electrical activity generated by the crista ampullaris of the left horizontal canal, in comparison with the electrical activity generated by the crista ampullaris of the right horizontal canal. The asymmetry in electrical discharge between the right and left sides favors the right side, so the right vestibular nerve is excited, and the chain of events is similar to that described for warm water stimulation of the right ear canal. Thus, left-sided Meniere disease causes a slow-phase eye movement to the left and fast-phase eye movement to the right; this represents right-beating nystagmus.

114.9.1 Electronystagmography and Videonystagmography Standard Battery

In electronystagmography (ENG), electrodes are placed on the outer canthus of each eye and a ground electrode is placed on the middle of the forehead (electrodes are also placed above and below one eye if eye movements are recorded in the vertical plane). ENG is based on the corneoretinal potential. The eyes have an electrical potential (corneoretinal potential) whereby the cornea has a positive electrical charge and the retina has a

negative electrical charge. The electrical potential difference between the cornea and retina makes the eye behave like a dipole. When horizontal eye movements are recorded, the noninverting electrode is placed on the outer canthus of the right eye and the inverting electrode is placed on the outer canthus of the left eye. When the eyes move to the right, the noninverting electrode detects a large positive charge; the positive cornea moves away from the inverting electrode, which therefore detects a smaller positive charge that is inverted to become a small negative charge. The resultant charge is positive. Thus, rightward eye movement is associated with a positive charge, and the pen of the device records an upward deflection. When the eyes move to the left, the noninverting electrode detects a small positive charge (because of dipole movement), and the inverting electrode detects a large positive charge that is inverted to become a large negative charge. The resultant charge is negative. Thus, leftward eye movement is associated with a negative charge, and the pen of the device records a downward deflection. □ Fig. 114.13 shows right-beating and left-beating nystagmus for an ENG recording.

Many vestibular clinics have adopted video recording techniques in place of the corneal retinal potential recording techniques in ENG devices. VNG devices substitute video eye tracking for measurement of the corneal retinal potential, so VNG testing is done without electrodes. The video eye tracking uses a video camera to measure pupil position and gaze angle. Generally, with VNG, the patient wears goggles within which a camera(s) is mounted. The goggle lens acts like a mirror to reflect the image of the pupil to the infrared camera, the output of which is fed to a computer (for analysis of the eye movements) and to a video monitor (for direct observation of the eye movements). Based on the reflection from the cornea, the x- and y-coordinates of the center of the pupil then are used to determine eye position and angle of gaze.

Clinics increasingly have adopted VNG testing in place of ENG testing because video eye tracking is more convenient than the use of electrodes. Additionally, VNG does not require time for light or dark adaptation, as does ENG. Other advantages of VNG over conventional ENG include increased accuracy of saccade velocity measurements, absence of muscle artifacts and electrical interference, and stability of the recording over time. VNG testing also can be performed in many blind individuals who lack or have an insufficient corneal retinal potential. Calibration must be accomplished at several points through the ENG test battery but is generally necessary only at the beginning of VNG. Regarding the magnitude of the SPV, the interpretation is very similar for ENG and VNG. □ Fig. 114.14 shows the results of a VNG test battery for a patient.

Saccade Test

Saccades originate from the frontal eye field of the cortex, which projects to the contralateral pontine paramedial reticular formation. Neural activity then is transmitted through neurons to the ipsilateral abducens nucleus (ultimately to the ipsilateral lateral rectus muscle) and to the contralateral oculomotor nuclei (and ultimately to the contralateral medial rectus muscle). Thus, a left saccade is controlled by the right frontal eye field, left pontine paramedial reticular formation, left abducens nucleus to the left lateral rectus muscle, and right oculomotor

Fig. 114.13 Electronystagmography (ENG) recording (horizontal channel) showing (a) right-beating nystagmus and (b) left-beating nystagmus. (a) The diagonal line on the right side of any vertical line shows that the eye movement is slowly to the left (slow phase) because the pen deflection is downward from the top of the vertical line; the vertical line that follows, a rapid upward deflection, shows that the eye movement is quickly to the right (fast phase), bringing the eyes back to midline. Because the fast component is to the right, it is labeled as right-beating nystagmus. (b) The diagonal line on the left side of the vertical line shows that the eye movement is slowly to the right (slow phase). The steep downward vertical line that follows shows that the eye movement is then quickly to the left (fast phase), bringing the eyes back to midline. Because the fast component is to the left, it is labeled left-beating nystagmus. A quick method for determining beating direction is to look at a vertical line and a diagonal line beginning at the top of the vertical line; if that diagonal line is on the right side of the vertical line, then the nystagmus is right-beating; if the diagonal line is on the left side of the vertical line, the nystagmus is left-beating.

nuclei to the right medial rectus muscle. The saccade test usually involves a light bar. The patient is instructed to quickly look between two targets (without head turns) in the horizontal and vertical planes. The tracing of the saccade waveform can be obtained in VNG as well as ENG; it shows rectangular waves in normal individuals. The VNG printout for the saccade test shows (1) peak SPV as a function of degrees from the midline, (2) accuracy of the saccade (degree of overshoot or undershoot) as a function of degrees from midline, and (3) latency of the saccade (time from the onset of the target to the onset of the eye movement) as a function of degrees from midline. The latency parameter is more susceptible to aging effects. Saccade test results for a patient are shown in □ Fig. 114.14. Abnormalities on saccadic testing, such as saccadic dysmetria (overshoot or undershoot of saccades, primarily affecting

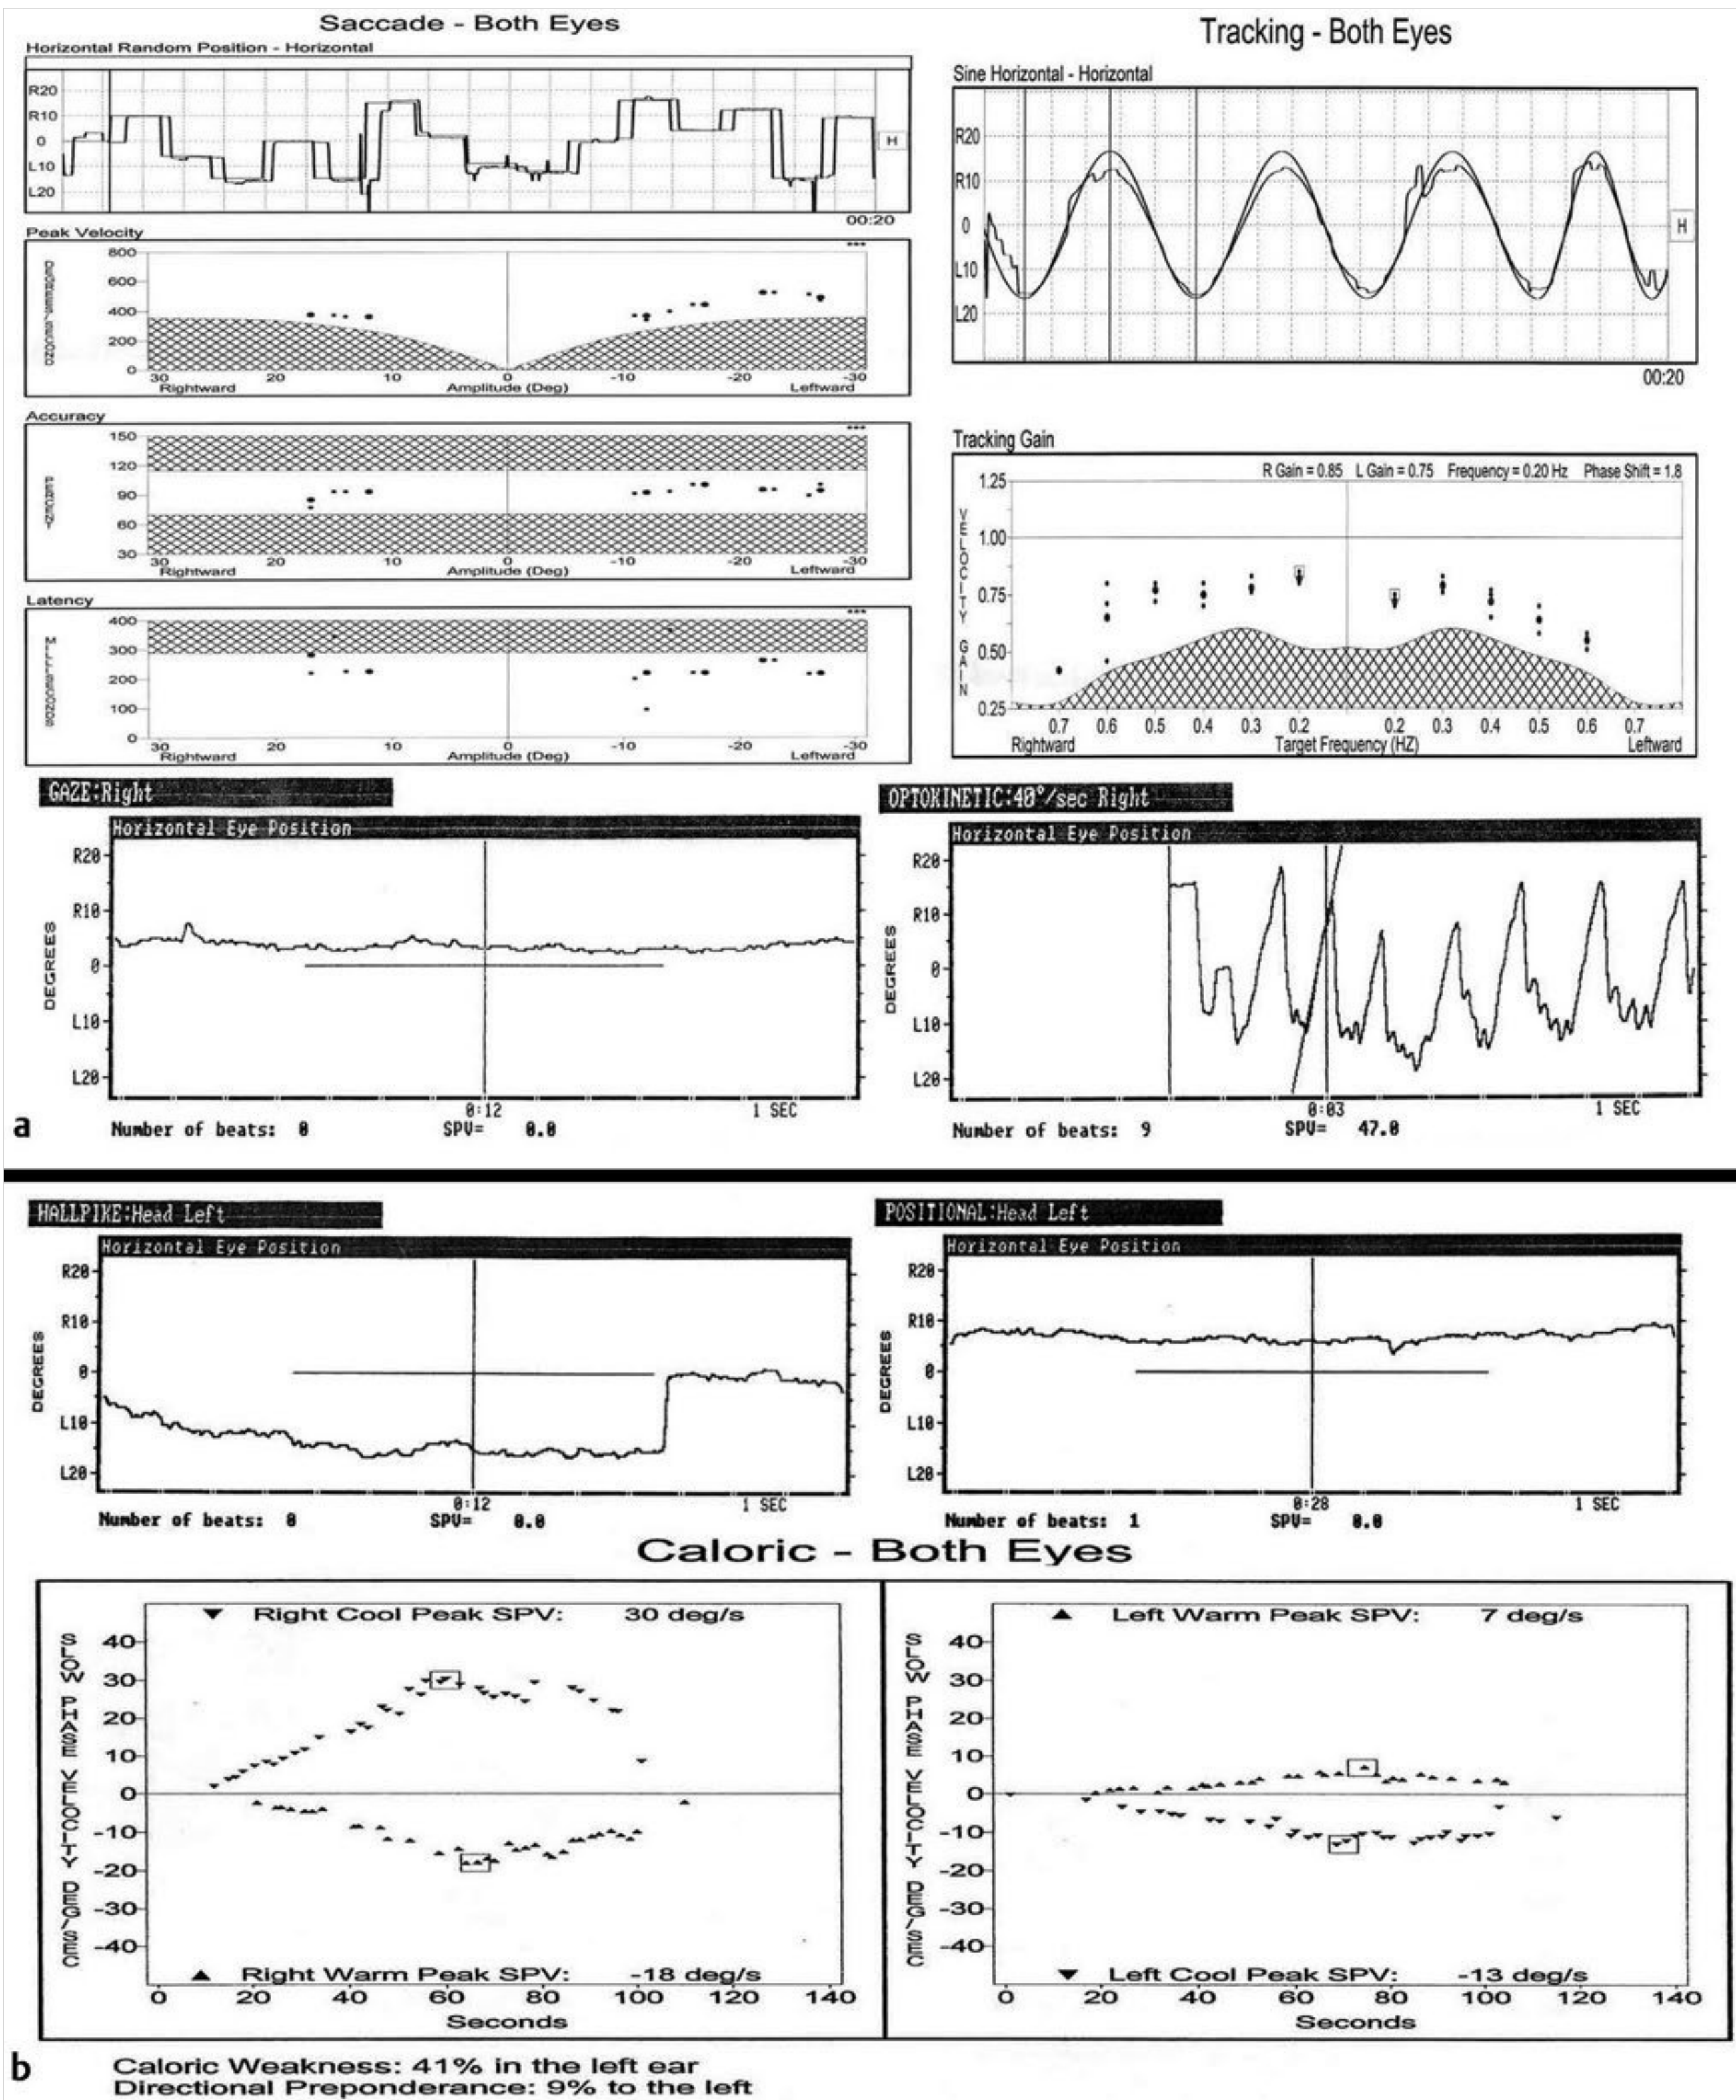

Fig. 114.14 Videonystagmography (VNG) test results. (a) Saccadic tracking (slow-phase velocity [SPV], accuracy, and latency) is within normal limits in this patient. Gaze testing (shown only for gaze right) reveals no nystagmus for gaze center, left, or right. Pendular tracking is within normal limits (see smooth sinusoidal curves and tracking gain within normal limits). (b) Hallpike maneuver produced no nystagmus with head right or left (only head left shown). Positional testing produced no nystagmus with head supine, right, left, or hanging (only head left is shown here). Bithermal calorics revealed a total right ear SPV of 48 degrees (30 minus -18) and a total left ear SPV of 20 (7 minus -13). Unilateral weakness (%) is calculated as $[(48 - 20)/(48 + 20)] \times 100 = 41\%$ weakness in the left ear in this case. Directional preponderance (DP; %) reveals a total right-beating nystagmus of $[-(-18) + 7] = 25$ degrees per second and a total left-beating nystagmus of $(30 + 13) = 43$ degrees per second, so the DP is $(25 - 43)/(25 + 43) \times 100 = -35\%$ (DP to the left, within normal limits). The caloric findings are consistent with left peripheral vestibular pathology. A left acoustic neuroma was confirmed at surgery.

accuracy), saccadic slowing (SPV abnormally reduced), and delayed saccades (abnormally increased latencies), may be consistent with central nervous system disorder. Fatigue, inattention, and drug effects need to be ruled out with saccadic slowing and delayed saccades.

Smooth Pursuit (Tracking) Test

The smooth pursuit system enables the tracking of a target moving slowly and smoothly in a sinusoidal manner. The smooth pursuit system maintains the image of the target on the fovea during the sinusoidal movement of the target. The origin of smooth pursuit eye movements is the parieto-occipital visual association area of the cerebral cortex ipsilateral to the direction of movement of a target. Thus, visual pursuit of a target slowly moving to the left is controlled by the left hemisphere. Neural activity from the parieto-occipital visual association area of the cerebral cortex is transmitted through neurons to the ipsilateral pontine paramedian reticular formation, and then to the ipsilateral abducens nucleus (and ultimately to the ipsilateral lateral rectus muscle) and contralateral abducens nucleus (and ultimately to the contralateral medial rectus muscle). The patient is instructed to visually follow a light target moving sinusoidally (back and forth), usually on a light bar. The tracing of the smooth pursuit waveform can be obtained with VNG as well as ENG; it shows a smooth, sinusoidal waveform in normal individuals. With VNG, the measures of interest are (1) velocity gain (peak eye velocity divided by peak target velocity) as a function of frequency for rightward and leftward target movement and (2) phase angle (degree to which eye movement lags or leads target movement) as a function of frequency in each direction. Smooth pursuit test results for a patient are shown in □ Fig. 114.14. Bilateral saccadic pursuit, manifested by reduced velocity gain (<0.2), may be consistent with a central nervous system disorder; drug effects, inattention, and lack of understanding of the instructions must be ruled out. Unilateral saccadic pursuit, manifested by asymmetry in velocity gain, is a nonlocalizing finding. Unilateral saccadic pursuit may be consistent with acute spontaneous nystagmus associated with an acute peripheral vestibular lesion; in this case, the saccadic pursuit is impaired, with visual pursuit in the direction of the fast phase of the spontaneous nystagmus.

Optokinetic Test

In traditional ENG testing, the optokinetic eye movement system was presumed to be involved when an individual attempted to follow visual targets moving across the visual field, such as a display of vertical stripes moving with a constant velocity toward the right or toward the left. With a light bar, the stimuli are a series of lights (like pulses) moving to the right followed by a series of lights (like pulses) moving to the left. The patient is instructed to watch the images without head turns. The use of a monitor or projection system enables a much greater proportion of the visual field (ideally, at least 90%) to have repeated moving stimuli; this kind of stimulus is more effective than the light bar stimulus, which involves a limited visual field. Studies suggest that the nystagmus recorded on the optokinetic test includes a smooth pursuit as well as an optokinetic component. The smooth pursuit component is minimized

during the “optokinetic after nystagmus” component whereby recording continues in darkness after about 30 seconds of recording in the light condition. The instructions influence the nature of the response in optokinetic testing. If the patient is instructed to follow a single target in the optokinetic visual field, the smooth pursuit component is emphasized in the response; the response to this instruction is called “look nystagmus.” If, however, the patient is instructed to stare at the center and attempt to count the number of targets passing by, the smooth pursuit component is minimized, and the optokinetic component is maximized in the response; the response to this instruction is called “stare nystagmus.” The parameter of interest for optokinetic nystagmus (look or stare) is the velocity gain as a function of time for each stimulus (e.g., 40 degrees per second for the images moving left and 40 degrees per second for the images moving right). □ Fig. 114.14 shows the results of optokinetic testing for a patient. Bilaterally reduced optokinetic nystagmus, manifested by bilaterally reduced velocity gain, may be consistent with a central nervous system disorder; drug effects, visual impairment, and inattention must be ruled out. Unilaterally reduced optokinetic nystagmus, manifested by asymmetric velocity gain, may be consistent with a central nervous system disorder or may reflect the presence of spontaneous nystagmus. The clinical significance of abnormal optokinetic findings is strengthened when they are obtained in conjunction with other abnormal ENG/VNG findings. Aging also increases the likelihood of abnormal findings on optokinetic testing. These limitations reduce the clinical utility of this ENG/VNG optokinetic subtest.

Gaze Test

During the gaze test, the patient sits with the head erect and looks straight ahead at a light target on the light bar at different points, such as, midline, 25 to 30 degrees to the right of midline (horizontal right), 25 to 30 degrees to the left of midline (horizontal left), 25 to 30 degrees above midline (vertical up), and 25 to 30 degrees below midline (vertical down). The presence of spontaneous nystagmus is established by examining the recordings of the eyes midline with vision and also with vision occluded (by “shuttered” goggles in VNG or by eye closure in ENG). The VNG printouts show the SPV over time (waveform). □ Fig. 114.14 shows the results of gaze testing for a patient. In normal individuals, spontaneous nystagmus is absent or minimally present during the gaze midline (or with vision occluded). The presence of significant spontaneous nystagmus is a nonlocalizing finding. If spontaneous nystagmus is present and is unchanged in intensity and direction with eccentric gaze positions, then the gaze nystagmus reflects spontaneous nystagmus; if it changes in intensity or direction with gaze position, then gaze nystagmus also is present.

Bilateral gaze nystagmus that is right-beating for right gaze and left-beating for left gaze, and that has an intensity in the nonoccluded vision condition that is undiminished compared with that in the occluded vision condition, may be consistent with central nervous system pathology, usually brainstem pathology; drug effects, however, must be ruled out.

If significant spontaneous nystagmus is present and gaze nystagmus beats in the same direction as the spontaneous nystagmus in both eccentric gaze positions, then the possibility of a

pattern reflecting Alexander's law should be considered, whereby the nystagmus intensity increases with gaze in the direction of the fast phase of the spontaneous nystagmus. For example, a patient demonstrates left-beating spontaneous nystagmus and left-beating nystagmus on right and left horizontal gaze that is strongest for the left horizontal gaze (because of the additive effects of combining spontaneous and gaze nystagmus when the direction of the gaze is in the direction of the spontaneous nystagmus) and weakest for the right horizontal gaze (because the gaze is in the direction opposite that of the spontaneous nystagmus). Such pattern is usually consistent with peripheral vestibular pathology (in this example, on the right side), although the possibility of central nervous system pathology cannot be ruled out. Horizontal unilateral gaze nystagmus refers to nystagmus for a single eccentric gaze direction; this finding may be consistent with a central nervous system disorder if its intensity in the normal visual condition is undiminished relative to that in the occluded vision condition (or the nystagmus is present in the normal visual condition but not in the vision occluded condition).

Vertical gaze nystagmus (down-beating or up-beating) may be consistent with a central nervous system disorder.

Dix-Hallpike Procedure

The Dix-Hallpike procedure usually is performed before static positional tests so that if benign paroxysmal positional vertigo (BPPV) is present, movement into the various positions during static positional testing does not fatigue the BPPV. Posterior semicircular canal BPPV can be identified with the Dix-Hallpike procedure. With the traditional maneuver, the patient sits with the head turned slowly 45 degrees to the right and with the eyes open. The clinician, who is behind the patient and has one hand at the top of the patient's head and the other hand on the patient's back, then rapidly pulls the patient back down, keeping the head in the turned position, until the patient is lying supine with the head hanging to the right over the end of the examining table. The patient is asked whether any dizziness is experienced. The nystagmus should be up-beating and torsional toward the ear that is underneath. The patient then is returned to the sitting position, and the procedure is repeated if nystagmus was present to determine if the response is fatigable. This entire procedure then is repeated with the head turned to the left (after the patient is brought back to the sitting position). The most useful parameters to examine are the SPV over time and the nystagmus waveforms. The Dix-Hallpike results for a patient are shown in □ Fig. 114.14. The classic response, consistent with posterior semicircular canal BPPV, is characterized by the following: (1) Latency of the nystagmus is less than 10 seconds; (2) the nystagmus, which develops in intensity and then declines in intensity, is transient and has a duration of less than 1 minute; (3) the nystagmus and symptoms of dizziness are fatigable on the repeated maneuver; and (4) the nystagmus is up-beating with a torsional component in the direction of the underneath ear when the patient is brought to the supine position. Thus, classic Dix-Hallpike findings are both localizing and lateralizing. The response is nonclassic if any of these features are not noted, and the results are nonlocalizing.

Static Positional Tests

With positional testing, recordings are made with the patient in various positions, including the following: (1) supine with head elevated 30 degrees, (2) supine with head turned 90 degrees to the right or right lateral (whole body right on the right side), (3) supine with the head turned to the left 90 degrees or left lateral (whole body left on the left side), and (4) head hanging (lying on the examination table with the head hanging over the end of the table). Lateral positions are preferred to the head-turned positions because the latter can elicit cervical vertigo in some individuals and neck rotation ability is restricted in some individuals. All positional testing is accomplished in the vision occluded condition (eyes closed in ENG). The patient performs mental tasking (e.g., count by twos, name animals) to prevent nystagmus suppression. If nystagmus is present in any position, then testing under visual fixation is performed to determine whether visual fixation can reduce the nystagmus; inability of visual fixation to reduce the nystagmus is suggestive of a central nervous system disorder. The parameters of interest are the SPV over time and any nystagmus waveforms. Static positional test results for a patient are shown in □ Fig. 114.14.

Positional nystagmus that is present in the eyes occluded condition (and is absent under the visual fixation condition) is considered to be abnormal if its SPV exceeds the normative cutoff value (e.g., 4 degrees per second for VNG, 6 degrees per second for ENG) for at least one position. It is a nonlocalizing (peripheral or central vestibular pathology) finding.

Horizontal positional nystagmus that is present in the eyes occluded condition and is direction-changing within a single head position in the eyes occluded condition may be consistent with a central nervous system disorder.

Positional nystagmus (any intensity) present in the eyes occluded condition and in the visual fixation condition is a pathologic, nonlocalizing finding if visual fixation significantly reduces the intensity; it is consistent with a central nervous system disorder if visual fixation fails to significantly reduce the intensity.

Vertical positional nystagmus in the eyes occluded condition is considered to be consistent with a central nervous system disorder if its magnitude exceeds the normative cutoff value (about 6 to 7 degrees per second) and visual fixation fails to reduce the intensity of the nystagmus.

Alcohol ingestion should be ruled out if (1) direction-changing geotropic nystagmus is obtained whereby the nystagmus is right-beating with the right ear down and left-beating with the left ear down (and absent in the sitting and supine positions) or if (2) direction-changing ageotropic nystagmus is obtained whereby the nystagmus is right-beating with the left ear down and left-beating with the right ear down.

Caloric Testing

Standard alternate binaural bithermal caloric testing involves the injection of cool or warm water or air directly into an ear canal with the patient supine and the head elevated about 30 degrees. Testing is done with vision occluded (eyes closed in ENG) and then in the normal visual condition (eyes open in ENG) to test for visual fixation suppression after peak SPV is

obtained in the vision occluded condition. The patient does mental tasking during the vision occluded condition to prevent nystagmus suppression. Each ear is irrigated, one at a time, with a cool stimulus or a warm stimulus (or vice versa). With water irrigation, the cool temperature is set to about 30°C and the warm temperature is set to about 44°C. With air irrigation, the cool temperature is set to about 21°C and the warm temperature is set to about 51°C. In normal individuals, the SPV of the nystagmus is within normative limits and approximately equal for the two ears for each temperature, and it is right-beating for right warm and left cool irrigations and left-beating for left warm and right cool irrigations. The parameter of greatest interest is the SPV over time for each irrigation. Caloric test results for a patient are shown in □ Fig. 114.15

The presence of bilateral weakness is assessed by looking at (1) the sum of the peak SPV across the four irrigations, (2) the sum of the peak SPV for the right ear (across the warm and cool irrigations) and the sum of the peak SPV for the left ear (across the warm and cool irrigations), and (3) the peak SPV for each irrigation. If the total peak SPV across the four irrigations is assessed, bilateral weakness is thought to be present when it is less than approximately 20 to 22 degrees per second. If the individual ear SPV (across both temperature irrigations) is assessed, then bilateral weakness is thought to be present when the peak SPV for each ear is less than about 12 degrees per second. If the SPV for each irrigation is assessed, then bilateral weakness is thought to be present when each peak SPV is less than approximately 8 degrees per second. Bilateral weakness is consistent with bilateral peripheral vestibular pathology or a central nervous system disorder. The peak SPV also is examined for the presence of hyperactive responses (>60 to 150 degrees per second) in one or both ears; the normative cutoff value differs widely among investigators but more commonly ranges between about 140 and 150 degrees per second. It is a relatively rare finding, particular when it is unilateral, and may be consistent with cerebellar dysfunction when tympanic membrane perforation and technical factors are ruled out. Some clinics also perform ice water calorics when caloric responses are absent to determine if any residual response is present with ice water stimulation.

If bilateral weakness is absent, the presence of unilateral weakness (as a percentage) is calculated with the following formula: $\{[(\text{right cool peak SPV} - \text{right warm peak SPV}) - (\text{left warm peak SPV} - \text{left cool peak SPV})] / (\text{right cool peak SPV} + \text{right warm peak SPV} + \text{left cool peak SPV} + \text{left warm peak SPV})\} \times 100$. This formula essentially is equivalent to the total peak SPV for the right ear minus the total peak SPV for the left ear, with this difference then divided by sum of the total peak SPV across all four irrigations, times 100. Unilateral weakness is abnormal if its absolute value exceeds a criterion level (20 to 25%). A significantly positive unilateral weakness indicates left ear weakness, whereas a significantly negative unilateral weakness indicates right ear weakness (peripheral vestibular pathology). Any spontaneous nystagmus should be considered in the interpretation of caloric responses.

Typically, right warm and left cool irrigations yield right-beating nystagmus, and left warm and right cool irrigations yield left-beating nystagmus. In normal individuals, the right-beating nystagmus and left-beating nystagmus are similar in magnitude (although opposite in direction). An individual has directional preponderance (DP) if the magnitudes of the caloric responses beating in one direction are stronger than those beating in the other direction. Thus, the DP (%) = $\{[-(\text{peak SPV right warm} - \text{peak SPV left cool}) - (\text{peak SPV right cool} + \text{peak SPV left warm})] / (\text{peak SPV right warm} + \text{peak SPV left cool} + \text{peak SPV left warm} + \text{peak SPV right cool})\} \times 100$. The clinical significance of DP is controversial and neither lateralizing nor localizing; however, the presence of significant DP does indicate whether the nystagmus beats more strongly in one direction than another. DP is significant if it is greater or equal to 25 to 30%. A positive DP value indicates that responses obtained from the left cool and right warm irrigations (right-beating) are stronger than the responses from the right cool and left warm irrigations (left-beating); a negative DP value indicates that the left-beating responses are stronger than the right-beating responses.

Failure of fixation suppression (%) is calculated by dividing the SPV obtained just before the effect of visual fixation is determined by the peak SPV (normal visual condition after visual fixation). This generally is measured for at least two irrigations

Fig. 114.15 Sinusoidal harmonic acceleration results in a normal patient. Note that the gain, phase, and symmetry are within the normal range at all chair oscillation frequencies.

(right and left warm or right and left cool). Complete suppression by fixation yields a fixation index near 0% whereas complete lack of fixation yields a fixation index exceeding 100%. Abnormal failure of fixation suppression greater than approximately 50 to 60% is consistent with a central nervous system disorder.

A recent study of 77 patients with unilateral peripheral vestibular pathology and 80 control subjects revealed caloric test sensitivity and specificity values of 83% and 78% respectively. The most important caloric parameter was unilateral weakness, followed by the SPV for warm irrigations, followed by SPV for cool irrigations. DP was of limited clinical importance in the differential diagnosis of unilateral peripheral vestibular pathology.

114.9.2 Sinusoidal Harmonic Acceleration

SHA testing involves measurement of the slow-phase velocity (SPV) of nystagmus induced by side-to-side sinusoidal rotations of a motorized chair in a dark room; the patient is tested (the head is tilted downward by about 30 degrees for perpendicular orientation of the horizontal semicircular canals relative to the rotational axis) with the eyes open (and performs mental arithmetic to prevent suppression of nystagmus), and recording electrodes are placed at the outer canthi of the eyes with a ground electrode on the forehead. With chair rotation in the clockwise direction, the SPV of the nystagmus is counterclockwise, and vice versa. Chair rotation typically is performed over at least five multiple sinusoidal oscillation frequencies (e.g., 0.01, 0.02, 0.04, 0.08, 0.16, 0.32, and 0.64 Hz) with peak angular velocities of 50 to 60 degrees per second. The instrumentation performs a fast Fourier transform analysis to remove the fast phase so that the eye SPVs can be reported in comparison with those of the head/chair. The parameters generally measured include phase, gain, and symmetry. Phase represents the temporal relation between SPV (degrees per second) of the eyes and SPV of the head/chair and is expressed in degrees. With a phase lead, the peak SPV of the eyes occurs before the peak SPV of the head/chair; with a phase lag, the peak SPV of the eyes occurs after the peak SPV of the head/chair. The gain parameter represents the SPV of the eyes divided by the SPV of the head/chair. Symmetry (%) refers to the difference between peak SPV of the eyes in the condition in which the chair moves clockwise (slow phase of the eye movement is in the opposite direction) and peak SPV of the eyes in the condition in which the chair moves counterclockwise (slow phase of the eye movement is in the opposite direction), referenced to the total of the maximum eye SPVs in both directions. The instrumentation printout of the rotary chair results generally displays each of these parameters as a function of chair oscillation frequency. □ Fig. 114.15 displays the SHA results from a normal individual.

Typical findings for a unilateral acute peripheral vestibular lesion such as vestibular neuritis or active Meniere disease include the following: abnormally increased phase leads, largely at the lower oscillation frequencies, and asymmetry, whereby the peak SPV in one direction (usually toward the side of the lesion) is greater than that in the opposite direction, particularly at the higher frequencies. In the case of a slowly developing peripheral vestibular lesion, such as a vestibular schwannoma, a vestibular compensation process occurs that often normalizes

results for the symmetry parameter; thus, if vestibular compensation has occurred, then the sole abnormal finding may be increased phase leads that are greatest at the lower oscillation frequencies. When abnormal findings are obtained on the symmetry measure, they can be monitored over time to see if central compensation occurs, which is correlated with a diminution of the subjective feeling of dizziness. Symmetry results need to be adjusted when spontaneous nystagmus is present; for example, a left-beating spontaneous nystagmus augments the left-beating nystagmus that occurs with right rotations and decreases the right-beating nystagmus that occurs with left rotations. The results of a recent large sample study of patients with a variety of peripheral vestibular disorders and a control group revealed that the correct classification of individuals as normal or as having unilateral peripheral vestibular impairment is best for the 0.01-Hz frequency, second best for the 0.1-Hz frequency, and third best for the 0.05-Hz frequency (the oscillation frequencies evaluation included frequencies of 0.01, 0.02, 0.05, 0.1, and 0.2 Hz at the peak velocity of 50 degrees per second). The phase parameter had the greatest diagnostic utility. SHA test sensitivity and specificity at 0.01 Hz were 84% and 64% respectively. The sensitivity and specificity of the unilateral weakness measure on caloric testing in this group were 83% and 79% respectively.

Gain often is abnormally reduced in bilateral peripheral vestibular pathology. Abnormally reduced gain has sometimes been observed in unilateral acute peripheral vestibular lesions. Very low gain results limit the diagnostic utility of other SHA parameters.

The SHA test yields information about asymmetry in the peripheral vestibular system in response to low-frequency (slow) stimulation. A benefit of the SHA test is that it furnishes information about the presence of residual caloric responses in patients who have absent response to bithermal caloric stimulation, including ice testing. Also, similar to caloric vestibular testing, the SHA test is sensitive only to pathologies that affect the horizontal semicircular canal or superior vestibular nerve. The best application of SHA testing is for the detection of bilateral vestibular pathologies; it is more challenging to detect unilateral vestibular disorders with SHA testing, which involves the simultaneous stimulation of both ears. SHA testing also has value for monitoring central compensation over time in unilateral peripheral vestibular disorders.

114.9.3 Computerized Dynamic Platform Posturography

CDPP provides an evaluation of the patient's ability to use visual, vestibular, and somatosensory/proprioceptive input to remain standing upright without swaying or falling. This ability not only depends on the reception of appropriate sensory input by the brain but also requires coordination of the muscles such that the body mass is centered over an area spanned by the feet (center of gravity [COG]); the ability to stand upright involves both sensory and motor components. Sway refers to movement in the COG and is assessed in the anteroposterior and lateral planes. Pressure sensors on the force plate(s) of the platform detect pressure changes exerted on the platform associated with sway with feet and/or body movement.

Table 114.3 Conditions for each component of the sensory organization test in computerized dynamic platform posturography

Sensory organization test	Platform, visual surround, eyes open or closed	Sensory input to the brain: visual, vestibular, somatosensory
1	Eyes open Visual surround stable Platform fixed	Visual accurate Vestibular operational Somatosensory accurate
2	Eyes closed Platform fixed	Visual absent Vestibular operational Somatosensory accurate
3	Eyes open Visual surround changes Platform fixed	Visual conflict Vestibular operational Somatosensory accurate
4	Eyes open Visual surround stable Platform moves	Visual accurate Vestibular operational Somatosensory inaccurate
5	Eyes closed Platform moves	Visual absent Vestibular operational Somatosensory inaccurate
6	Eyes open Visual surround moves Platform moves	Visual inaccurate Vestibular operational Somatosensory inaccurate

The patient stands on a platform while wearing a harness to prevent falls. A visual surround is in front and to the sides of the patient. Both the visual surround and/or the platform can move under computer control. The test is performed in the eyes open and eyes closed condition; in the eyes open condition, the test is administered under normal vision and distorted vision (the visual surround sways so that visual cues are inaccurate).

The two components of the CDPP test are the sensory organization test (SOT) and the motor control test (MCT). The SOT has six subtests (□ Table 114.3). The most difficult subtest is SOT 6 because both visual input and somatosensory input are distorted, creating sensory input conflict to the brain; balance in this subtest is dependent upon the vestibular system. Distorted input affects balance more than absence of input. The equilibrium score (%) is provided for each subtest based on the magnitude of sway. A composite equilibrium score across the subtests also is provided. The range in equilibrium scores is 0 to 100% with 0% indicating a fall and 100% indicating no sway and good stability.

□ Fig. 114.16 shows the CDPP test findings in a patient. The sensory analysis looks at the pattern of results across the SOT subtests and displays how well the patient uses somatosensory input to maintain postural control (based on a comparison of the results of SOT1 and SOT2), visual input to maintain postural control (based on a comparison of SOT1 and SOT4), and vestibular input to maintain postural control (based on SOT1 and SOT5), and the degree to which reliance on visual input is appropriate (based on SOT3 and SOT6). Higher scores indicate better performance. The COG alignment scatterplot shows the COG relative to the center of base support before each trial. In normal individuals, the COG is near the center of the base. The strategy analysis results indicate the extent to which a patient moves his or her COG around the ankle or hip to maintain postural control; the ankle strategy is dominant in normal individuals, and the less efficient hip strategy is dominant in many individuals with equilibrium problems. Unlike electromyography recordings, CDPP testing does not involve the placement

of transdermal electrodes on the body. Therefore, conclusions about ankle versus hip strategies based on CDPP findings are subject to the disadvantage of a lack of direct muscle information.

In the MCT, the platform makes sudden front-to-back or back-to-front jerk movements (translations) of small, medium, and large amplitudes. The muscle reaction latency of each foot to each of these two types of translations is reported. The MCT results also are shown in □ Fig. 114.16. Prolonged MCT latencies may be suggestive of a lesion within the long loop pathway involving the nonvestibular, spinal cord, brainstem, and/or subcortical components of the pathway. Examples of pathologies that may be associated with bilaterally prolonged MCT latencies include peripheral neuropathy and multiple sclerosis. Examples of localized brainstem lesions that may be associated with prolonged MCT latencies include stroke and cerebral palsy.

The major purpose of CDPP testing is to examine postural control in patients whose sole balance complaint is unsteadiness or unexplained falls and in patients with bilateral hypofunction, which puts them at increased risk for falls, particularly as age increases. Some have suggested such testing in all patients who experience unsteadiness or balance difficulty during periods when vertigo is absent. Thus, from the otologic perspective, CDPP essentially represents functional assessment for the purpose of planning and monitoring vestibular and balance rehabilitation to reduce the risk for and rate of falls.

114.9.4 Vestibular Evoked Myogenic Potential Testing

In the VEMP test, change in muscle tone is elicited by brief, intense acoustic stimulation and is recorded electromyographically with surface electrodes placed on the skin overlying the neck or spinal muscles. The VEMP is a vestibulocollic reflex originating in the saccule with neural transmission through the inferior vestibular nerve and descending vestibular spinal

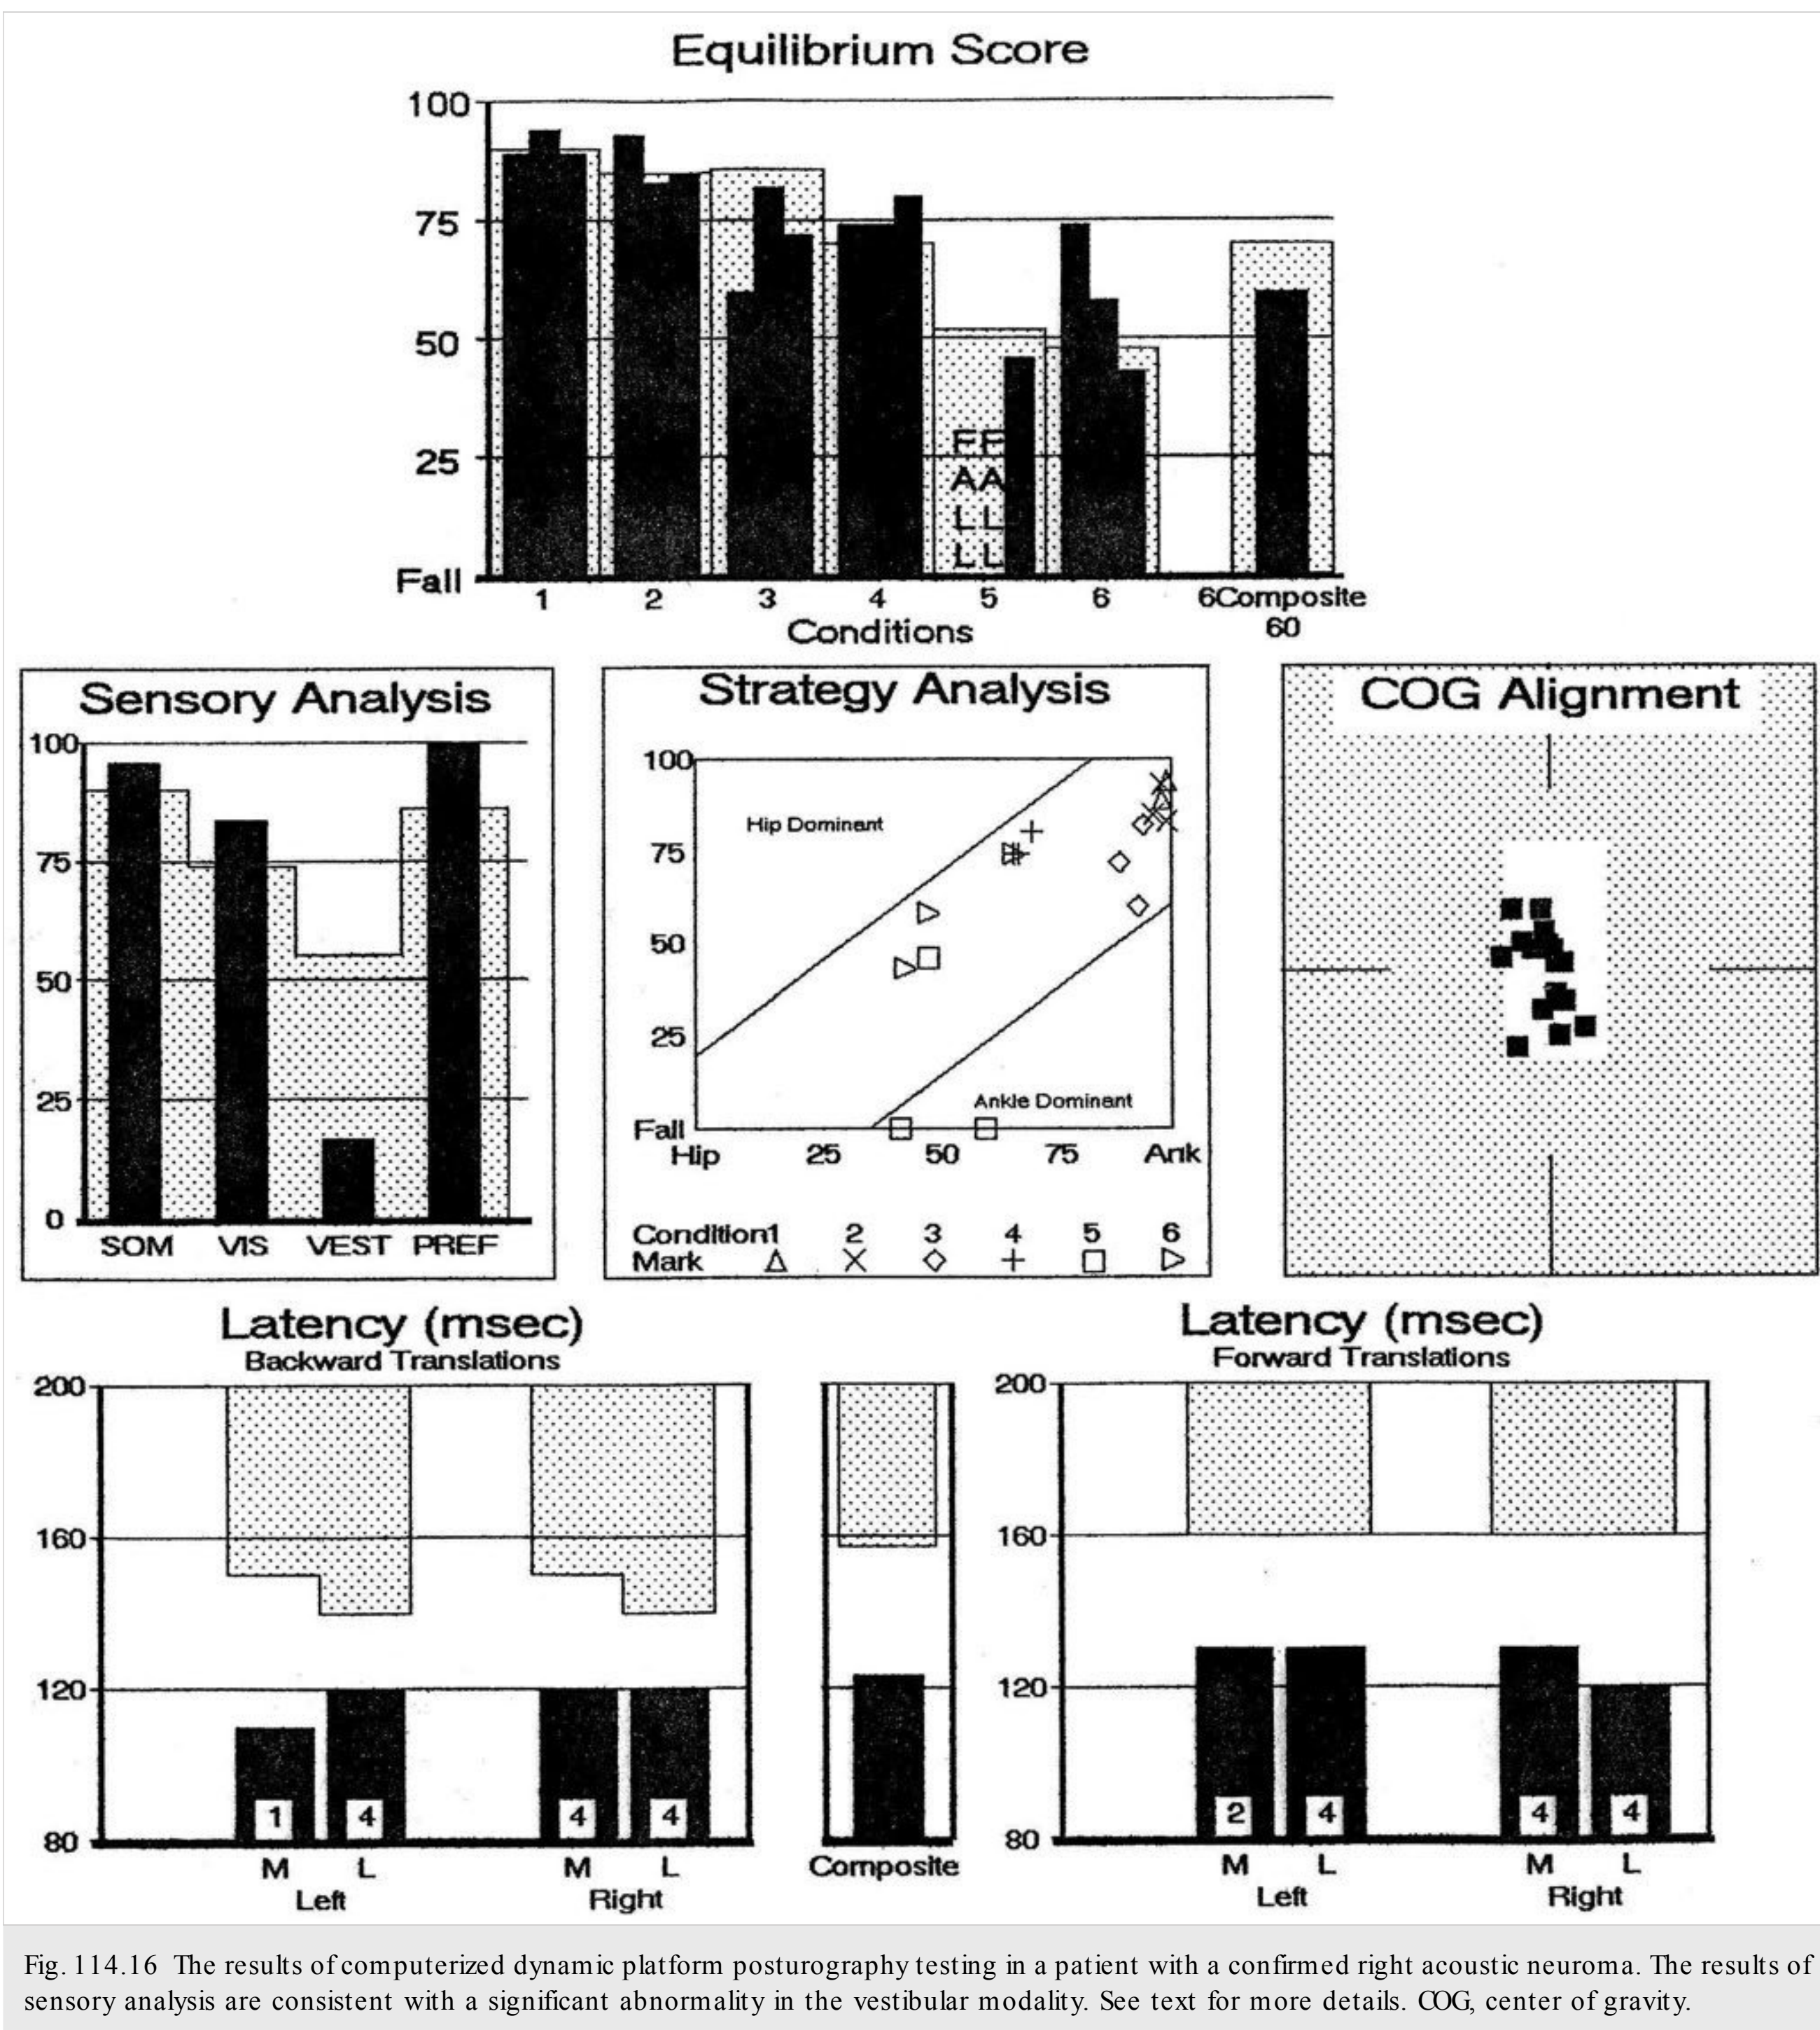

Fig. 114.16 The results of computerized dynamic platform posturography testing in a patient with a confirmed right acoustic neuroma. The results of sensory analysis are consistent with a significant abnormality in the vestibular modality. See text for more details. COG, center of gravity.

pathways that supply the neck and spinal muscles. The saccule is positioned in the labyrinth just below the anterior half of the stapes footplate, so intense sound may elicit responses from the hair cells of the maculae of the saccule, which ultimately result in muscle tone changes within a contracted muscle. The maculae of the saccule detect linear acceleration in the horizontal or vertical plane when the head and body move together as a single unit. The VEMP notably differs from an auditory evoked potential in that it can be elicited by nonacoustic (e.g., tactile) as well as acoustic stimulation and is myogenic rather than neurogenic.

Elicitation of VEMPs is optimized with tone bursts at the nominal frequency of 500 or 1000 Hz. As with auditory evoked potentials, averaging and filtering of the responses are employed. The most commonly employed electrode sites (ipsilateral to the ear receiving acoustic stimulation) involving the sternocleidomastoid muscle (cervical VEMP) are as follows: (1) noninverting (active) electrode on the upper belly of the sternocleidomastoid muscle, inverting electrode on the sternum, and ground over the sternocleidomastoid muscle; (2) noninverting electrode on the forehead, inverting electrode over the

Fig. 114.17 Vestibular evoked myogenic potential recording from a normal individual.

belly of the sternocleidomastoid muscle, and ground over the middle of the sternocleidomastoid muscle. The former montage yields an initial positive deflection that is upward (P1) and then a negative deflection (N1); with the latter montage, deflections are in the reverse direction (i.e., downward for P1 and upward for N1). □ Fig. 114.17 shows a VEMP from a normal individual. The VEMP also can be recorded from the infraorbital region; the literature for cervical VEMPs is much larger than that for infraorbital VEMPs because the infraorbital VEMP is an emerging technology. The origins of infraorbital VEMPs currently are believed to be the utricle and superior vestibular nerve.

In a commonly employed approach to achieve sufficient tensing of the sternocleidomastoid muscle, the patient is lying down in a supine position (typically at a 30-degree angle, as for caloric vestibular testing) and in a semirecumbent position with the neck turned maximally to the side away from the ear receiving the acoustic stimulation; the patient then lifts his or her head just off the table. Often, the ongoing electromyographic activity is monitored to ensure that muscle tension during testing remains stable. The signal stimulation period needs to be short to reduce the adverse effects of muscle fatigue on the response and to minimize the possibility that the patient will recruit other muscles to maintain the head elevation. The VEMP parameters of interest include its threshold, P1 latency, N1 latency, and the P1–N1 (VEMP) amplitude in each ear. The interaural latency difference is measured based on P1 and N1. The asymmetry ratio (%) is calculated as follows: [VEMP amplitude (right – left)] divided by [VEMP amplitude (left + right)] x 100. For cervical VEMPs in a normal adult, the VEMP threshold occurs at about 70 to 90 dB HL, P1 latency is about 12 to 13 milliseconds, and N1 latency is about 22 to 23 milliseconds. Normative data based from the individual testing center are used to define the upper limits of normalcy for these parameters. Conductive hearing impairment generally abolishes an AC VEMP.

A major application of the VEMP has been to evaluate patients with superior semicircular canal dehiscence. The VEMP threshold may be significantly better (i.e., lower) in patients with superior semicircular canal dehiscence than in normal individuals because the dehiscence shunts sound energy away from the cochlea through the vestibular labyrinth.

The VEMP is absent or its amplitude is reduced in approximately 80% of patients with vestibular schwannoma, reflecting involvement of the inferior vestibular nerve, and it may be abnormal even when caloric findings are normal; low specificity rates around 50% have been reported.

Study findings suggest that absent VEMPs or VEMPs with decreased amplitude may occur in patients with vestibular neuritis when the inferior vestibular nerve is involved.

A limitation of the VEMP affecting test–retest reliability and intersubject comparisons is normalization of muscle tone. Obtaining a prestimulus, baseline electromyogram to normalize the electromyogram helps alleviate this limitation but does not overcome it because of muscle tone changes during acoustic stimulation. Maturation and aging affect the VEMP, so normative data for the various age groups need to be obtained. Given the sensitivity and specificity rates in the literature for the various disorders, and the great diversity in recording, stimulus, and instrumentation parameters, VEMPs should be interpreted cautiously and in conjunction with other vestibular, otologic, and audiological findings.

115 Radiology of the Temporal Bone

George Alexiades

115.1 Introduction

Temporal bone imaging is an important diagnostic tool for the otolaryngologist–head and neck surgeon. The two main imaging modalities used today are computed tomography (CT) and magnetic resonance (MR) imaging. The strength of CT lies in optimal viewing of the bony architecture of the temporal bone, whereas MR imaging is excellent at delineating soft-tissue structures. MR imaging does not image bone well at all.

115.2 Computed Tomography

CT is the process of using a computer to create an image from multiple “slices” of X-rays. The early CT machines were known as CAT (computed axial tomography) scans because they generated images only in the axial plane. Newer machines are able to gather the data and reformat the image in any plane, or even create a three-dimensional image.

In temporal bone imaging, CT is excellent for showing the bony architecture. (From this point forward, all references to CT scans will be with the assumption that they are weighted for bone—i.e., the contrast and brightness of the image were changed to reveal bony architecture while showing all soft-tissue densities as a medium gray.) This is in contrast to typical soft tissue–weighted CT scans, which can show different densities of soft tissues; however, they tend to overexpose bone and obscure its architecture. On the temporal bone scan, bone

and highly calcified tissue will appear white, air will appear black, and soft tissue and fluid will appear gray (□ Fig. 115.1).

The temporal bone is actually made up of five different bones: the squamous bone, petrous bone, mastoid, tympanic ring, and styloid process. The squamous bone is the lateral flat bone to which the temporalis muscle attaches. The petrous portion comprises the medial pyramidal bone, which houses the otic capsule and middle ear space. The mastoid comprises the lateral aerated portion of the temporal bone. The tympanic ring is a U-shaped bone that forms the anterior, inferior, and posterior walls of the external auditory canal. The tympanic ring articulates with the squamous bone anteriorly (forming the tympanosquamous suture) and with the mastoid bone posteriorly (forming the tympanomastoid suture). Finally, the styloid process arises out of the inferior aspect of the temporal bone and serves as an excellent landmark for the stylomastoid foramen, through which the facial nerve exits the temporal bone.

In assessing temporal bone CT scans, it is important to view the bone globally before focusing on the pathology. The lifelong history of the temporal bone can be deduced by its characteristics on the scan. The three main features of the temporal bone to assess on a CT scan are its development, pneumatization, and aeration.

Development refers to the presence, absence, or malformation of the labyrinthine structures: the cochlea, semicircular canals, vestibule, and internal auditory canal. In a well-developed bone, these structures will all appear normal, signifying normal development of the ear in utero (weeks 3 to 16 of gestation).

Fig. 115.1 Axial computed tomographic scans of the left temporal bone. The scan on the left is a more superior cut. A, antrum; B, middle cranial fossa; C, posterior cranial fossa; D, subarcuate artery; E, superior semicircular canal; F, posterior semicircular canal; G, internal auditory canal; H, vestibule; I, lateral semicircular canal; J, vestibular aqueduct.

Fig. 115.2 Axial computed tomographic scans of the left temporal bone. The cuts are more inferior than the cut in □ Fig. 115.1, and again the scan on the left is a more superior cut. A, labyrinthine segment of facial nerve; B, geniculate ganglion; C, tympanic segment of facial nerve; D, head of malleus; E, body of incus; F, sigmoid sinus; G, petrous apex; H, cochlea; I, manubrium of malleus; J, long process of incus; K, external auditory canal; L, stapes suprastructure (very faint) and footplate.

Fig. 115.3 Axial computed tomographic scans of the left temporal bone. These are more inferior cuts, and again the scan on the left is a more superior cut. A, foveate depression (gasserian ganglion lies within it); B, basal, middle, and apical turns of the cochlea; C, mastoid air cells; D, petrous carotid artery; E, temporomandibular joint; F, descending facial nerve; G, cochlear aqueduct.

Pneumatization refers to the presence or absence of air cells in the mastoid. A well-pneumatized bone will show extensive air cells in the mastoid and minimal bone marrow in the mastoid tip. Oftentimes, there is pneumatization of the petrous apex. Pneumatization occurs from birth until early adolescence and is

inhibited by frequent episodes of otitis media or prolonged serous otitis media. However, inhibition can be reversed by ventilating the middle ear space with tubes. Finally, aeration refers to the status of the air cells present—whether they are filled with air or fluid. This refers to the short-term status of the ear.

Fig. 115.4 Coronal computed tomographic scans of the left temporal bone, moving in an anterior to posterior direction (left to right). A, cochlea; B, malleus; C, external auditory canal; D, middle cranial fossa; E, internal auditory canal; F, vestibule; G, superior semicircular canal; H, round window niche; I, lateral semicircular canal; J, descending facial nerve.

An ear can have poor pneumatization and normal aeration, which would signify frequent ear infections during childhood that the patient is no longer experiencing. Conversely, a well-pneumatized temporal bone that is poorly aerated signifies a current problem in the ear, without necessarily a chronic history of infections.

□ Fig. 115.1, □ Fig. 115.2, and □ Fig. 115.3 show all the major landmarks in the temporal bone through a series of axial images as one progresses in a superior to inferior direction. □ Fig. 115.4 shows coronal cuts through the temporal bone. It is important to note that a CT scan shows the bony anatomy of the ear and that these structures are identified as such. The membranous structures of the inner ear lie within these bony structures. The vestibule is the central bony chamber that houses the utricle and saccule and that the semicircular canals enter. The internal auditory canal is the bony canal through which the facial, cochlear, and superior and inferior vestibular nerves all course on their way from the brainstem to the otic capsule. The vestibular aqueduct is a bony channel that houses the endolymphatic duct as it courses to the endolymphatic sac. Finally, the cochlear aqueduct is a bony channel that lies parallel and inferior to the internal auditory canal and courses from the cerebellopontine angle to the basal turn of the cochlea at the round window. It does not house any structures but is often patent in younger persons and serves as a tract for inflammation in the cochlea and subsequent hearing loss in patients with meningitis, which explains why there is preferential ossification of the cochlea at the basal turn in these instances.

Cholesteatoma is one of the more common diagnoses for which a CT scan is obtained. The diagnosis of cholesteatoma is based on the physical examination, and the CT scan serves only to delineate its extent. Only in infrequent cases can a definitive diagnosis of cholesteatoma be made on a CT scan. □ Fig. 115.5 shows an axial and a coronal cut through a temporal bone with cholesteatoma. Here, scalloping of the bone is clearly evident, which is a hallmark of cholesteatoma. Erosion of the otic capsule is another sign of an erosive lesion. Ossicular erosion can be seen in chronic otitis media and cannot be used for the diagnosis of cholesteatoma.

In addition, a contrast agent can be used during CT to identify vascular lesions. Iodine is the contrast agent used, and care must be taken in individuals with an allergy to iodine, asthma, or renal insufficiency. MR imaging has largely replaced CT of the temporal bone with contrast because it offers much better contrast of the soft-tissue structures.

Fig. 115.5 (a) Axial and (b) coronal temporal bone computed tomographic scans demonstrating a cholesteatoma lateral to the incudomalleolar joint, with erosion of the scutum.

Fig. 115.6 Axial magnetic resonance images of normal internal auditory canals. (a) T1 before contrast. (b) T1 after gadolinium contrast (note enhancement of the sigmoid sinus and nasal mucosa). (c) T2 sequence (note that the cerebrospinal fluid spaces and globes are bright). a, cerebellum; b, mastoid; c, fourth ventricle; d, carotid artery; e, sigmoid sinus; f, cochlea; g, carotid artery; h, temporal lobe; i, cerebellopontine angle (note cochlear and inferior vestibular nerves traversing angle and entering the internal auditory canal).

Fig. 115.7 Magnetic resonance images showing a large left vestibular schwannoma that is indenting the brainstem. (a) The lesion is bright on T1 with gadolinium (arrow). (b) It is darker on T2 (arrow).

Fig. 115.8 (a) Coronal T1-weighted magnetic resonance (MR) image with gadolinium shows a cholesterol granuloma extending from the mastoid up into the temporal lobe (arrow). (b) Axial T2-weighted MR image of the same patient. Note that the lesion is bright on both T1 and T2 imaging (arrow).

115.3 Magnetic Resonance Imaging

MR imaging technology is relatively new; it was first used in humans in 1977. Unlike CT, which uses ionizing radiation, MR imaging uses powerful magnetic fields to align hydrogen atoms in the body. In temporal bone radiology, whereas CT is used to visualize the bony anatomy, MR imaging is excellent for delineating soft-tissue anatomy. Various pulse sequences can be used to increase the contrast between tissues. This depends on the time of excitation (TE) and the repetition rate (TR) of the magnetic field. Furthermore, contrast (gadolinium) can be used during MR imaging to help identify lesions with increased vascularity. MR imaging machines today typically use a 1.5-T (tesla) magnet, with 3.0-T magnets becoming more commonplace. With increased strength comes increased resolution.

The first sequence created for MR imaging was the T1-weighted sequence. This sequence has a relatively short TE and TR. In MR imaging of the brain, the cerebrospinal fluid (CSF) will appear dark, subcutaneous fat will have a higher density, and there will be good contrast between the gray and white matter. Intravenous gadolinium is often used with T1-weighted imaging to visualize neoplasms. T2-weighted imaging uses a relatively long TE and TR; as a result, CSF and other tissues with a high water content appear very bright. Fat-density tissues appear much darker on T2-weighted than on T1-weighted images; this weighting is very good for demonstrating edema in tissues. The FIESTA (fast imaging employing steady-state acquisition) sequence is a high-resolution T2-weighted imaging sequence that is often used to visualize the internal auditory canals and cerebellopontine angles to identify neoplasms, even in the absence of contrast injections. A FLAIR (fluid-attenuated inversion

recovery) sequence is created to suppress the signal of CSF. This is often useful in visualizing lesions such as multiple sclerosis plaques or in assessing whether fluid in the mastoid is CSF in cases of suspected CSF leak. Many other sequences are available for MR imaging but fall outside the scope and depth of this chapter.

One of the most common indications for ordering MR imaging of the internal auditory canals is to rule out the presence of a cerebellopontine angle lesion in the evaluation of asymmetric sensorineural hearing loss (□ Fig. 115.6). Of these lesions, vestibular schwannoma, also known as acoustic neuroma, is the most common. This is covered in depth in Chapter 134, Posterior Skull Base Diseases and Surgery. □ Fig. 115.7 shows the imaging characteristics of a typical vestibular schwannoma. The lesion is of medium density on T1 sequencing and enhances with gadolinium contrast. On T2, the lesion fades and is usually seen as a filling defect of the internal auditory canal. Similar imaging characteristics exist for meningiomas, which are also commonly found in the cerebellopontine angle, with the exception that meningiomas can be differentiated by “dural tails.” Because meningiomas arise from the dura, enhancement of the dura often extends beyond the border of the tumor. Also, meningiomas are not always based in a pattern concentric to the internal auditory canal, but may arise in a fashion eccentric to the internal auditory canal.

Cholesterol granuloma is another common lesion of the temporal bone and often arises in the petrous apex of a well-pneumatized temporal bone. In this location, obstructed air cells subsequently bleed into themselves, creating a slowly expanding mass that can be quite destructive if left untreated. Because of the presence of blood breakdown products and a high water content, cholesterol granulomas tend to be bright on T1 and T2 sequences (□ Fig. 115.8).

115.4 Roundsmanship

- CT of the temporal bone is excellent for delineating bony anatomy, whereas MR imaging is excellent for providing soft-tissue detail.
- MR imaging rule of thumb: as one goes from T1- to T2-weighted images, fat fades (becomes dark on T2) and inflammation enhances (becomes brighter on T2).

116 Diseases of the External Ear

Christopher J. Linstrom

116.1 Introduction

The typical otolaryngologist–head and neck surgeon sees many patients with infections of the external ear. The infections may be classified by location, cause, and time course as acute, subacute, or chronic. Before discussing the individual disease processes, we review the normal anatomy and physiology of the external ear.

116.2 Anatomy and Physiology

The external ear is composed of the auricle and external auditory canal (EAC). Both contain elastic cartilage derived from mesoderm and a small amount of subcutaneous tissue, covered by skin with its adnexal appendages. There is fat but no cartilage in the lobule. The auricle is derived from six hillocks, three each from branchial arches 1 and 2 (□ Fig. 116.1). During normal gestation, the cartilaginous hillocks merge to form the auricle, and with selective growth of the mandible, the auricle rises from its original position near the lateral commissure of the mouth to the temporal area. The tragus and antitragus form a partial barrier to the entrance of macroscopic foreign bodies.

The EAC canal is derived from the first ectodermal branchial groove between the mandibular (1) and hyoid (2) arches. The epithelium lining this groove contacts the endoderm of the first pharyngeal pouch, thus forming the tympanic membrane, the

most medial extent of the EAC. Connective tissue of mesodermal origin is found between the ectoderm and endoderm and becomes the fibrous layer of the tympanic membrane. Because of its origin, the EAC, including the lateral surface of the tympanic membrane, is derived from ectoderm and is lined by squamous epithelium.

The process of canalization is complete by about week 12 of gestation, at which time the canal fills with epithelial tissue. The canal ordinarily recanalizes by about week 28 of fetal life.

The outer 40% of the EAC in its anterior and inferior aspect is cartilaginous and contains a thin layer of subcutaneous tissue between the skin and cartilage. The inner 60% is osseous, is formed primarily by the tympanic ring, and contains very scant soft tissue between the skin and periosteum. The average length of the adult external auditory canal is 2.5 cm. Because of the oblique position of the tympanic membrane, the posterosuperior part of the canal is about 6 mm shorter than the anteroinferior portion. The junction of the cartilaginous and bony portions of the canal is a narrowed section termed the isthmus.

Laterally to medially, the canal curves slightly superiorly and posteriorly in a gentle 'S' shape. Three macroscopic defense mechanisms protect the EAC and lateral surface of the tympanic membrane: the tragus and antitragus, the skin with its cerumen coat, and the isthmus of the canal.

The skin of the cartilaginous canal contains many hair cells and sebaceous and apocrine glands, such as cerumen glands. Together, these three adnexal structures provide a protective function and are termed the apopilosebaceous unit. Glandular secretions combine with sloughed squamous epithelium to form an acidic coat of cerumen, one of the primary barriers to infection of the canal. An invagination of the epidermis forms the outer wall of the hair follicle, and the hair shaft forms the inner wall. The follicular canal is the space between these two structures. The alveoli of the sebaceous and apocrine glands empty into short, straight excretory ducts, which drain into follicular canals. Obstruction of any part of the ductal system predisposes to infection.

The canal is normally a self-protecting and self-cleansing structure. The cerumen coat gradually works its way past the isthmus to the lateral part of the canal and sloughs externally. Instrumentation and excessive cleansing of the canal disturb this primary protective barrier and may lead to infection. Individual variations in the anatomy of the canal may predispose some people to wax accumulation.

The canal interfaces on all but its lateral surface. Medially, it is bound by the tympanic membrane, which when intact is a good barrier to the spread of infection. The horseshoe-shaped tympanic ring separates the canal from the middle cranial fossa. The posterior bony canal serves as the anterior boundary of the mastoid cavity. Several vessels penetrate the canal, especially along the tympanomastoid suture, which may be involved in the hematogenous extension of infection from the canal to the mastoid segment. Posterior to the cartilaginous canal, dense connective tissue overlies the mastoid, which may become secondarily infected.

Fig. 116.1 The auricle is formed from six auricular hillocks, three each from branchial arches 1 and 2.

Superiorly, the canal is bound by the middle cranial fossa and inferiorly by the infratemporal fossa and base of the skull. Infections extending through the roof of the canal may extend into these structures. Anteriorly, the canal is bordered by the temporomandibular joint and the parotid gland.

The lymphatic drainage of the canal is an important channel for the spread of infection. Anteriorly and superiorly, the canal drains to the preauricular lymphatics in the parotid gland and the superior deep cervical nodes. The inferior portion of the canal drains into the infra-auricular nodes near the angle of the mandible. Posteriorly, the lymphatics drain into the postauricular nodes and the superior deep cervical nodes. The auricle and EAC receive their arterial supply from the superficial temporal and posterior auricular branches of the external carotid artery. Venous drainage from the auricle and meatus is via the superficial temporal and posterior auricular veins. The former joins the retromandibular vein, which usually divides and joins both jugular veins; the latter joins the external jugular vein but may also drain to the sigmoid sinus through the mastoid emissary vein.

Sensation to the auricle and EAC is supplied by cutaneous and cranial nerves, with contributions from the auriculotemporal branches of the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagus (X) nerves and the great auricular nerve from the cervical plexus (C2–C3). The vestigial extrinsic muscles of the ear—anterior, superior, and posterior auricular—are supplied by the facial nerve (VII).

116.3 Infectious and Inflammatory Diseases

116.3.1 Otitis Externa

Otitis externa is a spectrum of infection of the EAC. The appearance of the canal varies according to the time course of infection: acute, subacute, or chronic.

Acute otitis externa is a bacterial infection of the canal caused by a break in the normal skin/cerumen protective barrier in the milieu of elevated humidity and temperature. Acute otitis externa may be caused by anything that results in removal of the protective lipid film from the canal, allowing bacteria to enter the apopilosebaceous unit. It usually begins with itching in the canal, and scratching by the patient allows bacteria to proliferate in locally macerated skin and sets up an itch–scratch cycle. The moist environment of the canal is now a perfect medium for rapid bacterial growth. Later, pain ensues as the swollen soft tissues of the canal distract the periosteal lining of the bony canal. As the disease progresses, purulent discharge begins, and the auricle and periauricular soft tissues may become involved.

In patients in whom the disease does not resolve after treatment, a subacute or chronic form may occur. This condition represents a spectrum of disease ranging from mild drying and scaling to complete obliteration of the canal by chronically infected, hypertrophic skin.

Bacteriology

The usual pathogens responsible for acute otitis externa are *Pseudomonas aeruginosa*, *Proteus mirabilis*, staphylococci, strep-

tococci, and various gram-negative bacilli. For a mild or uncomplicated infection, culture of the canal is ordinarily not taken because it will usually demonstrate a mixed pattern of growth. For recalcitrant infections, culture may identify a predominant organism and assist in the choice of antibiotic therapy.

Natural History

The natural history of untreated acute otitis externa is one of increasing pain, swelling, and discharge from the canal. The infection may spread to the adjacent periauricular soft tissues, face, and neck. In an immunocompromised patient, what began as an isolated superficial infection of the apopilosebaceous unit of the EAC may progress to perichondritis, chondritis, cellulitis, and erysipelas. Rich lymphatic and hematogenous drainage pathways favor the spread of infection to local and regional sites in the head and neck. Few patients progress to such an advanced stage before seeking medical attention.

The natural history of chronic otitis externa is far less dramatic than that of its acute counterpart. The chronic scaling and itching may lead to repeated episodes of acute otitis externa. With time, the canal skin may become lichenified, and ultimately the canal may become completely obliterated.

Medical Evaluation

The history and functional inquiry should include information regarding duration, number of occurrences, nature and severity of pain, antecedent otologic disease, previous auricular instrumentation or trauma (especially the use of cotton-tipped applicators), and predisposing factors, such as diabetes, radiotherapy, or any condition causing immunosuppression. Any previous otologic or head and neck surgery is noted.

Pain, fullness, itching, and hearing loss are the four major symptoms of external otitis, although not every patient has each symptom.

Physical Examination

On initial inspection, redness, swelling, lateral protrusion, discharge, and evidence of cellulitis involving the periauricular tissues should be noted. Pain with distraction of the auricle is typical in the setting of otitis externa.

The canal should be thoroughly débrided and examined. Topical and local anesthesia is usually of little effect in hyperemic, macerated tissue and no substitute for reassurance and patience. The canal may be cleaned with suction, a cerumen loop, or alligator forceps. Gentleness and thoroughness in cleaning the ear are very important.

Differential Diagnosis

The differential diagnosis of external otitis is large and includes conditions with similar features, such as necrotizing otitis externa, bullous external otitis, granular external otitis, perichondritis, chondritis, relapsing polychondritis, furunculosis, and carbunculosis, as well as many dermatoses, such as psoriasis and seborrheic dermatitis. All have features in common with acute and chronic external otitis yet enough dissimilarities to be considered distinct clinical entities.

Fig. 116.2 Otitis externa, moderate acute inflammatory stage. The external auditory canal is more edematous than in the acute stage, with the lumen nearly obliterated and with a more profuse exudate.

Carcinoma involving the EAC may present as infection, and in its earliest stages it is often mistaken for infection and treated inappropriately. The most common malignant neoplasm of the external ear is squamous cell carcinoma, although other primary carcinomas have been described: basal cell carcinoma, malignant melanoma, ceruminous adenoma or adenocarcinoma, adenoid cystic carcinoma, and metastatic carcinomas to the temporal bone with extension to the EAC, such as breast, prostatic, small (oat) cell, and renal cell carcinomas.

Staging

The clinical course of external otitis may be divided into the following stages: preinflammatory; acute inflammatory (mild, moderate, or severe); and chronic inflammatory. Typically, the preinflammatory stage begins when the stratum corneum becomes edematous because of removal of the protective lipid layer and acid mantle from the canal, resulting in plugging of the apopilosebaceous unit. As obstruction continues, a sense of fullness and itching begins. The disruption of the epithelial layer allows the invasion of bacteria that either reside in the canal or are introduced on foreign objects inserted into the canal. This produces the acute inflammatory stage, which is accompanied by pain and tenderness of the auricle. In the earliest stage, the skin of the EAC shows mild erythema and minimal edema (□ Fig. 116.2). A small amount of a clear or slightly cloudy secretion may be seen in the canal. As pain and itching increase, the disease progresses to the moderate stage, in which the canal shows more edema and a thicker, more profuse exudate (□ Fig. 116.3). Further progression of the inflammation leads to the severe inflammatory stage, characterized by increased pain and obliteration of the lumen of the canal. A profuse, purulent exudate and edema of the canal skin may obscure the tympanic membrane. In addition, small white papules are often visible on the surface of the canal skin. *P. aeruginosa* or another gram-negative bacillus can almost always be cultured at this stage. In

the severe stage, the physician often sees evidence of extension of the infection beyond the canal to involve the adjacent soft tissues and cervical lymph nodes.

In the chronic inflammatory stage, the patient experiences less pain but more profound itching. The skin of the external canal is thickened, and superficial flaking may be seen. This condition is likened to eczema and may range from mild drying and thickening of the canal to complete obliteration of the external canal by chronically infected, hypertrophic skin (□ Table 116.1).

Medical Treatment

The four fundamental principles in the treatment of external otitis in all stages are: (1) frequent and thorough cleaning; (2) the judicious use of appropriate antibiotics; (3) the treatment of associated inflammation and pain; and (4) recommendations regarding the prevention of future infections. In any stage of infection, thorough cleaning is a priority. In the preinflammatory stage, a complete cleaning may be all that is required. In the absence of purulence, a brief course of an acidifying drop such as aluminum sulfate–calcium sulfate is effective in discouraging bacterial or fungal growth.

Treatment of the acute inflammatory stage varies with the extent of disease. In the mildest form, cleaning as above is indicated. An antibiotic otic drop is recommended to cover what is probably a *Pseudomonas* infection. At this stage, edema of the EAC should not be severe, and the patient should be able to instill drops into the ear by tilting the head to the side or by lying down with the involved ear upright. In the moderate stage of inflammation, edema of the canal may interfere with the instillation of drops. The physician should then insert a porous expandable wick into the canal and instill drops on it. Often, the canal may accommodate two or even three wicks. As the wick expands, it presses the soft tissues and periosteum centrifugally; this alone may relieve pain. The wick is removed by the

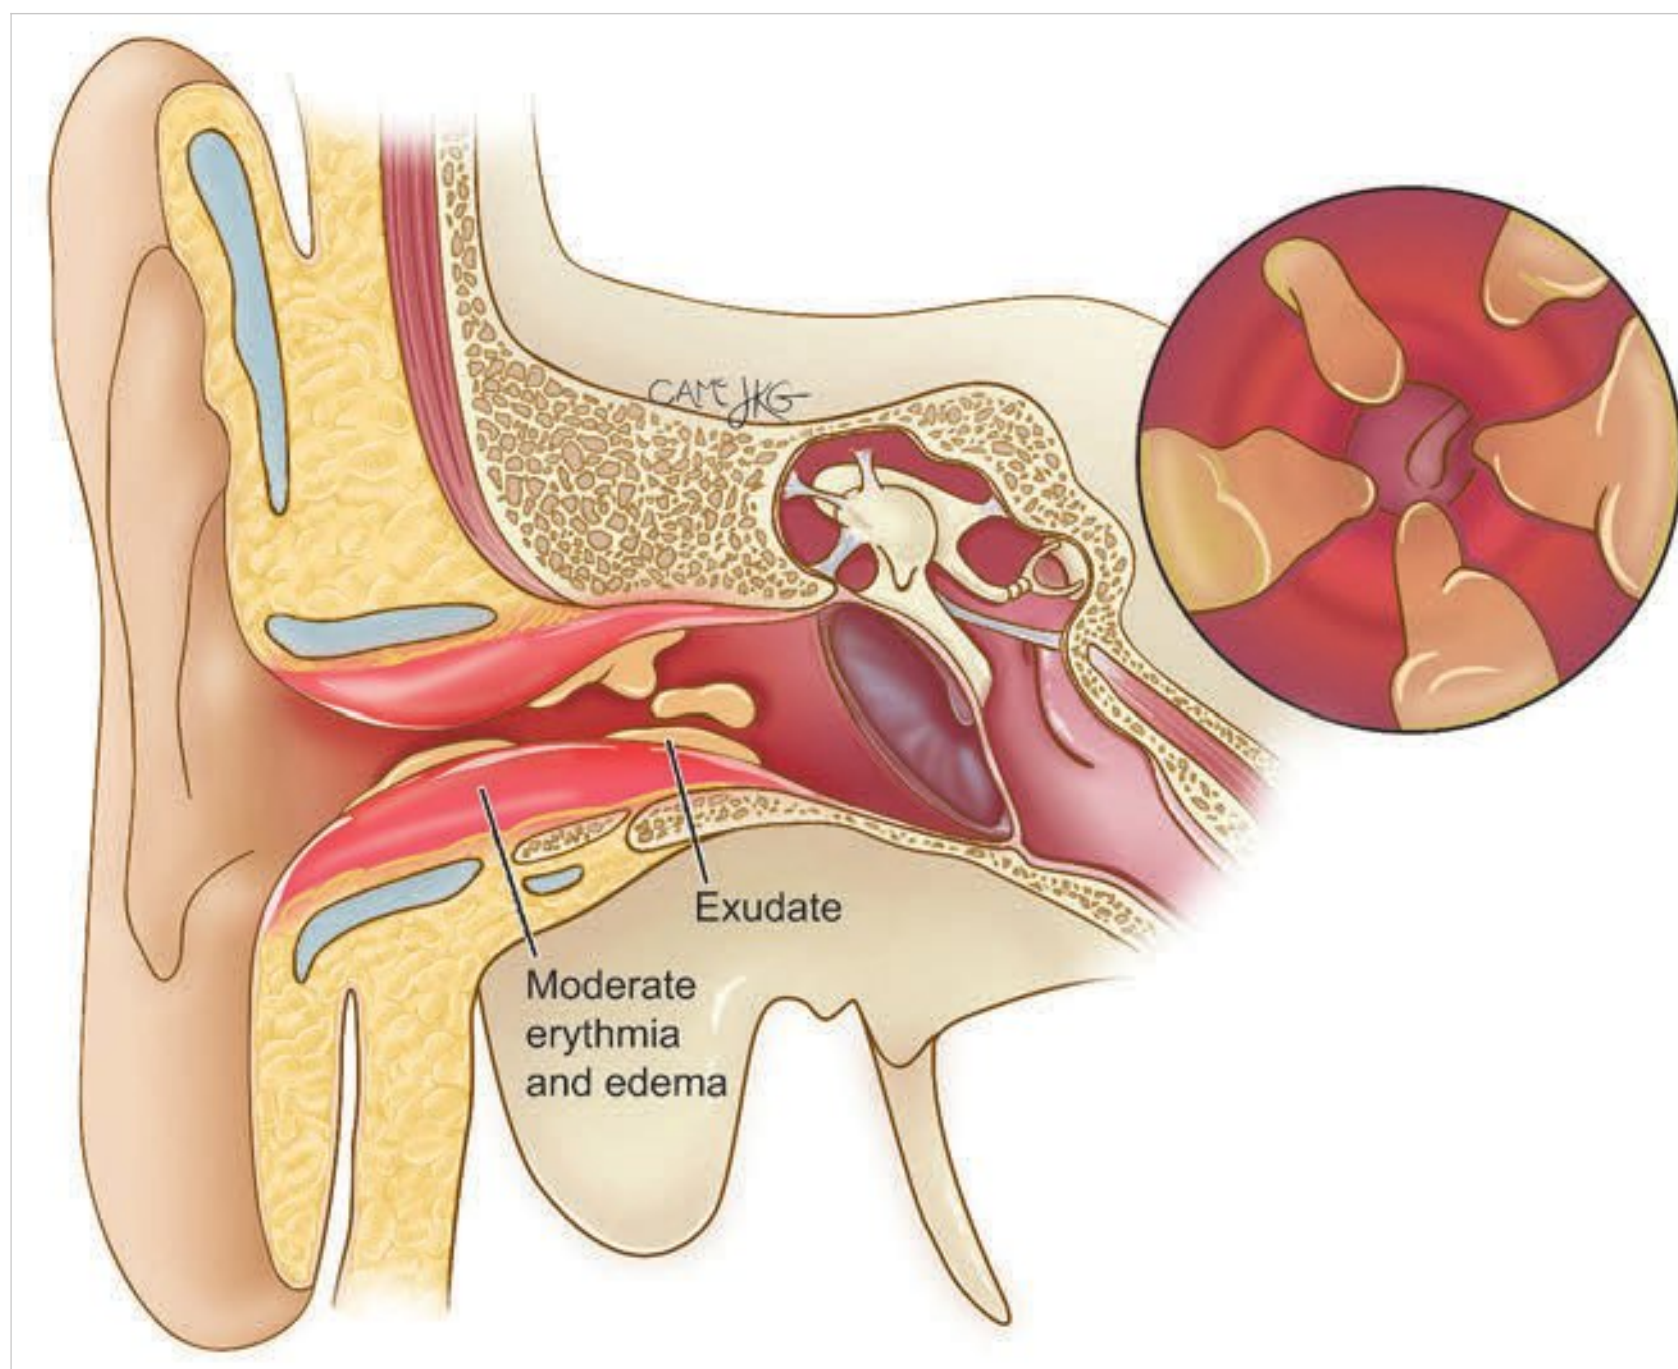

Fig. 116.3 Otitis externa, severe stage. Infection extends beyond the limits of the canal to involve adjacent soft tissues and cervical lymph nodes. Erythema of the conchal skin and scaliness are secondary to profuse drainage.

Table 116.1 Diagnosis of otitis externa

History	Physical examination		Laboratory	
Pain	Preinflammatory	Mild erythema	Culture	<i>Pseudomonas aeruginosa</i>
Fullness		Edema		<i>Proteus mirabilis</i>

Discharge		Erythema		<i>Streptococcus species</i>
		Edema	Radiology	Rarely indicated
	Chronic inflammatory	Discharge		
		Thickening, flaking of canal skin		
		Eczematization		
		Ulceration		

physician at the time of reexamination. If the edema has not been significantly reduced, repacking is indicated. Antibiotic drops should be continued for at least 2 to 3 days after the cessation of pain, itching, and drainage so that complete eradication of infection may be ensured. An oral analgesic is often prescribed for pronounced pain. The patient is cautioned to avoid manipulation of the canal. If the infection has not spread beyond the boundaries of the external canal, the use of oral antibiotics will be of little to no value.

In the severe stage, infection usually extends beyond the limits of the canal. In addition to the cleaning, packing, and use of antibiotic drops discussed previously, soft-tissue involvement is treated by administering an oral antibiotic with broad-spectrum coverage. In addition to antipseudomonal ear drops, common choices of oral antibiotics include antipseudomonal fluoroquinolones (e.g., ciprofloxacin or levofloxacin), antistaphylococcal penicillins, and cephalosporins. In children younger

than 12 years of age, one should discuss the use of these medications with the patient's pediatrician before prescribing oral fluoroquinolones.

Warm soaks (normal saline or a mild aluminum sulfate–calcium acetate solution) are also useful for treating the crusting and edema involving the auricle and surrounding skin. Culture of the canal for aerobic bacteria and/or fungi is indicated only for patients in the severe stage or for patients who have previously been treated without resolution. Treatment is generally continued for 10 to 14 days if there is a good response. For the rare patients who do not respond to this regimen, hospitalization, vigorous daily local care, repeated culturing, and intravenous antibiotics are indicated.

The chronic stage of external otitis is manifested by marked thickening of the skin of the EAC due to long-standing infection. Examination reveals flakes of dry, scaly skin in the canal. Although removal of debris is recommended, this may

be difficult because of narrowing of the lumen of the canal. Repeated cleaning and the instillation of antibiotics and steroids are indicated. Triamcinolone acetonide 0.25% cream or ointment, fluocinolone 0.01% oil, or dexamethasone sodium phosphate 0.1% ophthalmic drops may be used. A final office visit is important to ensure that the infection has completely resolved and the canal is back to its normal state.

All patients should be instructed to avoid future infections by not instrumenting the ear. Swimmers should be taught to towel dry the concha and lateral canal, to shake water out of the canal, or to instill an acidifying drop after swimming. Patients who have repeated infections are best advised to use an acidifying drop composed of equal measures of vinegar and water, or ethyl alcohol and water, when exposed to high humidity. One should suspect otomycosis if all other reasonable measures have failed and should treat with drying agents, especially powders. Custom-made ear molds are useful for these patients.

Recalcitrant Otitis Externa

The physician will be able to judge very quickly which patients are responding. The prolonged use of antibiotic drops may suppress the return of the normal flora of the external canal and lead to a fungal superinfection. This should be suspected, especially if a grayish matted discharge is found in the ear even when telltale hyphae are absent. If a fungus has been cultured, the infection should be treated with drying agents such as powders, an antifungal drop, or a systemic oral antifungal medication such as fluconazole. If no progress is made in the office, rare patients may have to be admitted as inpatients. Frequent and thorough examination and cleaning are essential. Subtle signs of chronic middle ear disease (e.g., granulation tissue or the opening of a tiny perforation) may be obscured by a swollen tympanic membrane, giving a “fish mouth” appearance to the perforation. A “sewer cap” of crust on the drum may reveal a cholesteatoma underneath. Signs of underlying chondritis or perichondritis, especially diffuse crusting or exudative weeping, may be present. Computed tomography (CT) of the temporal bones may give additional information.

The patient is placed on daily aural drops, preferably one covering *P. aeruginosa*, and intravenous antibiotics with gram-positive and gram-negative coverage. Ciprofloxacin is a reasonable initial treatment, but in very rare cases, a cephalosporin together with an aminoglycoside is a logical combination if monotherapy is unsuccessful. Therapy should be tapered according to culture and sensitivities. Severely swollen ears may calm down with required steroids.

Many recalcitrant infections occur because of noncompliance or chronic instrumentation of the canal skin. The patient should be counseled to amend bad habits. The rare patient will need to be admitted for intravenous antibiotics and daily aural toilet (see Box Treatment of Otitis Externa (p.918)).

Surgical Management of Hypertrophic Chronic Otitis Externa

When such local measures are insufficient to eradicate infection and reestablish the lumen of the canal, it is necessary to remove the involved canal skin and any adjacent involved cutaneous or cartilaginous tissue. This is very rarely required but is best done

through a postauricular incision, which allows better visualization of the involved tissues. A generous amount of conchal cartilage is removed to effect a wide meatoplasty. The bony canal is enlarged with a drill; the intraoperative use of a facial nerve monitor facilitates protection of the vertical segment of the facial nerve. The canal is resurfaced with a split-thickness skin graft that is temporarily held in place with stents or packing.

Treatment of Otitis Externa

Medical

- Frequent, thorough cleaning
- Antibiotic coverage
 - Drops
 - Oral
 - Intravenous as needed
- Treatment of inflammation, pain
- Recommendations for prevention

Surgical

- Excision of involved canal skin
- Wide meatoplasty
- Resurfacing of the canal with a split-thickness skin graft

116.3.2 Skull Base Osteomyelitis (Necrotizing [Malignant] Otitis Externa)

This potentially life-threatening disease should be viewed within the larger context of osteomyelitis of the temporal bone and skull base. Thanks in large part to newer antipseudomonal antibiotics, the prevalence of skull base osteomyelitis (SBO) has decreased significantly, although the disease still may be seen, especially among diabetics, the immunocompromised, and the elderly. SBO remains within the differential diagnosis of a refractory external ear infection in the patient at risk.

Bacteriology

The causative organism is almost always *P. aeruginosa*, although other organisms, such as *P. mirabilis*, *Aspergillus fumigatus*, *Proteus* species, *Klebsiella* species, and *Staphylococcus* species, have been isolated.

Natural History

The natural history of SBO is one of relentless progression to involve the cranial nerves, especially the facial nerve. The pain is inexorable and deep-seated. Multiple cranial nerves may be affected, especially cranial nerves VII, IX, X, and XI.

Presenting Complaints

The diagnosis of SBO is made in a patient with the appropriate history, physical examination findings, and supporting laboratory findings. Four key features are seen: (1) persistent, deep-seated, severe otalgia for longer than 1 month; (2) persistent

purulent otorrhea with granulation tissue for several weeks; (3) diabetes mellitus, another immunocompromised state, or advanced age; and (4) cranial nerve involvement.

SBO usually begins as an acute external otitis that does not resolve despite medical therapy, as described previously. The history is significant for a long-standing infection of the external canal accompanied by aural discharge and severe, deep-seated pain. The disease usually occurs in elderly patients with poorly controlled diabetes, although it may be found in any chronically ill, debilitated, or immunocompromised patient, and the HIV status should be assessed if unknown.

Physical Examination

Most patients with SBO have granulation tissue visible in the inferior aspect of the canal (or even extruding from it) that may obscure the tympanic membrane (a rare finding in routine cases of otitis externa). The skin of the canal is often erythematous, indurated, and sometimes macerated. Purulent secretions are common. Lower cranial nerve palsies may be seen.

Radiographic Findings

CT of the temporal bone with contrast will yield excellent bony detail, with less precise information about soft tissue. It may define subtle bony changes, such as erosion of the anterior canal wall with involvement of the temporomandibular joint and erosion of the tympanic ring and base of the skull. It may demonstrate soft-tissue thickening and mastoid clouding.

Magnetic resonance (MR) imaging without and with gadolinium enhancement may be advantageous in defining the medial extent of disease at the skull base. Dural enhancement and involvement of the medullary bone spaces are seen with central skull base invasion. Underlying cerebral involvement is easily visualized with gadolinium-enhanced MR imaging. MR imaging yields very imprecise information about bone. The patency of the dural sinuses and great vessels of the neck may be assessed in a noninvasive fashion with MR angiography or venography. Changes seen on MR imaging do not quickly resolve with clinical improvement, so although MR imaging is a useful diagnostic tool to assess the extent of disease, it is less useful to follow the clinical course of SBO.

Technetium 99m bone scanning and gallium 67 scanning have been advocated in the evaluation of SBO. Their sensitivity for the presence of infection is far greater than their specificity for the cause. ^{99m}Tc scanning gives excellent information about bone function but poor information about bone structure. A positive scan is thought to represent osteoblastic activity as little as 10% above normal. The scan is positive in acute and chronic osteomyelitis and in areas of active bone repair without infection, as in trauma. Its use in the evaluation of SBO is complementary to that of ⁶⁷Ga scanning. ⁶⁷Ga is thought to be incorporated into proteins and polymorphonuclear leukocytes at sites of active infection as a ⁶⁷Ga-lactoferrin complex. It will highlight an acute infective focus but not the full extent of an osteomyelitic process. As treatment progresses, the ⁶⁷Ga scan will revert to normal (negative), while the ^{99m}Tc scan will lag behind for many months. Baseline studies with both are thus recommended, so that sequential imaging can be used to monitor the response to therapy. Planar scintigraphy with indium 111-labeled leukocytes has been demonstrated to yield better results for the detection of osteomyelitis than either planar scintigraphy or tomography with ⁶⁷Ga- and/or ^{99m}Tc-methylene diphosphonate and may replace the former two radionuclide modalities in the evaluation of patients suspected to have SBO (□ Table 116.2).

Differential Diagnosis

Other diseases to be included in the differential diagnosis are severe acute otitis externa, squamous cell carcinoma, glomus jugulare tumor, cholesteatoma, nasopharyngeal carcinoma, Hand-Schüller-Christian disease, eosinophilic granuloma, Wegener granulomatosis, and clival chordoma. In the appropriate clinical setting, a high index of suspicion is appropriate.

Medical Treatment

Swab and/or tissue cultures of the EAC should be obtained. If present, granulations should be biopsied and sent to rule out carcinoma or other pathology. Because *Pseudomonas* is so frequently the predominant organism, the patient is treated with antipseudomonal antibiotics for an extended period, often for 6 weeks or more. Monotherapy is discouraged in the treatment of

Table 116.2 Diagnosis of necrotizing external otitis

History	Physical examination	Laboratory	
Persistent otalgia	Granulation tissue in external canal	Culture	Pseudomonas aeruginosa (almost always)
Persistent purulent otorrhea			Proteus mirabilis
	Purulent discharge		Aspergillus fumigatus
Diabetes mellitus	Cranial neuropathy, especially in cranial nerve VII		Klebsiella species
Advanced age			Staphylococcus species
		Radiology	Computed tomography with contrast
Immunocompromise			Magnetic resonance imaging with contrast Technetium 99 m scan Gallium 67 scan

SBO. Two antipseudomonal antibiotics are ordinarily chosen from among several alternatives (including gentamicin or tobramycin with or without ticarcillin or piperacillin) to achieve synergy and to avoid the emergence of a resistant strain of bacteria. Alternative antibiotics include mezlocillin or azlocillin, ceftazidime, imipenem, aztreonam, amikacin, norfloxacin, and ciprofloxacin or any of the other appropriate antipseudomonal fluoroquinolones. If an aminoglycoside is chosen, peak and trough levels and hearing must be carefully monitored. It is wise to treat in concert with an infectious disease colleague to help select those medications that will be of greatest benefit with the least toxicity. If the ear remains purulent despite adequate intravenous antibiotics and local care, cultures should be repeated to look for the emergence of a resistant organism; ciprofloxacin resistance has been reported in 20% of patients undergoing long-term (6 weeks or more) therapy for osteomyelitis.

An early clinical feature of successful treatment is the cessation of pain, and patients may be tempted to discontinue therapy once this occurs. Regardless of the choice of medication or mode of delivery, patients must understand that they will require meticulous aural toilet and antibiotic treatment for at least 6 weeks and vigorous management of their serum glucose levels. Either in the hospital or in the office, the ear is débrided carefully under the microscope on a regular basis until granulations have subsided. The patient is placed on antipseudomonal otic drops and appropriate systemic antibiotics. Diabetes is aggressively managed and the diet carefully monitored.

Hyperbaric oxygen is thought to facilitate osteoneogenesis and to promote the repair of diseased bone and thus may be of value in the most severe cases. The cost and inconvenience of hyperbaric oxygen therapy have limited its availability. Its use is recommended for patients who have advanced disease with significant skull base or intracranial involvement, recurrent disease, or infections refractory to antibiotic treatment.

Patients with disease refractory to intravenously administered antibiotics may require surgical control of the infected site.

Surgical Treatment

Most patients can be managed medically, and the role of surgery in SBO remains controversial. Surgical débridement of tissue and osteomyelitic bone is usually reserved for patients who do not respond to conventional therapy. Additionally, surgery provides tissue for culture in these refractive cases to look for resistant organisms or for a new organism, such as an invasive fungus. The progression of pain despite aggressive medical therapy, the persistence of granulations, and the development of cranial nerve involvement are all ominous signs that call for more aggressive medical therapy and possibly surgical intervention.

With the onset of facial paralysis, early surgical removal of granulation and, when necessary, decompression of the descending facial nerve have provided excellent return of function. The primary surgical goal is to relieve the entrapped nerve and allow its natural return of function. Serial electroneuronography (ENOG) has been used to detect the electrical degeneration of cranial nerve VII in patients with clinically complete facial paralysis. Electroneuronography showing more than 90% electrical degeneration of the facial nerve may support surgical

Table 116.3 Treatment of necrotizing external otitis

Medical Treatment	Surgical Treatment
Hospital admission	Excision of granulation tissue
Intravenous antibiotics	± Middle ear exploration
Daily cleaning, débridement	± Mastoidectomy
	± Facial nerve decompression
	± Temporal bone resection if no response

decompression of the involved segment of the nerve. However, the entire concept of facial nerve decompression in the context of SBO remains controversial; the mainstay of therapy for SBO remains medical, not surgical.

Surgical treatment, including abscess drainage, débridement of sequestra, and more extensive resection of bone and soft tissue, should be individualized depending upon the patient's overall health status and response to more conservative measures (□ Table 116.3).

Prognosis

Mortality remains significant, especially in the immunocompromised patient. The progression of disease results in severe, unremitting pain within the ear and at the base of the skull and extension of the infection to the mastoid, parotid, lower cranial nerves, and transverse and sigmoid sinuses. Osteomyelitis of the skull base may lead to meningitis, brain abscess, and death. Poor prognostic factors include facial paralysis, polyneuropathy and intracranial extension (see Box Complications of Necrotizing External Otitis (p.920)).

Complications of Necrotizing External Otitis

- Cranial neuropathy (cranial nerve VII and lower)
- Progression despite aggressive local care (to mastoid, parotid, lower cranial nerves, base of skull, dural venous sinuses, and brain)
- Meningitis
- Brain abscess
- Death

The diagnosis and management of SBO remains an otolaryngologic challenge. Perhaps the greatest advances in its treatment have resulted from the recognition of SBO as a distinct entity and a clear understanding of its pathophysiology. A team approach involving the cooperation of otolaryngology, endocrinology, and infectious disease may enhance the overall outcome. The advent of the fluoroquinolones and other antipseudomonal antibiotics has significantly lowered the morbidity and mortality associated with SBO.

116.3.3 Conditions Related to External Otitis

Several other infectious and inflammatory diseases are included in the differential diagnosis of otitis externa.

Radiation-Induced Otitis Externa

Another form of otitis externa occasionally occurs after radiotherapy of the region of the external ear. The predominant symptoms result from the inflammation and infection that result when radiotherapy weakens local defense mechanisms and resident bacteria flourish. When the otitis externa is limited to the skin of the EAC, treatment measures, with particular attention to water avoidance, are appropriate. In the worst form of osteoradionecrosis with purulent infection, sequestra of devitalized tissue should be removed and replaced with vascularized tissue.

Bullous External Otitis

Bullous external otitis is a very painful condition in which vesicles or bullae are noted in the bony portion of the external canal. The vesicles are commonly hemorrhagic and should not be ruptured because secondary infection may ensue. *Pseudomonas* may be one of the causative organisms, so appropriate otic drops are recommended. Packing and irrigation of the canal should be avoided because they tend to prolong the course of this disease.

Granular External Otitis

Granular external otitis often resembles the earliest stage of necrotizing external otitis in that there may be small granular plaques or pedunculated granulations in the external canal. This condition may occur in patients who have not been fully treated for a previous episode of external otitis; it may also occur as a result of contact dermatitis (e.g., exposure to hairspray). After the topical or local anesthesia, the removal of granulation tissue, placement of a wick in the canal, and instillation of antibiotic drops will usually resolve the problem. Oral antibiotics should be given if the infection extends beyond the canal. If the patient is diabetic or debilitated, the diagnosis of necrotizing external otitis is entertained and treated appropriately.

Perichondritis and Chondritis

Perichondritis (inflammation of the perichondrium) and chondritis (inflammation of the cartilage) may follow or complicate infections of the EAC or result from accidental or surgical trauma to the auricle. The condition is painful, and the patient often describes severe itching deep within the canal. With time, the skin over the affected area becomes crusted with squamous debris, and the involved cartilage begins to weep. The ear is indurated and erythematous; often, the canal swells shut. The surrounding soft tissues of the face and neck may become involved.

In the mildest stages, thorough débridement and treatment with topical and oral antibiotics are generally sufficient. If these measures do not succeed, the ear is débrided again, and cultures are taken. Appropriate treatment for common pathogens, especially *Pseudomonas*, is begun and tapered according to culture results. Ciprofloxacin is a logical choice for moderate stages, combined with an antipseudomonal drop such as gentamicin or a fluoroquinolone drop.

If the infection spreads to involve regional soft tissues and lymphatics, the patient should be hospitalized and parenteral

treatment with adequate coverage for *Pseudomonas* begun. In difficult cases, the ear should be cultured before treatment is started. For patients with recalcitrant infections, infectious disease consultation is often helpful. At every stage of the disease, frequent and thorough débridement of the canal is essential. The metabolic requirements of cartilage are low, and its blood supply is appropriately diminished. Once infection has become established in the perichondrium or cartilage, it is extremely difficult to treat. If subacute or chronic infection, evidenced by inexorable weeping, continues, surgical intervention is indicated.

The affected area is cleansed and injected with local anesthetic containing epinephrine. Incisions are made, and the dissection is taken down to the affected cartilage. If it has lost its normal “pearly white” appearance, it is most likely necrotic and should be excised. Often, necrosis extends farther than can be grossly visualized. Small irrigation drains are placed beneath the flaps and sutured to the skin. The skin flaps are closed. The drainage ports are irrigated with an antibiotic (e.g., 50,000 U of bacitracin dissolved in 250 mL of normal saline). The drains are advanced as the condition resolves. Parenteral antibiotics, otic drops, and aggressive local care continue until the infection has resolved.

Furunculosis and Carbunculosis

Furunculosis and carbunculosis are conditions resulting from gram-positive infections, usually staphylococcal, of the hair follicles. The primary lesion is usually a small, well-circumscribed pustule that may enlarge to become a furuncle or merge with several similar lesions to form a carbuncle. The infection occurs most commonly at the junction of the concha and canal skin.

For treatment to be successful, any accumulated infectious material must be removed. Spontaneous drainage can often be encouraged with the use of warm soaks, supplemented by topical and oral antibiotics and wicks if necessary. If these measures fail to relieve obstruction of the canal, incision and drainage under local anesthesia are indicated.

Infectious Eczematoid Dermatitis

Infectious eczematoid dermatitis results from the drainage of contaminated or purulent material from the middle ear into the floor of the external ear and adjacent infra-auricular skin. This drainage causes a secondary infection or an autosensitization phenomenon manifested by crusted plaques in the canal. Treatment is directed at control of the underlying middle ear infection. Supportive treatment of the external canal reaction consists of the removal of accumulated debris, application of sterile saline soaks to the crusted areas, and application of an antibiotic cream or ointment.

Otomycosis

Otomycosis is a fungal infection of the skin of the external canal. Although fungi may be the primary pathogens, they are usually superimposed on a chronic bacterial infection of the external canal or middle ear. Secondary otomycosis tends to recur if the underlying primary infection is not controlled. All fungi have three basic growth requirements: moisture, warmth, and

darkness. Altering moisture will discourage fungal growth. *Aspergillus* species are the most common, usually *A. niger*. If aural culture should grow *A. fumigatus* or *A. flavus*, one should consider a more invasive infection.

Pruritus is the primary clinical complaint. The otoscopic examination commonly reveals a white, black, or dotted gray membrane. Thorough cleaning under a microscope with the patient supine to remove any fungal debris is the first and absolutely most important step in therapy. Thorough aural toilet is supplemented by the topical application of an acidifying solution such as aluminum sulfate–calcium acetate or of a drying powder such as boric acid. Clotrimazole cream or solution may also be used. In the presence of a tympanic membrane perforation or a patent ventilation tube, the application of clotrimazole drops or lotion may be very painful. Thorough cleaning and drying therapies such as powders are best. Metacresyl acetate may be painted on the margin of a perforation or an infected ventilation tube. This is best done under the microscope. This medication should not enter the middle ear cleft because it is quite irritating. In recalcitrant infections, a foreign body such as a ventilation tube acts as the nidus for infection and should be removed. Tympanoplasty is best performed to close an intermittently draining perforation with a superimposed fungal infection.

Gentian violet is usually well tolerated in patients with mastoid cavities, although it is best left out of the middle ear cleft in the presence of a perforation. Because it will permanently stain skin and clothing, small amounts are used with adequate protection of the surrounding area.

Treating physicians should realize that all drops are formulated with moisture and do not persist indefinitely in a homogenized state. Eventually, the water component will separate from the precipitate of the active medical ingredient. Water is exactly what fungi need to grow. Adding drops indefinitely to an ear with otomycosis may prove counterproductive, and an acidifying powder such as boric acid or a compounded powder (as described below) will often help dry an ear with a refractory infection.

Many patients with refractory otomycotic infections may have had previous mastoid surgery, and often the canal wall has been taken down. Because of moderate to severe hearing loss, these patients may need to wear a hearing aid with a closed mold. Careful instruction to the patient, meticulous débridement of the ear, and the use of a drying agent such as boric acid powder, chloromycetin–sulfanilamide–amphotericin B powder, or chloromycetin–sulfanilamide–tolnaftate powder will often help clean the cavity. The use of ointments in cavities with closed hearing aids may promote fungal growth due to the accumulation of moisture. In refractory cases, gentian violet or metacresyl acetate may be used topically.

Herpes Zoster and Herpes Simplex

Herpes zoster and herpes simplex are viral infections known to affect the EAC. The patient initially experiences a period of burning pain or localized headache, and vesicles usually appear within several days. When the vesicles coalesce and rupture, crusts are formed. Herpes zoster tends to appear unilaterally in a dermatomic distribution. Involvement of the facial nerve may

produce paresis or paralysis (herpes zoster oticus or Ramsay Hunt syndrome). Treatment is supportive, with the topical application of a drying agent, such as hydrogen peroxide, for crusts. The status of the facial nerve is carefully followed; surgical decompression of the facial nerve may be a consideration if it is clinically paralyzed and electrical criteria are met by ENOG testing. Many patients excoriate the blisters, and bacitracin ointment or a suitable substitute should be applied to prevent superinfection. Acyclovir, famciclovir, and valacyclovir have been shown to ameliorate herpetic infections, especially herpes zoster oticus. The latter two have easier dosing schedules and are better absorbed orally than acyclovir. Also, famciclovir may reduce the duration of postherpetic neuralgia. However, it will cause a transitory rise in hepatic enzyme production and must be used with caution.

Dermatoses

Allergic and irritant contact dermatoses may mimic diffuse external otitis. Causative agents may be absolute (so noxious that a reaction occurs in everyone exposed, such as strong acids or alkali) or relative (noxious to susceptible individuals, usually after repeated exposures, such as various soaps or the plastic mold of a hearing aid). Allergic contact dermatitis refers to a delayed hypersensitivity reaction resulting from substances such as poison ivy, nickel compounds (found in some earrings), and rubber compounds (especially in headphones). The typical reaction presents as erythema, weeping, and vesiculation accompanied by itching. The patient may produce a secondary infection by scratching. Treatment consists of removal of the causative agent and the use of topical steroids and astringents. Topical or systemic antibiotics are indicated for the treatment of infection. Systemic steroids may be indicated for severe cases. In rare cases (e.g., a patient with a cochlear implant and hypersensitivity to plastic), the external, ear level receiver/stimulator may be painted with a different material or covered with a cloth casing to separate it from the skin.

External Ear Disease and HIV Infection

Among the external ear manifestations seen in HIV disease is Kaposi sarcoma, which presents with reddish blue lesions typically described as hemorrhagic nodules. The lesions may be discrete or confluent. Although chemotherapy, radiotherapy, and interferon alfa have been used for therapy, the treatment of auricular and canal lesions is rarely necessary. Infections of the external ear in HIV-infected patients are caused by both typical and atypical pathogens. Recurrent herpetic infections and *Pneumocystis carinii*-infected aural polyps have been reported in the EAC as a result of chronic otitis media.

Another external ear manifestation of HIV disease is seborrheic dermatitis, which tends to be more widespread and refractory to treatment than the same condition in HIV-negative patients. Necrotizing external otitis in the HIV-positive patient adds another level of concern regarding its treatment. An infectious disease consultant should be involved in the overall care of the HIV-positive patient. The use of the protease inhibitor medications has made these otologic manifestations exceedingly rare.

116.3.4 Relapsing Polychondritis

Relapsing polychondritis is an intermittently progressive disease marked by the inflammatory destruction of cartilage. Although it is thought to be an autoimmune disorder, the exact cause is unknown. Cartilage of the external ears, larynx, trachea, bronchi, and nose may be involved. The symptoms are episodic, with fever, anemia, erythema, swelling, and pain, and an elevated sedimentation rate is noted during acute episodes. Sparing of the earlobe is the rule and is useful in distinguishing this disease from a cellulitis. As the disease progresses, symptoms of increasing respiratory obstruction may become apparent if tracheal cartilage is involved. Labyrinthine disturbances are rarely present. The diagnosis is made on the basis of the history and physical examination, supported by an elevated sedimentation rate. Biopsy of the involved cartilage may show necrosis, inflammation, and fibrosis. Treatment is with oral corticosteroids, and rarely with intravenous steroids.

116.4 Traumatic Injuries of the External Ear

116.4.1 Blunt Injuries

Shearing forces to the auricle, commonly seen in sports such as boxing and wrestling, may disrupt the normal perichondrium of the auricular cartilaginous framework, causing seroma or hematoma formation. The lobule is composed primarily of fat covered with skin and is less susceptible to injury. Because it is malleable throughout life, auricular cartilage is more likely to be injured by shearing forces than by blunt trauma. It rarely fractures.

If uninfected, very small seromas of the auricle may be observed, and larger ones aspirated. If the seroma reaccumulates, it should be treated under sterile conditions with drainage; a bolster-type dressing with dental rolls and through-and-through, nonabsorbable sutures should be placed to obliterate the potential space for reaccumulation of the seroma. If the seroma is infected, there is a risk that the cartilage itself may become necrotic and lost. The ear should be incised and drained and the patient put on broad-spectrum antibiotic coverage; drains should be placed. The goal is to prevent loss of the cartilaginous frame.

The same principles apply to hematomas of the auricle, except that observation is rarely an option. Because the cartilaginous frame is at greater risk, the hematoma should be drained and a compressive dressing applied with dental rolls sutured on either side. If the hematoma reaccumulates or is very large, drains should be placed, and the ear should be treated until the skin flaps remain flat. Preservation of the cartilaginous framework with prevention of a “cauliflower” or “boxer’s” ear is the goal. Once auricular cartilage has been lost and reparative scarring has begun, the auricle is doomed to reparative malformation. Intervention must be undertaken soon after any injury if it is to be effective.

116.4.2 Sharp Trauma to the Auricle

The result of sharp trauma to the auricle may range from a small injury, such as an earlobe torn during piercing, to com-

plete avulsion of the auricle, usually after a motor vehicle accident. The auricle has a plentiful blood supply and as a general rule will heal if the cartilaginous and soft-tissue structures remain even partly attached, less so if complete avulsion has occurred. If remnants or the entire auricle can be salvaged, these should be cleansed and reimplantation attempted in the acute situation.

Torn lobes may be caused by gravity when a heavy earring works its way over time through the lobe or by acute injury when an earring tears through the lobe. Inflammation and infection should be treated. The torn lobe may be repaired in the office; the lobe may be repierced at a later stage.

Animal and human bites of the auricle are by definition contaminated. The edges of the wound must be decontaminated with local antiseptics. Tetanus toxoid should be given. Broad-spectrum antibiotic coverage for the most likely oral flora, including microaerophilic streptococci and anaerobes such as *Bacteroides*, is indicated. If remnants of the auricle have been salvaged, these may be thoroughly washed, decontaminated, and reattached with sutures. If only the auricular cartilage remains, it should be cleaned of soft-tissue attachments, decontaminated, and buried in a subcutaneous pocket (e.g., behind the auricle, in the forearm or abdomen) for later use.

Shearing avulsions are much more difficult to treat. The auricular remnant, if found, may be mangled, torn, or abraded. If a part or all of it appears viable, an attempt at surgical reattachment is worthwhile, with all rules of antiseptics obeyed. However, if it has been lost or is beyond retrieval, the edges of the EAC should be freshened and tacked away and the canal packed with Gelfoam (Pfizer, New York, NY) or another material to help prevent acquired stenosis of the EAC. The patient must then be counseled regarding the main steps of auricular reconstruction (costochondral cartilage harvest, sculpture, and subcutaneous implantation; lobular transposition; auricular lateralization) as required. A very good option in these severe cases is the insertion of osseointegrated titanium posts for anchoring an auricular prosthesis. A well-made auricular prosthetic device for the properly selected patient is an excellent option with very acceptable cosmetic results. As well, porous high-density polyethylene (Medpor; Porex Surgical, Newnan, GA), covered with a vascularized temporoparietal flap, can yield an excellent aesthetic result; however, in many cases, implant exposure or infection has occurred years after surgery with resultant stenosis of the EAC. This type of repair must be chosen carefully with regard to the age and usual activities of the recipient.

116.4.3 Thermal Injuries

Burns of the auricle are classified by their nature (thermal burns, ultra-cooling burns due to frostbite) and the degree of the injury to the skin: first-degree leading to erythema, second-degree (blistering), or third-degree (full-thickness) burns. In first- and second-degree burns, pain is present; in third-degree burns, the sensory nerve endings have been destroyed and the affected area is anesthetic. It is of great importance to elicit a detailed history of the nature and time course of the injury.

Upon inspection, the area may be erythematous and blistered (first- and second-degree burns), blackened with eschar (third-degree burns), or white, hard, and cold (frostbite) as a result of extreme vasoconstriction. It is important to suspect that the

extent of the injury extends beyond what is apparent on inspection. This is especially true in electrical injuries. A thermal burn should be cooled quickly with cold/iced compresses to waste the built-up heat within the tissue in an attempt to prevent necrosis by cell expansion and disruption. Frostbite is rewarmed more slowly with warming compresses. If frostbite extends to larger areas of the body, the patient may be placed in a warming bath, or warming intravenous solutions may be used. The extremity should not be rubbed lest shearing forces cause further damage.

Broad-spectrum antibiotic coverage against expected organisms such as *Pseudomonas* species and common skin flora (streptococci and staphylococci) should be given. Topical ointments and creams such as 1% silver sulfadiazine creams may be used. Surgical débridement should be delayed until the wound “declares itself” and a line of demarcation between healthy and dead tissue becomes apparent. Once this has happened, the débridement of dead tissue and application of topical antiseptic ointments may encourage healing in first- and second-degree burns. More severe burns may require split- or full-thickness grafting. There is no reason to rush into repair until the full extent of the injury is obvious. A facial plastic surgeon experienced in the treatment of burns and in reconstructive surgery is an important colleague in the care of patients with thermal and frostbite injuries to the auricle and EAC.

116.4.4 Acid Burn of the External Auditory Canal and Auricle

This rare occurrence causes massive denaturation of the skin, surrounding soft tissue, and supporting cartilage and may result in partial or complete loss of the auricle and EAC. Acids of industrial concentration, such as sulfuric acid and other fortified acids (or alkalis), are the usual agents. The injury is almost never accidental but is part of a criminal assault. As with any chemical burn, the caustic agent must be removed with copious and prolonged irrigation.

If the auricle has been severely damaged, it may ultimately undergo partial or complete autoamputation. A hypertrophic scar and/or keloid will inevitably form and is treated with compressive dressings and/or steroid injections (triamcinolone 10 mg/mL or 40 mg/mL) as necessary. The injured auricle may be allowed to “declare itself,” as with thermal and frostbite burns. It is important to inspect the EAC and tympanic membrane and to make every effort to flush any noxious agent from these areas and salvage as much normal tissue as possible. The EAC may be packed with medicated Gelfoam or another packing material.

These types of injuries are almost never isolated but are often part of a much larger picture, including inhalation injuries and trauma to vital internal organs and the extremities. It is important to think “beyond the ear,” especially if there has been a history of smoke inhalation. These patients are properly assessed by the trauma and burn services, as well as otolaryngology.

116.4.5 Fractures of the External Auditory Canal

Foreign objects placed into the EAC may cause lacerations of the canal. These types of injuries are rare. Far more common are

injuries to the EAC caused by trauma to adjacent structures. Because of its anatomical boundaries, the EAC is susceptible to injuries associated with trauma of the temporomandibular joint (e.g., a blow to the jaw) or fractures of the temporal bone, most commonly longitudinal fractures.

Inspection of the EAC reveals a “step” deformity of the canal. A flail piece of bone may be seen, with or without an accompanying laceration. Passive movement of the jaw may cause the bone fragment to move.

The patient should be inspected for additional areas of injury, both fractures of the jaw and other otologic injuries, such as traumatic perforation of the tympanic membrane, damage to the ossicular chain, facial nerve injury, and injury to the vestibular labyrinth. A tuning fork test should, at a minimum, be done; ideally, a screening audiogram should be performed. Radiographic studies (e.g., mandibular views, panorex, CT of the petrous temporal bones) should be obtained as indicated.

Treatment is of the underlying cause; if the mandible has been fractured, the fracture must be reduced and the patient usually placed in intermaxillary fixation. Temporal bone fractures, even those associated with cerebrospinal fluid (CSF) otorrhea, are ordinarily observed, with the patient placed in bed at about 45 degrees until the CSF otorrhea subsides. The ear should not be manipulated. If there is witnessed and progressive facial nerve dysfunction, in which case the likely site of injury is at the geniculate ganglion, the nerve is followed clinically and electrically with serial ENOG and/or needle electromyographic studies and may need to be decompressed.

If a flail piece of bone in the EAC, usually at the scutum or tympanomastoid suture line, becomes infected or otherwise bothersome, it may be removed. It is rarely necessary to repair soft-tissue lacerations. The EAC may be packed with Gelfoam moistened with otologic drops or another packing material.

116.5 Noninflammatory Lesions of the External Ear

116.5.1 Lesions of the Auricle

Congenital Lesions

Preauricular Skin Tags

These consist of redundant tissue, usually comprising skin and fat, found near or just anterior to the tragus. If the mass contains cartilage, it is a remnant of auricular tissue, left over from auricular development. It may be a duplication of one or several of the ectodermal hillocks of His. Preauricular skin tags or auricular remnants are nonfunctional, and most parents request that they be removed. However, they may carry with them cultural connotations, such as a child being “favored.” If held on with only a soft-tissue stalk, the skin tag may be lassoed with a silk suture, tied at the base, and allowed to undergo necrosis and fall off. If cartilage is found within the lesion, excision should be done in the operating room, with the knowledge that the facial nerve may be very superficial in young children. The patient is seen as needed until the scar has healed. Electrocautery is rarely necessary in the excision of these lesions and should be used carefully.

Preauricular Pits

These are depressions or sinuses lined with squamous or columnar epithelium that are found in front of the anterior root of the helix. They are heritable and often bilateral; inheritance is thought to be in an autosomal-dominant fashion with variable expression. The pits may elaborate keratin and/or mucous and may become infected. If quiescent, they are observed. If filled with uninfected debris, they may be treated with warm compresses and the material expressed from outside the opening. If the pit or sinus becomes recurrently infected, it may require excision. It is important to remove the entire tract if it is excised.

First Branchial Cleft Cysts, Sinuses, and Fistulas

These result from anomalous duplication of the EAC and may occur between the EAC and structures anterior or inferior to the auricle, including the neck. They are classified according to the Work system. Work type I anomalies contain only ectodermal derivatives and may be thought of as a “parallel” duplication of the EAC. Work type II anomalies contain both ectodermal and mesodermal derivatives and may be found extending between the EAC and the parotid in any relationship to the extratemporal facial nerve, including bisecting the nerve. The treatment of first branchial cleft cysts, sinuses, and fistulas is by excision. These anomalies may contain keratin debris that can become infected. If infected, they may require incision and drainage, but this is not recommended if it can be avoided. The cyst, sinus, or fistula may be gently probed with a sterile, malleable lacrimal probe or another suitable instrument to map out its pathway. The opening may be gently filled with dye such as methylene blue before excision. A rim of tissue around the internal opening is resected with the specimen, and every attempt is made to excise the tract in toto, leaving none of it behind. If the tract is suspected to course in any relation to the extratemporal facial nerve, the excision should be done in a more formal way. A modified Blair incision is made and the parotid is exposed, as is the facial nerve at least from the stylomastoid foramen to the pes anserinus and distal branching points, with the use of intraoperative facial nerve monitoring. The cyst, sinus, or fistula must be carefully dissected from the intact and stimulated facial nerve. The first attempt at excision is usually the most thorough because the anatomy of the lesion is best preserved. With each incision and each subsequent surgical attempt at removal, the anatomy becomes more distorted and the chance of complete resection less.

Cutaneous Cysts

Cysts of ectodermal and sebaceous origin may be found in any relationship to the auricle. If growing and painful, a cyst should be excised along with an ellipse of skin over the lesion to be used as a soft-tissue “handle,” allowing excision of the cyst with its tract and surrounding soft tissue. It is important to make every attempt to identify and excise every bit of the cyst lining; there always is one. If the cyst has become acutely infected and is ready to burst, the patient is treated with oral antibiotics and warm soaks. The cyst may need to be incised and drained, but this is not optimal. Once the acute infection has subsided, the cyst should be excised.

Acquired Lesions

Chondrodermatitis Nodularis Chronica (Winker Nodule)

This is a benign lesion with the appearance of a “punched-out crater.” It is found most commonly in older men at the rim of the helix, as well as in other areas of the auricle. It is thought to be caused by the breakdown of elastic fibers due to chronic sun exposure. The lesion may be painful to touch or pressure. This distinguishes it from other dermatologic lesions, such as senile keratosis, keratoacanthoma, cutaneous horn, and skin cancer (squamous or basal cell), which are usually painless.

Treatment is by full-thickness excision that includes the supporting cartilage. The defect is reconstructed with a full-thickness skin graft or local advancement flaps.

Gouty Tophi of the Auricle

These are deposits of uric acid in crystalline form in the auricle, often at the helix. The patient will have hyperuricemia and should have other markings of gout, such as arthropathy(ies) and involvement of the great toe(s). Serologic markers for uric acid will confirm the suspected underlying diagnosis. If quiescent, the nodule may be observed. If painful or inflamed, it is removed under local anesthesia. Histopathologic examination will reveal fusiform, washed-out casts of monosodium urate with an accompanying inflammatory surround: polymorphonuclear leukocytes, histiocytes, and foreign body giant cells.

The patient should be treated for gout with the daily administration of allopurinol. Colchicine and other anti-inflammatory medications are used for acute exacerbations.

Bacterial Perichondritis

This is distinguished from relapsing polychondritis, which is a nonbacterial autoimmune condition that is treated with steroids. Bacterial perichondritis is distinguished by crusting, weeping, and exudate from the auricle and by pus. If there are signs of bacterial infection, the ear must be treated with antibiotics.

Infection of the perichondrium of the auricle and supporting cartilage is an urgent problem. It may be a sequela of otologic surgery or trauma, or it may follow external otitis. Predisposing factors include diabetes and any cause of relative immunosuppression. The patient presents with a swollen, painful, erythematous auricle, usually crusting and weeping. Swabs are taken for Gram stain, culture, and sensitivity. The most common organism isolated is *P. aeruginosa*. Oral antibiotics with good gram-negative coverage, such as fluoroquinolones, should be started along with warm soaks. Treatment may begin at home, but the patient must be seen frequently, even daily, until the ear either improves or fails to. In the latter case, the patient should be hospitalized, broad-spectrum intravenous antibiotics started, and drains placed under the skin of the auricle and irrigated with an antibiotic solution such as bacitracin. Diabetes must be brought under strict control; patients often require a sliding scale of insulin. Necrotic cartilage should be excised and every effort taken to save as much of the cartilaginous auricular framework as possible.

Sebaceous Cysts

These true cystic collections occur as a result of sebaceous gland obstruction. They have a true lining and may occur anywhere in the head and neck. The scalp, nape of the neck, and auricle are favored sites. If small and nonpainful, they may be observed. The acutely infected sebaceous cyst is treated with a broad-spectrum oral antibiotic and may occasionally have to be drained. If it becomes larger and painful, the sebaceous cyst is excised, with care taken to remove all of the cyst lining. This is best done when the cyst is distended and not infected. If any of the cyst lining is left behind, it will likely regrow.

Neoplasia of the Auricle and External Auditory Canal

The auricle and EAC may give rise to both benign and malignant neoplasia, based upon the cell of origin. Benign processes include actinic keratosis, papilloma, and other lesions. Cancers of the auricle and EAC include basal cell carcinoma, squamous cell carcinoma, and melanoma (melanotic and amelanotic). Rarer cancers of the auricle and EAC include Kaposi sarcoma (now much less frequent in HIV disease since the advent of protease inhibitors and other reverse transcriptase inhibitors) and ceruminous adenocarcinoma, seen either alone or in association with multiple cylindromas of the scalp, face, and EAC.

Malignancies with the potential for hematogenous metastasis to the temporal bone (but not necessarily to the auricle or EAC) include renal cell carcinoma, small (oat cell) adenocarcinoma of the lung, breast cancer, cancer of the prostate, and cutaneous melanoma.

In the majority of skin cancers, malignancy is an end-stage result of chronic sun (actinic) exposure. The amount and longevity of sun exposure are of the greatest importance. Tanning lotions with protection against the ultraviolet rays of the sun are of relative recent widespread use. A thorough history of sun exposure, the work history (indoor vs. outside work), and a history of the use of tight-fitting ear molds leading to chronic irritation of the EAC should be elicited.

Slowly growing malignancies such as basal cell cancer may persist for years before the patient seeks help. Far less frequently, advanced cancers of the auricle may occur as part of an aggressive picture of skin cancer, especially squamous cell carcinoma of high grade. In this small number of cases, the auricle and/or skin of the EAC must be partially or completely resected, possibly with a neck dissection and possibly with a lateral temporal bone resection, and the wound closed with local, pedicled, or free vascularized flaps. The extent of the disease, assessed by clinical examination, radiographic examination, and examination of the histopathologic margins, will determine the extent of the dissection. Surveillance and local control may help to avoid these more advanced cases.

116.5.2 Lesions of the External Auditory Canal

Keratosis Obdurans

This is an acute-upon-chronic condition of the external ear in which the EAC is plugged by an accumulation of dense, inspissated

keratin debris. Acute infection, swelling, pain, and hearing loss follow. In very advanced cases, in response to chronic irritation and infection, the normally thin architecture of the squamous epithelium lining the canal may become lichenified, and the canal may be plugged by dense debris and secondarily stenotic.

The typical patient with this problem is elderly, often in a nursing home in which care of the ear is neglected. If and when the ear becomes acutely infected, the patient will be brought to the otologist. It is important to distinguish this entity, if possible, from acute otitis externa, osteomyelitis of the skull base, and other plausible conditions. The history usually yields the answer if it can be accurately obtained.

These ears are difficult to treat, in large measure because of pain, but will usually respond well to careful, thorough cleaning under microscopic vision in the office, rarely in the operating room, and very rarely under general anesthesia. The ears are exquisitely painful to clean, and thus pain must be eliminated before aural toilet. The patient may require a four-quadrant block of the EAC with local anesthesia. Most patients will allow the ear to be cleansed in the office. There is usually an “onion skin” appearance to the epithelial debris because it has been collecting for many months to years. Although the diagnosis is apparent with gross inspection, material should be sent for pathologic examination to ascertain that this is keratin debris and nothing else. The physician may not be able to clean the ear completely in one sitting; the patient may need to return for several sessions and the ear be medicated with an appropriate acidifying solution between visits.

The important difference between this and other, similar conditions, such as cholesteatoma of the EAC, is that once it is completely cleaned and topically medicated, the ear with keratosis obdurans will often slowly and gradually revert back toward a healthy appearance. The change toward health may be quite remarkable once aural toilet commences. The inciting event of dense packing of squamous debris and superinfection has been cured, and the ear can now resume a more normal appearance. This does not happen with external ear cholesteatoma. Prevention of recurrence is via appropriate otologic therapy and routine office-based débridement.

External Auditory Canal Cholesteatoma

This is a cyst of squamous debris found in the EAC. It has many features in common with primary acquired cholesteatoma: it has an active matrix that elaborates keratin debris, and it may locally erode bone and soft tissue. Unlike keratosis obdurans, it does not revert toward a normal state once obstruction and local infection have been relieved and treated. There may be an antecedent history of trauma, otologic surgery, acquired stenosis, or chronic inflammation, but most patients have no identifiable cause. The tympanic ring, especially its anterior and inferior aspects, is a favored site for EAC cholesteatoma. The patient may initially present with otologic complaints due to blockage by keratin debris: hearing loss, fullness, symptoms of infection, rarely dizziness or vertigo, and most rarely involvement of the facial nerve.

An edge-enhanced CT of the temporal bones reveals features of cholesteatoma with bony erosion and scalloped edges. EAC cholesteatoma is usually a localized disease process, often

unilateral, bilateral in fewer patients. Depending upon the site and size of the EACC, there may be normal hearing, hearing loss of a conductive or mixed nature, or, if the otic capsule has been violated, anacusis. Facial nerve involvement is rare.

The mainstay of treatment is routine office-based débridement, advice to the patient about water precautions, and the judicious use of acidifying drops and/or powders as needed. If the EAC cholesteatoma becomes obstructed, rendering the ear difficult to clean, limited localized surgery including meatoplasty may be indicated to facilitate aural toilet. Surgery to eradicate all foci of the cholesteatoma has proved of little value, and so EAC cholesteatoma, unlike primary and secondary cholesteatoma of the middle ear and mastoid, is managed medically, not surgically. There is really very little need for surgery in even the most advanced cases.

The surgeon must also have a precise mental road map of the problem with microscopic detail. This may be facilitated by CT, but there is no substitute for careful microscopic evaluation. In very advanced cases, the jugular bulb, tympanic facial nerve, and structures of the otic capsule may be exposed. Extreme caution must be used in dealing with these most delicate structures.

Having the patient soften the squamous debris at home for several days with an organic solvent (baby oil, olive oil, docusate) before scheduled office débridement will greatly facilitate cleaning. If inner ear structures of the vestibular labyrinth have been exposed, the patient may experience precipitous and violent vertigo due to the caloric effect of the suction. It is best to débride the ear manually under the microscope with small tools such as a cerumen loop, round knife, or alligator forceps while the patient is in the supine position, and to use a minimal amount of suction just at the end of the cleaning. Because cleaning may be needed as often as every 3 to 4 months, the physician and patient must work together to achieve the best system that will keep the erosive potential of EAC cholesteatoma in check and cause the least amount of discomfort to the patient.

It is important to be aware of developmental defects in the formation of the tympanic ring that may lead to chronic irritation, weeping, and the collection of keratin debris and so mimic cholesteatoma of the EAC and other entities. A persistent foramen tympanicum, or foramen of Huschke, is an anatomical variation of the tympanic portion of the temporal bone due to a defect in normal ossification of the tympanic ring during the first 5 years of life. It is not a true foramen because no neurovascular structures traverse it; rather, it is a defect of tympanic bone ossification due to abnormal mechanical forces during early postnatal life or to genetic factors, thus far undefined. Its location is at the anteroinferior aspect of the EAC, posteromedial to the temporomandibular joint. Based on retrospective radiographic series, persistent foramen tympanicum has been estimated to occur in 4.6 to 9.1% of individuals, with an average dimension of 4.2 mm in the axial plane and 3.6 mm in the sagittal plane. CT of the temporal bone performed at thin intervals (0.6-mm section thickness, 0.3-mm section increment) with an ultra-high resolution filter will best image this entity if it is present.

Persistent foramen tympanicum, or foramen of Huschke, should be kept in the differential diagnosis in cases of refractory

chronic otitis externa and especially of cholesteatoma of the EAC. It may predispose the patient to injury of the EAC, tympanic membrane, or middle ear cleft during temporomandibular joint arthroscopy and may facilitate the spread of infection or tumor from the EAC into the infratemporal fossa and vice versa.

Cerumen Impaction

The subject of wax impaction may seem banal, but few other conditions in our specialty can be remedied within a single office visit to the tremendous relief and satisfaction of the patient. Many patients with wax impaction will present with hearing loss, fullness, tinnitus, autophony, and rarely imbalance or vertigo. The history and physical examination, including tuning fork testing, will usually confirm the diagnosis and exclude other causes. Most patients will admit to using cotton squabs and other foreign bodies in the EAC. Patients wearing tightly fitting hearing aid molds or other ear pieces may be predisposed to wax impaction. The treatment and prevention of wax impaction, however nonglamorous, are fundamental to what we do, and one should develop a reliable method to care for this most common problem.

Realizing that the ear is exquisitely sensitive, especially an erstwhile normal EAC now impacted with wax, the physician must treat carefully, cautiously, slowly, and with reassurance. Patients can tolerate many manipulations of the ear if what will be done is explained to them and is done slowly. A few extra seconds of counsel and reassurance are well worth the effort. All reasonable attempts should be made to thoroughly clean wax impactions in one office visit.

There are a few important factors to remember: (1) Avoid blind, forceful irrigation. (2) The patient should assume a comfortable position, which may vary from sitting to lying recumbent. (3) The physician should anticipate a vasovagal response and be prepared to treat it immediately because it may occur with any instrumentation of the EAC. (4) A microscope provides better visualization than a hand-held otoscope, as well as the ability to work bimanually. (5) Reassure the patient; a relaxed patient will allow a more thorough procedure. (6) Use reasonable techniques for a reasonable length of time. (7) Have pressed gelatin foam and alligator forceps readily available, which can be applied focally if the canal skin is abraded during manipulation. (8) Inspect all parts of the tympanic membrane to look for other signs of disease, such as a perforation or attic retraction cholesteatoma, after the ears have been cleaned.

Patients should be counseled to avoid placing any foreign body into the ear to clean it. A weekly rinse of 3% hydrogen peroxide or an acidifying drop may help the ear to cleanse itself. However, some patients will require manual débridement at regular intervals to maintain canal patency.

Foreign Body

Foreign bodies in the EAC may be either organic or inorganic. Several broad principles must be observed in treating a patient with a suspected or known foreign body, all based upon common sense. (1) For young children, “if one foreign body, there may be two or three.” Remember to check the nose in addition to the ears for foreign bodies. (2) Living foreign bodies (usually

insects) must be killed first, then removed. The patient is usually quite bothered by the beating of an insect's wings or other movement. This is silenced with lidocaine or mineral oil. (3) Batteries and acid-eluting foreign bodies must be removed as soon as possible because they may cause extensive chemical burns to the EAC. This is a rather urgent otologic situation, and the patient should be treated in the office or operating room without delay. (4) Do not attempt to remove foreign objects, such as beans or bugs, with irrigation because they may swell and compound the problem. (5) The ear is exquisitely sensitive. A patient who cannot tolerate the pain may need to be immobilized to prevent tympanic membrane or middle ear injury during removal of the foreign body. For an uncooperative or hysterical patient, general anesthesia may be required. (6) Only an experienced physician with proper instruments and magnification and in the proper setting should attempt to remove any foreign body from the EAC. If these are not available, the patient should be taken to the operating room. (7) A reasonable attempt to establish audition in the ear in question with at least a tuning fork test should be made before the removal of a densely impacted foreign body.

Aural Polyp

Polyps are soft-tissue masses, usually circumscribed and glistening, that often obstruct the EAC. An aural polyp may be thought of as a flag—an indicator of an underlying disease such as chronic otitis media or a cholesteatoma with concomitant inflammation. The polyp usually arises from the middle ear mucosa (respiratory epithelium) but may arise directly from the tympanic membrane as a reaction to a foreign body, such as a ventilation tube.

An aural polyp is often a physical obstruction to local medical treatment of disease in the EAC. Polyps may be treated in several ways: locally with astringents (e.g., silver nitrate, trichloroacetic acid, 20% phenol) to reduce the mass of the polyp or by removal. Astringents tend to work well because of the myxomatous nature of polyps; they are inflammatory tissue and contain a lot of water. Reducing this fraction alone will shrink the mass and allow topical therapy to start working.

An aural polyp must be removed with caution. The surgeon should have a clear idea of the most likely site of origin: a perforation, a cholesteatoma, or a foreign body reaction to a tube. If there is any suspicion that the polyp is attached to a deeper structure, such as the facial nerve, the stapes footplate, or a dehiscence of the vestibular labyrinth, or if a herniation of the meninges and/or brain (meningoencephalocele, encephalocele) cannot be excluded, the polyp should not be manipulated until definitive radiologic studies (CT and/or MR imaging with and without +/- contrast) more precisely define the anatomical site of origin.

The polyp, once grasped with an appropriately sized instrument, should be “smeared” and never forcibly removed from the ear. An inflammatory polyp will easily yield to gentle manipulation. Another underlying disease process may be more resistant, and again, the polyp should never be removed with force.

All material removed from the body must be sent for pathologic examination, and an aural polyp is no exception. Once removed, the polyp should be examined histologically, even if the

tissue removed has all of the gross features of a polyp, and definitely identified as an inflammatory polyp; other entities, such as glial tissue, brain, and neoplasm, must be excluded.

Dermatologic Conditions of the External Auditory Canal

The EAC may be thought of as a blind pouch lined with skin. There are several differences between the skin of the EAC and skin elsewhere in the body. Specialized systems, such as the apilosebaceous unit and ceruminous glands, are present in the skin of the EAC, but not elsewhere. The EAC is thus susceptible to many of the dermatologic processes found elsewhere in the body. Much of what otologists treat may be generally classified as chronic otitis externa, but the EAC may also manifest purely local problems, such as contact dermatitis and neurodermatitis (lichen simplex chronicus). The EAC may also manifest systemic conditions such as psoriasis, eczema, atopic dermatitis, seborrheic dermatitis, acne vulgaris, and sarcoidosis.

The patient may present with an acute otitis externa and typical symptoms of itching, serous or mucous drainage, fullness, and hearing loss. The history is a key feature toward a correct diagnosis. Both ears must be given careful scrutiny under the microscope, and the physician will often see a similar state in the EAC for many dermatologic conditions. Very dry skin and signs of mechanical excoriation aid in determining the root cause; the baseline problem is that the skin is too dry, leading to pruritus, scratching, and violation of the skin and its lymphatics. The result is a perfect setup for acute otitis externa: a warm, moist, dark environment—just what bacteria and fungi need for growth. This set of otologic problems is cyclical. The baseline is “too dry,” but acute exacerbations may cause the ear to become moist and acutely infected.

Drops do not remain drops forever; eventually, they become the residue of the drops and the liquid into which the active ingredient of the drops was dissolved. Therefore, drops add fluid and often water to the ear, again providing an enhanced environment for bacterial overgrowth. Desiccating powders are often a better choice in the acutely infected, moist ear. Once the ear has reached its “baseline,” gentle moistening with steroid oils (e.g., fluocinolone 0.01% oil; prednisolone forte 1% ophthalmologic solution) or creams/ointments (triamcinolone 0.025%) once or twice a week may maintain the ear. The patient must be cautioned not to instrument the ear.

Unfortunately, chronic otitis externa is poorly understood by most general physicians and also by many otolaryngologists. The typical patient has been treated with several different drops in the hope that finding “the perfect drop” will solve the problem. Ultimately, there is no cure for many of these conditions, but the treatment of acute exacerbations and the judicious use of steroids will go a long way to help care for the patient.

Osteomas and Exostoses of the External Auditory Canal

Osteomas

Osteomas (□ Fig. 116.4) of the external auditory canal are true neoplasms; they are often unilateral, solitary, and peduncu-

Fig. 116.4 (a) Coronal and (b) sagittal section of a right ear showing a single stalk of an osteoma.

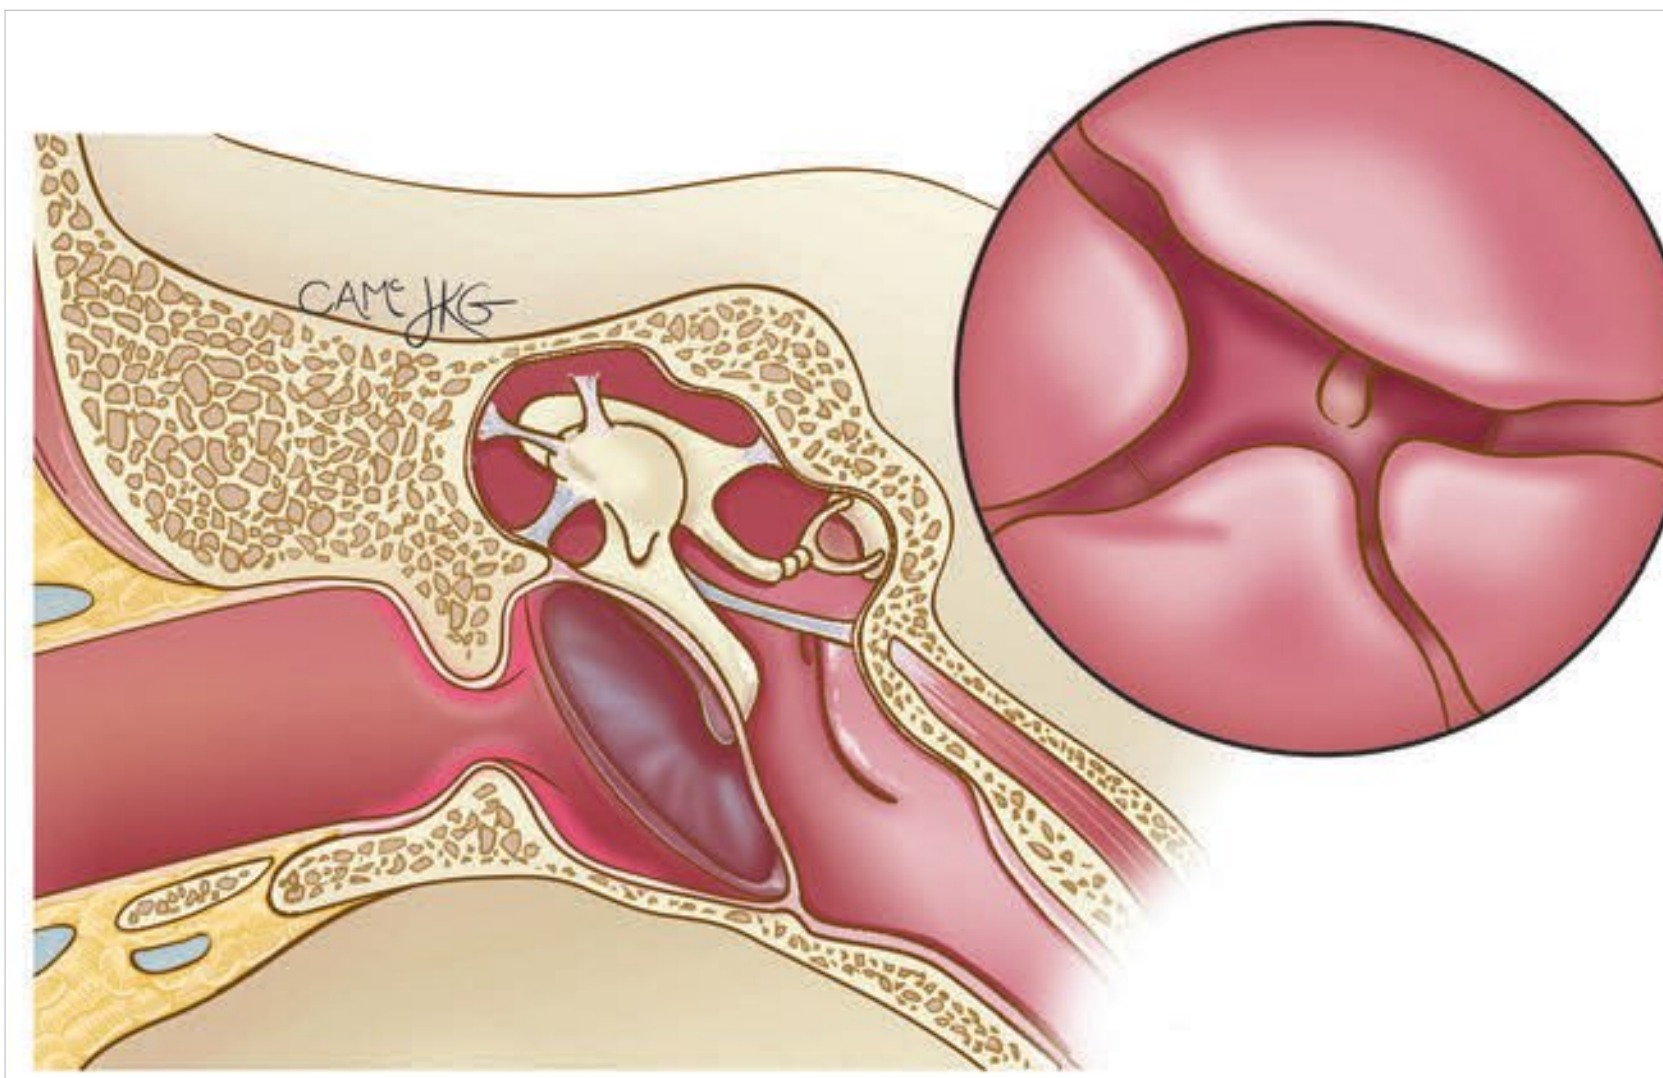

Fig. 116.5 (a) Coronal and (b) sagittal section of a right ear showing broad-based growth centers of exostoses.

lated, and they are not related to exposure to cold water or air. They usually occur at the tympanosquamous suture line in a more lateral location than exostoses. A solitary, large osteoma may fill a good portion of the EAC, causing all of the problems of advanced exostoses. On CT, an osteoma may be more heterogeneous, with areas of cancellous bone, and less dense than an exostosis. Usually, a stalk leading to the osteoma can be seen under the microscope or on CT.

Exostoses

Exostoses (□ Fig. 116.5 and □ Fig. 116.6) of the EAC are acquired, benign, broad-based growths of bone occurring within the EAC, most often near the tympanomastoid or tympanosquamous suture line. They are often bilateral and more advanced in one ear than in the other. Exostoses are not true neoplasms. They are bony calluses or hyperostoses arising from the tympanic ring. They typically do not have a stalk. The presumed pathophysiology is refrigeration osteitis, the effect of chronic exposure of the bone of the EAC to cold water or air in activities such as swimming, surfing, skiing, and boating.

If the one or several bony lesions are small and most of the tympanic membrane is clearly visible, the ear is observed. There are several reasons to shave down an exostosis or to remove an osteoma:

Fig. 116.6 Right axial computed tomographic scan of the temporal bone showing exostoses.

1. The patient has recurrent infections of the EAC. Trapped squamous debris and wax will become a nidus of recurrent EAC infections, and the obstruction should be removed.
2. The patient has conductive hearing loss due to wax/debris impaction. With severe obstruction(s), even a small amount of wax and debris will cause conductive hearing loss.
3. The usual bony and soft tissue landmarks are less distinct. It is not wise to wait this long because the surgeon must rely upon landmarks of the EAC to perform the surgery.
4. It will allow the patient to be properly fitted with a hearing aid.

Exostoses may occur along with other conditions (e.g., otosclerosis). If the exostoses are too large for the usual transcanal approach to be used, they should be removed from the ear with the greater hearing loss. The ear should be allowed to heal, the hearing retested, and then the stapedectomy performed.

All patients for whom surgery is being considered must have a formal hearing test and an edge-enhanced, noncontrast CT of the temporal bones to show landmarks around the bony lesion(s): the tympanic membrane, middle ear and ossicular chain, and tympanic and vertical course of the facial nerve. The surgeon should have a very good idea during the preoperative preparation not only of what the ear looks like under the microscope, but also of what radiologic landmarks will help to guide the dissection.

Surgery may be done through the EAC or through a postauricular approach. The important word is to “shave” the exostosis(es) carefully. Exostoses grow slowly, and by the time the patient requires surgery, these lesions have been present for many years; it is highly unlikely that they will grow back any more quickly. Therefore, there is no need to remove every millimeter of neo-ossification. A reasonable goal is to be able to see most of the perimeter of the tympanic membrane and to know that the EAC, after it heals, will be large enough to hold an ITC (in the canal) hearing aid mold. Because of the proximity of the vertical portion of the facial nerve and the tympanic membrane, nothing more than shaving the bone need be done. It is wise to perform this surgery under general anesthesia and to monitor the facial nerve electrophysiologically.

In the extremely rare cases in which all landmarks have been lost, it is best to dissect anteriorly and superiorly, where the facial nerve is unlikely to be found, until a known landmark (such as the tympanic membrane) is encountered. Approaching from behind while the vascular strip is retracted with a Penrose drain or another suitable retractor may also provide landmark clues.

The surgical technique for the removal of an osteoma is somewhat more straightforward and simpler than that for exostoses. The lesion is ordinarily removed via a transcanal approach, but a postauricular approach may be required for an extremely large osteoma. Because there is ordinarily a stalk leading to the osteoma, it can be tapped with a 2- to 4-mm nasal osteotome and the osteoma delivered. The remaining stalk can be shaved down with a diamond bur. The remainder of the care is the same as with exostoses.

Although the patient is ordinarily asked to give consent for a split-thickness skin graft, this is almost never necessary because of the redundancy of skin over the exostoses or osteoma.

The skin of the EAC is incised in a horizontal fashion around the midpoint of the lesion(s) with a round knife or similar instrument, and the skin is “window-shaded” fore and aft away from the bony growth, which is then shaved with an appropriately sized diamond bur or tapped out with an osteotome. Once the bony growths have been reduced and the tympanic membrane is easily seen, the remaining skin is placed back flat and trimmed if necessary, and the EAC is packed for about 3 to 4 weeks. The patient must be advised that the ear will take about 6 to 8 weeks to heal properly. It is extremely rare to have to revise this type of surgery if it is done carefully and conservatively.

116.6 Conclusion

With a thorough knowledge of the normal embryology, anatomy, and physiology of the external ear, in addition to an understanding of the natural history of the various common disease processes that occur in this location, the treatment of the patient with external ear disease becomes logical. However, it is not always easy. Most conditions can be managed with the recommendations outlined in this chapter. There is no substitute for patience and thoroughness.

116.7 Roundsmanship

- An understanding of the various disease entities occurring in the external ear is predicated on a knowledge of the embryology, anatomy, and physiology of the canal.
- Infection and blockage of the apopilosebaceous unit are the precursors of infectious otitis externa.
- Otitis externa presents as a spectrum of disease and may be classified into preinflammatory, acute inflammatory, and chronic inflammatory stages.
- Four principles form the basis of treatment for all stages of infection of the external ear: thorough cleaning, antibiotic therapy, control of inflammation and pain, and recommendations to prevent infection. Of these, the first is the cornerstone of therapy.
- Recalcitrant and recurrent otitis externa must be treated aggressively with daily local care and antibiotics, often in the hospital. Patience and thoroughness are needed for successful treatment.
- Necrotizing external otitis is a disease occurring in immunosuppressed patients. It must enter the differential diagnosis of any patient with nonresolving acute external otitis.
- There are four hallmarks of necrotizing external otitis: persistent otalgia; persistent otorrhea and granulation tissue; diabetes mellitus, advanced age, or immunocompromised state; and cranial nerve involvement.
- Necrotizing external otitis must be treated aggressively. Management includes proper radiographic imaging to map the extent of disease, meticulous local care, control of diabetes or immunodeficiency (when possible), and antibiotics. Surgery is rarely required. Mortality remains significant in patients with cranial nerve involvement.

117 Conditions of the Middle Ear and Mastoid

Ronald A. Hoffman

117.1 Introduction

Conditions of the middle ear and mastoid can be categorized as infectious/inflammatory, neoplastic, metabolic/genetic, and iatrogenic/traumatic. Because of anatomical and physiologic interdependency, diseases arising in the middle ear often affect the mastoid, and vice versa. Disease limited to the middle ear usually presents as hearing loss or otorrhea. Mastoid disease may be silent, unless there is an acute suppurative component or associated bone destruction. Facial nerve paresis or paralysis, vertigo, or central nervous system complications may implicate mastoid extension.

117.2 Infectious/Inflammatory Conditions

117.2.1 Otitis Media with Effusion

The most common disorders of the middle ear are infectious/inflammatory, in particular otitis media (OM) of childhood (□ Fig. 117.1). Otitis media is the most common reason for childhood visits to the pediatrician, and it is estimated that 80% of children will have at least one episode by the age of 5 years. Otitis media can be subdivided into two general types: otitis media with effusion (previously and often still referred to as serous otitis media) and acute otitis media (previously called acute suppurative otitis media). Otitis media with effusion and acute otitis media result from poor eustachian tube function and the general immunologic immaturity of childhood. The

eustachian tube, lined with upper respiratory tract mucosa, is normally closed but is opened by the action of the muscles of chewing and swallowing. Normal eustachian tube function allows aeration of the middle ear space and contiguous mastoid air cell system, as well as egress of the secretions from the middle ear. The eustachian tube becomes obstructed in children in association with upper respiratory tract mucosal diseases, primary ciliary dyskinesia, enlarged adenoids, and adenoid infection, and in association with general anatomical and physiologic immaturity. Eustachian tube dysfunction in adults usually results from upper respiratory tract mucosal disease, an acquired disease such as Wegener granulomatosis, or nasopharyngeal malignancy. A unilateral serous otitis media in an adult (particularly one of Chinese origin and especially one with ipsilateral cervical lymphadenopathy) without a history of preceding upper respiratory tract infection or barotrauma should alert the clinician to the possibility of nasopharyngeal carcinoma.

When the eustachian tube fails to function normally, middle ear gases are absorbed by the middle ear mucosa, creating negative middle ear pressure. Negative pressure and the activation of inflammatory mediators cause the egress of fluid into the middle ear, creating otitis media with effusion. Such fluid usually resolves spontaneously as the pathology affecting the eustachian tube resolves. The most common symptoms of otitis media with effusion are ear fullness and hearing loss. In many children, particularly younger children, otitis media with effusion may be asymptomatic. Physical findings include a dull and immobile tympanic membrane that does not move on pneumatic otoscopy. There may be a visible air–fluid level or air bubbles in the middle ear.

In otherwise healthy children who have no speech or language delays and no evolving pathologic changes to the tympanic membrane, the treatment of otitis media with effusion can be expectant observation, often for 6 to 9 months. If there is upper airway disease, treatment should be oriented toward improving upper airway health, with secondary improvement in eustachian tube function. Oral decongestants and steroid nasal sprays are often useful in the presence of active upper airway disease, but there is little evidence that these modalities are of value in the absence of such pathology. A course of oral antibiotics is reasonable, even though otitis media with effusion does not present with the signs or symptoms of the acute infection of otitis media (see below). Studies have shown that as many as 30% of fluid specimens from patients who have otitis media with effusion may be culture-positive. However, antibiotics are not recommended as prophylaxis to prevent otitis media with effusion, particularly with the increased incidence of antibiotic-resistant microbes.

Ultimately, if middle ear fluid does not resolve, a myringotomy with insertion of a ventilation tube is indicated. This surgical procedure is usually performed under light general anesthesia. A small incision is made in the tympanic membrane (myringotomy), and a ventilating tube is placed into the incision. Small ventilation tubes will usually remain in place and aerate the middle ear for 6 to 9 months. Longer-lasting tubes should be reserved for recurrent disease. Most authors agree

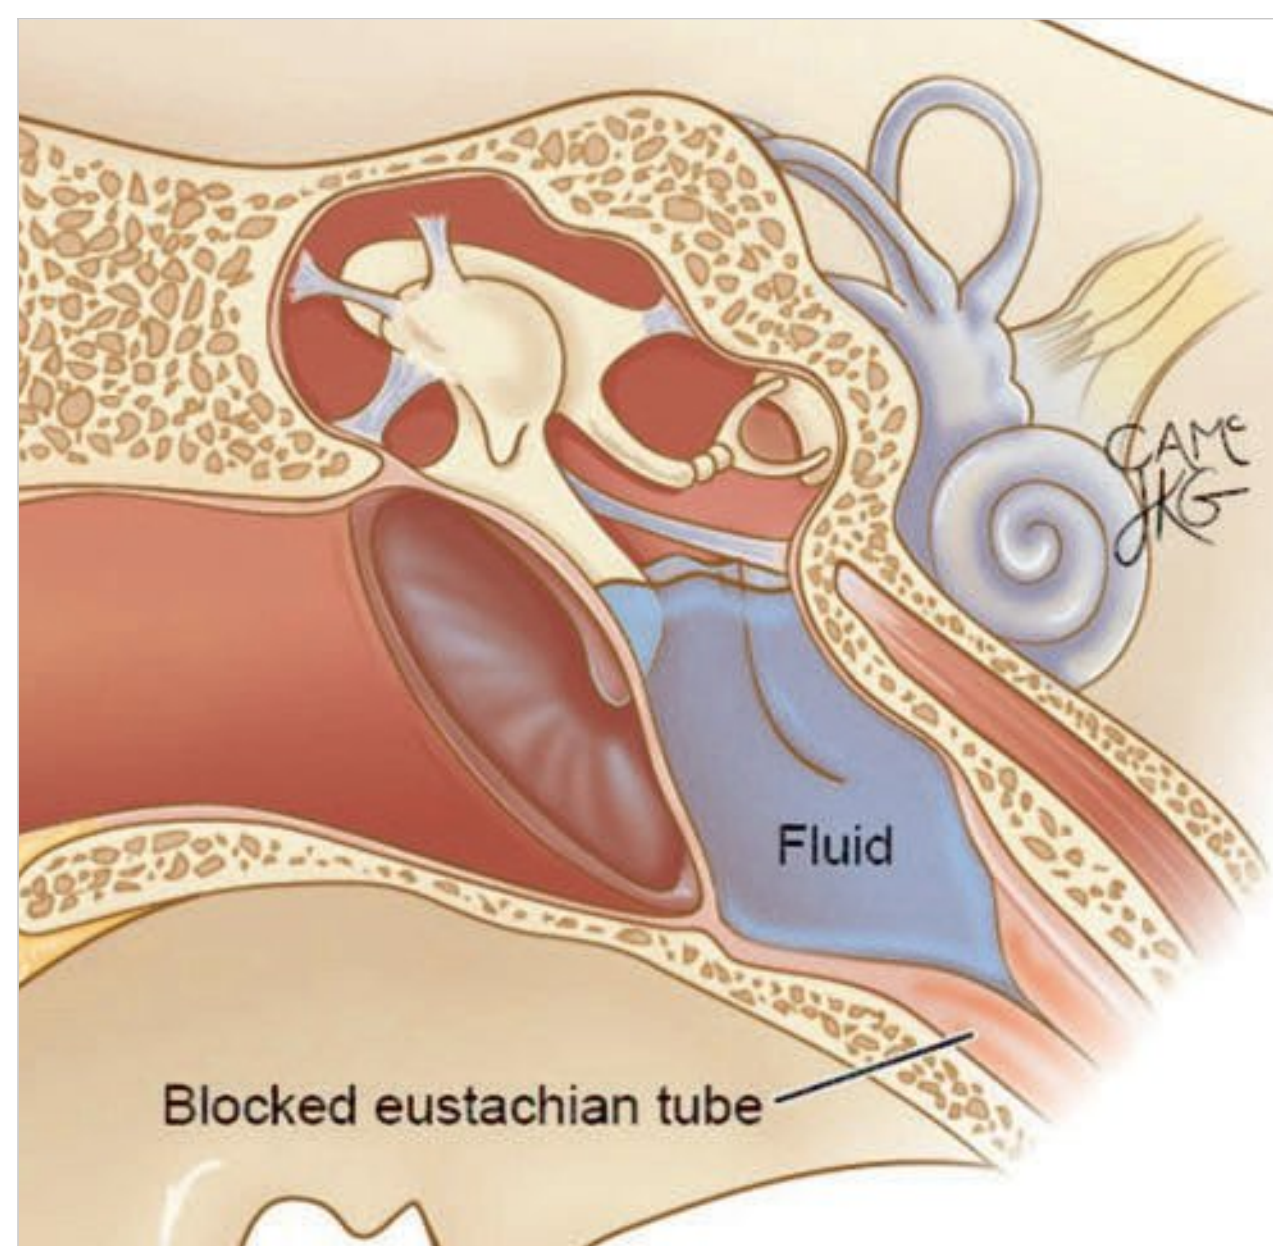

Fig. 117.1 Coronal schematic of the structures of the ear, demonstrating eustachean tube dysfunction and effusion in the middle ear.

that the adenoids should not be removed at initial myringotomy; removal should be reserved for recurrent cases. Eighty-five percent of children need tubes only once. The most common complication of myringotomy with tube insertion is otorrhea, which occurs in approximately 10% of cases. Other, less common complications include a persistent tympanic membrane perforation, cholesteatoma, or chronic otorrhea.

117.2.2 Acute Otitis Media

Acute otitis media is an acute infection of the middle ear space that may be viral or bacterial in origin. The most common bacterial pathogens are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and group A streptococci. Acute otitis media can be an isolated occurrence or recurrent. In children, otitis media with effusion and acute otitis media often represent a continuum of disease. A middle ear effusion is repeatedly infected, and the effusion persists between acute exacerbations. The signs and symptoms of acute otitis media include fever, pain, and otorrhea if the tympanic membrane spontaneously ruptures. Young children will often be toxic, with a high fever, diarrhea, irritability, and general lethargy. Physical examination reveals pus in the external auditory canal if the tympanic membrane has ruptured. If the tympanic membrane is intact, the middle ear may appear white, or the tympanic membrane may be bulging and erythematous.

In May 2004, the American Academy of Pediatrics and the American Academy of Family Physicians jointly issued a clinical practice guideline for the treatment of children with acute otitis media, encouraging less use of antibiotics and greater use of analgesics. Children older than 2 years of age who are not febrile and are mildly symptomatic can be treated with expectant observation and oral analgesics. Children younger than 2 years of age should be treated with a 10-day course of oral antibiotics. Amoxicillin is the initial drug of choice, followed by amoxicillin/clavulanate or cefuroxime. Bacterial resistance has become an increasing problem. Accordingly, myringotomy with ventilating tube insertion has become more commonly used as a treatment of acute otitis media.

117.2.3 Bullous Myringitis

Bullous myringitis is characterized by the presence of one or more bullae on the tympanic membrane or, less commonly, on the wall of the external auditory canal. Bullous myringitis has historically been said to be caused by *Mycoplasma pneumoniae*. However, studies have failed to establish such a relationship. Rather, bullous myringitis appears to be a specific clinical manifestation of the same pathogens that are usually associated with acute otitis media. The clinical hallmark of bullous myringitis is disproportionate pain, relieved as the blisters rupture. There is often bloody drainage into the external auditory canal after rupture. Treatment is with oral antibiotics and analgesics.

117.2.4 Tuberculous Otitis Media/Mastoiditis

Tuberculous otitis media usually involves both the middle ear and contiguous mastoid. Tuberculous otitis, caused primarily by

Mycobacterium tuberculosis (less often by atypical mycobacteria) is rare, accounting for 0.04% of cases of chronic suppurative otitis media. Tuberculous otitis media is usually diagnosed based on cultures obtained when infection has been resistant to standard oral antibiotic therapy, or on histopathology of biopsies obtained at surgery. No definitive signs or symptoms lead to the diagnosis of tuberculous otitis. Although tuberculous otitis has historically been said to cause multiple tympanic membrane perforations, it more often presents as a single perforation associated with conductive hearing loss and/or painless otorrhea. If a biopsy specimen is available, pathology will reveal noncaseating granulomas and acid-fast bacilli. Polymerase chain reaction testing may confirm the presence of acid-fast bacilli before cultures become positive. A past medical history of tuberculosis, as well as evidence of systemic disease, should be sought. Treatment is medical, usually 6 to 9 months of oral anti-tuberculous drugs, often in combination. Infectious disease consultation is appropriate.

117.2.5 Sequelae of Otitis Media

The most common complication of untreated or persisting otitis media with effusion is chronic adhesive otitis, in which the tympanic membrane retracts and adheres to middle ear structures (□ Fig. 117.2). The most common symptom is hearing loss. There is a characteristic “sunken” appearance on physical examination and a lack of tympanic membrane motion on

Fig. 117.2 Perforation of a right tympanic membrane.

Fig. 117.3 Severely atelectatic right middle ear.

pneumatic otoscopy. Audiometric studies will usually reveal a conductive hearing loss. The treatment of adhesive otitis includes addressing the underlying eustachian tube dysfunction and the insertion of a myringotomy tube. Cartilage reinforcement tympanoplasty, in which cartilage is incorporated into the tympanic membrane, may successfully increase tympanic membrane rigidity and prevent recurrent retraction.

Adhesive otitis media or recurrent acute otitis media may predispose to chronic suppurative otitis. Chronic suppurative otitis media can result in or be associated with a perforation of the tympanic membrane (□ Fig. 117.3) or chronic infection in the mastoid bone. Tympanic membrane perforations can be asymptomatic or can present with hearing loss or otorrhea. When they are acutely infected, there can be pain. The perforation should be visible on otoscopy. Acute rupture of the tympanic membrane usually heals spontaneously. Chronic perforations that do not heal on their own may necessitate surgical reconstruction.

All infectious or inflammatory processes that arise within the middle ear have a propensity to affect the mastoid. Computed tomography (CT) of the temporal bones performed in the presence of otitis media with effusion will virtually always show asymptomatic opacification of the mastoid. An acute suppurative component will lead to symptomatic mastoiditis, usually presenting as pain. In younger children, the presenting features may be fever and a postauricular, subperiosteal abscess that is secondary to rupture through a thin lateral mastoid cortex. Rarely, the presenting symptom is a secondary complication, such as facial nerve paresis or paralysis, vertigo secondary to a

labyrinthine fistula, or a central nervous system complication, such as an epidural or brain abscess. CT is the key to accurate diagnosis and may reveal coalescent mastoiditis or more aggressive bone destruction. Surgical exploration is often necessary, in addition to appropriate antibiotics, to make a definitive histopathologic diagnosis and effect a cure.

Cholesteatoma is an abnormal cystic mass of exfoliated keratin, shed from skin (□ Fig. 117.4). There are many descriptors of cholesteatoma. Cholesteatoma can be acquired or congenital. Congenital cholesteatoma arises as a result of epithelial rests that fail to migrate from the middle ear to the external auditory canal during embryogenesis. Congenital cholesteatoma often presents as an asymptomatic white mass behind an intact tympanic membrane in a child without a prior history of ear surgery.

An acquired cholesteatoma resulting from untreated chronic otitis may be secondary to adhesive otitis media (retraction cholesteatoma) or to a tympanic membrane perforation (perforation cholesteatoma). The cholesteatoma can be further categorized anatomically as a pars flaccida, pars tensa, or combined cholesteatoma. A cholesteatoma can also be characterized as cystic, shed (a buildup of a mass of free keratin debris), or en plaque (as when skin migrates on the undersurface of the tympanic membrane and invades the adjacent mesotympanum and epitympanic recesses).

Adhesive otitis media can cause retraction pockets, which are deeply retracted areas of the tympanic membrane. Shed skin from the normal surface epithelium of the tympanic membrane can build up in these deep pockets and expand to form a “cystic” cholesteatoma, with a matrix surrounding the keratin debris. Alternatively, cholesteatomas occurring in the presence of a chronic tympanic membrane perforation may develop from external tympanic membrane skin that migrates through the perforation. Lacking a capsule, they may shed a mass of skin that builds up in the middle ear or, less commonly, the mastoid. The migrating skin may shed little or no keratin debris and simply be en plaque.

Finally, cholesteatomas can be classified as traumatic or iatrogenic. Traumatic cholesteatomas can be secondary to an implosive injury to the tympanic membrane, as may be caused by an inserted Q-tip or a water skiing fall, or secondary to a basilar skull fracture. Basilar skull fracture can cause a direct invagination of skin into the mastoid. Iatrogenic cholesteatoma can be secondary to any middle ear surgery.

On physical examination, cholesteatoma has a characteristic, white appearance. Laboratory testing includes audiometry and imaging studies, usually CT of the temporal bone. Untreated cholesteatoma usually results in chronic middle ear or mastoid infection. This most often presents as painless ear discharge and/or hearing loss. Local bone destruction can cause permanent conductive or sensorineural hearing loss, vertigo due to a labyrinthine fistula, or facial nerve paralysis. Untreated cholesteatoma can be associated with intracranial extension and present as an epidural abscess, brain abscess, or meningitis.

Cholesteatoma is treated surgically in the majority of cases. The three goals of cholesteatoma surgery are (1) eradication of disease, (2) reconstruction of the tympanic membrane and/or ossicular chain, and (3) prevention of residual/recurrent disease. Eradication of disease is a technical challenge because any

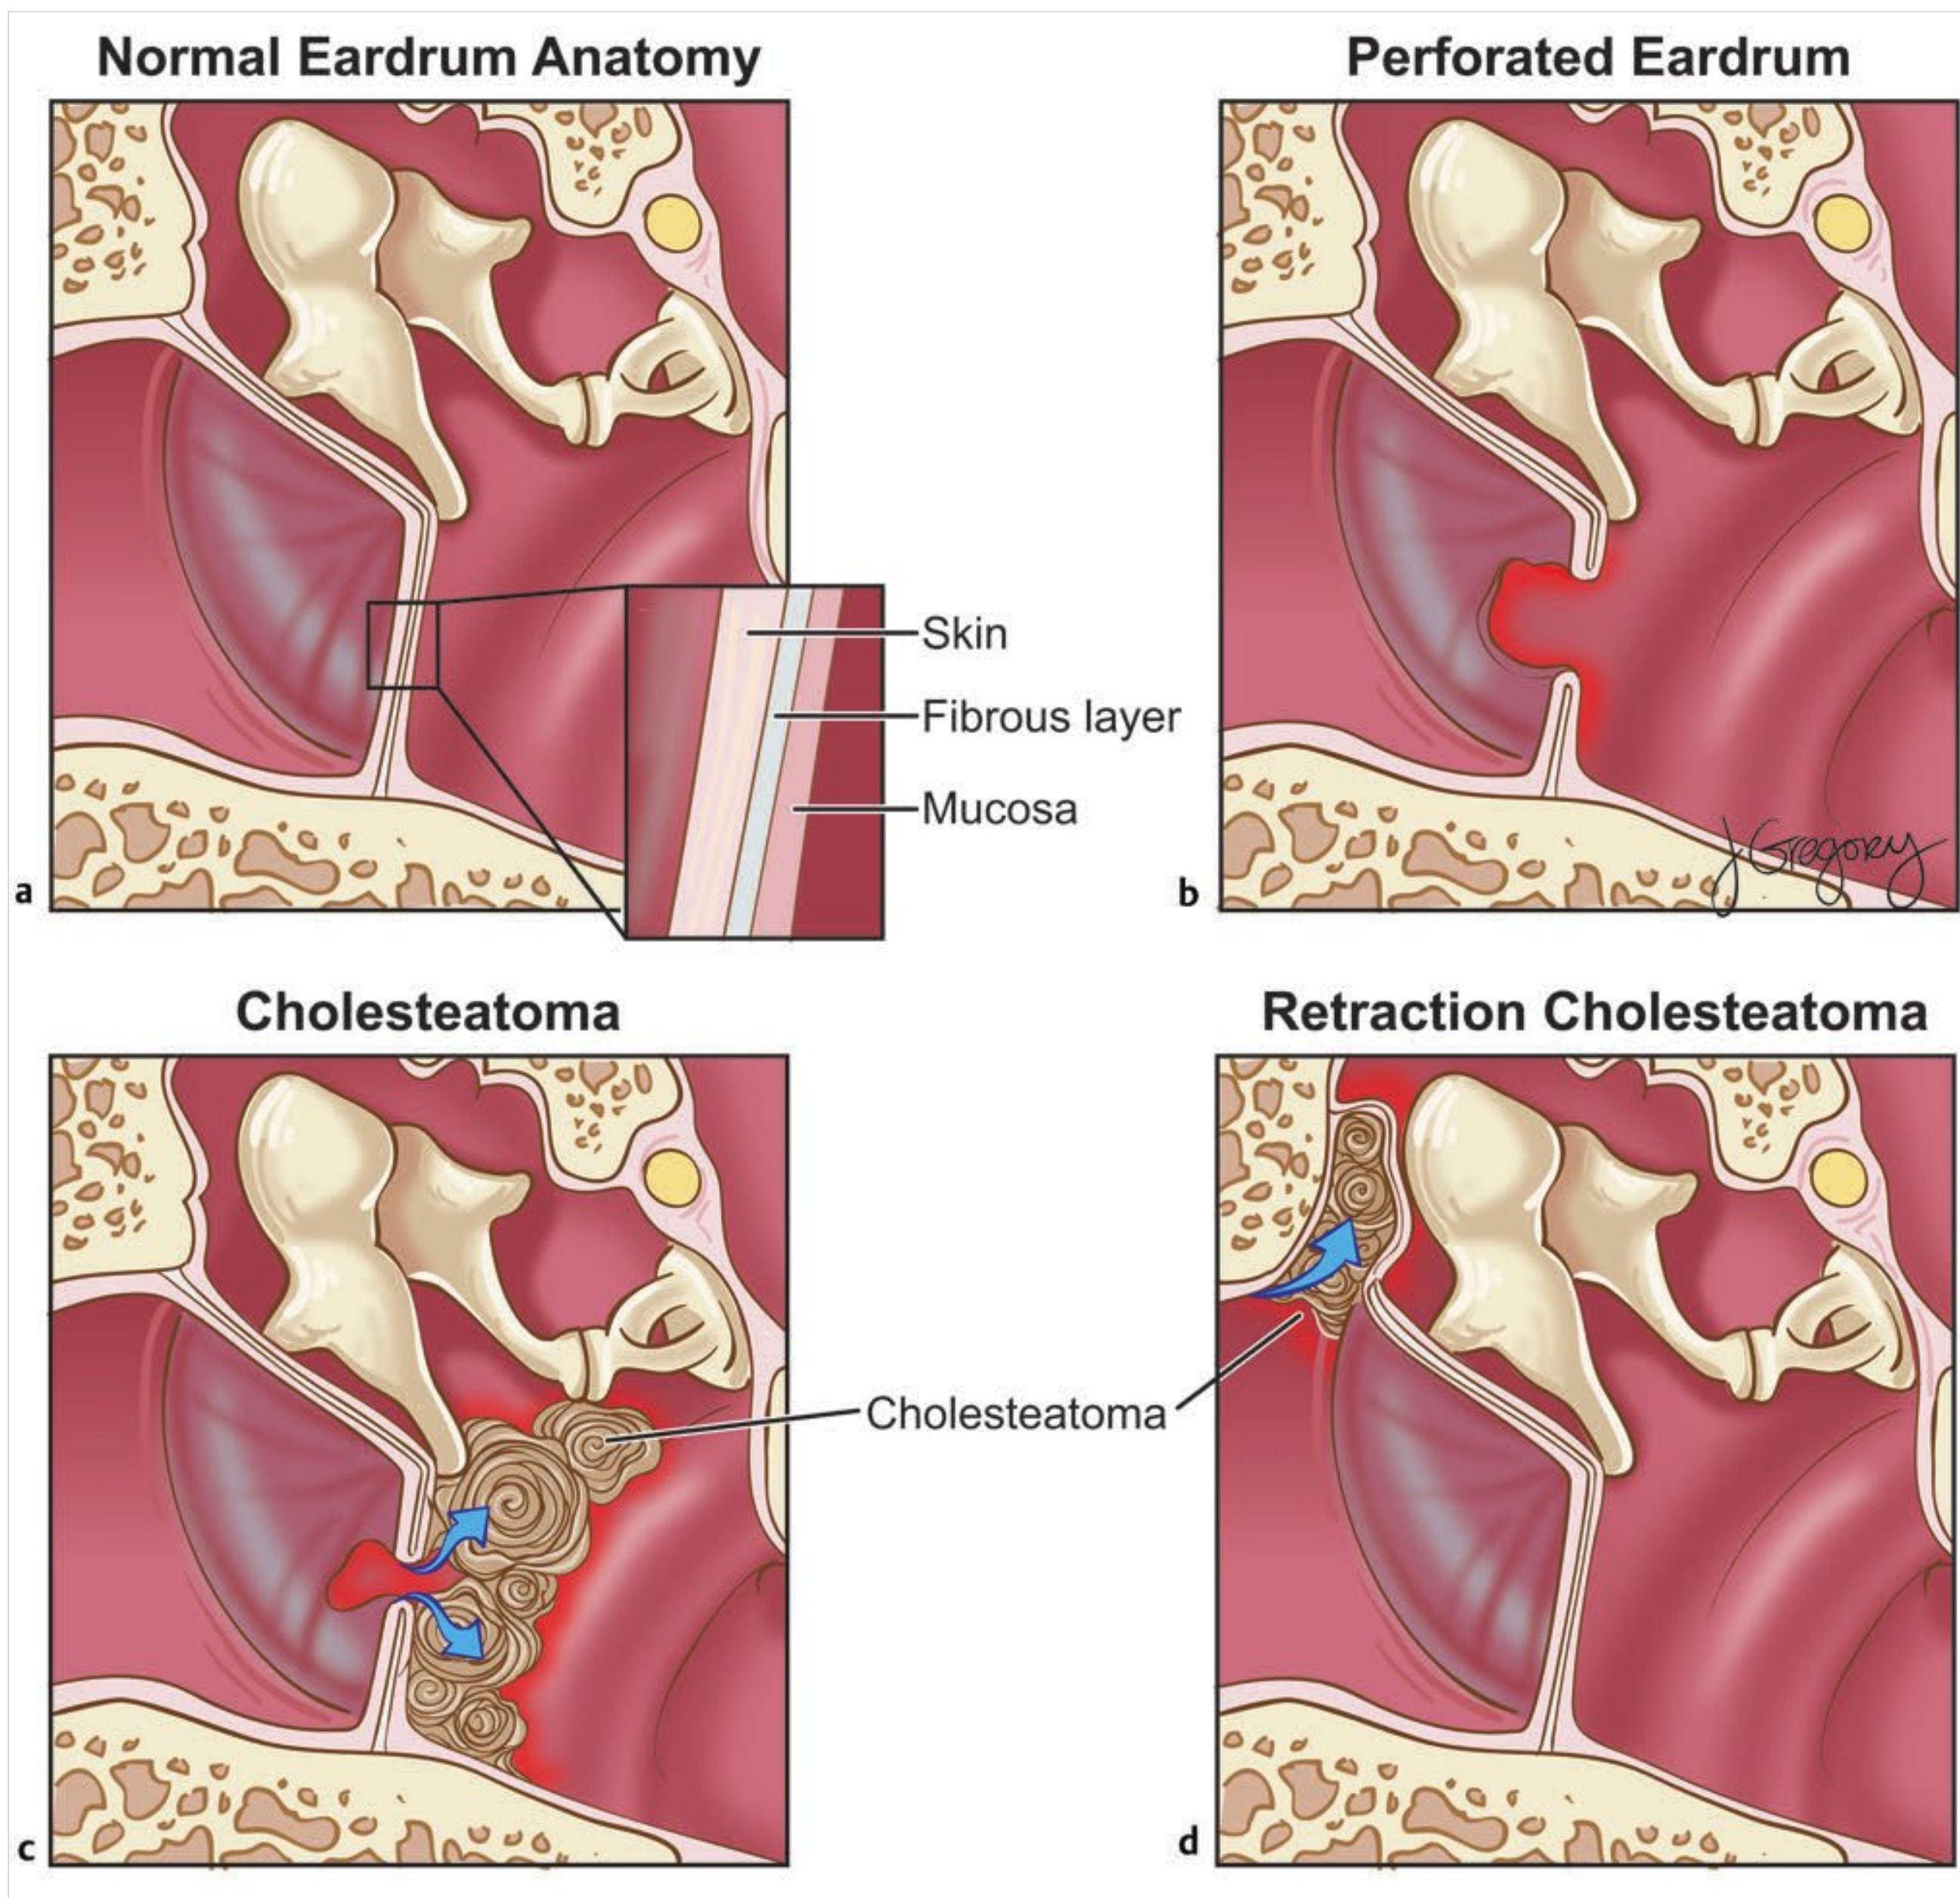

Fig. 117.4 (a) Normal anatomy of the tympanic membrane and middle ear. (b) Tympanic membrane perforation. (c) Squamous epithelium migrating through a tympanic membrane perforation into the middle ear to form a perforation cholesteatoma. (d) Development of a retraction cholesteatoma in an attic retraction pocket.

small residue of cholesteatoma matrix in the middle ear or mastoid can lead to residual disease, and the incidence of residual cholesteatoma is reported to be as high as 25%. Residual cholesteatoma occurs most often in the middle ear and epitympanum. It usually presents as a small “pearl” of cholesteatoma at the site of the abandoned matrix. Residual disease can be difficult to diagnose. Many surgeons advocate a planned second-look surgical procedure for residual disease 9 to 12 months after the initial surgery. CT may be useful in identifying residual disease, particularly if a baseline study demonstrates a well-pneumatized middle ear and mastoid. A small opacity that enlarges over time strongly suggests residual disease. There has been a recent trend toward using non-echo-planar diffusion-

weighted magnetic resonance (MR) imaging to detect residual disease. Dremmen et al reported a positive predictive value of 93% for the detection of cholesteatoma including lesions as small as 2 mm.

There are numerous technical approaches to reconstructing the tympanic membrane and ossicular chain, which are beyond the scope of this chapter. The critical factors for success include removing all disease, grafting the tympanic membrane with cartilage to prevent recurrent retraction disease, and adequately assessing the status of the ossicular chain in order to maximize reconstructive efficacy. Recurrent disease, which develops in about 25% of patients, is best prevented by cartilage reinforcement tympanoplasty.

There continues to be controversy regarding canal wall up versus canal wall down tympanomastoid procedures. Ears in which the normal anatomy is preserved with canal wall up mastoidectomy certainly heal faster, may have better postoperative hearing, and do not require the maintenance of a mastoid bowl, which is associated with complications. Taking the canal wall down can improve mastoid and attic exposure, particularly when the dura is low-lying or the sigmoid sinus is located far anteriorly. There is general agreement that the canal wall should be taken down if a patient is likely to be unreliable in follow-up because a canal wall down ear is generally safer. In other settings, the key issue should be the location of the disease. Taking the canal wall down does not improve exposure of the middle ear, facial recess, or sinus tympani. If disease is in the epitympanum, a transcanal or transmastoid atticotomy may suffice. Taking the canal wall down, with proper exteriorization of the epitympanum, nearly eliminates the possibility of recurrent retraction disease. Residual disease in the mastoid should be easily managed in the office setting with a canal wall down procedure. A middle ear that becomes adhesive following a Bondy modified radical mastoid procedure, in effect, autoconverts to Bondy radical.

117.3 Middle Ear Neoplasms

Middle ear tumors, other than cholesteatoma, are unusual. A glomus tumor is a benign nonchromaffin paraganglioma arising from paraganglia (glomus bodies) of the parasympathetic nervous system. Glomus bodies are small (0.25 to 0.50 mm) ovoid patches of paraganglionic cells that are dispersed throughout the body, mostly in association with autonomic nervous tissue. In the head and neck, glomus bodies are found at the carotid bifurcations, along the vagus nerve, and in the temporal bone arising along the Jacobson nerve (tympanic branch of the glossopharyngeal nerve, or cranial nerve IX). When functionally active, glomus bodies are chemoreceptive organs that detect changes in arterial partial pressures of oxygen and carbon dioxide and increase or decrease stimulation to the brainstem respiratory centers.

Glomus tumors, after cholesteatomas, are the most common tumors of the middle ear. Glomus jugulare tumors arise over the dome of the jugular bulb and extend into the middle ear and mastoid. Glomus tympanicum tumors arise on the promontory and are more often limited to the middle ear. Both present as a middle ear mass, often with a red hue (□ Fig. 117.5). The average age at presentation is 52 years, and females are more commonly affected than males in a ratio of 5:1 to 6:1. Rarely, glomus tumors can metastasize to distant organs, even though they do not appear histologically malignant. One to three percent are endocrinologically active, secreting catecholamines or dopamine. Symptoms associated with endocrine activity include excessive sweating, hypertension, tachycardia, anxiety, and weight loss.

The most common symptoms are pulsatile tinnitus and hearing loss. The diagnosis is suspected upon otoscopic identification of a middle ear mass. CT of the temporal bones helps differentiate isolated glomus tympanicum tumors from larger, extensive glomus jugulare tumors. Of critical importance, CT rules out an ectopic carotid artery or a jugular bulb diverticulum, either of which can mimic a glomus tumor. MR imaging

Fig. 117.5 Small, posteroinferior glomus tympanicum tumor of the right ear.

and angiography are helpful diagnostic adjuncts. The treatment of glomus tympanicum tumors is surgical removal. Glomus jugulare tumors can be embolized and surgically removed, or if large, they can be embolized and treated with radiation. Occasionally, what was thought to have been a glomus tumor will turn out postoperatively to have been a lower cranial nerve schwannoma, a meningioma, or a benign adenomatous tumor of the middle ear mucosa. Primary malignancies of the middle ear are extremely rare.

117.4 Metabolic Disorders of the Middle Ear

117.4.1 Otosclerosis

Otosclerosis is a disorder of bone remodeling that affects the bone of the otic capsule but no other bone in the human body. There are two phases to this process: a continuous resorption of the dense bone of the cochlear capsule and the simultaneous deposition of new, softer, more vascular bone. The etiology of otosclerosis is unknown. Approximately 50% of patients with otosclerosis have a positive family history, strongly suggesting a genetic factor that is yet to be identified. Other proposed etiologies include a metabolic disease of bone, an autoimmune disorder, a response to measles virus, and an abnormal response to hormonal factors. Otosclerosis usually begins in the late twenties or thirties, is more common in women than in men, and is bilateral in half of patients.

Otosclerosis occurs most often as a distinct focus of abnormal bone at the juncture of the anterior edge of the footplate of the stapes and the adjacent otic capsule. This focus of abnormal bone fixes the stapes and causes a conductive hearing loss, which is the most common presenting symptom of otosclerosis. Other associated symptoms include tinnitus, sometimes pulsatile, and ear fullness. The physical examination is normal, with

the exception that tuning fork tests suggest a conductive hearing loss. On occasion, there is a red blush to the promontory of the middle ear due to the underlying hypervascular bone, the so-called Schwartze sign. Audiometric testing reveals a predominantly conductive hearing loss. Therapeutic options include expectant observation, hearing aids, and surgery. Expectant observation may be acceptable if the hearing loss is mild or unilateral. Amplification, in the form of a hearing aid, should restore hearing to normal or nearly normal and is risk-free. Stapedectomy, the surgical removal of the stapes and replacement with a stapes prosthesis, returns hearing to nearly normal in 97% of patients. The main risk of stapedectomy surgery is complete loss of hearing in the operated ear due to inner ear injury. This complication occurs in approximately 1% of surgeries. Other risks include the new onset of tinnitus, dizziness, facial nerve injury, and postoperative taste disturbance.

Occasionally, otosclerosis will diffusely invade the surrounding otic capsule and cause a severe to profound sensorineural hearing loss. This can happen with or without disease affecting the stapes. If there is no conductive component, such patients are not candidates for stapedectomy. They benefit from hearing aids until their hearing loss reaches a degree at which a cochlear implant is merited. Some data support the use of oral fluoride and calcium to stabilize the sensorineural component of otosclerosis.

117.4.2 Paget Disease

Paget disease is characterized by increased osteoclastic activity that causes extensive remodeling of bone. The skull and temporal bone are often involved. The most common otologic symptom is progressive hearing loss, which is usually a mixed loss. The hearing loss may be associated with tinnitus and dizziness. The diagnosis is made with imaging studies. Treatment is medical.

117.4.3 Osteogenesis Imperfecta

Osteogenesis Imperfecta is a genetic connective tissue disorder that affects collagen. The hallmarks of osteogenesis imperfecta are brittle bones that easily fracture, blue sclerae, and hearing loss. Osteogenesis imperfecta may be associated with a conductive hearing loss due to a discrete bony focus similar to that seen in otosclerosis or a sensorineural hearing loss due to cochlear involvement. The diagnosis is made by family history, genetic testing, and imaging studies. A stapedectomy is an option in patients with limited disease causing a conductive hearing loss.

117.5 Autoimmune Disorders Affecting the Middle Ear and Mastoid

Rarely, an autoimmune disorder can present as chronic, non-cholesteatomatous otitis. Wegener granulomatosis is a systemic disease characterized by necrotizing granulomatous vasculitis

of the upper and lower respiratory tract and renal disease. The presenting ear symptoms may be serous otitis media secondary to nasopharyngeal obstruction of the eustachian tube, or chronic middle ear and mastoid granulomatous disease. The diagnosis is made on biopsy and serologic identification of cytoplasmic antineutrophil cytoplasmic autoantibodies (c-ANCA) in peripheral blood. Recently, autoimmune disease related to immunoglobulin G4 (IgG4) has been reported to mimic recurrent, chronic otitis and mastoiditis. IgG4-related disease is characterized by an overabundance of IgG4-positive plasma cells in affected tissues and, frequently, elevated serum IgG4 levels. This clinical entity was first described in the context of autoimmune pancreatitis. The diagnosis is made by the identification of plasma cells immunohistochemically positive for IgG4 and an elevated peripheral serum level of IgG4. In both cases, the treatment is medical.

117.6 Traumatic Injuries to the Middle Ear

Traumatic injuries to the middle ear are often self-inflicted. Manipulation of the ear with a Q-tip, hair pin, or pen can result in a perforation of the tympanic membrane and disarticulation of the ossicular chain. If the trauma results in sensorineural hearing loss or vertigo, emergent surgical exploration may be necessary to seal a possible perilymphatic fistula of the inner ear. Blunt trauma to the head can cause a temporal bone fracture. Temporal bone fractures are classically categorized as longitudinal (along the axis of the external auditory canal) or transverse (perpendicular to and traversing the internal auditory canal). Many temporal bone fractures are a complex combination of the two. Temporal bone fractures, particularly longitudinal, can cause a tympanic membrane rupture and ossicular discontinuity. The diagnosis is confirmed on CT. If there is a sensorineural component to the hearing loss, a perilymphatic fistula should again be suspected. Occasionally, severe trauma can lead to cerebrospinal fluid otorrhea through a tympanic membrane perforation.

117.7 Roundsmanship

- The most common disorders of the middle ear are infectious/inflammatory, in particular otitis media of childhood.
- Unilateral serous otitis in an adult, particularly in association with ipsilateral cervical lymphadenopathy, suggests carcinoma of the nasopharynx.
- A red mass of the middle ear is most often a glomus tumor, but imaging is essential to rule out an ectopic carotid artery or a jugular bulb diverticulum.
- Adequate treatment of cholesteatoma is predicated on a thorough knowledge of the anatomy and location of the pathology.
- The most common cause of a unilateral conductive hearing loss, in the absence of a prior history of ear infection or surgery, is otosclerosis.

118 Surgery for Chronic Ear Disease

John F. Kveton and Christopher J. Linstrom

118.1 Introduction

The successful management of chronic ear disease depends upon the surgical techniques employed to eradicate the disease within the temporal bone. The surgeon must possess a solid understanding of the basic surgical approaches to the temporal bone and, more importantly, must know when to adapt these particular approaches to the surgical situation at hand. This chapter will outline a systematic, step-by-step approach that should be employed by the surgeon to manage chronic ear disease. A disciplined surgical perspective is critical for the successful application of this approach to obtain deeper exposure within the temporal bone.

118.2 A Systematic Approach to the Temporal Bone

The easiest way to understand this approach to chronic ear disease is to remember how temporal bone dissection is learned in the temporal bone laboratory. One begins by first learning the surface anatomy of the temporal bone, followed by a cortical mastoidectomy. Deeper dissection progresses to expose the antrum and the ossicular heads in the epitympanum. One next proceeds with identification of the facial nerve and chorda tympani nerve, opening of the facial recess, and exposure of the stapes and long process of the incus within the middle ear. Finally, for a wider-field exposure of the middle ear and anterior epitympanum, the posterior canal wall is removed. This method of exposing the mastoid and middle ear regions can be adapted to deal with any disease encountered within the temporal bone and can be successfully employed if the surgeon develops a disciplined attitude to adhere to this method in all cases.

118.2.1 Incision

A postauricular incision is mandatory in the management of patients with chronic ear disease. Transcanal approaches should be reserved for noninfected middle ear procedures, such as tympanoplasty for a dry tympanic membrane perforation or ossiculoplasty. Endaural approaches to the mastoid are mainly of historical interest and will not be described in this chapter. The postauricular approach to the mastoid is safer and is the foundation for this systematic approach to mastoid surgery. Before the postauricular incision, vascular strip incisions are made in the ear canal (□ Fig. 118.1).

The postauricular incision is made 5 to 10 mm behind the postauricular crease after the region has been infiltrated with local anesthetic with epinephrine. This incision should begin 10 mm above the crus of the helix and extend around to the mastoid tip. The incision should involve only the subcutaneous tissue, avoiding the temporalis muscle and musculoperiosteal layer over the mastoid bone. The subcutaneous layer over the temporalis muscle should be developed, and either the areolar tissue over the temporalis fascia or the temporalis fascia should

be harvested. After placement of a self-retaining retractor to expose the musculoperiosteum over the mastoid, the mastoid region should be palpated to identify the temporal line (which becomes the root of the zygoma in the anterior margin of the exposure). This is an important landmark in the initial exposure for mastoid surgery because the middle cranial fossa dura is almost never inferior to the temporal line. With electrocautery, an incision is now made through the temporalis muscle 5 to 10 mm superior and parallel to the temporal line, as far as the retraction allows. Electrocautery is now used to make another incision perpendicular to the temporal line down to the mastoid tip. The musculoperiosteal flaps are elevated to expose the whole mastoid bone, and the self-retaining retractor reflects the flaps to maintain exposure. The vascular strip elevates out of the ear canal with the anterior musculoperiosteal flap so that the ear canal and middle ear are accessible through this exposure. Middle ear disease can now be addressed and preparation for tympanoplasty accomplished. Disease around the oval window should be left in place at this time and the middle ear packed with epinephrine-soaked absorbable gelatin material.

118.2.2 Simple Mastoidectomy

All procedures for chronic ear disease begin in this manner. Under the operating microscope, the mastoid cortex is inspected, with note taken of the temporal line and its relationship to the spine of Henle and fossa mastoidea. This provides a rough indication of the proximity of the middle cranial fossa dura to the ear canal, and therefore of how difficult the mastoid procedure will be.

Fig. 118.1 Before the postauricular incision, a vascular strip is outlined with angles and straight Beaver blades.

Fig. 118.2 Mastoidectomy is begun by using a large cutting bur to identify the middle fossa dura along the temporal line.

With a cutting bur and continuous suction–irrigation, drilling is now begun about two drill diameters above the temporal line. Drilling should begin anteriorly above the external auditory canal and extend posteriorly to the incision in smooth continuous strokes until the dura is identified through a thin layer of bone (□ Fig. 118.2). Once the dura has been identified, the mastoid cortex can be removed inferior to the dura, down to the mastoid tip and skeletonizing the posterior canal wall. The central mastoid air cells are now removed by following the sigmoid sinus medially and maintaining the dural plate over the tegmen superiorly. Following the tegmen, the Körner septum is encountered, and once it has been removed, the lateral semicircular canal is seen in the antrum. With the lateral semicircular canal in view, progressively smaller burs can be used to open the aditus ad antrum until the short process of the incus is identified. Further dissection anteriorly will expose the heads of the incus and malleus. The remaining central mastoid cells and mastoid tip are opened to remove residual mastoid disease. The vertical segment of the fallopian canal may be exposed if necessary at this time (□ Fig. 118.3).

With this exposure, most chronic mastoid and middle ear inflammatory disease can be managed. All thickened granulation tissue can be removed in the mastoid and attic regions through the mastoid, and the middle ear disease can be managed through the ear canal. Successful disease removal can be measured by the free flow of irrigation fluid from the attic into the middle ear. Once this is accomplished, tympanoplasty can be performed.

118.2.3 Facial Recess Exposure

Exposure of the middle ear and ossicles via the facial recess is an indispensable tool for the otologic surgeon to effectively eradicate disease that is too extensive for a simple mastoidectomy exposure. The facial recess approach is mandatory in cholesteatoma surgery in which a staged approach is planned, and

in fact it should be used in any case of posterior–superior retraction pocket disease or attic cholesteatoma. This approach is also helpful in chronic inflammatory disease when the ossicular chain is encased in granulation tissue. Working through the facial recess allows complete removal of disease around the ossicular chain to correct the associated conductive hearing loss. In the event that ossicular erosion has occurred, the facial recess provides a better approach for measurement and placement of the ossicular prosthesis, whether it is an autograft or prosthesis.

Whether the decision to use the facial recess approach is made at the onset of the surgery (as in cholesteatoma cases) or during the simple mastoidectomy, the surgical technique should not vary. Once the attic has been widely opened, the vertical segment of the facial nerve is defined. The digastric ridge in the opened mastoid tip should be traced anteriorly, and the vertical segment of the facial nerve will be identified as it enters the stylomastoid foramen. With a thin a layer of bone kept over the fallopian canal, the nerve should be followed superiorly toward the lateral semicircular canal until the second genu has been uncovered. In this process, the chorda tympani nerve will be identified as it courses somewhat posterior to the plane of the vertical segment, so that as the vertical segment is being identified, care must be taken to avoid injury to the chorda tympani. The chorda tympani should be preserved at this time in the surgery to serve as the lateral limit of dissection. Drilling lateral to the chorda tympani nerve will result in entering the ear canal lateral to the annulus of the tympanic membrane. Once the vertical segment of the facial nerve has been identified, progressively smaller smooth diamond burs are used to remove all bone lateral to the vertical segment but medial to the chorda tympani to complete the facial recess approach (□ Fig. 118.4).

In cases of chronic suppurative otitis media, granulation tissue can now be removed from the posterior tympanum and the ossicular chain assessed. In these cases, the posterior bony

Fig. 118.3 (a) Upon completion of a simple mastoidectomy, the tegmen plate, sigmoid sinus, malleus and incus heads, and lateral semicircular canal are identifiable. (b) As seen intraoperatively in a left ear, the bluish shade indicates thin bone at the tegmen tympani and overlying the sigmoid sinus.

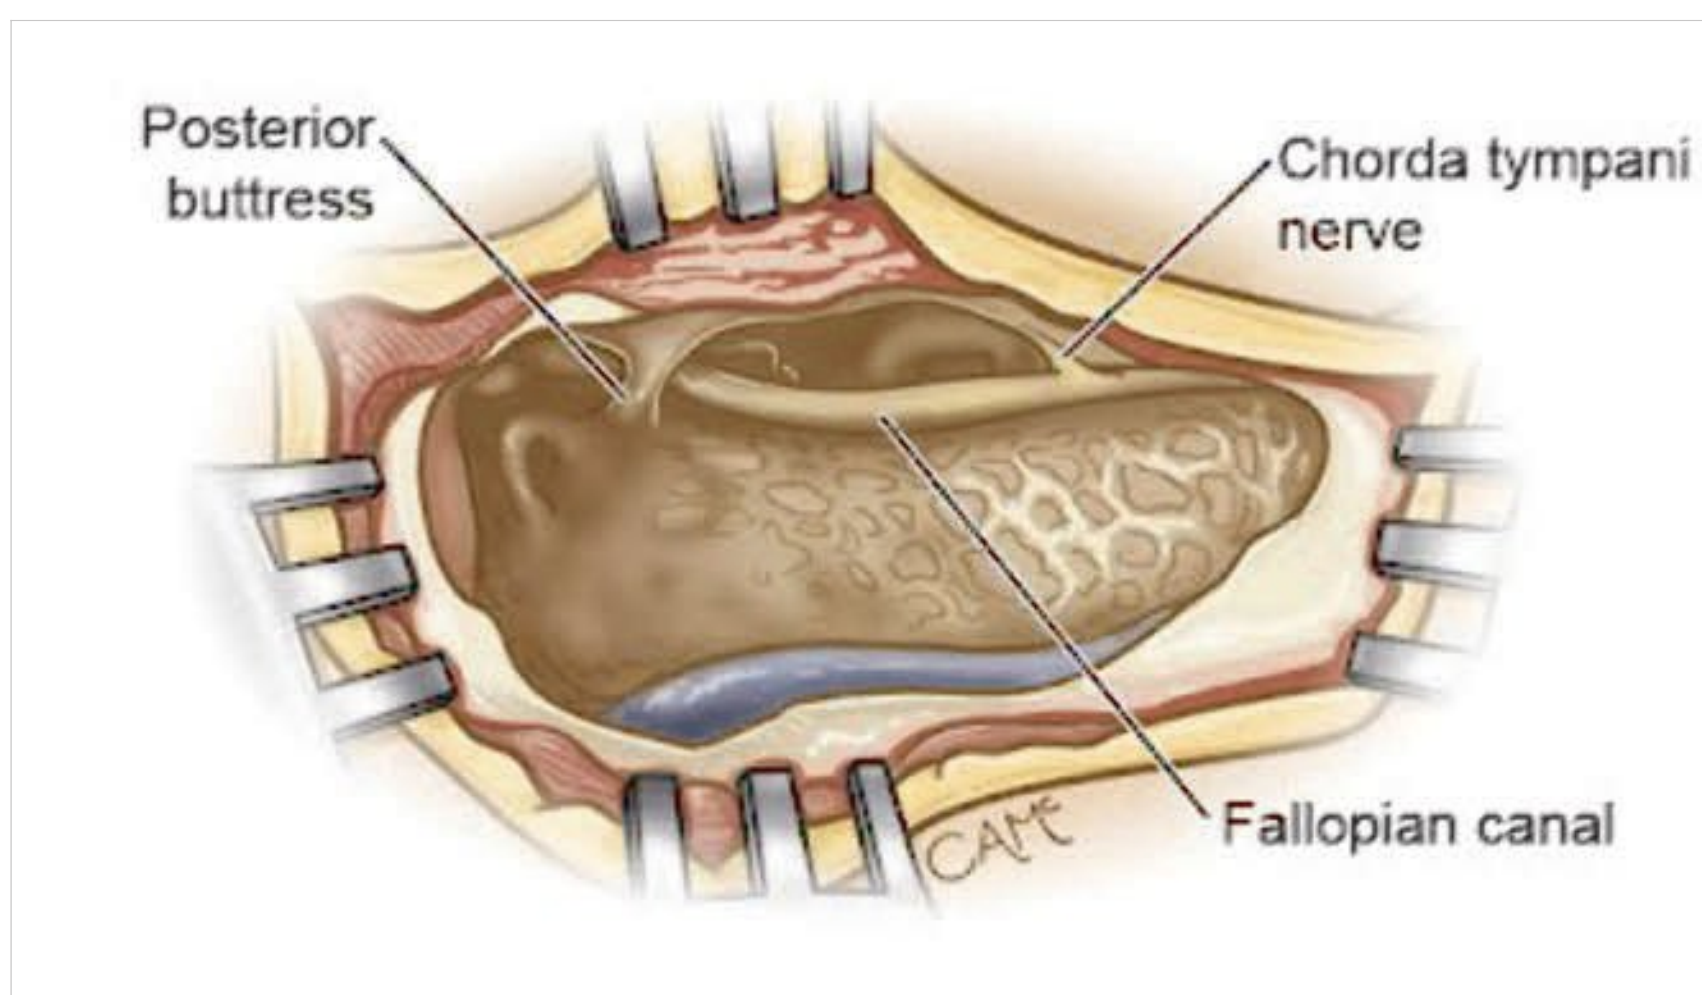

Fig. 118.4 The boundaries of the facial recess are the posterior buttress superiorly, the chorda tympani nerve laterally, and the fallopian canal medially.

buttress is maintained to stabilize the incus at the posterior incudal ligament.

The visualization of the posterior tympanum that is provided by the facial recess approach makes possible the resection of the vast majority of cholesteatomas encountered by the otologic surgeon, so that the need for a canal wall down procedure

is avoided. The number of canal wall down procedures would dramatically increase if the facial recess approach were not used because most cholesteatomas cannot be totally removed with the simple mastoidectomy approach.

Cholesteatoma management through the facial recess approach begins by viewing the cholesteatoma and its relationship

Fig. 118.5 (a) Removal of the posterior buttress provides better access to the anterior epitympanum for (b) removal of the malleus head and cholesteatoma in the posterior tympanum and anterior epitympanum.

to the ossicular chain. If the cholesteatoma is medial to the incus or anterior to the malleus head with an intact ossicular chain, the ossicular chain must be disarticulated to remove the disease. If ossicular erosion is present, disarticulation of the remaining ossicles is necessary. Disarticulation of the intact ossicular chain is begun by first cutting the incudostapedial joint, then separating the incudomalleolar joint with a sickle knife and removing the incus from the surgical field. With a 2-mm smooth diamond bur, the posterior bony buttress is removed, and the internal portion of the second genu of the facial nerve is defined as it enters the horizontal segment of the facial nerve, so that the facial nerve can now be traced from the horizontal segment through the second genu to the vertical segment. With this enhanced exposure, cholesteatoma can be removed from the stapes, oval window, and most of the middle ear. If the chorda tympani nerve is involved in cholesteatoma, it should be cut and removed with the specimen. If cholesteatoma is entering the sinus tympani, a small diamond bur can often remove a bony overhang inferior to the pyramidal eminence and anterior to the vertical segment of the facial nerve to provide access for

removal of the disease. Extending the facial recess exposure by removing the chorda tympani to drill more inferiorly may be necessary (□ Fig. 118.5).

The majority of attic cholesteatomas involve the malleus as well, and inadequate resection of the malleus and surrounding bone is a common reason for recurrence. Recurrence in the attic can be reduced by adhering to the surgical steps of facial recess cholesteatoma resection. After the cholesteatoma has been managed around the stapes and oval window region, a small diamond drill is used to expose the malleus head. The head of the malleus is amputated to expose the anterior epitympanum. A diamond drill is used to smooth out the tegmen plate and open the anterior epitympanum. The cog must be removed to obtain this exposure. Any cholesteatoma remnants can now be removed, and the horizontal segment of the facial nerve can be examined as it progresses superior to the cochleariform process on its way to the geniculate ganglion. This exposure also provides better visualization of the semicanal of the tensor tympani region toward the eustachian tube orifice. Finally, a small diamond bur should be used to drill the bony margins of

Fig. 118.6 Wider removal of the superior canal wall once the posterior canal wall has been removed allows better healing of the mastoid defect.

Fig. 118.7 Attention to the inferior bony transition into the mastoid tip results in a more rounded mastoid cavity that will reepithelialize more uniformly.

the attic defect (if present) to ensure complete removal of the disease before reconstruction.

118.2.4 Canal Wall Down Mastoidectomy

Removal of the posterior bony canal wall is the final step in this systematic approach to the surgical removal of middle ear and mastoid disease. Even if the surgeon identifies the need to take this step early in the procedure, he or she must follow the previous steps of the facial recess exposure to perform the procedure appropriately. The surgeon must identify the facial nerve and develop the facial recess before proceeding with the posterior canal removal. Disciplined adherence to this technique protocol will result in a more successful outcome because of the importance of a low-lying facial ridge for healing and later cleaning of the mastoid defect.

Once the facial nerve has been identified via the facial recess approach, the major portion of the posterior canal can be removed with several bites of a bone rongeur or a large cutting bur (□ Fig. 118.6). The most critical stage of this procedure now occurs, which is the development of smooth bony transitions into the attic superiorly and into the inferior bony canal inferi-

orly. Progressively smaller diamond burs are used to remove residual bone covering any air cells within the anterior epitympanum, making the tegmen essentially continuous with the anterior–superior external canal. Removal of these anterior epitympanic cells usually uncovers cholesteatoma and also avoids mucoid drainage after healing. Inferiorly, varying amounts of bone are removed to widen access to the tympanic membrane and produce a smooth, wide transition into the mastoid tip. This technique prevents the accumulation of keratinous debris in the postoperative cavity. The wide exposure can be expanded to resect any residual cholesteatoma within the hypotympanum by drilling down the inferior anulus. Cholesteatoma in the sinus tympani can be reached by removing more bone anterior to the vertical segment of the facial nerve once the posterior canal wall has been removed (□ Fig. 118.7).

As important as the bony dissection is for the removal of chronic disease, the development of an appropriately sized external meatus is critical for the long-term success of a canal wall down procedure. The conchomeatoplasty begins after all bone dissection has been completed. The medial surface of the conchal cartilage is exposed by sharply dissecting all soft tissue away with a curved iris scissors. A semilunar incision is then made as the cartilage turns laterally so that auricular protrusion is preserved while maximal expansion of the external auditory

Fig. 118.8 Development of the superiorly based conchomeatal flap is key to successful healing of a canal wall down mastoidectomy.

meatus is obtained. Now, beginning in the ear canal, an incision is made in the inferior canal at 6 o'clock and carried straight out of the ear canal through the meatus to the new margin of the cartilage. The incision is then turned along the margin of the cartilage halfway up the distance of the conchal bowl. A second incision is begun at 12 o'clock in the ear canal and is carried out of the ear canal between the tragus and the root of the helical crus (□ Fig. 118.8). Hemostasis should be quickly achieved, and any exposed cartilage at these incisions is sharply resected with a curved iris scissors or No. 15 blade. This superiorly based conchomeatal flap should line the posterior–superior aspect of the mastoid defect and serve as a source of reepithelialization of the mastoid bowl (□ Fig. 118.9). Once this flap has been developed, closure of the middle ear can be performed with a large piece of temporalis fascia or pericranium. Gelfoam (Pfizer, New York, NY) should be placed into the Eustachean tube and the anterior mesotympanum, but the graft should be placed onto the promontory and span the oval window to lie directly on the facial nerve and lateral semicircular canal. If the stapes is absent, a bone strut or cartilage may be used for ossicular reconstruction, but the purpose of this procedure is the development of a dry ear with a sealed middle ear rather than hearing restoration. The auricle is then reflected into position, and the conchomeatal skin flap may be secured posteriorly by placing two absorbable sutures at the lateral margins of the flap and securing them posteriorly to the musculoperiosteal layer. The post-auricular incision is then closed with a deep subcuticular stitch. The mastoid defect may be filled with ophthalmic antibiotic ointment or packed with surgical Nu-Gauze (Johnson & Johnson, New Brunswick, NJ) impregnated with antibiotic ointment.

118.3 Tympanoplasty

After disease in the middle ear and mastoid has been dissected and removed, in most cases the tympanic membrane will at

least need to be reinforced if not reconstructed. A study of various techniques of tympanoplasty is therefore logical after a discussion of mastoidectomy; these may be performed with mastoidectomy or alone.

Other than traumatic perforations in an erstwhile normal drum, almost all perforations of the drum occur in the context of chronic otitis media or cholesteatoma and involve at least partial eustachian tube dysfunction. The surgeon must keep this in mind. It is not uncommon in the technique of tympanoplasty to account for poor eustachian tube function by placing a ventilation tube through the grafting material in order to ventilate the middle ear.

Tympanoplasty is the placement of soft tissue or cartilage without or with adnexal attachments in a favorable way to reconstruct a defect in the ear drum. Paper patching of an acute perforation involves many of the same principles as a Wullstein type I tympanoplasty, to be discussed, but it does not use soft tissue to repair the drum and therefore is not properly considered a tympanoplasty.

The basic mechanism of repair is that the freshened epithelial edge from the rim of the perforation or from the surrounding external auditory canal will migrate over the scaffold of soft tissue until it meets another area of squamous epithelium, when it will stop proliferating as a consequence of contact inhibition. It is essential that there be absolutely no entrapment of squamous epithelium beneath the soft-tissue scaffold. If it is trapped, it will almost always result in the formation of a keratoma or a cholesteatoma.

118.3.1 Classification

Tympanoplasty may be classified in several ways:

1. By the technique of soft-tissue placement used (overlay technique, underlay technique, combined technique)
2. By that part of the native ossicular chain before reconstruction to which any prosthetic or soft tissue is applied (Wullstein classification)
3. By combined techniques that use soft tissue and cartilage or another strengthening material (e.g., cartilage tympanoplasty)

118.3.2 Technique of Soft-Tissue Placement

Overlay Technique

The overlay technique is indicated for large, nearly total or total perforations; for previous tympanoplasty failures; for large perforations in which there is a severely blunted anterior angle of the external auditory canal; and for cases in which the primary goal is to achieve a grafted, safe, and dry ear, with hearing a secondary and minor consideration.

Approach

Although any tympanoplasty may be performed via a transcanal approach, the best view of the ear will be obtained via a postauricular approach. This is the recommended technique and allows not only the best view but also perfect placement of all grafting material. The auricle itself will hide a well-placed

Fig. 118.9 Reepithelialization of the mastoid bowl will occur from the conchomeatal flap in the sinodural angle and the anterior canal wall skin.

postauricular incision. The incision need not be long. If there is a bony excrescence, a prominent anterior overhang, or a pronounced tympanomastoid or tympanosquamous suture line, this will need to be drilled down, which is best done from behind, with the ear opened maximally. The vascular strip incisions (□ Fig. 118.10) may be done through the canal or from behind, according to the preference of the surgeon, but the exposure should be as great as possible, with every millimeter of the drum remnant easily visible.

The overlay grafting technique requires that all of the squamous epithelium surrounding the perforation and the surrounding skin of the external auditory canal be removed and saved to graft the lateral surface of the new scaffold of fascia as a free graft of squamous epithelium (□ Fig. 118.11). If there is a

prominent anterior bony overhang, the skin over it should be carefully “window-shaded” away from the middle ear cleft and held away while the bony external auditory canal is carefully drilled down and shaped so that every millimeter of the fibrous annulus can be seen (□ Fig. 118.12). This is often a quick task, but it must not injure an intact, mobile ossicular chain. Acoustic trauma due to a rapidly rotating microdrill will be transmitted through the ossicles, causing a high-tone (usually >6 kHz) acoustic trauma. To thin the anterior bony canal, diamond drills alone should be used because they are less likely to skip or jump. It is of the utmost importance that the ossicular chain be visible and indeed viewed at every moment of drilling. If the bone is too thin, the drill may approach the glenoid fossa, the capsule of which lies just anterior to the tympanic ring. If

Fig. 118.10 Overlay technique of tympanoplasty begins with vascular strip incisions and elevation.

Fig. 118.11 The residual tympanic membrane and surrounding external canal skin are elevated and saved for later grafting.

Fig. 118.12 Bony overhangs of the medial canal are removed to allow complete visualization of the annulus.

yellow fat is encountered, the dissection has proceeded too far anteriorly. The fat should be gently reduced with a bipolar cautery and otherwise left alone. The patient may have trismus postoperatively.

Once all portions of the tympanic membrane remnant have been visualized, the squamous epithelium over the drum and the anterior canal is removed and saved as a free graft. There is usually a remnant of the fibrous annulus left, but very little else of the native drum. Temporalis fascia that has been air-dried is

Fig. 118.13 Dried temporalis fascia is cut to size and split to allow passage below the handle of the malleus.

now cut in the shape of the new drum, and a slit is fashioned to allow the handle of the malleus to pass above (lateral) to the graft (□ Fig. 118.13). The slit is cut in such a way that the redundant fascia will drape over the upper part of the malleus. The fascia is supported medially with absorbable gelatin sponge (Gelfoam) or another packing material. The fascia is now spread out to cover the entirety of the perforation and often resembles an intact, healed drum (□ Fig. 118.14). The free graft of epithelium is spread out into the anterior angle between the edge of the fascia and the anterior tympanic ring (□ Fig. 118.15). A folded piece of dry Gelfoam (the “dry roll”) is tucked carefully

Fig. 118.14 The fascia is placed under the malleus.

Fig. 118.15 The free graft is placed over the fascia.

Fig. 118.16 Postauricular incision provides access to the external canal as well as to temporalis fascia.

into this anterior angle. This will help jump-start the epithelialization of the lateral surface of the drum. If other pieces of thin skin are available, they may be placed epithelial side up on the lateral surface of the fascia to encourage epithelialization. The lateral surface of the fascia and squamous epithelium “sandwich” is now supported with either dry or moist Gelfoam. It is helpful to place a leaf of moistened Gelfilm (Pfizer) immediately lateral to the fascia and Gelfoam. This will greatly facilitate cleaning the ear in the postoperative stage. The vascular strip is returned to its proper position, and the postauricular incision is closed in layers. As a final check, the vascular strip is carefully everted, then replaced to its proper position and held there by pieces of Gelfoam. Cotton or another packing material is placed into the meatus, and the ear is dressed with a dry mastoid or similar dressing.

Fig. 118.17 Overlay tympanoplasty begins with vascular strip incisions and elevation of the tympanomeatal flap anteriorly.

Underlay Grafting Technique

This technique is ideal for smaller, discrete perforations with an intact, articulated, and mobile ossicular chain. A posterior approach is preferred (□ Fig. 118.16). All steps of the approach to and the preparation of the perforation are the same as for the lateral grafting technique (□ Fig. 118.17), except for the placement of the fascia. Once the perforation has been prepared, the fascia is placed underneath the perforation, as far anteriorly toward the eustachian tube orifice as possible. The fascia is supported on its medial surface with pieces of Gelfoam, either dry

Fig. 118.18 Gelfoam is placed in the middle ear cleft to support the fascial graft.

or moistened (□ Fig. 118.18). The combined fascia and drum remnant are returned to their proper positions, with the edges of the squamous epithelium unfurled (□ Fig. 118.20). The lateral surface of the reconstructed drum is packed with Gelfoam (□ Fig. 118.20). The remainder of the technique is the same as with lateral grafting.

Combined Technique

All steps of this technique are the same as with the underlay grafting technique except that the drum remnant is taken off the long process of the malleus. The fascia is placed under the remnant of the drum but then over the handle of the malleus. The fascia is supported on its medial and lateral surfaces with Gelfoam. The remainder of the technique is the same as with underlay grafting.

118.3.3 Ossicular Reconstruction

The classification of tympanoplasty by the level of ossicular reconstruction was first described in the 1950s by Horst Wullstein. The five subdivisions describe increasingly more medial repairs. The recipient native ossicle defines the classification. Even if an ossicular reconstruction augments the native ossicle, or if a prosthesis (partial or total ossicular prosthesis) is to be used, the nomenclature is nonetheless derived from the native ossicle remaining before reconstruction. The actual technique of fascial grafting does not affect this classification.

1. Wullstein I: The drum is repaired to an intact malleus and mobile ossicular chain.
2. Wullstein II: The drum is repaired to an intact and mobile incus.
3. Wullstein III: The drum is repaired to an intact and mobile stapes superstructure (columellar repair).

Fig. 118.19 The tympanomeatal flap is replaced over the temporalis fascia.

Fig. 118.20 The vascular strip is replaced and the canal packed with Gelfoam for lateral support.

4. Wullstein IV: The drum is repaired to an intact and mobile stapes footplate.
5. Wullstein V: The drum is repaired to a controlled fenestration into the otic capsule (generally to a fenestration of the horizontal or lateral semicircular canal or of an immobile stapes footplate).

118.3.4 Combined Technique

There is a growing awareness among otologists that fascia by itself is not strong enough to withstand the negative pressure of chronic eustachian tube dysfunction. In some cases of pronounced eustachian tube dysfunction, a pressure-equalizing tube is placed through the fascial graft before reconstruction. In other cases, stronger grafting material (e.g., a very thin piece of cartilage) is used either as a cantilever from the scutum or as a replacement of part or all of the drum.

118.4 Risks and Complications of Chronic Ear Surgery

Most complications associated with chronic ear surgery occur because of loss of surgical orientation and can be avoided by following this disciplined approach with precise dissection and meticulous hemostasis. Sensorineural hearing loss may occur by ossicular trauma or inadvertent fenestration of the otic capsule. Contact of the incus with the otologic drill during either the mastoidectomy or tympanoplasty, especially at the posterior buttress, produces high-frequency sensorineural hearing loss. Such loss can also be caused by the forceful manipulation of any ossicle, but especially the stapes, during the resection of disease in the oval window. Fenestration of the otic capsule can lead to partial and often total hearing loss, depending on the size of the fenestration and the length of time between the injury and recognition of the injury. The lateral semicircular canal is most vulnerable to injury with the otologic drill. This usually occurs in a contracted mastoid with low-lying dura or in a bloody surgical field when the surgeon has become disoriented. Fistulization of a semicircular canal or the cochlea can be found during removal of cholesteatoma. A small fistula (<2 mm) may be uncovered and sealed with hydroxyapatite cement or bone wax, but cholesteatoma matrix must be maintained in larger fistulas. The most critical feature in the management of otic capsule fistula is prevention of the loss of perilymph. Avoidance of suctioning during manipulation of the fistula will prevent significant loss of perilymph with subsequent hearing loss. Avulsion of the stapes footplate during the removal of chronic granulation tissue or cholesteatoma is another cause of hearing loss. Fistulization of the otic capsule is also associated with vestibular injury. Permanent vestibular damage produces immediate severe vertigo with usual compensation of balance function over 6 to 12 weeks. Positional vertigo or mild disequilibrium may be permanent after severe injury.

Injury to the facial nerve is the most feared risk associated with chronic ear surgery. Continuous facial nerve monitoring is mandatory for these cases, but it should not be viewed as an assurance that facial nerve injury will not occur. The most common site of injury to the facial nerve is at the second genu as the nerve enters the vertical segment. The angle of the nerve at the second genu is highly variable, and often the nerve sheath can be mistaken for granulation tissue in a chronically infected mastoid. To avoid facial nerve injury in this area, the surgeon can positively identify the lateral semicircular canal by following the middle cranial fossa dura into the antrum, then dissect more inferior to the lateral semicircular canal along the vertical segment of the facial nerve before approaching the second genu

region. The horizontal segment of the facial nerve is the next most common site of injury; injury here is usually caused by the manipulation of disease in the presence of a dehiscent nerve. If disease is identified in the oval window region, a facial recess exposure is mandatory to ensure removal without facial nerve injury. In these cases, the second genu of the facial nerve should be clearly identified, and a small diamond drill should be used to follow the nerve into the horizontal segment. Any manipulation of disease should then be in a plane parallel to the facial nerve, with gentle palpation performed to assess dehiscence of the fallopian canal. Injury to the proximal portion of the horizontal segment of the facial nerve can be avoided by noting the cochleariform process and following the nerve superior to this bony landmark. Dysgeusia can occur after chronic ear surgery as a consequence of removal of the chorda tympani nerve. Taste disturbances are a recognized result of chronic ear disease and often predate surgical intervention. In the presence of cholesteatoma, the chorda tympani nerve should be resected with the disease. Dysgeusia is usually self-limiting over several months.

Dural injury, with or without cerebrospinal fluid (CSF) leak, can be avoided by immediate identification of the dura on beginning the mastoid procedure and skeletonization of the dural plate with a diamond drill during the procedure. At times, disease may erode through the dural plate, causing dural thinning and CSF leak. Dural exposure can be managed by gentle bipolar cauterization, which will remove any residual disease and contract the dura. In the presence of a CSF leak, reconstruction of the tegmen plate with hydroxyapatite cement is most effective. Inadvertent opening of the sigmoid sinus can be managed with bipolar cauterization in small tears, but a large tear of the sinus requires suture repair and possible extradural sinus obliteration. Unintentional fenestration of the posterior bony canal wall should be avoided by careful monitoring of the drill during the mastoid procedure. In the treatment of attic cholesteatomas, reconstruction of the canal wall defect is mandatory. This is best accomplished with tragal cartilage attached to perichondrium that spans the surrounding bone. Bone PATE should be used to repair small bone defects or reinforce thinning of the canal bone more laterally.

The greatest risk associated with tympanic membrane grafting techniques of any sort is graft failure. Tympanoplasty, in experienced hands, should succeed in more than 90% of cases, and the success rate should approach 95 to 97%.

Ossicular reconstruction with tympanoplasty carries a built-in risk for trauma to the oval window and thereafter to the inner ear, especially in the context of severe eustachian tube dysfunction. The tonic, progressive inward migration of a middle ear prosthesis may eventually penetrate the integrity of the oval window, leading to partial or complete neurosensory hearing loss, vertigo, and tinnitus. This must be anticipated and managed with a pressure-equalizing tube, a cartilage tympanoplasty, or staging. A postoperative dead ear is a devastating complication.

Failure of tympanic membrane repair, with or without conductive hearing loss, can occur after tympanomastoidectomy. This usually is a result of uncontrolled infection in the immediate postoperative period and is associated with persistent purulent discharge after surgery. Delayed or recurrent perforation is the result of poor eustachian tube function.

118.5 Roundsmanship

- A disciplined approach to mastoid dissection results in more efficient, complication-free surgery.
- Identification of the mastoid tegmen is the first step in a simple mastoidectomy.
- Following the dura into the antrum will prevent injury to the lateral semicircular canal.
- A facial recess approach is mandatory when cholesteatoma is identified during surgery for chronic ear disease.
- To remove the posterior bony canal, the facial recess approach should be performed first.
- Do not suction over an otic capsule fistula.
- Regardless of the technique used, success in tympanoplasty is directly proportional to the careful visualization and preparation of the perforation and the placement and stabilization of the soft-tissue graft.
- All soft-tissue grafts must be placed so that no squamous epithelium is trapped underneath it. Because skin has minimal growth requirements, trapped squamous epithelium will almost always result in keratoma or cholesteatoma formation.
- If superficial temporalis fascia has already been used and is in short supply, consider using pericranium.
- Severe and chronic Eustachian tube dysfunction is not affected by surgery on the tympanic membrane. The deleterious effect of Eustachian tube dysfunction on healing and aeration of the middle ear cleft must be anticipated, and the placement of a pressure-equalizing tube or a cartilage graft to support the drum may be of benefit in these cases.

119 Syndromic and Nonsyndromic Hearing Loss

Carol A Silverman

119.1 Introduction

Universal newborn hearing screening programs in which the hearing of all newborns is screened (based on electrophysiologic techniques) before discharge from the newborn nursery have been legislated or voluntarily implemented throughout all states and territories of the United States. Although these programs have enabled the early identification of many children with hereditary hearing loss, they can never succeed in identifying all cases of genetic hearing loss because some forms of genetic hearing loss do not manifest until long after birth. The early identification of hearing loss, especially before 6 months of age, affords the opportunity for early intervention, such as speech–language therapy, hearing aid amplification, or cochlear implantation, which in turn promotes the acquisition of speech and language and maximizes favorable educational outcomes.

Hereditary hearing loss accounts for at least 60% of the occurrences of hearing loss in developed countries. More than 400 genes for hearing loss have been identified. Nonsyndromic hearing loss accounts for approximately 70 to 80% of cases of genetic hearing impairment; syndromic hearing loss accounts for the remainder of cases of genetic hearing impairment.

The term congenital hearing loss signifies the presence of hearing impairment at birth, such as that associated with cytomegalovirus infection. Hereditary hearing loss can manifest at birth or after birth, sometimes many years after birth. The nature of the hearing loss can be progressive or nonprogressive and unilateral or bilateral. The degree and configuration of the hearing loss are variable across various genetic disorders and can be variable even within a particular genetic disorder.

119.2 Mendelian and Nonmendelian Inheritance

119.2.1 Mendelian Inheritance

Mendelian patterns of inheritance include autosomal-dominant (AD), autosomal-recessive (AR), X-linked recessive, and X-linked dominant. With AD inheritance, the typical mating is between

an affected parent who is heterozygous for the condition (one altered allele of the gene and one unaltered allele of the gene) and an unaffected parent who is homozygous (identical unaltered alleles). The so-called Punnett square (□ Table 119.1) for this situation demonstrates that the probability of an offspring expressing the AD hearing loss trait is 50%. An offspring who does not inherit the Dd genotype will not be a carrier of the allele for hereditary hearing loss. A pedigree of the affected individuals in each generation of a family tree usually shows vertical transmission, in which the hearing loss trait appears in multiple, successive generations. With AD inheritance, there generally is no predilection for gender, so the hearing loss is transmitted equally by each parent. A mating between two affected parents, each with AD hearing loss, yields a Punnett square reflecting Dd by Dd mating, which is associated with a 25% probability of a homozygous affected offspring (DD), a 50% probability of a heterozygous affected offspring (Dd), and a 25% probability of an unaffected offspring (homozygous dd genotype). The phenotype of a homozygous affected offspring (DD genotype) typically is more severe than the phenotype of a heterozygous affected offspring (Dd genotype). An unaffected offspring (homozygous dd genotype) does not pass on the disorder to future offspring.

A genotype associated with a particular condition (e.g., Dd) in which the condition (e.g., hearing loss) is not expressed is said to be incompletely penetrant. The term expressivity describes variation in the phenotype associated with a specific genotype (e.g., Dd) such that two individuals with the same genotype may display different phenotypes.

With AR inheritance, the typical mating is between two carrier parents who both are heterozygous for the condition (one altered allele of the gene and one unaltered allele of the gene) and who do not exhibit hearing loss. For AR inheritance, the Punnett square (□ Table 119.2) displays a 25% probability that an offspring will express an AR hearing loss trait and a 50% probability that an offspring will be a carrier. With AR inheritance, a pedigree showing the affected individuals in each generation of a family tree usually indicates horizontal transmission, in which the hearing loss trait appears within a single generation rather throughout multiple, successive generations. As

		Affected female parent: genotype	
		X	x
Unaffected male parent: genotype	X	XX (female without hearing loss, homozygous genotype)	xX (female with hearing loss, heterozygous genotype)
	Y	XY (boy without hearing loss, hemizygous genotype)	xY (boy with hearing loss, hemizygous genotype)

Table 119.5 Punnett square for X-linked dominant inheritance from an affected mother

		Unaffected female parent: genotype	
		X	X
Affected male parent: genotype	x	xX (female with hearing loss, heterozygous genotype)	xX (female with hearing loss, heterozygous genotype)
	Y	XY (boy without hearing loss, hemizygous genotype)	XY (boy without hearing loss, hemizygous genotype)

with AD inheritance, there generally is no predilection for gender, and the hearing loss is transmitted equally by each of the parents. With a mating between two parents who have AR hearing loss, the Punnett square is rr by rr , which yields 100% of offspring with AR hearing loss.

For X-linked recessive inheritance, the phenotype is expressed in males having an altered allele on the X chromosome and in females having two copies of the altered allele. The most typical mating is between a carrier female and an unaffected male. For X-linked recessive inheritance, the Punnett square (□ Table 119.3) indicates that the probability of a girl being a carrier is 50% and that the probability of a boy having a hearing loss is 50%. An affected man does not transmit the disorder to any son; a male offspring receives the unaffected Y chromosome from the father and the X chromosome from the mother. A carrier woman can transmit the altered allele to either her son or her daughter. A mating between an affected male and a carrier female represents xY by xX ; for this mating, the probability that a male offspring will have X-linked recessive hearing loss is 50%, the probability that a female offspring will have X-linked recessive hearing loss (xx genotype) is 50%, and the probability that a female offspring will be a carrier is 50%.

X-linked dominant inheritance is much less common than X-linked recessive inheritance. For X-linked dominant inheritance, a mating between an affected female and an unaffected male represents the xX by XY genotype. The phenotype is expressed with the xX genotype, as in AD inheritance. With a mating between an affected female (who usually is heterozygous) and an unaffected male, the Punnett square displaying the probabilities of inheritance of particular genotypes (□ Table 119.4) shows that the chance that a female offspring will have hearing loss (xX genotype) is 50% and that the chance that a male offspring will have hearing loss (xY genotype) is 50%. A mating between an unaffected female and an affected male represents

the XX by xY genotype. With this mating (□ Table 119.5), 100% of all female offspring will have hearing loss because the altered x allele is inherited from the father, and none of the male offspring will have hearing loss because the unaltered X allele is inherited from the mother.

The severity of the phenotype in X-linked dominant inheritance is greater in males than in females. In women with the xX genotype, one allele is normal, whereas in men with the xY genotype, there is only one allele, that on the X chromosome, and that altered allele is producing an abnormal (or no) protein.

The existence of sign language and schools for the deaf has enabled deaf persons to form communities, and as a result, the frequency of matings between deaf individuals, known as assortative mating, has increased. Parents who both have the same form of AR deafness are homozygous for the same recessive allele. Consequently, 100% of their offspring will be deaf; such matings, which yield deafness in 100% of the offspring, are termed noncomplementary matings. The term complementary mating is used if all offspring from matings between individuals with different forms of genetic deafness (or between individuals with environmentally induced deafness or between an individual with environmentally induced deafness and an individual with recessive deafness) have normal hearing.

119.2.2 Mitochondrial Inheritance

DNA is found not only in the nuclei of cells, but also in the mitochondria within cell cytoplasm. Mitochondria supply energy to the cell in the form of adenosine triphosphate (ATP) and also are involved in other cellular processes, such as cell differentiation, cell death, and cell signaling. Each cell has hundreds of mitochondria. If a cell has both altered and normal mitochondrial DNA, the condition is termed heteroplasmy of mitochondrial DNA. If the cells have only altered mitochondrial DNA, the

condition is termed homoplasmy of mitochondrial DNA. Homoplasmy is associated with more severe symptoms and an earlier onset of symptoms than heteroplasmy. Heteroplasmy is more common than homoplasmy; because the number of affected mitochondria inherited can vary, the phenotypic expression can be more variable with heteroplasmy than with homoplasmy. Mitochondrial DNA inheritance is solely through the mother, and not the father, because mitochondrial DNA is found in oocytes but not in sperm cells. The prevalence of mitochondrial hearing loss has been estimated to be 1% in the population with prelingual hearing loss and 5 to 10% in the population with postlingual, nonsyndromic hearing loss.

119.3 Nonsyndromic Hearing Loss

The vast majority of cases of genetic hearing loss (70 to 80%) are nonsyndromic. Of individuals with nonsyndromic hearing loss, approximately 60 to 75% have AR inheritance of the hearing loss. The locus of each of the genes associated with nonsyndromic AR hearing loss is labeled DFNB with an Arabic numeral postscript.

119.3.1 Connexin Hearing Loss

The most common nonsyndromic AR hearing loss results from mutations in the connexin family of genes, particularly in the GJB2 gene (gap junction protein β_2), which encodes connexin 26, and the GJB6 gene (gap junction protein β_6), which encodes connexin 30. Mutations in the GJB2 gene may account for up to 50% of cases of nonsyndromic AR severe to profound hearing loss in several populations. The genes of the connexin family are responsible for the formation of gap junction proteins that enable the recycling of potassium ions after sensory hair cell stimulation in the cochlea. The most common connexin gene mutation is the GJB2 mutation, and the most common of the connexin 26 gene mutations is 35delG/30delG (most frequently observed in the European and American Caucasian populations). The 167delT mutation is most commonly observed in Ashkenazi Jews, the 235delC mutation is specific to Asian populations, the R143W mutation is most commonly observed in some African populations, and W24X mutation is seen primarily in Spanish/Slovak and Indian populations. Approximately 90 different GJB2 mutations have been identified. Although the vast majority of GJB2 mutations are associated with nonsyndromic AR deafness, some rare mutations have been associated with AD syndromic forms of deafness (e.g., Vohwinkel syndrome, ectodermal dysplasia keratitis–ichthyosis deafness syndrome).

The hearing loss is of prelingual onset. In one study of 234 patients having GJB2 mutations, approximately 82% demonstrated severe or profound sensorineural hearing loss, and the remaining 18% had mild to moderate sensorineural hearing loss. The audiometric configuration was a corner audiogram (with hearing present only at the lowest frequencies) in about 41%, downsloping in about 29%, flat in about 24%, and U-shaped in 5%. A rising (upsloping) audiometric configuration was not observed in any of the individuals. The audiometric configuration of the hearing impairment was more likely to be symmetric than nonsymmetric.

Some mutations in the connexin 32 gene have been associated with X-linked dominant Charcot-Marie-Tooth type I disease. This form, which affects 7 to 10% of individuals with Charcot-Marie-Tooth disease, is associated with a variable phenotype that sometimes shows mild-to-moderate sensorineural hearing loss but more commonly displays gait disturbances and Achilles contractures.

119.4 Syndromic Hearing Loss

119.4.1 Autosomal-Dominant (DFNA) Hearing Loss

Waardenburg Syndrome

The most common cause of AD syndromic hearing loss is Waardenburg syndrome, which has variable penetrance. Approximately 1 to 2% of cases of profound hearing loss result from Waardenburg syndrome. The most common forms of Waardenburg syndrome are type I and type II. Type I Waardenburg syndrome is more frequent and is associated with mutations in the PAX3 gene, which encodes the paired box 3 transcription factor. Clinical features associated with Waardenburg syndrome type I include the highly penetrant dystopia canthorum (more laterally situated medial canthi of the eyes) and one or more of the following: sensorineural hearing loss that usually (but not always) is congenital, nonprogressive, bilateral, and symmetric (hearing loss penetrance is 36 to 58%); a broad and high nasal bridge; synophrys (“unibrow”); iris pigmentation abnormalities such as heterochromia iridis (different colors of the iris), intensely blue eyes, or bicolored eyes; hair that is prematurely gray or has a white forelock, or eyebrows or eyelashes that show whitening; hyperpigmentation and/or hypopigmentation of the skin (e.g., white or light skin patches); and vestibular symptoms (vertigo, dizziness, or imbalance) and abnormalities on various vestibular function tests.

Type II Waardenburg syndrome is distinguished by the general absence of dystopia canthorum, the presence of more highly penetrant hearing loss (less severe than in type I, but usually progressive), and the presence of heterochromia iridis. The most common gene mutation associated with type II Waardenburg syndrome is the MITF gene mutation; the MITF gene encodes the microphthalmia-associated transcription factor. Types III and IV Waardenburg syndrome are rare forms; the former is associated with the clinical features of type I in conjunction with upper limb contractures and hypoplastic muscles, and the latter is associated with the clinical features of type II in conjunction with Hirschsprung disease, manifested by obstructions and dilations of the colon resulting from dysfunction in colonic autonomic innervation.

Branchio-otorenal Syndrome

The inheritance pattern of branchio-otorenal syndrome usually is AD. The most commonly occurring clinical features of this syndrome include the following: (1) usually severe (but can be mild to profound) hearing loss (conductive, sensorineural, or most commonly mixed) that can be progressive and of delayed onset; (2) preauricular pits; (3) bilateral renal defects varying from hypoplasia or dysplasia to agenesis; and (4) branchial

fistulas involving the lower neck. Less frequently occurring clinical features include malformed pinnae (e.g., cupped pinnae or lopped ears with malformation of the antihelix), external auditory canal stenosis, preauricular skin tags, and lacrimal duct aplasia. In addition to external auditory canal stenosis, temporal bone abnormalities can involve the ossicles, cochlea, vestibular aqueduct (e.g., enlarged vestibular aqueduct), and horizontal semicircular canal. The syndrome usually results from a mutation in the *EYA1* gene, which encodes transcription factors.

Treacher Collins Syndrome (Mandibulofacial Dysostosis or Franceschetti-Klein Syndrome)

Treacher Collins syndrome, an AD disorder of craniofacial morphogenesis resulting from impaired embryologic development of the first and second branchial arches, results from a de novo mutation in 60% of cases. Penetrance is high and expressivity is variable. The mutation generally is found in the *TCOF1* gene but also may be found in the *POLR1D* and *POLR1C* genes on chromosome 5q. The estimated incidence is 1 in 50,000 live births.

Clinical features involve the head and neck. The dysmorphic facial features include the following: downward-sloping (antimongoloid) palpebral fissures; colobomas of the lower eyelids; depressed malar bones (cheek bones); colobomas (gaps or defects) of the lower eyelids, often with absent eyelashes on the lower lid medial to the colobomas; retrognathia; malformed auricles; broad mouth; and pointed nasal prominence. Some may have cleft lip and/or palate. The soft-tissue facial dysmorphism generally is bilaterally symmetric, whereas the bony facial features can be asymmetric. The facial bone hypoplasia often is associated with dental malocclusion and numerous dental caries.

The otologic clinical features include bilateral auricular malformations with microtia in up to 85% of patients, stenosis or atresia (often complete) in one-third of patients, fused malleus/incus remnant in 90% and abnormal stapes in 73%. The radiologic findings often reveal failed pneumatization of the mastoid bone and a bony cleft on the lateral temporal bone that makes the facial nerve susceptible to surgically induced injury. The small middle ear space and the bony cleft on the lateral temporal bone limit the number of patients who have Treacher Collins syndrome with atresia who can be considered as candidates for surgery. Obstructive sleep apnea was present in 54% of children and 41% of adults in a recent cohort study of patients with Treacher Collins syndrome. The obstruction is multilevel but is most significant at the level of the oropharynx/hypopharynx.

Audiologic evaluation usually reveals a maximal, bilaterally symmetric conductive hearing loss with a rising audiometric configuration that may also slope at the high frequencies. In approximately 17% the hearing loss is mixed. A recent study revealed that bone-anchored hearing aids (BAHAs) can be successfully implanted with greater functional gain than can be achieved with conventional bone conduction hearing aids. Because the thickness of the calvarial bone often is poor or irregular, additional holes need to be drilled or materials for bone augmentation need to be employed for sufficient placement of the fixture.

Because this syndrome can be identified by prenatal testing in embryos, prenatal diagnosis and genetic counseling should be recommended to parents. Additionally, a multidisciplinary

approach to management should be employed, including otolaryngology, audiology, speech and language pathology, general dentistry, and orthodontics evaluations.

Neurofibromatosis

Neurofibromatosis type I (von Recklinghausen syndrome) accounts for the vast majority of cases of neurofibromatosis, and the prevalence of unilateral vestibular schwannoma is approximately 2 to 4%. The National Institutes of Health diagnostic features of neurofibromatosis type I (NF1) include at least two of more of the following: six café au lait spots, two or more neurofibromas of any form or at least one plexiform neurofibroma, optic pathway glioma, two or more Lisch nodules (iris hamartomas) that extend from the iris but do not impair vision, an osseous lesion (e.g., sphenoid dysplasia or tibial pseudoarthritis), axillary or inguinal freckling, and first-degree relative with NF1. Although the inheritance is AD in approximately half of cases, a de novo genetic mutation is involved in the other half of the cases.

Although bilateral vestibular schwannomas occur in approximately 95% of patients with neurofibromatosis type II (NF2), this type of neurofibromatosis accounts for only a small proportion (5 to 10%) of cases of neurofibromatosis. The estimated incidence of NF2 ranges from 1 in 33,000 live births to 1 in 87,410 live births. The NF2 gene (tumor suppression protein) mutation is located on chromosome 22, whereas the NF1 gene is located on chromosome 17. The Wishart form of NF2 (more severe form) is associated with early onset of the disease; numerous schwannomas and meningiomas develop, and death by 40 years of age may be the final outcome. The Gardner form (less severe form) is generally associated with later onset of the disease; the schwannomas remain relatively stable for years, and fewer schwannomas and meningiomas develop. Approximately one-third of individuals with NF2 are mosaic for the mutation; therefore, individuals with mosaicism may have tumors in a localized area of the body.

The vestibular schwannomas, which generally develop by 30 years of age, are associated with sensorineural hearing loss and other symptoms that can be found in persons with vestibular schwannomas (e.g., vertigo or other balance problems, tinnitus). Other cranial nerve schwannomas may also develop, particularly involving the trigeminal or oculomotor nerves bilaterally. Other tumors associated with NF2 most commonly include intracranial meningiomas, multiple cutaneous tumors (generally peripheral nerve schwannomas), and multiple spinal tumors. Cutaneous lesions are generally less prominent in individuals with NF2 than in those with NF1. Visual impairment and eventual blindness may result from cortical and posterior subcapsular cataracts; the visual impairment less frequently is associated with retinal hamartomas.

The modified National Institutes of Health diagnostic criteria for NF2 include any one or more of the following: (1) bilateral vestibular schwannomas; (2) first-degree relative with NF2 and either a unilateral vestibular schwannoma or at least two of the following: meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities; (3) unilateral vestibular schwannoma in conjunction with at least two of the following: meningioma, glioma, neurofibroma, posterior subcapsular lenticular opacities; (4) two or more meningiomas in

conjunction with either a unilateral vestibular schwannoma or at least two or more of the following: schwannoma, glioma, neurofibroma, cataract.

Vestibular schwannomas may be managed by watchful waiting in patients with small tumors and good hearing, surgical tumor removal (hearing-conservative approaches vs hearing-ablative approaches), or stereotactic irradiation. The hearing loss can be managed with aural rehabilitation, hearing aids, sign language, or cochlear auditory brainstem implants. Patients with NF2 should have imaging studies of the entire central nervous system (intracranial and spinal) and neurologic, otologic, neuro-ophthalmologic, and audiology examinations. Genetic testing and counseling should be recommended. Annual monitoring, from about 10 years of age until approximately the fourth decade of life, should include intracranial magnetic resonance (MR) imaging, brainstem auditory evoked potentials testing, and audiology evaluation. Siblings also should be screened (MR imaging or genetic testing) for NF2.

Other

The inheritance mode of otosclerosis, discussed elsewhere in this book, is thought to be AD with reduced penetrance. The absence of a positive family history in up to half of the cases has led to the hypothesis of complex inheritance representing interactions between various genetic and environmental factors.

119.4.2 Autosomal-Recessive Hearing Loss

Usher Syndrome

Usher syndrome is a group of AR conditions associated with congenital, bilateral sensorineural hearing impairment and retinitis pigmentosa (a retinopathy affecting the rod photoreceptors); the retinitis pigmentosa is manifested initially by impaired night vision and later by tunnel vision, sometimes resulting in total blindness. Usher syndrome is phenotypically and genetically heterogeneous. The prevalence of Usher syndrome is 2 to 4% in the profoundly deaf population and is 50% in the deaf-blind population in the United States.

Usher syndrome is classified as follows: type I (30 to 40%), type II (60 to 70%), and type III (2 to 4%). Type I Usher syndrome is characterized by congenital, bilateral profound deafness; absence of vestibular function (which is associated with delayed motor developmental milestones); and progressive retinitis pigmentosa, the onset of which generally occurs before puberty. Type I Usher syndrome has been associated with mutation in any one of seven genes, with USH1B the most common genetic subtype. Management of the hearing loss with cochlear implantation generally is beneficial.

Type II Usher syndrome, which is less severe than type I, is characterized by congenital sloping, moderate to severe sensorineural hearing loss (management usually is with hearing aids), normal vestibular function, and retinitis pigmentosa, the onset of which typically is before the age of 20 years. The hearing loss may be slowly progressive. The vast majority of genetic mutations associated with type II Usher syndrome are attributed to the USH2A gene, which encodes usherin (a transmembrane protein).

Type III Usher syndrome is characterized by progressive sensorineural hearing loss of variable onset, retinitis pigmentosa of variable onset, and vestibular function that ranges in degree from normal to absent. Type III Usher syndrome is the most commonly occurring form of this syndrome in the Ashkenazi Jewish population. The predominant genetic subtype is USH3A, which encodes clarin-1 (a transmembrane protein). The retinal impairment associated with Usher syndrome can be detected by electroretinography before the development of visual signs and symptoms; thus, persons who are at risk for Usher syndrome should undergo electroretinography to allow maximal time for adapting to the visual impairment.

Pendred Syndrome

Pendred syndrome may account for approximately 7 to 10% of cases of hereditary prelingual deafness. It is largely characterized by sensorineural hearing loss (which typically is profound and prelingual) and goiter. The goiter, present in the majority of individuals with Pendred syndrome, usually appears after the first decade of life; affected patients are more frequently euthyroid than hypothyroid. The inclusion of goiter as a criterion for the diagnosis of Pendred syndrome results in substantial underassessment. Positive findings on the perchlorate discharge test are seen in the vast majority of individuals with Pendred syndrome.

In a report of 33 patients, nearly all demonstrated bilateral, symmetric, sloping, severe to profound hearing loss. The patients generally reported that the onset of hearing loss had been during early childhood or that it had been present at birth; 27% reported progressive hearing loss. Based on a difference of more than 8% on the duration parameter, unilateral weakness of 9 to 100% was observed in 41% of patients, bilateral weakness in 50% of patients, and a complete absence of caloric responses in one individual. In approximately 90% of those who underwent radiologic testing, computed tomography (CT) revealed an enlarged vestibular aqueduct (with enlarged contents), and in 18% of those with an enlarged vestibular aqueduct, a Mondini cochlear malformation also was present.

Mutations of the SLC2A4 (PDS) gene, which encodes pendrin, are largely responsible for Pendred syndrome. Pendrin, a transporter of chloride and iodide, is expressed in the inner ear, thyroid, and kidney.

An enlarged vestibular aqueduct in conjunction with sensorineural hearing loss also can occur in individuals who do not have Pendred or branchio-otorenal syndrome.

Jervell and Lange-Nielsen Syndrome

This syndrome is characterized by a markedly prolonged QT interval on the electrocardiogram, which indicates abnormal cardiac repolarization, in conjunction with sensorineural hearing loss. The cardiac abnormality can lead to recurrent syncope, ventricular arrhythmia, and sudden death in childhood. It is the more severe of the variants of the long-QT syndrome. Another variant of long-QT syndrome is Romano-Ward syndrome, which has cardiac features that are similar to those in Jervell and Lange-Nielsen syndrome but is not associated with sensorineural hearing loss. The Jervell and Lange-Nielsen syndrome, characterized by AR inheritance, is associated with mutations of

the gene *KCNQ1* or *KCNE1*, which encodes proteins that conduct the I_{Ks} current. It may be responsible for as much as 1% of the population with profound hearing loss.

A multinational study of 186 patients with Jervell and Lange-Nielsen syndrome revealed that cardiac arrest and sudden death occurred in 27% the median age at death was 8.5 years. At least one cardiac event occurred in 86% by the age of 3 years, 50% had experienced a cardiac event. In 93% of the life-threatening cases (cardiac arrest and sudden death), the triggers were exercise and emotions. In 90.5% the mutation involved the *KCNQ1* gene, and in 9.5% the mutation involved the *KCNE1* gene. A QT interval longer than 550 milliseconds in conjunction with syncope during the first year of life represented a significant risk factor for a life-threatening cardiac event. The severity of the cardiac events was substantially greater for boys than for girls. The efficacy of therapy with β -blockers was limited; a life-threatening event occurred in 27% of the patients while they were on such therapy. The authors proposed that defibrillator implantation be considered for those infants and children with Jervell and Lange-Nielsen syndrome who also have this risk factor (prolonged QT interval of >550 milliseconds and syncope during the first year of life).

Sickle Cell Disease

Sickle cell disease, which affects 1 in 400 African Americans in the United States, is a hereditary disorder associated with abnormal protein in the erythrocytes, which leads to a change in their morphology. Sickle cell disease comprises a group of hemoglobinopathies associated with abnormal forms of hemoglobin: sickle cell anemia (hemoglobin SS), hemoglobin SC disease, hemoglobin D disease, β -thalassemia, and hemoglobin E disease. Affected erythrocytes have difficulty traversing blood vessels because of their sickle shape, and they are also stickier than normal erythrocytes, even when their morphology is unsickled. As a result, blood flow is occluded. Characteristics of sickle cell disease include the following: hand-foot syndrome (swelling of the hands and feet because of obstructed blood flow); splenic sequestration (enlargement of the spleen resulting from insufficient blood flow through the spleen because of an excessive number of sickle cells); hemolytic anemia (premature breakdown of the blood cells); painful episodes or crises (which occur when sickle cells become trapped in the small blood vessels); stroke or brain damage; renal failure; pneumonia or acute chest syndrome similar to pneumonia; leg ulcers; and stroke. The estimated prevalence of sensorineural hearing impairment varies considerably from study to study. The sensorineural hearing loss, hypothesized to result from sickling/stickiness of the erythrocytes in the stria vascularis, can be unilateral or bilateral and is variable in degree. One study indicated that 80% of patients with sickle cell disease and hearing impairment have the hemoglobin SS sickle cell variant. The percentage of patients with hearing impairment in addition to sickle cell disease was low, not exceeding 7% for the other sickle cell disease variants.

119.4.3 X-Linked (DNF) Hearing Loss

Alport Syndrome

The mode of inheritance in Alport syndrome is X-linked dominant. Features of this syndrome include sensorineural hearing

loss, progressive glomerulonephritis (inflammation of the glomeruli of the kidneys), and ocular abnormalities, most notably ocular flecks and lenticonus (bulging of the lens capsule and underlying cortex). The bilateral, high-frequency (generally > 3,000 Hz) sensorineural hearing loss results from lesions of the capillary basement membrane of the stria vascularis, analogous to the lesions in the glomerular capillary basement membrane. The onset of hearing loss generally is within the first two decades of life and is progressive during childhood, stabilizing in adulthood. Hearing loss penetrance is about 83% in males and 57% in females. The progressive kidney disease begins with hematuria; by about 25 years of age, 94% of males and 3% of females demonstrate renal insufficiency evidenced by abnormally elevated serum creatinine. The ocular flecks appear as yellow or white spots in the macular and midperipheral regions of the retina. The lenticonus usually is anterior and bilateral, resulting in refractive errors.

The results of a large genotype-phenotype correlational study (N=681 from 175 families) of X-linked Alport syndrome in the United States revealed hearing loss in 89% and ocular abnormalities in 30%. Hematuria was present in microscopic form in 91% and in macroscopic form in 49%. Proteinuria followed the onset of hematuria in 85%. The average age at the onset of end-stage renal disease varied with the type of mutation; it was 25 years for those with truncating mutations and as late as 37 years for those with missense mutations. Renal failure progressed to end-stage renal disease in 60% generally in conjunction with hypertension. Ocular abnormalities were less frequent in those with missense mutations (20%) than in those with other mutations (36 to 50%). Similarly, hearing loss, a predominant feature regardless of mutation type, was less frequent in those with missense mutations (84%) than in those with other mutations (94 to 100%).

Alport syndrome is genetically heterogeneous—X-linked dominant in 85% of cases and AR or AD in about 15% of cases. Various mutations in the *COL4A5* gene, which encodes type IV collagen, expressed in the basement membranes of the kidney, ear, and eye, are responsible for the X-linked form of Alport syndrome.

Congenital Fixation of the Stapes Footplate with Perilymphatic Gusher

A stapes gusher is a serious and unusual complication of stapes footplate surgery in males with X-linked recessive hearing loss (combined low-frequency conductive and high-frequency sensorineural hearing loss) in which opening of the stapes footplate leads to a profuse outflow of perilymphatic fluid, and consequently severe to profound hearing loss and dizziness. Radiographic imaging can reveal congenital malformations of the audiovestibular system (enlarged vestibule and dilation of the lateral end of the internal auditory canal along with deficiency/absence of bone between the lateral end of the internal auditory canal and basal end of the cochlea). The hearing loss and malformations generally are milder in female carriers.

Snik et al commented on the surprising finding of acoustic reflexes in these patients despite the presence of significant air-bone gaps. They hypothesized that the air-bone gaps reflect an asymmetry between the scala tympani and the scala vestibuli that increases the efficiency of the transduction of skull

vibrations during bone conduction testing into cochlear fluid vibrations, and that ultimately yields better than expected bone conduction thresholds and artifactual air–bone gaps. Their audiologic investigations of a patient who had not undergone stapes surgery revealed normal tympanometric findings with present contralateral acoustic reflex. The latencies on auditory brainstem response testing were consistent with the presentation level rather than with the presentation level corrected for the air–bone gap (because conductive components are expected to decrease the effective stimulation level at the cochlea). They concluded that the third window (aqueducts and vascular and neural channels of the cochlea) is enlarged in patients who are stapes gushers, resulting in more efficient transduction of skull vibrations into cochlear fluid vibrations and ultimately better than expected bone conduction thresholds and significant, artifactual air–bone gaps. This condition is associated with mutations largely in the POU3F4 gene, which encodes a POU homeodomain transcription factor.

119.4.4 Mitochondrial Hearing Loss

MERRF and MELAS

The sample sizes in studies of mitochondrial disorders in children generally have been small. A recent study of 26 children with established mitochondrial disorders and audiologic data revealed that 58% had hearing loss (38% sensorineural, 8% conductive, and 4% mixed; normal hearing sensitivity in the remainder). Approximately 47% were female. Of the 9 children who were followed over time, 44% had progressive hearing loss. Of the 15 children with hearing loss, MERRF (myoclonic epilepsy with ragged red fibers) had been diagnosed in 1 and MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, stroke-like episodes) had been diagnosed in 3. These two disorders are mitochondrial encephalopathies. The features of MERRF include mitochondrial myopathy and progressive myoclonus epilepsy. The features of MELAS include encephalomyopathy with stroke-like episodes and lactic acidosis. In the children with MELAS, the hearing loss was symmetric and sensorineural, but the configuration and severity were variable; one child, with bilateral, symmetric, moderately rising to mild sensorineural hearing loss, appeared to have findings possibly consistent with auditory neuropathy spectrum disorder (as evidenced by sensorineural hearing loss with present otoacoustic emissions). The child with MERRF appeared to have a progressive disorder because the otoacoustic emissions amplitude decreased over time and the cochlear microphonic was absent; the sensorineural hearing loss was asymmetric (moderate in the right ear and mild in the left). All waves were absent bilaterally on auditory brainstem response testing. The findings were possibly suggestive of auditory neuropathy spectrum disorder. In light of the possible progression of hearing loss and possible occurrence of auditory neuropathy spectrum disorder, the authors recommend audiologic monitoring including auditory brainstem response and otoacoustic emissions testing.

MELAS and MERRF are genetically heterogeneous disorders. The variability in clinical features is consistent with heteroplasmy of the mitochondrial DNA.

Aminoglycoside Ototoxicity and Maternally Inherited Diabetes and Deafness

The mitochondrial A1555G mutation in the 12S rRNA gene confers susceptibility to bilateral sensorineural hearing loss from aminoglycoside antibiotics. This mutation also can be associated with nonsyndromic hearing loss. The frequency of the mitochondrial A1555G mutation in aminoglycoside ototoxicity appears to be greatest in Asian populations. In the United States, the mitochondrial A155G mutation is seen in approximately 15% of individuals with hearing loss from aminoglycoside antibiotics.

Maternally inherited diabetes and deafness (MIDD) is largely associated with a point mutation (A to G substitution) at position 3243 of the mitochondrial DNA that encodes the gene for transfer RNA. Characteristics of MIDD include diabetes, usually of insidious onset; sensorineural hearing loss; possibly abnormalities on brain scans (present in more than 50%); psychiatric disorders (e.g., recurrent depression, schizophrenia, various phobias); macular retinal dystrophy (present in 86%); myopathy observed as exercise-induced muscle cramps or weakness; cardiac abnormality (e.g., left ventricular hypertrophy without hypertension or cardiac autonomic neuropathy); renal disease; short stature resulting from a deficiency of hypothalamic growth-releasing hormone; and gastrointestinal complaints (e.g., constipation and pseudo-obstruction). The onset of the bilateral sensorineural hearing loss, which is of cochlear etiology, usually is in early adulthood and usually precedes the diagnosis of diabetes; the hearing loss is either slowly or rapidly progressive, initially high-frequency in configuration, then becomes more severe and affects all frequencies. The severity is worse and the rate of progression is faster in males than in females.

119.5 Genetic Aspects of Age-Related Hearing Loss

Susceptibility genes may underlie the variability in the configuration and degree of sensorineural hearing loss associated with aging. Heritability estimates range from 35 to 55% suggesting that about 35 to 50% of the variability in hearing sensitivity in older adults is due to genetic factors, with the remaining proportion associated with environmental factors.

The apolipoprotein E (APOE) gene encodes apolipoprotein E, a component of very low-density lipoproteins, which play a role in keeping cholesterol levels within normal limits. This gene has been implicated in Alzheimer disease, generalized atherosclerosis, stroke, and macular degeneration. The APOE ϵ 4 allele is the variant that most strongly predisposes to these disorders. A recent study has implicated the APOE genotype in age-related hearing loss. In this population-based study of elderly individuals (85 years of age or older), after adjustments for atherosclerosis and cognitive function, the degree of age-related hearing loss was most severe in those with the APOE ϵ 4/APOE ϵ 4 genotype, second most severe in those with only one copy of the APOE ϵ 4 allele, and least severe in those without the APOE ϵ 4 allele.

119.6 Genetic Testing and Counseling

The GTR: Genetic Testing Registry Web site (<http://www.ncbi.nlm.nih.gov/gtr>) provides information on the specific genetic tests available on a research or diagnostic test basis. Genetic testing as part of newborn hearing screening programs is becoming more widespread. The results of genetic testing may yield information (e.g., possible progressive nature of hearing loss, association with other symptoms that need management) that can guide parents and families in the planning process, and that may obviate the need for other expensive and more invasive medical tests. Genetic testing can be (1) prenatal, based on samples collected from an embryo or fetus during amniocentesis or chorionic villus sampling; (2) diagnostic, to identify the genetic aspect of a medical condition; (3) part of the newborn screening process, to identify a particular hereditary form of deafness, such as that associated with abnormalities of connexin 26; or (4) carrier screening to identify disorders such as sickle cell disease. Parents must be afforded the opportunity to decline genetic testing. Usually, genetic testing is based on a blood sample.

Genetic testing can have significant implications for family relationships. Many individuals are concerned that employer or health/life insurer access to the results of genetic testing can lead to job discrimination or health/life insurance discrimination. Federal legislation, particularly the Genetic Information Nondiscrimination Act (GINA) of 2008, as well as legislation passed by many states, does exist to protect individuals from discrimination based on genetic information, but increased legislation is needed for more comprehensive protection from discrimination.

Medical professionals, including otolaryngologists, need to be sensitive to cultural issues related to deafness. Within the Deaf community, deafness often is not viewed as a disability to be prevented or cured. Rather, being Deaf (capitalization of the letter D to signify deaf culture with communication by American Sign Language) is valued by the Deaf community, so that genetic testing procedures employed by members of the Deaf community may be viewed as a means to ensure that the unborn child will be deaf.

Genetic counseling may have to be recommended to explain the implications of the results of genetic testing, including those regarding family planning and future pregnancies.

119.6.1 Comprehensive Evaluation Procedures

A comprehensive otolaryngologic evaluation should include a physical examination to identify features associated with syndromic hearing loss: craniofacial/cervical abnormalities or facial asymmetries; ear or cervical pits/tags; hypopigmentation or hyperpigmentation of the skin, or café au lait spots; prematurely gray hair or a white forelock; small or malformed pinnae; canal stenosis; tympanic membrane abnormalities; goiter; abnormal shape, slant, and color of the eyes and intercanthal distance; abnormal number of fingers or toes, or webbed fingers or toes. Balance and gait also should be assessed because

abnormalities can be associated with syndromic or nonsyndromic hearing loss.

A family history should include questions about consanguinity in the family and whether any family member has one or more of the following features: hearing impairment or the need to use a hearing aid, particularly during childhood or early adulthood; premature graying of the hair or a white forelock; renal or urinary problems; cardiac problems; thyroid problems; widely spaced or multicolored or differently colored eyes, or visual problems including night blindness, tunnel vision, cataracts, and glaucoma; pits or tags on the ear or neck; ears that are abnormal in shape or size; bones that break easily or frequently; arthritis or problems with joints. A pedigree analysis based on the history contributes to the arousal of suspicion for particular inheritance patterns. The ethnicity and country of origin should be established for family members with hearing loss.

A complete audiologic evaluation should be done to establish the type and severity of the hearing loss and its configuration, and serial audiologic testing should be done to rule out the progression of hearing loss. A hereditary hearing impairment can be of delayed onset, occurring many years after birth, particularly some forms of AD hearing loss. If hereditary hearing loss is suspected, family members should be tested because individuals with hearing loss may be unaware of their hearing problem. Auditory brainstem response testing can be used to estimate behavioral thresholds in infants, including those who are difficult to test, and also to determine the site of a lesion (cochlear vs retrocochlear). Otoacoustic emissions testing helps to determine the presence of peripheral hearing loss. Audiologic management may include evaluation and fitting for a hearing aid or other sensory aid, such as a cochlear implant, and/or assistive listening device.

If balance or gait problems are present or suspected, a vestibular evaluation should be performed, which may include electronystagmography/videonystagmography, rotary chair testing, and posturography. Such testing can help differentiate between Usher type I and type II syndrome.

Patients with visual problems (e.g., Alport syndrome, Stickler syndrome, NF2, Norrie disease, Usher syndrome) should be referred to ophthalmology. Urinalysis and laboratory tests (for serum creatinine levels) should be performed, and referral to a nephrologist for renal follow-up should be considered when a syndrome with renal impairment (e.g., Alport syndrome, branchio-otorenal syndrome) is suspected. Referral to a cardiologist should be considered when cardiac problems are present that raise suspicion for syndromes associated with cardiac abnormalities (e.g., Jervell and Lange-Nielsen syndrome). Radiologic studies such as a high-resolution CT of the temporal bone should be considered to document inner ear malformations (e.g., branchio-otorenal syndrome, Pendred syndrome, Treacher Collins syndrome). MR imaging studies should be considered when (1) NF2 is suspected, (2) progressive hearing loss is present but CT scans are normal, or (3) the audiologic findings are consistent with a retrocochlear site of the lesion. Referral to endocrinologist should be considered when diabetes is suspected or for thyroid function testing (e.g., perchlorate discharge) when Pendred syndrome is suspected; a limitation of perchlorate discharge testing is that it is nonspecific.

When hereditary hearing loss is identified in children, referral for psychoeducational management should be made so that an individualized education plan can be developed. The pediatrician is an important member of the interdisciplinary team in children with hearing loss. Family members need to be fully informed of the various treatment/habilitation options.

The 2002 (reaffirmed in 2005) American College of Medical Genetics (ACMG) statement “Genetics Evaluation Guidelines for the Etiologic Diagnosis of Congenital Hearing Loss” presents triage/testing as follows:

1. Upon suspicion of syndromic hearing loss, gene-specific mutation testing often can be done.
2. Upon suspicion of nonsyndromic hearing loss when the hearing loss is an isolated case in the family, do cytomegalovirus testing and GJB2 (connexin 26) mutation screening.
3. Upon suspicion of nonsyndromic hearing loss when two or more first-degree family members (including the patient) have hearing loss, do GJB2 (connexin 26) mutation screening.
4. Upon suspicion of nonsyndromic hearing loss in conjunction with the presence of a pedigree suggestive of dominant inheritance, do mutation screening for connexin-related deafness and other genes.
5. Upon suspicion of nonsyndromic hearing loss in conjunction with a pedigree suggestive of mitochondrial inheritance, test for the A1555G mutation and the A7445G mutation.
6. Upon suspicion of nonsyndromic hearing loss when both parents have hearing loss, connexin-related deafness may be involved, and the mating may be between individuals who both have GJB2 hearing loss. Genetic testing can reveal if the child has GJB2 deafness. The ACMG Expert Panel cautions that a negative mutation screen does not rule out genetic hearing loss.

A recent study was performed on the diagnostic yield of various tests within a test battery ordered for 270 children referred to the otolaryngology department of two large city hospitals. The results revealed that the diagnostic yield of the entire battery (CT of the temporal bone, MR imaging of the brain and internal auditory canal with contrast, connexin 26 genetic testing, genetics consultation, ophthalmologic consultation, electrocardiography, renal ultrasound, and fluorescent treponemal antibody absorption [FTA-ABS] testing) was 43%. The diagnostic yield for the stepwise addition of each test/consultation was determined because uniform application of the entire test would have resulted in an inefficient use of health care resources and would have necessitated numerous health care visits. The first test, CT, was found to have a diagnostic yield of 14%. Addition of the second test, MR imaging, increased the diagnostic yield to 24%. Addition of the third test, connexin 26 testing, raised the diagnostic yield to 38%. Addition of the fourth test, genetics consultation, further increased the diagnostic yield to 42%. The fifth test, renal ultrasound, increased the diagnostic yield only slightly (to 43%). The diagnostic yield did not increase further with the addition of ophthalmology, electrocardiography, and FTA-ABS testing.

No overlap was found between the group of children who were positive on imaging testing and the group of children with connexin 26 mutations. The diagnostic yields of imaging and ophthalmologic consultation were greater when syndromic

hearing loss was suspected than when nonsyndromic hearing loss was suspected. On the other hand, the diagnostic yield of connexin 26 testing was significantly greater when nonsyndromic hearing loss was suspected. MR imaging and CT had similar sensitivities in detecting inner ear abnormalities, although the latter was slightly more sensitive in the detection of enlarged vestibular aqueducts and the former had slightly higher sensitivity in the detection of hypoplastic or aplastic cochlear nerves. Additionally, MR imaging identified brain pathology associated with congenital cytomegalovirus infection.

119.7 Internet Resources

1. OMIM (<http://www.ncbi.nlm.nih.gov/omim>)

This Web site is a comprehensive compendium providing descriptions of the clinical features, inheritance, gene mapping, and clinical management for different genetic syndromes, with references.

1. Hereditary Hearing Loss Homepage (<http://hereditaryhearingloss.org>)

This Web site furnishes descriptions of genetic syndromes with links to OMIM. It is maintained by Guy Van Camp (University of Antwerp) and Richard Smith (University of Iowa).

1. GTR: Genetic Testing Registry (<http://www.ncbi.nlm.nih.gov/gtr>)

This Web site furnishes extremely wide-ranging information on genetic diseases, including descriptions of the genetic tests for various genetic disorders; the locations of genetic clinics (evaluation and counseling); the National Society of Genetic Counselors directory; the American Board of Medical Genetics list of board-certified geneticists; access to GeneReviews, which provides summaries of various hereditary disorders (including disease characteristics, diagnosis/testing, and genetic counseling); a talking glossary of genetic terms; and access to the orphaned portal on rare diseases and orphan drugs.

1. Harvard Medical School Center for Hereditary Deafness (<http://hearing.harvard.edu>)

This Web site furnishes information on hereditary hearing loss and genetic tests, consumer resources, PowerPoint lectures on genetics, and research opportunities.

1. Interactives DNA (<http://learner.org/interactives/dna/index.html>)

This interactive Web site furnishes information on DNA; the history of the discovery of DNA; the Human Genome Project; genetic inheritance, including Mendelian inheritance and complex inheritance; Punnett squares; sex linkage; genetic engineering; and associated ethical and social issues.

119.8 Roundsmanship

- The vast majority of cases of genetic hearing loss (70 to 80%) are nonsyndromic. Inheritance of the hearing loss is AR in approximately 60 to 75% of individuals with nonsyndromic hearing loss.

- The most common nonsyndromic AR hearing loss results from mutations in the connexin family of genes, particularly the GJB2 gene (gap junction protein β_2), which encodes connexin 26.
- Obtain audiologic evaluations of family members when genetic hearing loss is suspected.
- Mitochondrial inheritance plays an important role in maternally inherited diabetes and deafness (MIDD) and aminoglycoside ototoxicity.
- Genetic testing is possible for many genes. Mutations in the GJB2 gene may account for up to 50% of cases of nonsyndromic, AR, severe to profound hearing loss in several populations.
- The diagnostic work-up of a patient with suspected hereditary hearing loss can follow the triage/testing approach recommended in the American College of Medical Genetics (ACMG) statement “Genetics Evaluation Guidelines for the Etiologic Diagnosis of Congenital Hearing Loss,” or the step-wise diagnostic battery recommended by Lin et al.

120 Noise-Induced Hearing Loss and Hearing Protection

Maurice Miller

120.1 Introduction

Exposure to noise in and out of the workplace accounts for more new cases of sensorineural hearing loss and accompanying tinnitus than all other causes combined. Presbycusis is believed by some to be the most common etiology of hearing loss in the adult American population. However, exposure to noise and aging typically occur simultaneously because while workers are employed for 40 years or longer in industries where they are exposed to high levels of noise, they simultaneously experience a four-decade-long aging of their auditory system. Current regulations to prevent hearing loss resulting from exposure to high levels of noise assume an additive effect of noise and age, but these factors may operate synergistically; exposure to high levels of noise may hasten premature aging of the auditory system.

Some reports indicate that acetylsalicylic acid, which typically has transient effects on hearing, may cause permanent, irreversible hearing loss in persons employed in noisy operations. Such interactive relationships need to be explored and reflected in updated criteria to provide more realistic methods of protecting workers' hearing.

Exposure to noise in recreational environments is a significant additional factor contributing to sensorineural hearing loss (SNHL) and tinnitus. Loud musical performances and the use of MP3 players for extended periods of time at high-intensity levels can affect the hearing of young persons who are not yet employed. More than 61 million Americans are exposed, on a regular basis, to various forms of nonoccupational hearing loss. Audio-protective agents to prevent or reverse noise-induced hearing loss are under active investigation and will be discussed later.

120.2 Legislative Background

It has been estimated that more than 10 million American workers are exposed to time-weighted levels of sound pressure of 85 dBA and greater. Among the industries in which such levels routinely occur are agriculture, mining, construction, manufacturing, utilities, transportation, and the military, although other industries and occupations may also expose workers to such high levels of noise.

Occupational noise and many other occupational hazards are not controlled by marketplace incentives alone, and government bodies have become involved in addressing, controlling, and regulating these hazards. Regulations to control the noise hazard in industry fall within the province of the federal government, specifically the Occupational Safety and Health Administration (OSHA), a branch of the U.S. Department of Labor. All industrial and occupational operations are within its jurisdiction, although "small business employers," usually defined as those with fewer than 25 employees, are exempt from OSHA regulations. The OSHA Hearing Conservation Amendment to the Occupational Noise Exposure Standard (29 CFR 1910.95) was passed in March 1983 and was implemented in April of

that year, although a number of specific and important modifications have occurred since its passage.

Although it was preceded by various organizational consensus statements, the 1983 OSHA Occupational Noise Exposure Standard remains the national basis for most occupational hearing conservation programs. It is arguably the most important regulation designed to protect hearing since the beginning of the Industrial Revolution, yet it represents a minimal rather than an optimal effort to preserve worker hearing. The OSHA regulation is designed primarily to protect workers' hearing from exposure to noise in the workplace.

It is important to note the distinction between workers' compensation, which covers occupational hearing loss to varying degrees, and federal legislation. In the United States, state governments are responsible for promulgating compensation laws, whereas workplace health and safety standards fall under the jurisdiction of the U.S. Department of Labor. Coverage for occupational hearing loss varies from state to state, but federal regulations are uniform throughout the nation.

120.3 Pathophysiology of Noise Exposure

Noise can damage hearing when direct cochlear injury results from acoustic trauma during a single or a few exposures to extremely high levels of acoustic energy (e.g., an explosion). Isolated acoustic trauma can also damage the middle ear (e.g., ossicular chain discontinuity or tympanic membrane injury from sudden pressure changes). In acoustic trauma, the sound reaching the sensory structures in the cochlea exceeds the physical limits of these elements, and hair cells in the cochlea and supporting structures are damaged.

Far more frequent, and a major concern of occupational hearing conservation programs, are the effects of long-term chronic exposure to occupational noise. Chronic exposure to noise initially causes a temporary hearing loss, and the shift in hearing usually recovers within 14 hours. Repeated exposures may result in a permanent noise-induced hearing loss. The change to permanent loss is related to the intensity of the sound, duration of the exposure, frequency characteristics of the sound, and individual susceptibility, a risk criterion probably related to genetic factors.

Long-term exposure to moderate levels of noise usually causes edema and the distortion of sensory cells, a group of changes that have been termed physiologic metabolic exhaustion. Metabolic exhaustion is the point at which the threshold shift, usually in the range of 3,000 to 6,000 Hz and often bilateral, is a recoverable SNHL. Further exposure of unprotected and vulnerable ears has been shown to result in the complete absence of hair cells or their replacement by scar tissue, primarily in the basilar turns of the cochlea. When the degeneration of hair cells occurs, there is a permanent, usually irreversible, SNHL. Exposure to high levels of noise results in hair cell trauma. If the damage exceeds the ability of the hair cells to repair themselves, they die. Hair cells can die in different ways—either

through apoptosis (an active mode of hair cell death requiring an energy supply) or through necrosis (a passive mode of cell death resulting in an early disintegration of cells).

120.4 Hearing Impairment and Tinnitus from Blast Trauma and Traumatic Brain Injury

The auditory system has been particularly at risk for damage during military deployment in Iraq and Afghanistan because most injuries are the result of blast explosions from improvised explosive devices: mortar, suicide bombs, and others. It has been estimated that 20% of the 1.6 million troops deployed in Iraq and Afghanistan have experienced traumatic brain injury. The most common residual long-term symptoms in military personnel with traumatic brain injury are intractable tinnitus and hearing loss, which were reported by 27% of veterans in 2007.

Head injury, by definition, can damage the central nervous system. The early and thorough identification and diagnosis of central auditory processing disorders in patients with head injury are crucial to improving and maintaining central auditory processing ability, as well as overall auditory function. Traumatic brain injury can also affect any part of the peripheral auditory system, and a complete evaluation of function from the outer and middle ear to the temporal cortex (early and later auditory evoked responses) is essential; disorders of both peripheral and central auditory function often coexist.

120.5 Occupational Hearing Conservation Program

The main components of an occupational hearing conservation program to protect worker hearing are the following:

1. Measurements of sound pressure levels in the work environment and levels of worker exposure to quantify the need for the program
2. Periodic audiometric testing of workers
3. Review of audiometry findings and case histories by a professional and appropriate referral
4. Personal hearing-protective devices and employee education program
5. Evaluation of the effectiveness of the program

Our discussion concentrates on the role of the hearing professional in the occupational hearing conservation program, particularly the audiologic and otologic aspects.

In many work environments, different departments assume responsibilities for the various aspects of the program: engineering or industrial hygiene departments for noise measurements, safety or industrial hygiene departments for hearing-protective devices, and nursing for audiometry. The hearing professional needs to have an ongoing relationship with each of the above departments or other departments that are involved in execution of the program. Although the hearing professional may not be directly involved in noise measurements or the personal hearing-protective aspects of the program, it is his or her

responsibility to make sure that these critical aspects of the program are being covered and properly managed.

Sound level meters record noise levels, and audio or noise dosimeters measure noise exposures. The latter, which are worn on the worker's body, are preferred when noise exposure changes during the course of a workday. Dosimeters also record the varying noise levels and times of exposure, permitting the occupational hearing conservation team to identify and in many cases provide solutions to high-level exposures during a workday.

In the absence of data provided by use of the above instruments, a noisy area that needs attention to preserve worker hearing can be suspected when any of the following occur:

1. Workers must increase their voice levels to communicate with fellow employees.
2. Workers need to be within 1 to 2 inches of fellow workers to be heard.
3. Worker complaints of tinnitus and muffled hearing are reported after exposure to the work environment.

OSHA requires that all employees whose noise exposure reaches or exceeds the "action level" (85 dBA) for a time-weighted average of 8 hours undergo pure-tone air conduction audiography. Baseline and annual audiograms are required. The required audiometric test for noise-exposed workers consists of air conduction threshold measurements at 500, 1,000, 2,000, 3,000, 4,000, and 6,000 Hz in each ear. The addition of 8,000 Hz can aid in distinguishing noise-induced hearing loss from presbycusis. The majority of these tests are performed by occupational hearing conservationists, and microprocessor audiometers are used for such tests. In a review of the audiometric and case history data, the specialist should be familiar with the worker's specific occupation, the degree and level of occupational noise exposure, the ambient noise level in the audiometric test environment, the date of the most recent audiometer calibration, and relevant case history data.

It is appropriate for the professional to recommend otologic and/or audiologic evaluation, as indicated, including specific procedures, such as auditory brainstem response (ABR) testing, otoacoustic emissions (OAEs) testing, and vestibular evaluation. Employees requiring middle ear surgery, surgical relief of Meniere disease, or management for acoustic tumors should be referred to experienced otologic surgeons in the area where the employee lives or works.

120.5.1 Data Collection and Analysis

Shortly after the initiation of the program, companies with a significant number of noise-exposed employees will be generating a significant amount of audiometric and audiologic data. The employees' noise exposure, use of personal hearing protection, and air conduction thresholds are recorded, along with the results of a baseline test noting the presence or absence of a standard threshold shift (STS) at 2,000, 3,000, and 4,000 Hz for each ear. The results of the otoscopic screening examination are collected and can be managed with analyzed with dedicated software.

The audiometric data can be used to assess the effectiveness of the overall program, alert workers to impending hearing loss, and reveal potential employer liabilities for compensable

hearing loss. The incidence of occupational noise-induced hearing loss, evidenced by the STS (an average change of 10 dB or greater at 2,000, 3,000 and 4,000 Hz in either ear compared with the baseline, with age adjustments allowed), is one indicator of the effectiveness of the occupational hearing conservation program. Incidence rates of 5% or less, decreasing with each year, provide such evidence.

120.5.2 Protection of Residual Hearing and Prevention of Further Hearing Loss

Among the most significant components of the occupational hearing conservation program is protection of the workers' hearing. Engineering controls that reduce noise exposure at the source represent the ultimate solution for noise control. Rotating or administrative controls that move employees to quieter areas of the industrial operation, so that total exposure during the workday is kept to a "safe" level, have limited applications and are impractical in many operations. Until noise can be and is controlled at the source, personal hearing-protective devices, properly fitted and consistently used, will remain the major method for protecting and preserving workers' hearing. The occupational hearing conservation team is faced with a general unwillingness of workers to use hearing protection, who offer a variety of reasons for noncompliance. Although protection of the eyes is generally widely accepted, hearing protection is not because the onset of chronic noise-induced hearing loss is a gradual, subtle, painless, and bloodless process. Although the issuance and monitored use of hearing-protective devices often falls within the province of a company's safety department, the hearing professional must be assured that appropriate hearing protection is being issued and its use monitored. And just as ineffective hearing protection must be avoided, overprotection is similarly to be avoided because it encourages nonuse, may unnecessarily interfere with interpersonal communication, and may prevent the detection of important warning signals.

Personal hearing-protective devices provide a barrier between the noise source and the cochlea. The basic types are ear plugs, ear muffs, and semiaurals. Ear plugs are the predominant form of protection and used in about 80% of industrial applications. The most widely used type is the user-molded or formable plug made of a soft polymer. Ear muffs consist of a plastic cup attached to an adjustable headband. The cups are made to fit snugly against the head with foam or liquid-filled cushions. Ear plugs are subject to variations from the manufacturer's stated noise reduction ratio (NRR) when a worker inserts the device into his or her external auditory canal. Ear muffs are less subject to such variations, although they too can be "sabotaged" in a number of ways. Ear plugs should be used with caution, if at all, by any workers with insulin-dependent diabetes, particularly those working in areas where fresh running water is not available.

The hearing professional should be aware of the procedures implemented to determine the degree of use and effectiveness of noise protectors, as defined by the National Institute of Occupational Safety and Health (NIOSH).

Experts in the field of hearing protection recently reached a consensus on a revised American National Standards Institute (ANSI) standard for measuring the real-ear attenuation (REAT)

of hearing-protective devices. The REAT measures the change in the sound level entering the ears of a subject wearing a hearing-protective device in an occupational hearing conservation program after placement of the device either by a thoroughly trained user (method A) or by an inexperienced, novice user (method B).

Critical to the success of the hearing-protective device program is the employee education program. Attendance at the annual employee education program is required (unlike audiometric testing, which is nonmandatory but must be made available to the employee). The employee education program explains the effects of noise on hearing, the purpose and use of various personal hearing-protective devices, and the audiometric procedures that will be offered. The hearing professional is strongly advised to be an integral part of the employee education program and should be personally present to answer questions from employees in attendance. In many respects, the employee education program is the most critical component of the occupational hearing conservation program.

Although the majority of ear plugs in use are passive, there is also a role, albeit a limited one, for active hearing protectors. Active devices can increase the attenuation of low-frequency noise by about 15 to 20 dB in comparison with the attenuation provided by the widely used passive protectors. The active type provides low-frequency protection when the worker is exposed to repetitive or continuous noises that are relatively constant in their frequency spectrum and level. They incorporate microphones and amplifiers that transmit external sounds to earphones mounted inside the hearing-protective device.

120.5.3 Otoprotective Agents for Noise-Induced Hearing Loss

Many agents have and are being tested in animals to determine if they can prevent or lessen the effects of temporary or permanent noise-induced SNHL. Some agents are administered to prevent these losses and are designed to be used before noise exposure. A few, referred to as rescue agents, are taken within hours or a few days after the noise exposure to prevent permanent hearing loss and are designed to act before cochlear damage becomes permanent.

No otoprotective agents are currently approved by the FDA. ACEmg (β -carotene, vitamin C, vitamin E, and magnesium) and D-met (D-methionine) appear to be the most promising otoprotective agents, although NAC (N-acetylcysteine) and ebselen are also contenders. These agents, based on studies in rodents, appear to provide protection from aminoglycoside- and cisplatin-induced damage to hair cells. An oxidative mechanism may explain their action against these toxicities.

120.6 Roundsmanship

- Noise-induced hearing loss is a ubiquitous threat to hearing in the modern, noisy world.
- Groups of patients especially at risk include teenagers and young adults, especially those individuals who frequent rock concerts and other venues where music is electronically amplified to aphysiologic levels.

- Any period of exposure to noise loud enough to cause tinnitus has probably caused a temporary threshold shift in hearing. This should be understood as a severe warning sign—the ear will not tolerate this level of noise exposure repeatedly.
- Individuals who must be or choose to be exposed to noise should wear hearing protection. It is not possible to protect the ear completely from unwanted noise exposure. Hearing protection may significantly help decrease noise-induced hearing loss in these individuals.
- For any patient at risk for noise-induced hearing loss, an annual hearing test is the minimum requirement for hearing safety.

121 Sudden Idiopathic Sensorineural Hearing Loss

Christopher J. Linstrom

121.1 Introduction

Virtually every physician working in otolaryngology-head and neck surgery will at some time encounter a patient with sudden, unprovoked neurosensory hearing loss. This problem is sufficiently common that the general ear, nose, and throat physician should be able to recognize it, distinguish it from hearing loss with other likely causes, obtain a history and conduct a physical examination, order the appropriate initial diagnostic tests, and start the patient on proven forms of treatment in a timely fashion. The efficacy of treatment diminishes with the passage of time after the initial awareness of hearing loss. Thus, it is incumbent upon every otolaryngologist to have a sound awareness of this problem and to start treatment immediately, or to make a direct and timely referral to an otologist/neurotologist who will.

Sudden idiopathic sensorineural hearing loss (SNHL) was first described by DeKleyn in 1944. It is typically characterized by the new onset of unilateral hearing loss that develops within 72 hours. By convention, at least three midrange frequencies should be involved. There may be associated fullness and/or tinnitus in the affected ear. Imbalance or vertigo may also be present and is a negative prognosticator for the recovery of hearing, along with advanced age and lack of measurable hearing at the time of the first audiogram. Favorable prognostic factors are younger age and measurable hearing, especially word discrimination and an upward-sloping or “cookie bite” pattern on the first audiogram. Wide fluctuations of hearing are a negative prognosticator for the future recovery of hearing.

121.2 Incidence of Disease

Sudden idiopathic SNHL has an estimated incidence of 5 to 20 per 100,000 persons per year. This incidence is approximately the same as that for Meniere syndrome (15 per 100,000 per year). The true incidence may be underestimated because spontaneous recovery has been reported to occur in 32 to 65% of untreated or placebo-treated patients. A “window of opportunity” of several weeks to a few months exists, during which the oral or injected (transtympanic) administration of steroids may help the recovery of hearing. The likelihood of recovery diminishes as time passes. If the hearing loss is mild, many patients do not recognize it and therefore delay seeking medical attention. Aural fullness is often misdiagnosed as eustachian tube dysfunction, and the patient is treated for a cold or influenza before an audiogram establishes that a neurosensory loss of hearing has actually occurred. This further delays treatment. As more and more general practitioners become aware of this entity, the delays in diagnosis and treatment will inevitably lessen.

It is important for all physicians to realize that a tuning fork examination yields information only about the physics of audition (i.e., sounds heard by air conduction should be perceived as louder than sounds heard by bone conduction). A tuning fork examination yields very little reliable information about the actual level of audition. That must be determined in an audio-

metric booth by a properly trained and qualified audiologist, never by the patient himself or herself.

121.3 Applied Anatomy

The anatomy of the cochlear and vestibular apparatus has been described in other chapters of this book and will not be repeated here. Sudden idiopathic SNHL is purely neurosensory, not conductive, in nature. It is by definition not provoked by anything known to the patient and should not occur in the context of chronic suppurative otitis media with or without perforation or cholesteatoma. The antecedent history should in fact be “no history.” Sudden idiopathic SNHL does not occur in the context of sudden changes in resting barometric pressure, as one would expect with a perilymphatic fistula. The patient ordinarily does not experience a warning sign that the ear is changing. The hearing loss is indeed sudden, not slow, in onset. The onset does not mimic the slow, gradual, and inevitable decline in hearing associated with an acoustic neuroma or another slowly growing tumor of the retrocochlear pathways of hearing.

121.4 The Disease Process

121.4.1 Etiology

There is no known “cause” for sudden idiopathic SNHL. This disease does not run in families, is not heritable, is not caused by a known infectious agent, and is not the end stage or tangential product of any known systemic illness, such as rheumatoid arthritis or other connective tissue disorders. If a cause of the hearing loss is known, then it is no longer “idiopathic.”

121.4.2 Pathogenesis

Proposed causative theories suggest vascular etiology, a viral etiology, or both. Because this condition is not lethal, fresh autopsy specimens do not exist, and the pathophysiology of sudden idiopathic SNHL, although logically postulated, remains unproven. There is no animal in which sudden idiopathic SNHL is known to occur naturally. Although vascular occlusion of the cochlea in an animal model has been shown to produce SNHL, this is not idiopathic (i.e., the cause is known). In the absence of fresh histopathologic evidence, speculation is the best one can do. This, of course, is of little comfort to the patient, who is as mystified as the treating physician as to what precisely has occurred. Evidence to support a vascular theory of sudden idiopathic SNHL includes the following:

- Sudden onset, suggestive of infarction
- Case reports of sudden deafness occurring in association with known systemic vascular disease
- Histopathologic demonstration of cochlear changes due to vascular occlusion in animal models

However, temporal bone studies of patients with sudden idiopathic SNHL who donated their temporal bones after natural

death have not demonstrated labyrinthine ossification, the hallmark of labyrinthine ischemia. Evidence to support a viral theory includes the following:

- A temporal relationship between active viral upper respiratory illness and sudden idiopathic SNHL has been shown.
- Patients with sudden idiopathic SNHL have been shown to have antibody titers to several viruses.
- Postmortem histopathologic specimens of human temporal bones have shown atrophy of the organ of Corti, spiral ganglion, and tectorial membrane; unraveling of myelin; and relative preservation of the spiral ganglion cells. These findings are consistent with viral infection. However, no specimen exists for the acute period of this illness because it is not lethal. Thus, no comment can be made about the causative nature of these histologic findings.
- In animal laboratory experiments, inflammatory cytokines produced in response to viral disease may interrupt gap junction pathways in the cochlea, resulting in suddenly decreased function and the death of hair cells within the cochlea. Early treatment with corticosteroids has been seen to reverse this process.

121.4.3 Natural History and Progression

Most patient presenting with sudden idiopathic SNHL have reached a nadir of hearing loss at the time of presentation. Patients' hearing may infrequently fluctuate downward for 1 to 3 days before settling to its lowest point. What the ear should not do is fluctuate down, recover, then fluctuate down again in a repetitive cycle, which suggests cochlear hydrops. This is not the typical pattern of hearing loss associated with sudden idiopathic SNHL. Patients who present with measurable hearing have a better chance of recovery. Patients who present with little if any measurable hearing and either have vertigo or are older than approximately 60 years have a poorer prognosis for recovery.

121.4.4 Potential Disease Complications

The major potential complication of sudden idiopathic SNHL is that the disease entity is a “red herring”—the presentation of a retrocochlear lesion, such as an acoustic neuroma, another benign neoplasm, or metastatic disease to the temporal bone. Although sudden hearing loss due to benign retrocochlear disease is rare, it may occur. Thus, a thorough diagnostic evaluation of every patient with sudden idiopathic SNHL should include a retrocochlear radiographic study, preferably magnetic resonance (MR) imaging with or without contrast.

121.5 Disease Grading

There is no accepted staging system for patients presenting with sudden idiopathic SNHL. Prognostication of the response to treatment, as previously discussed, is predicated upon the amount of measured residual hearing at the time of the initial audiogram.

121.6 Medical Evaluation

Patients with sudden idiopathic SNHL are generally healthy, in midlife, with few if any underlying medical problems. If the patient is known to have hypertension, diabetes, or another medical problem, such as glaucoma, coronary artery disease, or systemic vascular disease, these should be carefully controlled by the internist because they will have a direct bearing on the form of treatment. It is important to know if women in the child-bearing years are pregnant. Other than a careful medical history to elicit concomitant medical conditions that could be exacerbated by the administration of steroids, it is usually not necessary to perform any blood testing that the patient's primary care physician or internist would have on record. There is no serum marker for sudden idiopathic SNHL.

121.6.1 Presenting Complaints

The chief complaint of the patient is unilateral acute hearing loss. By accepted definition, it should have occurred over a time period of no more than 72 hours. It should never be bilateral hearing loss or sequentially bilateral loss; it is unilateral. Additional features, such as aural fullness, tinnitus, dizziness, and vertigo, may accompany the chief complaint, which is hearing loss.

121.6.2 Clinical Findings, Physical Examination

The patient should have a general head and neck examination that concentrates on the ear, and ordinarily there should be no physical findings that would in themselves explain the hearing loss.

121.6.3 Testing

A tuning fork test with at least one or two forks in the speech frequencies (e.g., 512 Hz, 1,024 Hz) should be done. The examiner should have a good idea that the hearing loss is neurosensory and not conductive in nature before sending the patient for an audiogram,

A standard minimum audiogram consists of pure tones presented separately by air and bone for each ear, a test of word recognition presented separately for each ear, and immittance testing including testing of the middle ear muscle response if possible, depending upon the anatomy. Audiograms that do not provide this minimal information should be immediately discarded and the hearing tested by a trained professional.

Regardless of the supposed diagnosis and treatment plan, if the hearing is indeed asymmetrically decreased, a radiographic evaluation of the retrocochlear pathways should be performed, ideally with well-done MR imaging of the temporal bones, base of the skull, and brain without and with gadolinium enhancement. Patients who are claustrophobic may be able to withstand open or “stand-up” MR imaging. The quality of these studies is ever improving. Patients who cannot undergo MR imaging for anatomical reasons (e.g., implanted ferromagnetic hardware) may undergo computed tomography (CT) of the temporal bones with contrast enhancement. The utility of auditory brainstem reflex (ABR) testing, compared with the cur-

Fig. 121.1 Initial audiogram of 60-year-old man with sudden sensorineural hearing loss in the right ear.

rent level of diagnostic accuracy of MR imaging and CT with contrast, is simply too low for it to be recommended as a routine diagnostic tool. Well-done MR imaging with contrast is a definitive study in that its sensitivity for detecting and specificity for excluding retrocochlear disease are in the range of 98 to 99%.

121.6.4 Differential Diagnosis

Once retrocochlear pathology has been excluded, the main items in the differential diagnosis are Meniere syndrome, a perilymphatic fistula of the oval or round windows, autoimmune inner ear disease (which may present in a sequential fashion), otosyphilis, and structural abnormalities of the otic capsule that might predispose the patient to hearing loss.

Meniere Syndrome.

Endolymphatic hydrops may rarely present as sudden hearing loss without vertigo. The classic presentation is a collection of symptoms, usually unilateral: increasing fullness, pressure, and tinnitus in the affected ear, followed by a drop in hearing acuity and violent, unprovoked vertigo lasting one to several hours. The history is so characteristic that it usually yields the correct diagnosis by itself without additional testing. If vertigo is absent, one could postulate hydrops, but the characteristic

prodrome and collection of symptoms are absent in sudden idiopathic SNHL. In addition, unlike Meniere syndrome, sudden idiopathic SNHL is not episodic. Many patients with sudden idiopathic SNHL are in fact treated with steroids, a low-salt diet, and a salt-wasting diuretic early in the course of the illness. The lack of a second episode usually clears up any doubt as to what has actually occurred.

Perilymphatic Fistula

Perilymphatic fistula is almost always diagnosed after a sudden and violent change in the resting barometric environment of the ear, such as a violent sneeze, a rapid descent in an aircraft in which the ear pressure could not be equalized, or underwater scuba diving in which the pressure could not be equalized. The history is paramount to making a proper diagnosis. The history almost always includes a sudden loss of hearing accompanied by violent vertigo. It is ordinarily not something to guess about, but is readily apparent from the history.

Autoimmune Inner Ear Disease

Autoimmune inner ear disease is usually bilateral and presents as inexorable, downwardly fluctuating neurosensory hearing loss. The hearing loss is usually symmetric, although one ear may be farther down than the other. In rare cases, one ear loses hearing first, and then after a few months or even years, the

Fig. 121.2 One-year follow-up audiogram of the same patient shows some modest recovery of hearing in the right ear after treatment with oral steroids.

other ear begins to lose hearing. The main features of this condition are the pattern of fluctuation and the time course over a period exceeding 72 hours. The onset is ordinarily not sudden; rather, the inevitable downward pattern of loss occurs over a period of weeks and months.

Syphilis

Syphilis is the “great masquerader,” and indeed late or latent syphilis may infrequently cause sudden acute hearing loss. One feature suggestive of otosyphilis is that the hearing in both ears may fluctuate in an alternating fashion; an ear will hear poorly on day, better the next day, and so on. Up and down, fluctuating, bilateral hearing loss is not seen with sudden idiopathic SNHL. Any patient with sudden idiopathic SNHL should be tested for historical exposure to *Treponema pallidum* with a fluorescent treponemal antibody absorption (FTA-ABS) test, or its equivalent.

Structural Abnormalities of the Otic Capsule

Structural abnormalities of the otic capsule, especially patent vestibular aqueduct, may predispose a person to sudden hearing loss. A history of head trauma or any head injury should be elicited. This is almost never found in an adult. In addition, if profound hearing loss of any nature is noted in a child, edge-

enhanced CT of the temporal bone without contrast should be performed to look for a structural abnormality of the temporal bone on both the affected side and the side with better hearing. The most common finding will be a patent vestibular aqueduct, usually with a greatest width of more than 1.8 to 2.0 mm. If this is discovered, the child must avoid all sports in which the head could be struck.

121.7 Treatment

121.7.1 Medical Treatment

Steroids

The mainstay of the treatment for sudden idiopathic SNHL is steroid administration, either orally or via transtympanic injection, or both. Most patients can be treated by at least one method. The 1980 landmark paper of Wilson et al, and those of many authors thereafter, have clearly demonstrated the benefits of exogenous steroid administration in the treatment of sudden idiopathic SNHL. Although there is no “recipe” for treatment, most patients will be able to withstand a treatment protocol of oral steroid, usually prednisone, taken as a single dose or in divided doses equaling 1 mg/kg of body weight per day. This will usually equal 60 to 80 mg per day for most adult patients. It is important for patients to be counseled that the treatment pro-

Fig. 121.3 Setup for an intratympanic injection of dexamethasone. A 1.0-mL tuberculin syringe is filled to approximately 0.5 mL with a 27-gauge long needle. The topical anesthetic, 20% phenol, is applied with a drop applicator (long, black instrument). The injection site is usually the near the round window. For multiple injections, one should choose different sites to decrease the chance of causing a tympanic membrane perforation.

gram is for a brief period only, that the potential side effects, although significant, are transient, and that there are no other medications whose efficacy has been proved to equal that of steroids. The exact anti-inflammatory mechanism of steroids remains unknown. They intimately affect the biochemical pathways of carbohydrates, inhibit multiple inflammatory cytokines, and produce multiple glucocorticoid and mineralocorticoid effects. Steroids stabilize cell membranes and make them more structurally intact and less leaky, thereby acting as anti-inflammatory agents. Even though their exact mechanism of action is unknown, steroids are known to be of benefit in sudden idiopathic SNHL, a form of nerve hearing loss in which hearing is potentially restorable (□ Fig. 121.1 and □ Fig. 121.2).

Oral steroids are given in a “burst then taper” pattern, in which a high “shoulder” of medication is given for a period of 10 to 14 days, followed by a period of tapering of approximately 5 to 7 days. As the amount of exogenous steroid is decreased, the adrenal glands will again supply endogenous cortisol. Steroids have several potential side effects, and the patient should be made aware of them:

Weight Gain

A transient gain of 3 to 5 lb is common with the use of oral steroids because of both the retention of water and

Fig. 121.4 Typical injection sites (asterisks) for a left eardrum.

appetite stimulation. Ordinarily, the weight gain is transient, and compensatory weight loss will occur as the steroid is tapered.

Increased Serum Glucose

This is ordinarily not a problem for the patient who does not have diabetes. However, patients who have borderline diabetes or are known to have diabetes that is controlled with either oral hypoglycemic agents or insulin may have to alter their daily regimen while on exogenous steroids. Any physician who prescribes oral steroids must inquire about this, and the patient must either know how to regulate the serum glucose by himself or herself or seek the help of another treating physician. Patients with brittle, insulin-dependent diabetes may not be candidates for oral steroids.

Hypertension

Exogenous steroids cause water retention, and thus the patient's resting blood pressure may increase. For the normotensive patient, steroids ordinarily will be very well tolerated. Patients with labile hypertension must be managed carefully by an internist or cardiologist during the period of oral steroid use. These patients may require an increase in the dose of their regular antihypertensive agent or an additional medication to regulate the blood pressure.

Fig. 121.5 Initial audiogram of a 65-year-old man with sudden idiopathic sensorineural hearing loss in the left ear. After treatment with oral corticosteroids, the patient showed some improvement and subsequently was treated with intratympanic steroid injections.

Gastritis

Oral steroids may cause rather pronounced gastritis and should be taken with food or with an over-the-counter or prescribed antacid or hydrogen ion blocker such as omeprazole, esomeprazole, or dexlansoprazole. These agents will ordinarily significantly reduce acid reflux while the patient is taking oral steroids.

Insomnia

Almost all adults report that exogenous steroids affect their normal patterns of sleep, usually the transition between a state of tiredness and sleep. Therefore, it is practical to attempt to take the full daily dose by about 2 PM, so that blood levels of the steroid are decreasing when the patient ordinarily tries to fall asleep in the evening. The tendency to insomnia ordinarily decreases as the daily dose is tapered.

Avascular Necrosis

Avascular necrosis of the weight-bearing joints is an idiopathic reaction to any exogenous steroid in any form that may occur in approximately 1 per 200,000 individuals. This may lead to a precipitous osteoarthritis causing necrosis of the articular surfaces of the weight-bearing joints, most especially the femoral heads. It is not dose-related. Any patient contemplating the use of oral steroids must be informed of the risk for this rare but significant potential complication.

Other Conditions

Patients who have poorly controlled glaucoma or who are pregnant will ordinarily not be allowed to take exogenous steroids. It is of great importance that the patient's overall care be coordinated with his or her primary care physician. In certain instances, the underlying medical problem(s) preclude the use of oral steroids, and the only other available method of treatment would be intratympanic administration.

Antiviral Medication

One of the two main putative pathophysiologic mechanisms of sudden idiopathic SNHL is viral infection of the cochlea. Antiviral agents such as acyclovir, valacyclovir, famciclovir, and ganciclovir may be used along with steroids in the treatment of sudden idiopathic SNHL when a viral etiology is strongly suspected. However, their benefit at this time is unproven, and they are no longer the mainstay of treatment for this condition.

Intratympanic (or Transtympanic) Steroids

It is known that exogenous steroid is of benefit to patients with sudden idiopathic SNHL. What is unknown at present is the preferred means of delivering the steroid, either per os or via the round or oval window, although this is the subject of active and intense inquiry. Patients who cannot or will not take oral steroids or who have failed a course of oral steroids may benefit from intratympanic steroids. The administration of steroid in

Fig. 121.6 Audiogram after oral and intratympanic corticosteroid treatment.

this fashion for this indication has been studied rigorously and has been shown to be of benefit for sudden idiopathic SNHL. The choice of steroid depends upon several factors; the pharmacokinetics (the mineralocorticoids are more highly absorbed than the glucocorticoids), the relative discomfort to the patient depending upon the resting pH of the solvated steroid, and the availability of the steroid all affect the choice of steroid to be used.

Most treating physicians will choose dexamethasone (4 or 10 mg/mL) and administer about 0.5 mL through the topically anesthetized (20% phenol or trichloroacetic acid) tympanic membrane (□ Fig. 121.3 and □ Fig. 121.4). The patient is placed in the Trendelenburg position for about 25 to 30 minutes and asked not to swallow in order to keep the steroid within the middle ear cleft. The patient is then brought to the supine position thereafter, the excess steroid is suctioned from the middle ear, and a few otic antibiotic drops are instilled into the external canal of the treated ear.

Other choices for steroid injection include hydrocortisone sodium succinate and methylprednisolone sodium succinate. These have been shown in a rodent model to achieve higher concentrations in the inner ear when given intravenously. However, injections of these agents into the middle ear cleft are quite painful, may induce an acute inflammation not unlike

acute otitis media, and in general are less likely to be well tolerated. Patients may experience transient vertigo and discomfort after the first dexamethasone injection into the middle ear cleft, but most tolerate the medication very well. The same cannot be said for methylprednisolone and hydrocortisone, which are quite noxious to the middle ear.

A hearing test of the treated ear (pure tone, bone, discrimination, no immittance) is repeated 1 week after the second injection (given 3 to 7 days after the first injection). If the ear shows signs of improvement in either the speech recognition threshold (SRT) or the word discrimination score (WDS), the intratympanic injections continue until a “ceiling effect” of improvement in the SRT or, more likely, the WDS is achieved. Further injections will be unlikely to be of any additional benefit. If, on the other hand, there is no improvement in either the SRT or WDS after two injections, no further injections are performed (□ Fig. 121.5, □ Fig. 121.6, □ Fig. 121.7, □ Fig. 121.8).

The main risk of intratympanic injection of steroid is perforation of the tympanic membrane. The use of a small-bore needle with the minimum amount of topical anesthetic will usually decrease this risk. For patients undergoing repeated injections, alternating the injection site will also decrease the risk. Treatment during pregnancy should be discussed and coordinated

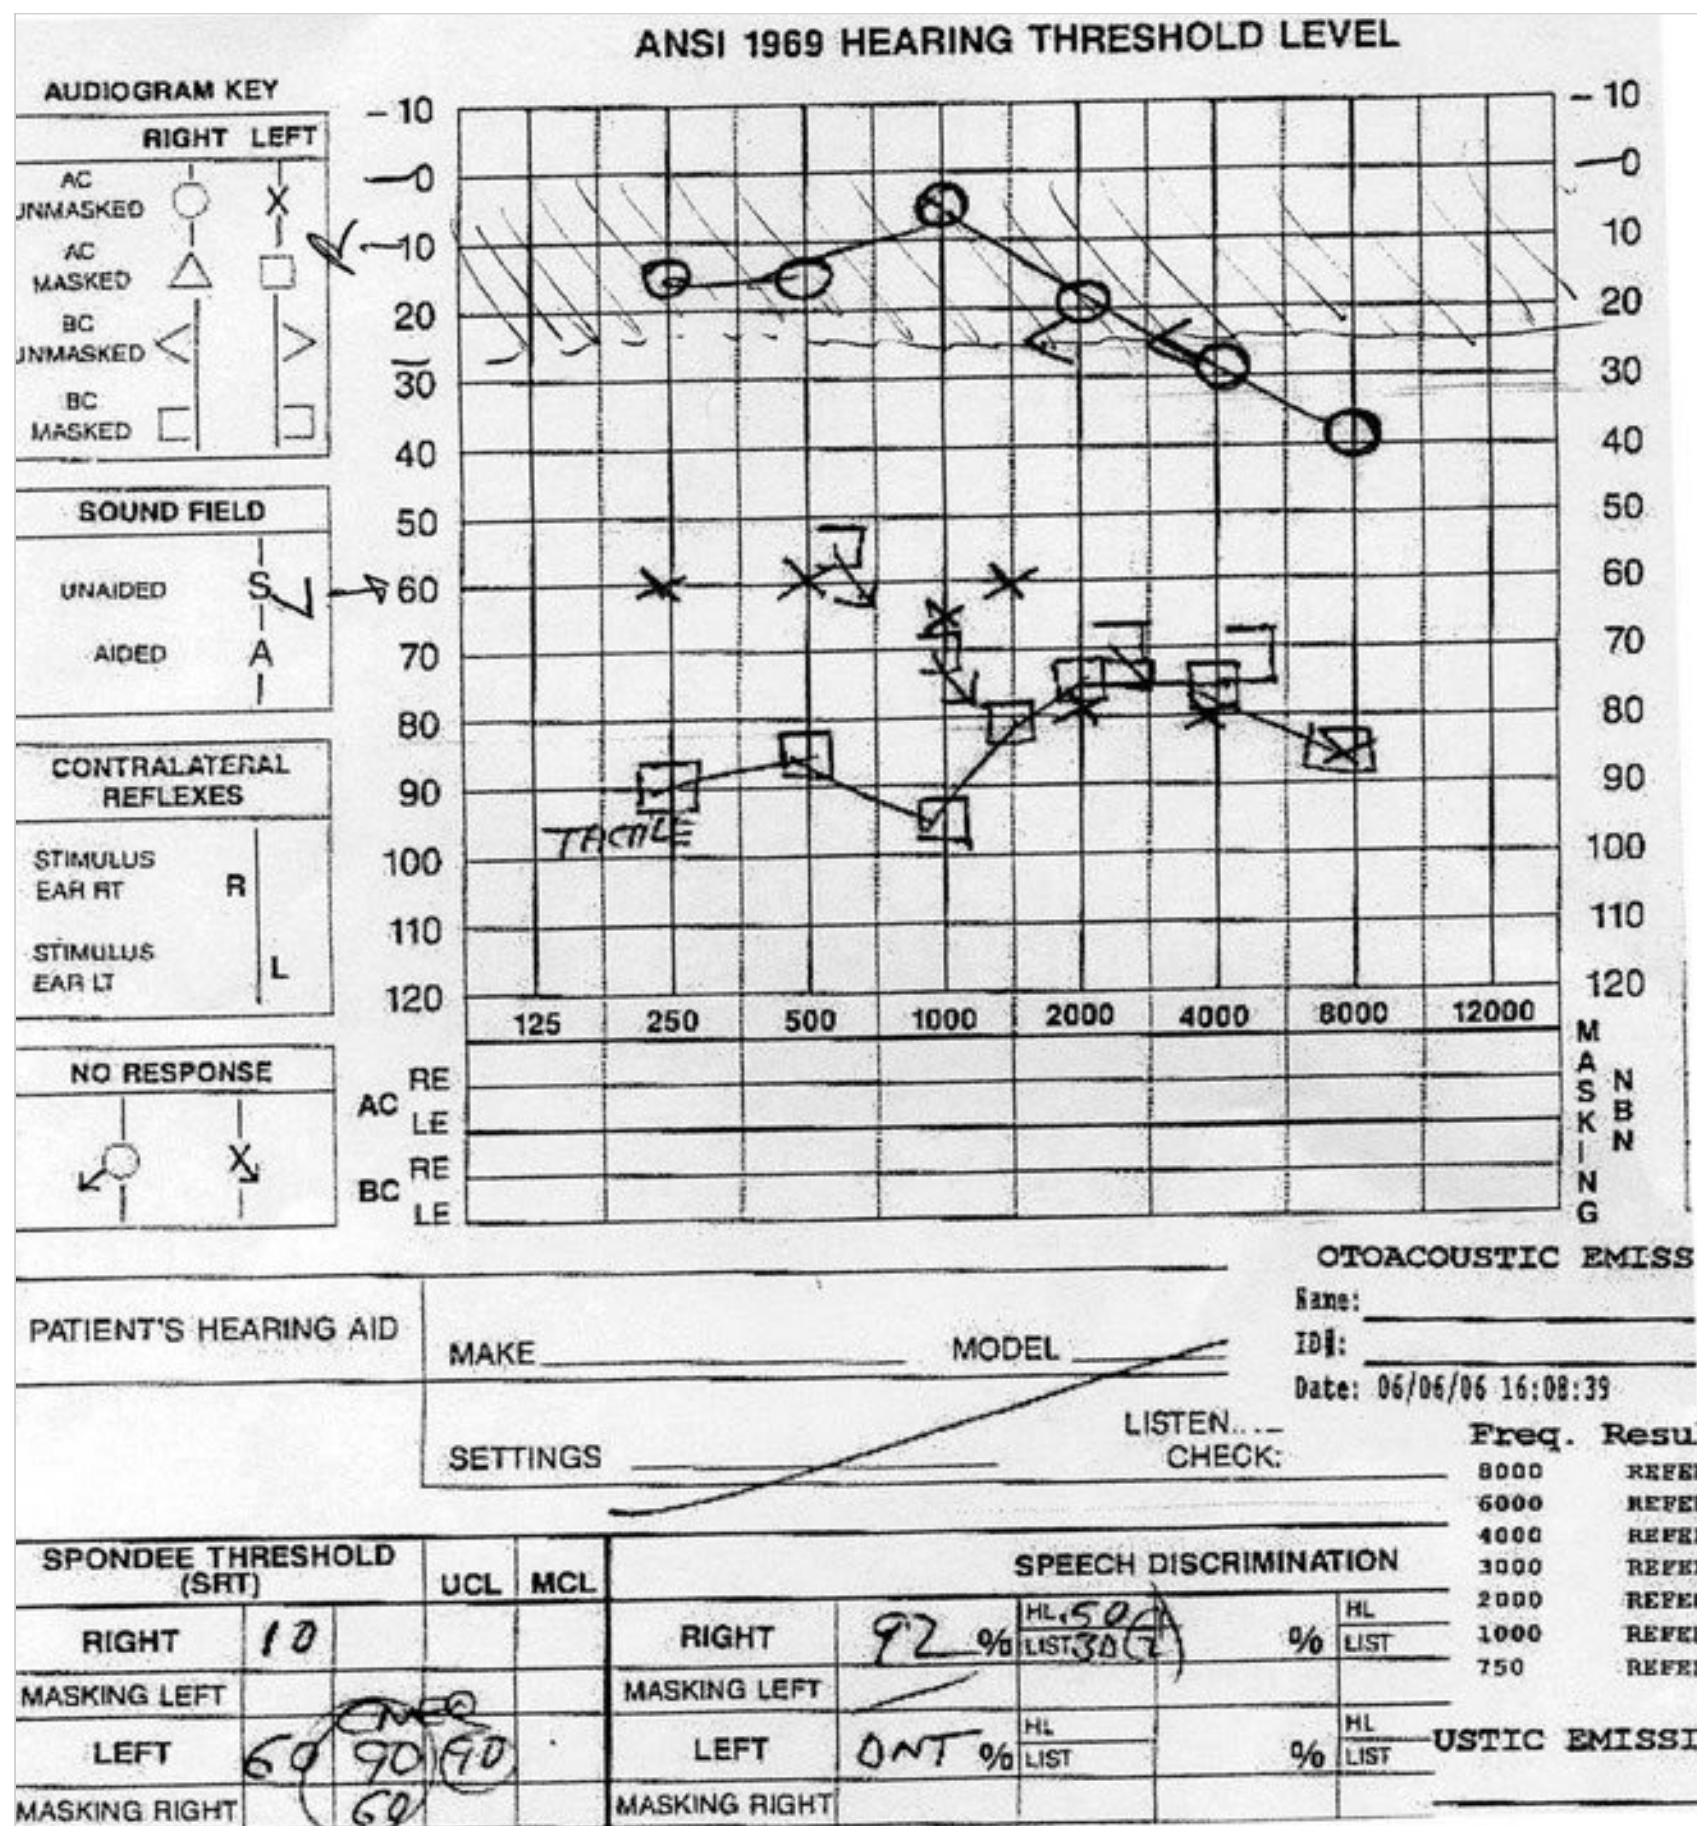

Fig. 121.7 A 61-year-old woman with sudden sensorineural hearing loss in the left ear 5 days before audiogram, with a brief (24-hour) period of vertigo but constant tinnitus. She was treated with dexamethasone orally followed by four intratympanic injections.

with the patient's obstetrician. Although the amount of injected steroid is small, at least some of it is likely to be ingested via the eustachian tube and gut and thus will be absorbed systemically.

121.7.2 Surgical Treatment

There is no known surgical treatment to restore neurosensory hearing loss that is idiopathic and sudden. Any other entity is not strictly sudden idiopathic SNHL. Middle ear exploration and the packing of suspected fistulas of the oval and round windows are of no value in sudden idiopathic SNHL.

121.8 Prognosis and Response to Treatment

The response of a patient to either oral or injected steroid depends upon several factors. The three most salient are the following:

1. The amount of measurable hearing (pure tone and speech recognition) at the time of the first audiogram.
2. The pattern of the first audiogram. An upward-sloping hearing loss and a "cookie bite" hearing loss with only the mid frequencies affected are good prognosticators, whereas both a severely downward-sloping pattern of loss and a "flat out" pattern of immeasurable hearing loss are poor prognosticators.

3. The time course between the occurrence of sudden hearing loss and the administration of steroids. A time delay of more than 2 weeks is certainly unfavorable. The sooner steroids are administered, the more likely a beneficial response.

The numbers vary widely depending upon the reported series of patients, the type of medical treatment given, and the criteria used to define "beneficial response" versus "little response" or "no response."

Patients with sudden idiopathic SNHL can be divided basically into three groups, as can patients with many other disease processes.

121.8.1 Good Responders

Patients with mild or moderate levels of hearing loss, good discrimination scores, and the absence of vertigo are likely to be the best responders. The patient with an upward-sloping or "cookie bite" audiogram and measurable residual hearing will show the most favorable response. Many will recover nearly normal or normal hearing, and routine audiometric follow-up is performed within 6 months.

121.8.2 Midlevel Responders

These patients present with worse levels of hearing and poorer initial discrimination scores, and they may have imbalance or vertigo along with hearing loss. They are likely to recover some

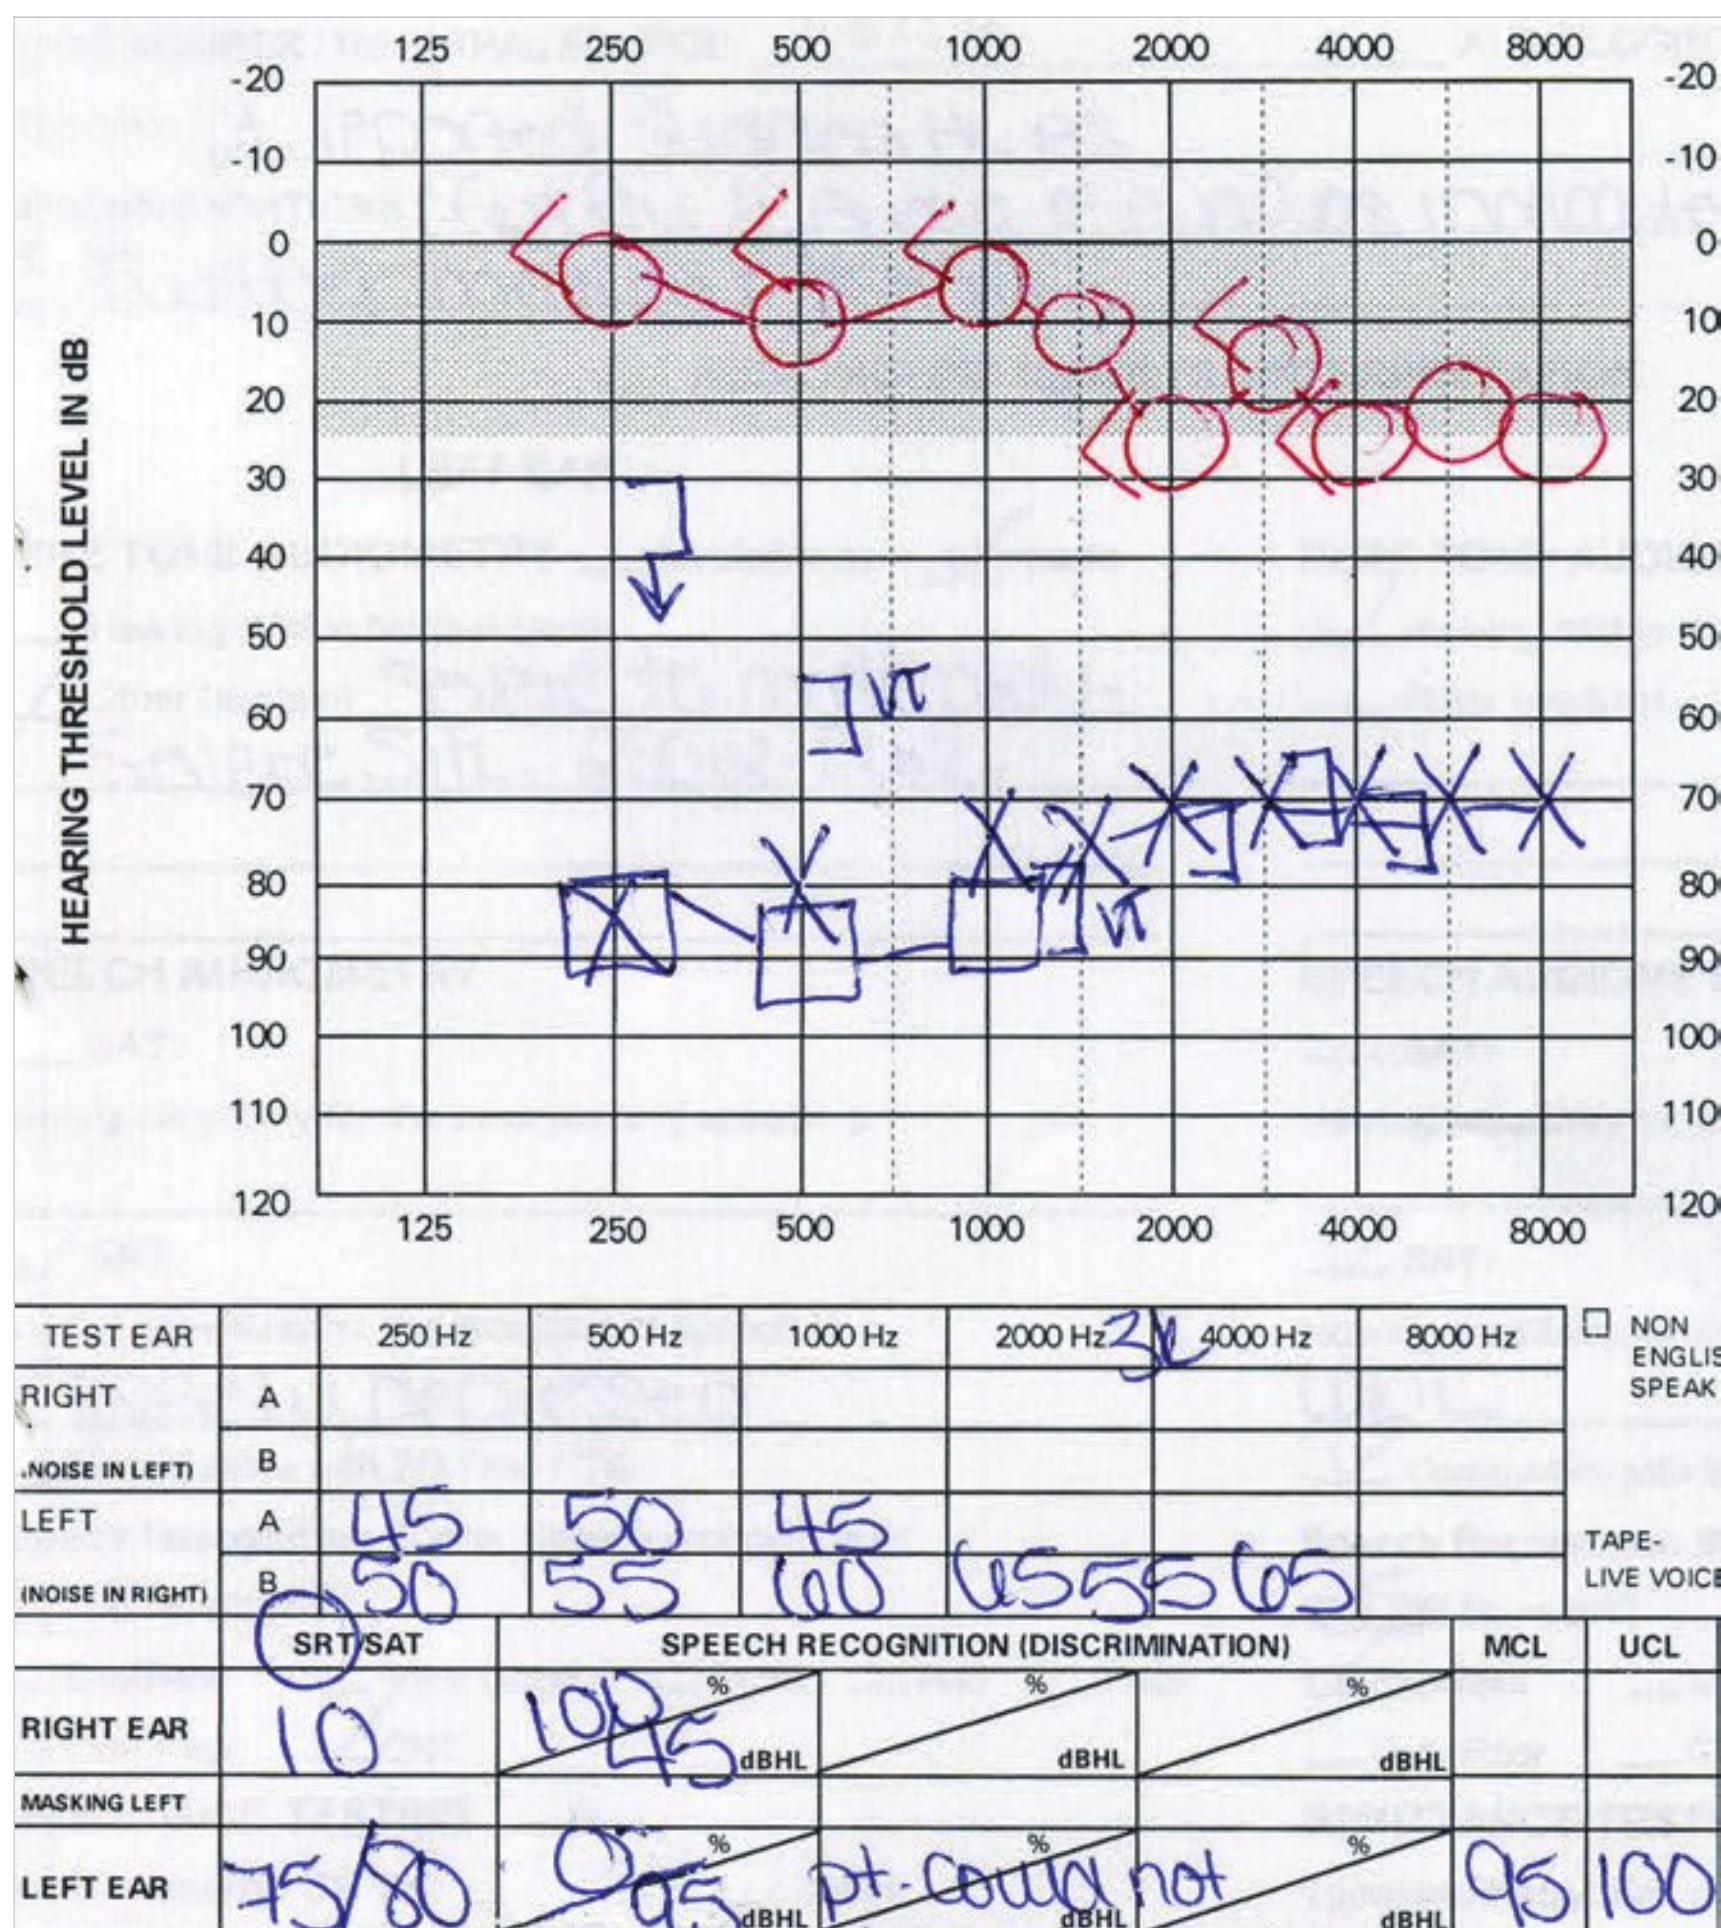

Fig. 121.8 Follow-up audiogram of the patient in Fig. 121.7 after treatment.

of their hearing, but it is almost never completely normal, and they may or may not become candidates for amplification in the affected ear. Follow-up audiograms should be obtained within 6 months and the status of the hearing assessed.

121.8.3 Poor Responders

These patients present with flat, “all gone” audiograms after therapy, tend to be older (past 60 years of age), and usually have violent vertigo along with their sudden hearing loss. In fact, these patients may have labyrinthitis. They should be counseled that it is highly unlikely that they will regain any hearing regardless of treatment and that they should use a sound-shunting device, such as a contralateral routing of signals (CROS) device or a bone-anchored hearing aid (BAHA). Many if not most of these patients have seen numerous physicians and otologists, have tried both oral and injected steroids, and are looking for a miracle. With empathy, the physician must be a realist, offer these patients a careful and thorough diagnosis, and help them to accept the loss of hearing on the affected side. One important step along the way is to emphasize that it is highly unlikely that the patient will lose hearing in the opposite (good) ear and that, were this to happen, the patient would never truly become deaf because he or she would be a candidate for cochlear implantation. It is important to reassure the patient that the sudden loss of hearing on one side does not in any way mean that the

second ear is condemned to the same fate. This is the (usually) unspoken fear of every patient, and it should be dispelled. With the physician’s kindness and empathy, the patient with unrecoverable, profound sudden idiopathic SNHL may be helped to accept the loss of hearing and to take positive measures to improve his or her overall ability to communicate. Without a doubt, these are most difficult patients to treat.

121.9 Roundsmanship

- Sudden idiopathic SNHL occurs in approximately 1 to 2 per 100,000 persons per year. It is not precipitated by any known cause.
- Sudden idiopathic SNHL is almost always unilateral. If a patient should suffer sudden hearing loss in the contralateral ear, another cause, such as autoimmune hearing loss, should be investigated.
- Steroids are the treatment for sudden idiopathic SNHL. They may be given by mouth or injected through the tympanic membrane. They are the mainstay of treatment for recovery and should be offered unless there are medical contraindications to their use.
- There is a “window of opportunity” for the treatment of sudden idiopathic SNHL of about 4 to 6 weeks, after which time the likelihood of hearing recovery is greatly diminished. It is

of great importance that once this entity is suspected or diagnosed, proper treatment be initiated as soon as possible.

- There is currently no evidence that antiviral medication is of benefit to patients with Sudden idiopathic SNHL.
- Every patient with sudden idiopathic SNHL should undergo a retrocochlear evaluation, optimally MR imaging of the internal auditory canals without and with edge enhancement, to exclude the small possibility that an acoustic neuroma is the cause of the hearing loss.

122 Ototoxicity

Katrina R. Stidham

122.1 Introduction

The term ototoxicity is used to describe damage to the function of the inner ear, specifically the cochlea, balance canals, and/or auditory–vestibular nerves, due to an external exposure or toxin. The term is most often used to describe dysfunction caused by medical drugs, but ototoxicity can also be caused by the abuse of medical drugs or the use of street drugs. In addition, radiation damage to the inner ear may be referred to as ototoxicity. Finally, chemical exposures, as may be experienced in the workplace, can cause ototoxicity. Any agent that can cause temporary or permanent dysfunction of the inner ear is considered ototoxic.

122.2 Incidence of Disease

The incidence of ototoxicity depends on the individual ototoxin and dose administered. Individual incidence rates for specific agents are listed below.

122.3 Terminology

122.3.1 Cochleotoxicity

Cochleotoxicity is damage to the hearing organ (cochlea, cochlear nerve). Symptoms include hearing loss and tinnitus. Hearing loss is usually bilateral and symmetric (unless there has been a direct insult to one ear, as would occur in directed radiation therapy). Hearing loss typically begins at high frequencies and progresses to low frequencies.

122.3.2 Vestibulotoxicity

Vestibulotoxicity is damage to the balance organ (semicircular canals, utricle, saccule, vestibular nerves). Symptoms can vary from mild imbalance to more severe dizziness and vertigo with nausea and vomiting. Individuals with severe vestibulotoxicity may suffer from ataxia, head tilt, and oscillopsia.

122.4 Applied Anatomy

The cochlea is a tonotopic, snail-shaped organ. High-frequency sensitivity is located in the basal (outer) turn of the cochlea, and low-frequency sensitivity is situated in the apical (inner) turn. The nerve endings, known as hair cells, consist of three rows of outer hair cells and one row of inner hair cells. The outer hair cells act as an amplifier of the acoustic signal, while the inner hair cells convert the acoustic signal to an electrochemical signal. This signal is passed on to the spiral ganglion cells located in the central portion of the cochlea and ultimately transmitted to the brain.

The vestibular organ consists of the semicircular (balance) canals, utricle, and saccule. The vestibular epithelium is composed of two types of sensory hair cells, referred to as type I and type II cells. Increased and decreased discharges of the hair cells

from each inner ear send signals to the brain regarding spatial orientation, acceleration, and angular rotation.

122.5 The Disease Process

122.5.1 Etiology

More than 130 drugs have been identified as potentially ototoxic. However, many cases of drug-induced ototoxicity have been anecdotally reported, often in patients without pretreatment audiograms. Some agents with known ototoxicity, such as nitrogen mustard and dihydrostreptomycin, are no longer clinically available. In addition to ototoxic drugs, there are multiple chemical exposures and radiation therapies with documented ototoxicity. The following are currently available agents with definite or probable ototoxic potential.

Chemotherapy Agents

Platinum Analogues: Cisplatin, Carboplatin

Both of these chemotherapeutic agents are known to be ototoxic, with a significant cochleotoxic effect. Cisplatin has a high incidence of documented ototoxicity, with an incidence of cochleotoxicity of up to 100% documented when ultra-high-frequency audiometric thresholds are included. Carboplatin, although less toxic than cisplatin, is still a risk, particularly in higher doses. Both agents are radiosensitizers and have a synergistic ototoxic effect with radiation therapy. Platins can cause early hearing loss but also can have progressive ototoxic effects for several months after the completion of treatment.

Antibiotics

Aminoglycosides: Gentamicin, Streptomycin, Tobramycin, Amikacin, Neomycin, Kanamycin

Aminoglycosides have been estimated to cause ototoxicity in anywhere from 2 to 45% of adults and 0 to 2% of infants. Amikacin, kanamycin, and neomycin are more cochleotoxic, whereas gentamicin and streptomycin tend to cause more vestibulotoxic damage. Tobramycin, although less toxic overall, has both cochleotoxic and vestibulotoxic effects. Long-term use with a higher cumulative dose increases the risk for ototoxicity, as can high peak and trough levels of individual doses. Concurrent use of diuretics can also increase the risk for ototoxicity. In addition, a subset of patients has been identified with a genetic susceptibility to aminoglycoside ototoxicity, due to a mutation in mitochondrial ribosomal RNA. These individuals are highly susceptible to aminoglycoside ototoxicity, with even one dose leading to severe hearing loss.

Aminoglycosides have historically been used in topical medications for the ear, including in Cortisporin Otic (neomycin) and tobramycin ophthalmic solutions. Neither of these drugs is actually FDA-approved for use in ears with perforated tympanic membranes or tympanotomy tubes. Although no convincing human data exist to prove that these drugs definitely cause

ototoxicity when administered topically, care should be taken when these medications are prescribed, and if at all possible, an alternative ototopical agent should be used.

In recent years, a specific therapeutic benefit of aminoglycoside ototoxicity has been used to advantage in otology. Gentamicin is frequently used in the management of Meniere disease. The antibiotic is injected into the middle ear and allowed to perfuse the inner ear to create a controlled vestibulotoxic effect. This therapy has been more than 90% successful in controlling symptoms of Meniere disease in patients who fail to respond to conservative medical management.

Vancomycin

Vancomycin has been associated with several reports of increased tinnitus and anecdotal reports of decreased hearing. No definitive data exist on the true ototoxic effects of this antibiotic when it is administered alone. There is, however, evidence of increased risk for ototoxicity when it is administered concurrently with aminoglycosides.

Macrolides: Erythromycin, Clarithromycin, Azithromycin

Reports of macrolide ototoxicity are relatively infrequent. The effects are often reversible, although there have been a few reported cases of irreversible hearing loss. No systematic review of these antibiotics in regard to ototoxic effects has yet been completed.

Loop Diuretics: Furosemide, Bumetanide, Ethacrynic Acid

It is estimated that approximately 7% of patients taking loop diuretics may experience ototoxic symptoms in the form of tinnitus or hearing loss. The symptoms are usually self-limited and reversible in adults with no other comorbidities. Irreversible hearing loss has been reported in neonates and in patients with renal failure. Loop diuretics have also been shown to have a synergistic effect with other ototoxic medications, particularly aminoglycosides, leading to an increased risk for irreversible hearing loss.

Quinine Derivatives: Quinine, Hydroxychloroquine, Mefloquine

Quinine derivatives have been documented to cause both cochleotoxic and vestibulotoxic symptoms, with hearing loss, tinnitus, vertigo, and nausea. Hearing loss is usually reversible, but permanent hearing loss has been reported.

Aspirin and Nonsteroidal Anti-inflammatory Drugs

Tinnitus is a commonly recognized side effect of aspirin. The incidence of ototoxicity with aspirin is estimated to be 1% and is probably higher in elderly patients and those with dehydration. Symptoms of tinnitus and a mild to moderate flat hearing loss occur and are usually reversible within 24 to 72 hours after the medication has been discontinued. Nonsteroidal anti-inflam-

matory drugs have a much lower rate of ototoxicity, but cases of irreversible loss have been documented.

Narcotics: Hydrocodone/Acetaminophen, Codeine/Acetaminophen, Propoxyphene

Each of these narcotics has been associated with ototoxicity, specifically with cochleotoxicity and hearing loss. Hearing loss has been documented primarily in patients with long-term and abusive use of these medications. Effects can be severe, with some patients progressing to profound hearing loss, necessitating cochlear implantation.

Radiation

Any patient who receives whole-brain irradiation or radiation involving the temporal bone is at risk for radiation ototoxicity. The groups most commonly affected include patients with primary or metastatic brain cancer and patients with head and neck cancer. The effects of radiation are dose-dependent, and there is also a documented synergistic effect of radiation and platins. Hearing loss can be acute or delayed. Patients are at long-term risk for the progression of hearing loss, which often becomes noticeable years after the completion of therapy.

Occupational Chemicals

Multiple chemical agents to which an individual may be exposed in an industrial environment can also lead to ototoxicity. Some documented ototoxins include the following: toluene, xylene, styrene, carbon disulfide, ethyl benzene, trichloroethylene, carbon monoxide, benzene, ethyl benzene, n-butanol, n-hexane, and solvent mixtures. In addition, chemical ototoxins have been proved to have a potentiating or synergistic effect with exposure to noise in worsening ototoxic damage. Thus, several professions that involve exposure to both chemical ototoxins and noise, including painting, printing, boat building, construction, furniture making, the manufacture of metal, leather, and petroleum, fueling vehicles, firefighting, and weapons firing, may be associated with a heightened risk for hearing loss or vestibular damage.

122.5.2 Pathogenesis

The pathogenesis of ototoxicity is not entirely understood and probably varies from agent to agent. In permanent cochleotoxicity, there appears to be damage to the stria vascularis, which leads to secondary damage to the hair cells. The outer hair cells are more commonly affected first, proceeding from basal to apical turn. The inner hair cells are affected secondarily, again proceeding from basal to apical turn. Thus, ototoxicity typically causes high-frequency hearing loss first. Damage to the spiral ganglion cells can be secondary to, or in some cases independent of, hair cell damage. Vestibular ototoxicity typically causes selective damage to type I hair cells, although type II cells can also be affected.

With many of the agents causing permanent ototoxic effects, an increase in the formation of oxygen free radicals and depletion of the antioxidant enzyme system lead to permanent cell death. Platin agents accumulate in the cochlea and are

integrated into the DNA, leading to an overload of oxygen free radicals while the production of important antioxidant enzymes is downregulated, including superoxide dismutase, catalase, and glutathione peroxidase. Aminoglycosides have been found to bond with iron to form iron–aminoglycoside complexes. The complexes disrupt mitochondrial protein synthesis and lead to the formation of free oxygen radicals, which cause cell death. The iron–aminoglycoside complexes can persist in the inner ear for up to 6 months after administration, causing ototoxic effects long after the medication has been stopped.

In contrast, loop diuretics, which usually have temporary ototoxic effects, create a change in the ionic gradient between the fluid spaces (perilymphatic space and endolymphatic space) in the inner ear. This change can cause swelling of important supporting cells in the stria vascularis, which is usually reversible once the medication is cleared from the cochlea.

Other clinical and external factors may increase the likelihood that an agent will cause ototoxicity in an individual patient. Some of the factors that may increase the risk for ototoxicity are listed in the Box Risk Factors for Ototoxicity (p.977).

Risk Factors for Ototoxicity

- Renal disease/dysfunction
- Extremes of age: children younger than 5 years of age and the elderly
- Prior or concurrent cranial irradiation plus ototoxic medication
- Simultaneous administration of two ototoxic medications
- Genetic predisposition
- Poor hydration
- Prolonged medical therapy
- Noise exposure
- Preexisting hearing loss
- Immunocompromise

122.5.3 Natural History and Progression

The natural history and progression of ototoxicity are entirely dependent on the ototoxic agent to which the patient is exposed. Platin agents may cause hearing loss acutely as well as several months after treatment has been completed. Aminoglycosides can also stay in the inner ear for up to 6 months after treatment and cause hearing loss or balance dysfunction long after the completion of treatment. The effects of radiation therapy can be progressive for decades after the initial treatment. Finally, although many ototoxic medications have permanent effects, the effects of a few, including loop diuretics and aspirin, may be reversible with cessation of the medication.

122.6 Medical Evaluation

Patients with potential ototoxicity should always be medically evaluated to rule out other causes of their symptoms. Often, patients receiving ototoxic therapies are very ill and at risk for other problems that can affect hearing or balance function. All

patients should have a careful examination of the ear to evaluate for possible cerumen impaction, middle ear effusion, and acute otitis media. Patients with asymmetric hearing loss and vestibular symptoms should have imaging, usually magnetic resonance imaging of the brain with contrast, to rule out other pathology that may be causing symptoms.

122.6.1 Presenting Complaints

The presenting complaints of a patient with ototoxicity depend on the associated ototoxic effects of the specific ototoxin administered. Patients with cochleotoxic effects will have tinnitus and hearing loss. The hearing loss can vary in severity from mild, high-frequency loss to profound hearing loss across all frequencies. Hearing loss is usually symmetric except in cases of direct radiation therapy to one ear. Patients with vestibulotoxicity may have mild dizziness, disequilibrium, and nausea, and those with more severe dysfunction may experience severe vertigo and vomiting. Those with total or nearly total vestibulotoxic effects can experience severe ataxia and oscillopsia.

122.6.2 Clinical Findings, Physical Examination

The ear examination for patients with both cochleotoxicity and vestibulotoxicity is usually normal. Subjective hearing loss may be appreciated on interview of the patient. Patients with vestibulotoxicity may have abnormalities on completion of their neurotologic examination. These can include nystagmus, inability to perform Romberg and tandem Romberg maneuvers, and unsteady gait or ataxia. Oscillopsia may be noted with ambulation.

Other bedside tests that can be performed include the dynamic visual acuity test and the horizontal head thrust test. In the dynamic visual acuity test, the patient is asked to look at an eye chart. The examiner then rotates the patient's head back and forth and asks the patient to read the smallest line again. Someone with an intact vestibulo-ocular reflex should be able to focus on the same line, whereas the patient with oscillopsia will be able to read only a much larger print. In the horizontal head thrust test, the examiner turns the patient's head quickly to one side and then the other and then asks the patient to fix the eyes on a specified point straight ahead. The examiner looks for catch-up saccades, which can be a sign of vestibular damage.

Bedside evaluations can be helpful in determining if a patient may have possible ototoxic effects, particularly when the consideration is to urgently stop a potentially ototoxic medication. However, for a complete and accurate evaluation, patients require formal testing.

122.6.3 Testing

The primary problem in evaluating ototoxicity is that damage is often done before measurable changes can be appreciated on standard testing and before subjective symptoms appear. In addition, patients may not be able to fully recognize or communicate the symptoms of ototoxicity. This is particularly a concern in very young patients and those who are very ill.

Cochleotoxicity Testing

The following tests are recommended for patients at risk for cochleotoxicity:

- High-frequency audiography: This tests frequencies up to 20,000 Hz to detect hearing loss before it reaches the lower frequencies of speech and language range.
- Distortion product otoacoustic emissions (DPOAEs): These measure outer hair cell function and have been shown to change before changes are documented on the audiogram.
- Auditory brainstem response (ABR) and auditory steady state response (ASSR): Both of these are objective parameters of electrical signals from the brain. They can be used to test or screen patients at risk who cannot complete standard audiometric testing.

Vestibulotoxicity Testing

- Videonystagmography (VNG): This assesses the integrity of the peripheral vestibular system through stimulation of the horizontal semicircular canals. The system is stimulated at a relatively low frequency of 0.002 to 0.004 Hz, lower than that typically experienced by the vestibulo-ocular reflex (VOR).
- Rotational chair testing: This stimulates the VOR at a more physiologic rate of 0.01 to 1.28 Hz. It can also provide information about possible dysfunction of the inner ear balance canals.
- Computerized dynamic posturography (CDP): This is a test of postural stability and assesses quantitatively how much balance dysfunction a vestibulotoxic insult may have caused.

122.7 Monitoring for Ototoxicity

Patients receiving ototoxic agents should be monitored throughout the course of their treatment for signs of ototoxicity. Practically, it is much easier to monitor for cochleotoxicity than for vestibulotoxicity because the testing is easier for the patient to undergo and can be completed in an inpatient setting. There are several sources for suggested guidelines, but no uniformly endorsed screening protocols, and most centers formulate a version of their own guidelines. Unfortunately, outside research and university hospitals, monitoring for ototoxicity is often not consistently completed. In addition, at least three different guidelines are used for defining ototoxicity, including the American Speech-Language-Hearing Association (ASHA) criteria, the Brock hearing loss criteria, and the Common Terminology Criteria for Adverse Events (CTCAE). The latter two break down hearing loss into grade levels. Unfortunately, these have been recognized in recent years as insufficiently sensitive to assess early ototoxicity accurately. To define the presence or absence of ototoxicity, the ASHA criteria should be used. All three of these ototoxic grading systems are outlined in the Box Ototoxicity Grading Systems (p.978).

The following are suggested guidelines for ototoxicity monitoring.

122.7.1 Baseline Evaluation

A baseline evaluation should be completed for all patients before, or as close as possible to, the first ototoxic treatment. This

should include (1) otoscopy/tympanometry; (2) pure-tone air conduction/bone conduction audiometry, including ultra-high-frequency audiometry; (3) DPOAE testing; and (4) ABR/ASSR testing, as indicated.

Ototoxicity Grading Systems

American Speech-Language-Hearing Association criteria for hearing loss

- Pure-tone threshold change of ≥ 20 dB at one frequency
- Pure-tone threshold change of ≥ 10 dB at two adjacent frequencies
- Loss of responses at three consecutive test frequencies at which responses were previously obtained when otoacoustic emissions or auditory brainstem response was used

Brock hearing loss grades

- Grade 0: hearing thresholds < 40 dB HL at all frequencies
- Grade 1: hearing thresholds ≥ 40 dB HL at 8,000 Hz
- Grade 2: hearing thresholds ≥ 40 dB HL at 4,000 to 8,000 Hz
- Grade 3: hearing thresholds ≥ 40 dB HL at 2,000 to 8,000 Hz
- Grade 4: hearing thresholds ≥ 40 dB HL at 1,000 to 8,000 Hz

Common Terminology Criteria for Adverse Events (CTCAE) hearing loss grades

- Grade 1: threshold shift of 15 to 25 dB relative to baseline, averaged at two or more contiguous frequencies in at least one ear
- Grade 2: threshold shift of 25 to 90 dB, averaged at two contiguous frequencies in at least one ear
- Grade 3: hearing loss sufficient to indicate therapeutic intervention, including a hearing aid (e.g., > 20 dB bilateral HL in speech frequencies, > 30 dB unilateral HL, and requiring additional speech–language services)
- Grade 4: indication for cochlear implant and requiring additional speech–language services

122.7.2 Monitoring during Treatment

Monitoring should continue during treatment, with the above protocol repeated at each level of monitoring. The frequency of monitoring may depend on the individual agent given and the frequency of treatment but in general should be as follows: (1) For patients undergoing cisplatin/carboplatin treatment, monitoring should be completed just before the next dose. (2) For patients receiving aminoglycosides or other ototoxic antibiotics, testing should be completed once or twice per week throughout treatment. (3) For patients receiving cranial radiation, testing should be completed before and after treatment.

Throughout the course of treatment, patients should be clinically monitored for any signs or symptoms of ototoxicity. Testing should be repeated urgently if any symptoms of ototoxicity arise. Patients who present with possible vestibulotoxic symptoms should undergo urgent vestibular testing when feasible. The treating physician should be notified immediately of any ototoxic symptoms and objective findings. At that time, the

following should be considered when clinically an option: (1) reduction of dose; (2) change in dosing administration; (3) change to a less toxic or non-ototoxic treatment option (this option should be initiated immediately if vestibulotoxic symptoms from aminoglycoside treatment are noted).

122.7.3 Monitoring after Treatment

For all patients undergoing ototoxic therapies, monitoring should be completed for at least 1 year following treatment at the recommended intervals of 4 weeks, 3 months, 6 months, and 1 year. Patients with a documented shift in hearing will require evaluations at least yearly on a long-term basis to follow hearing loss. In addition, patients undergoing cranial irradiation should have testing every 6 months for the first few years and then yearly follow-up thereafter, even if no hearing loss is detected in the first few years.

122.8 Treatment

As previously noted, the initial and urgent intervention for ototoxicity is immediate suspension of the ototoxic agent if at all possible. Subsequent treatment is directed at the damage caused by ototoxicity.

For patients with cochleotoxicity, the long-term effects may include hearing loss and tinnitus. When hearing loss affects the speech and language spectrum, patients should be fitted with appropriate amplification, usually in the form of a hearing aid. For the rare patient with severe–profound hearing loss, cochlear implantation is very successful. Tinnitus can be managed with amplification, biofeedback, background noise, and, when needed, anxiolytics and antidepressants.

Patients with vestibulotoxicity should be initiated into a vestibular rehabilitation therapy program as soon as possible. Vestibular rehabilitation therapy can benefit many patients by improving their overall balance function and providing coping strategies for managing their loss of balance. Unfortunately, in patients with severely damaged vestibular function, long-term balance problems persist and may lead to permanent disability.

Research is ongoing to evaluate possible otoprotective measures that can be taken for patients receiving ototoxins without

compromising the efficacy of the treatment for its intended purpose. Much of this research is focusing on the role of antioxidants in preventing ototoxicity. Promising data have been obtained from both animal and human studies, but currently otoprotective treatments are used only in research protocols and are not clinically available.

122.9 Roundsmanship

- Ototoxic agents can cause permanent damage to hearing and balance function both during and following the completion of treatment, with progressive effects often lasting for several months to years after the completion of therapy.
- Patients receiving an ototoxic treatment should be screened before treatment, then monitored closely throughout the course of therapy and after the completion of treatment.
- When possible, cessation or adjustment of the ototoxic medication should be considered to limit damage to the inner ear.
- Intervention with amplification and balance therapy is necessary to rehabilitate patients with ototoxic effects.

123 Auditory Neuropathy

Helen R. Salus

123.1 Introduction

The diagnostic term auditory neuropathy is used to describe a condition affecting a variety of individuals (mainly children) who meet the following criteria: (1) Their understanding of speech (speech recognition ability) is disproportionately poorer than what would be predicted from the pure-tone thresholds on the behavioral audiogram; (2) delays in speech and language development in children often occur in association with auditory neuropathy; (3) otoacoustic emissions (OAEs) are present, at least in the initial stages of the condition; (4) auditory brainstem responses (ABRs) are often abnormal and may be absent.

123.2 Terminology

From the point of view of neurology, the term neuropathy refers to pathology that is confined to the peripheral nerve fibers without involving the neuronal cell bodies. However, the term auditory neuropathy (AN) was proposed by Rapin and Gravel to be used when the pathologic changes encompass the spiral ganglion cells, or their axons, or cranial nerve (CN) VIII as a whole. Thus, AN is neither a sensory nor a central auditory disorder. Nonetheless, because of diagnostic limitations, the precise site of the lesion cannot be established in many patients who present with auditory neuropathy-like symptoms, causing some controversy regarding the appropriate use of the term auditory neuropathy.

Cases exist in which damage initially may be confined to sites peripheral to CN VIII (e.g., the inner hair cells [IHCs]), with later progression of disease from transsynaptic degeneration then affecting the spiral ganglia cells and their axons; these later pathologic changes meet the definition of neuropathy. The degeneration may further advance rostrally through the brainstem cochlear nuclei and central auditory pathway into the cortex. Neuropathies are categorized as demyelinating, axonal, or mixed. Demyelination impairs the conduction of signals in affected nerves. Axonal neuropathy (axonopathy) is characterized by axonal loss, with dropout of the fastest-conducting fibers. Typically, muscle abnormality is greater with axonal peripheral neuropathies than with demyelinating neuropathies. However, the boundary between demyelinating neuropathy and axonal neuropathy is not always clear because histologic evidence suggests focal secondary demyelination and remyelination in some cases.

The term auditory dyssynchrony is used more liberally than the term auditory neuropathy. Auditory dyssynchrony encompasses a broader spectrum of pathologies than auditory neuropathy; it includes conditions, such as IHC loss, that represent sensory rather than neural pathology. The more recently employed term auditory neuropathy spectrum disorder (ANSND) is preferred to the term auditory dyssynchrony by some clinicians and researchers. Related terms include auditory neural synchrony disorder and auditory synaptopathy.

123.3 Incidence

AN/ANSND is a relatively rare condition with onset at any age from birth to the seventh decade of life. In the majority of cases, the reported onset is before the age of 10 years. No estimates of gender prevalence have been reported. Approximately 25% of persons with AN/ANSND have no known associated developmental or medical risks. The majority of patients who have AN, however, present with risk factors such as prematurity, hyperbilirubinemia, genetic hearing disorders, or sensory motor neuropathies.

Estimates of the incidence of AN/ANSND vary from 1 to about 10% in schools for the deaf. Estimates of the incidence range from 0.5 to 15% in persons with sensorineural hearing loss. In one hospital study, AN (based on permanent hearing loss, present cochlear microphonic [CM], abnormal or absent ABR waveforms, and present transient evoked OAEs [TEOAEs] or distortion product OAEs [DPOAEs]) was noted in 5% of 428 children in whom hearing loss was diagnosed. In another study, of 5,199 children at risk for hearing loss (based on neonatal factors or family history) who received hearing screening, 0.23% were identified with AN based on absent ABR waveforms and present CM. In another study, of 17 patients with AN, the authors estimated a high prevalence of AN in China, although they did not state any specific prevalence.

123.4 Disease Characteristics

Persons with AN/ANSND exhibit specific diagnostic and behavioral characteristics consistent with absent neural function in the presence of normal cochlear or outer hair cell (OHC) function. They may have normal hearing sensitivity or hearing loss ranging from mild to profound in magnitude. Nonetheless, persons with AN/ANSND, even those with normal hearing sensitivity, exhibit speech recognition scores that are disproportionately poor relative to the magnitude of the hearing impairment. The difficulty in the identification/recognition of speech is further exacerbated in the presence of noise.

The diagnostic hallmarks of AN/ANSND are present (at least initially) OAEs and present CM (an electrical response occurring just before the ABR), together with an abnormal or absent ABR. Thus, normal OHC function (at least initially) and faulty or dyssynchronous neural responses are the characteristics of the disorder. The findings on neuroimaging evaluations typically are normal. Although AN/ANSND can affect persons of all ages, from infancy through adulthood, in the majority of cases, AN/ANSND is diagnosed in early childhood.

The condition was first reported in the 1970s as the seemingly paradoxical finding of a discrepancy between an absent ABR and recordable hearing thresholds (albeit with some elevation in thresholds). Initially, the disorder had been inappropriately termed a central auditory dysfunction. Later, it was labeled an auditory neural synchrony disorder. The term auditory neuropathy was introduced by Starr et al. The disorder (AN/ANSND) also can be associated with vestibular pathology.

123.5 Etiology and Pathophysiology

Much remains to be understood regarding the pathophysiology and etiology of AN/ANSD. These disorders are associated with several possible sites of lesion. In some cases, the disorder may involve isolated IHC dysfunction or a synaptic dysfunction between CN VIII and the hair cells; with the latter site of lesion, the disorder category would fall under the broader umbrella of ANSD rather than AN. Damage to the nerve itself can result in AN/ANSD. A combination of these problems may occur in some cases. Although the OHCs generally are more prone to damage than the IHCs, the OHCs often seem to function normally in persons with AN/ANSD. Loss of OAEs and progressive hearing loss are more likely to be a result of axonal loss in the efferent system—axonopathy or mixed neuropathy—than a result solely of a demyelinating neuropathy.

Although AN/ANSD often is diagnosed in persons with unremarkable medical histories, certain medical conditions can be associated with the disorder. There are reports of AN/ANSD diagnosed in patients with hyperbilirubinemia, hypoxia, mumps, Guillain-Barré syndrome, Friedreich ataxia, hereditary sensory and motor neuropathy (HSMN), Charcot-Marie-Tooth disease, Refsum disease, Mohr-Tranebjaerg syndrome, or olivopontocerebellar degeneration, and in patients with HIV/AIDS.

In the majority of patients with AN/ANSD, the condition is bilateral rather than unilateral. For example, Berlin et al identified bilateral AN/ANSD in 241 (93%) of 260 pediatric and adult patients. Of the 19 unilateral cases, 13 affected the left ear and 6 affected the right ear; 10 patients were male and 9 were female.

In one study, a review of the histories of 153 pediatric patients (from birth to 18 years of age) with a diagnosis of AN/ANSD revealed unremarkable history and pregnancy only in 38%. Multiple risk factors were identified in many of the patients: history of premature birth (48%), history of bilirubinemia (48%), history of exchange transfusion (20%), anoxia (17%), history of ototoxicity (29%), and history of artificial ventilation (23%). The findings of a review of the histories of 197 patients across all ages in the same study revealed that 32 (16%) of the patients had family members with ANSD, suggesting a genetic mutation(s) as the underlying cause. A mutation in the gene for otoferlin (a protein that may have a role in neurotransmitter release at the hair cell synapse) was documented in some of these participants; 6 of the 32 patients had mitochondrial disease, 3 had a diagnosis of HSMN (possibly encompassing Charcot-Marie-Tooth disease), 3 had optic nerve atrophy, 13 had cerebral palsy, and 3 had a history of kernicterus.

Many patients in whom AN/ANSD is identified in infancy and early childhood present with a history of serious neonatal illness and have a greatly increased risk for neurodevelopmental delays. Among the symptoms reported by the parents of young patients with AN/ANSD are apraxia, ataxia, cerebral palsy, hypotonicity, seizures, feeding problems, gross and fine motor skills delays, nystagmus, strabismus, sensory integration issues, tactile defensiveness, and autistic tendencies.

123.5.1 Inner Hair Cell/Primary Afferent Damage

Possible etiologies of IHC/primary afferent damage have been hypothesized to be ototoxicity from carboplatin or deferoxamine (Desferal; Novartis, East Hanover, NJ) treatment, excessive release of glutamate from the IHCs as a result of acoustic trauma or presbycusis, chronic cochlear hypoxia secondary to in utero hypoxia, perinatal anoxia, vascular accident and hematologic hemoglobin disorder, and genetic mutations (otoferlin). Selective IHC loss was documented in the cochleas of premature infants studied in neonatal intensive care unit autopsies. The findings of normal OAEs in conjunction with a corner audiogram (showing behavioral responses only for intense low-frequency sounds) and negative magnetic resonance (MR) imaging findings with regard to CN VIII status are consistent with IHC hypofunction with anterograde loss of afferents and other synaptic connections.

123.5.2 Interruption in the Afferent-to-Efferent Loop

Interruption in the afferent-to-efferent loop is supported by the findings of absent contralateral efferent OAE suppression in persons with AN/ANSD. The afferent part of the loop refers to the myelinated afferent fibers (type I) from the IHCs to the cochlear nuclei with fiber transmission to the superior olivary complex, whereas the efferent part of the loop refers to the olivocochlear bundle, which has contralateral medial synaptic connections to the cochlear OHCs.

123.5.3 Cranial Nerve Neuropathy

The most typical example of CN VIII involvement representing AN sensu stricto would be HSMNs, including Charcot-Marie-Tooth disease, Friedreich ataxia, Refsum disease, and Mohr-Tranebjaerg syndrome (X-linked recessive disorder of mitochondrial metabolism).

123.6 Newborn Hearing Screening and Differential Diagnosis

123.6.1 Newborn Hearing Screening

Universal newborn hearing screening programs are now implemented in the majority of states in United States. The limitation of newborn hearing screening programs with regard to AN/ANSD lies in the fact that many of them employ OAE but not ABR screening procedures. The Joint Committee on Infant Hearing 2007 position statement includes auditory neuropathy/dyssynchrony in infants admitted to the neonatal intensive care unit within the definition of disorders targeted for identification via newborn hearing screening programs. Additionally, the 2007 position statement, in order to identify auditory neuropathy/dyssynchrony, mandates ABR testing for babies who spend more than 5 days in the neonatal intensive care unit. Nevertheless, a significant proportion of patients with AN/ANSD with onset

Table 123.1 Auditory pathway sites of lesion and physiologic test responses

Abbreviations: ABR, auditory brainstem response; acoustic MEMR, ipsilateral and contralateral acoustic reflex tests; AP, action potential; CM, cochlear microphonic; CN, cranial nerve; HCs, hair cells; IHCs, inner hair cells; MEMR, middle ear muscle reflex; MLD, masking level difference; OAEs, otoacoustic emissions; OHCs, outer hair cells; SGCs, spiral ganglion cells; +, recordable response; –, nonrecordable response.

Note: Table applies only to cases of severe pathology.

^aThere were no reported cases of pathology limited to the synapses between the IHC axons and the dendrites of the SGCs.

^bThere were no reported cases selectively limited to the pathology of IHCs or SGCs.

before 2 years of age have no known risks. Thus, the chances of the condition going undetected in early infancy remain high.

123.6.2 Differential Diagnosis

The diagnostic protocol for AN/ANSD involves a multidisciplinary approach with an emphasis on audiologic and medical assessment. The audiologic battery to rule out AN/ANSD should include audiometric testing, suprathreshold speech recognition assessment, acoustic immittance testing (tympanometry and acoustic reflex testing), and OAE and ABR testing. In addition, masking level difference (MLD), electrocochleography (ECoChG) for measurement of the compound action potential and CM, efferent suppression of OAEs (olivocochlear reflex) testing, and vestibular testing may be performed. Although vestibular pathology may exist in conjunction with AN/ANSD, confirmed peripheral vestibular nerve and/or vestibular nerve end-organ pathology in the absence of AN/ANSD signs cannot be accepted as indication of AN/ANSD.

The appropriateness of specific tests must be considered with reference to the maturation of the auditory mechanism and the behavioral test abilities of the specific patient. A categorization of the auditory pathway sites of lesion and expected electrophysiologic test responses (recordable versus nonrecordable) are presented in □ Table 123.1.

The OAE and ABR findings cannot differentiate between selective damage to IHCs and CN VIII damage. If a CN VIII site of lesion cannot be confirmed, then ANSD should be used as a

diagnostic term; the diagnosis of AN is acceptable if the patient is diagnosed with other peripheral neuropathies.

123.7 Audiometry and Speech Recognition Testing

Pure-tone air and bone conduction testing of individuals with AN/ANSD produces diverse audiometric configurations. The results may vary from normal hearing sensitivity to hearing impairment ranging from mild to profound. Some patients may present with rising or unusual audiometric configurations. Most cases of AN/ANSD are bilateral, although asymmetric hearing loss was reported by Berlin et al in about 23% (24 of 103) of patients with bilateral AN/ANSD. In another study, of 16 children with AN/ANSD, mild to moderate hearing loss was observed in 5, moderate to severe hearing loss in 2, severe to profound hearing loss in 7, and fluctuating hearing loss in 2. The majority of these children (63%) presented with multiple associated risk factors: hyperbilirubinemia (24%), prematurity (19%), genetic syndrome (10%), low birth weight (5%), and hydrocephalus (5%). The mean pure-tone average (based on 1,000, 2,000, and 4,000 Hz) for a group of 66 ears with AN/ANSD was 57 dB HL in another study.

The type of hearing impairment associated with AN/ANSD is sensorineural, or it is mixed if a problem (unrelated to AN/ANSD) affecting the outer and/or middle ear is superimposed on the sensorineural hearing impairment. Otitis media and other middle ear conditions may easily obscure the presence of

AN, particularly in infants and young children, who are more prone to otitis media than adults.

Discrepancies between measured behavioral thresholds and ABR results are reported in the literature.

A high proportion of individuals with AN/ANSD present with poor agreement between the pure-tone average suprathreshold speech recognition score for speech materials presented in a quiet background and the score for speech materials presented in background noise, which increases the difficulty of recognizing and identifying speech.

123.7.1 Acoustic Immittance

Because AN/ANSD is a neural pathology, the tympanometry results should be unremarkable. The high incidence of middle ear pathologies unrelated to AN/ANSD (e.g., otitis media) can make the diagnosis of AN/ANSD problematic.

The ipsilateral and contralateral acoustic reflexes were reported to be absent in persons with AN/ANSD when a low-frequency probe tone (typically 226 Hz) was used. However, inasmuch as a multitude of studies have shown absent acoustic reflexes in neonates and infants when low-frequency probe tones are used, future research needs to examine the acoustic reflex responses when middle- and high-frequency probe tones are used. Tactile middle ear muscle responses were shown to be present in patients with AN/ANSD.

123.7.2 Otoacoustic Emissions

Patients with AN/ANSD usually exhibit robust OHC activity on TEOAE tests and DPOAE tests. TEOAEs are present in ears with mild cochlear loss of up to about 30 dB HL, and DPOAEs can be present in ears with up to moderate hearing impairment. OAEs may be absent or diminish over time because of a deterioration in hearing sensitivity or as a result of a middle ear problem. However, no correlation exists between hair cell function and the magnitude of hearing loss, as the latter in AN/ANSD appears to be related to the degree of neural disease or disruption in the transmission of neural potentials in response to acoustic stimuli. Starr et al reported absent TEOAEs in 30% of 63 ears of patients with AN/ANSD; TEOAEs were absent bilaterally in 25% and were absent unilaterally in 5%. Of the 11 patients with AN/ANSD who had absent TEOAEs, 9 had previously had present TEOAEs.

In patients with absent OAEs due to middle ear pathology, the response of the cochlear hair cells can be assessed from the CM recorded by using surface electrodes with ABR instrumentation, particularly with insert earphones. In patients with AN/ANSD, as in individuals without hearing problems, the waveform is inverted, with changes in stimulus polarity (rarefaction phase vs condensation phase). The results of some studies reveal decreases in OAEs over time despite the absence of changes in the CM. Both OAEs and CMs are dominated by OHC activity. However, the tests may be differentially sensitive to various degrees of the OHC damage, or reflect different hair cell functions.

Efferent Suppression of Otoacoustic Emissions

In the phenomenon of efferent suppression of OAEs (olivocochlear reflex), amplitude reduction or phase change results from the inclusion of an additional stimulus. Efferent suppres-

sion is observed in healthy ears but is absent in patients with AN/ANSD. Berlin et al reported that the phenomenon of efferent suppression of TEOAEs when continuous contralateral broadband noise is used represents a small reduction of 2 to 3 dB over a 20-millisecond study interval but a larger reduction of 6 to 8 dB in normal individuals under microstructural analysis after stimulus cessation. The phenomenon was entirely absent in patients with probable AN/ANSD, as evidenced by hearing sensitivity close to normal limits and absent ABRs, and in patients with Charcot-Marie-Tooth disease, who had normal OAEs, substantial hearing impairment as evidenced by audiometric thresholds, absent acoustic reflexes, and absent ABRs.

123.7.3 Auditory Brainstem Response and Cochlear Microphonic

In an evaluation of patients suspected to have AN/ANSD, Teagle et al performed ABR testing by presenting high-intensity click stimuli via insert earphones, with separate recordings for condensation and rarefaction phase stimuli. The use of single-polarity stimulation facilitates identification of the CM. The CM can be differentiated from the neural response of the ABR because the CM waveform reverses with change in stimulus polarity from condensation to rarefaction phase (and vice versa), whereas the CM latency remains essentially unchanged despite increases or decreases in stimulus intensity. For each single-polarity stimulation, recordings should be obtained at two stimulus intensities that differ by 10 dB to determine whether latency changes are occurring with changes in stimulus level. To rule out stimulus artifact during recordings with single-polarity stimulation, the sound tubing of the insert phone can be disconnected or clamped and the recording repeated; disappearance of the waveform component assumed to be the CM establishes the component as being biological in nature rather than a recording artifact.

Some investigators have reported larger-amplitude and longer-duration CMs in some patients with AN/ANSD. For example, Starr et al observed significantly larger CM amplitudes in patients with AN than in normal individuals, and longer-duration CM responses (e.g., the phase-inverted CM responses peaked at about 0.4 millisecond in a normal subject and in a patient with AN but persisted to 3 milliseconds in the latter patient but to 0.7 millisecond in the former subject. The CM amplitude exceeded the age-adjusted limits, reflecting 2 standard errors of estimates for the control group in 40% of the patients with AN/ANSD.

Absent or abnormal ABR waveforms are typical in patients with AN/ANSD. Starr et al observed a present click-elicited ABR in 21% of a group of 33 patients (66 ears) with AN/ANSD; the ABRs were characterized by a low-amplitude wave V and an absent wave I. The absolute wave V latency was prolonged in 62.5% of the 16 recordings. No significant differences were observed between CM amplitude or pure-tone average (based on 1,000, 2,000 and 4,000 Hz) in patients with AN/ANSD and present ABRs versus CM amplitude or pure-tone average in patients with AN/ANSD and absent ABRs.

123.7.4 Summating Potential Recorded on Electrocochleography

The summating potential (SP) measured during ECochG (extra-tympanic recordings) with click stimuli was preserved in a

study of three adult patients with AN/ANSD. Findings on the SP were inconclusive in a study of 57 ears with AN/ANSD; the SP was absent 50% of the ears with AN and in 50% of the 27 normal, control ears.

123.7.5 Masking Level Difference

The MLD is defined as the improvement in masked threshold between dichotic and diotic (or monotic) signal presentation. MLD is absent in patients with AN/ANSD. For example, the lack of any improvement in monaural masked thresholds (monotic condition) for low-frequency tones after the addition of correlated contralateral noise (dichotic condition), as observed in six patients by Starr et al, was consistent with AN/ANSD. Absent MLD in AN/ANSD differentiates the pathology from a cochlear or conductive hearing loss, in which the MLD is present, albeit reduced in magnitude when compared with that in normal subjects. The differential diagnosis value of MLD may, however, be obscured in patients with severe or asymmetric pure-tone configurations.

123.7.6 Vestibular Tests

The presence of a disorder of the vestibular branch of CN VIII and its end organs in patients with AN/ANSD was demonstrated in three patients with symptoms of vestibular disorder whose vestibular evaluations produced abnormal caloric and damped rotation measurements. Saccades, smooth pursuit eye movements, and optokinetic nystagmus were normal.

A comprehensive medical assessment should include a thorough history, physical examination, and laboratory testing. MR imaging is recommended as part of a pediatric evaluation to visualize labyrinthine and internal auditory canal morphology, CN VIII integrity, and brain structure. In cases of stenosis of the internal auditory canals, temporal bone pathology, inner ear malformation, or cochlear luminal obstruction, high-resolution computed tomography may be recommended, as well.

123.8 Management

The management of a patient, especially a pediatric patient, with variable audiometric results and an uncertain audiologic prognosis, combined with a history of major neonatal illness and a high risk for neurologic developmental problems, may require the involvement of multiple specialties. The team may include therapeutic and educational specialists (e.g., speech–language pathologist, educational audiologist, physical therapist, educational therapist).

Systematic monitoring of the auditory status is of the utmost importance in infants and young children, especially those with findings suggestive of AN/ANSD and no other neuropathologic manifestations. The perceptual consequences of the condition may jeopardize speech and language acquisition in affected children.

The case management of patients with AN/ANSD often includes a trial of conventional types of amplification and the use of assistive listening devices, particularly to determine cochlear implant candidacy. One recent study found that of 85 patients with AN/ANSD, 61% received no benefit from hearing aid amplification, 25% received benefit restricted to hearing environmen-

tal sounds, 11% received benefit sufficient to facilitate language acquisition, and 3% received good benefit. Of the 49 patients with AN/ANSD (47 of whom were younger than 12 years of age) who received a cochlear implant, outcomes were judged to be successful in 86%, reflective of slow progress in 2%, and uncertain in 4%; outcomes could not be assessed (implantation too recent) in 8%. Of the 260 patients with AN/ANSD, 13 (5%) had mild forms of pathology that did not necessitate intervention with hearing aids or cochlear implants, although all of these patients reported difficulty communicating in noisy situations. Many of these children require enrollment in communication rehabilitation programs.

Research studies report improvements after implantation in neural responses that were absent or abnormal preoperatively. A longitudinal investigation of 39 children with AN/ANSD (78 ears) and cochlear implants (60 implanted cochleas) revealed that the children with implants who had abnormal electrical ABRs achieved substantially poorer speech recognition scores than the children with implants who had normal electrical ABRs at 1 and 2 years after implantation.

123.9 Roundsmanship

- In patients with AN, the understanding of speech (speech recognition ability) is disproportionately poorer than what would be predicted from the pure-tone thresholds on behavioral audiogram.
- Delays in speech and language development in children often are seen in association with AN.
- OAEs are present, at least in early AN/ANSD (OHC function is usually intact or minimally impaired).
 - OAEs frequently are more robust than would be predicted from the behavioral audiogram.
 - Poor OAEs in AN/ANSD are suggestive of efferent involvement (axonal neuropathy).
 - Efferent suppression of OAEs is absent.
- Hearing sensitivity is normal or sensorineural hearing loss is present, ranging from mild to profound. It may be bilateral (asymmetric or symmetric) or unilateral.
- A severely abnormal (beginning at wave I) or absent ABR and evidence of a large CM suggest that the disorder arises from a cochlear and/or CN VIII pathology (rather than a more central process).
 - The ABR deteriorates with increasing degrees of IHC and primary cochlear afferent neuronal degeneration (consistent with progressive demyelination).
- The medical history is unremarkable, or the condition is comorbid with anoxia, hypoxia, hyperbilirubinemia, a genetic disorder (HSMN, Charcot-Marie-Tooth syndrome, mitochondrial enzymatic deficit, Friedreich ataxia, olivopontocerebellar degeneration), an immune disorder (e.g., Guillain-Barré syndrome), an infection (e.g., mumps), or another condition.
- The identification of newborns at risk for AN/ANSD requires OAE and ABR screening.
- The approach to management should be multidisciplinary (otorhinolaryngology, audiology, pediatrics, neurology, speech–language pathology, physical therapy, educational therapy, and other specialties, depending on the comorbidity).

- Management should involve hearing aids and assistive listening devices, cochlear implants (some limited research findings suggest that a normal preoperative or perioperative electrical ABR is a predictor of improvement after implantation), and speech–language therapy.

124 Tinnitus

Christopher J. Linstrom

124.1 Introduction

Tinnitus, which is an unpleasant sound coming from one or both ears or from the head, is an annoying problem for both the patient and the treating physician. It is usually accompanied by neurosensory hearing loss, but not always, and is rarely found in individuals with completely normal hearing in both ears. Tinnitus is usually bothersome when the sound environment is otherwise quiet (e.g., in the early morning and late evening hours). If tinnitus interferes with sleep, sleep deprivation may be significant. There is no medical or surgical “cure” for tinnitus. Many medicines have been tried; none are universally successful. There is no uniform antidote for tinnitus.

A proper evaluation for tinnitus includes a carefully taken history to exclude likely treatable causes of hearing loss (e.g., otosclerosis), an otologic examination, a well-done audiogram, and additional diagnostic tests as indicated by the complaint and the audiogram. Unilateral hearing loss or tinnitus should be investigated in an age-appropriate fashion, such as with enhanced magnetic resonance (MR) imaging with gadolinium contrast.

The treatment for tinnitus consists of positive and negative measures, as will be described below.

124.2 Incidence of Disease

Many individuals who have been exposed to an extremely loud noise of a sudden nature (e.g., a gun blast, an explosion near the ear, a train or fire engine horn close by) or to excessively loud noise for a prolonged period (in a nightclub, at a rock concert) will experience at least a transient change in their threshold of hearing and/or a temporary noise emanating from the ear or head. This may lead to tinnitus, which is usually short-lived. As the temporary threshold shift improves, so generally does the tinnitus. Although most patients with tinnitus have no antecedent history, the most common history is one of exposure to noise, especially in industry, military service, etc. The rare patient will have a known cause of tinnitus (e.g., otosclerosis) or may have had antecedent otologic disease treated medically or surgically that can be identified as the cause of tinnitus. Medical intervention (e.g., the use of an ototoxic aminoglycoside such as streptomycin, amikacin, or gentamicin) may be the cause of tinnitus.

124.3 Terminology

Tinnitus may be classified as continuous or pulsatile, erratic, and high-, medium-, or low-pitched. Other than whether the tinnitus is pulsatile (a vascular cause until proved otherwise) or nonpulsatile, the words used to describe the tinnitus (“No, doctor, I have chirping, not ringing”) are irrelevant. What is relevant is that the sound is coming from within the ear or head, not from without.

124.4 Applied Anatomy

Most ears with tinnitus are normal in appearance and have no abnormal features. Very rarely, a wax impaction or even hair touching the tympanic membrane may cause tinnitus. Patients with otosclerosis at any stage may have tinnitus. Although retrocochlear imaging is often performed for unilateral or pulsatile tinnitus, the initial screen often images soft tissue (magnetic resonance [MR] imaging), not bone, because it is more likely that a soft-tissue abnormality will be found than a defect in bone.

124.5 The Disease Process

124.5.1 Etiology

The putative causes of tinnitus depend upon the anatomical part of the ear that is capable of causing tinnitus. The cause of tinnitus may also predict its treatment and outcome. If the patient has tinnitus accompanied by a pathologic process in the external auditory canal (e.g., wax impaction, acute otitis externa) or in the middle ear cleft (e.g., serous otitis media, acute otitis media, traumatic perforation of the tympanic membrane, glomus tympanicum), or a potentially reversible condition of the inner ear (e.g., otosclerosis, sudden idiopathic sensorineural hearing loss, Meniere syndrome), treatment of the underlying cause may relieve the tinnitus. All of these rarely cause only tinnitus. The vast majority of patients who complain of head and/or ear noise have neurosensory or mixed hearing loss in varying degrees. This is by far the most common cause of tinnitus, and any investigation should begin with an evaluation for this problem.

124.5.2 Pathogenesis

Depending upon whether the offending cause is reversible or nonreversible, and on whether exposure to the cause (loud industrial noise or music) continues, tinnitus may be unchanged, made worse, or in most cases tolerated by the brain. Indeed, once the patient has been assured that nothing serious has been discovered, such as a skull base tumor, the anxiety caused by the complaint is often markedly diminished to the point at which the patient can “live with it.” This is true of the vast majority of patients. The rare patient, often one multitasking many very stressful life events (e.g., a sick child or parent, a difficult work situation, impending possible negative outcomes, future surgery), may be at an emotional crossroad in trying to deal with the problem and may require the assistance of a psychotherapist or another professional who can aid in stress management. For the average patient, a thorough investigation and reassurance with the use of common techniques such as masking (sound substitution) will go a long way toward managing the nuisance of tinnitus.

124.5.3 Natural History and Progression

The bother of tinnitus usually remains unchanged or may actually decrease as time passes. Rarely does it worsen, and if it does, this is often the result of progression of an underlying cause (e.g., a neoplasm) or continued noise exposure.

124.5.4 Potential Disease Complications

Tinnitus per se cannot cause a serious complication, such as death. As part of an underlying problem, it is not only annoying but also may be one of several complaints that warrant further investigation. Asymmetric hearing loss with unilateral tinnitus or pulsatile tinnitus of any nature requires appropriate investigations until serious disease has been excluded. Pulsatile tinnitus should be assumed to be of a vascular nature until proven otherwise.

124.6 Disease Grading

There is no accepted grading system for tinnitus. Tinnitus is a subjective complaint, and each patient is his or her own “metric.” As previously discussed, tinnitus is classified as “pulsatile” or “nonpulsatile,” as continuous or intermittent, and by the patient’s description. One clinical quantifier is the sleep deficit. A patient who is sleep-deprived because of tinnitus is in a rather urgent state because sleep deprivation affects many aspects of a patient’s life, especially work productivity. Every effort should be made to investigate the likely causes of tinnitus in a timely fashion and to offer some type of relief that will restore refreshing sleep. Such a patient may also have sleep apnea, and the history should include questions about anything that would be depriving the patient of sleep. The patient may need to be referred to an appropriate medical professional, who will likely obtain a sleep study and may prescribe a trial of nocturnal continuous positive airway pressure (CPAP).

The judicious and conservative use of soporifics, either over-the-counter medications such as various antihistamines (diphenhydramine, chlorpheniramine maleate) or prescription medications such as zolpidem (Ambien; Sanofi-Aventis, Bridgewater, NJ) and diazepam (Valium; Genentech, South San Francisco, CA) may at least temporarily aid sleep. They are more psychologically than physically addicting and should be used with caution.

124.7 Medical Evaluation

The medical history in the patient with tinnitus is straightforward: time of onset; unilateral or bilateral; continuous, irregular, or pulsatile (always significant), etc. It is important to elicit the “sentinel event,” if any, such as significant noise exposure. This may aid in directing the patient to obtain earplugs or muffs if continued noise exposure is likely.

124.7.1 Presenting Complaints

Patients will describe what they are hearing. The important features have been mentioned. Other than pulsatile tinnitus, the

adjectival description of the sound has very little import, if any, for either diagnosis or treatment.

124.7.2 Clinical Findings, Physical Examination

After the head and neck, the ears are carefully examined, preferably under the microscope. Wax and debris should be cleaned because they may themselves rarely cause tinnitus. Most patients have a normal otoscopic examination. Tests of audition with tuning forks should be done.

The rare patient with objective tinnitus should be examined in a very quiet space, preferably an audiometric booth. All likely sources of a bruit or sound (neck, ears, mastoid areas, orbits) should be examined with a stethoscope in a quiet space.

124.7.3 Testing

The very first and key test to obtain for any patient with tinnitus is a well-done audiogram consisting of pure tones, masked bone, word discrimination, and immittance, performed separately for each ear. Self-administered audiograms may be widely erroneous and are to be condemned. A professionally performed audiogram is an absolute necessity for several reasons: (1) It establishes the level of audition separately for each ear. (2) It will graphically demonstrate any asymmetry of hearing. (3) It gives an idea of the likely frequency of the offending noise. (4) The presence or absence of the acoustic reflex and reflex decay may guide the examiner toward a more thorough retrocochlear evaluation.

The typical patient with tinnitus will have symmetric, downward-sloping hearing loss at frequencies between 1 and 6 kHz. High-tone loss is more commonly found on an audiogram than low-frequency loss. Patients with noise exposure will typically have a nadir around 4 kHz, consistent with noise exposure. Unless the patient has unilateral tinnitus, the investigation may stop at this point. Patients who have unilateral symptoms or asymmetry on the audiogram should undergo a retrocochlear investigation that is age-appropriate. If the patient is 85 years old and a retro-cochlear lesion is found, it is observed, not treated; one may choose auditory brainstem response (ABR) or stacked ABR testing, or surveillance with the audiogram repeated in 1 to 2 years. If, however, the patient is young enough that any discovered retrocochlear lesion will be treated, not just observed, then a more sensitive and specific test with greater predictive value should be obtained, ideally contrast-enhanced MR imaging or, if this is contraindicated, computed tomography (CT) of the brain with contrast focused on the cerebellopontine angles and internal auditory canals. These are more accurate by geometric proportions than ABR testing and have in large measure supplanted all other retrocochlear tests. Each method yields photographic proof of the anatomy of the retrocochlear system. However, the minimum size for identification is still in the range of 2 mm with contrast-enhanced MR imaging and larger with contrast-enhanced CT. If the patient is young enough that either stereotactic radiotherapy or surgery would be a consideration, then definitive imaging should be done and all other retrocochlear tests bypassed.

124.8 Treatment

124.8.1 Medical Treatment

1. The mainstay of medical treatment for virtually all forms of tinnitus is “masking,” better described as “sound substitution.” A sound of any nature from any source (e.g., fan, air purifier, radio, television, device that generates “white” or “pink” noise) that is less noxious to the ear than the sound emanating from the ear may be chosen to cover the offending sound. Every patient with tinnitus should understand the concept of masking and judiciously employ it. It is a technique for everyone with the problem. Many patients use masking techniques without being aware that they do so. Certainly, head or ear noise is in general less bothersome in a noisy, crowded environment than in a perfectly quiet room, such as a library. Patients intuitively understand this concept, and it should be explained and stressed. It is the cornerstone of all therapy.
2. Noise avoidance must be stressed. The ear with tinnitus will respond in a most bothersome fashion to continued noise exposure. The patient must be educated that acoustic instruments such as an unamplified orchestra or singer can rarely produce enough volume to cause noise-induced hearing loss. As long as the listener is in the body or nave of the auditorium, the cumulative volume will dissipate the intensity of the sound. (Of course, if one is sitting directly in front of the brass section of an orchestra, the effect is a bit more dangerous to hearing.) The same is not true of electrically amplified music. Many amplified bands, including bands with vocalists, will play at a decibel level almost equal to that of a jet aircraft taking off (130 to 140 dB). This level of sound is inhumanly loud; the ear is not designed to sustain such sound levels for any length of time, and significant noise-induced hearing loss can occur after even short intervals of exposure.
3. Avoiding central nervous system stimulants such as coffee, tea, and other methylxanthines may help to ameliorate tinnitus.
4. Acetylsalicylic acid (ASA), or aspirin, provokes tinnitus in a dose-related manner. For the rare patient who requires large doses of ASA to relieve joint or spine pain, reducing the dose or choosing a non-ASA medication may help tinnitus.
5. Many so-called “smart phones” such as the iPhone have associated free or modestly priced masking applications (“apps”) that can be downloaded onto the phone and transmitted through an earpiece or headphone for masking purposes.

124.8.2 Surgical Treatment

Other than the eradication of vascular tumors or the correction of an arteriovenous malformation or a venous malformation such as a venous diverticulum, there is no specific surgical treatment to eradicate tinnitus. Patients with otosclerosis and tinnitus often state that the subjective annoyance of tinnitus is relieved after successful stapedotomy or stapedectomy. However, tinnitus is never the reason for this surgery because of the inherent risk to neurosensory hearing. Restoring the conductive component of the hearing loss toward the nerve line is the only reason to perform stapedectomy and accept its potential risks,

chiefly the 0.3 to 0.5% incidence of complete deafness after primary surgery and the 1% incidence after revision surgery.

In the past, elective labyrinthectomy with the insertion of an electrical stimulating device near the round window membrane, and even cochlear implantation via the round window or cochleostomy, were attempted, all without success in eradicating tinnitus. Recently, attempts to diminish or ablate tinnitus have been made by inserting an electrode into the Heschl gyrus. However, one must weigh the risk of placing a foreign body into the brain against the potential benefit; success rates have been questionable. This technique is mentioned for the sake of completeness but is not to be recommended. There is no substitute for a thorough diagnostic plan and traditional therapy that must include masking.

124.9 Prognosis

Most patients with tinnitus are significantly relieved after a thoroughly performed series of diagnostic tests, as previously described, has been discussed with them and they are told that nothing untoward or life-threatening has been found. Normal test results are of great therapeutic benefit in cases of tinnitus. The patient will learn over time that head or ear noise is not an indication of something seriously wrong and will come to ignore it. This is the very best course of treatment—to ignore the problem. In most cases, the bother of tinnitus tends to subside with time.

Other patients cannot attend to mental tasks and need to employ some form of masking during waking hours. There are many forms which the patient may use, such as commonly found items around the home or office (e.g., fan, air freshener, radio, television, generator of “white” or “pink” noise).

124.10 Roundsmanship

- Tinnitus, an unpleasant sound emanating from the ear or the head, is a symptom, not a disease.
- The investigation of tinnitus requires an audiogram and occasionally, if the tinnitus is unilateral, a retrocochlear study (e.g., MR imaging).
- Masking is the mainstay of therapy for all patients with tinnitus.
- There is no medical or surgical antidote for tinnitus. Many over-the-counter and prescription medications exist touting relief from tinnitus. None have been proved statistically successful in carefully performed studies.
- The elimination of known offending agents, such as methylxanthines (e.g., caffeine, nicotine) and noise, may significantly help patients with tinnitus.
- Diagnostic thoroughness, masking, the rare use of medicines, and patience are the best methods of treating tinnitus.
- Most forms of nonpulsatile tinnitus improve with time. Noise exposure is extremely noxious to an ear with tinnitus.
- Truly pulsatile tinnitus is the symptom of a vascular lesion until proved otherwise.
- A rare patient may have objective pulsatile tinnitus, heard by the examiner as well as the patient. An appropriately designed vascular study (CT with contrast, MR angiography, MR venography, four-vessel angiography) must be done to obtain

a definitive diagnosis in these rare cases. Treatment of the underlying lesion may ameliorate the pulsatile tinnitus.

125 Retrocochlear Hearing Disorders

Robert Hong and Seilesh C. Babu

125.1 Introduction

An estimated 10% of individuals worldwide are afflicted with hearing loss. In the vast majority of cases, sensorineural hearing loss is cochlear in origin, often secondary to exposure to loud noise, aging, and/or genetics. However, in an important minority of cases, the lesions responsible for sensorineural hearing loss are retrocochlear—located medial to the cochlea in the auditory pathway. Retrocochlear lesions are considered to involve the auditory nerve. A lesion more central to the auditory nerve that involves the central nervous system, although technically also located medial to the cochlea, is for categorization purposes considered to be a central as opposed to a retrocochlear cause of hearing loss.

In considering the types of lesions that can lead to retrocochlear hearing loss, it is helpful to understand the anatomy of the auditory nerve. The auditory nerve is the part of the vestibulocochlear nerve (eighth cranial nerve) that is responsible for hearing. It exits the cochlea to run within the internal auditory canal (IAC), leaving the IAC at the porus acusticus to enter the cerebellopontine angle (CPA) before entering the brainstem to project to the cochlear nuclei of the medulla. Lesions of the auditory nerve can occur via compression of the nerve by tumors (or less commonly, adjacent blood vessels) within the IAC or CPA. The nerve can also be compressed via growth of the surrounding bone of the IAC, as is seen in proliferative bony disorders. Alternatively, retrocochlear hearing loss can be due to lesions that originate within the auditory nerve. Physiologic dysfunction of the nerve may occur, as in auditory dyssynchrony. The nerve may degenerate with age, as in neural presbycusis. The nerve may be missing, as in agenesis of the auditory nerve. Finally, the integrity of the nerve may be affected by a neurologic disorder that similarly affects other parts of the central nervous system, such as multiple sclerosis.

125.2 The Disease Process

125.2.1 Tumors of the Internal Auditory Canal and Cerebellopontine Angle

One of the most important reasons why otolaryngologists are asked to assess a patient with newly diagnosed sensorineural hearing loss is to evaluate the likelihood that a tumor may be causing the hearing deficit. The most common tumor found in the IAC/CPA is a vestibular schwannoma (acoustic neuroma), which is a benign tumor that may originate from either the superior or inferior branch of the vestibular nerve. This is typically a slow-growing tumor, with an average growth rate of 1 to 2 mm per year. As the tumor grows, it compresses and/or stretches the adjacent cochlear nerve, causing a retrocochlear hearing loss. Alternatively, a growing tumor may occlude the blood supply to the cochlear nerve, such as by compressing the internal auditory artery within the IAC, also leading to hearing loss. As the tumor grows further, it expands within the CPA,

compressing other, nearby cranial nerves and causing potentially life-threatening brainstem compression.

Other, less common tumors involving the IAC/CPA may also lead to retrocochlear hearing loss via similar mechanisms. The second most common tumor of the IAC/CPA is a meningioma, which is a benign tumor arising from the arachnoid villi. Neuromas originating from the other nerves within the IAC can also lead to hearing loss, including facial neuromas (facial nerve) and cochlear schwannomas (cochlear nerve). Other rare tumors that can arise in this region include lipomas, hemangiomas, and metastatic tumors (such as from breast, prostate, or lung cancer).

125.2.2 Neural Presbycusis

The progressive loss of sensorineural hearing associated with old age is termed presbycusis. Patients older than 55 years of age can be expected to lose hearing at an average rate of 9 dB per decade as a result of age-related degeneration of different structures within the auditory pathway. These structures include those found within the cochlea, such as the hair cells (sensory presbycusis), basilar membrane (mechanical presbycusis), and stria vascularis (metabolic presbycusis), as well as those found behind the cochlea, such as the first-order neurons of the auditory nerve (neural presbycusis). In neural presbycusis, which is the only type of presbycusis that leads to a retrocochlear hearing loss, the classic audiometric pattern is speech recognition scores that are lower than expected based on pure-tone audiometry in combination with a slowly down-sloping high-frequency sensorineural hearing loss.

125.2.3 Auditory Dyssynchrony

Auditory dyssynchrony (also known as auditory neuropathy) has become better known since the use of objective measures to assess hearing, particularly otoacoustic emissions (OAEs) and auditory brainstem response (ABR) testing, has become widespread as part of newborn hearing screening programs. Auditory dyssynchrony is defined by an abnormal ABR (reflecting auditory nerve dysfunction) in the context of normal OAEs (reflecting normal outer hair cell function within the cochlea) in a patient without other retrocochlear pathology (such as a tumor of the IAC/CPA). The exact site of the lesion responsible for auditory dyssynchrony is unknown and may vary from patient to patient; lesions of the inner hair cells of the cochlea, auditory nerve, or intervening neural synapse between the cochlea and auditory nerve may all fit this definition. Two groups of patients with auditory dyssynchrony have been described. The predominant group includes infants in whom the condition is found during the course of neonatal hearing screening. It has been estimated that auditory neuropathy is responsible for approximately 7% of cases of permanent hearing loss in children. Although the cause is often unknown, correlations between neonatal insults (especially hyperbilirubinemia and hypoxia)

and auditory dyssynchrony have been found. The second group includes young adults, typically patients with multiple neuropathies. For example, neurologic disorders such as Charcot-Marie-Tooth syndrome and Friedreich ataxia may lead to degeneration of the auditory nerve with auditory dyssynchrony.

125.2.4 Temporal Bone Osseous Dysplasias

Rare disorders of the temporal bone involving abnormal bone remodeling may be associated with retrocochlear hearing loss. The mechanism by which hearing loss occurs is abnormal osseous growth around the internal auditory canal, causing stenosis of the IAC and compression of the auditory nerve. Osseous dysplasias do not exclusively cause retrocochlear hearing loss—for example, bony proliferation can also narrow the external auditory canal, resulting in a conductive hearing loss. Of these disorders, the ones most likely to lead to IAC stenosis are the osteopetroses (marble bone disease), a group of hereditary diseases characterized by immature, dense bone secondary to abnormal remodeling, in which a characteristic “chalky” sclerosis of bone is evident on computed tomography (CT). Two other bony dysplasias may also on rare occasions cause IAC stenosis and retrocochlear hearing loss. The first is fibrous dysplasia, in which normal bone is replaced by weak, immature fibro-osseous tissue that has a classic “ground glass” appearance on CT. The second is Paget disease, in which haphazard osteoclastic and osteoblastic activity leads to abnormal bone deposition and the appearance of multiple translucencies on CT, reflective of demineralized bone.

125.2.5 Other Disorders

A number of other etiologies of retrocochlear hearing loss have been described. Congenital absence of the auditory nerve is an important cause to consider in infants born with profound sensorineural hearing loss because it is a contraindication to cochlear implantation. Radiographic imaging demonstrating a narrow IAC (<3 mm in diameter) or magnetic resonance (MR) imaging demonstrating the absence of signal corresponding to the auditory nerve is consistent with this diagnosis. However, such radiographic findings do not guarantee the absence of functional auditory nerve fibers because children with apparent cochlear nerve aplasia on imaging have undergone implantation and demonstrated responses to auditory stimuli.

Disorders of the central nervous system can affect the auditory nerve and result in retrocochlear hearing loss. In patients with multiple sclerosis, demyelination of the auditory nerve can lead to hearing loss. Neurosyphilis is another disorder that can result in lesions of the auditory nerve and hearing loss. However, hearing loss as the sole presenting symptom is unusual in these disorders; patients often have lesions that affect multiple parts of the central nervous system and are not specific to the auditory nerve.

Another potential cause of retrocochlear hearing loss is compression of the auditory nerve by adjacent blood vessels. Vascular loops from nearby branches of the posterior or anterior inferior cerebellar artery have been implicated. However, such a diagnosis is controversial because many patients without hearing loss may also have blood vessels that appear on MR images to be touching the auditory nerve.

125.3 Medical Evaluation

125.3.1 History and Physical Examination

It is important to take a thorough history in the evaluation of a patient with hearing loss. The character of the hearing loss should be probed. A sudden or asymmetric sensorineural hearing loss, or the presence of unilateral nonpulsatile tinnitus, often prompts additional work-up for a retrocochlear etiology. All patients should be questioned about the presence of associated ear symptoms, including tinnitus, otorrhea, otalgia, and vertigo. Patients should also be asked about any history of exposure to loud noise, ear surgery, hearing aid use, and hearing loss in the family. When children are evaluated, it is important to ask the parents if the child passed a newborn hearing screen, to help determine if the hearing loss is congenital or acquired. The child’s birth history and development should also be assessed for clues about the etiology and severity of the hearing loss.

The physical examination of the head and neck will often be normal in a patient with retrocochlear hearing loss. Otoloscopic examination is useful in evaluating for other (nonretrocochlear) causes of hearing loss, such as a middle ear effusion or tympanic membrane perforation. The results of the Weber and Rinne tuning fork tests will be consistent with a sensorineural hearing loss. Occasionally, patients with a retrocochlear hearing loss may have other cranial nerve deficits, such as those associated with a large cerebellopontine angle tumor.

125.3.2 Audiometric Evaluation

All patients who have hearing loss should be evaluated with an audiogram at their initial visit. The audiometric evaluation is helpful in determining if additional work-up for a retrocochlear hearing loss is indicated. The finding of sensorineural hearing loss on pure-tone audiometry is consistent with both cochlear and retrocochlear etiologies. The following additional audiometric findings increase the clinician’s suspicion of a retrocochlear loss, often prompting further testing.

Asymmetry of Hearing Loss.

Concern for a retrocochlear lesion (in particular a tumor of the IAC/CPA on the affected side) occurs when a patient demonstrates a significant asymmetry in sensorineural hearing loss. The exact criteria for significant asymmetry are controversial. Obholzer et al suggested the criteria of asymmetry of more than 15 dB at two adjacent pure-tone frequencies for unilateral hearing loss, and asymmetry of more than 20 dB at two adjacent frequencies for bilateral hearing loss. This yielded a sensitivity of 97% and a specificity of 49% when further testing with MR imaging was ordered to evaluate for an IAC/CPA tumor.

Poor Speech Discrimination Out of Proportion to Degree of Hearing Loss

Individuals with cochlear sensorineural hearing loss typically do not experience a significant degradation of their ability to understand speech until they have a hearing loss of at least

60 dB HL. In contrast, a patient with a retrocochlear loss may exhibit poor speech discrimination despite relatively good pure-tone thresholds. It has been shown that 75% of the auditory nerve fibers can be damaged before a decrease in pure-tone thresholds is seen, whereas good speech discrimination requires the preservation of the majority of such fibers. Thus, an IAC/CPA tumor that compresses the auditory nerve will result in an earlier deterioration of speech discrimination than of pure-tone thresholds.

Rollover

Rollover is a classic finding consistent with retrocochlear pathology, in which as the intensity of speech is increased, it becomes more difficult for patients to understand the speech. The theory is that in patients with a retrocochlear lesion, fatigue of the auditory nerve increases as sound intensity increases, making speech perception more difficult.

Decruitment

Decruitment is another classic finding in patients with retrocochlear pathology, in which as the intensity of a sound is increased, its perceived loudness increases at an abnormally slow rate. Some patients may even perceive a decrease in loudness as sound intensity increases. This is again related to an increased susceptibility to auditory nerve fatigue with a retrocochlear lesion. Decruitment, however, is not routinely assessed in an audiometric evaluation.

Abnormal Acoustic Reflexes

Acoustic reflex testing has also traditionally been used to determine the likelihood of a retrocochlear lesion by assessing contraction of the stapedius muscle in response to loud sounds. This reflex is thought to be important in protecting the ear from acoustic trauma. Two measurements have been correlated with retrocochlear lesions. The first is an abnormally elevated (if not absent) acoustic reflex threshold, in which a sound stimulus needs to be presented at an abnormally high intensity to trigger the reflex. The second is an abnormally fast acoustic reflex decay, in which the stapedius muscle is unable to sustain contraction during the presentation of a continuous loud sound. In both cases, these findings reflect increased fatigue of the auditory nerve, induced by a retrocochlear lesion, in response to high-intensity sound stimuli. However, although more than 75% of patients with a vestibular schwannoma will demonstrate abnormal acoustic reflexes, this test is no longer routinely used to rule out a retrocochlear lesion because of its high false-negative rate.

125.3.3 Further Work-up

If a patient is suspected of having a retrocochlear hearing loss, additional work-up is warranted. Some have suggested using ABR testing as the most cost-effective next step in the screening process, though this is controversial. ABR testing involves the measurement of auditory evoked potentials. Electrodes are placed on the patient's head to measure changes of electrical activity in response to the presentation of a sound stimulus.

Fig. 125.1 Standard auditory brainstem response (ABR) of a patient with a left acoustic neuroma. The right ear demonstrates normal ABR waveforms. The left ear demonstrates prolonged absolute latencies for waves I, III, and V, consistent with the patient's diagnosis of an acoustic neuroma.

The measured activity occurs in a wavelike pattern, as the stimulus is transmitted in a peripheral to central direction through the auditory system: from the auditory nerve (waves I and II) to the cochlear nucleus (wave III) to the superior olivary complex (wave IV) to the lateral lemniscus (wave V) to the inferior colliculus (waves VI and VII). The presence of a retrocochlear lesion is suspected when the appearance of the expected waves of the ABR is delayed, either in a relative sense (the affected ear is compared with the opposite normal ear, or early waves are compared with later waves in the same ear) or in an absolute sense (□ Fig. 125.1). A poor ABR waveform on the affected side is also consistent with a retrocochlear lesion. However, the use of ABR testing is limited for a number of reasons. First, it is not useful in patients with a severe (>70 dB HL) hearing loss because the ABR waveform will be abnormal strictly because of the severity of hearing loss. Second, ABR testing is good for detecting larger tumors but may miss smaller ones (<1 cm), with a reported sensitivity above 95% for tumors larger than 1 cm and a sensitivity of 79% for those smaller 1 cm. Thus, patients with a normal ABR can be relatively but not absolutely confident that they do not have an acoustic neuroma.

Recently, the use of stacked ABR testing to screen for acoustic neuromas has become more popular. In stacked ABR testing, masking noise of different frequencies is used in conjunction with the traditional auditory click stimulus to derive measured waveforms reflecting neural activity across the entire auditory spectrum. This is in contrast to the standard click-evoked ABR, in which the measured waveform is dominated by the response of high-frequency auditory nerve fibers. As a result, the stacked ABR test is more sensitive for detecting small acoustic tumors because a tumor affecting only low-frequency auditory nerve fibers would result in a normal standard ABR but an abnormal stacked ABR. Stacked ABR testing has been reported to have a sensitivity of 95% and a specificity of 88% for detecting small (≤ 1 cm) acoustic tumors. Patients with an abnormal ABR require additional MR imaging to evaluate for a retrocochlear lesion.

Fig. 125.2 Magnetic resonance image (T1 with gadolinium) demonstrating a small (0.5 cm) acoustic neuroma located in the left internal auditory canal. The neuroma enhances with contrast (asterisk).

The gold standard to evaluate for a retrocochlear lesion is MR imaging with gadolinium contrast, and many clinicians will bypass ABR testing in favor of MR imaging to obtain a definitive diagnosis more quickly. MR imaging can detect IAC/CPA tumors as small as a few millimeters in diameter, with these tumors demonstrating characteristic enhancement after the administration of contrast (□ Fig. 125.2). However, some patients cannot undergo MR imaging—for example, because of the presence of metal in the body (e.g., cardiac pacemakers, shrapnel, hemostatic clips in the brain). If these patients need to be evaluated for a retrocochlear lesion, CT with intravenous contrast and/or ABR testing should be used. If CT is used, patients should be aware that it may miss tumors smaller than 1.5 cm.

125.3.4 Auditory Dyssynchrony versus Neural Presbycusis versus Central Auditory Processing Disorder

Some adults may complain of difficulty hearing, particularly in noisy environments, but have relatively normal pure-tone thresholds and speech discrimination scores (in quiet) on audiometric evaluation. The need for additional work-up from this point is controversial. Some clinicians will attribute these patients' complaints to neural presbycusis, particularly if they are older. Others will obtain OAE and ABR testing to evaluate for auditory dyssynchrony. (It should be noted, however, that the absence of OAEs does not rule out auditory dyssynchrony in adults, as many adults with normal hearing lose their OAEs with age.) Yet others will obtain testing to evaluate for a central auditory processing disorder (CAPD). CAPD is a controversial diagnosis in which difficulty hearing in the context of normal peripheral auditory function is attributed to problems with auditory processing by the central nervous system. No consensus criteria exist for the diagnosis of CAPD, although most

testing involves an evaluation with sensitized speech (in which speech is distorted in some manner to reduce intelligibility, such as with the addition of background noise). If CAPD is diagnosed, auditory rehabilitation is prescribed, although the effectiveness of such therapy is inconclusive.

125.4 Treatment

125.4.1 Retrocochlear Hearing Loss

Treatments with respect to hearing are similar for retrocochlear and cochlear hearing loss. Hearing amplification is useful for mild to moderate hearing loss, with a decrease in utility noted as the severity of hearing loss increases. Patients who have retrocochlear loss may find hearing aids relatively less helpful than those who have cochlear loss because amplification often makes speech sounds louder but not more understandable. Patients with bilateral severe to profound sensorineural hearing loss may be candidates for cochlear implantation, as long as the integrity of the cochlear nerve has not been compromised (e.g., by a tumor of the IAC).

125.4.2 Tumors of the Internal Auditory Canal and Cerebellopontine Angle

The treatment of tumors of the IAC and CPA is discussed in detail elsewhere in this book. Briefly, the options fall into three categories: observation, surgery, and stereotactic radiosurgery. Observation is typically reserved for older individuals with small tumors. If surgery is selected, the decision must be made either to sacrifice hearing (via a translabyrinthine approach) or to attempt to preserve hearing (via a middle cranial fossa or retrosigmoid approach). Stereotactic radiosurgery is another option for preserving hearing, although long-term outcomes have yet to be determined.

125.4.3 Auditory Dyssynchrony

Infants who are evaluated for hearing loss often have failed objective testing, typically OAE and/or ABR testing. The combination of normal OAE and abnormal ABR test results is consistent with auditory dyssynchrony. Infants with auditory dyssynchrony are typically followed until behavioral audiometric thresholds can be obtained, so that the degree of hearing loss can be determined. Patients with auditory dyssynchrony may have anywhere from a mild to profound sensorineural hearing loss. The initial treatment for auditory dyssynchrony is hearing amplification. Some children may derive a significant benefit from hearing aids. (In contrast, few adults with auditory dyssynchrony benefit; they report that hearing aids make speech louder but not more understandable.) Additional measures, such as preferential seating in classrooms and the use of FM systems, may be useful. Speech and language therapy should also be considered for all children with auditory dyssynchrony because both are often impaired as a consequence of the hearing impediment. Finally, cochlear implantation should be considered for children who continue to struggle with hearing despite amplification. Such a decision should be undertaken carefully because cases of spontaneous resolution of auditory

dyssynchrony before 1 year of age have been reported. Additionally, although cochlear implantation is widely accepted for treating auditory dyssynchrony when it is associated with a severe to profound sensorineural hearing loss, its role in treating milder degrees of associated hearing loss requires further study.

125.5 Roundsmanship

- A retrocochlear etiology should be considered for all patients with sensorineural hearing loss. Initial clinical suspicion is heightened when patients demonstrate asymmetric sensorineural hearing loss, asymmetric nonpulsatile tinnitus, speech perception worse than expected based on pure-tone audiometry, or auditory fatigue.
- The gold standard for the evaluation of retrocochlear hearing loss is MR imaging of the internal auditory canal with gadolinium. Other tests that may have clinical value in selected cases include ABR testing and CT.
- Auditory neuropathy is a retrocochlear disorder most commonly diagnosed in young children with normal OAEs and abnormal ABRs. The mainstays of therapy include hearing amplification and speech–language therapy. Cochlear implanta-

tion is reserved for those who do not demonstrate significant improvement with these measures.

126 Middle Ear Implants

George Alexiades

126.1 Introduction

Conductive hearing loss is one of the most common indications for middle ear surgery. A conductive hearing loss results when sound is not effectively transmitted through the ossicular chain to the inner ear. It may occur in many situations, such as cerumen impaction, otitis externa, tympanic membrane perforation, middle ear effusion, and ossicular erosion and/or fixation. Conductive hearing loss is commonly found in patients with cholesteatoma, chronic otitis media, and otosclerosis and is a frequent result of otologic surgery. This chapter will concentrate on the prostheses used when continuity of the ossicular chain is disrupted. Numerous techniques and materials are used for ossiculoplasty. Many of the materials that were in vogue years ago have been replaced by lighter, more biocompatible materials.

126.2 Incidence of Disease

It is unclear what the incidence of conductive hearing loss is because it is associated with many causative disease processes. Chronic suppurative otitis media, with or without cholesteatoma, and otosclerosis are the most common situations that result in ossicular problems. Other causes of conductive hearing loss include temporal bone trauma, osteogenesis imperfecta, and various genetic syndromes.

126.3 Terminology

Traditional ossicular chain reconstructions are classified according to the Wullstein classification on a scale of I through V. A type I tympanoplasty consists of a primary tympanic membrane repair (myringoplasty) with an intact ossicular chain. In a type II tympanoplasty, the tympanic membrane is grafted to the incus. The tympanic membrane is grafted directly to the stapes suprastructure in a type III tympanoplasty. In a type IV tympanoplasty, the tympanic membrane is grafted onto a mobile stapes footplate. A type V tympanoplasty has also been described and consists of grafting the tympanic membrane to the oval window or a lateral semicircular canal fenestration.

Middle ear implants are classified according to the point of origin from which the prosthesis spans the ossicular gap. The two major classes are partial ossicular reconstruction prosthesis (PORP) and total ossicular reconstruction prosthesis (TORP). A PORP is used when the incus is eroded but the stapes suprastructure is intact. A TORP is required when the incus and the stapes suprastructure are eroded but an intact, mobile stapes footplate remains. In situations in which there is a fixed stapes footplate, stapes prostheses, in a variety of shapes and materials, may be used. The two most common stapes prosthesis shapes are the wire-piston and the bucket handle. These typically span from the long process of the incus to a stapedotomy in the footplate or, in the case of a stapedectomy, to a vein or perichondrial graft placed over the oval window. In patients with erosion of the long process of the incus, a longer prosthe-

sis can be used to span the gap from the manubrium of the malleus to the stapedotomy/stapedectomy site.

126.4 Materials

Before the 1970s, autologous ossicular remnants, cartilage, or bone, as well as homografts, were used for ossicular chain reconstructions. The most common ossicular reconstruction in which the patient's own tissue is used is the incus interposition. In this instance, the long process of the incus is usually eroded by disease, resulting in ossicular discontinuity. The incus is removed and remodeled to fit on top of the stapes suprastructure and underneath the manubrium of the malleus, thus restoring continuity of the ossicular chain. In situations in which the incus is unavailable, multiple materials have been used over the years, ranging from gold, stainless steel, polytetrafluoroethylene (Teflon; DuPont, Wilmington, DE), fluoroplastic, and bio-glass to hydroxyapatite, ionomeric cement, and titanium. Titanium has become the material of choice for PORPs and TORPs because it is biocompatible, lightweight, and strong. □ Fig. 126.1 shows a typical titanium PORP in use today. The head of the prosthesis is wide and sits underneath the tympanic membrane, while the bottom of the prosthesis attaches to the stapes suprastructure. The shaft is usually adjustable in length. □ Fig. 126.2 shows a typical TORP, which has a similar head, but the shaft is longer and lies on the stapes footplate. In addition to being used as a material for prostheses, ionomeric cement has been used to fuse the incus remnant to the stapes suprastructure in cases of erosion of the long or lenticular process of the incus. Stapes prostheses are still made from a variety of materials: stainless steel, platinum, titanium, and fluoroplastic, or from combinations thereof (□ Fig. 126.3).

126.5 Results

The rates of successful hearing depend on the type of prosthesis used. Stapedectomies have the highest success rate; closure of the air-bone gap to within 10 dB is achieved in approximately 90% of cases. When PORPs are used, closure to within 20 dB

Fig. 126.1 Partial ossicular reconstruction prosthesis (PORP).

Fig. 126.2 Total ossicular reconstruction prosthesis (TORP).

occurs about 70 to 80% of the time, which is considered acceptable. TORPs fare even worse, with closure of the air–bone gap to within 20 dB achieved in only 50 to 60% of cases. The results of incus interposition grafts are comparable to those of PORPs. Comparisons of the various materials in use for ossiculoplasty yield varying results; however, the trend suggests that titanium is the material of choice today.

Hearing results after ossicular chain reconstruction ultimately depend upon the status of the mucosa and aeration of the middle ear cleft. Hearing results in situations of eustachian tube dysfunction will be poorer than those in cases of good middle ear aeration. In addition to the formation of a serous effusion, retraction of the tympanic membrane negatively impacts surgical success. Continued negative middle ear pressure is believed to be a significant risk factor for prosthesis extrusion and/or displacement.

126.6 Complications

The most common complication of ossicular reconstruction is persistent conductive hearing loss. The variables described earlier all affect the success of ossiculoplasty and do not depend merely upon choice of prosthesis material or proper sizing. Prosthesis migration and/or extrusion is another frequent complication of ossiculoplasty. It is currently recommended that a cartilage graft be laid between the head of the prosthesis and the tympanic membrane to act as a thin biological barrier and reduce extrusion rates. Rates of extrusion for currently available prostheses are in the range of 5 to 10% for PORPs and TORPs. As would be expected, the rates of extrusion increase over time. Stapes prostheses are generally more stable, and prosthesis displacement and/or erosion of the long process of the incus

Fig. 126.3 Wire–piston stapes prosthesis.

resulting in ossicular discontinuity is uncommon (3 to 5%). Chorda tympani nerve stretch injury or transection occurs in approximately 15% of patients undergoing tympanoplasty and results in either temporarily or permanently altered taste; stretch injuries are more symptomatic than nerve transections in these cases. Facial nerve injury is also exceedingly rare in ossiculoplasty without concomitant mastoidectomy and occurs in fewer than 1% of cases. Permanent sensorineural hearing loss is quite rare with the use of PORPs and TORPs; however, the incidence of sensorineural hearing loss is 0.5% in primary stapedectomy and 1% in revision stapedectomy.

126.7 Roundsmanship

- Although currently available ossicular reconstruction prostheses are made of a number of materials, titanium has become the material of choice because of its light weight and strength, and the ease with which the length of the prosthesis can be adjusted.
- Ossiculoplasty results in successful hearing in about 90% of patients with stapedectomies, 60 to 70% of those with PORPs, and 50 to 60% of those with TORPs.
- The status of the middle ear is critical in successful ossiculoplasty.

127 Otosclerosis and Stapedectomy

Seilesh C. Babu

127.1 Introduction

Otosclerosis is a disease that affects the otic capsule of the temporal bone, resulting in conductive, mixed, or rarely a sensorineural hearing loss. Causes of otosclerosis can remain elusive and have been known to include endocrine, metabolic, traumatic, and autoimmune disorders. Otosclerosis may also be hereditary.

127.2 History

Hearing restoration for otosclerosis via a fenestration procedure was described in 1938 by Lempert. Rosen and Shea furthered the work of their mentor by performing stapes mobilizations and stapedectomies. In 1956, Shea first performed a stapedectomy for otosclerosis. In 1969, Schuknecht and Applebaum introduced the technique of stapedotomy, in which the stapes superstructure is resected but the footplate is preserved. The adaptation of the laser to microsurgery has been a more recent innovation that has made stapes surgery more accurate and less risky.

127.3 Clinical Findings

The hearing loss associated with otosclerosis is typically conductive and presents in middle adult life. Occasionally, it may present earlier or may represent congenital stapes fixation. The treatment is similar for both presentations, but the risk for complete hearing loss needs to be discussed with family members when hearing loss presents early in a child and surgery is contemplated. A positive family history is found in approximately 50% of patients. In some patients, a mixed hearing loss and a gradual worsening of the sensorineural component develop as a result of cochlear involvement with otosclerosis. The degree of eventual sensorineural involvement is unpredictable. Otosclerosis is estimated to be unilateral in approximately 15% of cases. Tinnitus may be associated with otosclerosis and varies in intensity and character.

Audiometry reveals a low-frequency conductive hearing loss initially, which usually progresses to a larger air–bone gap as the degree of fixation increases at the footplate of the stapes. In other audiometric testing, impedance plethysmography often is normal or can show reduced tympanic membrane compliance. The stapedial reflexes classically are abnormal; however, they may be within normal limits depending on the degree of stapes fixation.

127.3.1 Carhart Notch

An apparent loss in bone conduction, first described by Carhart in 1950, occurs at around 2,000 Hz on audiometry in patients with otosclerosis. This is secondary to loss of the contribution of the middle ear to bone conduction. Upon vibration of the mastoid bone, the ossicular chain vibrates slightly out of phase, causing a movement of the stapes footplate relative to the coch-

lea. In otosclerosis, this does not occur. Carhart found that otosclerosis reduces bone conduction thresholds by 5 dB at 500 Hz, 10 dB at 1,000 Hz, 25 dB at 2,000 Hz, and 15 dB at 4,000 Hz.

127.4 Differential Diagnosis

The diagnosis of otosclerosis is based on the clinical and audiometric findings. Progressive conductive hearing loss, a normal otoscopic examination with an intact and mobile tympanic membrane, no evidence of eustachian tube dysfunction, a negative Rinne test result, and an absent stapedial reflex are typical findings in otosclerosis. Other processes should be considered in patients with conductive hearing loss. Ossicular discontinuity, middle ear effusion or disease, tympanosclerosis, Paget disease, osteogenesis imperfecta, and degenerative arthritis may all cause conductive deafness. In addition, causes of ossicular fixation should be considered, including lateral ossicular fixation and incus–anulus fusion. Another consideration is superior semicircular canal dehiscence. The stapedial reflex can help differentiate this condition from otosclerosis because the reflex should be intact in superior semicircular canal dehiscence; however, variable presentations of the reflex can occur depending on the degree of stapes fixation present. VEMP (vestibular evoked myogenic potential) testing and computed tomography (CT) of the temporal bone may be used to rule out superior semicircular canal dehiscence.

127.5 Management of Otosclerosis

127.5.1 Amplification

Patients may use hearing aids as an alternative to surgery. These carry little risk but will obviously not prevent further progression of the otosclerotic process. The disadvantage of the use of hearing aids for a long period is that it may reduce the success rate and may increase the complication rate of surgery years later as the otosclerosis progresses. If the patient has a significant mixed hearing loss before surgery, he or she may require a hearing aid after stapes surgery. However, the patient may require a less powerful, more effective hearing aid with better sound quality.

127.5.2 Medical Management

The value of medical therapy for otosclerosis is controversial. Medical therapy may be considered for patients with a predominantly sensorineural hearing loss.

Shambaugh first predicted that otosclerotic lesions could be stabilized with the use of sodium fluoride. This agent is thought to slow or halt the progression of otosclerotic hearing loss by neutralizing and inactivating the hydrolytic and proteolytic enzymes of otospongiotic lesions. Sodium fluoride promotes the maturation of active otospongiosis by reducing its vascularity

and bone resorption activity and by increasing new bone formation, eventually inactivating otosclerosis.

Over-the-counter preparations of sodium fluoride include Monocal and Florical (Mericon Industries, Peoria, IL). Monocal is absorbed in the intestine rather than in the stomach and may cause fewer side effects. Recommended doses vary, typically two tablets per day to minimize side effects, which include stomach upset, allergic itching, and increased joint pain. Fluorosis, the most severe side effect in the treatment of osteoporosis, has not been noted with lower doses of fluoride therapy. Women of childbearing age should be informed that fluoride medication can be teratogenic during the first 6 weeks of fetal development.

127.5.3 Surgical Management

Stapedectomy is typically considered for patients with an air-bone gap of at least 15 dB, reversal of Rinne testing with a 512-Hz tuning fork, speech discrimination scores of 60% or better, and no contraindication to surgery. The ear with the worse hearing should be addressed first. Early procedures entailed removal of the entire stapes footplate and the placement of grafted tissue over the oval window, followed by the piston. With newer technology, such as the microdrill and laser, stapedotomy (opening into the vestibule) has become a more common technique because it results in less trauma and better hearing.

Stapedectomy Prostheses

Many different prostheses of various materials have been developed for stapedectomy. Some of the designs that have proved most effective and are still in use today include the McGee piston and the Robinson bucket handle prostheses. The implantation of metallic prostheses must be carefully considered because of potential issues with magnetic resonance imaging compatibility. Appropriate nonferromagnetic metals, such as platinum, titanium, and stainless steel, may be used safely. Numerous types of prostheses are available and have been successfully used in stapes surgery. Surgeon preference usually leads to the selection of a safe and effective prosthesis.

Lasers in Stapedotomy

Several different types of lasers have been adapted for stapedotomy. Lasers allow vaporization of the stapes footplate with minimal vibratory effect. This technology also causes minimal thermal injury to the perilymph. Complex revision stapes surgery that traditionally was associated with high risk and low success rates is now performed much more effectively with laser.

Several types of lasers are available for otologic surgery, including argon, potassium titanyl phosphate (KTP), and carbon dioxide (CO₂) lasers. Argon and KTP lasers have similar wavelengths and properties. The wavelength of an argon laser is 488 nm, whereas the KTP laser wavelength is 532 nm. The visible wavelengths of these two lasers provide excellent target accuracy because the aiming beam and the surgical beam are the same. Both fiber-optic handheld probes and micromanipulators can be used with these lasers. Argon and KTP laser radiation is

poorly absorbed in bone and perilymph, so that potential risk to the saccule and utricle is increased during use.

The wavelength of the invisible CO₂ laser is 10,600 nm. CO₂ lasers are absorbed in bone and perilymph, an ideal characteristic that allows stapedotomy to be performed safely. Studies have shown that use of the CO₂ laser in the open vestibule causes a rise in the perilymph temperature of only 0.3°C. One of the advantages of the CO₂ laser for stapedotomy, the high rate of absorption in the perilymph, results in a low penetration depth of only 0.01 mm.

Because the CO₂ laser beam is invisible, a second aiming beam (helium–neon [HeNe], 612 nm) is required, and the calibration of these two lasers must be ensured. Until recently, CO₂ laser was available for use only with a micromanipulator. Fiber-optic delivery of the CO₂ laser has now been introduced, allowing the benefit of handheld manipulation.

Stapedotomy Procedure

The procedure may be performed with intravenous sedation or general anesthesia. Antibiotics and often steroids are given preoperatively.

After sterile preparation and draping, local anesthetic is infiltrated into the ear canal and postauricular region. This should be done slowly and deliberately, and blanching of the ear canal skin should be observed to ensure adequate anesthesia and hemostasis.

A small piece of subcutaneous fascia or fat is harvested from a postauricular incision and saved for later use.

The speculum should then be secured in the speculum holder. The largest speculum that can comfortably fit into the ear canal should be used for the greatest exposure.

A 6- to 8-mm tympanomeatal flap is created. The chorda tympani nerve is preserved and the middle ear entered. Adequate exposure is attained by using a microdrill and/or curet on the osseous annulus (□ Fig. 127.1) until the stapedial tendon and inferior portion of the tympanic facial nerve are well seen. Malleus and incus mobility are ensured, and stapes fixation is confirmed by manual palpation.

The incudostapedial joint is lasered before it is separated with a joint knife (□ Fig. 127.2). To allow better stability of the stapes superstructure, the stapes tendon is lasered after the joint has been separated (□ Fig. 127.3). The posterior crus of the stapes is then lasered (□ Fig. 127.4) as close to the footplate as possible to prevent the stump of the crus from later interfering with placement of the piston. If the anterior crus is visible, it can also be lasered. The superstructure is then briskly down-fractured away from the facial nerve and removed (□ Fig. 127.5).

Small fenestra laser stapedotomy can be performed via a rosette technique wherein multiple laser applications (□ Fig. 127.6) with the 0.2-mm spot size are used to gradually create a 0.7-mm fenestra (□ Fig. 127.7). Although the CO₂ wavelength will minimize the risk to the inner ear, care must still be taken not to allow the laser to pass through adjacent, previously created holes in order to prevent injury to the inner ear, especially if perilymph has leaked out to cause a dry fenestra. Absence of the perilymph takes away the natural protection of the vestibular end-organs. Those surgeons who choose to use visible spectrum lasers (KTP or argon) instead of the invisible

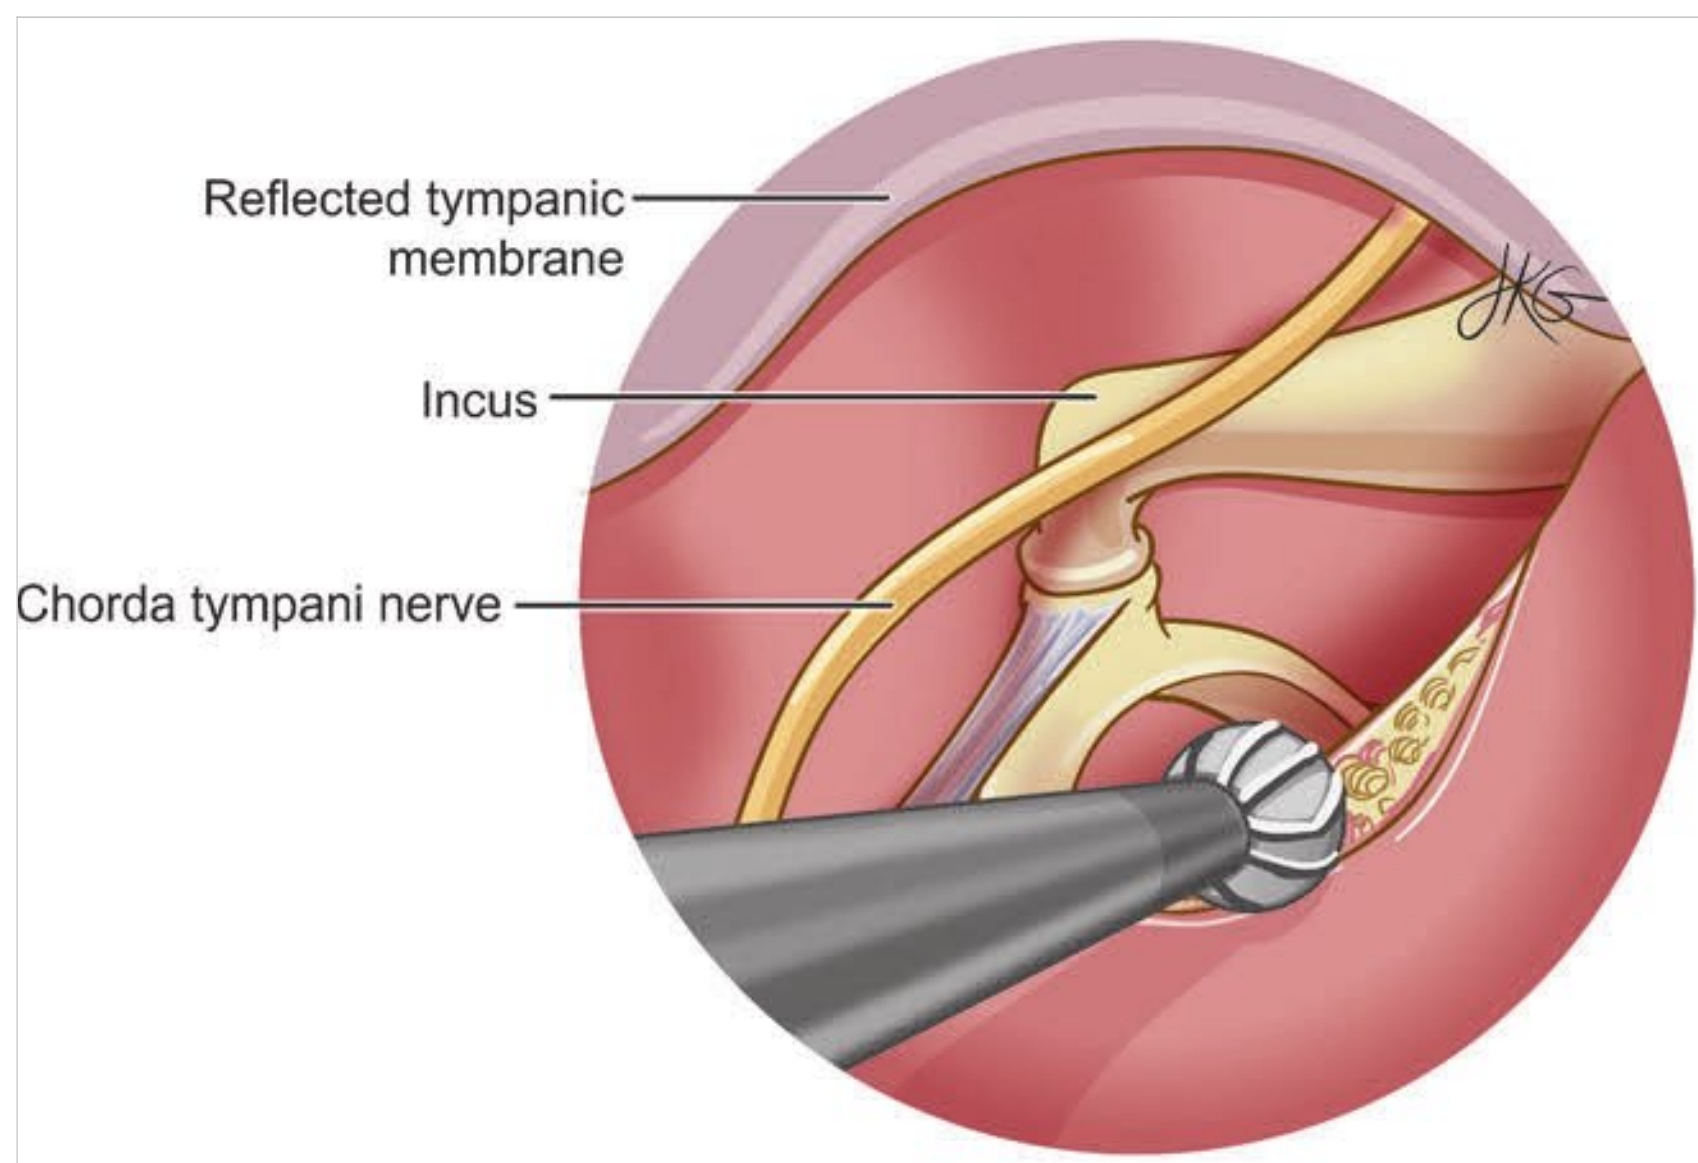

Fig. 127.1 Adequate exposure of the stapes footplate often necessitates removal of some of the osseous annulus.

Fig. 127.2 Separation of the incudostapedial joint with a joint knife.

wavelength CO₂ laser must take even greater care because visible lasers can pass through perilymph, potentially causing injury to the inner ear.

Measurements may be taken from the incus to the stapes footplate opening. Typically, the stapes prosthesis measures 4.25 mm in length and 0.5 mm in diameter. These dimensions seem to be appropriate for 90 to 95% of patients undergoing surgery. The stapes piston is then inserted into the fenestra with a small alligator forceps.

Once its position is confirmed, the piston is crimped onto the incus (□ Fig. 127.8), and then its position at both the incus and the footplate is confirmed under high-power magnification. The previously harvested fascia is cut into 3 mm pieces, which are moistened and packed around the piston at the fenestra. A

critical maneuver before closure is to move the malleus and look for movement of both the incus and piston. The tympanomeatal flap is then replaced. A whisper test confirms improved hearing, and several pieces of saline-soaked Gelfoam (Pfizer, New York, NY) are placed over the tympanomeatal flap and tympanic membrane. An antibiotic ointment that is not ototoxic, such as bacitracin, is then instilled in the external auditory canal. Most patients may be discharged the same day if they live within an hour or two of the hospital.

Intraoperative Issues

Anatomical variants may be found at the time of middle ear exploration done for possible stapes surgery. When these are encountered, erring on the side of patient safety is of critical importance. If a low-hanging facial nerve contacting the stapes or a persistent stapedia artery is identified, the surgeon will not be faulted for aborting the procedure.

Narrow Oval Window Fenestra

A difficult scenario in stapes surgery is dealing with a narrow oval window niche. This limits the surgeon's ability to create an appropriately sized fenestra and makes it difficult to know if the fenestra created may in fact be too narrow, which will restrict movement of the piston. A narrow niche can often be markedly improved by using the laser to vaporize approximately 1 mm of promontory bone just below the stapes. This improves visibility and allows accurate placement of the piston.

Incus Erosion/Subluxation

Erosion of the incus is a common finding at revision stapedectomy. In dealing with incus erosion, the surgeon must assess whether reconstruction is possible with the remaining incus or whether reconstruction to the malleus or drum is necessary. In certain modification techniques, bone cement may be used to rebuild the incus and anchor the prosthesis. Alternative prostheses, such as the Big Easy offset piston and the Lippy-

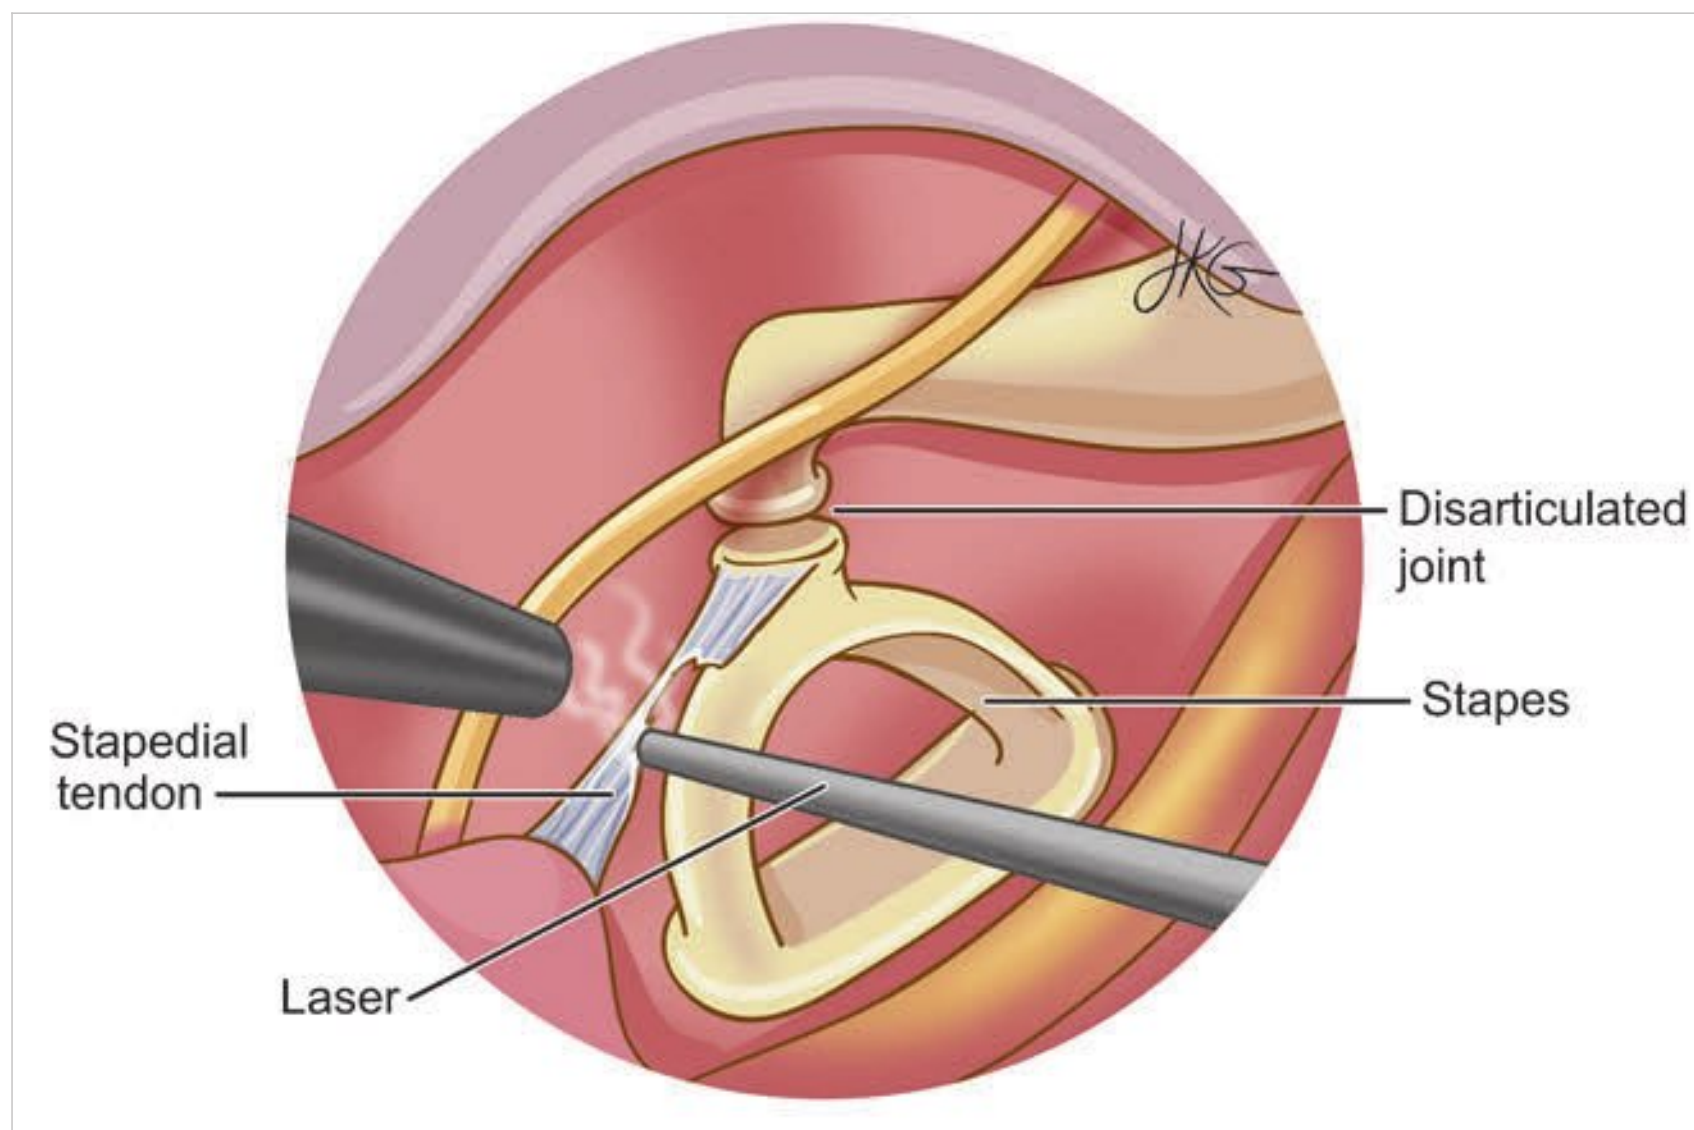

Fig. 127.3 The stapedial tendon is lysed with laser.

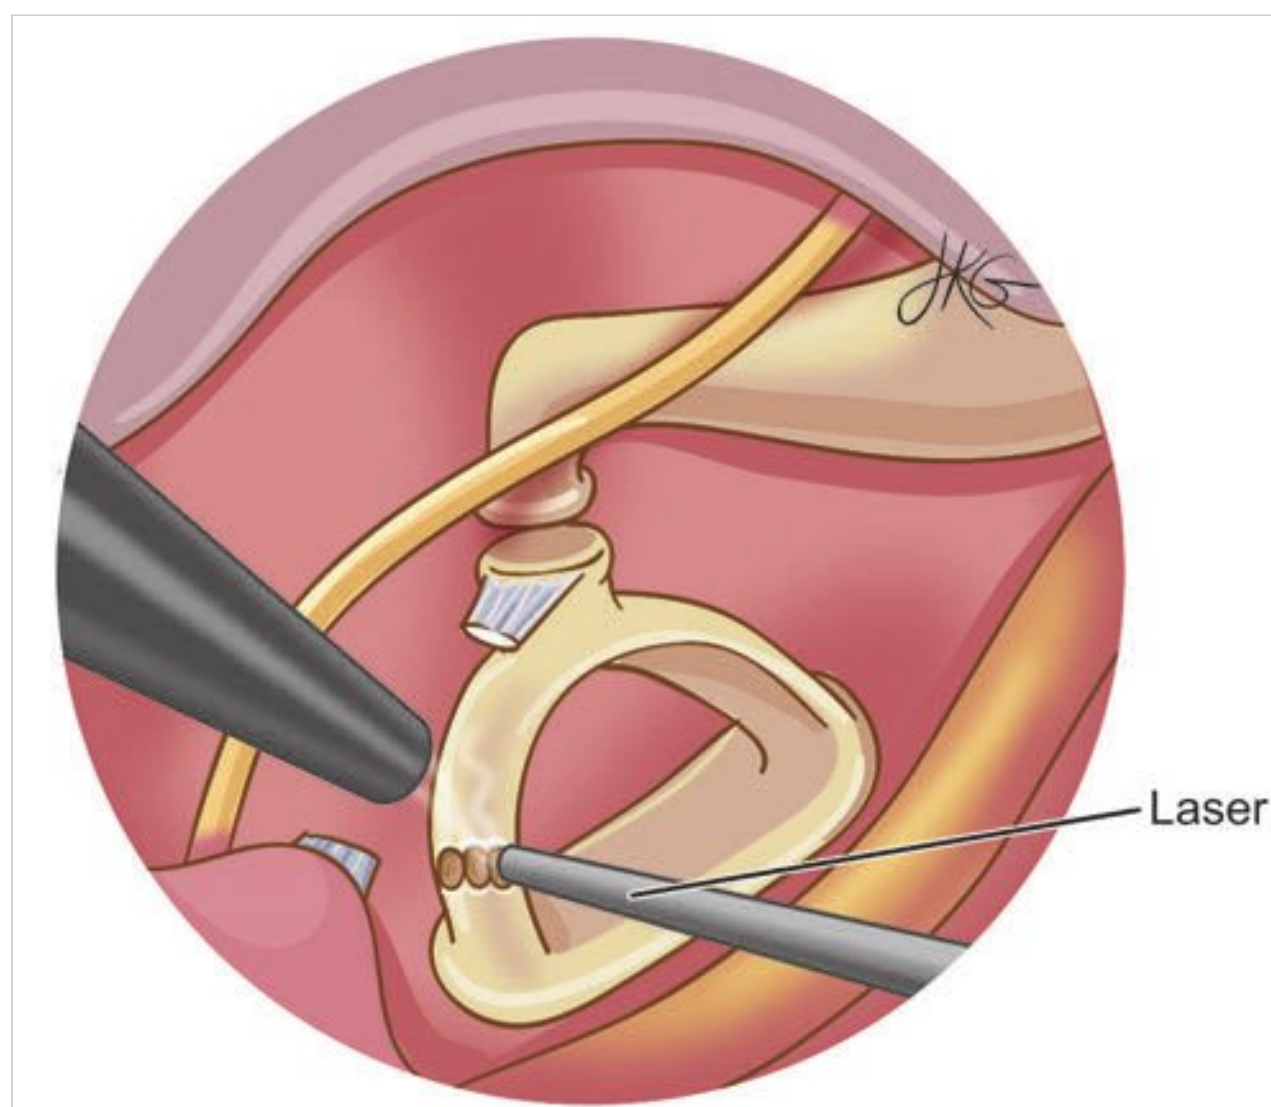

Fig. 127.4 The posterior crus of the stapes is lasered.

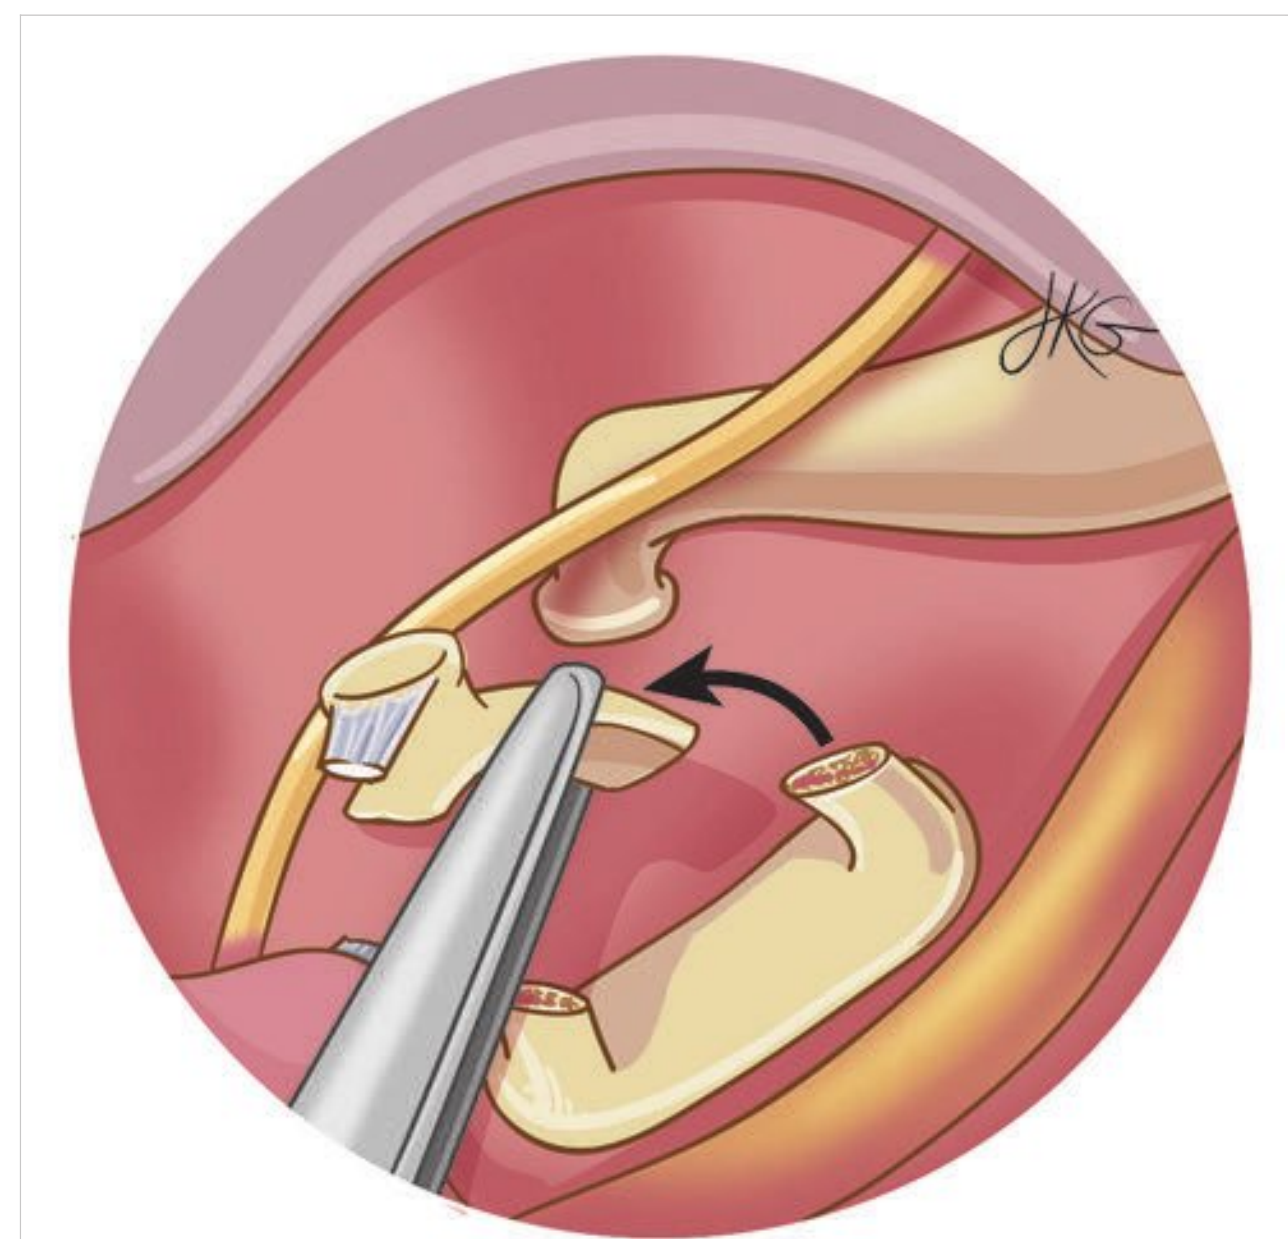

Fig. 127.5 The remaining stapes superstructure is down-fractured and removed.

modified Robinson prostheses, may also be effective if the incus erosion is mild to moderate. If incus erosion is severe, a malleus-to-oval window prosthesis may be used and the procedure performed by an experienced surgeon.

Postoperative Complications

In the postoperative patient with significant dizziness, tinnitus, and/or hearing loss, one must consider the most likely differential diagnosis. Etiologies include serous labyrinthitis, perilymphatic fistula, a deep piston, and reparative granuloma. Patients should be monitored closely; the timing and severity of symptoms as well as the physical examination findings are key factors in determining the likely cause and treatment.

Serous Labyrinthitis

The most common cause of postoperative inner ear symptoms after routine stapedotomy is thought to be “serous labyrinthitis,” which occurs during routine “successful” stapes surgery. This complication may be associated with individual variations in inner ear sensitivity. Most patients appear to benefit from a short course of oral steroids. If rapid improvement is not noted, the packing should be removed (even at an early stage postoperatively), the ear examined, and the hearing assessed. Reparative granuloma, perilymph fistula, and a deep or long piston should be excluded.

Fig. 127.6 A rosette pattern is lasered on the stapes footplate.

Fig. 127.7 Creating a small stapedotomy.

Oval Window Fistula

Oval window fistula was relatively common in the past when Gelfoam and blood were used in the fenestra instead of tissue seals. Oval window fistula after stapedectomy may occur in the early postoperative period or years later. Fluctuating or progressive hearing loss is noted, as well as tinnitus with or without vertigo. Trauma or a change in barometric pressure may precede the symptoms. The clinical examination may include fistula testing, typically performed simply with digital pressure or pneumotoscopy to elicit dizziness. Audiometric findings include sensorineural hearing loss, although hearing loss is not always present on the audiogram. The diagnosis is rarely seen when a tissue seal of fascia or vein has been used. Middle ear exploration and grafting of the oval window with tissue is indicated if a fistula is thought to be present.

Deep Piston/Prosthesis

The incidence of deep insertion of the piston within the vestibule is low in experienced hands. Most commonly, this complication occurs when the length of the chosen piston is more than the standard length of 4.25 mm. The diagnosis is strongly considered when either a longer prosthesis was used or the patient experienced dizziness intraoperatively during placement of the piston through the fenestra. As in patients with perilymph fistula, digital pressure or pneumotoscopy often elicits dizziness; however, the onset of symptoms is usually immediately after surgery, whereas fistulas may occur quite late. CT after stapedectomy has not been shown to be reliable in determining the depth of piston insertion within the vestibule. Thus, imaging after stapedectomy has limited value in identifying a piston that is too deep within the vestibule.

Other etiologies of vertigo should be considered, including benign paroxysmal positional vertigo (BPPV), a depressed footplate fragment, or reparative granuloma. BPPV in the postoperative period may be secondary to surgical injury to the utricle or due to the free flow of particles from the fenestra. This

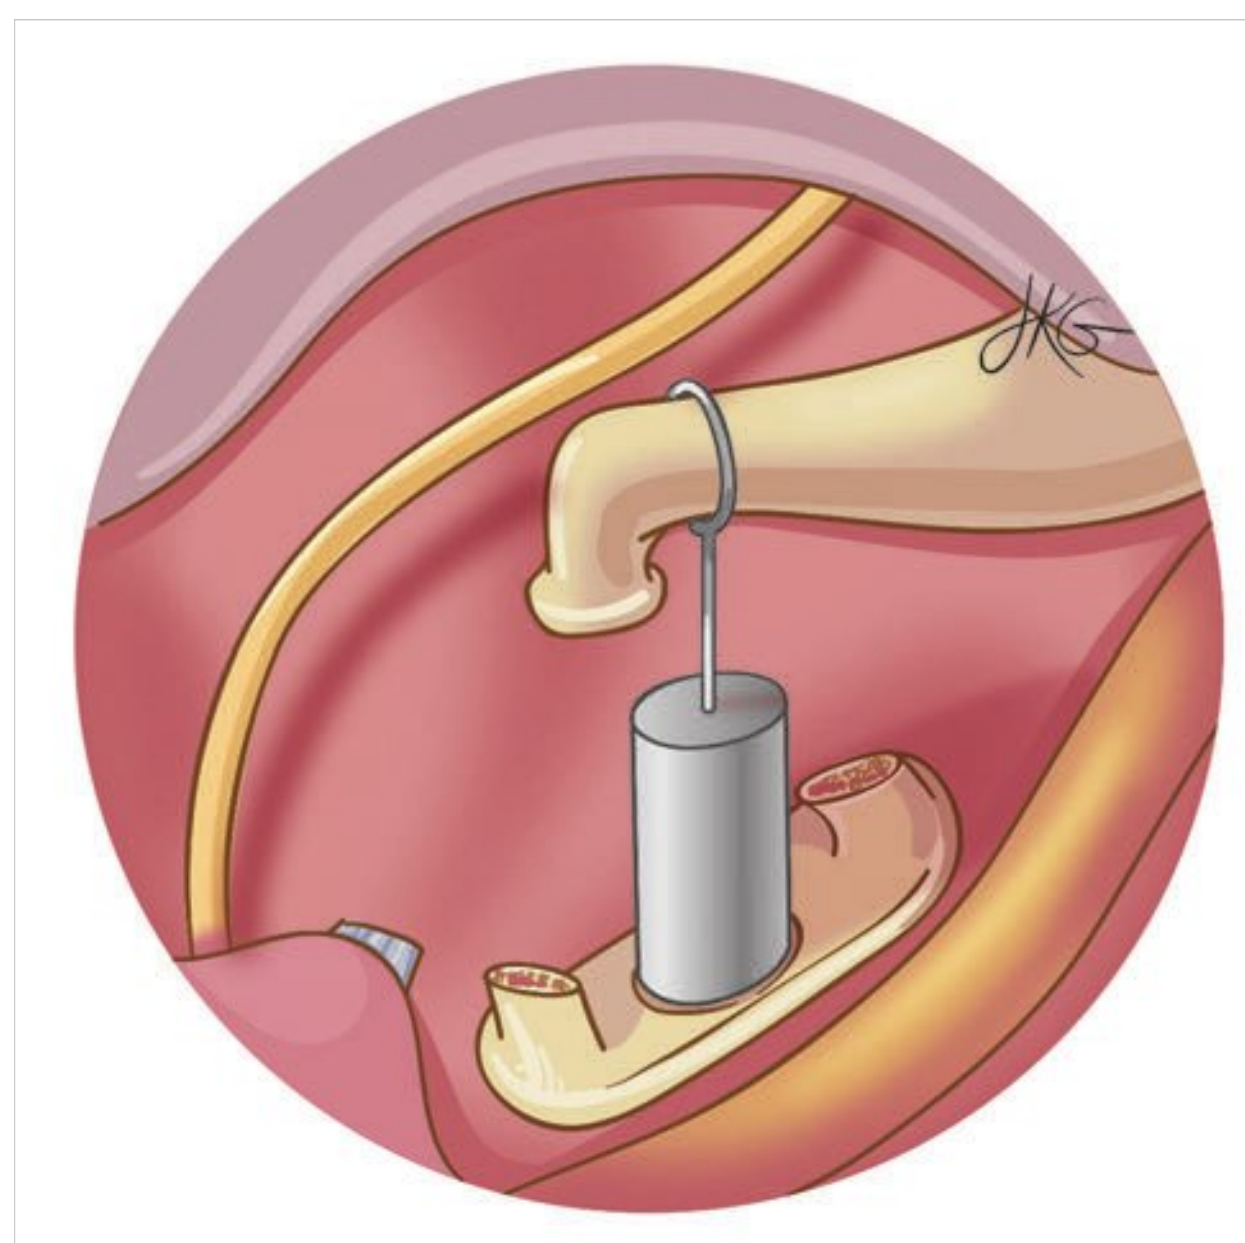

Fig. 127.8 Stapes prosthesis in place in stapedotomy and crimped on the long process of the incus.

condition is typically self-limiting, and patients often benefit from canalith repositioning maneuvers.

Reparative Granuloma

The hallmark of reparative granuloma is progressive sensorineural hearing loss after earlier postoperative hearing improvement. This may be associated with vertigo, aural fullness, or tinnitus. Often, the audiogram reveals a mixed hearing loss that is most severe in the high frequencies. If this diagnosis is considered, the packing in the external auditory canal should

be removed and the ear examined. The tympanic membrane typically appears thickened, and bright red tissue is visualized along the tympanomeatal flap and lenticular process of the incus.

The cause of this rare complication is currently unknown. Surgical exploration should be considered if it is suspected. Significant granulation tissue around the oval window and prosthesis is noted on exploration. Multinucleated giant cells are noted histologically, signifying foreign body reaction. The granuloma should be lasered away, the prosthesis removed, and a tissue seal placed over the oval window. Another prosthesis is usually not placed, and depending on the hearing level, revision surgery in 6 months may be considered. Alternatively, a hearing aid or bone-anchored hearing aid may be considered.

Persistent Postoperative Conductive Hearing Loss

In the case that the postoperative audiogram shows no improvement in hearing, one must consider malleus fixation, a fenestra that is too tight, piston displacement, or superior canal dehiscence. After superior canal dehiscence is ruled out, the patient may be reexplored. If malleus head fixation is found, mobilization may be considered, which is ideally done after the incudostapedial joint (or piston) has been separated to minimize labyrinthine trauma. Refixation of the malleus after mobilization, though, is not uncommon. Thus, alternatively, an atticotomy may be performed to remove the malleus head and incus, with subsequent ossicular reconstruction performed between the malleus and oval window.

Postoperative Otitis Media

Acute otitis media in the postoperative period is a rare complication. This is especially concerning because bacteria may enter the labyrinth and can rarely lead to meningitis. Antibiotic therapy should be instituted, myringotomy considered, and the patient's condition monitored closely.

Results of Stapes Surgery

Approximately 90% of patients undergoing primary stapes surgery have a conductive deficit of 10 dB or less when measured 6 to 12 months after stapedectomy. In these studies, about 5% of patients have an unsatisfactory result, with an estimated average air–bone gap of 15 dB or higher. The air–bone gap closure typically remains stable through time. A long-term sensorineural hearing loss affecting the high frequencies may occur with time and may be a consequence of presbycusis or cochlear otosclerosis.

The experience of the surgeon is clearly a predictor of stapes surgery outcomes. Experienced surgeons in one study more accurately placed the stapes prosthesis and caused less cochlear trauma than novice surgeons. The number of resident stapedectomies performed in training programs over the past several decades has declined significantly, and more recent graduates have become increasingly reluctant to perform stapes surgery. Consequently, although an otologic fellowship is not a prerequisite for performing stapes surgery, otolaryngologists should

honestly evaluate their training, experience, and microsurgical skills before opting to perform stapes surgery.

127.6 Summary

Otosclerosis is a common cause of conductive hearing loss for which surgical treatment is highly successful, with a low incidence of complications in experienced hands. The nonsurgical treatment of otosclerosis includes fluoride therapy and amplification. Laser stapedotomy is the definitive treatment for hearing restoration.

Generous exposure of the middle ear, the use of laser technology, and compulsive attention to detail before, during, and after stapedectomy are critical elements to achieve optimal results and minimize complications.

127.7 Roundsmanship

- Otosclerosis typically presents with conductive or mixed (rarely sensorineural) hearing loss.
- A Carhart notch occurs because stapedial vibration at the round window at around 2,000 Hz on bone conduction testing is diminished in a patient with stapes fixation, resulting in a factitious finding of sensorineural hearing loss.
- Sodium fluoride reduces vascularity and bone-resorptive activity, thereby inactivating foci of otospongiosis.
- Although all patients should be measured to determine the appropriate length of a stapes prosthesis, most are treated appropriately with a length of 4.25 mm.
- Palpation of the malleus to observe piston motion should always be performed to ensure an intact sound-conducting mechanism.
- Common causes of postoperative vertigo include a long prosthesis, benign paroxysmal positional vertigo, a depressed footplate fragment, and reparative granuloma.

128 Baha and Other Osseointegrated Temporal Bone Implants

Katrina R. Stidham

128.1 Introduction

The bone-anchored hearing aid or Baha is an osseointegrated temporal bone implant that conducts sound through the skull and directly into the inner ear. It has been shown to be effective in treating patients with conductive hearing loss, mixed hearing loss, or unilateral profound hearing loss.

128.2 Terminology

128.2.1 Baha

Baha is a patented technology owned by Cochlear (Cochlear Baha Products and Services, Mölnlycke, Sweden). In the past, BAHA was an acronym for bone-anchored hearing aid, but the company has dropped use of the acronym and instead prefers to describe the technology as an osseointegrated temporal bone implant under the product line of Baha.

128.2.2 Osseointegration

Osseointegration is the active process of bone growing into or assimilating an implanted material. Osseointegration provides very strong fixation for a prosthesis, which essentially becomes an integrated part of the bone.

128.2.3 Osseointegrated Hearing Aid

The term osseointegrated hearing aid is used to describe the Baha and any other hearing aids that are fixed by osseointegration.

128.2.4 Single-Sided Deafness

The term single-sided deafness (SSD) is used to describe a situation in which an individual has profound hearing loss in one ear with very poor discrimination that cannot be improved with conventional hearing aid technology.

128.3 Applied Anatomy

Sound normally passes in waveforms into the ear canal and to the eardrum. The sound waves cause the eardrum to vibrate, and the vibration drives movement of the ossicular chain. The ossicular chain, in turn, transmits the vibratory nature of the sound waves to the cochlea, where the acoustic signal is translated into an electrical signal, and the cochlear nerve transmits the information to the brain.

The cochlea is encased in bone that is contiguous with the skull. It has long been known that when a sound wave is applied directly to the skull, the skull can conduct the wave effectively to the inner ear. In this way, the normal passage of sound through air, which requires a functioning eardrum and ossicular

chain, is effectively bypassed. This phenomenon is known as bone conduction. It can be demonstrated by pressing a vibrating tuning fork to the skull. Bone conduction of sound is regularly used in audiometric testing to distinguish between conductive and sensorineural hearing loss. In situations of conductive hearing loss, in which there is a problem with sound conduction from the environment to the inner ear, bone conduction thresholds are normal, whereas air conduction thresholds are elevated.

128.4 Function and Components of Osseointegrated Hearing Aids

128.4.1 History of the Baha and Other Osseointegrated Hearing Aids

The concept of osseointegrated hearing aids began with research in the 1950s related to dental implants. At that time, Per Ingvar Brånemark discovered that titanium could be accepted as part of living bone. He described this process as osseointegration and began research on creating titanium dental implants. In 1977, Professor Brånemark and a colleague in otolaryngology, Anders Tjellström, suggested that bone-anchored implants could be used to help patients with conductive hearing loss who could not benefit from traditional amplification.

Before that time, patients with conductive hearing loss were treated with transcutaneous bone conduction hearing aids. Traditional bone conduction devices consist of a hearing aid that is placed on a metal headband on one side of the head and a transducer that presses against the skull on the opposite side of the head. The hearing aid picks up the sound and transfers it via a cable to the transducer, which in turn conducts sound through the skull to the inner ear. Unfortunately, bone conduction aids have several inherent problems. First, the soft tissue between the transducer and the skin attenuates the sound, reducing sensitivity and causing distortion. Second, because of the pressure needed to transmit the sound, the devices are very uncomfortable and have to be repositioned frequently. Third, with the need to wear a metal band across the head, cosmesis is a significant concern. Because of these combined problems, the overall compliance rate with traditional bone conduction hearing aids is low. However, for patients with atresia and severe stenosis, this type of hearing aid was previously the only option available for sound amplification.

The first Baha was placed in Sweden in 1977, and over the next several years, many technologic advances were implemented to improve the functionality of the device. The obstacle of combining the transducer and hearing aid in the same unit was overcome by elastically suspending the hearing aid below the transducer. The second problem was to create a coupling system that would allow the hearing aid to easily be coupled to and decoupled from the abutment while a high level of

mechanical impedance was maintained. The coupling system also had to have a low profile and withstand debris from hair, sweat, and hair products. A unique flexing male-to-female coupling system was designed that, with a few modifications, is still in use today.

The Baha was first approved by the FDA in 1996 for use in adults with mixed and conductive hearing loss. It was subsequently approved for implantation in children 5 years of age and older in 1999, and was approved for bilateral fittings in 2002.

In the early 2000s, research was carried out to evaluate the functionality and benefit of the Baha in patients with unilateral profound hearing loss, also known as Single-Sided Deafness or SSD. These were patients, usually with a sudden severe shift in hearing, experiencing significant functional difficulties. Before the Baha, the only option for a patient with SSD was either no intervention or a CROS hearing aid. The CROS (contralateral routing of sound) hearing aid consists of a device with a microphone worn in the ear with poor hearing and an amplifier worn in the ear with good hearing. Sound is picked up on the side of the deficit and transmitted to the good ear. Because the Baha transmits sound through the entire skull, it essentially functions in the same way as the CROS device, and the patient does not have to wear an amplifier in the opposite ear. Initial research was positive, and the FDA approved the Baha for use in patients with SSD in 2002.

Recent developments have focused on improving the internal technology of the hearing aid. The initial devices were based on analogue technology. Recent generations of Baha devices are based on digital technology and have improved qualities, including automatic directional microphone, microphone position compensation, automatic noise reduction, and active feedback cancellation. All of these advances are designed to improve the functionality of the devices.

The Baha has also been modified for use in young children. An elastic headband, referred to as the softband, was approved by the FDA in 2002. It allows the device to be worn much more comfortably than it can with the conventional metal headband. The softband is indicated for children too young to undergo surgical placement of a titanium implant.

In 2009, Oticon Medical (Somerset, NJ) released a competing osseointegrated hearing aid that mimics Baha technology. It is marketed under the name Ponto and has many of the same features as the Baha. In June 2011, Sophono (Boulder, CO) released an implant with a magnetic attachment that does not have a percutaneous abutment. Cochlear has also recently developed a magnetic attachment for the Baha as well.

128.4.2 Components of the Baha

The Baha basically consists of three parts: the titanium implant, the abutment, and the external processor (□ Fig. 128.1). The titanium implant and abutment are usually packaged and placed at surgery as a combined unit, but they can be separated if there is a need to change to a longer abutment. The external processor is coupled to the abutment via a unique flexing male component on the external processor that attaches to a fixed female component on the abutment. The external processor houses the transducer and the digital hearing aid.

Fig. 128.1 Baha components include the titanium implant inset into bone; the abutment, which serves to link the external processor to the implant; and the external processor.

128.4.3 How the Baha Works

The external processor, through its coupling to the abutment (and ultimately the titanium implant), transmits sound directly through the skull.

In patients with a conductive hearing loss, the device bypasses the problematic natural amplifiers of the eardrum and middle ear bones and conducts sound waves directly to the inner ear. The device can be programmed to provide hearing thresholds within a normal range when the device is worn.

In patients with SSD, the device transmits sound through the skull to the opposite inner ear. The microphone picks up sounds on the side with poor hearing that would otherwise be missed. For persons with SSD, the Baha is particularly useful in environments with background noise or competing noise.

128.4.4 Indications and Testing for Use of the Baha

There are basically two categories of patients who are potential Baha candidates: those with conductive or mixed hearing loss and those with SSD.

Common diagnoses in patients with conductive hearing loss who are potential Baha candidates include aural atresia, congenital syndromic hearing loss (e.g., Treacher Collins syndrome, CHARGE [coloboma, heart disease, atresia of the nasal choanae, retarded growth and/or development, ear abnormalities or deafness] syndrome), chronic draining ear, and otosclerosis. The current FDA criteria for fitting the Baha system require a pure-tone average bone conduction threshold equal to or better than 45 dB HL, a speech discrimination score of 60% or better, and an air conduction threshold equal to or poorer than the bone conduction threshold.

Common diagnoses in patients with SSD include sudden sensorineural hearing loss, acoustic neuroma, trauma, Meniere disease, labyrinthitis, and congenital unilateral hearing loss. The

FDA criteria for fitting a Baha in a patient with SSD include profound hearing loss in the affected ear and essentially normal hearing in the opposite ear.

An individual patient in either group can evaluate the potential benefit of the device by listening with a demo device on a metal headband or test rod. The demo device is not as good as the implanted device because of the presence of soft tissue between the device and the skull, but it gives the patient a reasonable approximation of the benefit that may be anticipated.

128.5 Surgery for the Baha

128.5.1 Surgical Procedure for Placement

Surgery for placement of the Baha is a relatively simple procedure that takes approximately 30 minutes to complete. For adults, the procedure can be done with intravenous sedation and local anesthetic. For children, the procedure is completed with general anesthesia. Surgery requires a dedicated drill unit, drill tips, and implants, all produced by the implant manufacturer. Modifications to the technique have been developed over the years, and individual surgeons have different methods for incision and soft-tissue reduction. The following technique is the vertical incision method.

Before anesthesia is administered, a mark is made on the surgical side, approximately 5 cm behind the ear canal. It is important to ask the patient about specific preferences regarding hats or glasses, and to have the patient to bring these to the surgery center. Usually, the device can be positioned away from such hindrances. For patients with prior surgical defects, such as from a previous suboccipital approach to tumor, the incision will need to be modified to take in account present bony defects.

In the operating room, the area is shaved and prepared for surgery. Depth of soft tissue is measured using a needle prior to anesthetic injection and appropriate abutment length is selected accordingly. A generous amount of local anesthetic with epinephrine is infiltrated into the area of the incision and surrounding soft tissue down to the skull. A 3-cm vertical incision is made.

The bone is then prepared for placement of the implant. A 10-mm area of perisoteum in the center of the incision is opened to expose the bone beneath. With a guide drill, an opening is first created to a depth of 3 mm (□ Fig. 128.2). The bone is carefully examined, and if it is adequate, the guide drill length is increased to 4 mm. If the bone is inadequate for drilling to a depth of 4 mm, the surgeon proceeds to the next step, using a 3-mm countersink and a 3-mm implant.

Following the determination of bone adequacy, the countersink drill bit is placed, and drilling is carried out with copious irrigation just to the depth that the countersink recess is created in the bone (□ Fig. 128.3). The combined titanium implant and abutment is then opened, and without touching the implant, the surgeon uses the rotating hand piece to pick it up. A very slow rotation is used to place the implant, initially without irrigation until the first threads of the screw are in the bone and subsequently with copious irrigation until the implant is

Fig. 128.2 A guide drill is used to gauge the depth of bone.

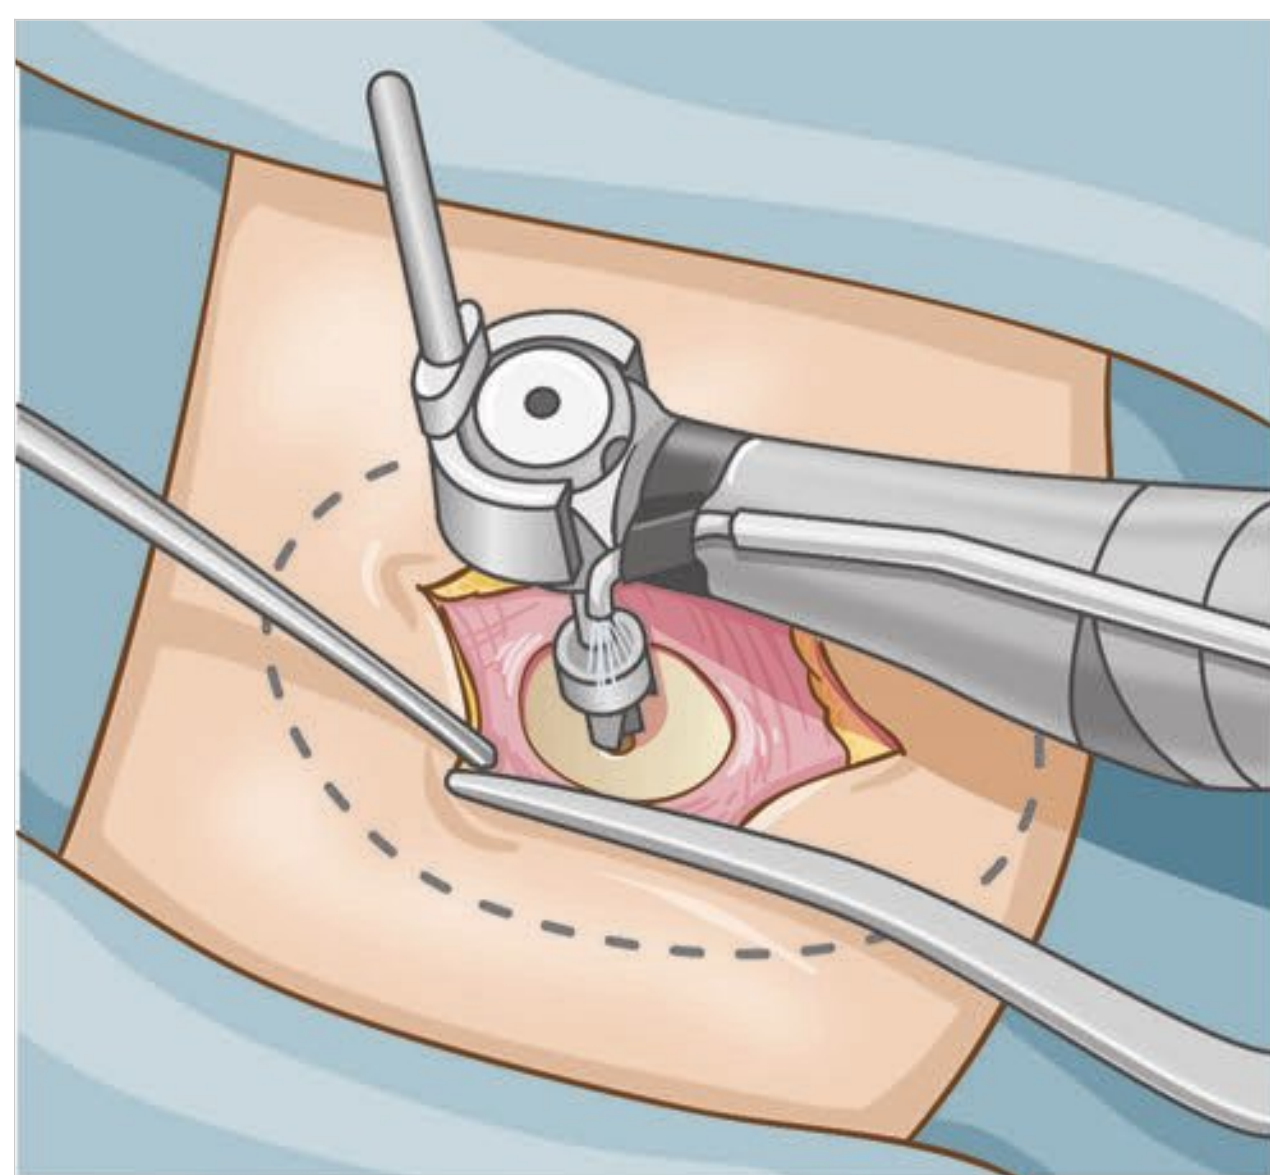

Fig. 128.3 Countersink drilling.

seated flush with the bone (□ Fig. 128.4). The wound is closed around the implant, with the abutment left exposed. A healing cap is placed on the abutment, and a pressure dressing is applied (□ Fig. 128.5).

Alternatively, a two-stage procedure can be completed, with placement of only the osseointegrated titanium implant; the skin is closed directly over it after soft-tissue reduction. After osseointegration is complete, the surgeon returns and makes a punch incision over the implant and attaches the abutment. Some surgeons choose the two-stage procedure for children in whom there is a concern about hitting or disrupting the abutment before full osseointegration.

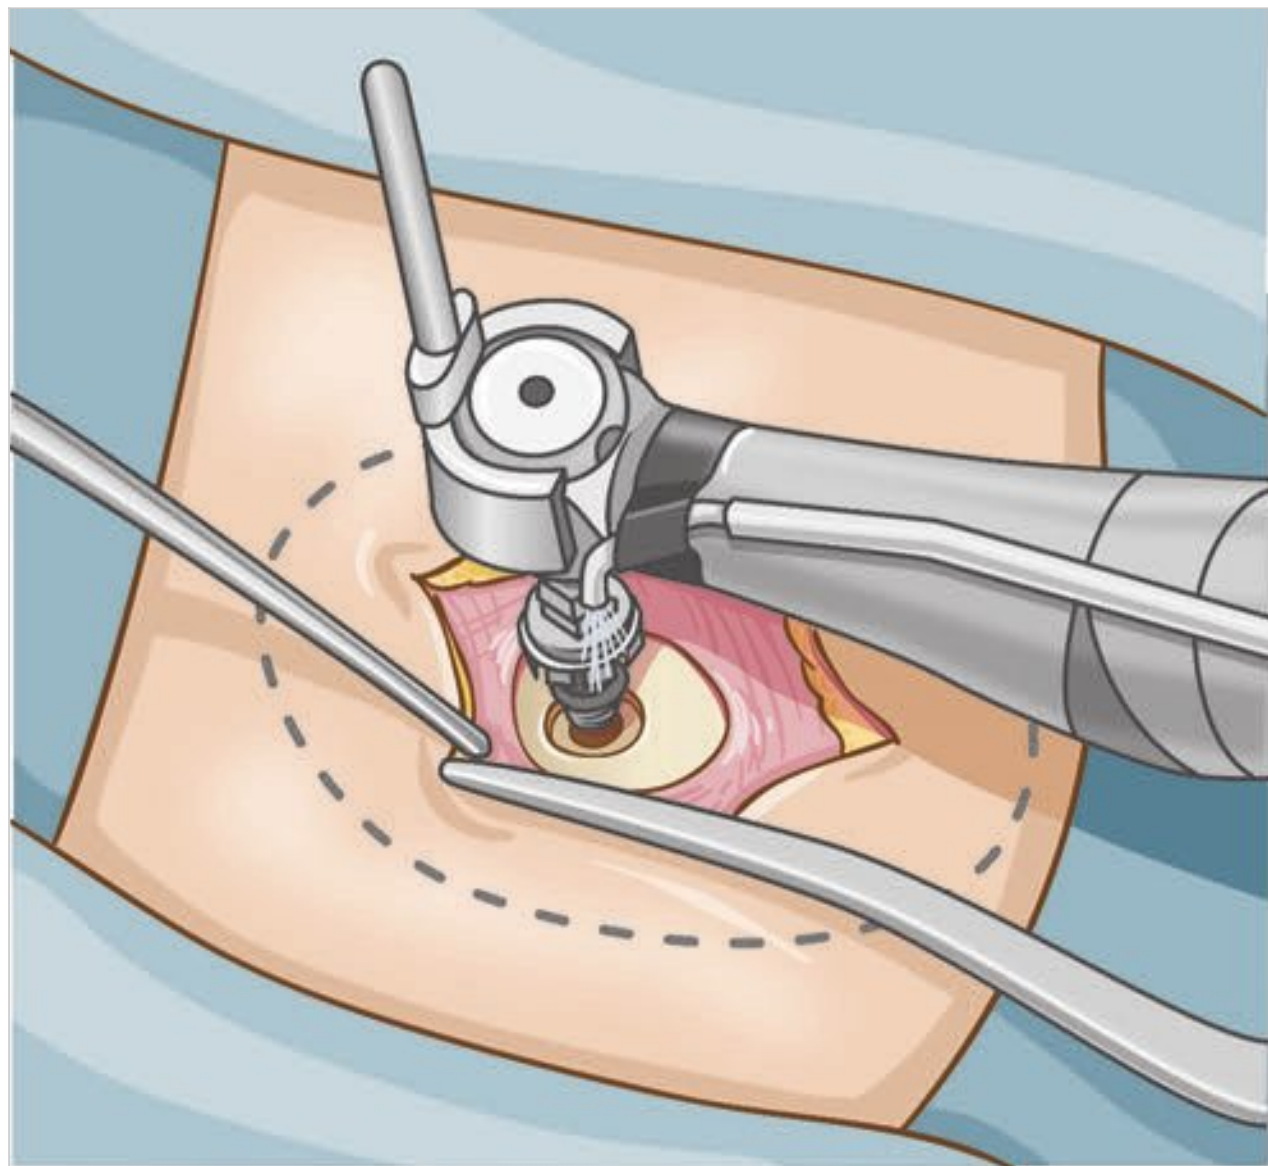

Fig. 128.4 Placement of the combined titanium implant and abutment.

128.5.2 Complications of Surgery

As with any surgical procedure involving placement of an implant, there can be intraoperative, immediate postoperative, and late postoperative complications.

Intraoperative complications are few and consist primarily of bleeding from soft tissue and bone. There is, however, a potential risk for dural exposure and cerebrospinal fluid leak. Many surgeons have not found dural exposure itself to be a problem, and the implant can be safely placed with exposed dura.

Postoperative and long-term complications have been reported in 8 to 59% of Baha patients. The most common long-term complications are soft-tissue overgrowth and skin infection at the abutment site. Other problems include abutment and fixture dislodgement, exposed bone at the abutment site, scalp paresthesia, persistent pain, failure of osseointegration, granulation tissue and bleeding at the abutment site, feedback problems, neuroma, keloid, and hematoma.

Skin irritation, infection, and overgrowth are thought to be due in part to the percutaneous nature of the implant and in part to the surgical approach and abutment design. Most of the skin irritation problems can be managed locally with topical steroids and antibiotic ointment. Cauterization and oral antibiotics are employed in more severe cases. When complete skin overgrowth occurs, surgery is necessary to reexpose the abutment and thin the skin. Some patients can be managed by placing a longer abutment, which usually resolves the problem. Recent modifications in surgical technique and abutment design have been associated with lower complication rates.

128.6 Hearing Benefits of the Baha

The Baha has been shown to provide objective and subjective benefit in patients with bilateral conductive and mixed hearing loss, unilateral conductive and mixed hearing loss, and SSD.

Fig. 128.5 The healing cap is positioned over the abutment.

For patients who have bilateral conductive hearing loss, the benefits are the most obvious because their only other means to amplify hearing is often a bone conduction device worn on a headband. Patients who have bilateral conductive loss experience significant improvement in speech thresholds with a unilateral Baha fitting. However, the greatest benefit is achieved in patients who receive bilateral implants. Initially, this benefit was questioned because one device can obviously conduct sound to both cochleas. However, improvements in directional hearing and speech recognition in quiet and in noise with bilateral fittings compared with unilateral fitting have been documented. Patients who have bilateral implants also report a significant increase in quality of life on standardized questionnaires compared with those who have unilateral Baha placement.

Patients with unilateral conductive hearing loss have been noted to have better hearing in quiet and in background noise, with significant improvement on speech-in-noise tests. Sound localization is not changed for the majority of patients using the Baha, although a subset of patients have had definitive improvement in localization, as well. In general, greater benefits are seen in patients who have acquired conductive hearing loss compared with those who have congenital conductive hearing loss, due in part to overall better unaided scores for directional hearing and understanding in noise for the group with congenital hearing loss.

For patients with SSD, Baha has been documented to improve performance on speech-in-noise tasks. No improvement in localization has been documented. This lack of localization is attributed to the fact that all sound is directed into one functional cochlea, and normal cues of interaural timing and intensity are not restored with the amplification. Patients report significant subjective benefit in multiple hearing situations, including listening in quiet, listening in a group, listening at a dinner table, and listening to TV or radio. In addition, an increase in quality of life and a decrease in hearing handicap scores have been documented.

128.7 Roundsmanship

- Osseointegrated conductive hearing aids are beneficial for patients with conductive and mixed hearing loss, and for those with unilateral profound hearing loss.
- Osseointegration of the Baha allows it to conduct sound effectively through the skull to the inner ear.
- The most common complications of soft-tissue overgrowth and skin infection can usually be managed with topical medications. Revision of the abutment site may occasionally be required.
- The Baha improves sound localization in patients with bilateral conductive hearing loss when two devices are fitted.
- For patients with unilateral conductive hearing loss and single-sided deafness, the Baha improves hearing in noise but in general does not improve sound localization.

129 Cochlear Implantation

Christopher J. Linstrom

129.1 Introduction

Hearing loss in any degree for any reason handicaps the ability of a person to communicate. Background noise worsens this handicap. For a patient with bilateral hearing loss so severe that medical care (amplification) or surgical care (e.g., eradication of chronic ear disease or a cholesteatoma, or correction of the conductive component of hearing loss in otosclerosis) has not brought the hearing up to an amplifiable level, a cochlear implant may be the next best alternative.

It is important to keep a few basic facts in mind. Firstly, a patient whose hearing can be amplified will generally communicate globally better than a patient with a cochlear implant. Secondly, a cochlear implant is not a hearing aid. It is an electrical representation of sound. It works in a very different way from any analog or digital hearing aid. Thirdly, unilateral hearing loss is not an indication for cochlear implantation; a normal or nearly normal ear will always function better than an ear with a cochlear implant. Furthermore, a cochlear implant is not a substitute for normal hearing. Finally, the cochlea and, most importantly the spiral ganglion cells from the eighth cranial nerve are housed in the hardest bone in the body, the petrous temporal bone. Although they are themselves soft-tissue structures, they are protected from many disease processes affecting the temporal bone, so that cochlear implantation is possible.

This chapter will focus on the evaluation of the patient with severe to profound hearing loss, on various means used to habilitate hearing, and on the steps taken before and during cochlear implantation with the goal of rehabilitating the patient who has a hearing handicap and restoring a better means of communication.

129.2 Incidence of Disease

It is estimated that 21 million Americans are sufficiently hearing-impaired to require some form of treatment, whether through amplification or surgery, including cochlear implantation. Of those with significant hearing loss, it is difficult to estimate how many would qualify for cochlear implantation. The minimum age for cochlear implantation in the United States is 12 months, although this number is being pushed downward. There is no upper age limit for cochlear implantation. The audiometric and general health status of the patient alone determines the upper age limit.

When a person is discovered to have hearing loss and seeks medical attention for this problem, the medical professional who encounters the patient should investigate several basic features. Is the hearing loss unilateral or bilateral? Was it of sudden or gradual onset? Does it fluctuate? Has there been a return of any hearing? What medical or surgical means has the patient used to habilitate his or her hearing? Is the hearing loss associated with any other ear-related problem, such as chronic ear disease? Is there any other complaint, such as dizziness/vertigo or facial nerve weakness? Is there a family history of hearing loss? Does the patient remember previously hearing well in the

affected ear? What medical and/or surgical problems does the patient have, if any, that might cause hearing loss?

129.3 Terminology

Hearing is measured in decibels (dB) of hearing level. For standard audiometric measurement, the worse the hearing, the higher the decibel level of the hearing threshold, commonly measured as the speech reception threshold (SRT). The SRT is the level at which the subject is aware of 50% of the words in a list of equally weighted two-syllable words, although the number of syllables per word in the word list will vary depending upon the language tested. A second, complementary parameter to test hearing is the word recognition score (WRS), expressed as the percentage of correctly heard words from a list of single-syllable words presented without context. In English, the single-syllable word will be chosen from a list of “consonant–nucleus–consonant” (CNC) words presented by convention at 35 dB above the SRT. The WRS is a difficult test because every part of the word must be heard and recognized independently and divorced from any context. The SRT and WRS are separate but complementary tests and should be done independently for each ear. Of all test parameters, these two items will yield the greatest amount of information about the subject’s level of audition.

Hearing loss may be classified as mild, moderate, severe, or profound. Each category implies approximately a 20-dB worsening of hearing. The term deaf to any hearing professional is associated with immeasurable hearing at or below 110 to 120 dB. Very few patients who claim to be “deaf” have this extremely poor level of hearing (□ Fig. 129.1).

129.4 Applied Anatomy

The basic anatomy of the outer, middle, and inner ear has been presented in this book. For a consideration of cochlear

Fig. 129.1 Levels of audition.

implantation, the ear should have normal anatomy and eustachian tube function. In rare cases, the patient may have had severe chronic ear disease and already undergone otologic surgery. The patient and surgeon must bear in mind that a cochlear implant is a large foreign body, roughly the size of a silver dollar, with an electrode array (or two arrays in one FDA-approved model) at one end. Any preexisting otologic disease must be eradicated before a cochlear implant can be placed into the mastoid and inner ear. In some cases, cochlear implantation must be staged; first, the external and middle ear are exenterated of any disease and surgically overclosed. After a suitable period of about 4 to 6 months, if the ear is free of active disease, an implantation may be done. In patients who have had bacterial meningitis, the otic capsule may be filled in with scar tissue (labyrinthitis ossificans), or in rare cases of advanced otosclerosis, the otic capsule is distorted to such a degree that only a few electrodes of the array can be implanted. In other cases, a split electrode array is made, and the cochlea is fenestrated in two places to allow both an orthograde and a retrograde insertion of the electrodes. In general, the greater the number of active electrodes that are implanted, the better the patient's word recognition will be.

129.5 The Disease Process

Deafness has hundreds of causes, and the likely causes based upon the patient's history and physical examination must be investigated, as would be done in any medical or surgical process. Hearing loss in general may be classified as congenital or acquired. The most common causes of congenital hearing loss are heritable, and most of these are subclassified as nonsyndromic forms of hearing loss.

The most common cause of acquired hearing loss in children is bacterial meningitis, especially meningococcal meningitis. This gram-positive infection leads to a severe immune reaction that causes labyrinthitis ossificans, with severe scarring of the basal and higher turns of the cochlea. Many of these children will have a precipitous loss of hearing, and cochlear implantation should not be delayed because the window of opportunity between the onset of meningitis and the development of labyrinthitis ossificans is a matter of weeks to a few months. If a child has little measurable hearing, implantation should be done as soon as the severe hearing loss has been established and the child is well enough to undergo the procedure.

A more complete list of the causes of hearing loss is given in □ Table 129.1. All of these items will be factored into the differential diagnosis of hearing loss. The patient's history of hearing loss will usually determine which factors merit investigation.

129.6 Medical Evaluation

The history of the hearing impairment is the single most important step guiding the investigation and rehabilitation of the patient. The diagnostic steps will vary depending upon the patient's age and prior audition, if any.

129.6.1 Children

Most parents give hearing the benefit of the doubt for no more than 12 months. If the child is not reliably responding or starting to babble by the first birthday, the parents usually seek medical intervention. The child with suspected speech delay or suspected hearing loss eventually requires a professional evaluation of hearing. It is important to investigate this problem

Table 129.1 Common causes of hearing loss

Congenital hearing loss	Acquired hearing loss
<ul style="list-style-type: none"> • Familial/genetic <ul style="list-style-type: none"> ◦ Syndromic versus nonsyndromic • Gestational, delivery-related, perinatal <ul style="list-style-type: none"> ◦ Prematurity, hypoxia, anoxia, hyperbilirubinemia • Infectious <ul style="list-style-type: none"> ◦ Rubella, toxoplasmosis, syphilis, cytomegalovirus infection, herpes • Teratogens <ul style="list-style-type: none"> ◦ Thalidomide • Congenital malformations of the otic capsule <ul style="list-style-type: none"> ◦ Michel aplasia <ul style="list-style-type: none"> – Agenesis of the otic capsule, both bony and membranous; middle and external auditory canal may be normal ◦ Mondini-Alexander dysplasia <ul style="list-style-type: none"> – Partitioning defect of the bony and membranous labyrinth; subclassification termed by degree and location of partitioning defect ◦ Scheibe dysplasia <ul style="list-style-type: none"> – Bony labyrinth normal; membranous dysplasia of the cochlea and saccule (pars inferior); membranous utricle and semi-circular canals normal (pars superior) ◦ Alexander dysplasia <ul style="list-style-type: none"> – High-frequency neurosensory hearing loss caused by partial aplasia of cochlear aqueduct ◦ Bing-Siebenmann dysplasia <ul style="list-style-type: none"> – Vestibular labyrinth abnormal; cochlear labyrinth may be abnormal 	<ul style="list-style-type: none"> • Familial/genetic <ul style="list-style-type: none"> ◦ Syndromic versus nonsyndromic • Infectious <ul style="list-style-type: none"> ◦ Meningitis ◦ Chronic otitis media ◦ Cholesteatoma ◦ Labyrinthitis <ul style="list-style-type: none"> – Serous (sterile) – Bacterial – Viral: mumps, measles, influenza • Trauma <ul style="list-style-type: none"> ◦ Head trauma (temporal bone, base of skull fracture) ◦ Iatrogenic trauma (otologic surgery) • Aminoglycosides <ul style="list-style-type: none"> ◦ Kanamycin, amikacin: primarily cochleotoxic ◦ Streptomycin, gentamicin: primarily vestibulotoxic, may affect cochlea if doses high enough • Metabolic <ul style="list-style-type: none"> ◦ Paget disease ◦ Cochlear otosclerosis • Autoimmune <ul style="list-style-type: none"> ◦ Autoimmune neurosensory hearing loss • Idiopathic <ul style="list-style-type: none"> ◦ Endolymphatic hydrops (Meniere syndrome)

Table 129.2 Important questions for cochlear implant candidates

For younger children (0 to 2 years)	For older children (older than 2 years)	For adults
Normal gestation?	Do the parents remember the child hearing well?	When did the patient become aware of the hearing loss?
Infections during pregnancy (e.g., genital herpes)?	History of frequent ear infections?	Was it sudden or progressive? Is there progression of loss?
Mother immunized for rubella and toxoplasmosis?	Over what period of time was hearing loss noted?	Is the hearing loss in one or both ears?
Delivered by cesarian section? If so, why?	Does the child remember hearing in each ear?	Does the hearing fluctuate?
Apgar scores (at 1 minute and at 5 minutes)?	Has the child ever had a serious head injury?	Does the patient have a history of chronic ear disease?
Neonatal jaundice?	Has the child ever been hospitalized for a serious ear infection?	Is there a history of significant noise (especially military or industrial) exposure?
Did the neonate have any phototherapy or exchange transfusion for jaundice?	Has the child ever had meningitis?	Familial history of hearing loss?
History of sepsis?	Has the hearing ever been measured?	Is the hearing loss related to puberty or to pregnancy?
Intravenous antibiotics, especially an aminoglycoside?	Has the child ever been treated for hearing loss?	Has the hearing loss previously been documented?
Neonatal hearing screening done?		
Familial history of hearing loss?		
Parental consanguinity?		
Parental hearing normal?		

with care and to be aware of the familial and social issues involved.

A single test does not yield all of the information about the child's hearing. If there is reasonable doubt about the level of audition, it is wise to state so at each point of the investigation, to be empathetic, but above all to be truthful based upon the current knowledge.

A number of specific questions are helpful when a patient with suspected speech delay or hearing loss is evaluated, and these differ for pediatric and adult patients (□ Table 129.2). The adult patient will usually have a very good idea about the onset and progression of hearing loss in one or both ears, can generally give a thorough medical history, and may even be wearing a hearing aid.

129.6.2 Presenting Complaints

In addition to hearing loss, the parents of young patients and older patients themselves may describe related problems of tinnitus, imbalance, or very rarely facial nerve involvement. It is very rare for young children themselves to complain of dizziness. Young children do not have this mental concept or the vocabulary to describe it. The parent will usually notice that the child cannot sit upright alone or is very clumsy in walking, etc. These complaints must be investigated, and the collaboration of a pediatric neurologist is crucial for such cases.

Older patients will usually have a very good way of describing concomitant otologic complaints. As indicated, these should be investigated with the appropriate means and treated.

129.6.3 Physical Examination

For most patients presenting with hearing loss, the physical examination is usually noncontributory, but it is important to rule out chronic ear disease (especially cholesteatoma) in all patients.

With children, the parents will usually know if there is anything abnormal about the shape or size of a child's ear (e.g., in a case of congenital auricular atresia). This is noticed at birth in almost all cases. The parents usually know about other "syndromic" causes of hearing loss, such as Pierre Robin malformation, Alport disease, Goldenhar syndrome, and other first arch abnormalities, unless the otologist is the first medical professional to evaluate the child.

129.6.4 Testing

Audiometry

It is difficult to fully express how important each and every test of audition is; fundamental and profound recommendations with far-reaching effects are made based upon tests of audition. Each test must be designed in an age-appropriate manner for the subject with the knowledge that not every subject may be able to inform the examiner of the exact level of audition. For very young subjects, objective tests of audition are employed. For older subjects, the standard audiogram assumes that the patient understands the test and is willing to comply with the examiner to ascertain the true level of audition.

Objective Tests of Audition

Otoacoustic Emissions

The cochlea is not solely a passive conduit of sound from the footplate of the stapes, through the conversion of shearing forces of the perilymph to electrical impulses transmitted thence to the eighth cranial nerve. The cochlea interacts with the auditory environment in a very active way, producing a weak sound, called the cochlear microphonic, in response to sound stimulation. The otoacoustic emission (OAE) measures this sound of the cochlea produced in response to received sound. It occurs in the outer hair cells of the cochlea in response to sound stimuli. A probe with both a sound source and a highly sensitive microphone is placed into the external auditory canal. A weak sound stimulus is presented to the ear. The ear responds by producing a very weak sound (about 3 to 4 dB in amplitude) virtually immediately. Several different responses may be obtained, depending on the function used. If there is hearing loss from any etiology of approximately 40 dB or greater, the OAE will not occur. Thus, the OAE is of great value as an audiometric screening tool, especially in the neonatal period. It is a “pass or fail”-type of audition test. Patients who pass the screen are assumed to have at least cochlear hearing; those who do not are scheduled for retesting and for additional tests of audition.

Auditory Brainstem Reflex

The auditory brainstem reflex (ABR) is an evoked response of the cochlea, eighth cranial nerve, cochlear nerve nucleus, mid-brain, and higher centers of hearing to a sound stimulus. It is obtained by an “averaging” computer that is calibrated to exclude competing bioelectrical signals, such as those from the electroencephalogram and electrocardiogram, and to allow only signals of predetermined latency and amplitude to pass. The ABR is used to test both cochlear and retrocochlear pathways of hearing. In neonates and babies who fail the OAE screen, the ABR is of great value both to determine the presence of audition and also to give some idea of the level at which audition can be expected to occur. Sound may be presented by air or to the mastoid bone. The ABR can establish the presence of audition or predict its level, or it can be used as a retrocochlear screen after an abnormal result of sound field, conditioned orientation response (COR), ABR, or standard audiometry testing.

Radiography

Structural abnormalities of the otic capsule, such as patent vestibular aqueduct, partitioning defects (e.g., Mondini deformity, single-sac abnormality), and dysplasia/aplasia (e.g., Michel aplasia), are best demonstrated by edge-enhanced computed tomography (CT) of the petrous temporal bone without contrast, which yields important information about the bone–air interface. Soft tissue is less well delineated on CT. For purposes of preoperative planning, CT is usually the only radiographic test required because it will provide important information about the structure of the inner ear, structure of the middle ear cleft, amount of mastoid pneumatization and aeration, and course of the facial nerve.

Magnetic resonance (MR) imaging with and without gadolinium contrast gives important information about soft tissue. Bone and air are both seen as a black silhouette on MR images.

If vascular abnormalities are suspected, MR angiography or MR venography may be designed along with MR imaging. It is important to note that MR angiography and MR venography cannot be added to the MR imaging data once the latter have been obtained. They are a different data set and must be requested “up front.”

It is also important to remember that both CT and MR imaging are tests of anatomy, not of function. They will yield information about space requirements for an implant within the otic capsule but give no predictive information about the function of any cochlear implant.

Serology

For otherwise healthy children, the yield of routine blood testing for causes of neurosensory hearing loss is very poor. Nonsyndromic causes of hearing loss, such as a connexin deficiency, may be diagnosed by the appropriate special genetic tests. Most adult patients have very little in their medical history to suggest the utility of specific serologic testing. A “shotgun” approach to serologic screening should not be used because it is cumbersome to both patient and medical provider, rarely yields clinically important information, and represents an unnecessary expense. The physician should know what he or she is specifically looking for before ordering any test. For most patients, age-specific blood work will be required before implantation, and no other serologic testing.

129.6.5 Differential Diagnosis

See □ Table 129.1.

129.7 Treatment

129.7.1 Medical Treatment

Patients with downwardly fluctuating sensorineural hearing loss will have been or should be treated with an oral corticosteroid, with or without an antimetabolite such as methotrexate. Continuation of medical treatment depends on clinical success; patients who fail medical treatment and progress inexorably to severe or profound hearing loss will require implantation.

Some forms of neurosensory and mixed hearing loss may respond to medical treatment. The most common examples are sensorineural hearing loss resulting from syphilis and autoimmune sensorineural hearing loss. Both are treated with corticosteroids. If a patient tests positive for syphilis and has never been treated, intramuscular followed by oral penicillin (with probenecid) may be added to the treatment plan. The anti-inflammatory effect of steroids may help restore some hearing. For patients who have hypertension, diabetes, glaucoma, or osteoporosis, coordinated care with the appropriate medical specialists is necessary.

The medical treatment of hearing loss in almost all cases will include a trial of amplification. This is common sense, except in cases in which the audition is so poor that it is obvious from the audiogram that no hearing aid could possibly benefit the patient. For patients with measurable hearing, a trial of amplification of at least 6 weeks should be offered. The procedure of cochlear implantation includes some form of cochleostomy,

which may be expected to remove any residual cochlear hearing. In rare cases, the residual cochlear hearing may be preserved, but the patient must be made aware that in every case it is likely that any residual measurable hearing will be gone.

The only exception to the trial of hearing amplification is in cases of bacterial meningitis, especially culture-proven meningococcal meningitis. The risk for the development of labyrinthitis ossificans is so great that the patient should undergo implantation as soon as profound hearing loss can be established and he or she is medically cleared for the procedure.

129.7.2 Surgical Treatment

Patient Selection

Patients who have been completely evaluated and have been given, when appropriate, a trial of amplification, and have failed, may then progress to a cochlear implant. Because of the irreversibility of cochlear implantation, a thorough and routine evaluation is required.

It is intuitive that the patient most likely to benefit from a cochlear implant would be one who has already developed a system of oral communication (i.e., can hear, speak, read, and write a language and has a good idea of how his or her own speaking voice should sound). Such a patient is a postlingually deafened adult.

A somewhat less favorable candidate would be a postlingually or perilingually deafened child, still less favorable a prelingually deafened child.

A prelingually deafened adult (born deaf, with little speech and communication via sign language) would be expected to have very little sound perception and prognostically would be expected to be the poorest performer, as a consequence of the lack of the trophic effect of sound upon the spiral ganglion cell population, cochlear nerve, cochlear ganglion cell bodies, and cells of the midbrain and auditory cortex.

Because the cochlea is minimally functional or nonfunctional, an electrical stimulating device is placed that will depolarize the residual (and expectedly healthy) spiral ganglion cells with an envelope of electromagnetic information, regulated by time (pulses per millisecond) and place (frequency-specific stimulation). The electrical engineering specifics of the workings of a cochlear implant are too complex for a brief discussion. However, there are common themes in every cochlear implant that should be understood. All cochlear implants are designed with the following basic features:

1. External receiver (directional microphone). This is usually worn at ear level and is positioned to pick up the sound source, the naturally occurring or analog signal. These signals include the human voice, music, noise, and other sounds. The received analog signal is transmitted to the external speech processor. This part of the cochlear implant resembles a behind-the-ear (BTE) hearing aid.
2. External speech processor. This is usually built into the BTE external receiver complex. It may also be designed to be clipped to a belt or placed in a back pack for very young children. The analog signal received by the directional microphone is filtered and digitized, converted into a digital representation of sound, and presented to the external transmitting coil as a digitized electronic signal. For reasons of

efficiency and size, not all of the sound envelope can be represented. Enough of it is represented to eventually give the spiral ganglion cells and eighth cranial nerve information about place (pitch), time (rhythm), amplitude (loudness), and timbre (the quality of a sound). It is here that the analog signal is processed (external speech processor), converted into a digital envelope of sound information through various coding strategies, and then sent on its way to the external transmitting coil.

3. External transmitting coil. This part of the cochlear implant consists of a centrally placed, coated magnet surrounded by the transmitting antenna. The external transmitting coil is held by its magnet over a magnet of opposite polarity implanted within the internal receiver/stimulator. The transmitting antenna of the external transmitting coil passes the digitized electric signal via electromagnetic induction across the scalp to the internal receiver/stimulator. The external transmitting coil is connected to the external receiver and external speech processor by a wire and appears to be an added part to the BTE device. Thus, all ear-level cochlear implants have the same basic features, but the design and style of each manufacturer will vary.
4. Internal receiver/stimulator. This is the only part of a cochlear implant that is surgically implanted. It consists of an internal magnet, the polar opposite of the magnet of the external transmitting coil, and the receiver/stimulator apparatus.

A bony well in the outer table of the parieto-occipital cortex of the skull is usually drilled to accommodate the body (also called the “can”) of the internal receiver/stimulator. Each manufacturer has a slightly different design of the “can” and will supply a sterile metallic pattern to help in planning the bony well (the sterile “dummy”). The device will be anchored with permanent sutures after placement through soft tissue, through a suture hole drilled into the outer table and diploë, or over a small titanium post. The internal receiver/stimulator should be stabilized as it heals. The internal receiver/stimulator contains the multichannel electrode, which is composed of several proximal stiffening (inactive) electrodes and distal stimulating (active) electrodes.

The multichannel electrode has been demonstrated to definitively transmit an electronic representation of sound better than the single-channel electrode. As would be expected, each manufacturer will have a slightly different design for the electrode array; all are multichannel electrodes. The electrode array is placed into the cochlea through a cochleostomy drilled near the round window or through a cochleostomy that incorporates the round window. Recently, some implant surgeons have returned to placing the electrode array through the round window. Recent evidence indicates that placement of the electrode array into the scala tympani rather than into the scala vestibuli is associated with better performance. Infrequently, especially in “drill out” cases of labyrinthitis ossificans, the electrode array must be placed into the scala vestibuli. These patients will definitely be expected to have sound perception, but their overall performance may not be as good as with a scala tympani insertion. The spiral ganglion cell population and thereafter the cochlear nerve are stimulated via electromagnetic induction, which produces the perception of sound.

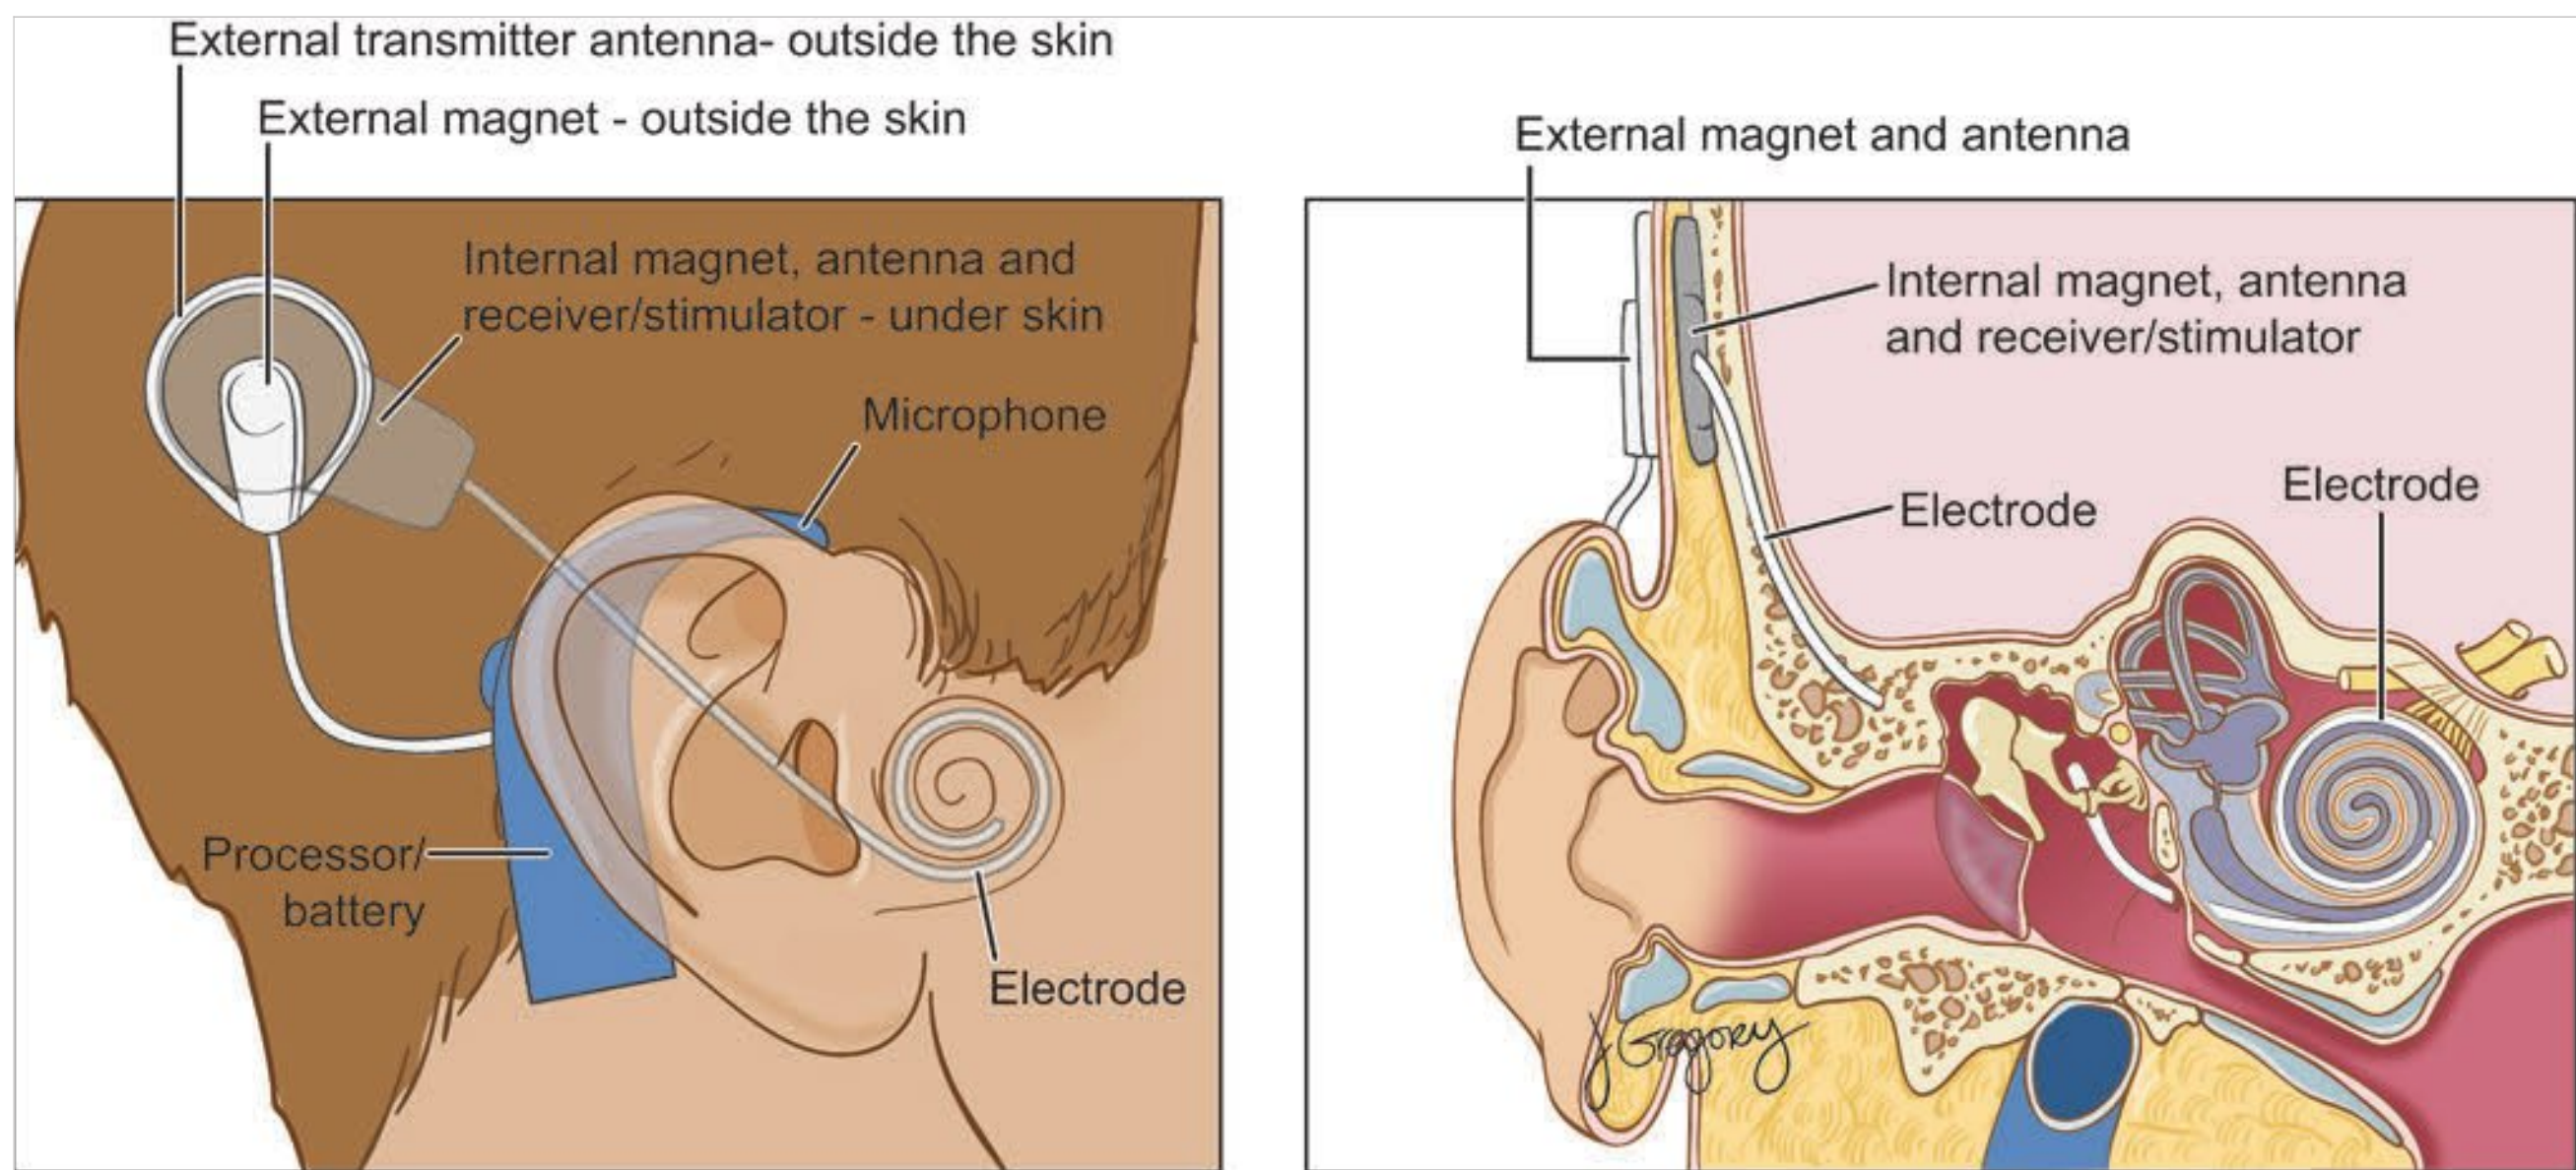

Fig. 129.2 Schematic representation of a cochlear implant.

A schematic representation of a cochlear implant is shown in □ Fig. 129.2. There are other designs available worldwide that have not yet obtained FDA approval for use within the United States. All have the same basic features, but they differ significantly not only in design but in coding strategy for conversion of the analog to digital envelope of sound and how this is represented and passed to the cochlea. Each of the three FDA-approved manufacturers has made extensive information available on the Internet, and the reader is referred to the Web site address provided at the end of this chapter.

Unusual Cases

Infrequently, underlying disease will lead to structural abnormalities that will either prevent complete insertion of the electrode array or necessitate placement of a split electrode array.

The most common causes of these structural abnormalities are labyrinthitis ossificans after meningitis, leading to incomplete insertion, and cochlear otosclerosis, causing severe distortion of the otic capsule. Other cases of dysgenesis of the otic capsule may require a straight electrode array, a shortened electrode array, or a non-modiolar-hugging array. In all cases, edge-enhanced, thin-section CT of the temporal bone performed before implantation will help the surgeon decide which array to use.

In rare cases, such as patients with hearing loss after surgical removal of or stereotactic irradiation for a neurofibroma of the eighth cranial nerve (neurofibromatosis type II), there will no longer be a useful cochlear nerve. In these patients, an auditory brainstem implant may be used, but its efficacy would not be expected to approach that of a standard cochlear implant because the tonotopic representation of sound structurally mirrored in the multichannel electrode array is not reproduced with the same precision and nuances as in the auditory brainstem

implant. In general, its utility would be for the awareness of environmental sounds and to aid in lip reading, but little else. It is of some benefit to these very difficult patients, but it lacks the robust reproduction of sound expected of a cochlear implant.

129.8 Prognosis

Many metrics are used to measure the efficacy of a cochlear implant. Almost all of them show a preoperative histogram worse than its postoperative counterpart, no matter what metric is used to measure the outcome. If the patient can be brought up to the level of soft speech, into an area called the “speech banana” (see □ Fig. 129.1), he or she can be expected a benefit of audition significantly above the preimplant level. Not all patients will derive the same benefit, especially if the lack of cochlear hearing has been long-standing over many years. Such a patient may obtain information about directionality but would not be expected to enjoy the same benefit as would a recently deafened, timely implanted patient. The latter patient would be expected to have a very robust spiral ganglion cell population and an otherwise healthy eighth cranial nerve, and to benefit much more than a patient who has been deaf for longer than 5 to 10 years. The more recently hearing ear is the ear that is usually implanted for this very reason.

129.9 Complications

- Flap failure and extrusion
- Soft failure
- Device failure/obsolescence
- Trauma
- External component breakage and loss

129.10 Roundsmanship

- A cochlear implant is not a hearing aid. It is an electrical (analog to digital) representation of sound. It works in a very different way from any analog or digital hearing aid.
- Unilateral hearing loss is not an indication for cochlear implantation. A normal or nearly normal ear will always function better than an ear with a cochlear implant.
- A cochlear implant is not a substitute for normal hearing.
- A cochlear implant converts analog sound energy to a digital representation, then transmits this via electromagnetic induction through the scalp to the internal receiver/stimulator and then to the cochlea.

- The indications for cochlear implantation are strict. Every effort should be made to rehabilitate the patient by medical and other surgical means before an implant is chosen.

130 Vestibular Pathology: Evaluation and Clinical Syndromes

Ana H. Kim, Clare Dean, and Ronald A. Hoffman

130.1 Introduction

The proper diagnosis and management of balance disorders result from a thorough history and physical examination with subsequent appropriate laboratory evaluation. The basic anatomy and physiology of the vestibular system are covered in Chapter 113 of this book. However, the reader is reminded that vestibular pathology may arise from a dysfunction in any of the major vestibular pathways and centers (□ Fig. 130.1).

130.2 History

130.2.1 The Chief Complaint

Balance symptoms that arise from disorders of the inner ear (semicircular canals, utricle, and saccule) can range from a vague sense of imbalance to a sense of being “off,” or feeling “drunk,” or that the body or the world is turning or moving. This last symptom, the sense of bodily motion, particularly that

the body or the environment rotating, defines the word vertigo. It is important to remember that vertigo is a symptom, not a disease entity. It is critical to take all balance complaints seriously and not be of the opinion that only vertigo constitutes real pathology.

130.2.2 History of the Present Illness

The features documented in the history of the present illness must be focused on identifying the source of the balance problem. Is the dizziness constant or intermittent? Was the onset associated with any systemic illness? Is the dizziness positional? Are there any precipitating or relieving factors? Is there hearing loss? If so, is the hearing loss unilateral or bilateral, progressive or sudden, and does it fluctuate with episodes of dizziness? Tinnitus may be defined as “a noise in the ear or head.” If present, it should be ascertained whether the tinnitus is unilateral or bilateral, constant or intermittent, pulsatile or nonpulsatile, and whether it occurs in concert with episodes of dizziness. Is there

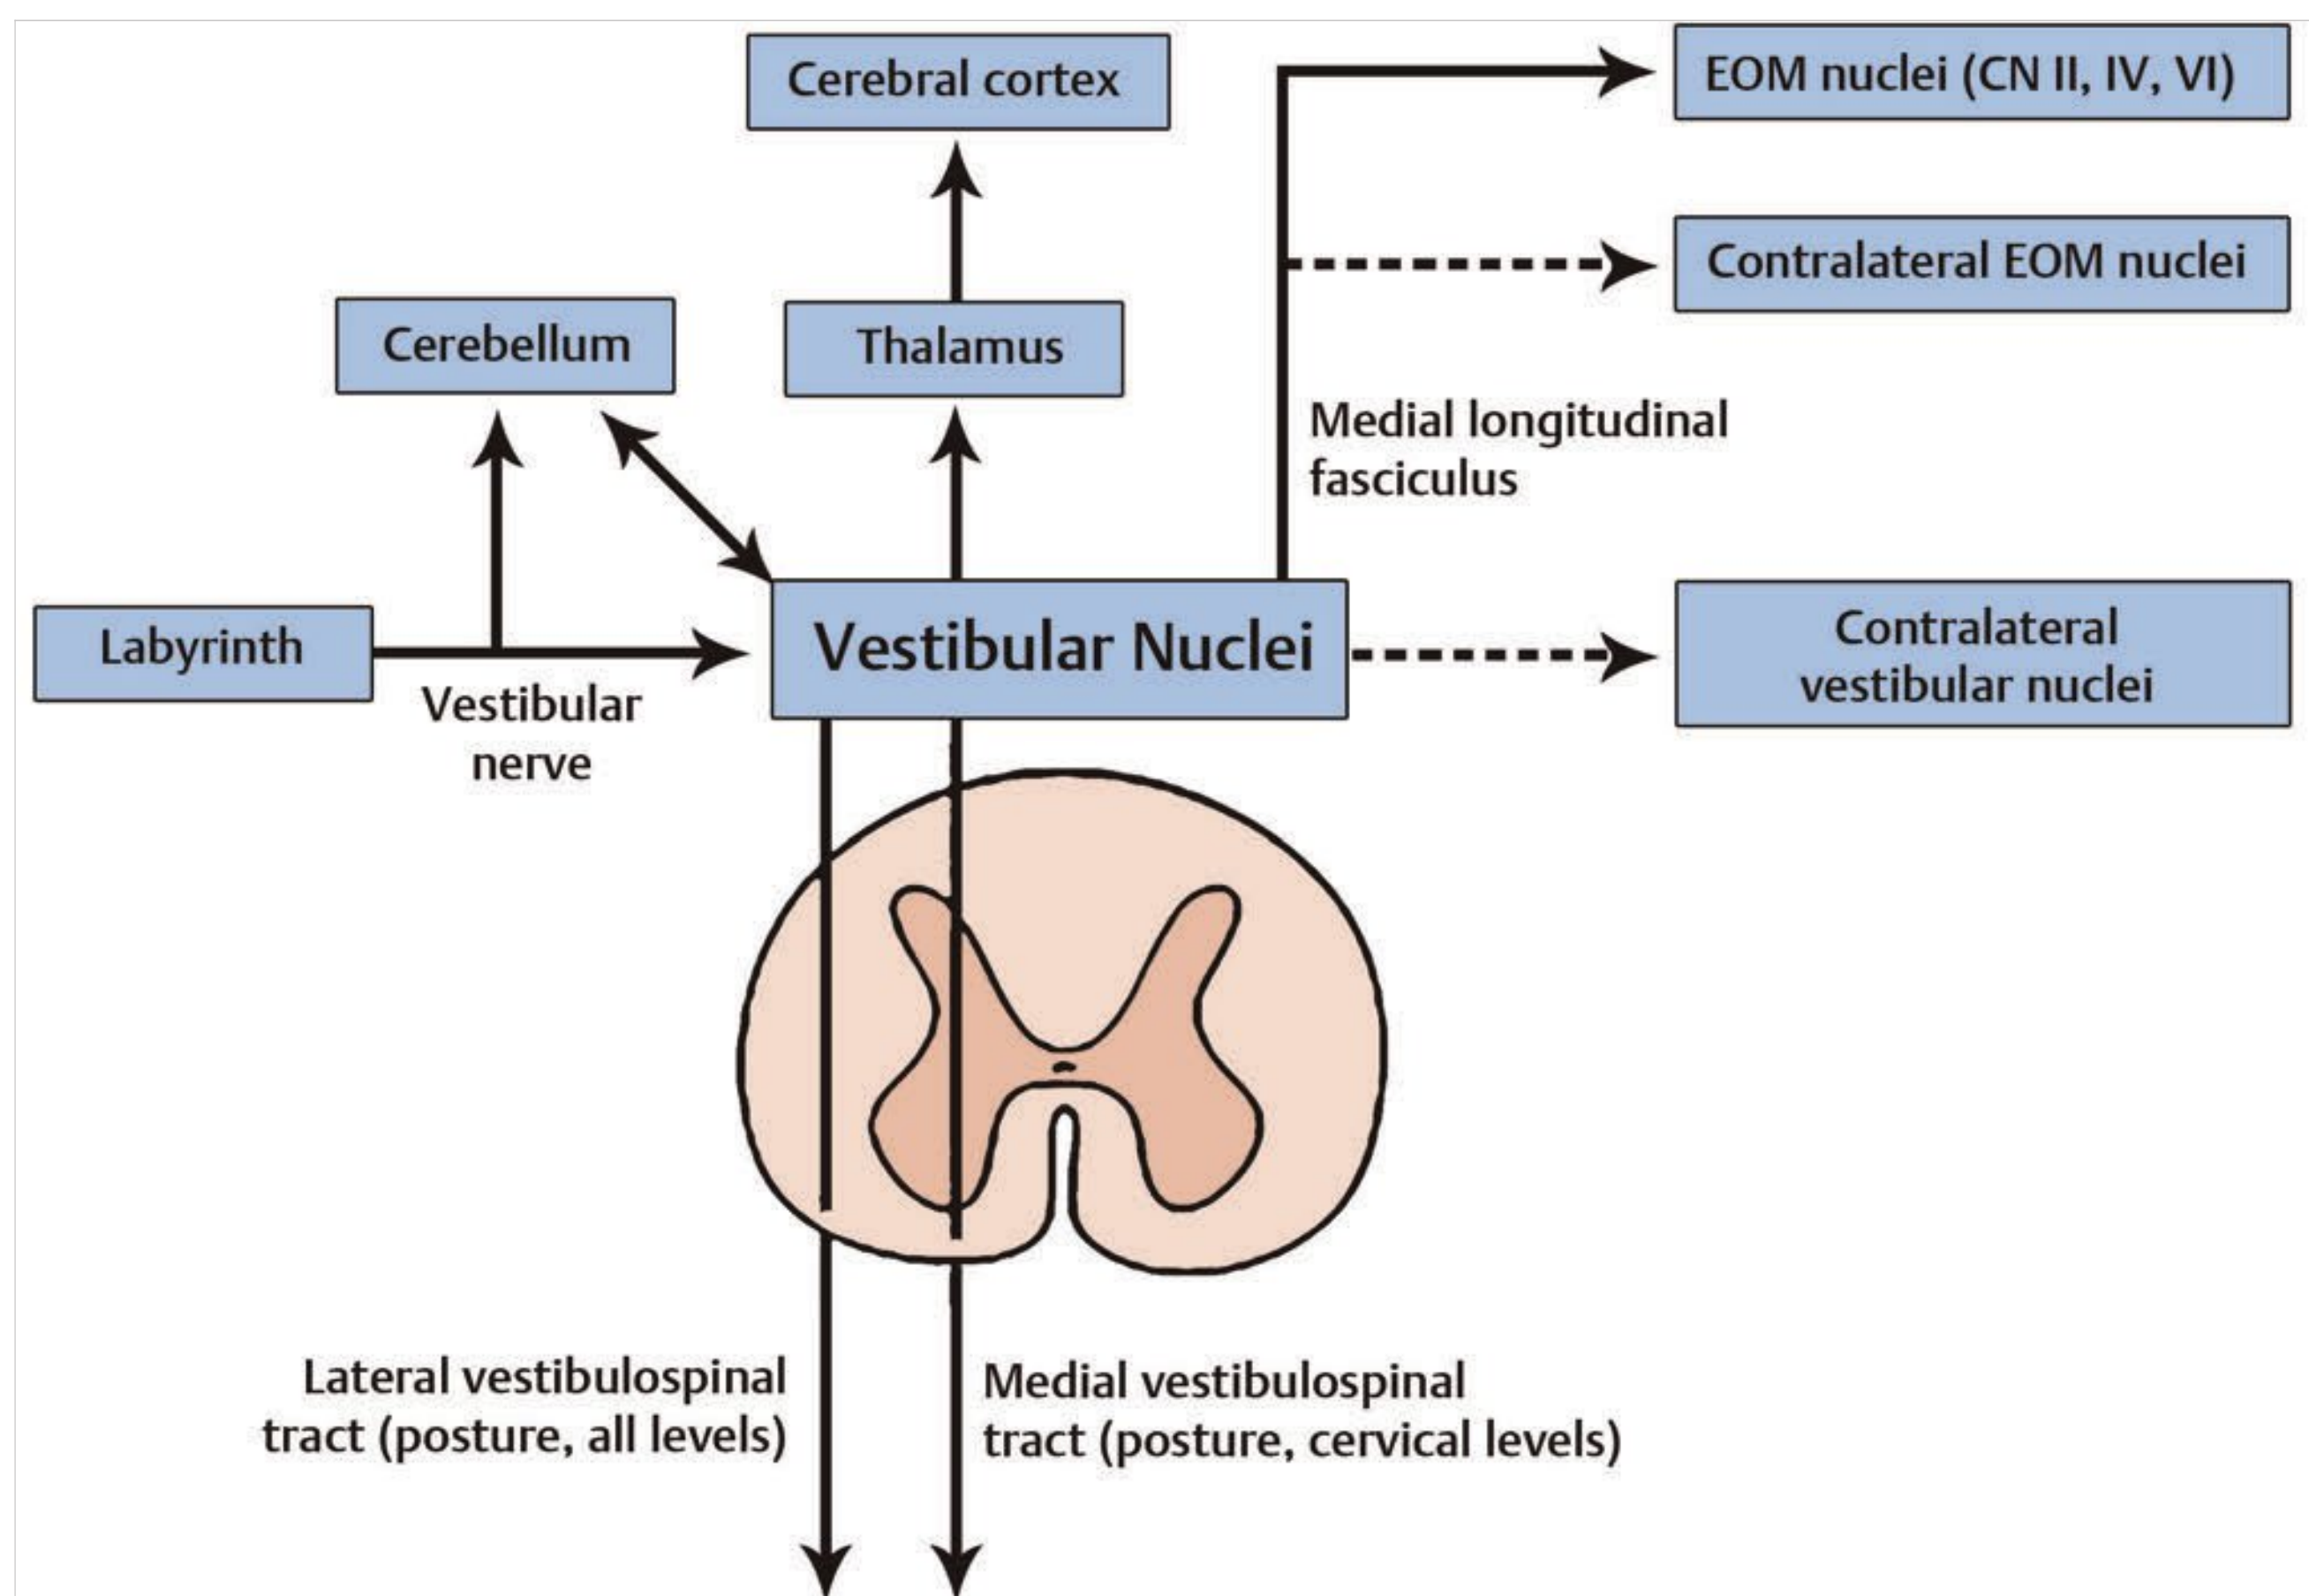

Fig. 130.1 Major vestibular pathways and centers.

a sense of ear fullness? If so, is it unilateral or bilateral, and is it associated with the episodes of dizziness? Has there been any recent head trauma or barotrauma? Does loud sound make the dizziness worse? Does lifting heavy objects or blowing the nose make the dizziness worse? Is there any history of ear pain or drainage? Is there any past medical history of ear infection or surgery? Are there any associated neurologic symptoms? In particular, are there any symptoms of migraine headache, cranial nerve symptoms, or cerebellar symptoms?

130.2.3 Review of Systems

A thorough review of systems is necessary to identify any new systemic diseases that might be associated with dizziness or hearing loss.

130.2.4 Past Medical History

A full past medical history is important, with emphasis upon general medical conditions that might cause dizziness, medications that might be associated with dizziness, and prior hospitalizations and the possible administration of ototoxic medications.

130.2.5 Family History

It is obviously important to assess for any familial history of hearing loss, dizziness, migraine headache, or other neurologic disorders.

130.2.6 Physical Examination

The neurotologic physical examination focuses on the ear and central nervous system. The core elements include the following:

- A thorough examination of the external and middle ear, including a fistula test if indicated
- Tuning fork testing as a hearing screen
- Assessment of cranial nerves III through XII, with an emphasis on eye movements and nystagmus (□ Table 130.1)
 - Smooth pursuits: The patient follows the examiner's finger from one extreme of the visual field to the other in smooth pursuit. Some patients must be encouraged to concentrate when they do this. Poor pursuits suggest cerebellar pathology.

- Saccades: The examiner holds up one finger to the left and one to the right of the patient's visual field. The patient is instructed to look from finger to finger. "Overshoot" of the target suggests cerebellar pathology.
- Saccadic catch: The patient's gaze is fixed on the examiner's nose. The patient lowers the head 15 degrees to bring the horizontal semicircular canal into the horizontal plane. The head is moved from side to side slowly and then gently thrust to the left; this maneuver is then repeated to the right. The patient should be able to maintain a fixed gaze on the examiner's nose. If there is a saccadic catch, it suggests peripheral hypofunction on the side of the direction of head thrust associated with the catch.
- Frenzel goggles: These are a valuable adjunct during an evaluation for induced nystagmus. The lenses prevent visual fixation, which powerfully inhibits nystagmus. The magnification of the lenses (20 diopters) and the lights enhance the clinician's observations.
 - Spontaneous nystagmus: The patient is instructed to gaze forward, to the left, and to the right. Nystagmus (the fast phase) beats away from a hypoactive ear or toward a hyperactive ear. First-degree nystagmus occurs only with the eyes in the direction of the slow phase. Second-degree nystagmus occurs with the eyes in the direction of the slow phase and in the center. Third-degree nystagmus occurs in all three stations of gaze. Up-beating or down-beating nystagmus strongly suggests central pathology.
 - Headshake-induced nystagmus: The head is lowered 15 degrees to bring the horizontal semicircular canal into the horizontal plane. The head is moved from side to side gently for 15 seconds. This is stopped, and the patient opens the eyes and looks forward. If there is a unilateral vestibular weakness of 60% or greater, there will usually be a headshake-induced nystagmus with the fast phase away from the hypoactive ear. Headshake-induced nystagmus in the presence of a normal caloric irrigation result on videonystagmography suggests a central velocity storage abnormality.
 - Dix-Hallpike maneuver-induced nystagmus: The patient sits on a flat table, the examiner turns the patient's head toward himself or herself, and then lays the patient back, head hanging over the edge of the table, as quickly as possible. The patient is observed in this position for induced nystagmus for 60 seconds.

Table 130.1 Eye movements

Class of eye movement	Main function
Fixation	Holds image of a stationary object on the fovea
Vergence	Moves eyes medially so image of single object is placed simultaneously on both foveas
Vestibular	Holds images steady on retina during brief head rotations
Optokinetic	Holds images steady on retina during sustained head movements
Smooth pursuit	Holds image of a moving target on fovea
Nystagmus	Resets eyes during prolonged rotation and direct gaze toward the oncoming visual scene
Saccades	Rapid eye movement that brings image of interest onto fovea

Table 130.2 Physical findings that differentiate peripheral from central vertigo

Characteristic	Peripheral vertigo	Central vertigo
Intensity	Severe	Mild
Fatigability	Fatigues, adaption	Does not fatigue
Eye closure	Symptoms worse with eye closure	Symptoms better with eye closure
Nystagmus	Horizontal, may be unilateral, rotary	No effect or enhances nystagmus
Ocular fixation	Suppresses nystagmus (may not suppress in acute phase)	No effect or enhances nystagmus
Associated symptoms	Nausea, hearing loss, sweating	Weakness, numbness, falls more likely

- Assessment of cerebellar function
 - Rapid finger to nose exercise
- Romberg and sharpened (tandem) Romberg testing

The physical findings that differentiate peripheral from central vertigo are summarized in □ Table 130.2.

130.2.7 Laboratory Testing

Laboratory testing will depend upon the history and physical examination findings. The most commonly performed tests include the following:

- Pure-tone and speech audiometry establishes the presence, degree, and type of hearing loss.
- Auditory evoked brainstem response (ABR) measures auditory potentials from the ear to the brainstem. ABR is not performed routinely in the evaluation of patients with a vestibular disorder. Historically, it has been used to screen for vestibular schwannoma.
- Electrocochleography (ECoChG) measures cochlear potentials that reflect abnormalities in fluid dynamics. An elevated SP (summing potential)/AP (action potential) ratio may be encountered in endolymphatic hydrops or perilymph fistula and can be helpful in identifying the offending ear.
- Vestibular evoked myogenic potential (VEMP) testing has been well documented to be helpful in identifying patients with superior canal dehiscence syndrome.
- Videonystagmography assesses the function of the vestibular end-organs, the central vestibulo-ocular pathways, and oculomotor processes. A subtest of videonystagmography is warm and cold water caloric irrigation, in which the eye movements clinically observed with Frenzel goggles in response to caloric stimulation of the horizontal semicircular canal and superior vestibular nerve are objectively recorded. Caloric testing allows a selective determination of unilateral vestibular responsiveness.
- Rotational chair testing quantifies the vestibulo-ocular reflex and helps differentiate peripheral from central pathology.
- Dynamic posturography involves a battery of tests that help to assess the functional capacity of a patient with a balance disorder.
- Imaging studies
 - Magnetic resonance (MR) imaging
 - Computed tomography (CT) of the temporal bones
- Selected serologic studies
 - Syphilis (fluorescent treponemal antibody [FTA]), Lyme titer, autoimmune (antinuclear antibody [ANA], rheumatoid factor [RF], erythrocyte sedimentation rate [ESR])

130.3 Differential Diagnosis of Vertigo

The diagnostic paradigm for common causes of dizziness is described in this chapter. An overview of the algorithm for evaluation of the dizzy patient is shown in □ Fig. 130.2.

130.3.1 Peripheral Causes of Vertigo

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo (BPPV) is the most common type of vertigo in otherwise healthy adults. BPPV occurs when free-floating otoconia cause movement of the vestibular sensory epithelia. The most common cause of BPPV is head trauma, but it can be of viral or of unknown cause. Patients will describe the sudden onset of rotatory vertigo, lasting seconds to minutes, in specific positions. The vertigo is usually noticed in bed, when they roll over or look up or down. There may be a prior history of similar episodes in the past that resolved spontaneously. There should be no history of hearing loss or tinnitus and no associated neurologic symptoms. The physical examination will be normal with the exception of Dix-Hallpike testing, in which the patient will experience vertigo and nystagmus will be observed when the offending ear is down. The most typical form of BPPV involves the posterior semicircular canal; the nystagmus is rotatory and down-beating toward the lower ear. The minimum laboratory work-up is a pure-tone and speech audiogram, which should be normal or show a symmetric hearing loss. The treatment of BPPV consists of a head maneuver that moves and relocates the offending otoconia, known as the Epley maneuver.

Meniere Disease

Meniere disease results from an abnormal buildup of endolymph and presents as a classic symptom complex of ear fullness, drop in hearing, tinnitus, and vertigo. The symptoms may last minutes to days, resolve spontaneously, and recur at unpredictable and irregular intervals. Not all of the symptoms in the complex must be present to make the diagnosis. Meniere disease is of unknown etiology. It should be viewed as a common set of symptoms reflective of several possible underlying pathologies: too much endolymph production; too little endolymph absorption; or viral, genetic, toxic, or metabolic disorders. Unfortunately, we do not have the diagnostic tools to reliably elucidate these possibilities. Diseases that can mimic Meniere

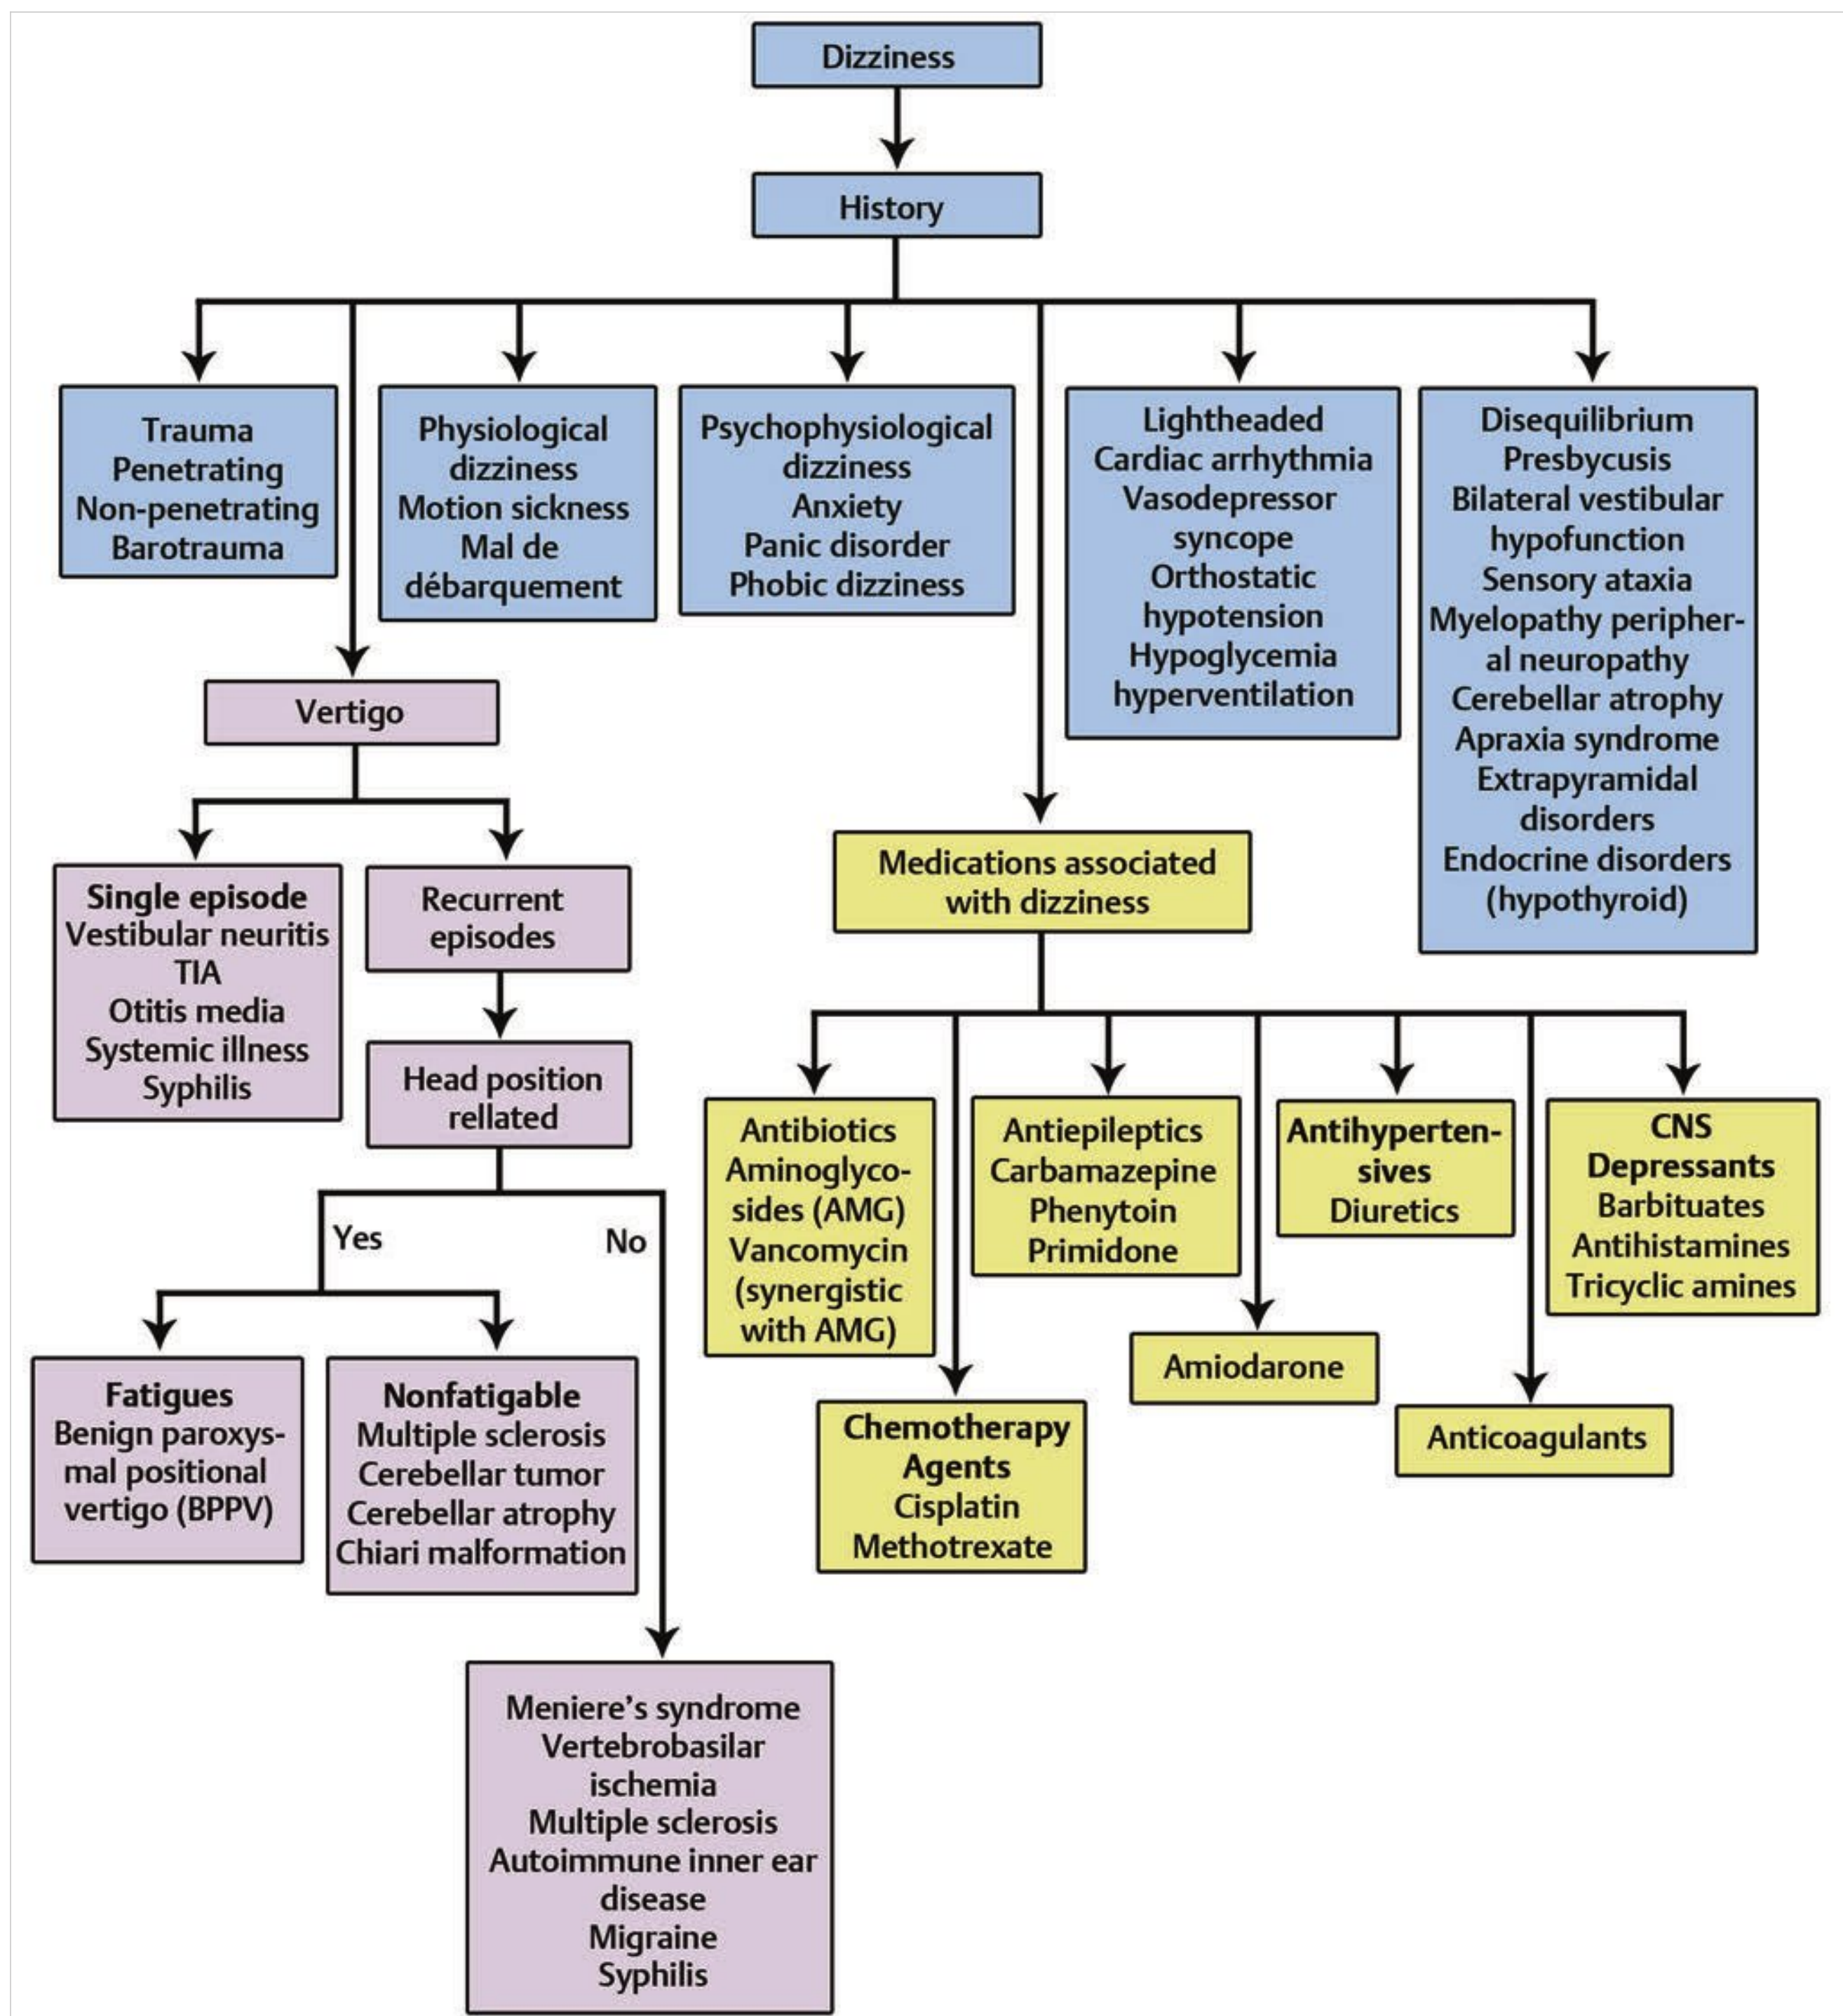

Fig. 130.2 Algorithm for evaluation of the dizzy patient.

disease include acoustic neuroma, perilymphatic fistula, Lyme disease, syphilis, autoimmune inner ear disease, and multiple sclerosis. If a specific etiology can be identified, Meniere syndrome is diagnosed as opposed to idiopathic disease. Meniere disease is bilateral in about 25% of patients. Over time, the hearing loss ceases to fluctuate and becomes more severe, and the acute attacks of vertigo “burn out” and give way to a constant sense of imbalance.

Physical findings are few. During an acute attack, nystagmus can be observed. Between attacks, abnormal tuning fork testing may be the only finding. Audiometry documents a sensorineural hearing loss, often more noticeable in the low frequencies, that fluctuates on repeated testing. ECoChG may confirm hydrops. Vestibular testing is not usually necessary to make the diagnosis, which relies heavily on the patient’s history. MR imaging with gadolinium enhancement is mandatory to rule

out an acoustic neuroma, multiple sclerosis, and other central nervous system pathology.

Initial treatment is with salt restriction to 2 g a day, an oral diuretic, and vestibular suppressants as necessary. If medical therapy is not adequate, vestibular ablation can be performed. This is done most often with intratympanic gentamicin therapy. Surgical alternatives include endolymphatic sac decompression, labyrinthectomy, and vestibular neurectomy.

Delayed Endolymphatic Hydrops

This diagnosis is made when episodic vestibular symptoms, similar to those in Meniere disease, develop months or years after a sensorineural hearing loss of any cause. For example, this condition may develop after a congenital hearing loss, after an idiopathic sudden or progressive hearing loss, or following a “dead ear” after stapedectomy surgery. Some authors feel that the syndrome is a variant of Meniere disease, with endolymphatic hydrops developing as a sequela of prior otologic pathology, so that it is referred to as delayed endolymphatic hydrops. The diagnosis is confirmed by documented hearing loss and the absence of other ear pathology.

Viral Neuritis

Viral neuritis is due to inflammation of the vestibular portion of the eighth cranial nerve. The history is critical in establishing the presence of a systemic viral infection close to the time of the onset of vertigo. The presence of hearing loss or tinnitus excludes this diagnosis. Physical examination may reveal nystagmus, but the findings are otherwise normal. Pure-tone and speech audiometry should be normal. Treatment is with vestibular suppressants. The symptoms usually resolve within several days to weeks.

Labyrinthitis

This condition produces an acute vestibular crisis with a history similar to that of vestibular neuritis. However, the vertigo is accompanied by a sudden hearing loss, usually within a few hours before or after the onset of vertigo. The recovery period should be similar to that seen in vestibular neuritis. Hearing may be recovered, or the hearing loss may persist.

Perilymphatic Fistula

Perilymphatic fistula is an abnormal leakage of perilymph via the oval or round window. It is almost always the result of implosive or explosive pressure changes due to head trauma, barotrauma, or Valsalva maneuver. The history is the key to the diagnosis. Symptoms may be isolated dizziness or vertigo, with or without hearing loss or tinnitus. Perilymphatic fistula can mimic Meniere disease. On physical examination, pneumatic otoscopy can precipitate or exacerbate symptoms, a so-called positive “fistula test.” There is no diagnostic laboratory test. The presence of a fistula can be confirmed only by surgical exploration of the middle ear. The treatment is surgical repair of the leak.

Dehiscent Superior Semicircular Canal Syndrome

Dehiscent superior semicircular canal syndrome is a loss of bone over the dome of the superior semicircular canal that exposes its endosteum to the dura. The cause is unknown. The most common symptom is episodic dizziness or vertigo, precipitated by loud noise or Valsalva maneuver. Hearing loss is common and may be a low-frequency conductive loss with preservation of the acoustic reflexes. Based on the history and audiometric findings, the patient undergoes CT of the temporal bones, which is the diagnostic study. The treatment is surgical resurfacing of the dehiscence.

130.3.2 Central Causes of Vertigo

Migraine Headache (Vestibular Migraine)

Migraine headache can be associated with dizziness or vertigo as an aura. The diagnosis in these cases is obvious. However, other patients present with episodic vertigo without headaches, so that the diagnosis is obscured. In these cases, the spells of vertigo are similar to those of Meniere disease, but without the associated hearing loss, tinnitus, or aural fullness. A personal or family history of classic migraine is key because all diagnostic tests of inner ear function and radiographic findings are normal.

Vertebrobasilar Vascular Insufficiency

The vertebrobasilar artery supplies the essential structures of the vestibular system, including the inner ear, cranial nerve VIII, and the cerebellum. As a result, transient symptoms may occur as a consequence of reduced blood flow resulting from hypotension (including orthostatic hypotension) or cardiac arrhythmias. Some patients with diabetes mellitus or atherosclerosis have balance complaints and may have multiple small ischemic areas in the brainstem. Others may have intermittent vertebrobasilar artery insufficiency associated with postural changes, certain head positions, or exercise.

Acoustic Neuroma

Acoustic neuroma is a misnomer because this entity is a schwannoma that usually arises on the vestibular portion of the eighth cranial nerve and so is more properly called a vestibular schwannoma. The usual presenting symptoms are hearing loss and/or tinnitus. When an acoustic neuroma is associated with dizziness, the dizziness is usually vague and nonspecific, not frank vertigo. On occasion, an acoustic neuroma can mimic Meniere disease. The physical examination is usually normal, except for tuning fork testing. When an acoustic neuroma is large, cranial nerve V and VII findings may be noted. Pure-tone and speech audiometry reveals a unilateral or asymmetric sensorineural hearing loss. MR imaging with gadolinium enhancement is 100% sensitive and highly specific. Treatment options include continued observation, radiation, and surgery.

Multiple Sclerosis

Vertigo or dizziness is an initial symptom in 5 to 15% of patients with multiple sclerosis. Up to 50% of patients with multiple sclerosis become vertiginous at some time during the course of the illness. The vertigo may be transient or permanent and is usually accompanied by nystagmus. Cerebrospinal fluid and MR imaging studies are helpful in confirming the diagnosis.

Psychiatric Disorders

Patients with panic disorder and related anxiety disorders, such as agoraphobia, tend to have vestibular complaints. The pathophysiology is unclear. Patients may have difficulty distinguishing dizziness from anxiety attacks because they occur together. In addition, the dizziness may be nonspecific and possibly mask an underlying clinical depression.

130.4 Using the Clinical History to Guide Treatment Decisions

Most patients with acute vertigo will improve with supportive, expectant management. When this is not the case, and the symptoms have been present for months to years, it is important to determine whether the vestibular pathology is stable or unstable. If the symptoms are predictable and provoked by motion, then the patient has a stable vestibular lesion not yet completely compensated by the central nervous system. These patients are appropriate candidates for vestibular rehabilitation. On the other hand, if the symptoms occur spontaneously and without warning, the patient has an unstable peripheral dysfunction. Meniere disease is the prototype of an unstable vestibular dysfunction. These “unstable” patients are not suitable candidates for vestibular rehabilitation. They are managed with medical therapy, and if this fails, surgical interventions should be considered, depending on the etiology of the vestibulopathy.

130.5 Roundsmanship

- Frenzel goggles are a valuable adjunct during an evaluation for induced nystagmus. The lenses prevent visual fixation, which powerfully inhibits nystagmus.

- Up-beating or down-beating spontaneous nystagmus strongly suggests central pathology.
- Videonystagmography assesses the function of the vestibular end-organs, central vestibulo-ocular pathways, and oculomotor processes.
- Rotational chair testing quantifies the vestibulo-ocular reflex and helps differentiate peripheral from central pathology.
- Dynamic posturography involves a battery of tests that help to assess the functional capacity of the patient with a balance disorder.

131 Management of the Patient with Chronic Dizziness

Bryan D. Hujsak and Laura Lei-Rivera

131.1 Introduction

Dizziness ranks as one of the most frequent complaints in primary care medicine. Dizziness can arise from a number of causes, including but not limited to side effects of medications, cardiac conditions, psychological disorders, neurologic disorders, and dysfunction of the vestibular system. Dizziness arising from a vestibular disorder can be quite disabling. It may reduce not only quality of the life and well-being but also interpersonal relationships. The treatment of individuals with chronic dizziness can be quite challenging. It requires patience and confidence on the part of the practitioner to guide the patient through the murky waters of conflicting opinions and the multitude of medical tests used to rule out more life-threatening pathology. Many people with chronic dizziness do not show any outward signs of their disorder. As a result, they sometimes are unable to obtain the kind of empathy from friends, family, and health care practitioners that someone with a more visible disability receives. Sometimes, the symptoms they are experiencing may be attributed to the anxiety and depression that commonly accompany any disabling condition, limiting the care that might return them to their previous level of function. It is our hope that this summary of the management of patients with chronic dizziness will provide the reader with a deeper appreciation of the complexities involved in caring for this unique population of patients.

131.2 Classification of Vestibular Disorders

Vestibular disorders can be broadly defined as either stable or unstable lesions. Stable lesions are typically the result of a one-time insult to the system, such as vestibular neuritis or labyrinthitis. Episodic disorders that have been ameliorated through medical or surgical management can also be classified as stable. An example would be Meniere disease that has responded to a low-sodium diet and diuresis, ablative therapy with an intratympanic injection of gentamicin, vestibular nerve sectioning, or labyrinthectomy. Unstable lesions are those that continue to cause episodic bouts of vertigo, dizziness, and disequilibrium, potentially resulting in further degradation of the vestibular system. Examples include unmanaged Meniere disease, vestibular migraine, endolymphatic hydrops, and vestibular autoimmune disorders. Before any rehabilitation intervention is undertaken, it is critical that any episodic degenerative process be halted through medication or surgery, or the outcome will most certainly be less than optimal.

Vestibular disorders can be further classified as unilateral or bilateral, incomplete or complete, symmetric or asymmetric, and peripheral, central, or mixed. Peripheral disorders include any pathology that affects the vestibular end-organs or the vestibular portion of the eighth cranial nerve (e.g., vestibular neuritis). Bilateral peripheral dysfunction can be seen in patients with ototoxicity from the intravenous administration of an aminoglycoside or with Meniere disease. Any of these disorders

can cause partial or complete loss of function. Central disorders include any pathology that affects the vestibular nuclei, the cerebellum, or any of the connecting pathways in between (e.g., cerebellar degeneration, hydrocephalus, vascular insult, brainstem traction injuries, and basilar migraine). Demyelination at the nerve root entry zone of cranial nerve VIII occurs with multiple sclerosis and can be classified as a mixed peripheral–central disorder. Other mixed disorders include vestibular schwannomas compromising the cerebellopontine angle and acquired brain injury with labyrinthine concussion as a sequela. Classification in these categories can assist in the prognosis and may determine the most appropriate approach to rehabilitation. A combination of vestibular function testing, the clinical examination, and the patient’s report will aid the clinician in determining the type of vestibular dysfunction that is present.

131.3 Disablement Model

For most patients with vestibular dysfunction, once they have been stabilized medically, the symptoms of dizziness and imbalance resolve over time. As they begin to engage in their prior activities, gradually increasing the level of intensity, the system naturally recovers and adapts. However, in some individuals, barriers to this adaptive process prevent spontaneous recovery. Typically, it is these patients who require skilled rehabilitation to facilitate a more favorable outcome. Although the main objective of treatment is to eliminate the symptoms of dizziness and disequilibrium, this cannot always be achieved. In lieu of a complete recovery, management of the patient with chronic dizziness should emphasize a return to the patient’s prior level of function with a minimum of symptoms.

Traditionally, treatment has focused on addressing the underlying pathology. According to the medical model, if the pathology is eliminated, the impact on the patient’s life will also be diminished. Over time, this philosophy has fallen short, especially in disorders in which a complete cure is not available. In order to understand how pathology impacts an individual’s ability to function, many disablement models have been developed. The currently accepted model in rehabilitation is the International Classification of Function, Disability, and Health (ICF), developed by the World Health Organization (WHO). This multidirectional interaction model takes into account how a health condition impairs body structure and function. It also takes into account how this impairment affects an individual’s activity level and participation in activities of daily living. The ICF model is the first to formally acknowledge the influence of personal and environmental factors. Earlier models by WHO and Nagi considered pathology, impairments, functional disability, and handicap only in a bidirectional fashion. The significance of the ICF model lies in its broadened view of how the disease process impacts a person’s ability to function in society (□ Fig. 131.1).

In providing comprehensive management for patients with chronic dizziness, it is important for the practitioner to consider all levels of the ICF model. It is imperative that the patient

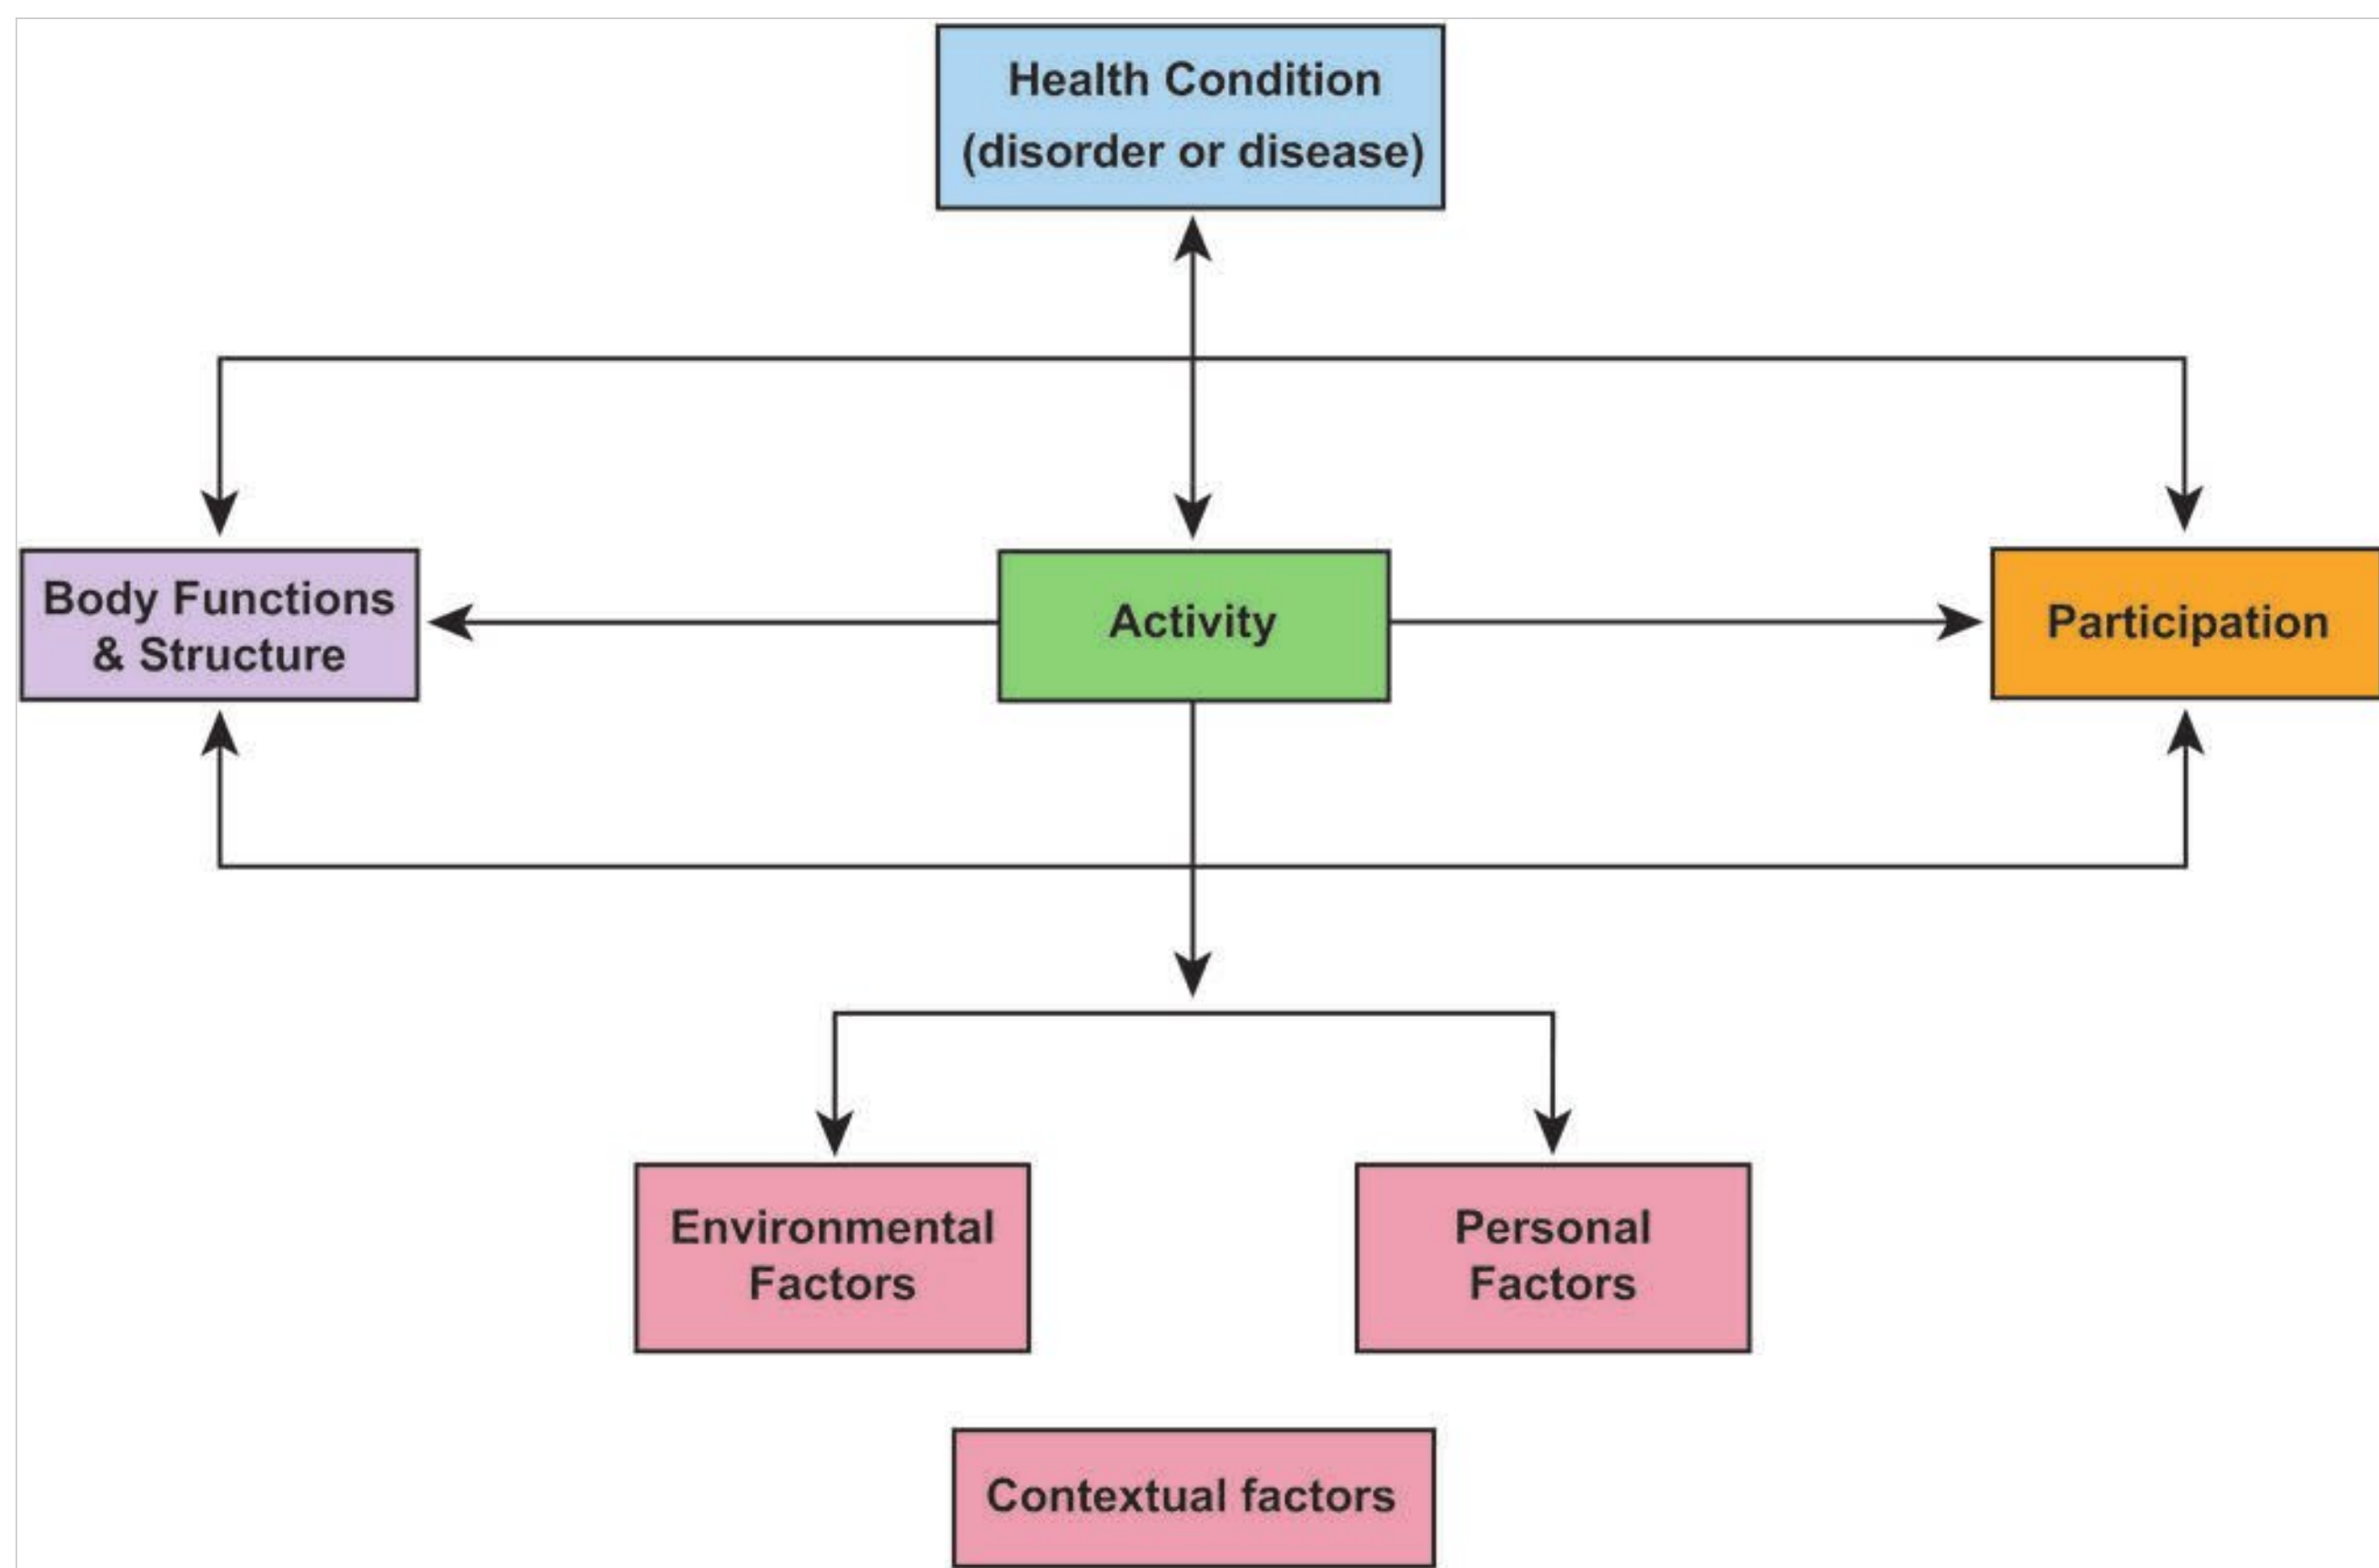

Fig. 131.1 International Classification of Function, Disability, and Health.

receive all possible medical and surgical care to minimize the impact of the health condition on body structure and function. Physical therapists, occupational therapists, and audiologists may provide skilled rehabilitation in order to facilitate adaptation of the system to any residual deficits. This helps to return the patient to pre-morbid levels of activity and participation. During the course of rehabilitation, these practitioners can also provide strategies that allow the patient to participate in activities of daily living with a minimum of symptoms. All practitioners participating in the care of these patients need to be mindful of the personal and environmental factors that either help or hinder the patient's recovery. If these barriers prove to be too large to overcome, consultation with psychiatry, psychology, and social work may be appropriate.

131.4 Principles of Treatment

The ultimate goal of rehabilitation is to return the individual to a pre-morbid level of function. Complete recovery can be defined as the patient's ability to tolerate all motions and activities without any remaining symptoms of vertigo, dizziness, or disequilibrium. Recent texts have delineated separate approaches for differing theoretical models of recovery. These have been described in a hierarchical fashion:

1. Adaptation/compensation
2. Habituation
3. Substitution

Separate modalities for each category are implemented in the hope of facilitating functional recovery. In terms of planning treatment strategies, the preferred result is one in which the central nervous system has adapted to the altered vestibular input caused by the pathology. Specific movements are prescribed that attempt to recalibrate the responses of the associated vestibular reflexes and their subsequent sensory integration. This is described as adaptation or compensation. A second treatment approach takes advantage of the neurologic phenomenon of habituation. A symptom-provoking stimulus, usually a head motion or position change, is presented to the patient in small increments followed by a specified recovery time. With repeated stimulation, the symptom response diminishes until the individual is no longer symptomatic with the particular movement. A third treatment approach is to substitute an alternative sensation for the missing vestibular information. In this approach, commonly used for patients with complete bilateral vestibular loss, vision and somatosensory information are optimized during the activity.

131.5 Treatment Modalities

The primary form of rehabilitative treatment is exercise. Early forms of exercise developed by Cawthorne and Cooksey recognized the need to move the eyes, head, and body in a repeated fashion. These maneuvers helped facilitate recovery by requiring the patient to move in directions that had been avoided

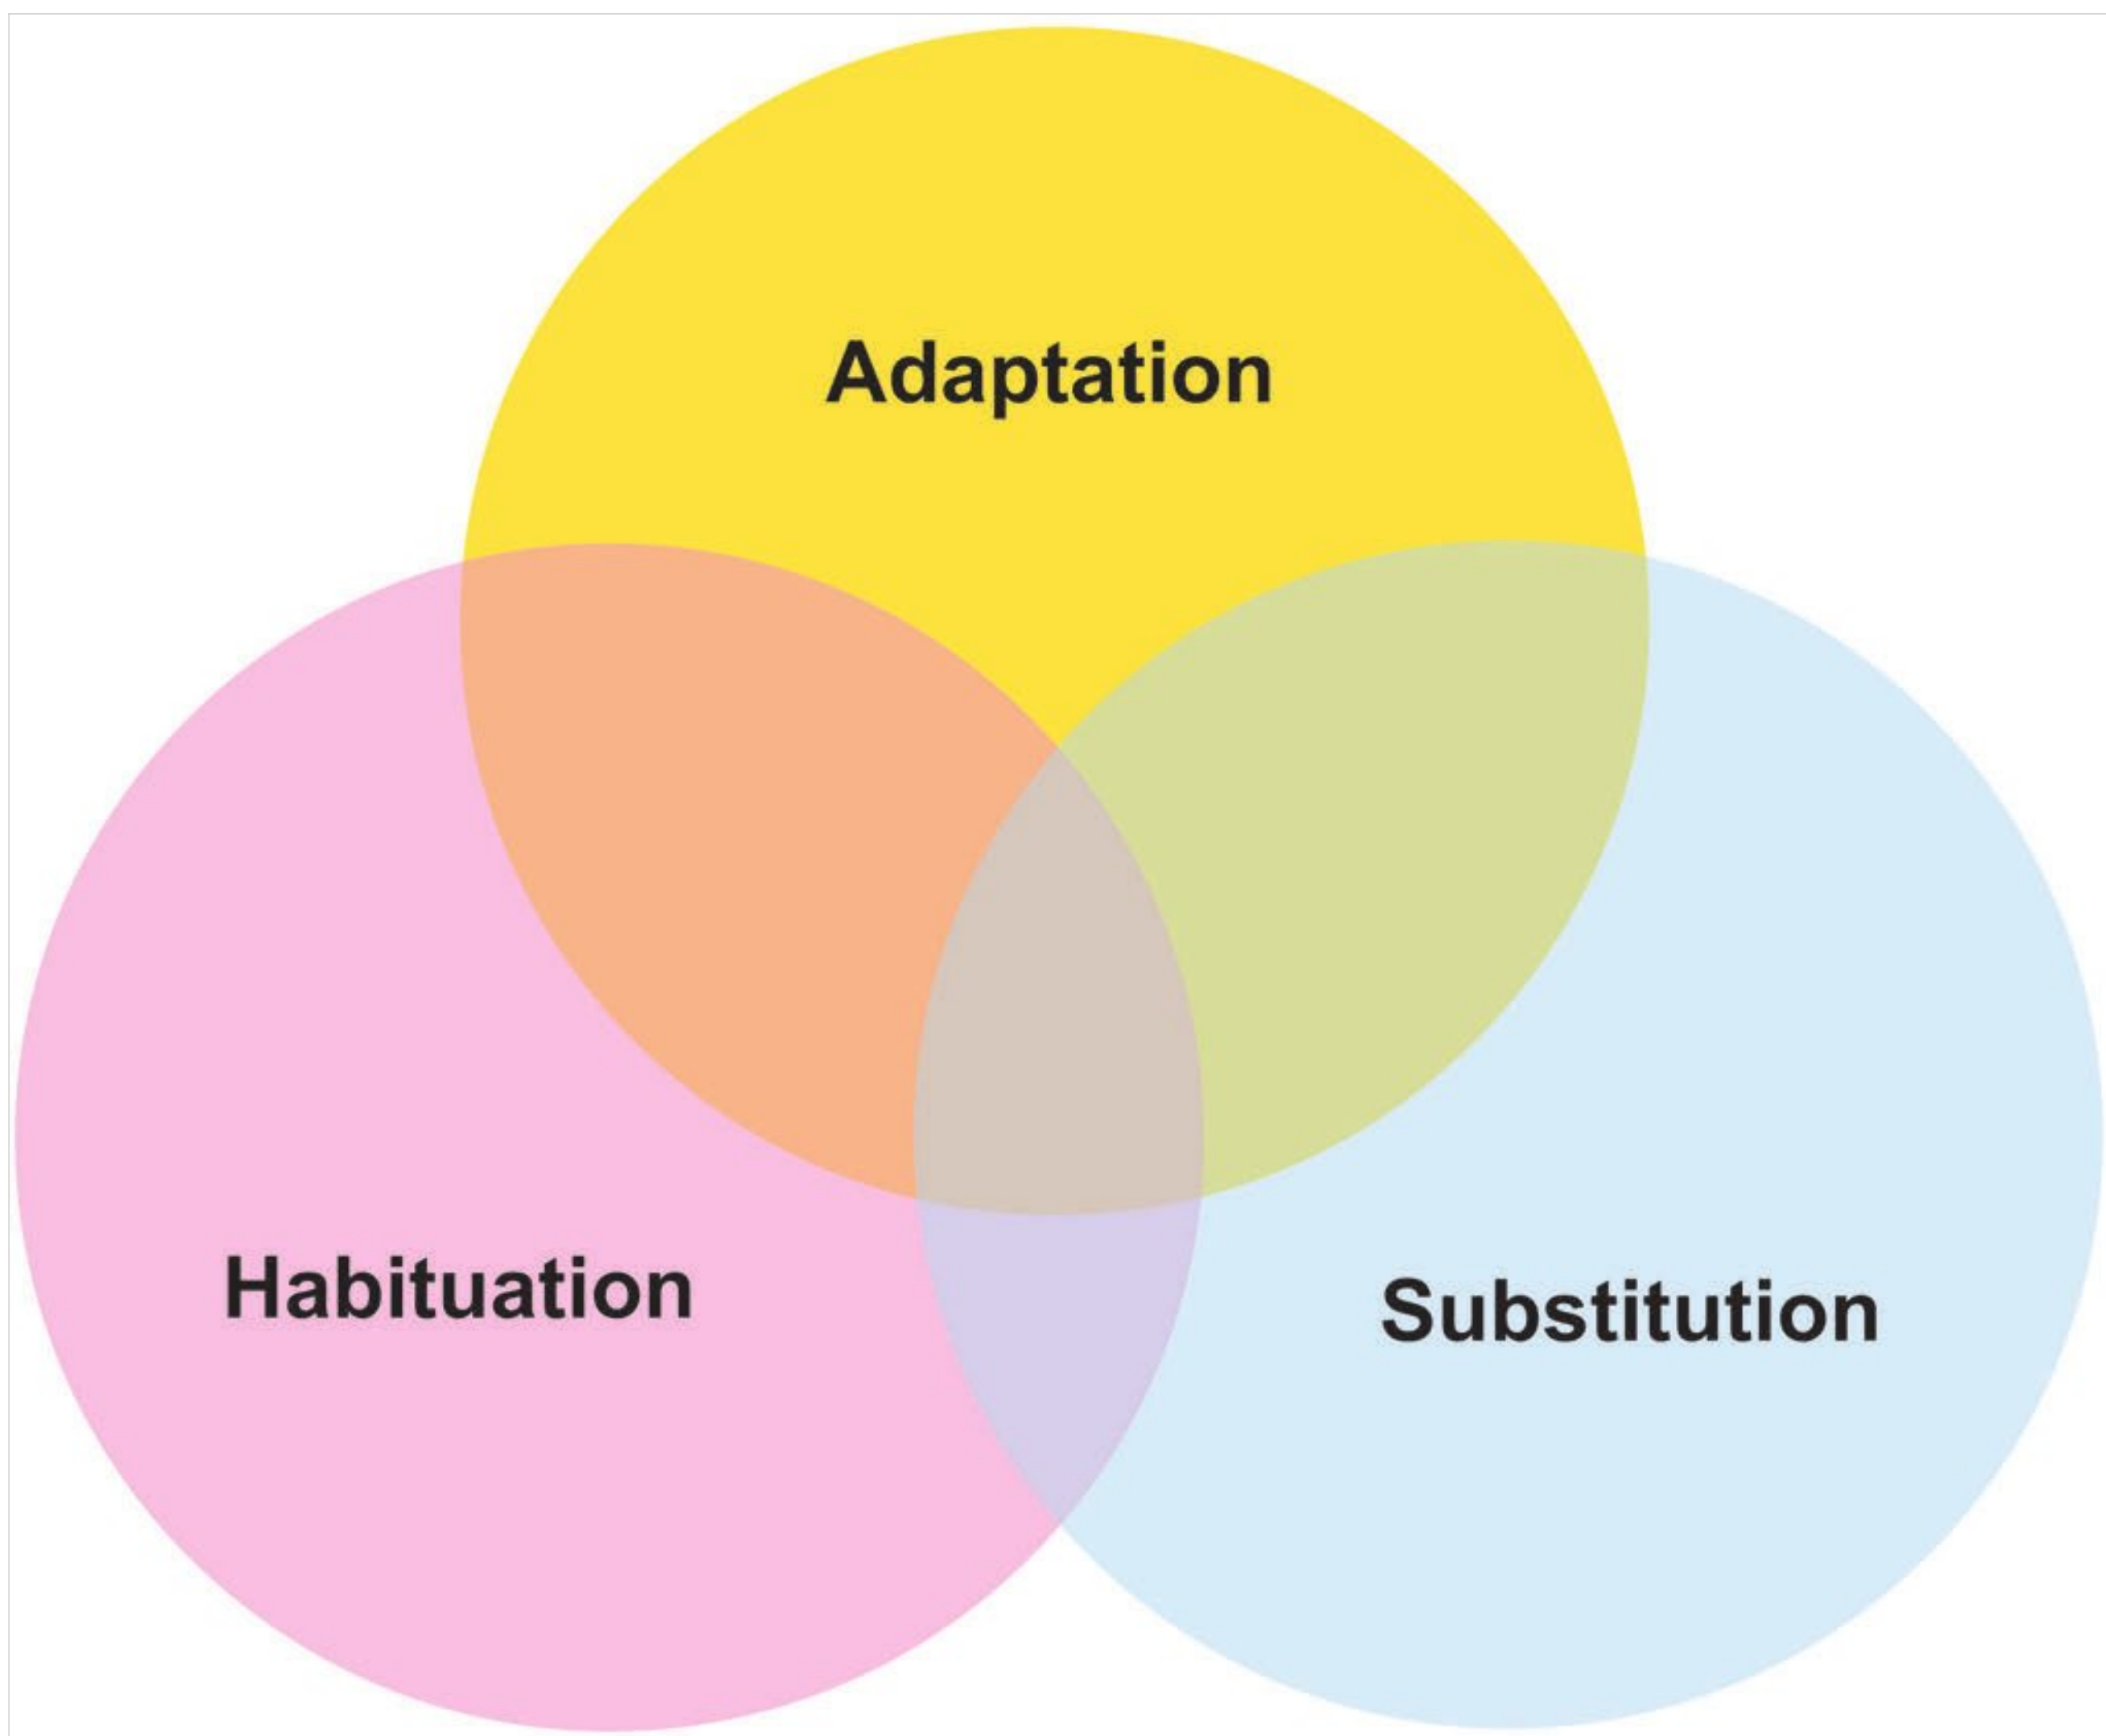

Fig. 131.2 Integrated recovery model.

because of a fear of dizziness. Although less sophisticated and specific than modern approaches, the continued use of these exercises may be effective with some patients, especially during the interim between consultation with the medical practitioner and the initiation of formal rehabilitation.

Although we can make clear theoretical distinctions among adaptation, habituation, and substitution, the movements used in treatment usually take advantage of all three effects. Initially, the dizziness provoked by the therapeutic motion may be too great for adaptation to be achieved, and tolerance of the motion through habituation may be required first. To a large degree, many patients spontaneously learn to substitute alternate senses to maintain their orientation. During visual fixation on stationary objects, visual cues override the erroneous signals generated by the vestibular system, improving equilibrium and minimizing dizziness. Also, many patients will maximize their proprioceptive input by increasing their double support time during gait, resulting in shorter, more deliberate steps. These substitution strategies become ineffective in conditions of absent visual stimuli (i.e., dark and dimly lit environments),

complex visual movements (i.e., crowds, stores), and uneven terrain (sand, grass, sidewalks; □ Fig. 131.2).

Modern approaches to treatment target three areas: gaze stability, postural reflexes, and sensory organization. Exercises are introduced at a level that challenges the patient's abilities but does not overwhelm his or her ability to complete the task. Each exercise is performed two to three times per day. Symptom provocation is not the primary objective in adaptation exercises, but it can be present as a minor side effect. If symptoms are provoked, the recovery time should be minimal because patients are instructed to recover from any symptoms before proceeding to the next exercise or activity.

Gaze stability exercises primarily address deficits in the vestibulo-ocular reflex. Patients are asked to fix their gaze on a simple, asymmetric target while oscillating the head through 30 degrees of yaw or pitch. This head motion is continued for a minimum of 90 seconds in both directions. If any degradation of the image is observed, patients are asked to slow down to maintain clarity and stability. Over time, they will be able to move their head at a faster rate. More complex targets are

progressively substituted for simple targets. Target motion adds another dimension to the exercise, approximating in vivo demands on the vestibular system.

Postural reflexes are challenged with both static and dynamic balance activities designed to improve the responsiveness of the vestibulospinal reflex. The vestibulospinal reflex is responsible for maintaining balance during changes in head or body position relative to the gravity axis (i.e., walking on an inclined surface) or displacement of the head outside the base of support (i.e., a head turn). These activities may include static standing with a progressively narrowed base of support, postural sway activities, gait with a progressively narrowed base of support, and gait with head turns.

Sensory organization is characterized by the reflexive selection of the appropriate orientation sense for a given environment. The brain selectively relies on visual cues, proprioceptive information, or vestibular information. If visual and somatosensory cues are manipulated during balance and gait activities, the system can be forced to use vestibular input to maintain balance. This manipulation is achieved by having the patient stand with the eyes closed, follow a moving object with the eyes, or stand on a compliant surface.

In addition to exercises, there are many products and devices that purport to be effective in managing chronic vestibular disorders. Some of these devices are based on the principle of sensory substitution, providing head and body position sensation via tactile stimulation of the body, feet, and even the tongue. Other devices provide controlled, measurable, sensory organization testing and training. Like the vestibular exercises previously described, they have their strengths and weaknesses and may not be effective with all patients. It is not our objective to promote or diminish the efficacy of these devices, but to urge clinicians to evaluate the evidence surrounding each device before incurring large expenses to their capital budget.

131.6 Barriers to Recovery

Most people respond favorably to therapy as long as the lesion is stable and the therapy provided is skilled and customized to the needs of the patient. Because therapeutic exercise is a very conservative form of management for vestibular disorders, it is important to recognize that not all patients are helped by vestibular rehabilitation. As with any disorder, failure via conservative management should compel the clinician to investigate the underlying cause. There are many reasons why a patient may not recover from lesions of the vestibular system. These barriers may also prevent progress with rehabilitation. Although not exhaustive, the following is a list of the more common causes.

One of the primary reasons for failure to adapt is that the patient has a misdiagnosed unstable lesion. Many times, patients are referred for therapy for what appears to be an unresolving vestibular neuritis. Unfortunately, the initial bout of vertigo assumed to be the result of neuritis is only the first of many episodes to follow. This is commonly seen in patients with Meniere disease or vestibular migraine. Once the pattern of episodic vertigo has been identified, the medical approach needs to be revised in order to stabilize the disorder.

Visual-perceptual forms of dysfunction are another major barrier to recovery. Of all sensory information processed by the

brain, 90% is related to vision, and therefore distortions in this system can be very disorienting. It is a common misconception that the vestibular system is the “balance organ.” The reality is that our visual system, not our vestibular system, is the primary orientation sense. Symptoms of dizziness can be compounded by or arise purely from visual-perceptual forms of dysfunction. These include, but are not limited to, cataracts, glaucoma, macular degeneration, visual field loss, refractive errors, and multifocal lenses. It is important to recognize that patients are usually the last to know that they cannot see as well as they should. This is because most pathology in the visual system occurs over time, and the brain is able to adapt to this slow deterioration. Therefore, a visual screen for acuity, dominance, vergence, confrontation visual fields, and extraocular eye movements should be a component of every clinician’s examination.

Emotional disorders are another common cause of failed recovery. It is expected that any patient with a vestibular disorder will have some degree of anxiety and depression related to the condition. This is a normal emotional response that can be considered pathologic only when it prevents the patient from participating at a level that would promote adaptation. This type of anxiety and depression is different from primary clinical anxiety and depression and is classified as an adjustment disorder. Other emotional disorders, such as premorbid mood disorders, personality disorders, and psychoses, will also have a negative effect on treatment outcome. It is important to educate the patient that management of both the psychological disorder and the vestibular disorder is needed in order to maximize functional improvement. In these cases, close work with a psychiatrist, psychologist, or social worker versed in vestibular disorders can be quite effective.

131.7 Alternatives to Traditional Treatment

In the past two decades, a growing body of evidence supporting tai chi as a valuable complementary treatment for vestibular disorders has emerged in the Western scientific literature. Tai chi, a traditional Chinese method of exercise derived from a martial arts form, has gained popularity as a treatment paradigm for a variety of human ailments, including balance impairment.

Tai chi is an appropriate form of exercise for individuals of all ages with a wide range of abilities and conditions, including the medically complex. It has applications for balance dysfunctions, orthopedic and neurologic rehabilitation, pain management, cardiovascular and respiratory disorders, mood and mental disorders, fitness, and general well-being. The beneficial effects of tai chi for which the evidence is most compelling appear to be related to functional balance and fall prevention.

Vestibular rehabilitation is a well-accepted exercise program intended for the treatment of persons with balance impairment caused by damage to the peripheral vestibular system. However, individuals with balance deficits resulting from central nervous system pathology or the involvement of multiple components of the sensory system do not generally have the same outcomes. Although patients with central pathology can achieve clinical and functional gains, implementing tai chi

training as an adjunctive therapy in the first group of patients may maximize treatment outcomes. In addition, the implementation of a tai chi program may help transition patients from supervised medical care to a longer-term community-based program. It is this lifestyle change that may have the most enduring effect of improving balance and wellness.

131.8 Conclusion

The management of patients with chronic dizziness arising from vestibular dysfunction can be very challenging, but also extremely rewarding. In order to achieve successful outcomes in this patient population, it is critical to properly classify the underlying disorder, involve the appropriate professionals in each patient's care, recognize influences beyond the pathology, and explore comorbidities in the face of slow or absent progress. Communication between the patient, physician, audiologist, and therapist is critical because the successful management of vestibular dysfunction is not an event, but a process.

131.9 Roundsmanship

- Vestibular rehabilitation is an effective form of conservative management for patients with stable peripheral and central vestibular dysfunctions.
- The management of patients with chronic dizziness requires considerations beyond pathology. Understanding the effects of physical impairment on social and environmental factors will result in optimal patient outcomes.

- Patients who do not respond to rehabilitation should be evaluated for comorbidities that may be preventing adaptation, habituation, and substitution. These may include visual-perceptual dysfunction, emotional disorders, or a previously unidentified unstable lesion.
- Adjunctive and alternative therapies like tai chi have been shown to be effective in promoting recovery and may also help in transitioning patients from medical care to participation in community-based activities.
- The effective management of patients with chronic dizziness may require additional support from psychology and social work to complement the medical and therapeutic care provided by the physician and physical therapist.

132 Diagnostic Assessment and Management of Acute Facial Palsy

Christopher J. Linstrom

132.1 Introduction

The management of a patient presenting with facial paresis or paralysis may at first seem like a daunting task to the clinician, and it should be remembered that “all that palsies is not Bell’s.” A thorough history and physical examination, with the reasoned development of a differential diagnosis, understanding, and the judicious use of clinical testing, will enable the physician to arrive at a specific diagnosis and formulate an appropriate treatment plan in cases of acute facial paralysis. This chapter will review the pertinent anatomy and physiology of the facial nerve and facial movement, with an emphasis upon the accurate evaluation and supportive and definitive care of the patient with facial paralysis. A review of the common etiologies of acute facial dysfunction and a plan for the treatment of acute facial paralysis will be given, along with several clinical case examples. A separate section will review electrodiagnostic testing of the facial nerve.

132.2 Relevant Anatomy and Physiology

Like many other structures in the head and neck, the facial nerve, cranial nerve (CN) VII, respects the rule of “economy of

means.” It is a composite nerve, primarily subserving motor function to the muscles of facial expression (branchial motor) but also, through the nervus intermedius of Wrisberg, carrying general sensory and special sensory fibers (taste) and preganglionic parasympathetic fibers (visceral motor) for lacrimation and salivation (to the submandibular and sublingual glands).

The facial nerve may be detected in embryonic life as early as the third week of gestation, when the embryo is 3 mm long. This collection of neural crest cells also gives rise to CN VIII and thus is called the facioacoustic primordium or crest.

The facial nerve becomes housed within the petrous temporal bone, taking the longest intraosseous course of any cranial nerve (□ Fig. 132.1). It has two major points of flexion, the first (superior) and second (inferior) genu, before taking a somewhat vertical course to leave the temporal bone at the stylo-mastoid foramen, where it branches at the pes anserinus (“goose’s foot”) into two main divisions, the temporofacial (superior) and cervicofacial (inferior) branches. These then travel between the superficial and deep lobes of the parotid to innervate the muscles of facial expression via five named branches: the temporal, zygomatic, buccal, marginal mandibular, and cervical rami. Proximal to the point of ramification, the facial nerve gives off three and sometimes four small branches: (1) the nerve to the stapedius muscle (within the facial canal); (2) the posterior auricular nerve to the occipitalis muscle;

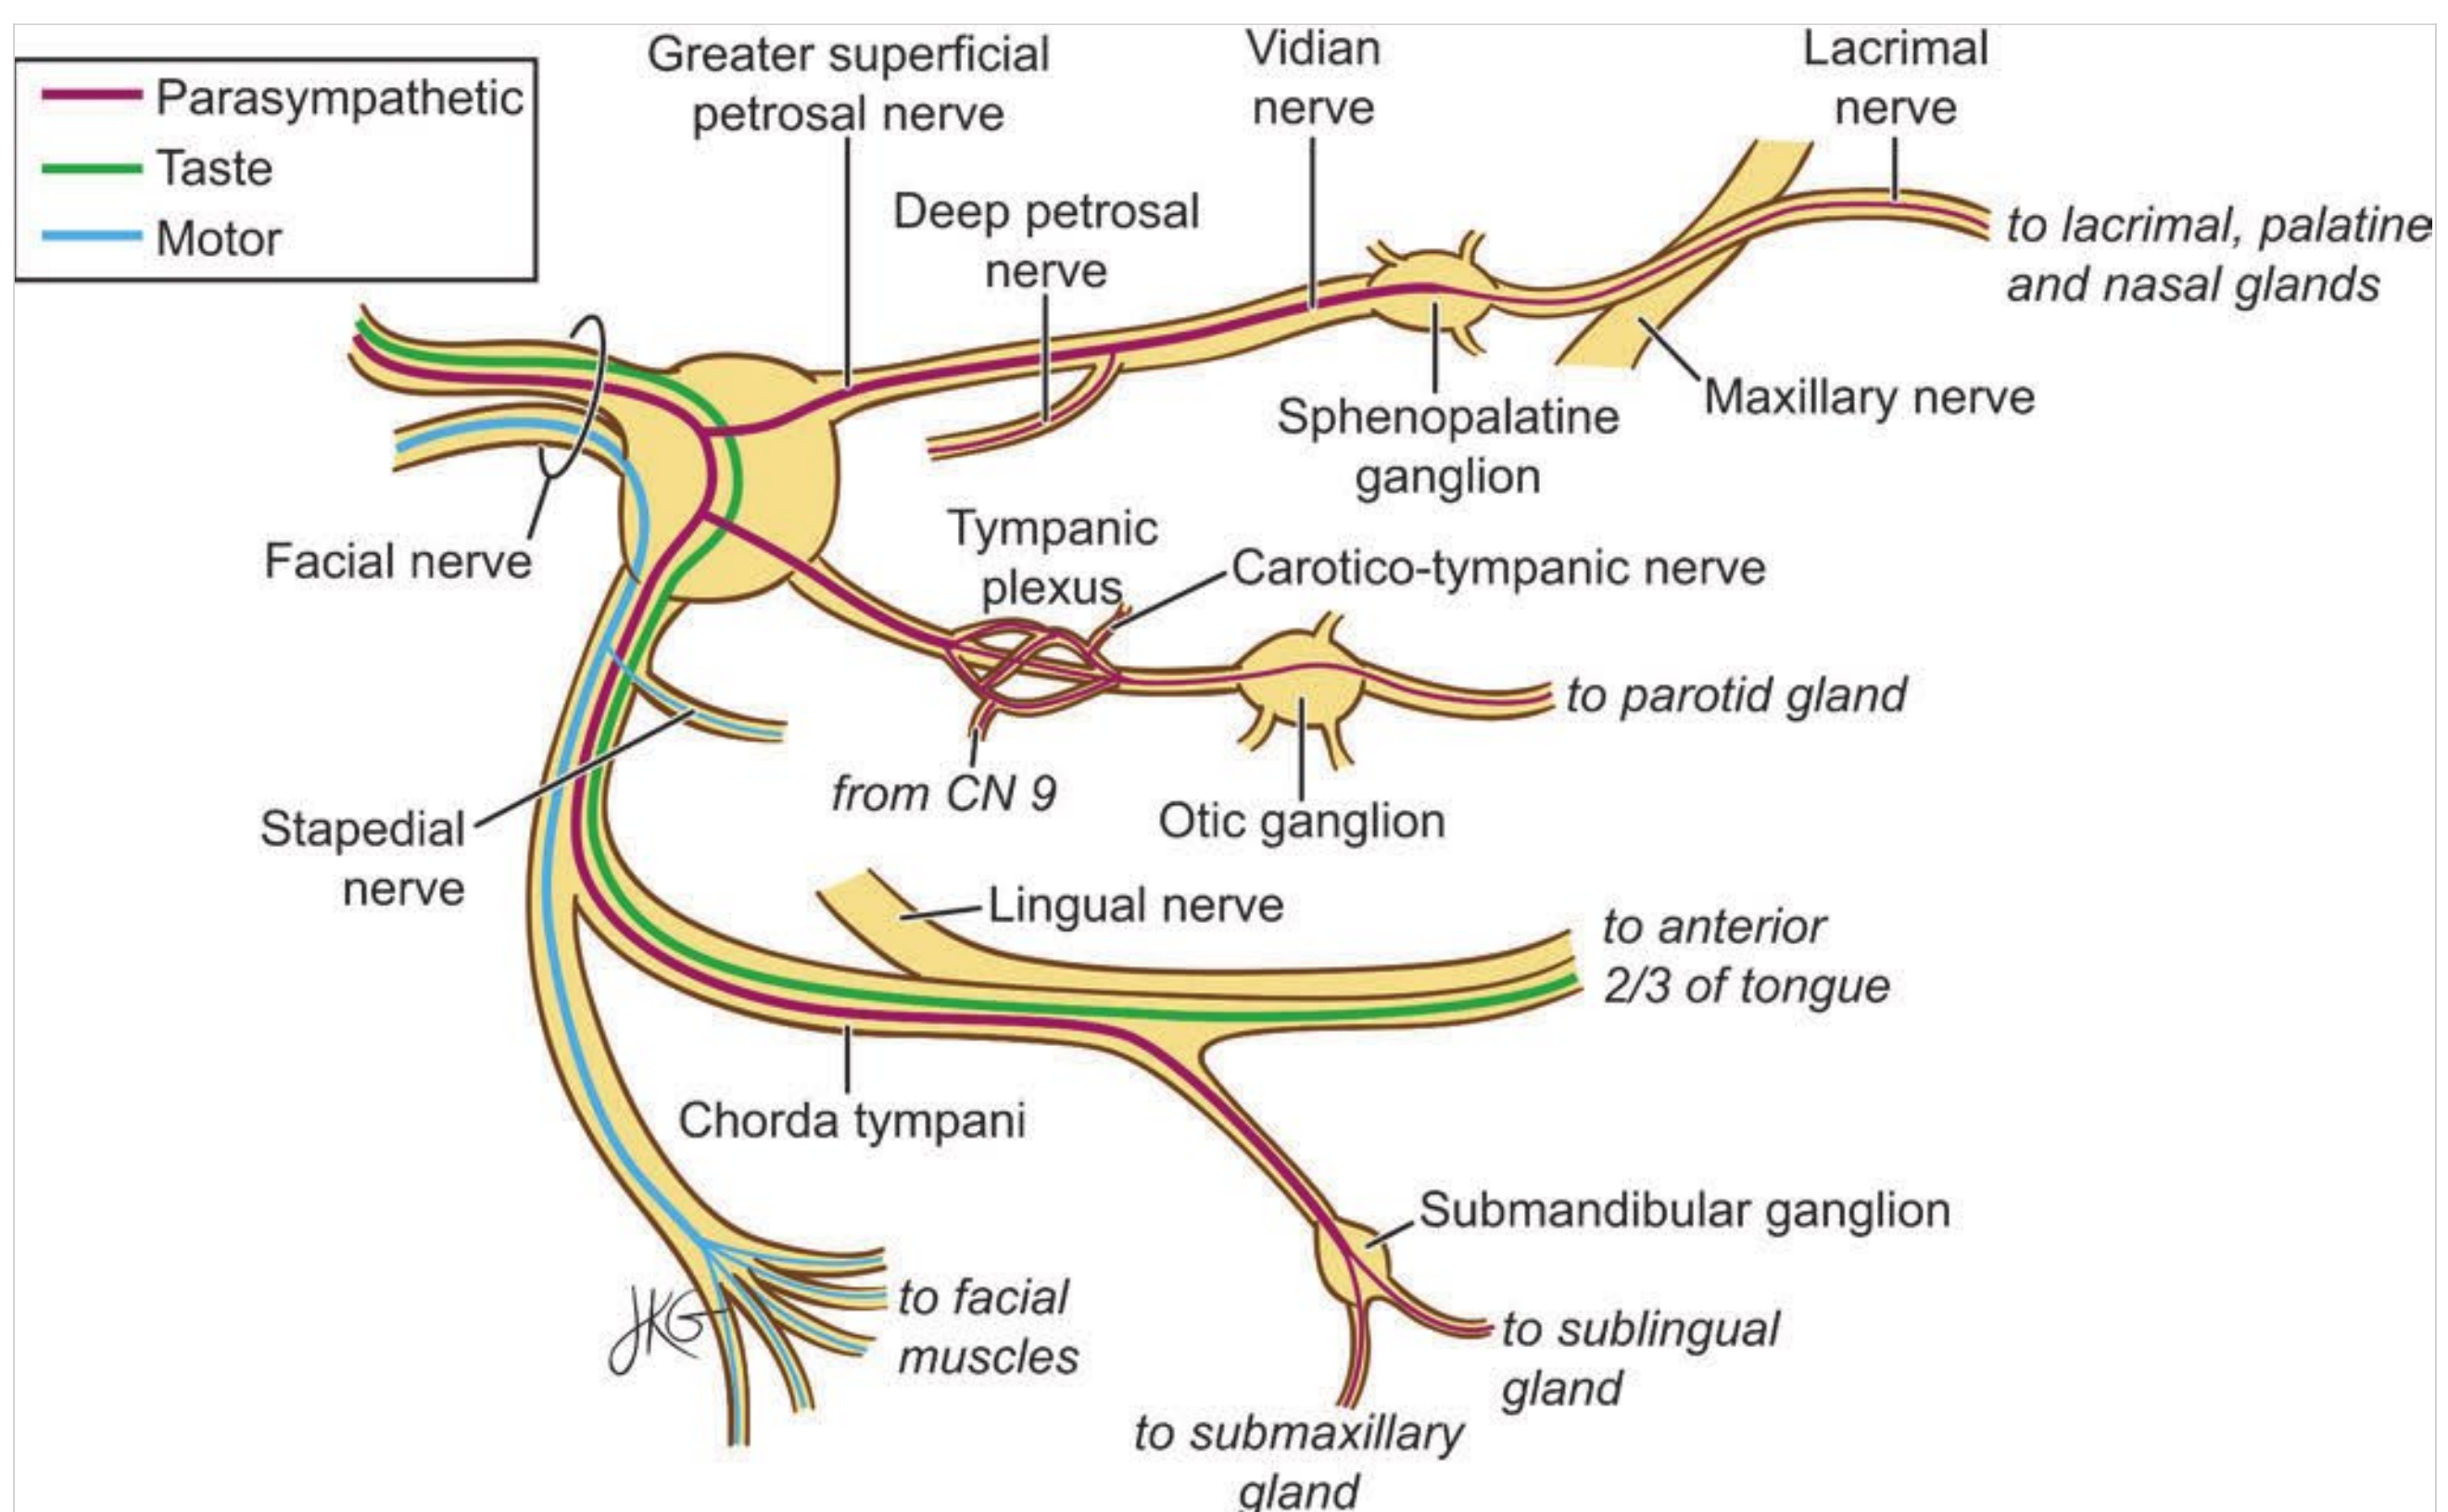

Fig. 132.1 Schematic of the facial nerve.

(3) the nerve to the posterior belly of the digastric muscle; and (4) the lingual branch, which the corda tympani joins to carry afferent special sensation (taste) for the anterior two-thirds of the tongue.

The nervus intermedius exits the brainstem near the motor nucleus of the facial nerve. Cell bodies for lacrimation and salivation, as well as vasomotor fibers destined for the nasal mucosa, arise in the superior salivatory nucleus and join the facial nerve after it has passed the abducens nucleus (CN VI); these structures travel together until the nerve reaches the geniculate ganglion. The greater superficial petrosal nerve takes off at this point, carrying preganglionic parasympathetic fibers for the pterygopalatine ganglion and eventually innervating the lacrimal, minor salivary, and mucosal glands of the palate and nose.

A small named contribution to the facial nerve, the corda tympani, carries special sensory fibers for taste from the anterior two-thirds of the tongue. Its cell bodies are located in the geniculate ganglion. These special sensory afferent fibers will eventually synapse in the medulla in the nucleus solitarius of the tractus solitarius. General sensation for the tongue, however, is mediated by the lingual nerve (CN V₃).

The principal motor functions of the facial nerve are indicated by its anatomical distribution. Teleologically, there are few branches to the extremes of the face because these areas do not serve either to protect the eye or to aid in alimentation. The muscles of facial expression, although of great importance, are of a secondary order because they are not required for life-sustaining functions. The facial nerve branches extensively and densely in the midface to innervate the orbicularis oculi, orbicularis oris, and buccinator, all necessary for life-sustaining functions. The orbicularis oculi and orbicularis oris serve both protective and expressive functions—hence the large amount of anatomy devoted to them.

The cornea, as will be described in greater detail below, is protected by an elaborate system. The afferent fibers of CN V₁ sense when the cornea becomes dry, and a reflex arc to efferent fibers of CN VII in the pons both stimulates lacrimation and initiates blinking. In health, it is an elegant and efficient system. With either an afferent sensory deficit or weakness of CN VII, this system may fail and place the cornea at risk for dryness and exposure.

132.3 Facial Paralysis: History

It is of the utmost importance to concentrate on the time course of facial paralysis. Paresis or paralysis of the face occurring over a matter of minutes (e.g., trauma) or hours (Bell palsy) is usually quite different from that occurring over a period of years (cholesteatoma involving the otic capsule, other inflammatory conditions of the temporal bone and facial nerve, facial nerve neuroma, or rarely acoustic neuroma). What was the overall general health of the patient at the time of the onset of facial dysfunction? Does the patient have any other metabolic disorders, such as diabetes? Did the paralysis occur during pregnancy? What was at first thought to be Bell palsy may in fact turn out to be something completely different after a careful history has been obtained.

Has the patient ever had an episode of paresis or paralysis similar to the current one on the same or opposite side of the

face? Are there any additional findings that the patient has noticed, has been told about, or remembers from a prior episode (e.g., fissuring of the tongue [lingua plicata], as in Melkersson-Rosenthal syndrome)? Was facial paralysis accompanied by vesicular lesions around the ear or soft palate (herpes zoster oticus)? Was any other otologic complaint, such as pain, aural discharge, tinnitus, or vertigo, associated with the loss of facial nerve function? Did facial paralysis occur in the context of otologic surgery? If so, it is important to hear from the referring surgeon or to determine from the operative report the exact nature of the disease being treated, the surgical procedure, and the suspected site of injury to the facial nerve.

Trauma to the temporal bone resulting in facial paralysis requires special consideration. If the patient or an observer remembers the nature of the trauma or it is well documented, this may aid in estimating the likely nature and extent of a facial nerve injury. So often, a patient with severe multisystem trauma is taken to the emergency department of a hospital, stabilized, operated upon for general, orthopedic, or neurologic injury, placed in a surgical intensive care unit (ICU), and thereafter sent to a non-ICU bed on a surgical floor for a few days before a nurse or house officer notices facial weakness or paralysis. Other body systems may have taken precedence and required urgent medical or surgical intervention before any thought was given to facial nerve injury. In other cases, facial nerve function is observed and documented immediately upon arrival in the emergency department. In this latter case, the decision to treat or observe may be more straightforward, much as in the possible surgical management of Bell palsy.

If the patient with traumatic facial paralysis was observed early on to move the face, one can safely bet that at least part of the facial nerve was intact and functioning. If the patient subsequently lost facial function completely, one would treat much as one would with Bell palsy: anti-inflammatory agents (steroids) first, with surgical decompression of the nerve to be considered if the patient lost all clinical and electrical function and was otherwise a surgical candidate.

If, however, the trauma patient has been observed to have no active facial movement upon arrival or was not observed at all early on and now has been found to have facial paralysis and is stable enough for the facial nerve to be evaluated, the temporal bone should be imaged with edge-enhanced computed tomography (CT), which will yield the greatest amount of anatomical information for the bone, air, and soft-tissue interfaces. Further management will be based on this result and the overall health of the patient. A comatose patient is obviously not a candidate for a facial nerve decompression. However, the same patient may be much more functional 2 to 3 months later and still have a facial nerve paralysis. In this case, he or she may be able to endure a facial nerve decompression to definitively manage the nerve, as indicated.

Facial paralysis is much more than a cosmetic deficit. Because eyelid closure depends upon an actively functioning orbicularis oculi, facial nerve dysfunction for any reason places the cornea at risk. With every eye blink, two very important actions happen to the tear film. (1) It is wicked from a superolateral point of production in the lacrimal gland in an inferomedial direction toward the superior and inferior lacrimal puncta. (2) It is then everted, much as a sheet is turned upside down in a dryer.

These two active functions ensure that the tear film is kept fresh and actively moving across the globe to lubricate the cornea. With facial paralysis, this active function is severely impeded or ceases, placing the cornea at risk for exposure. If there is a concomitant corneal afferent sensory deficit (CN V₁), especially in patients who have undergone resection of a large posterior fossa tumor involving CN V, the cornea is now at severe risk for exposure keratitis, abrasion, ulceration, and eventually endophthalmitis. If the condition is left untreated, the patient may ultimately lose sight in the affected eye. Because of the grave potential risk to the globe, it is important that the clinician focus carefully on the eye, especially the health of the cornea. Clinical tests of tearing, such as the Schirmer test, yield information about the quantity but not about the nature of the tear film produced. This information may be obtained by sampling and analyzing the tear film, looking at the hormonal content of the tear film, especially estrogen. In actual practice, this is rarely done by an otolaryngologist. The estrogen concentration in the tear film of postmenopausal women, for example, is decreased in comparison with that in the tear film of premenopausal women, and this decrease is thought to contribute in large measure to the complaint of “dry eye” in patients with otherwise normal facial nerve function. Awareness of the grave consequences of exposure keratitis will ordinarily suffice for both the doctor and patient to keep the eye moist. It is wise to enlist the collaboration of an ophthalmologist experienced in the care of the anterior chamber to help in the care of these patients.

132.4 Physical Examination: Evaluation of Facial Nerve Function

In cases of facial nerve paralysis, detection is generally simple. However, a mild paresis of only one part of the face may be noticeable to the patient alone, especially when the patient is fatigued, and to no other observer.

It is wise to complete the general head and neck examination before focusing on the face. In this way, the likelihood of overlooking potential contributory pathologies, such as a lesion in the parotid, base of the tongue, retromolar trigone, or nasopharynx, will be diminished. Not all pathology involving the facial nerve occurs within the temporal bone. Once the general ear, nose, and throat examination has been performed and is negative, a careful examination of the facial nerve should be performed.

A quick examination will reveal which part of the face has impaired movement. The patient must be instructed not to bite, but simply to try to move the face. Can the patient raise the eyebrow (while the examiner holds down the opposite, “normal” side)? Is there active eyelid closure? Or is there simply passive relaxation of the upper lid with or without a Bell reflex (upward rotation of the globe, protecting the cornea.) Is there an active closed-lipped smile? Do the extremes of the face (frontalis, depressor anguli oris) move? Where is the greatest deficit—upper face versus lower face versus the whole face? Is there synkinesis?

Active movement alone counts. It is a common fault of physicians who should understand the subtleties of facial function to mistake relaxation of the levator (CN III) with active eyelid

closure. This is not active eyelid closure. Even a newborn baby will demonstrate “crow’s-feet” formation at the lateral margins of the orbit while crying, and this pattern alone indicates active contraction of the orbicularis oculi and not relaxation of an adynamic upper lid. The examiner must elicit active motion as opposed to passive relaxation.

It is also important for the physician interested in treating patients with facial paresis/paralysis to study the normal face, to have a good idea of what is “normal.”

132.5 Facial Nerve Grading Systems

Most facial nerve grading systems are based upon the clinical observation of facial nerve function and not upon objective measures of linear displacement, velocity, or acceleration from repose. Although numbers have been assigned in these systems, the numbers should be thought of as “bins,” or levels of function. The various grades of function are not integers, and the assigned number cannot undergo mathematical subtraction or addition.

Two of the more commonly used systems will be described here: the House-Brackmann (H-B) grading system and the Fisch classification. Many other systems have been promulgated. The House-Brackmann system has been approved by the American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) for general use in describing facial nerve function. Although it is commonly used to describe facial function at any time along the course of facial dysfunction, it was actually devised to describe a state of function after medical or surgical intervention (i.e., later on in the course of disease). The House-Brackmann system is easy to learn and apply to the patient (□Table 132.1). The face may be divided into an upper face (containing the eyes) and a lower face. The dividing line in this system is an actively closing eye (H-B III) and an eye that cannot close on its own (H-B IV). Patients with normal facial function in all divisions of the nerve are H-B I; patients with flaccid/adynamic hemifacial function are H-B VI. Minimal paresis of the nerve but with active eyelid closure and no synkinesis is H-B II. Tone only of the face without active facial movement is H-B V. Any amount of synkinesis downgrades the patient to H-B III.

The ease of application of this system is also its greatest disadvantage. Not all H-B III patients are the same, as is true for patients in each H-B grade. There may be marked differences in the appearance of two hemifaces within the exact same classification, especially when the deficit is predominantly in the upper face. Nonetheless, the H-B system has proved to be of great utility in the evaluation and management of facial paralysis.

The second most commonly used system was developed by Fisch. He recognized the problem of sorting out facial function in rigid categories and tried to achieve a point-based grading system that might yield greater predictability for recovery from acute facial dysfunction. In his system, the hemiface is divided into five regions: frontal, eyelid, midface (buccal), mouth, and lower face, corresponding roughly to those regions innervated by the respective branches of the facial nerve: temporal, zygomatic, buccal, mandibular, and cervical rami.

Table 132.1 House-Brackmann classification of facial nerve function

Grade	Clinical description	Resting	Volitional
I	Normal	Normal facial function in all divisions	Normal facial function in all divisions
II	Mild dysfunction	Normal symmetry and tone; slight weakness noted	Mild dysfunction, usually at the extremes of the face; active eyelid closure
III	Moderate dysfunction	Obvious difference between the two sides	Greater dysfunction; active eyelid closure with forced movement
IV	Moderately severe dysfunction	Obvious, disfiguring asymmetry	Greater dysfunction; passive eye closure only
V	Severe dysfunction	Asymmetry at rest; tone only	Barely perceptible motion; passive eye closure only
VI	Total paralysis	Flaccid, adynamic face	Flaccid, adynamic face

Twenty points are awarded for each of the five facial regions, for a total of 100 points. Synkinesis subtracts points from the final score. A higher overall score is better than a lower score and is thought to predict greater return of function. Although this grading system takes a bit longer to calculate, it is intuitive and does attempt to use a clinical metric (i.e. regional observation) to predict outcome. However, it is not truly arithmetic in that the final grading system is ultimately subjective in design and cannot undergo strict mathematical functional analysis.

132.6 Testing

132.6.1 Objective Measurement of Facial Nerve Function

Many attempts have been made to measure facial nerve function in an objective way and thereby to remove observer bias from the calculation. Various methods have been quite ingenious in their ways of measuring facial nerve function.

Facial displacement may be measured linearly with surface electrodes and an electromyographic recording and measuring system. Neely et al and Holman et al used a subtracted-image, computer-assisted technique that measures the degree of facial surface deformation (per expression, per time segment) expressed as a summation of all pixels in the subtracted area. Light reflectance is taken as a two-dimensional marker of the three-dimensional surface deformation occurring during facial expression. Another system uses normal shadows of the various regions of the face and variations of luminance produced by changes of facial expression to calculate linear regional displacement. Landmark-based systems apply some type of fixed marker to the face, with facial movement from repose measured either by hand or via a video/computer digital interface.

These systems are advanced, eloquent, and supremely “believable” in that the data they generate are not subject to observer bias. Unfortunately, almost all of them have the built-in burden of advanced computation and are never real-time. Some require more than an hour of computer time to compute the data analysis for one requested movement (e.g., closed-lip smile). The clinical utility of objective facial nerve function systems is limited, but as a research tool they are superb. With faster “super computers” an objective, real-time metric of facial function may one day be possible.

132.6.2 Topognostic (Site-of-Lesion) Testing

Testing the various branches of the facial nerve for the presence or absence of function has been performed in an effort to locate the site of the lesion. The supposition for these tests is that decreased function at a given site identifies the approximate site of pathology and that the nerve proximal to this site is functioning. These suppositions are not always true. Topognostic testing has been shown to correlate poorly with the chronologic return of function. The accuracy of defining the absolute site of a lesion is also quite low. For these reasons, topognostic testing has largely been replaced by electrical testing of the facial nerve and radiographic imaging of the temporal bone. Perhaps the test of greatest utility is the Schirmer test because it may help identify an eye at risk for exposure keratitis. These tests are reviewed for historical interest (□ Table 132.2).

1. The Schirmer test measures the capillary flow of tears onto a filter paper placed into the inferior fornix of the eye, indirectly measuring the function of the greater superficial petrosal nerve, which is the first branch of CN VII. Tear production is usually markedly reduced in Bell palsy.
2. The stapedius reflex measures the contraction of the stapedius muscle, innervated by the facial nerve. It is usually absent in facial paralysis due to Bell palsy.
3. The blink reflex measures an involuntary reflex arc of the afferent CN V₁ (corneal sensation) to the trigeminal nerve and thence to the brainstem, with connections in the pons and out through the efferent CN VII to the orbicularis oculi. The arc is intact only if some active function of VII remains.
4. The rate and amount of salivary gland production from the submandibular gland may be measured by direct microcatheterization of the Warthin duct. A quantitative decrease in salivary production from the affected side has been thought to help locate the site of facial nerve involvement but is nonspecific.
5. Taste (via the chorda tympani) has been used as a qualitative test of facial dysfunction but has proved to be of little clinical use as a predictor of return of function.

The greatest potential use of topognostic testing remains in cases of temporal bone trauma in which the patient retains a slight amount of facial movement and in which there is a discrete area of injury to the nerve, identified on a CT scan. In these cases, topognostic testing may give clinical clues to the

Table 132.2 Topognostic testing of the facial nerve

Clinical test	Branch of facial nerve
Tearing (Schirmer test)	Greater superficial petrosal nerve
Immittance (stapedial reflex) testing	Stapedial branch
Salivary secretion (cannulation of Warthin duct)	Lingual branch (preganglionic parasympathetic fibers from chorda tympani to lingual nerve)
Blink test	Reflex arc of cranial nerve V ₁ (afferent) and cranial nerve VII (efferent)
Taste test	Chorda tympani nerve

precise area of injury. In the majority of cases, however, the face is flaccid and adynamic.

Because the point of greatest narrowing of the intratympanic facial nerve is at the meatal foramen and because supramaximal stimulation of the facial nerve with electroneuronography (compound muscle action potential) has been shown to be a better predictor of facial nerve outcome, topognostic testing is now of secondary utility and is indeed of historical interest in the diagnostic evaluation of idiopathic facial paralysis. The Schirmer test, along with slit-lamp fluorescein testing for punctate keratopathy, is still performed as part of a global assessment of corneal health. Other than this, topognostic testing is rarely done today because its utility is low compared with that of other tests.

132.6.3 Audiogram

All patients with facial paralysis, regardless of the suspected cause, should have an audiogram with a minimum battery of tests, performed separately for each ear, of pure tones, bone conduction (masked appropriately), word discrimination, and immittance with reflex decay, if the level of hearing permits. Otologic and neurotologic medical and surgical advice must be based upon a reliable audiogram performed by a trained and licensed audiologist.

Otoacoustic emission (OAE) testing and auditory brainstem response (ABR) testing may be considered if the patient is unresponsive or cannot otherwise cooperate with a behavioral audiogram. The OAE test is a “pass or fail” examination and will not detect the presence of audition below about 40 dB. Therefore, its utility is somewhat limited. If facial nerve neuroma is suspected as a part of retrocochlear pathology, the ABR test may be helpful as part of the test battery to determine if hearing can be preserved in the management of a neoplasm affecting the facial nerve.

As has already been described, the middle ear muscle reflexes (immittance) would be expected to be affected in facial paralysis, depending upon the site of the paralysis.

132.6.4 Electrical Testing of the Facial Nerve

The ordinarily possible test battery of the facial nerve is large and includes the following types of tests.

Minimal Excitability Test

This test employs a portable, battery-powered, transcutaneous stimulator of the facial nerve. A Hilger stimulator (WR Medical

Electronics, Stillwater, MN) or similar device is placed on the face near the stylomastoid foramen of both the normal (reference) and affected sides. The lowest stimulus intensity that excites all branches of the nerve on the unaffected side is considered the electrical baseline. A 2.0- to 3.5-mA difference between the normal and affected sides indicates impending denervation of the affected side. Advantages of this technique are its portability, relatively low electric current requirements, and relatively low level of discomfort for the test subject. The disadvantage is that the metric is subjective; the tester must judge that all branches are either moving or not. In addition, the test may excite larger branches more easily than smaller branches and give a false picture of the overall function of the nerve.

Maximal Excitability Test

A transcutaneous electrical device is employed to maximally saturate and stimulate both the unaffected and affected sides of the face. A subjective determination is made that the affected side is (1) the same as the normal side, (2) 50% diminished (minimally affected) when compared with the normal side, (3) 75% diminished (markedly affected) when compared with the normal side, or (4) 100% diminished (completely affected), with an absence of electrical stimulation. The advantage of this test is its ease of application. The obvious disadvantage is that it is a subjective test and lacks a metric to quantify the degree of facial dysfunction.

Supramaximal Tests (Electroneuronography/ Evoked Electromyography)

In electroneuronography (ENOG), a supramaximal stimulation of the facial nerve is applied at its junction with the face at the stylomastoid foramen, and the amplitude of the compound muscle action potential (cMAP) is recorded at the site of greatest amplitude. This technique allows a comparison of the response of the affected side with the unaffected side to be displayed and recorded and may be used to measure the relative integrity of working axons within the nerve. ENOG is very helpful for identifying nerve degeneration and for prognosticating the likelihood of return of function, as well as possible adverse sequelae of the affected nerve. ENOG is of clinical value when a nerve injury is “in evolution”—that is, after wallerian degeneration should have occurred (48 to 72 hours after the onset of paralysis) but within 2 to 3 weeks after the onset of facial paralysis. It is of little value after this time because of the dyssynchrony of fibers within an affected nerve. ENOG is also of secondary importance if any part of the affected side is actively

moving, and the clinical examination always takes precedence over ENOG.

When used during this window, however, ENOG has been shown to reliably predict good versus poor prognosis for recovery. A 90% threshold is used; patients who retain at least 10% of electrical function on ENOG testing are thought to have a better clinical outcome than those with 10% or less of electrical function.

Because of its ability to offer an objective metric and its relative ease of application, this test now supersedes almost all others in clinical use. It has become the mainstay of clinical practice. Its chief drawback is its learning curve; an inexperienced technician may erroneously stimulate the masseter (V) and obtain falsely encouraging results. These false-positive results occur mainly in children and in patients with very thin necks.

The term electroneuronography is synonymous with the term compound muscle action potential, which is used more commonly by neurologists.

Electromyography of the Facial Muscles

The response of an individual muscle or its fibers to either the voluntary initiation of movement or electrical stimulation may be recorded at the neuromuscular junction with monopolar (bare-tip) or coaxial (concentric) needle electrodes. Voluntary and spontaneously generated facial motor responses are measured and compared with those in neighboring groups on the affected side and in equivalent groups on the unaffected side.

Quantification in units of electric potential, current flow, or resistance may be used to indicate relative function versus lack of the same in a given muscle group. The greatest utility of electromyography (EMG) is in the measurement of facial nerve integrity and the prognostication of expected return of function in patients with significant neurapraxia, such as after acoustic neuroma dissection, or possible neurotmesis after temporal bone fracture.

EMG recordings made 10 to 14 days after the onset of clinical paralysis reflect the dynamic resting membrane potentials of postsynaptic elements. In this phase, the muscle membrane, deprived of “trophic” substances that are normally transported through the axon, undergoes changes that destabilize the resting potential. These changes produce spontaneous depolarizations reflected in the EMG as fibrillation potentials and are interpreted as indicators of persistent denervation.

Successful reinnervation generates high-frequency polyphasic potentials that increase in amplitude and duration and replace fibrillation potentials. These polyphasic potentials may be used to measure the course of reinnervation.

Magnetic Stimulation

Transcranial electrical stimulation has been performed in an effort to stimulate the facial nerve proximal to a suspected intratemporal lesion, and continuous orthograde stimulation has been used during the dissection of skull base lesions in which the facial nerve is adjacent to the pathologic process. Although less selective than other means of facial nerve stimulation, it has been demonstrated that the stimulation of cortical representations of the facial nerve is possible. This method of facial nerve stimulation has not yet gained widespread use.

Of these tests, ENOG and needle EMG are by far the most frequently utilized clinically. They provide real-time information about the status of the nerve, so that the course of facial paralysis in electrical evolution can be followed and the likelihood of recovery can be predicted.

In practice, in a patient with acute complete facial paralysis, most otologists will rely upon ENOG (cMAP) to guide the decision between medical treatment (steroids, antivirals, and lubrication) and surgical decompression of the facial nerve.

132.6.5 Radiographic Evaluation

For patients who have idiopathic facial paralysis without accompanying hearing loss, early radiographic imaging is usually not indicated because it will not affect either the clinical decision-making process or the eventual outcome. Because idiopathic facial paralysis (Bell palsy) results in inflammation of the nerve, especially at the meatal foramen, it is expected that magnetic resonance (MR) imaging of the temporal bone and brain will demonstrate enhancement of the nerve. This is usually found and in no way indicates a retrocochlear neoplasm. However, the finding of nerve enhancement does not exclude a retrocochlear neoplasm. It does commit the patient and the third-party payer to a second, follow-up MR imaging session after inflammation would be expected to have subsided, about 6 months later. If hearing in the two ears is equal, it is a waste of time, money, and effort to obtain MR imaging in the acute phase because inflammation will cause a positive result. All patients with idiopathic facial paralysis would be expected to recover at least some function. In now famous demographic studies, Peitersen described the natural history of untreated (but observed) idiopathic facial paralysis. No one who had truly idiopathic (Bell) palsy was left with a flaccid, adynamic face. Approximately 71% had nearly perfect recovery; 29% had imperfect recovery of either a facial region or synkinesis. One of the important findings of this study was that all patients had some recovery of facial function. Those who had no recovery did not strictly have Bell palsy and were further studied to exclude retrocochlear neoplasia, including facial nerve neuroma and other lesions. For these rare patients, a retrocochlear imaging study would be appropriate at this time, not during the acute inflammatory phase.

If there is asymmetric neurosensory hearing loss, unilateral tinnitus, involvement of another cranial nerve, or any concomitant neurologic deficit, these must be investigated as they would be if facial paralysis were not part of the clinical picture. It is the unilateral hearing loss, tinnitus, or other conditions that drive the retrocochlear investigation, not acute facial weakness.

Facial paralysis occurring in the context of acute or chronic inflammatory or infectious disease should be investigated as the underlying disease would be—that is, ordinarily with computed tomography (CT) of the temporal bone. The expected course of the intratympanic facial nerve is easy to follow in the normal temporal bone. Its expected location may be lost in inflammatory or infectious disease, thus pinpointing the likely site of facial nerve involvement.

Temporal bone trauma is best investigated with CT of the temporal bone. With edge-enhanced studies, the temporal bone may be imaged in any plane, including planes at a right angle to and coaxial to the suspected direction of the injury. Any angle

may be imaged with modern scanning equipment. In facial nerve trauma, one wants to best detail the bony architecture as it affects the normal and expected pathway of the intratympanic facial nerve. Ultimately, the decision must be made to observe or to operate, and the CT will better guide this decision than MR imaging. If there is complete loss of hearing along with facial paralysis, one would expect to find a transverse or mixed fracture of the temporal bone involving the otic capsule. If the otic capsule has been spared and if the patient has a conductive pattern of hearing loss, one would expect a longitudinal fracture of the temporal bone. Rarely, a discrete fracture line may be seen pointing to the geniculate ganglion with no other findings. Because the geniculate is “tethered” by the greater superficial petrosal branch, it is a likely site of injury and should be carefully inspected.

132.7 Differential Diagnosis

A complete listing of all the conditions that cause facial paralysis would be enormous, and it is impractical to investigate them in day-to-day clinical practice. It is important for the clinician to think broadly as he or she takes the patient’s history and let the patient’s story point toward the most likely cause of facial weakness. The time course of facial weakness is probably the most important part of the history. Also of great importance in the history is recurrence: has the patient ever had a similar episode on the same or opposite side? Does the patient have any known metabolic or neurologic problems, such as neurofibroma formation or a family history of these? The common causes of acute facial paralysis are presented in □ Table 132.3. For the general otolaryngologist practicing in a community setting, cases of acute facial paralysis will most frequently be Bell palsy (idiopathic) or associated with herpes zoster oticus, infectious/inflammatory conditions including Lyme disease, and temporal bone trauma. Other conditions are included for the sake of completeness but are rarely seen in a community-based practice.

132.8 Treatment

132.8.1 Medical Treatment

The mainstay of medical care for acute facial paralysis is lubrication and passive protection of the cornea, and the administration of corticosteroids. Any oral form of steroid may be chosen, with the dose equivalent of approximately 1 mg of prednisone per kilogram. Regardless of the cosmetic deficit, the patient must be instructed that the real problem at hand is ongoing exposure of the eye, and every effort must be taken to ensure that the cornea is kept moist.

There is controversial and inconclusive but nonetheless suggestive evidence from acute and convalescent serologic studies that idiopathic facial paralysis may be linked to a herpetic infection, especially herpes simplex type 1. Because of this, there is currently little objection to the addition of antiviral medications such as acyclovir and famciclovir to the medical treatment of acute idiopathic facial paralysis. For patients with known herpetic infections, such as Ramsey Hunt syndrome (herpes zoster oticus), antiviral medications would be indicated along with steroids, usually for 5 to 7 days. The patient’s hepatic function may need to be monitored for higher or longer dosing regimens.

Rarely, acute facial paralysis may be part of a polyneuropathy involving both the seventh and eighth cranial nerves, as is occasionally seen in Ramsey Hunt syndrome. These patients may require acute hospitalization and sedation to control vertigo.

In addition to artificial tears and salves, many other nonsurgical techniques are readily available to help in acute facial paralysis. The affected eye may be taped shut or may be covered with a clear plastic moisture chamber. This is somewhat bulky but changes the local milieu of the cornea from dry to moist and may be required acutely in exposure keratitis. Patching the eye is less desirable because the levator palpebrae superioris (CN III) remains functional and unopposed and may keep the eyelid open underneath the patch, especially during sleep. The lower lid may be suspended with a thin adhesive tape if tone is absent and ectropion develops. A small fusiform piece of adhesive tape placed above the tarsal crease may help to keep the upper lid in a somewhat ptotic position, thus improving passive closure of the eyelid. Patients are instructed in these local measures, and it is important to enlist the aid of an ophthalmologist to prevent any ocular injuries in the setting of incomplete eye closure.

Parenteral steroid medications are rarely indicated in the treatment of acute facial paralysis. However, they may be indicated in a patient who is hospitalized following traumatic multisystem injury and whose face is not actively moving. Depending upon concomitant injuries and the general state of the patient, it may be desirable to treat with intravenous or intramuscular steroid medication. Similarly, in patients with multiple cranial nerve involvement and vertigo, intravenous treatment with steroids and sedation may be of benefit if nausea and vomiting are severe and persistent.

132.8.2 Surgical Treatment

Eyelid

The oculoplastic literature is replete with various techniques used to protect the cornea in acute paralysis. One need not formally train in oculoplastic surgery to readily and adequately treat acute paralytic corneal exposure. A few simple surgical techniques are easy to master and should be in the armamentarium of any surgeon treating patients with facial paralysis. Most patients will do very well with a temporary tarsorrhaphy or a gold or platinum weight properly placed to counterbalance the levator. The technique of lid loading is straightforward and easy to learn, and it may be performed under straight local anesthesia in an office-based procedure room. However, it is important for the nonophthalmologist to know his or her limits. The Asian paralytic eyelid or an eyelid with in-turning lashes for any reason is a very difficult eyelid to manage. These paralytic eyelids often do poorly with standard, simple surgical techniques, and patients should be referred immediately to the oculoplastic surgeon.

Tarsorrhaphy

Tarsorrhaphy is a static technique of corneal protection. It does not aid in wicking the tear film across the globe. Although it has been the mainstay of treatment of the acutely paralytic eyelid, it has largely fallen into disfavor because other, dynamic techniques are readily available. Nonetheless, it is occasionally

Table 132.3 Differential diagnosis of facial paralysis

Etiology	Conditions	
Birth	Forceps delivery Myotonic dystrophy Möbius syndrome (facial diplegia associated with other cranial nerve deficits)	
Trauma	Cerebrocortical injuries Penetrating injury to the middle ear Brainstem injuries	Basilar skull fractures Barotrauma (altitude paralysis, scuba diving)
Neurologic	Opercular syndrome (cortical lesion in facial motor area)	Millard-Gubler syndrome (abducens palsy with contralateral hemiplegia due to lesion in base of the pons involving corticospinal tract)
Infectious	Necrotizing otitis externa Otitis media (acute or chronic)/mastoiditis Meningitis Parotitis Cholesteatoma (acquired or congenital) Chickenpox Herpes zoster oticus (Ramsay Hunt syndrome) HIV/AIDS Syphilis Lyme disease	Influenza Coxsackievirus infection Tuberculosis Mucormycosis Botulism Leprosy Malaria Scleroma
Metabolic	Diabetes mellitus Hyperthyroidism Hypertension	Pregnancy Acute porphyria
Vascular	Embolization for epistaxis (external carotid branches) Anomalous sigmoid sinus Intratemporal aneurysm of internal carotid artery Benign intracranial hypertension	
Neoplastic	Acoustic neuroma Meningioma Parotid tumors (benign or malignant) Sarcoma Facial nerve neuroma Metastatic carcinoma (breast, kidney, lung, prostate, thyroid); malignant melanoma	Fibrous dysplasia Hemangioblastoma Glomus jugulare Neurofibromatosis (von Recklinghausen disease) Hand-Schüller-Christian disease Leukemia
Toxic	Thalidomide (Miehlke syndrome: cranial nerves VI and VII with congenital malformed external ears and deafness) Lead intoxication	Carbon monoxide poisoning
Iatrogenic	Otologic, neurotologic, skull base, head and neck surgery Antitetanus serum Local anesthesia infiltration	Rabies vaccine Dental surgery, mandibular block anesthesia Embolization
Autoimmune/idiopathic	Bell palsy Temporal arteritis Guillan-Barré syndrome (ascending paralysis) Paget disease of bone Melkersson-Rosenthal syndrome (recurrent facial palsy, furrowed tongue [lingua plicata], facioliabial edema) Sarcoidosis (Heerfordt syndrome, uveoparotid fever, periarteritis nodosa, myasthenia gravis)	Multiple sclerosis Amyloidosis Hereditary hypertrophic neuropathy (Charcot-Marie-Tooth disease, Dejerine Sottas disease) Idiopathic thrombocytopenia purpura Osteopetrosis (marble bone disease) Kawasaki disease (infantile acute febrile mucocutaneous lymph node syndrome)

indicated, and the surgeon caring for patients with acute or chronic facial paralysis should understand the technique and be able to perform it.

The rare patient, especially one with a CN V₁ afferent deficit, may suffer from exposure keratitis despite common means of corneal protection. In certain instances, a lateral and/or medial tarsorrhaphy must be performed in order to narrow the area of corneal exposure and still allow frontal vision. The typical patient is elderly with a large, partially resected acoustic neuroma or meningioma extending anteriorly toward the petrous apex

and involving the trigeminal nerve. The patient may already have been treated with irradiation or for whatever reason is no longer a candidate for skull base resection. These rare patients must be managed in concert with an ophthalmologist experienced in the care of the cornea.

Temporary

Under local anesthesia and with corneal protection, one or two sutures (e.g., 4-0 silk) are placed in the lateral and/or medial canthal areas between the upper and lower lids. If the need is

expected to be temporary, the surgeon need not expose mucosa in order to create a controlled, apposed scar. A lateral tarsorrhaphy will limit lateral gaze; a medial tarsorrhaphy will limit medial gaze. The occasional patient may require both medial and lateral tarsorrhaphies. In this case, the field of vision will be severely limited.

Permanent

The technique is the same as that for temporary tarsorrhaphy with a few modifications. A small (2 x 3 or 4 mm) strip of skin and mucosa is removed from the upper and lower lids in the area of the intended tarsorrhaphy (lateral and/or medial). One or two mattress sutures are placed (with or without silicon bolsters) to appose the raw surfaces. These are left in place for 7 to 10 days, then removed in the office. The result should be a controlled and healed apposition of the upper and lower lids. Permanent tarsorrhaphy is indicated when an insensate cornea and paralytic eyelid place the cornea at extreme risk.

Palpebral Spring

A palpebral spring may be thought of as an open safety pin under the upper eyelid. Because the levator muscle (CN III) is almost always normal and unopposed, the eyelid will have normal opening forces. These opening forces are opposed by a spring, made from biocompatible material (usually gold) and inserted under the upper lid to force it into the closed position. This technique, although straightforward and relatively simple, in most cases requires revision because of slippage of the spring or because of the changing needs of opposing force as the eyelid recovers motor function. In large measure, it has been replaced by lid-loading techniques.

Lid Loading

The paralytic eyelid over time will be more and more at risk for exposure because the levator palpebrae superioris is unopposed and usually normal. Over time, the cornea will become progressively exposed and dry. In normal function, the tear film is actively pumped and wicked across the globe, as has been previously described. This process is diminished or absent in facial paralysis. Various techniques of loading the upper lid with various materials or implanting springs have been developed in an effort to counteract the tonic retraction of the unopposed levator. Although none of these methods is perfect when compared with normal, active eyelid closure or blink, some very simple techniques offer the patient with an affected cornea immediate benefit.

The most important technique is lid loading with a bar of pure (24-kt) gold or platinum weighing 0.6 to 1.6 g; weights are in increments of 0.2 g. The bar to be implanted is either taped or affixed to the paralytic eyelid with a temporary fixative, usually tincture of benzoin or double-sided adhesive tape. The patient is placed in a sitting position and is asked to relax the eyelid. The patient makes a decision about the most comfortable weight; the surgeon chooses the weight providing the best closure. Topical corneal anesthesia is provided with drops (0.5% tetracaine), and the lid is injected with 1% lidocaine with epinephrine 1:100,000. This outpatient procedure may be done under straight local anesthesia, with or without intravenous

sedation. Most patients will require a 1.0- to 1.2-g weight. The gold or platinum bar is implanted in a small pocket made at or above the level of the tarsal crease and is suture-fixed to the pretarsal soft tissue. A layered closure of the orbicularis oculi and skin must be performed because the foreign body (gold or platinum bar) crosses an incision line. When the eyelid is relaxed, gravity will allow the upper lid to close. It is important for the patient to be told that this technique provides better passive closure in the sitting or standing position, less so in the supine position. When facial function returns, the eyelid may feel excessively heavy because the now-functioning orbicularis oculi is reinforced with the weight. At this time, after consultation with the ophthalmologist, the weight may be removed.

Canthoplasty for Ectropion Repair

The paralytic lower eyelid may become ptotic over time and lead to further exposure of the cornea. Epiphora may become an additional problem due to sagging of the paralytic lower lid. This is especially so in patients age 55 and older in whom the normal supportive and elastic properties of the face have already weakened. For patients with facial paralysis who are older than 50 years of age, ectropion formation should be anticipated and the lower lid supported with a small lateral canthoplasty. This technique is easy to understand and master. The arch of the upper lid is drawn downward for about 6 mm. A line 4 to 5 mm medial to the lateral canthus is also drawn. The lower lid is injected with local anesthetic. The incisions to be made are grasped with straight hemostats placed in the inferior fornix, and the small triangle so clamped is removed. The inferior tarsal plate/lateral canthal tendon is supported with a suture of 5-0 clear nylon or other permanent suture placed at the lateral canthal tubercle. The skin is closed with interrupted sutures of 5-0 fast-absorbing gut.

Facial Nerve Decompression

Decompression of the facial nerve in the acute time period remains controversial. The main questions to be answered are the following: (1) In the acute situation, does facial nerve decompression significantly improve the outcome of facial paralysis over standard medical management? (2) Which patient should be selected for facial nerve decompression?

Very few well-designed, prospective, randomized clinical studies with large numbers of patients have attempted to answer these questions. The important work of Peitersen in studying the natural history of untreated idiopathic facial paralysis should loom large in the mind of any surgeon contemplating decompression of the facial nerve for a patient with Bell palsy. A further confounding factor is that the metric for the most part is subjective (i.e., the House-Brackmann or Fisch classification system). There is no universal, easy-to-apply objective system for measuring facial movement or expression, and electrical testing of the facial nerve is of value only within the first 10 to 14 days after the onset of facial paralysis.

For surgeons interested in this field, the seminal work of Professor Fisch must be carefully studied and mastered, with the acknowledgment that the numbers of patients both observed and treated are not large. In addition, to be recalled is that the outcome grading of facial movement was better by the surgeon

and worse by the patient, the person with the problem. In general, based upon his work in patients with idiopathic facial paralysis, a window of opportunity of approximately 2 weeks exists between the onset of clinical paralysis (not paresis) and electrical degeneration of 90% or more by ENOG testing in which decompression of the facial nerve (and especially the meatal segment of the facial nerve) will beneficially affect the clinical outcome of the nerve. Both the time window and indication for decompression remain controversial in cases of acute idiopathic facial paralysis.

Of less controversy are cases of traumatic facial paralysis and, for many surgeons, herpes zoster oticus.

Patients with temporal bone trauma may be treated in the same way as those with Bell palsy, depending upon the timing of observation of the face, as has been previously described.

The natural history of facial function after herpes zoster oticus is bleak for patients with both clinical and electric paralysis. Approximately 50 to 60% of patients with facial paralysis due to herpes zoster oticus will have adverse sequelae: lack of reinnervation and/or synkinesis. Because of the poor natural history of herpes zoster oticus, the case for surgical decompression may be more compelling in patients with this condition than in those with idiopathic facial paralysis.

Delayed Surgery for the Eye

The various techniques previously described may be used for patients with chronic facial paralysis. What may not be delayed is adequate lubrication and protection of the cornea. For patients with facial paralysis for 3 weeks or longer, it is wise to consult with an ophthalmologist experienced in corneal care to offer guidance about corneal health and the risk for exposure keratitis.

Patients with chronic facial paralysis and brow ptosis may have severely limited field vision on the affected side. The parietic eyelid may retract under the ptotic brow (lateral hooding) and cause poor natural toilet of the cornea. All of these factors may predispose the eye to blepharitis, chronic conjunctivitis, and further infection. In the chronic state, the needs and level of activity of the patient, such as driving and reading, must be taken into account. The vision in both the affected and unaffected eyes should be carefully evaluated. The elderly patient may have cataract formation that will require treatment. Glaucoma may be found in one or both eyes. The overall health of the eye must be evaluated along with the requirements of facial movement.

When indicated, the ptotic brow may be lifted with a variety of straightforward techniques (endoscopically, directly above the brow line, or through a re-created forehead crease; see Chapter 56). The lifted brow will now be in a more neutral position just above the level of the superior orbital rim and allow the upper lid to be seen. The upper lid may require lid loading at this time to counterbalance the chronic retraction of the levator oculi. The lower lid may have undergone ectropion formation that may require correction. An experienced ophthalmologist must be consulted to help thoroughly evaluate the vision in both eyes, as well as the overall needs and goals of the patient.

Face

Many techniques exist for facial reanimation. The surgical catalogue is far too great to describe in detail for the purposes of

this summary. The interested reader is referred Chapter 51 for further discussion.

Synkinesis after return of facial function may be relieved with the selective use of botulinum toxin (Botox; Allergan, Irvine, CA) to chemically denervate unwanted facial movement temporarily. If desired, a more permanent selective denervation may be achieved either chemically (with phenol or absolute alcohol) or surgically.

There is no surgical technique of facial reanimation that will equal a working, normal facial nerve. Reconstructive procedures are in essence attempts to restore facial symmetry (static procedures) or isolated and/or regional facial movement (dynamic procedures), but the patient will never possess the subtlety of mimetic facial expression provided by a normal, functioning facial nerve. This fact must be clearly understood by the patient (and physician) so that reasonable goals and expectations may be achieved. It is always better to underplay intended surgical results and have a delighted patient than to overstate them and have a disappointed one. Neither physician nor patient should yield to magical, unrealistic thinking.

The physician must carefully attend to the history and time course of the paralysis and the functional needs and goals of the patient. Consultation with other physicians and surgeons in related disciplines, especially ophthalmology, may be required to achieve the best overall plan for the patient. With all of these techniques, the best plan for restoring facial function to the individual who has facial paralysis may be reached.

132.9 Case Examples

132.9.1 Case 1: Recurrent Bell Palsy

A 13-year-old girl presented with a 7-day history of left facial paralysis. A prior episode of facial paralysis on the same side had occurred about 2 years prior. There were no other contributing findings: no fissuring of the tongue and no vesicles around the ear or in the nasopharynx. The hearing was within normal limits by tuning fork and audiometric examination. The left ipsilateral and right contralateral acoustic reflexes were absent, as expected. She had no facial movement on the left side (H-B VI/VI), but an intact Bell reflex (□ Fig. 132.2). ENOG was obtained and showed complete degeneration of the left facial nerve (□ Fig. 132.3). Nonenhanced CT of the petrous temporal bones was normal. Because by history she had recurrent facial paralysis, her parents were instructed that a surgical decompression of the left facial nerve would be advisable in order to increase the chances of a good outcome and help prevent recurrent episodes of left facial paralysis. They agreed to this and gave consent for the procedure. The patient underwent surgical decompression of the complete facial nerve (□ Fig. 132.4). She healed well and has a very slight weakness of the left ramus mandibularis as her only sequela (□ Fig. 132.5). She has been followed for longer than 10 years and has had no subsequent episodes of facial paralysis.

132.9.2 Case 2: Herpes Zoster Oticus

A 32-year-old man presented with right facial paralysis of 2 weeks' duration. He had no active eyelid closure and severe right facial dysfunction (H-B VI/VI). The facial paralysis had

Fig. 132.2 Case 1. (a,b) Left facial paralysis with an intact Bell reflex.

Fig. 132.4 Case 1: Intraoperative findings during left facial nerve decompression. A, head of malleus; B, short process of incus; C, left geniculate ganglion; D, labyrinthine segment of left facial nerve.

been preceded by an eruption of blisters around his right ear and lower face in the distribution of right CN V₁, and the patient presented to the office 8 days after the onset of facial paralysis.

The otoscopic examination was normal. The patient had a few healing blisters (□ Fig. 132.6) around the right ear, none in the oropharynx or nasopharynx. The tuning fork test at 512 Hz

Fig. 132.3 Case 1: Electroneuronogram shows 100% degeneration of left facial nerve function.

Fig. 132.5 Case 1: Postoperative result.

was normal, as was his level of audition. ENOG was obtained, which showed 64% degeneration of the seventh cranial nerve on the right (□ Fig. 132.7).

The patient had previously been started on very low doses of corticosteroids, which were changed to prednisone 60 mg/d for 10 days with tapering thereafter. He had already been treated with famciclovir 2 g/d for 7 days, which was not continued. The patient was using artificial tears during the day and lubrication at night, but he still had excessive dryness of the right eye during the day. A gold weight was inserted in the right upper lid under local anesthesia approximately 1 week after presentation. Serial ENOG never revealed degeneration of the right facial nerve of more than 62%. At the second week after presentation, a slight twitch of motion was detected in the right frontalis region. The right side of the face returned to normal function without synkinesis. Patient has now been followed for at least 3 years and is normal with an H-B I classification.

132.9.3 Case 3: Temporal Bone Trauma (Gunshot Wound)

A 27-year-old man was brought to a New York City emergency room after sustaining a gunshot wound to the right side of his face at close range (□ Fig. 132.8). He was unconscious on arrival

Fig. 132.6 Case 2: Vesicular eruption in the inferior right concha.

Fig. 132.8 Case 3: Gunshot wound to the right side of the face.

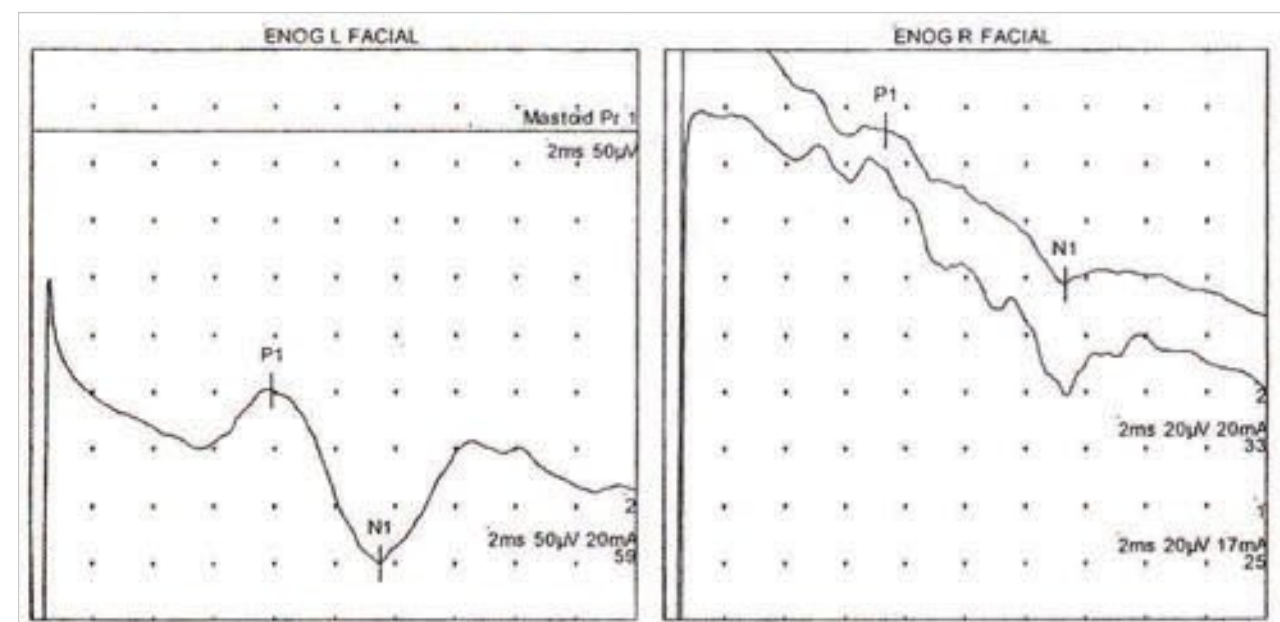

Fig. 132.7 Case 2: Electroneuronogram 3 days after the onset of right facial paralysis, showing partial degeneration of the right facial nerve. ENOG, electroneuronogram.

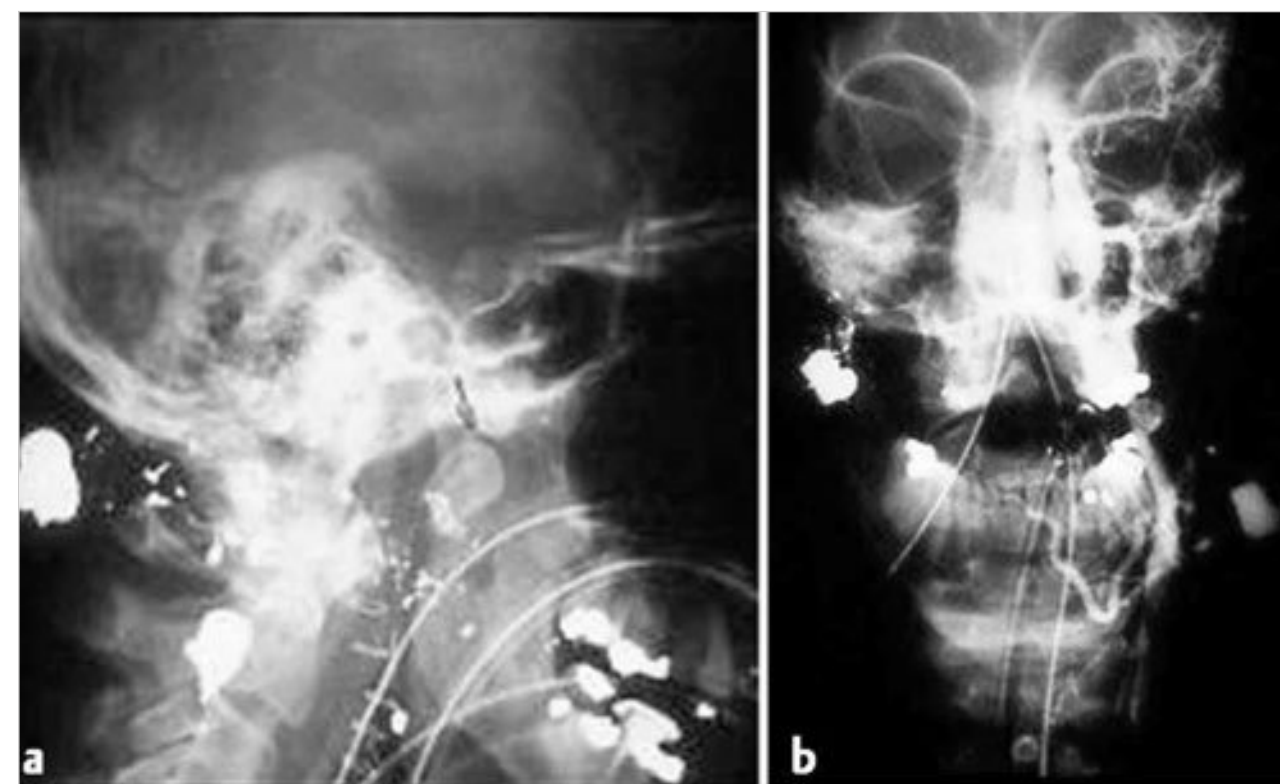

Fig. 132.9 Case 3: (a) Lateral and (b) frontal plain X-rays of the face and neck, with shrapnel in the right mastoid and left neck. (c) Angiogram of the left carotid artery, with shrapnel at the site of a pseudoaneurysm.

and was intubated and treated by the trauma team for vascular injuries to the right and left carotid arteries. The entry site of the bullet was seen on the right cheek. Plain films of the head and neck showed bullet fragments in the right mastoid, as well as around the bifurcation of the left common carotid artery (□ Fig. 132.9). After he regained consciousness, a complete right facial paralysis was noted. The patient subsequently underwent a right tympanoplasty with mastoidectomy, evacuation of shrapnel in the mastoid and right and left neck, and a modified right neck dissection. The right facial nerve had been injured by the bullet, and a reparative neuroma in formation was noted and excised. The proximal and distal ends of the facial nerve were found and freshened; a gap of about 2.5 cm was left. A

Fig. 132.10 Case 3: Segment of the great auricular nerve for grafting.

Fig. 132.11 Case 3: Interposition graft in place (asterisk).

Fig. 132.12 Case 3: Postoperative views of (a) eye closure (right gold weight in place) and (b) closed-lip smile. Note the relative flattening of the right nasolabial fold, droopy right upper lip, and inward curl of the right lower lip.

right great auricular nerve interposition graft was harvested (□ Fig. 132.10) and was sutured in place in an end-to-end fashion (□ Fig. 132.11). This patient also underwent placement of a gold weight in the right upper lid and a right lower lid shortening procedure at the same sitting.

The patient had additionally sustained significant injuries to his right external auditory canal and right temporomandibular joint and had to have subsequent surgery to repair these sites. He regained function to an H-B III/VI level with significant synkinesis (□ Fig. 132.12). After removal of the injured tympanic ring and a wide meatoplasty, there was closure of the conductive deficit in the right ear to within 10 dB.

Fig. 132.13 Case 4: Preoperative view of right facial paralysis. (a) Close-up view of eyes shows ptosis of the right upper lid with rounding and malposition of the right lower lid. (b) Paralysis of the lower right face.

132.9.4 Case 4: Cholesteatoma

A 39-year-old woman presented with a 6-week history of worsening facial nerve function and hearing loss on the right. By the time she was seen, she had no active facial movement in any part of the right side of her face (□ Fig. 132.13) and no hearing in the right ear by tuning fork examination.

Fig. 132.14 Case 4: Preoperative audiogram.

Two years before being seen, she had undergone two separate surgeries in Denmark to control “ear disease,” the first on the left and the second on the right. The left ear became dry, and she was wearing a behind-the-ear hearing aid on this side. During the surgery on the right side, a cerebrospinal fluid (CSF) leak had occurred, and she subsequently underwent repair of the CSF leak and overclosure of the right ear with abdominal fat. She reported a right facial weakness at the time of these two surgeries that subsequently recovered.

An audiogram showed no measurable hearing on the right (□ Fig. 132.14) and a mixed hearing loss on the left at 35 dB/100% word recognition score. The left canal-wall-down ear was safe and dry.

CT of the petrous temporal bones without contrast revealed an overclosed right ear with postoperative changes and a large tegmen defect of approximately 2 x 2 cm. The temporal lobe retained its normal contour. Soft tissue was seen immediately inferior to the temporal lobe, likely representing a fat graft. The right petrous apex was scalloped, and the normal appearance of the cochlea and intratympanic facial nerve was distorted. The normal bony appearance of the internal auditory canal was lost, with scalloping (□ Fig. 132.15).

Images of the left temporal bone showed postsurgical changes consistent with a canal-wall-down technique. The otic

Fig. 132.15 Case 4: (a) Axial and (b) coronal computed tomographic scans demonstrating a large petrous apex lesion.

capsule was intact, and there were no erosive changes of the petrous apex, as seen on the right.

MR imaging of the brain without and with gadolinium enhancement showed findings similar to those on CT, including an intact right temporal dura and a low-lying temporal lobe. Soft tissue immediately under the temporal lobe had the signal characteristics of fat; the signal within the right petrous apex was of low intensity on T1-weighted images and brighter on T2-weighted images, supporting the diagnosis of cholesteatoma of the petrous apex (□ Fig. 132.16).

Within a week of being seen, the patient underwent placement of a right upper lid gold weight and lateral canthoplasty, and she subsequently underwent a combined neurotologic/neurosurgical procedure. After placement of a lumbar drain, a middle fossa craniectomy was performed. The tegmen defect was exposed from below and above. A small dural dehiscence was suture-repaired, and the tegmen defect, which was larger than anticipated, was repaired with a 5 x 3-cm calvarial bone and tensor fasciae latae graft in an extradural fashion (□ Fig. 132.17).

Fig. 132.16 Case 4: (a) T1-weighted and (b) T2-weighted axial and (c) T1-weighted and (d) T2-weighted coronal magnetic resonance images demonstrating low-intensity signals on T1 and high-intensity signals on T2 images, consistent with cholesteatoma of the right petrous apex.

After the temporal lobe had been reduced, a cholesteatoma within the right petrous apex was immediately seen. Because the right ear had no measurable hearing, a right translabyrinthine approach was used to exteriorize the cholesteatoma. The usual landmarks of the otic capsule and tympanic facial nerve were gone. All visible cholesteatoma and its accompanying matrix were carefully removed. The bone surrounding the internal auditory canal was weak and decalcified. At the level of the internal auditory canal, a CSF leak was again encountered, and this was stopped with a single piece of tensor fasciae latae, a fat graft, and fibrin glue. Facial nerve function is not expected, and the patient will likely require a microneurovascular muscle graft (see Chapter 51).

132.10 Conclusion

More than any other patient, the patient presenting with acute, subacute, or chronic facial paresis/paralysis may challenge the treating physician with the complexity of the required fact finding, investigations, and diagnostic and therapeutic planning. Because of the complex nature of the facial nerve (a combined nerve) and its long course through the temporal bone, the etiologies of facial nerve compression and paralysis are numerous and varied.

132.11 Roundsmanship

- A thorough and careful history will almost always point toward the correct pathway for an investigation of facial paralysis.
- The facial nerve must be viewed in light of the whole patient, and especially the function of the inner ear.
- Regardless of the patient's cosmetic concerns, the affected eye and specifically the cornea are of primary concern. Attention should be focused upon eye care. In many cases, ophthalmologic intervention will be required, most especially in the patient with a concomitant afferent sensory deficit.
- Once a facial nerve completely loses function, it is highly unlikely that recovery will be perfect. Sequelae such as synkinesis and regional paresis may occur, and the patient must be so informed.
- Timely surgical decompression of the facial nerve in the appropriate patient who has both clinical and electrical degeneration of the nerve remains a viable option and should be offered. Time is of the essence, with surgical intervention undetaken no more than approximately 2 to 3 weeks after the onset of paralysis.
- Traumatic injury to the facial nerve is the most compelling reason for surgical decompression.

133 Anatomy of the Skull Base and Infratemporal Fossa

Maura K. Cosetti and Christopher J. Linstrom

133.1 Introduction

The skull base, or floor of the intracranial cavity, is a complex anatomical region that forms the border between the brain and the structures of the face and upper neck. A basic understanding of skull base anatomy is critical for the accurate diagnosis and effective management of lesions in this area. For otolaryngologists and neurosurgeons alike, treatment planning and surgical decision making depend on the relationship between the disease process or lesion and the adjacent intracranial and neurovascular structures.

The skull base is composed of five bones: the frontal, ethmoid, temporal, sphenoid, and occipital; of these, the frontal and temporal bones are paired. Each bone houses multiple foramina (□ Table 133.1) traversed by cranial nerves (CNs) I through XII (□ Table 133.2) and by arteries and veins (described in detail in the following sections). A knowledge of the contents, locations, and relationships of these neurovascular foramina is crucial in both diagnosing and treating skull base disease, as well as in understanding routes of spread of intracranial and extracranial disease.

Clinically and anatomically, bony landmarks divide the cranial base into three general regions—the anterior, middle, and posterior fossae (□ Fig. 133.1). The anterior fossa and middle fossa are separated by the lesser wings of the sphenoid bone and the planum sphenoidale, while the dorsum sellae, posterior

clinoid processes, and petrous temporal ridges separate the middle fossa from the posterior fossa. The skull base is longest in the anterior–posterior diameter and thinnest in the cranio-caudal direction, measuring only 3 to 5 mm in all areas except the petrous temporal bone. This chapter will describe the anatomical boundaries, contents, and pertinent extracranial relationships of the anterior, middle, and posterior fossae. Important anatomical–clinical correlations will be highlighted. The anatomical borders, contents, and pertinent intracranial relationships of the infratemporal fossae will also be discussed.

133.2 Anterior Skull Base

133.2.1 Borders and Foramina

The anterior cranial fossa is bordered anteriorly by the orbital portion of the frontal bone, posteriorly by the lesser wing and body of the sphenoid bone, and centrally by the cribriform plate of the ethmoid bone. Bilaterally, the frontal bone forms the lateral boundary of the anterior cranial fossa and houses the supraorbital foramen. The central cribriform plate is the deepest and thinnest portion of the anterior cranial fossa and contains 15 to 20 small foramina that transmit the olfactory nerves (CN I) from the olfactory bulb intracranially to the superior nasal mucosa. In the anteromedial portion of the cribriform plate is the crista galli, a superiorly directed bony projection between

Table 133.1 Foramina of the skull base

Intracranial foramen	Bone(s) involved	Structure(s) transmitted
Anterior cranial fossa		
Cribriform plate	Ethmoid	CN I
Middle cranial fossa		
Optic canal	Sphenoid	CN II, ophthalmic artery
Superior orbital fissure	Sphenoid	CNs III, IV, V ₁ , VI; superior ophthalmic vein
Foramen rotundum	Sphenoid	CN V ₂
Foramen ovale	Sphenoid	CN V ₃ , accessory meningeal artery, lesser petrosal nerve, emissary vein
Foramen spinosum	Sphenoid	Middle meningeal artery and vein
Foramen lacerum ^a		
Posterior cranial fossa		
Internal auditory meatus (porus acusticus)	Temporal	CNs VII, VIII; internal auditory artery and vein
Jugular foramen	Occipital, temporal	CNs IX, X, XI; internal jugular vein; inferior petrosal sinus
Foramen magnum	Occipital	Medulla oblongata, spinal root of CN XI, vertebral artery and vein, anterior and posterior spinal arteries and veins
Hypoglossal canal	Occipital	CN XII

Abbreviation: CN, cranial nerve.

^aThe foramen lacerum is not a true foramen. It is located at the junction of the sphenoid, temporal, and occipital bones and is covered by cartilage. The greater and deep petrosal nerves and the internal carotid artery pass over its intracranial surface.

Table 133.2 Cranial nerves and their function

Cranial nerve	Type of nerve	Function
Olfactory (I)	Sensory	Special visceral afferent for smell
Optic (II)	Sensory	Special visceral afferent for vision
Oculomotor (III)	Motor	All extraocular muscles except superior oblique and lateral rectus; striated muscle of the eyelid; pupillary constrictors
Trochlear (IV)	Motor	Superior oblique muscle; moves globe down and outward
Trigeminal (V)	Mixed	V ₁ : sensory to the upper face, nasal cavity, ethmoid and sphenoid sinuses V ₂ : sensory to the midface, hard and soft palate, maxillary sinus, maxillary dentition and gums V ₃ : motor to muscles of mastication, anterior belly of the digastric, mylohyoid, tensor tympani, tensor palatini; sensory to lower face and jaw, mandibular dentition and gums; taste to anterior two-thirds of the tongue (from CN VII) Autonomic ^a
Abducens (VI)	Motor	Lateral rectus muscle; moves globe laterally
Facial (VII)	Mixed	Motor: muscles of facial expression, stapedius, stylohyoid, posterior belly of digastric Sensory: taste sensation from anterior two-thirds of tongue carried via CN V ₃ and chorda tympani Autonomic: parasympathetic fibers originate in nervus intermedius and travel via chorda tympani and greater superficial petrosal nerve to tongue; lacrimal gland; submandibular, sublingual, and lingual salivary glands
Vestibulocochlear (VIII)	Sensory	Cochlear nerve: hearing Superior and inferior vestibular nerves: balance
Glossopharyngeal (IX)	Mixed	Motor: pharyngeal musculature, parotid gland Sensory: taste sensation from posterior one-third of tongue; sensation from pharynx and tympanic cavity; visceral afferent from carotid sinus and body Autonomic: parasympathetic to parotid gland
Vagus (X)	Mixed	Motor: striated muscles in larynx, pharynx, and soft palate; palatoglossus muscle of tongue; smooth muscles in heart, blood vessels, trachea, bronchi, esophagus, stomach, small and large intestine Sensory: taste sensation from epiglottis; sensory from external ear canal, tympanic membrane, pharynx, larynx, thoracic and abdominal viscera Autonomic: parasympathetic to abdominal and thoracic viscera
Spinal accessory (XI)	Motor	Trapezius and sternocleidomastoid muscles
Hypoglossal (XII)	Motor	All muscles of tongue except palatoglossus (CN X)

Abbreviation: CN, cranial nerve.

^aParasympathetic neurons do not originate in CN V; however, branches of CN V are used as carriers for the peripheral distribution of parasympathetic input from CNs VII and IX.

the cerebral hemispheres onto which the falx cerebri attaches. Anterior to the crista galli is the foramen caecum, a variable opening in the frontoethmoidal suture line through which a nasal emissary vein may communicate with the intracranial superior sagittal sinus. Immediately lateral to the cribriform plate is the fovea ethmoidalis, or roof of the ethmoid cavity. The fovea is thicker and frequently more superior than the adjacent cribriform plate, although anatomical variance in this area is common. Knowledge of these relationships and individual patient anatomy is an essential component of presurgical planning in both intranasal sinus surgery and the extirpation of anterior skull base lesions. At the anterolateral and posterolateral aspects of the cribriform plate, the anterior and posterior ethmoidal branches of the ophthalmic artery, respectively, exit the intracranial cavity to enter the nasal cavity. Posteriorly, the cribriform plate of the ethmoid bone articulates with the central portion, or body, of the sphenoid bone, forming the planum sphenoidale. The optic chiasm or chiasmatic sits in the midline, while posterolaterally, the lesser wings of the sphenoid form the anterior clinoid processes and the roof of the optic canals.

133.2.2 Contents

The contents of the anterior cranial fossa include the frontal lobes of the brain, olfactory bulbs and tracts, and inferior and superior sagittal sinuses. The olfactory nerve (CN I) is a primary afferent sensory nerve consisting of bipolar neurons with short peripheral and long central projections. The peripheral olfactory receptor cells are located in the superior 2-cm² aspect of each nasal cavity, adjacent to the cribriform plate, superior nasal septum, and superior-lateral nasal wall. Hundreds of central processes traverse the cribriform plate as unmyelinated fascicles, or fila olfactoria, with approximately 20 fila or olfactory nerves on each side of the crista galli. These nerves culminate centrally in the ipsilateral olfactory bulb, an extension of the brain on the ventral surface of the frontal lobe closely apposed to the cribriform plate. Disruption of this region by trauma, planned anterior skull base surgery, or unintentional iatrogenic injury during endoscopic sinus surgery can lead to cerebrospinal fluid (CSF) leak as well as disorders of smell, such as anosmia or hyposmia (inability or decreased ability, respectively, to

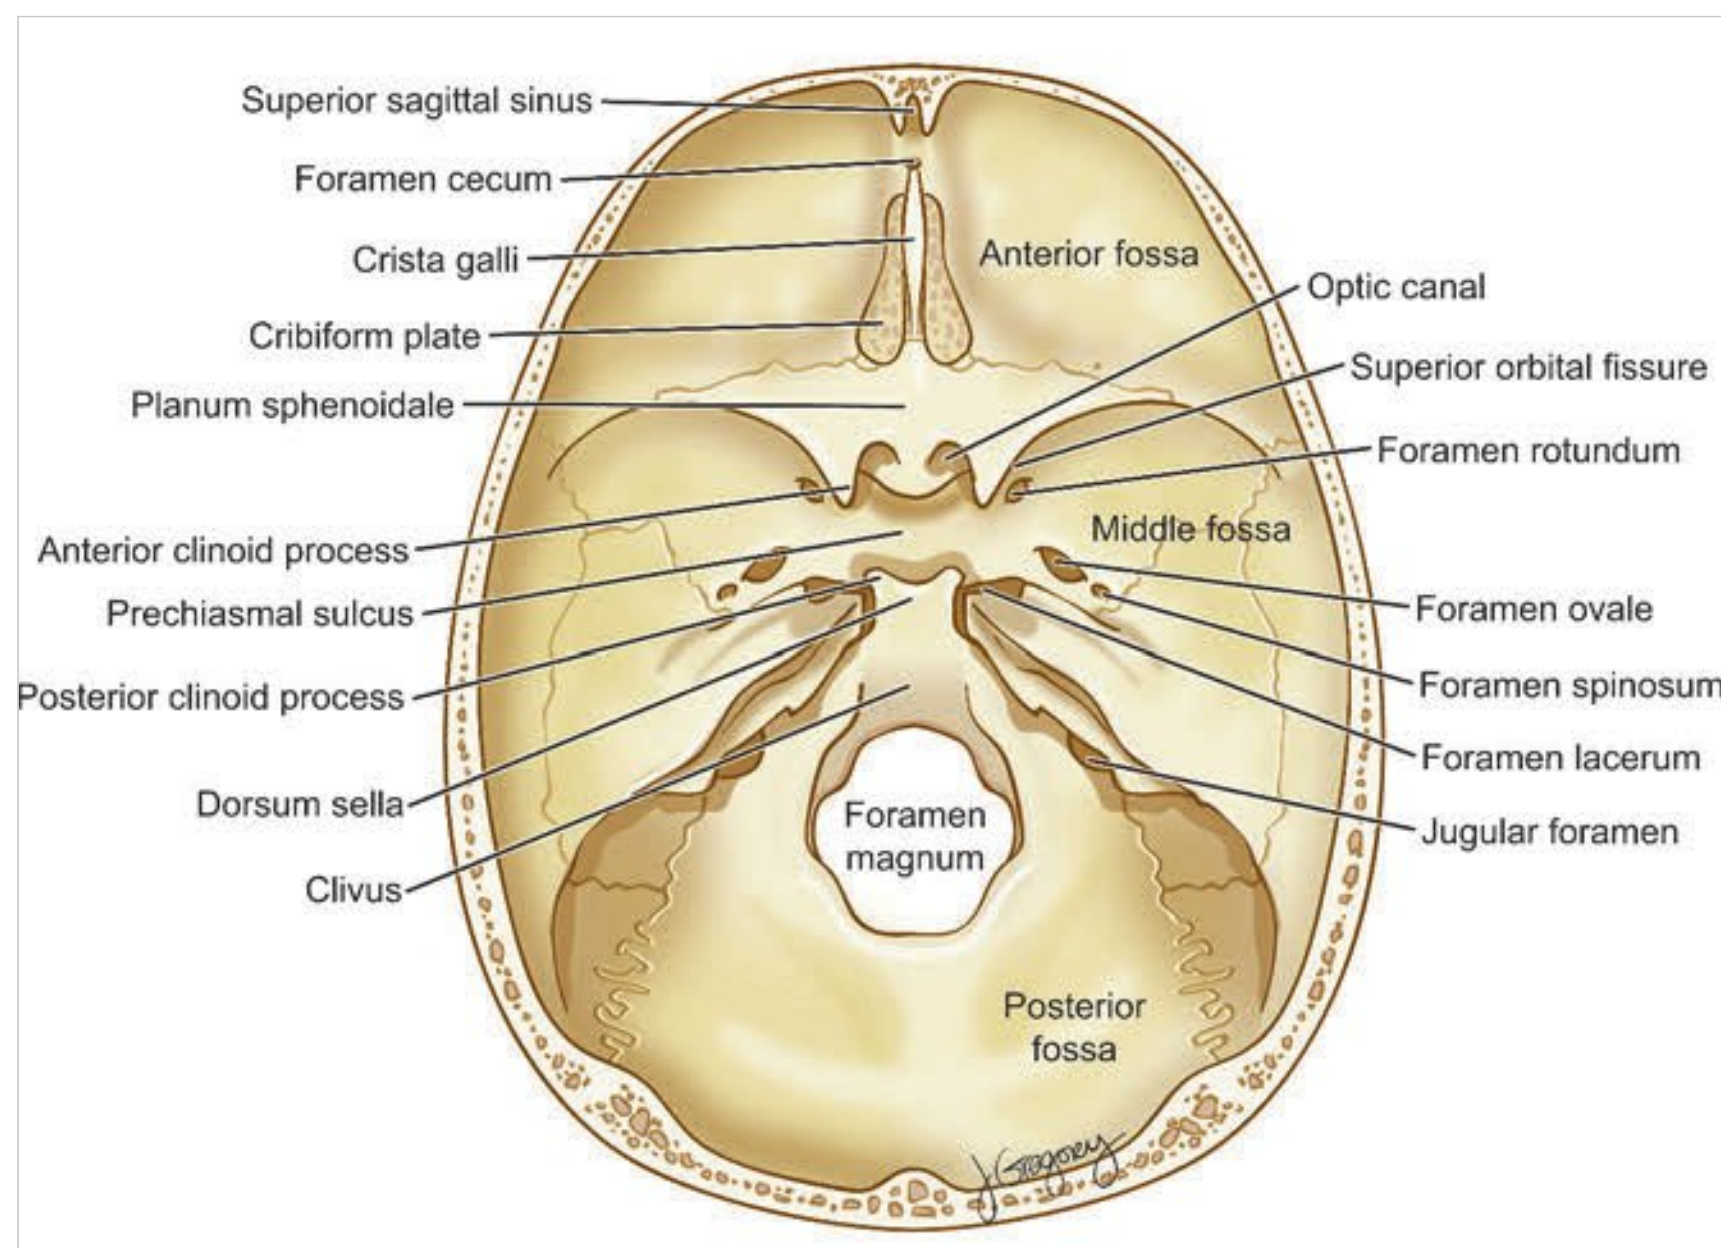

Fig. 133.1 Internal aspect of the skull base, with division into three distinct fossae.

detect odors). Following synapse in the olfactory bulb, secondary sensory neurons course posteriorly along the ventral frontal lobe as the olfactory tract. The venous contents of the anterior cranial fossa have implications for the intracranial spread of infection. The dural attachments to the frontal crest and the crista galli form the falx cerebri, which transmits the inferior and superior sagittal sinuses. These valveless venous channels drain the brain, meninges, and diploic spaces within the cranial bones, ultimately forming the internal jugular vein. In the anterior cranial fossa, the veins of Brechet, which are valveless, diploic veins of the posterior frontal bone, provide a venous route for the intracranial spread of frontal sinus infections. Patency of the foramen caecum, anterior to the crista galli, is the anatomical basis for developmental nasal anomalies such as nasal gliomas, encephaloceles, and meningoencephaloceles.

133.2.3 Extracranial Relationships

The major extracranial relationships of the anterior cranial fossa are with the orbits and paranasal sinuses. As previously described, the floor of the anterior cranial fossa serves as the roof of the orbits and the ethmoid and sphenoid sinuses and abuts the posterior wall of the frontal sinuses. Neoplastic lesions in these regions, such as esthesioneuroblastoma (a rare neoplasm originating from olfactory neuroepithelium), may extend into the anterior cranial fossa from below, whereas primarily intracranial processes may progress in the reverse direction. These relationships can also be exploited for surgical planning and used as routes of access to the anterior intracranial cavity.

The close proximity of the bony orbit to the anterior cranial and infratemporal fossae provides multiple routes for the transmission of intracranial or extracranial disease, including the posterior orbital foramina, such as the superior and inferior orbital fissures and the optic canals. Technically situated in the middle cranial fossa, the contents of the superior orbital fissure include the oculomotor nerve (CN III), trochlear nerve (CN IV), abducens nerve (CN VI), ophthalmic branch of the trigeminal nerve (CN V₁), and ophthalmic veins. The inferior orbital (in-

fraorbital) fissure transmits the maxillary branch of the trigeminal nerve (CN V₂) and infraorbital vessels, and unlike the superior orbital fissure, it communicates directly with the infratemporal and pterygomaxillary fossae. The optic canal contains the optic nerve (CN II) and ophthalmic artery.

133.3 Middle Skull Base

133.3.1 Borders

The middle cranial fossa is separated from the anterior skull base by the posterior aspect of the planum sphenoidale medially and by the lesser wings of the sphenoid bone laterally. The anterior wall and floor are formed by the greater wings and body of the sphenoid bone, while the posterior floor is composed of the anterior aspect of the petrous temporal bone. Laterally, the middle fossa is bounded by the squamous portion of the temporal bone and the anterior–inferior portion of the parietal bone. Posteriorly, the middle and posterior fossae are demarcated by the posterior clinoid processes medially and the petrous ridge of the temporal bone laterally. The petro-occipital fissure, a gap between the medial border of the petrous bone and the lateral border of the clivus, subdivides the middle cranial fossa into a central and two lateral compartments. Easily seen on radiologic imaging, this is an important landmark in preoperative surgical planning because of its close relationship with various middle fossa foramina.

Centrally located between the anterior and posterior clinoid processes, the sella turcica (Latin for “Turkish saddle”) occupies the central compartment of the middle fossa and has three distinct regions (□ Fig. 133.2). Anteriorly to posteriorly, these include the tuberculum sellae, which is an olive-shaped bony protuberance between the optic canals; the hypophyseal or pituitary fossa, which is a deep central depression that houses the pituitary gland; and the dorsum sellae. The dorsum sellae contains the sigmoid groove for the internal carotid artery as it navigates the middle fossa floor through the petrous apex into the cavernous sinus.

Fig. 133.2 Anatomical relationships near the sella turcica.

Along the floor and lateral walls of the middle fossa, a groove for the middle meningeal artery is typically visible where it courses superoposteriorly and traverses the intracranial side of the pterion (an area of very thin bone where the parietal, squamous temporal, and frontal bones and the greater sphenoid wings meet). The pterion is easily fractured by head trauma, and resulting disruption of the middle meningeal artery is a common cause of epidural hematoma. The petrous ridge, or crest, along the superior aspect of the temporal bone demarcates the posterior boundary of the middle cranial fossa. In a depression on the superomedial aspect of the petrous temporal bone, the trigeminal (CN V) or gasserian ganglion lies within a dural envelope called the Meckel cave. This arachnoid-lined, CSF-filled cavity houses the ganglion and neural fascicles of CN V in the middle fossa. The three divisions of CN V then exit the middle fossa through individual foramina (discussed in the following section.)

Along the midpetrous ridge, the arcuate eminence is a bony protuberance representing the superior extent of the superior semicircular canal. An important landmark in the middle fossa approach to the internal auditory canal, the arcuate eminence can be used to localize the geniculate ganglion of the facial nerve (CN VII) and the internal auditory canal. Bony dehiscence over the geniculate ganglion is not uncommon, and careful elevation of the dura during middle fossa surgery is required to avoid facial nerve injury in this area. Laterally, the thin tegmen tympani and tegmen mastoideum form the roof of the middle ear and mastoid, respectively; trauma or iatrogenic injury to these regions during otologic or mastoid surgery may lead to dural disruption and CSF leak requiring repair.

133.3.2 Foramina

As previously discussed, the superior orbital fissure and optic canal are bony apertures in the anterior aspect of the middle cranial fossa. Posteroinferior to the superior orbital fissure and lateral to the sella turcica, the foramen rotundum transmits the second division of the trigeminal nerve (CN V₂) from the middle

fossa through the lateral wall of the cavernous sinus to the pterygopalatine fossa. After exiting the skull, CN V₂ continues as the infraorbital nerve and provides sensory innervation to the cheek and maxillary dentition. Inferomedial to the foramen rotundum is the vidian canal, which transmits the vidian artery and nerve. The vidian nerve is composed of the greater superficial petrosal nerve and the deep petrosal nerve.

Unlike the first two divisions of CN V, the third division (CN V₃) does not pass through the cavernous sinus; instead, it exits directly from the Meckel cave through the foramen ovale. Also unlike the ophthalmic (CN V₁) and maxillary (CN V₂) divisions, the mandibular branch (CN V₃) carries both sensory and motor fibers providing innervation to the muscles of mastication (masseter, temporalis, and medial and lateral pterygoid muscles), the mylohyoid muscle, the tensor tympani and tensor veli palatini muscles, and the anterior belly of the digastric muscle. It also supplies sensation to the buccal mucosa, skin of the lower face, and mandibular dentition. In addition to CN V₃, the foramen ovale transmits the lesser superficial petrosal nerve, accessory meningeal branch of the maxillary artery, and emissary veins to the pterygoid plexus into the infratemporal fossa. Farther posterolaterally, the foramen spinosum contains the middle meningeal artery (described above). Formed by the greater wing of the sphenoid and the petrous apex of the temporal bone, the carotid canal transmits the internal carotid artery (also called at this level the petrous carotid artery) and its sympathetic plexus. Medial to the foramen ovale, the misnamed foramen lacerum is not a true foramen but rather the cartilaginous floor of the horizontal portion of the petrous internal carotid artery canal (□ Fig. 133.3).

133.3.3 Contents

The middle cranial fossa houses a number of vital structures, including the temporal lobes, pituitary gland, cavernous sinuses, intracranial portion of the internal carotid arteries, trigeminal ganglia, and CNs I through VI. In the central compartment of the middle fossa, strong dural attachments form the

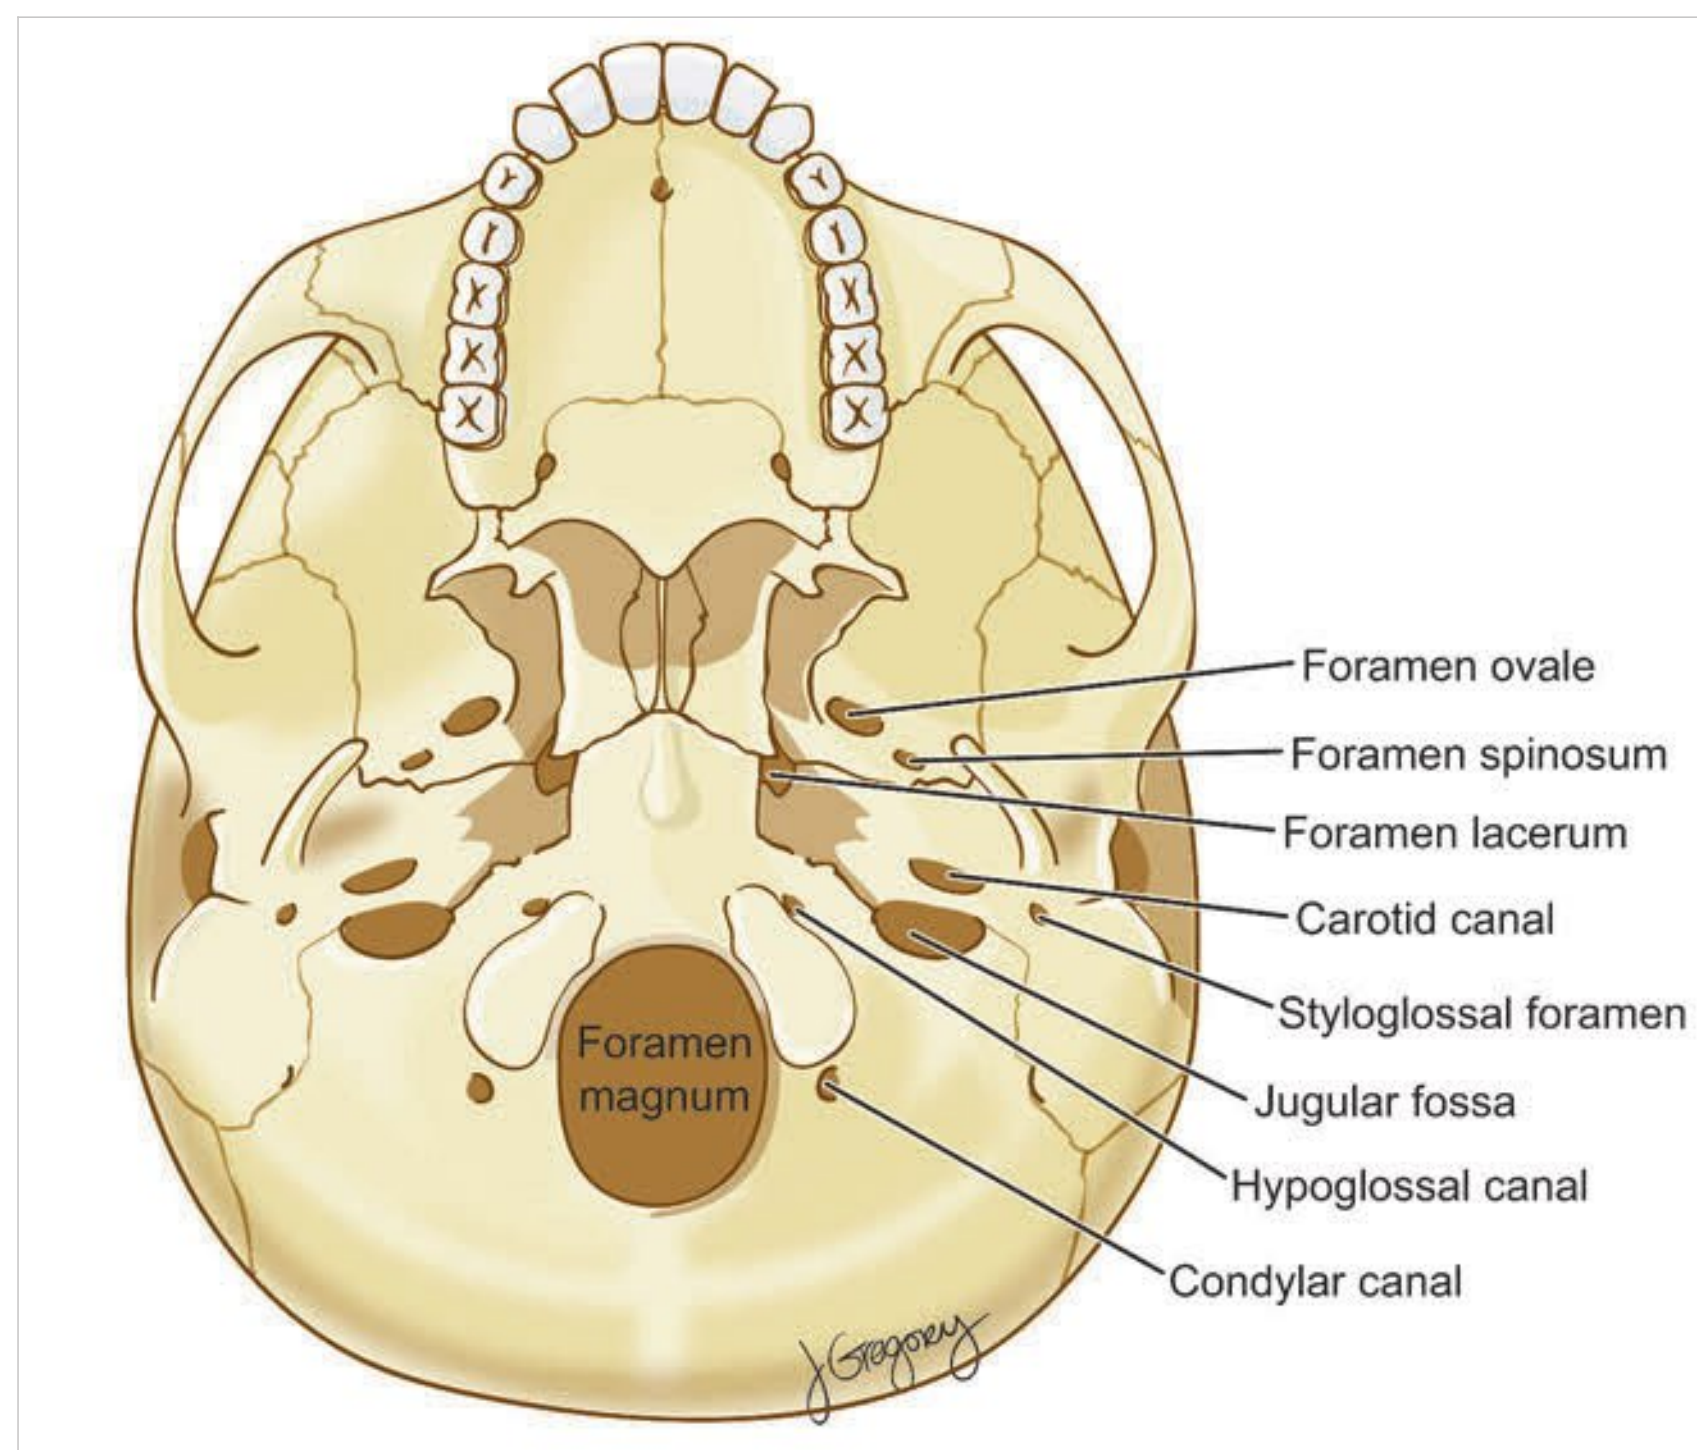

Fig. 133.3 Inferior view of the skull base.

diaphragmatic sella, a circular band of dural reflections that envelope the pituitary gland. Superiorly, the infundibulum (pituitary stalk) and the hypophyseal veins perforate this structure.

The cavernous sinuses are paired, septate venous sinuses, lined with dura, that drain inferiorly to the two pterygoid plexus and internal jugular veins. Bounded laterally by the anterior and posterior petroclinoid dural folds and extending posteriorly from the superior orbital fissure to the petrous apex, this complex region of venous sinusoids is traversed by various critical neurovascular structures. Centrally, the horizontal portion of the intracranial internal carotid artery runs in the through the cavernous sinus close to the lateral wall of the sphenoid sinus. The following CNs traverse the lateral wall of the cavernous sinus (listed in a superior to inferior direction): oculomotor (CN III), trochlear (CN IV), ophthalmic (CN V₁), and maxillary (CN V₂). Only the abducens nerve (CN VI) actually courses through the venous sinusoids in the center of the sinus. With its complex neurovascular components, the cavernous sinus plays an important clinical role in the intracranial transmission of infection. Tributaries of the cavernous sinus include the valveless veins of the face, sinuses, and dentition, so that a rapid spread of infection from these anterior, extracranial sites into the cavernous sinus is possible.

133.3.4 Extracranial Relationships

Surgical approaches to the middle fossa exploit the close proximity of the pituitary and clivus to the sphenoid sinus and nasopharynx inferiorly. Sellar pneumatization allows the endoscopic or microscopic trans-sphenoidal excision of pituitary disease because the middle cranial fossa can be entered through the roof of the sphenoid sinus. During procedures in the sphenoid sinus, care must be taken to avoid injury or disruption of the lateral wall because the course of the internal carotid artery

and optic nerve is immediately lateral to the thin sinus wall. Occasionally, bony dehiscence results in exposure of the internal carotid artery, CN II, or vidian nerve within the sphenoid sinus. In the middle fossa approach to the internal carotid artery, a transtemporal route through the squamous portion of the temporal bone is used to access internal carotid artery disease superiorly.

The nasopharynx is located posterior and inferior to the sphenoid sinus and anterior to the clivus. The foramen lacerum and horizontal intracranial internal carotid artery, as previously described, lie immediately superior to the superior border of the nasopharynx. In the superior-lateral nasopharyngeal wall, the sinus of Morgagni is a clinically significant region of muscular dehiscence. Here, the levator veli palatini and cartilaginous eustachian tube penetrate the superior constrictor muscle; through this weak area, nasopharyngeal infections and neoplastic processes may gain access to and invade the skull base.

133.4 Posterior Skull Base

133.4.1 Borders

The posterior cranial fossa is separated from the middle fossa by the dorsum sellae medially and by the petrous ridges of the temporal bones laterally. In the midline, the basal part of the occipital bone (called the basiocciput) and the basisphenoid bone form the clivus and the anteromedial wall of the posterior fossa. Anterolaterally, this boundary is formed by the posterior face of the temporal bone. The remaining posterior, lateral, and inferior borders are formed by the occipital bone. The occipitomastoid suture, the junction of the occipital bone with the mastoid portion of the temporal bone, courses in an anteromedial to posterolateral direction along the posterior fossa floor. Superiorly, the tentorium cerebelli attaches to the petrous ridge of

the temporal bone, creating a dural roof of the posterior fossa and a separation between the cerebellum below and the cerebral hemispheres above.

Centrally, the foramen magnum, the largest foramen of the skull base, is an opening in the floor of the posterior cranial fossa. The internal occipital crest courses in an anterior–posterior direction from the midline of the foramen magnum to the internal occipital protuberance and is the site of attachment for the falx cerebelli. This area is rich with venous sinuses; the dural folds of the falx cerebelli form the midline occipital venous sinus, which drains into the internal jugular vein. Superior to the internal occipital protuberance is a vertical groove for the superior sagittal sinus, while the horizontal grooves of the transverse sinuses are situated lateral to the bony protuberance. Laterally, the superior petrosal sinus is located at the junction of the transverse and sigmoid sinuses. Along the mastoid portion of the temporal bone, a sulcus for the sigmoid sinus can be identified coursing inferiorly toward the internal jugular foramen and vein. In the anterior midline, the paired inferior petrosal sinuses lie posterior to the clivus and anterior to the petrous apex.

133.4.2 Foramina

Like the floor of the middle cranial fossa, the floor of the posterior cranial fossa contains many important neurovascular structures and foramina, including CNs VII through XII, the medulla oblongata, and the jugular veins. The internal acoustic meatus, or porus acusticus, is located on the posterior face of the petrous temporal bone superior to the jugular foramen. This foramen transmits the facial (CN VII) and vestibulocochlear (CN VIII) nerves, the nervus intermedius, and the labyrinthine vessels (branches of the anterior inferior cerebellar artery) from the brainstem to the internal auditory canal of the temporal bone. Within the internal auditory canal, the facial nerve (CN VII) occupies the anterosuperior quadrant, separated from the superior vestibular nerve in the posterosuperior quadrant by a bony vertical crest (“Bill’s bar,” named for Dr. William House). Anteriorly, the bony transverse or falciform crest separates the facial nerve (CN VII) superiorly from the cochlear nerve inferiorly. At the lateral end of the internal auditory canal, or fundus, CN VIII innervates the inner ear; the superior and inferior vestibular nerves terminate in the vestibule and semicircular canals of the labyrinth, whereas the cochlear nerve traverses a multiply perforated osseous plate to enter the cochlear modiolus. The facial nerve, on the other hand, begins a complicated intratemporal course consisting of a short, narrow labyrinthine segment; a genu or bend, marking the location of the geniculate ganglion; and a horizontal, intratympanic segment that traverses the middle ear and ends in the descending or mastoid portion. The labyrinthine segment is the shortest and narrowest portion and thus the most susceptible to compression and injury from edema. After exiting the temporal bone through the stylomastoid foramen, located between the mastoid tip and styloid process, the nerve begins its extracranial course, ultimately innervating the muscles of facial expression. Also on the posterior face of the petrous bone, posterior and lateral to the porus acusticus, is the operculum or opening of the vestibular aqueduct (or endolymphatic duct) into the subarachnoid space of the posterior fossa. Enlargement of the duct is associated

with congenital sensorineural hearing loss or a predisposition to the later development of hearing loss and can be associated with other anatomical abnormalities of the inner ear, such as Mondini deformity of the cochlea. The jugular foramen is formed by the processus jugularis of the petrous temporal bone anteriorly and the occipital bone posteriorly and can be found at the most posterior aspect of the petro-occipital fissure. The jugular foramen was previously divided into two portions, the anteromedial pars nervosa and the posterolateral pars vascularis, but a new division into three compartments has been suggested. Anteriorly to posteriorly, these include the following: (1) the petrous compartment, containing the inferior petrosal sinus; (2) the neural intrajugular compartment, containing CNs IX, X, and XI and their respective ganglia, the Jacobsen nerve (from CN IX), the Arnold nerve (from CN X), and the posterior meningeal artery (a branch of the ascending pharyngeal artery); and (3) the sigmoid compartment receiving the sigmoid sinus and beginning of the jugular bulb. In the neural compartment, the glossopharyngeal nerve (CN IX) is located anteriorly and is separated from the inferiorly located vagus nerve (CN X) and spinal accessory nerve (CN XI) by a dural septum. Inferomedial to the jugular foramen, inferior to the bony protuberance called the jugular tubercle, is the hypoglossal canal. Located in the condylar portion of the occipital bone, this foramen transmits the hypoglossal nerve (CN XII) and its venous plexus. Also formed completely of occipital bone, the large, central foramen magnum serves as the primary connection between the brainstem and spinal cord. It contains the cephalic component of CN XI, the vertebral and posterior spinal arteries, and the medulla oblongata.

133.4.3 Contents

An understanding of the anatomy of the posterior fossa, which houses the midbrain, pons, medulla, and cerebellar hemispheres, as well as CNs VI through XII and many critical vascular structures, is crucial for any surgeon working in this area. The posterior fossa arterial contents include the paired vertebral arteries, which enter the posterior skull base through the foramen magnum, then ascend vertically ventral to CNs IX, X, and XI. After giving off the posterior inferior cerebellar arteries, the vertebral arteries join to form the basilar artery at the base of the pons. The basilar artery ascends on the intracranial aspect of the clivus against the midline pons and gives rise to multiple branches. Inferiorly to superiorly, these are the anterior inferior cerebellar arteries, the multiple short and long pontine arteries, and the superior cerebellar arteries, which form the posterior aspect of the circle of Willis (□ Fig. 133.4). Within the posterior fossa, the cerebellopontine angle is of unique importance to the otolaryngologist because of the location of the facial and vestibulocochlear nerves. The cerebellopontine angle extends from the abducens nerve (CN VI) and lateral aspect of the clivus anteriorly to the cerebellar flocculus posteromedially. Medially, it is bounded by the middle cerebellar peduncle, pons, and ventral cerebellum; it is bounded laterally by the posterior petrous temporal bone and inferiorly by CNs IX, X, and XI. The choroid plexus, a collection of CSF-producing ependymal cells, may pass through the foramen of Lushka into the cerebellopontine angle. Well-known surgical approaches to the internal auditory canal and cerebellopontine angle include the translabyrinthine

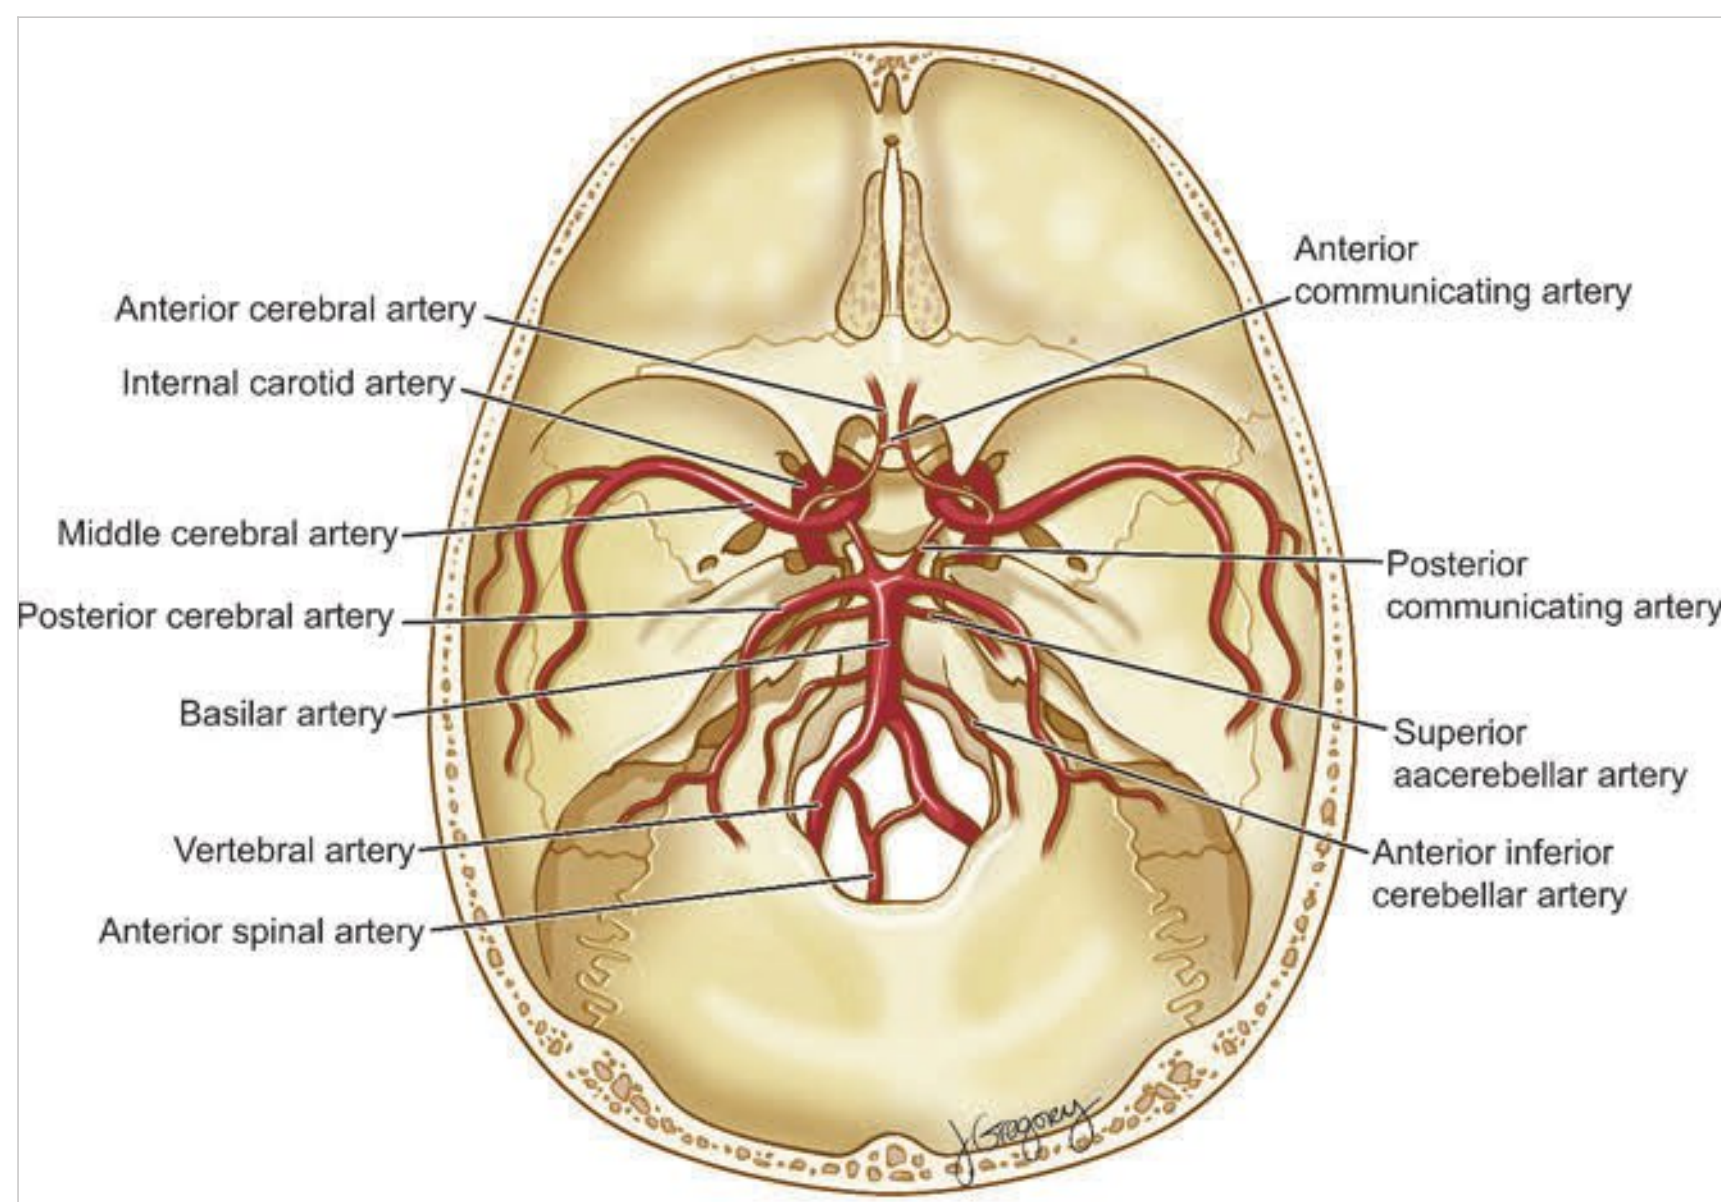

Fig. 133.4 Components of the circle of Willis.

approach through the mastoid portion of the temporal bone, the retrosigmoid approach through an occipital craniotomy, and the middle fossa approach through the squamous temporal bone (previously described). Although further description is beyond the scope of this chapter, knowledge of the anatomy in this region is fundamental to understanding the presentation, diagnosis, and treatment of cerebellopontine angle pathology.

133.4.4 Extracranial Relationships

Extracranial structures inferior to the posterior fossa include the musculature of the suboccipital region, specifically the sternocleidomastoid muscle, which originates on the mastoid tip of the temporal bone, and the posterior belly of the digastric muscle. The posterior musculature includes, from superficial to deep, the trapezius, splenius capitis, splenius colli, and semispinalis capitis muscles. Beneath these muscles, inferior to the superior nuchal line and superficial to the ligaments connecting the atlas to the axis, lies the suboccipital triangle. The contents of this region include the occipital and vertebral arteries, a complex of veins, the greater occipital nerve, and the C1 nerve. Suboccipital surgical approaches can be used for access to the vertebral arteries and foramen magnum. Additional inferior extracranial relationships of the posterior skull base include the deep neck spaces, such as the retropharyngeal, danger, and prevertebral spaces, as well as the cervical spine. The fascia of these spaces begins at the skull base and extends to the level of the tracheal bifurcation, diaphragm, and coccyx, respectively.

133.5 Infratemporal Fossa

133.5.1 Borders and Foramina

The infratemporal fossae are irregular, complex anatomical spaces that lie medial to the zygomatic arches and mandibular rami bilaterally. Anteriorly, the infratemporal fossa is limited by the posterior surface of the mandible and the inferior orbital fissure. The roof, or superior boundary, includes the inferior

surface of the greater wing of the sphenoid and the squamous temporal bone. Posteriorly, limits include the mastoid and tympanic temporal bone, while the inferior border comprises the superior aspect of the posterior belly of the digastric and the angle of the mandible. The infratemporal fossa communicates with the middle cranial fossa via various skull base foramina, notably the foramen spinosum and foramen ovale. Connection with the orbit is mediated by the inferior orbital fissure through the pterygopalatine fossa and pterygomaxillary fissure.

133.5.2 Contents

Muscular contents of the infratemporal fossa include the medial and lateral pterygoid muscles, the latter of which is divided into two muscular heads. The medial pterygoid runs from its origin on the medial side of the lateral pterygoid process and inserts on the medial surface of the mandible at the angle and ramus. Although both insert on the temporomandibular joint, the inferior belly of the lateral pterygoid arises from the lateral part of the lateral pterygoid process, and the superior belly attaches to the roof of the infratemporal fossa. Multiple branches of the mandibular nerve (CN V₃) traverse the infratemporal fossa, including the inferior alveolar, lingual, and buccal branches, the chorda tympani, and the otic ganglion. Exiting through the foramen ovale, CN V₃ carries motor fibers to the muscles of mastication and sensory fibers via the auriculotemporal, alveolar, lingual, and buccal branches. The chorda tympani branches from the facial nerve (CN VII) in the mastoid portion, courses through the middle ear and through the tympanic canaliculus in the petrotympanic suture, and enters the infratemporal fossa medial to the lateral pterygoid muscle, where it ultimately joins the lingual nerve. The primary arterial structure in the infratemporal fossa is the maxillary artery and its many branches. A branch of the external carotid artery, the maxillary artery enters the infratemporal fossa lateral to the lateral pterygoid muscle and proceeds anteriorly toward the pterygomaxillary fissure and pterygopalatine fossa. Venous drainage of the infratemporal fossa proceeds from the pterygoid venous plexus to

the facial vein anteriorly and the maxillary vein posteriorly. An extensive venous anastomotic plexus connects the pterygoid plexus with the cavernous sinus, ophthalmic veins, and pharyngeal venous plexus.

133.6 Conclusion

A fundamental knowledge of the borders, foramina, and extracranial relationships is necessary for the otolaryngologist, neurosurgeon, or skull base subspecialist. Familiarity with the anatomical features of each particular region plays a key role in understanding the presentation, pathophysiology, and treatment of skull base lesions. Clearly, a knowledge of the complex anatomy of the cranial base is also the foundation for safe extirpation of lesions in this region.

133.7 Roundsmanship

- A thorough understanding of the anatomy of the posterior cranial fossa is an absolute prerequisite for performing safe otologic and neurotologic surgery.

- Although many of the structures described herein appear at first reading to be complex, they follow a logical order based upon regional embryogenesis and development.
- Safe skull base surgery requires not only a thorough grounding in the local anatomy but also a lifelong dedication to the acquisition and perfection of surgical skill based upon laboratory microdissection. There is no substitute for hands-on microsurgical training.

134 Posterior Skull Base Diseases and Surgery

Seilesh C. Babu and Ryan G. Porter

134.1 Introduction

Although there are numerous diseases of the posterior fossa, the general otolaryngologist does not encounter most of them. This chapter will focus on the most common neoplasms that affect the seventh and eighth cranial nerve complex at the internal auditory canal and cerebellopontine angle (see Box Differential Diagnosis of Cerebellopontine Angle Tumors (p.1050)). Patients with these tumors often present first to the general otolaryngologist or primary care physician, and it is important that the diseases be identified and patients treated appropriately, or that they be referred to a subspecialist for further management. The two most common surgical approaches to the posterior fossa, the retrosigmoid (suboccipital) and the translabyrinthine approaches, will also be discussed.

Differential Diagnosis of Cerebellopontine Angle Tumors

- Vestibular schwannoma (“acoustic neuroma”)
- Meningioma
- Epidermoid (cholesteatoma)
- Arachnoid cyst
- Facial schwannoma (“facial neuroma”)
- Cochlear schwannoma (cochlear neuroma)
- Vascular lesions (e.g., hemangioma)
- Lipoma
- Metastatic carcinoma (e.g., breast carcinoma)

134.2 Applied Anatomy

Cranial nerves (CNs) VII (facial) and VIII (vestibulocochlear) exit the brainstem from their root entry zones at the pons and cross through the cerebellopontine angle (CPA) before entering the medial aspect of the internal auditory canal (IAC) at the porus acusticus. The nerves then travel in the IAC toward the fundus (lateral aspect of the IAC). The facial nerve travels anteriorly in the canal superior to the cochlear division of CN VIII. The superior vestibular and inferior vestibular branches of CN VIII travel posteriorly in the IAC. The facial and superior vestibular nerves are separated from the cochlear and inferior vestibular nerves at the fundus by the transverse crest. The facial nerve is separated anteriorly from the superior vestibular nerve by a vertical crest of bone (“Bill’s bar,” named for Dr. William House). After traveling through the fundus of the IAC, the nerves enter the inner ear, mastoid, or middle ear and ultimately innervate the cochlea, vestibular system, and facial and middle ear musculature.

The anterior inferior cerebellar artery, a branch of the basilar artery, is also located in the CPA. The anterior inferior cerebellar artery typically sends off an arterial branch to the inner ear through the IAC (the labyrinthine or internal auditory artery).

134.3 Epidemiology

The most common neoplasm affecting the CPA is the vestibular schwannoma (VS), also known as an acoustic neuroma. The incidence of VS is approximately 1 per 100,000 people. The second most common tumor affecting the CPA is the meningioma. In general, meningiomas are twice as common in females as in males and are most frequent after the fifth decade of life. Other tumors and lesions are much less common than VSs and meningiomas, but they must still be considered because their treatment may be markedly different.

134.4 Pathogenesis

VSs are benign neoplasms arising from Schwann cells on the vestibular portion of CN VIII. The inferior division of the vestibular nerve is affected by schwannomas almost twice as often as the superior division. VSs have two classic histologic patterns, Antoni A and Antoni B. The Antoni A pattern is characterized by compact cells and Verocay bodies, in which palisading nuclei line up beside anuclear, clear areas. A looser stroma, myxoid changes, and fewer cells characterize the Antoni B pattern (□ Fig. 134.1). Tumors are typically mixtures of both Antoni A and Antoni B types, with the Antoni A pattern predominating.

The growth rate of VSs is variable. In an analysis by Sughrue et al of 982 patients in 34 published studies who had decent hearing and tumors 2.5 cm or smaller in size, the mean tumor growth rate was 2.9 ± 1.2 mm/y with a minimum 26-month follow-up. Additionally, patients with slower-growing tumors (≤ 2.5 mm/y) had higher rates of hearing preservation than did patients with faster-growing tumors (75% vs 32% $p < 0.0001$).

Meningiomas are slow-growing and arise from arachnoidal cap cells. Although most meningiomas are sporadic, cranial irradiation (classically scalp irradiation for tinea capitis) and neurofibromatosis type II (NF2) are risk factors for development of the disease.

NF2 is an autosomal-dominant genetic disease due to a mutation of a gene on chromosome 22 (22q12) that causes a defect

Fig. 134.1 (a) Antoni A and (b) Antoni B areas from a schwannoma. The cells are spindle-shaped, and the nuclei can be seen lining up or “palisading” in areas that represent characteristic Verocay bodies (H&E, x100).

Fig. 134.2 Frenzel glasses are useful for magnifying a patient's eyes during an evaluation for nystagmus. They also obscure the patient's vision so that visual fixation is not possible.

in a tumor suppressor protein, merlin (also called schwannomin). Patients with NF2 are at increased risk for bilateral VSs as well as other central nervous system tumors, including meningiomas, other schwannomas, and ependymomas.

134.5 History and Physical Examination

Tumors of the CPA and IAC often present with unilateral hearing loss and tinnitus. A patient presenting with asymmetric hearing loss or asymmetric subjective tinnitus should prompt the clinician to investigate for retrocochlear pathology. Although some have been suggested, there are no universal guidelines on the degree of hearing asymmetry that should prompt further evaluation. A hearing loss of 10 db HL or more in multiple frequencies, especially in combination with impairment in auditory discrimination scores or other cranial nerve palsies, should raise suspicion for a neoplasm.

The work-up of any patient with a suspected lateral skull base lesion should include a detailed history and a head and neck examination, including otoscopy. A pertinent history includes the timing of the onset of hearing loss and tinnitus; history of otologic infections, previous head and neck surgery, imbalance, vertigo, falls, loss of coordination, or headaches; family history of brain tumors, including acoustic neuromas and meningiomas; past history of other neurologic tumors or any malignancies; and symptoms of cranial nerve dysfunction (e.g., facial hypesthesia, diplopia, dysphagia, aspiration, dysphonia, shoulder or tongue weakness). Symptoms of facial spasm or facial pain should lead the examiner to consider advanced disease or one of the rarer CPA pathologies.

Clinical vestibular testing should also be performed in all patients with suspected retrocochlear lesions because it can give clues about the status of the inner ears. Standard clinical vestibular testing should include observation for spontaneous nystagmus and post-head shake nystagmus, preferably with Frenzel goggles (□ Fig. 134.2), which eliminate fixation; a head thrust test; a Dix-Hallpike test to rule out benign paroxysmal positional vertigo; Romberg testing; cerebellar testing; and a Fukuda stepping test. Common findings in a patient with VS include a

Fig. 134.3 An audiogram typical of a patient with a right-sided vestibular schwannoma shows an asymmetric sensorineural hearing loss with impairment of speech discrimination on the affected side.

Fig. 134.4 Auditory brainstem response tracing from a patient with right-sided retrocochlear disease (vestibular schwannoma). The absolute latencies for waves III and V, as well as the interwave latency (I through V), are prolonged on the right side (above). The left side (below) is normal.

correction saccade after head thrust toward the lesion, post-head shake nystagmus with a fast phase away from the lesion, and a tendency to turn toward the lesion on Fukuda testing. Patients with large tumors can show signs of cerebellar dysfunction, loss of corneal reflex or facial hypesthesia resulting from CN V compression, or signs of lower cranial nerve dysfunction.

134.6 Testing

An audiogram, including speech reception testing, should be performed for every patient with suspected retrocochlear disease. Classic findings on standard audiometric testing include asymmetric sensorineural hearing loss and impaired speech discrimination on the side of the lesion (□ Fig. 134.3). Additionally, "rollover" is sometimes noted, in which an increase in the loudness of the presented speech sounds actually leads to a decrease in speech recognition ability at the louder level.

Auditory brainstem response (ABR) testing has been used in the past to screen for retrocochlear lesions (□ Fig. 134.4), but it lacks sensitivity for small lesions. The stacked ABR has been reported to increase sensitivity for smaller tumors, but it still has some problems, especially related to intersubject variability.

Fig. 134.5 T1-weighted magnetic resonance (MR) image after contrast shows enhancement of a left intracanalicular vestibular schwannoma (VS; arrow) on (a) axial and (c) coronal views. The VS is located where the cerebrospinal fluid signal is absent (arrow) in the left internal auditory canal on a (b) high-resolution, T2-weighted CISS (constructive interference steady state) sequence. The VS is not visible on noncontrast T1-weighted MR imaging. (d) The arrow points to the location of the tumor that is not visible.

The gold standard for the diagnosis of CPA tumors is gadolinium-enhanced magnetic resonance (MR) imaging of the brain, including thin-cut (≤ 3 mm) images through the IAC region. It is important to view T1 and T2 sequences, including contrast-enhanced images, in both coronal and axial sections. VSs, meningiomas, and malignancies typically enhance on contrasted T1 sequences. VSs and meningiomas are difficult to differentiate on MR imaging only. Meningiomas may exhibit a dural “tail sign” and/or hyperostosis of bone adjacent to the tumor. A dural “tail sign” refers to enhancement of a portion of the dura at the edges of the meningioma, giving the appearance of a “tail.” T1 sequences without contrast may reveal CPA lipomas, and T2 images are useful for locating epidermoids and arachnoid cysts. High-resolution T2-weighted images are also useful for confirming the presence of a space-occupying lesion, such as a VS, in the IAC. The VS will prevent cerebrospinal fluid (CSF) signal at the site of the lesion, which will show up as a hypointense area on T2 imaging (□ Fig. 134.5). Although relatively insensitive, this technique may be used as a screening tool in a low-risk patient if gadolinium was not administered. Standard MR imaging of the brain without dedicated, thin IAC cuts or without contrast may miss small lesions, and imaging should be repeated if the level of suspicion is significant.

For patients who are not candidates for MR imaging (e.g., metallic implants, problems with access), thin-cut computed tomography (CT) of the brain and temporal bones with contrast is the next best option, but it is not as sensitive as MR imaging and will not likely show small lesions. CT with contrast or ABR screening may be a reasonable option if the patient is elderly or

in poor health because it is unlikely that a subcentimeter benign tumor would be treated even if identified.

If the patient has a known CPA tumor or abnormalities on the clinical vestibular tests previously described for the physical examination, videonystagmography (VNG) should be performed. VNG will often show a weak caloric response on the side with the lesion (□ Fig. 134.6). VNG results can be used to counsel patients regarding their expected recovery following treatment; patients with preexisting large caloric deficits tend to recover faster because vestibular compensation in the contralateral inner ear and central nervous system (CNS) has already occurred before treatment. Some practitioners order facial nerve electroneurography before treatment to determine the subclinical insult to the facial nerve, which can help with patient counseling and treatment planning. Current studies have shown that electroneurography is not a good prognostic indicator of facial nerve function following tumor resection, although the studies have been done in limited patient populations. Further studies are needed to assess the prognostic role of electroneurography when the results are abnormal.

After a tumor has been identified on MR imaging, ABR testing is often performed as a baseline assessment before a hearing preservation approach is considered. If sufficient waveforms are present preoperatively, there will be a greater utility of intraoperative ABR testing to monitor the integrity of the cochlear division of the eighth nerve. Sedation is not typically needed to perform an ABR test in an adult, and many centers can obtain a baseline test in the office setting.

Fig. 134.6 Caloric testing (videonystagmography) from a patient with a right vestibular schwannoma. The test shows a 46% right-sided vestibular weakness. Both sides would be relatively symmetric in a patient with no vestibular dysfunction.

Table 134.1 American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) hearing classification system

Class	Pure-tone threshold (dB)	Speech discrimination (%)
A	≤30 and	≥70
B	>30 and ≤50 and	≥50
C	>50 and	≥50
D	Any level	<50

Source: Adapted from Committee on Hearing and Equilibrium guidelines for the evaluation of hearing preservation in acoustic neuroma (vestibular schwannoma). American Academy of Otolaryngology-Head and Neck Surgery Foundation, INC. *Otolaryngol Head Neck Surg* 1995;113 (3):179–80.

Conventional audiometric results in patients with VSs and other tumors of the CPA are typically reported with one of two scales. The American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) scale (□ Table 134.1) uses the pure-tone average (PTA) of the air conduction thresholds at 0.5, 1, 2, and 3 kHz and the speech discrimination score (SDS). The Gardner-Robertson classification system (□ Table 134.2) uses the poorer of the PTA or speech reception threshold (SRT) and the SDS to classify hearing in a range from class 1 (normal) to class 5 (no hearing).

134.7 Grading

VSs are often classified according to size: small (≤10 mm), medium (10 to 30 mm), large (30 to 40 mm), and giant (>40 mm). By convention, only the extrameatal portion of the tumor is measured. Intracanalicular tumors are simply referred to as “intracanalicular.” The extrameatal portion is measured with the axial MR imaging or CT scan that shows the largest portion of the tumor. Two linear measurements are taken, one of the maximal diameter in a plane parallel to the petrous ridge and one of the maximal diameter perpendicular to the first measurement. The square root of the product of the two measurements rounded to the nearest 0.5 cm is the tumor size (□ Fig. 134.7).

Meningiomas can be classified according to the World Health Organization (WHO) grading system. WHO grade I meningio-

Table 134.2 Gardner-Robertson classification for hearing preservation

Class	Pure-tone average or speech reception threshold (dB) ^a	Speech discrimination (%)
1	0–30 and	70–100
2	31–50 and	69–50
3	51–90 and	49–5
4	91–maximum loss and	4–1
5	No response and	No response

^aUse the better score. If the pure-tone average or speech reception threshold score and the speech discrimination score do not qualify the patient for same class, use the class appropriate for the poorer of two scores.

mas are the most common and typically have the most benign clinical course. The most common variants are the meningothe-
lial, fibroblastic, and transitional patterns. WHO grade II (atypical) and WHO grade III (anaplastic) tumors are less common.

134.8 Treatment

There are four major treatment options for tumors of the CPA and IAC: (1) observation, (2) microsurgical resection, (3) stereotactic radiosurgery, and (4) multimodality therapy. Observation is an option for smaller asymptomatic tumors or for tumors that do not appear to be growing at a significant rate. In a study of the natural history of 552 patients followed with observation and serial MR imaging for VSs over a mean of 3.6 years, significant growth occurred in 17% of tumors that were confined to the IAC and in 28.9% of tumors that extended beyond the IAC. The tumors that grew typically did so within 5 years of diagnosis. However, not all tumors have an indolent course. Some tumors grow rapidly, and patients require treatment to avoid complications of tumor growth, including hearing loss, dizziness, brainstem compression, hydrocephalus, and eventual coma or death. It is reasonable to observe small tumors with serial

audiograms and MR imaging. Typically, MR imaging and audiography will be repeated 6 months after the initial diagnosis of a tumor. If there is no significant change, testing may be repeated yearly. In a meta-analysis of patients with good hearing and small tumors, patients who had tumors with slower growth rates (≤ 2.5 mm/y) had higher rates of hearing preservation than did patients with faster-growing tumors (75% vs 32%, $p < 0.0001$).

Microsurgical resection can be categorized into hearing preservation and non-hearing preservation approaches. There are various criteria for deciding which approach to use, but the status of the patient's hearing and the tumor size are foremost in

Fig. 134.7 Measurement of a right-sided acoustic neuroma (AN). The petrous ridge is marked with a white dashed line. The largest diameter in a plane parallel to the petrous ridge (3.12 cm) times the largest diameter perpendicular to the first measurement (2.49 cm) equals 7.77 cm^2 . The square root of 7.77 equals 2.78. The final AN measurement equals 2.5 cm (2.78 rounded to the nearest 0.5 cm).

the decision-making process. “Serviceable hearing” is hearing that is realistically useful to the patient for understanding speech. Serviceable hearing includes hearing that is normal or nearly normal, as well as hearing thresholds that can realistically be rehabilitated with a hearing aid. A gross rule of thumb regarding serviceable hearing is the “50/50” rule. If a patient has a PTA (or an SRT) worse than 50 dB HL and an SDS worse than 50% (AAO-HNS class D or E, or Gardner-Robertson class 3, 4, or 5), the patient's hearing is considered to be generally not serviceable. Overall, the preservation of serviceable hearing (AAO-HNS class A or B) is possible in only about 40 to 50% of patients with tumors smaller than 2 cm.

Hearing preservation approaches include the middle cranial fossa approach and the retrosigmoid (RS) approach. A translabyrinthine (TL) approach is a non-hearing preservation procedure that gives the best overall view of the CPA with least amount of cerebellar retraction, at the expense of hearing. Factors affecting the decision-making process other than hearing status and tumor size include tumor location, patient age, vestibular function, and patient and surgeon preference (□ Table 134.3). The TL and RS approaches will be described below. Intraoperative facial nerve monitoring is standard during all approaches to the CPA.

134.8.1 Translabyrinthine Approach

Although it does not allow hearing preservation, the TL approach is a versatile option that is useful for any tumor size or location. The TL approach offers the surgeon the best view of the entire IAC and CPA whereby even the fundus (the most lateral portion of the IAC near the meatal foramen) can be visualized. Additionally, the TL approach allows the surgeon to view the vestibular nerves with relative ease because the facial nerve lies medially in this plane of dissection (□ Fig. 134.8).

The TL approach begins with an incision placed slightly posterior to a standard postauricular mastoidectomy incision, but in the same C-shape configuration. A generous mastoidectomy is accomplished first. Next, bone is removed from the sigmoid sinus, posterior fossa dura, and middle fossa dura. Some surgeons prefer to leave a small island of bone on the sigmoid sinus (“Bill's island”) to protect the sinus from instrumentation and the rotating drill shaft during further tumor exposure and

Table 134.3 Advantages and disadvantages of the three major approaches to the cerebellopontine angle and internal auditory canal

	Middle cranial fossa	Translabyrinthine	Retrosigmoid
Advantages	Hearing preservation possible No intradural drilling Low rate of headache	Consistent identification of facial nerve Not limited by tumor size No intradural drilling Wide exposure to posterior fossa Low recurrence rates Auditory brainstem implant placement possible Low rate of headache Minimal or no cerebellar retraction	Not limited by extrameatal tumor size Hearing preservation possible Wide exposure at brainstem Auditory brainstem implant placement possible Consistent identification of facial nerve Neurosurgeons most familiar with this approach
Disadvantages	Limited to small tumors Temporal lobe retraction Limited posterior fossa exposure Increased recurrence risk if tumor is unfavorably positioned	Definite complete hearing loss Neurosurgeons less familiar with this approach Requires abdominal fat graft	Limited exposure for lateral internal auditory canal Possible intradural drilling Higher rate of postoperative headache Possible need for cerebellar retraction

resection. A labyrinthectomy is performed, and the IAC from the fundus to the porus acusticus is skeletonized. The goal is to remove bone approximately 270 degrees around the circumference of the IAC. Often, the cochlear aqueduct is opened while a trough is drilled inferior to the IAC and superior to the jugular bulb. When the cochlear aqueduct is opened, CSF flows from the opening, slightly decompressing the posterior fossa.

The dura of the posterior fossa inferior to the superior petrosal sinus and superior to the jugular bulb region is carefully opened. The seventh and eighth cranial nerves can be seen arising from the pons before they travel to the IAC through the CPA. Laterally, at the fundus of the IAC, “Bill’s bar” can be palpated where it divides the facial nerve anteriorly from the superior vestibular nerve posteriorly. The transverse crest is seen separating the superior and inferior compartments of the IAC.

After tumor removal, the TL defect is usually closed with an abdominal fat graft because it is not possible to achieve a watertight dural closure following this approach. To prevent CSF rhinorrhea, the middle ear and eustachian tube are packed with periosteal or muscle tissue, and the mastoid antrum and air cells are covered with temporalis fascia and/or bone wax. The fat graft is gently packed into the craniotomy defect, and the wound is closed in layers over the fat.

134.8.2 Retrosigmoid Approach

The RS approach has the advantage of being familiar to most neurosurgeons, who may refer to it as the suboccipital approach. In reality, the two names are often used interchangeably, although the RS approach tends to be positioned slightly closer to the sigmoid and transverse sinuses. The RS approach has the ability to preserve hearing in selected cases, but hearing preservation with this approach is unlikely if exposure is needed in the lateral third of the IAC.

Intraoperative ABR monitoring is performed during an RS approach if hearing preservation is attempted. It is important to prevent antiseptic solution from accumulating in the external auditory canal because this will obscure ABR readings.

The RS approach begins with an incision similar to that of the TL approach. It is important to expose adequately the posterior portion of the mastoid tip and skull base. To minimize postoperative neck pain, care should be taken to incise the sternocleidomastoid muscle as close as possible to where it attaches to the skin near the mastoid rather than to cut through the belly of the muscle more inferiorly. A craniectomy is performed with cutting and diamond burs behind the sigmoid sinus and below the transverse sinus. A mastoid emissary vein is often encountered in the area posterior to the sigmoid sinus. Hemostasis is achieved with a combination of bipolar cautery and bone wax. Bone dust should be collected if an autologous cranioplasty is planned. Ultimately, an approximately 3-cm-diameter opening is made in the bone.

The posterior fossa dura is opened sharply along the posterior aspect of the sigmoid sinus and tacked open with braided nylon suture. Tumor may often be removed without drilling of the IAC, depending on how laterally the tumor extends past the porus acusticus. If the IAC must be drilled, Gelfoam (Pfizer, New York, NY) or other barrier materials are used to prevent the intradural accumulation of bone dust, which has been associated with postoperative headache and aseptic chemical meningitis.

The edges of the posterior fossa dura incision almost always become desiccated during tumor removal, but they can universally be rehydrated with irrigation so that they can be closed primarily for a watertight dural closure. The closure can be reinforced with a piece of muscle or synthetic dural repair matrix if necessary. It is important to separate the dural closure from the muscular closure to minimize the incidence of chronic postoperative headache. This can be accomplished by placing a

mixture of bone dust and blood (bone pâté) over the dural closure, followed by an abdominal fat graft. Alternatively, hydroxyapatite bone cement has been used to reconstruct the cranial defect with promising results. The wound is then irrigated and closed in layers over the cranioplasty site.

134.8.3 Staged Surgery and Multimodality Therapy

Occasionally, an intraoperative change in the patient's general health condition or a particularly difficult tumor removal may require cessation of a tumor resection before complete removal. Other times, a poor surgical candidate or an elderly patient with a large tumor may require subtotal resection for brainstem decompression without being kept under general anesthesia for the length of time necessary for total tumor removal. In any of these cases, the patient with a subtotal or nearly total tumor resection will be left with three options: (1) serial observation of residual tumor, (2) second-stage surgery for complete resection, and (3) postoperative stereotactic radiosurgery ("multimodality therapy"). Tailoring the treatment algorithm based on all of the available information has been shown to give patients the best chance for a favorable facial nerve outcome, especially patients with large VSs.

134.9 Complications

The primary goal of surgery for CPA tumors is the preservation of life. Mortality and stroke are extremely rare in this modern era of skull base microsurgery, and efforts are now aimed at decreasing the morbidity of treatment. The early removal of unnecessary indwelling catheters (arterial lines, Foley catheters), early ambulation, pneumatic compression devices, perioperative antibiotics, and incentive spirometry help to minimize complications common to all surgical patients. Additionally, there are unique complications that may occur after skull base surgery.

The risk for CSF leak following the surgical resection of VS has been reported to be as high as 10.6% in one meta-analysis of 5,964 procedures and was not related to patient age or tumor size. CSF leak can manifest as CSF rhinorrhea, otorrhea, or drainage of fluid through the skin incision. CSF leaks are treated with stool softeners, bed rest, lumbar drain, and/or surgical revision. Bacterial meningitis, another complication, is more common in the presence of CSF leak and is treated with intravenous antibiotics. Aseptic meningitis can be caused by intradural bone dust or other meningeal irritants and is typically treated with corticosteroids. Postoperative patients with fevers and signs of meningeal irritation should be evaluated promptly with a lumbar puncture and CSF analysis.

Immediate or delayed facial palsy can also occur following surgical resection. Immediate facial palsy is typically due to a neurapraxia resulting from stretching the nerve during tumor removal. Neurapraxic injury is more common with larger tumors. Rarely, a complete ipsilateral facial paralysis is due to nerve transection or other iatrogenic trauma. Delayed facial palsy may be due to a reactivation of latent viruses or delayed

surgical edema of the facial nerve. It can occur in up to 15% of patients, and some advocate the perioperative use of antiviral medication to minimize the incidence of this complication. Preoperative corticosteroids also help to control the rates of both immediate and delayed facial nerve weakness. The majority of patients with a delayed facial palsy recover most of their preoperative function, and 90% recover fully.

Headache is a common postoperative complaint following both the TL and RS approaches, but it is more common following RS surgery. As noted earlier, efforts to separate the dural closure from the nuchal musculature may help to control the rates of long-term post-craniotomy headaches.

Tinnitus is often present preoperatively. Although some patients notice improvement or resolution of their tinnitus after treatment, some patients actually develop a new onset of tinnitus. There have not been any accepted methods to improve or predict the outcomes of tinnitus.

Although not a complication, disequilibrium or vertigo is an expected postoperative symptom, especially after the TL approach. Patients usually have symptoms that are inversely proportional to their amount of weakness on preoperative caloric testing. Those with poorer preoperative inner ear function on the side of the tumor have begun central and contralateral compensation and are less affected by the acute loss of unilateral inner ear function. Early ambulation with assistance and focused vestibular rehabilitation beginning on postoperative day 1 are invaluable. Most patients do not need formal vestibular therapy after discharge.

134.10 Roundsmanship

- The two most common neoplasms of the CPA are vestibular schwannomas and meningiomas.
- The two non-hearing preservation approaches for the treatment of VS are the TL and the RS approaches.
- The four options for a patient with a diagnosis of VS are (1) observation, (2) microsurgical resection, (3) stereotactic radiosurgery, and (4) multimodality therapy (i.e., surgical resection + postoperative stereotactic radiosurgery).
- The gold standard for the diagnosis of VS is MR imaging of the brain and IAC with gadolinium contrast.
- NF2 is associated with an autosomal-dominant mutation in a gene located on chromosome 22 (22q12) that codes for a tumor suppressor protein, merlin.
- The most common grade of meningioma is WHO grade I.
- "Rollover" is seen when a patient with retrocochlear pathology has a decreasing SDS as speech is presented at louder levels.

135 Middle Cranial Fossa Anatomy and Surgery

Seilesh C. Babu and Matthew L. Kircher

135.1 Introduction

The middle cranial fossa (MCF), comprising the greater sphenoid wing and the temporal bone, forms the base of the skull upon which the temporal lobe rests. The anatomy, including the neurovascular structures that traverse the MCF and the cochleovestibular apparatus that lies within the petrous temporal bone, will be reviewed. Common disease processes and the basic surgical approaches relevant to the MCF will be the focus of this chapter.

The MCF approach was popularized by Dr. William House in the 1960s. The approach had been described previously, but it was the work of House that established this approach as a reliable surgical technique. Initially, its utility was in addressing vestibular schwannoma in patients with serviceable hearing and tumors that were relatively small and localized to the internal auditory canal. The indications for the MCF approach have since expanded to address multiple skull base pathologies, with the advantage that the labyrinth and its related structures can be approached from above, allowing the labyrinth to remain intact.

135.2 Common Indications for Middle Cranial Fossa Surgery

1. Middle and posterior cranial fossa neoplasms, including vestibular schwannomas, meningiomas, epidermoids, and arachnoid cysts
2. Petrous apex lesions, such as cholesterol granulomas, primary cholesteatomas, chondrosarcomas, and metastases
3. Superior semicircular canal dehiscence syndrome
4. Middle fossa encephalocele and cerebrospinal fluid (CSF) leak
5. Facial nerve decompression for facial nerve paralysis

135.3 Incidence of Disease

1. Vestibular schwannomas: Vestibular schwannomas account for more than 90% of neoplasms of the cerebellopontine angle (CPA) and internal auditory canal (IAC). Less common lesions include meningioma, epidermoid, and facial nerve schwannoma.
2. Petrous apex lesions: Petrous apex lesions are relatively rare and typically reported as small case series, even at large skull base surgical centers. However, incidental petrous apex findings are becoming more common because of the routine use of computed tomography (CT) and magnetic resonance (MR) imaging. Cholesterol granuloma is the most common lesion of the petrous apex.
3. Superior semicircular canal dehiscence (SSCD) syndrome: This entity was first described by Lloyd Minor in 1998. The incidence of anatomical canal dehiscence is 0.5% with only a small subset of patients actually experiencing symptoms.

4. Middle fossa encephalocele: The incidence of tegmen defects in this region ranges from 6% to 22%; once again, only a small subset of patients with tegmen defects will develop an encephalocele and/or CSF.
5. Facial nerve paralysis: Bell palsy is the most common cause of facial paralysis, with most patients recovering full facial function. Trauma to the facial nerve may also occur after a temporal bone fracture or during surgical procedures. Studies have identified poor prognostic factors for facial recovery that include progression to full paralysis and paralysis that does not recover within 3 weeks. Electrodiagnostic techniques can quantify neural degeneration and predict the likelihood of recovery. Patients at risk for poor recovery are rare but may benefit from facial nerve decompression to improve function.

135.4 Applied Anatomy

When the middle fossa floor is viewed from above, the gasserian ganglion is located at the anterior aspect of the petrous apex and gives off the three subdivisions of the trigeminal nerve. The mandibular division, V_1 , passes anteriorly through the superior orbital fissure. The maxillary and ophthalmic divisions, V_2 and V_3 , pass through the foramen rotundum and foramen ovale, respectively. Posterior to the foramen ovale lies the foramen spinosum, through which the middle meningeal artery enters the MCF. The greater superficial petrosal nerve exits from the geniculate ganglion at the lateral aspect of the internal auditory canal (IAC) and runs in an anteromedial direction across the floor of the MCF in parallel alignment with the deeper and more lateral tensor tympani muscle and Eustachian tube. The horizontal portion of the carotid artery lies medial to the Eustachian tube and inferior to the greater superficial petrosal nerve as it courses toward the cavernous sinus (□ Fig. 135.1).

Posteriorly, the arcuate eminence approximates the position of the superior semicircular canal, which tends to be perpendicular to the petrous ridge, although the orientation may be variable in some patients. Medially, the superior petrosal sinus runs along the petrous ridge. The IAC lies in approximately the same plane as the external auditory canal and is found medially at the bisected angle of the superior semicircular canal and greater superficial petrosal nerve. The cochlea lies medial and inferior to the geniculate ganglion at the junction of the greater superficial petrosal nerve and IAC. The vestibule is situated anterolateral to the superior semicircular canal between the lateral end of the IAC and the middle ear space.

After the superior wall of the IAC is removed, the facial nerve can be seen in the anterosuperior portion of the IAC and the superior vestibular nerve in the posterosuperior portion, separated by “Bill’s bar” in the lateral aspect of the IAC. The tegmen tympani and tegmen mastoideum are situated lateral to the labyrinth. This bone can be removed to reveal the epitympanum, the tympanic segment of the facial nerve, the ossicular chain, and the mastoid antrum.

Fig. 135.1 View of the right side in the middle cranial fossa surgical approach. 1, Internal auditory canal; 2, geniculate ganglion; 3, tympanic segment of facial nerve; 4, greater superficial petrosal nerve; 5, carotid artery; 6, eustachian tube; 7, tympanic membrane annulus; 8, cochleariform process; 9, long process of incus; 10, superior semicircular canal; 11, cochlea; asterisk, labyrinthine segment of facial nerve.

135.5 Etiology/Pathogenesis

1. Vestibular schwannoma: The most common lesion of the cerebellopontine (CPA) and IAC is vestibular schwannoma. A slow-growing benign tumor of the eighth cranial nerve sheath, it accounts for 8 to 10% of all intracranial tumors. These lesions exert pressure on surrounding neurovascular structures, thereby leading to auditory and vestibular symptomatology. The vast majority occur sporadically. Tumors with a genetic origin are typically manifestations of the neurofibromatoses types I and II.
2. Petrous apex lesion: The most common lesion of the petrous apex is cholesterol granuloma. Histologically, these lesions consist of a granulomatous response to cholesterol degradation components in blood. They develop in aerated portions of the temporal bone, including the petrous apex, distant to a lesion that prevents normal air cell aeration. Trauma or infection with hemorrhage is a major factor theorized to predispose to the formation of these lesions.
3. SSCD syndrome: SSCD syndrome is the result of bony dehiscence over the superior canal. There appears to be a developmental or congenital predisposition to these bony defects because the bone overlying the intact portions of the superior canal is significantly thinner in patients with unilateral dehiscence than in patients without SSCD. The onset of the signs and symptoms associated with SSCD syndrome typically occurs in adulthood, suggesting that patients with an already thin tegmen bone may be predisposed to the development of a dehiscence caused by overlying temporal lobe pulsations. The dehiscence effectively creates a third mobile window of the inner ear. Whereas sound pressure normally enters through the oval window and dissipates through the round window, the superior canal defect allows pressure to dissipate at this site. As a result, the superior canal is responsive to sound and pressure stimuli.
4. Middle fossa encephalocele: Congenital predisposition to middle fossa encephalocele is thought to result from a disturbance in the normal ossification and pneumatization of the temporal bone. This disturbance in turn creates a bony defect. However, encephalocele develops in only a small subset of patients with tegmen defects. Encephalocele formation and/or CSF leak is oftentimes associated with a locally destructive inflammatory process such as cholesteatoma or chronic otitis media, although surgical and nonsurgical trauma is also implicated. In addition, factors such as benign intracranial hypertension and obesity have been suggested.
5. Facial paralysis: Facial paralysis is most commonly due to Bell palsy, but herpes zoster oticus, temporal bone fracture, facial neoplasm, Melkersson-Rosenthal syndrome, Lyme disease, otitis media, and congenital causes must also be considered in the differential. Most commonly, facial nerve paralysis amenable to MCF decompression or repair is secondary to Bell palsy or to accidental or iatrogenic trauma.

135.6 Clinical Presentation

135.6.1 Vestibular Schwannoma

The typical clinical presentation of a vestibular schwannoma includes unilateral tinnitus and slowly progressive sensorineural hearing loss. Symptoms may be present for years before they are brought to the attention of a practitioner because these lesions tend to be slow-growing, averaging 2 mm of growth per year. Initially, a tumor confined to the IAC may be asymptomatic, but with growth, the cochleovestibular nerve, facial nerve, and labyrinthine vasculature become compressed. Many patients will describe a mild, nondebilitating imbalance because the contralateral labyrinth generally compensates well for single-sided vestibular loss. Also, the facial nerve tends to be relatively resistant to tumor compression and is affected only

by very large tumors. Those tumors that continue to grow may expand the IAC and protrude into the CPA. Rarely, much larger lesions will compress the brainstem, leading to hydrocephalus and even death from tonsillar herniation.

135.6.2 Petrous Apex Lesion

Patients with petrous apex lesions may present with a variety of symptoms and clinical findings. Classically, Gradenigo syndrome describes retro-orbital pain, otorrhea, and ipsilateral sixth cranial nerve paresis secondary to petrous apicitis. Cholesterol granuloma and other petrous apex lesions may also be diagnosed incidentally on imaging studies. However, larger lesions may present with hearing loss and vestibular weakness due to IAC compression. In addition, patients may experience headache and/or retro-orbital, facial, or neck pain, depending on the portion of the temporal bone affected.

135.6.3 Superior Semicircular Canal Dehiscence Syndrome

Patients with SCCD syndrome are variably affected by vertigo brought on by loud sounds (Tullio phenomenon), tragal compression, Valsalva maneuver, or nose blowing. In addition, autophony and sometimes bizarre complaints such as “hearing” one’s eye movements may be present. The Weber tuning fork test typically lateralizes to the affected ear, and patients also may hear a tuning fork placed on the lateral malleolus of the ankle. The clinical manifestations of SSCD syndrome are variable; some patients are affected solely by vestibular or auditory symptoms, whereas others will be affected by a combination. The application of positive pressure to the external auditory canal ultimately causes endolymph displacement, leading to an excitatory ampullofugal deflection of the superior canal. This excitation causes slow-component nystagmus directed upward and away from the affected ear with fast component nystagmus in the opposite direction. These evoked eye movements are in the plane of the superior canal.

135.6.4 Middle Fossa Encephalocele

This entity may present with a unilateral middle ear effusion, conductive hearing loss, a middle ear or mastoid mass, otorrhea, or meningitis or another intracranial infectious process. A common scenario is an adult patient presenting with a unilateral middle ear effusion and conductive hearing loss. After a benign nasopharyngeal examination, myringotomy and tube placement are performed, and the patient notes a persistent clear otorrhea. Leakage may be intermittent and occur spontaneously or with increased intracranial pressure (i.e., Valsalva maneuver).

135.6.5 Facial Paralysis

Facial function should be documented with an established system, such as the House-Brackmann grading scale, to quantify the dysfunction and track outcomes. The clinical presentation in facial paralysis is of the utmost importance in determining the etiology, with special attention to the onset, duration, and

severity of paralysis. A complete history and physical examination, including otoscopy, should be performed in all patients. Middle ear and parotid lesions responsible for facial paralysis may be evident on examination.

The acute onset of paralysis or paresis with full recovery within 3 weeks is seen in the majority of patients with Bell palsy. Those patients with a gradual onset of weakness over 3 weeks, failure to resolve incomplete paresis, failure to regain function after 3 to 6 months, recurrent facial palsy, facial pain, or associated cranial neuropathy should be considered for further work-up.

Immediate facial paralysis after trauma indicates significant nerve impingement or transection. Delayed weakness indicates the gradual development of nerve edema and blockage of axoplasmic flow.

135.7 Testing

135.7.1 Vestibular Schwannoma

Auditory and vestibular studies assess the functional integrity of the audiovestibular system and are the preferred initial screening studies. Based on this information, the decision to perform imaging studies for a definitive anatomical diagnosis is made.

Audiometry

Asymmetric sensorineural hearing loss or impairment of speech discrimination disproportionate to pure-tone loss on a routine audiogram is suggestive of a retrocochlear lesion.

Auditory Brainstem Response Testing

The brainstem response to a broadband click is recorded, and the latencies of wave V for the two ears are compared. An adjusted interaural latency for wave V greater than 0.2 milliseconds is considered abnormal and suggestive of retrocochlear pathology.

Vestibular Testing

Electronystagmography and caloric testing may reveal unilateral vestibular weakness when retrocochlear pathology is present.

Imaging

CT can provide useful information regarding temporal bone pathology, but MR imaging with gadolinium is the imaging choice of study for the evaluation of vestibular schwannoma. Schwannomas enhance with gadolinium and tend to be isointense or hypointense to brain on T1-weighted images and hyperintense on T2-weighted images.

135.7.2 Petrous Apex Lesion

Audiometry

Audiometry is a sine qua non before any intervention of the temporal bone.

Imaging

Characteristic CT and MR imaging findings are paramount in evaluating lesions of the petrous apex. The combination of CT and MR imaging provides the most complete radiologic assessment of petrous apex lesions, allowing the differentiation between benign and malignant lesions and normal anatomical variants.

135.7.3 Superior Semicircular Canal Dehiscence Syndrome

Audiometry

Routine audiogram may reveal a mild conductive hearing loss at lower frequencies and bone conduction thresholds below 0 dB nHL.

Vestibular Testing

Vestibular evoked myogenic potential (VEMP) responses have been used to assess for the presence of SSCD syndrome. In this test, nerve potentials evoked by clicks or tone bursts are recorded from surface electromyographic (EMG) electrodes placed over the ipsilateral sternocleidomastoid muscle while that muscle is tonically contracted. The reflex is thought to be activated by sound transmitted through the stapes footplate to the saccule and inferior vestibular nerve. The threshold for eliciting the VEMP response is lower in an ear affected with SSCD than in a normal ear.

Imaging

High-resolution CT scans reconstructed in the plane of and perpendicular to the plane of the superior semicircular canal can confirm the dehiscence of overlying bone. Of note, SSCD may be noted incidentally on imaging in patients without signs or symptoms of SSCD syndrome.

135.7.4 Middle Fossa Encephalocele

Laboratory

Collected fluid suspected to be CSF can be evaluated for a number of factors that are consistent with CSF composition. A glucose value that is 60% of serum levels, a protein concentration of less than 200 mg/dL, and a chloride level greater than normal serum levels are all consistent with CSF. However, it may be difficult to collect enough fluid to accurately assess these parameters. The identification of β_2 -transferrin, a protein found in CSF and perilymph, is the most sensitive and specific laboratory test to confirm the presence of CSF, with only small trace amounts of fluid required for testing.

Imaging

High-resolution CT scans are needed to define bony defects in the tegmen tympani or mastoid, and MR imaging is superior for defining soft-tissue and dural characteristics and confirming encephalocele communication with the intracranial cavity. CT with the intrathecal injection of metrizamide can

show CSF leak fistulas for diagnosis and localization. The use of other radiopaque intrathecal agents, such as fluorescein and indigo carmine, has been reported. The main limitation is that small or intermittent leaks can lead to false-negative test results.

135.7.5 Facial Paralysis

Laboratory

Laboratory panels including blood glucose, erythrocyte sedimentation rate, angiotensin-converting enzyme, Lyme titers, and VDRL (Venereal Disease Research Laboratory) testing, may be sent to evaluate for systemic causes of facial paralysis.

Electrophysiology

Most physicians use electroneuronography (ENOG) and EMG to determine the level of nerve injury. In cases of incomplete paralysis, ENOG may give prognostic information, although in general these patients have a good prognosis for full facial nerve recovery. In patients with complete paralysis, ENOG can estimate the amount of nerve fiber degeneration. It is used between 4 and 21 days after paralysis to allow time for the onset of wallerian degeneration. Voluntary EMG potentials are measured as well because these may be present in a regenerating nerve and would indicate a greater chance of facial nerve recovery. Degeneration of more than 90% on ENOG without voluntary EMG potentials indicates a greater likelihood of poor facial nerve recovery, and facial nerve decompression may therefore be considered.

Imaging

Facial paralysis after temporal bone trauma should be evaluated with high-resolution CT of the temporal bone. Infectious or inflammatory processes may show evidence of enhancement along the fallopian canal with gadolinium-enhanced MR imaging. In this situation, edema at the meatal foramen is posited to be the common epicenter of neural injury. In addition, CT and MR imaging are complementary in evaluating neoplastic processes involving the facial nerve.

135.8 Treatment

135.8.1 Middle Cranial Fossa Surgery: Basic Technique

A preauricular incision is extended along the temporal region. Temporalis fascia is harvested as necessary. The temporalis muscle is divided, and a 5 x 5-cm craniotomy is performed centered over the zygomatic root. The floor of the middle fossa is exposed by elevating the dura in a posterior to anterior direction to avoid injury to the geniculate ganglion. Dural elevation continues medially to the level of the superior petrosal sinus. The principal landmarks for orientation to the IAC are the greater superficial petrosal nerve and the arcuate eminence, a marker for the superior semicircular canal. With the surgeon working at the bisected angle of these landmarks, wide skeletonization of the IAC begins medially. With progressively smaller

diamond burs, the IAC is unroofed superiorly. Care must be taken in the lateral portion of the canal because of the proximity of the cochlea and vestibule. For tumor removal in the IAC, the dura of the IAC is opened and the facial nerve is freed from the tumor, with care taken to preserve the vascular structures as well. Once tumor removal is complete, the canal is sealed with autologous fat, fascia, or muscle, and the bone flap is replaced.

135.8.2 Potential Complications

CSF leak may occur if the dura is violated. This should be a consideration in older patients because the dura may be less resistant to injury and tear easily with elevation. Intracranial hematoma is a rare postoperative complication in which the patient may present with mental status change or severe headache. If this complication occurs, the patient must be returned to the operating room quickly for hematoma evacuation to prevent more serious sequelae. Language impairment caused by damage of the dominant temporal lobe must also be considered.

135.8.3 Disease-Specific Treatment Considerations

Vestibular Schwannoma

Treatment options include observation, stereotactic radiotherapy, and microsurgical resection. Vestibular schwannomas are typically slow-growing tumors. In fact, approximately one-third of tumors followed over a period of 5 years showed no growth on imaging. Nonetheless, serial MR imaging is indicated to track tumor progress because some tumors have been shown to display rapid growth. Poor operative candidates with tumors that display growth may be offered stereotactic radiotherapy as a primary treatment modality. In addition, patients who have undergone a subtotal resection because attempts at total resection might have caused undue facial nerve morbidity may receive adjuvant radiotherapy. Very large tumors causing brainstem compression are an absolute indication for surgery, with a higher risk for facial nerve dysfunction. Patients who have large tumors with significant CPA involvement may not be ideal candidates for primary radiation therapy because postradiation tumor swelling with hydrocephalus is a recognized complication. Ultimately, except for those with large tumors causing brainstem compression, patients may choose the treatment option that best suits them.

The primary surgical approaches used in the resection of a vestibular schwannoma are the translabyrinthine, retrosigmoid, and MCF approaches. The retrosigmoid and MCF approaches can potentially save hearing in selected patients. The translabyrinthine approach sacrifices hearing but is a more direct approach to the CPA and IAC, with the resultant advantage of requiring minimal brain retraction. The retrosigmoid approach is best suited for patients who have CPA-based lesions with limited IAC extension and serviceable hearing. Cerebellar retraction may be required for optimal exposure. The middle fossa approach is ideally suited for the resection of intracanalicular tumors in patients with serviceable hearing. The MCF approach requires temporal lobe retraction and thus provides limited medial exposure for lesions involving more than 1 cm of the CPA.

The success of hearing preservation depends in large part on maintenance of the cochlear blood supply. Disruption of the labyrinthine artery after IAC dissection despite cochlear nerve preservation can result in significant postoperative hearing loss. In addition, care must be taken to preserve the anterior inferior cerebellar artery, which may loop into the IAC.

Petrous Apex Lesion

The imaging characteristics of petrous apex lesions are paramount in establishing a diagnosis and determining the need for surgical intervention. Benign-appearing cystic lesions may be managed conservatively with observation. Solid tumors of the temporal bone and cholesteatoma are removed when first identified to prevent the further involvement of nearby vital structures. Drainage procedures are inadequate treatment for these lesions, and all reasonable efforts should be made to remove them entirely, while minimizing morbidity. Fortunately, the most common petrous apex lesion, cholesterol granuloma, is a benign cystic lesion that can be managed with drainage to an aerated portion of the temporal bone.

Drainage of a petrous apex cystic lesion is commonly performed via a transcanal infracochlear technique; however, anatomical constraints may sometimes limit this approach. The MCF craniotomy allows drainage of the cyst from above via the previously mentioned MCF surgical steps. Of note, the IAC is identified only as necessary to orient surgical landmarks. The cyst is opened, and a catheter is placed within the cyst and routed to an opening in the tegmen mastoideum to allow continued drainage.

Superior Semicircular Canal Dehiscence Syndrome

The severity of symptoms must be weighed against the risks and benefits of surgery. Some patients may choose lifestyle changes instead of surgery, simply avoiding stimuli that evoke symptoms (i.e., loud sounds, ambient pressure changes). Placement of a tympanostomy tube may be beneficial in some patients with principally pressure-induced symptoms. Autophony or a mild conductive hearing loss may be tolerable to some and intolerable to others. For those patients debilitated by symptoms, plugging or resurfacing of the superior canal may be offered.

This procedure may be done via a transmastoid or an MCF approach, each with inherent advantages and disadvantages. In general, the MCF approach requires temporal lobe retraction but offers a more direct examination of the superior semicircular canal for identification and manipulation. For canal occlusion, an MCF craniotomy is performed, and after exposure of the superior semicircular canal, harvested fascia is gently slid into the lumen of the bony superior canal, with care taken to preserve the underlying membranous superior canal. Overlying bone chips are then used to secure the fascia in place.

Besides the general risks inherent to MCF craniotomy, potential complications of superior semicircular canal occlusion include sensorineural hearing loss and initial worsening of imbalance symptoms postoperatively. Imbalance tends to improve with ambulation and physical therapy; however, recovery can be a longer and more difficult process in older patients.

Middle Fossa Encephalocele

Traumatic CSF leak tends to respond to conservative management with or without a lumbar drain. Middle fossa encephalocele with CSF leak requires surgical intervention to reconstitute the bony defect and prevent further encephalocele herniation. The current standard for encephalocele repair involves a multi-layered closure including a soft-tissue repair of the dura combined with a repair of the bone defect. The encephalocele is resected or reduced with bipolar cautery because it is inactive glial tissue. Temporalis fascia is typically used for soft tissue, with cortical bone grafts or hydroxyapatite synthetic bone cement used to reconstruct the bony defect. Transmastoid and middle fossa craniotomy approaches are routinely used to expose these leaks, often in combination. The transmastoid approach is best suited for isolated posterior tegmen defects. Anterior or medial sites are addressed via MCF craniotomy. In addition, multiple areas of tegmen dehiscence may be present and are best visualized from the MCF viewpoint. The potential for meningitis must be considered whenever a CSF leak is present.

Facial Nerve Paralysis

If a facial nerve has more than 90% degeneration on ENOG with absent EMG potentials, then patients may be offered MCF facial nerve decompression. Facial nerve decompression via MCF has been shown to have benefit only within 2 weeks after injury and is intended to reduce perineural edema and reestablish neural integrity along the labyrinthine, meatal foramen, and geniculate ganglion segments of the facial nerve in Bell palsy. Traumatic facial nerve injuries may also be explored through an MCF approach for decompression or repair via primary nerve anastomosis or grafting.

135.9 Roundsmanship

- The middle cranial fossa approach may be used to address small vestibular schwannomas in the internal auditory canal

or with moderate extension into the cerebellopontine angle in patients who have good preoperative hearing.

- Cholesterol granuloma and other petrous apex lesions may be addressed with a middle cranial fossa approach.
- Superior semicircular canal dehiscence may be treated with canal occlusion via middle cranial fossa exposure of the canal dehiscence.
- Middle fossa encephalocele and CSF leak are commonly repaired via a middle cranial fossa craniotomy.
- Facial nerve decompression or repair via middle cranial fossa craniotomy may be used in patients with complete facial paralysis and electrophysiologic testing indicating a poor chance of facial nerve recovery.

136 Vascular Tumors of the Skull Base and Petrous Apex Lesions

Raj Murali, Dhruve S. Jeevan, Jayson A. Neil, and Christopher J. Linstrom

136.1 Jugular Foramen Lesions

Tumors of the skull base pose a significant management challenge as a consequence of the proximity of complex neurovascular structures. Advances in anesthesia, imaging modalities, and microsurgical techniques have enabled the surgical removal of these lesions. Because of their rarity and the complexity of their management, these tumors are best managed by a multidisciplinary team that often includes a neurosurgeon as well as an otolaryngologist.

A variety of vascular tumors can affect the skull base, including hemangiomas, hemangiopericytomas, lymphangiomas, juvenile nasopharyngeal angiofibromas, angiomatous meningiomas, and paragangliomas (glomus tumors). As a whole, they are uncommon entities, and thus accurate information about their incidence is unavailable. Many of these lesions are beyond the scope of this chapter, and we will focus our attention on tumors of the jugular foramen and paragangliomas.

The jugular foramen is a complex structure in the skull base at the junction of the temporal and occipital bones. The most common vascular tumors of this region are glomus jugulare tumors. These benign tumors arise from the neuroendocrine autonomic chemoreceptor cells (glomus bodies) of the jugular bulb and surrounding region and are included in a group of tumors referred to as paragangliomas. Paragangliomas occur at various sites and include carotid body, glomus vagale (inferior vagal ganglion), and glomus tympanicum (middle ear) tumors. Although the tumors are usually slow-growing and hypervascular, they occasionally can be more aggressive or even malignant.

136.1.1 Incidence of Disease

Glomus jugulare tumors are very rare, with an estimated annual incidence of 1 per 1.3 million persons. Nonetheless, glomus jugulare tumors remain the most common tumors of the middle ear and are second only to vestibular schwannomas as the most common tumors of the temporal bone. The mean age of patients at presentation is between 40 and 70 years, and the tumors are more common in females than in males by a 6:1 ratio. There is a left-sided predominance, with a multicentric incidence of 3 to 10% in sporadic cases and of 25 to 50% in familial cases.

136.1.2 Applied Anatomy

The jugular foramen is perhaps the most complex of all the skull base foramina (□ Fig. 136.1, □ Fig. 136.2, □ Fig. 136.3, □ Fig. 136.4, □ Fig. 136.5, □ Fig. 136.6). It is an irregular gap in the skull base of the posterior cranial fossa between the temporal and occipital bones. Both neural and venous structures are transmitted through it. Sometimes, the terms jugular foramen and jugular fossa are used interchangeably to describe the jugular foramen. However, strictly speaking, the term jugular fossa should be limited to the deep, thumb-shaped depression that is seen on the external aspect of the skull base. Anatomically, this depression is just below the jugular foramen and houses the jugular bulb.

The foramen is separated by a fibrous band (jugular spine) into a larger posterolateral compartment (pars venosa) transmit-

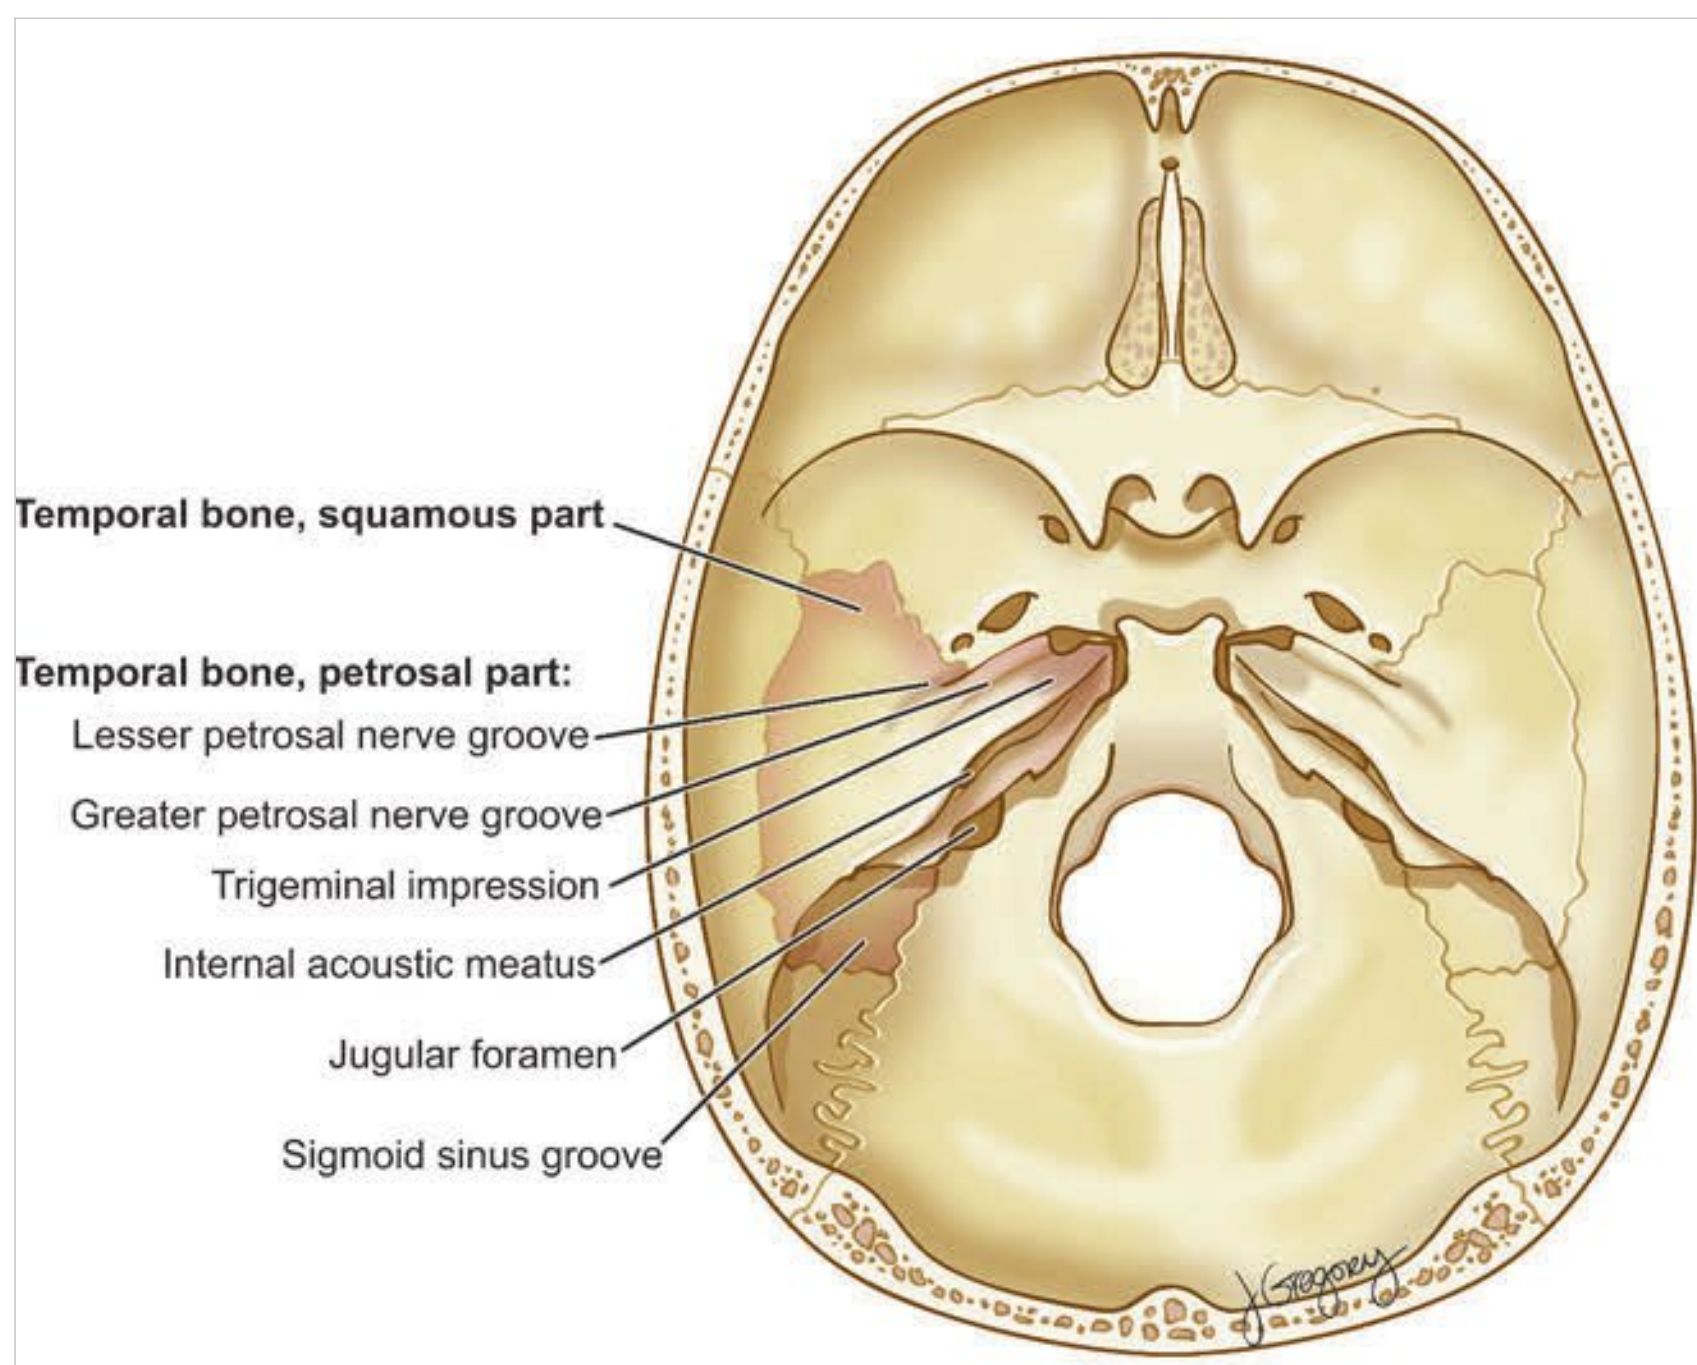

Fig. 136.1 Cranial base anatomy: superior view.

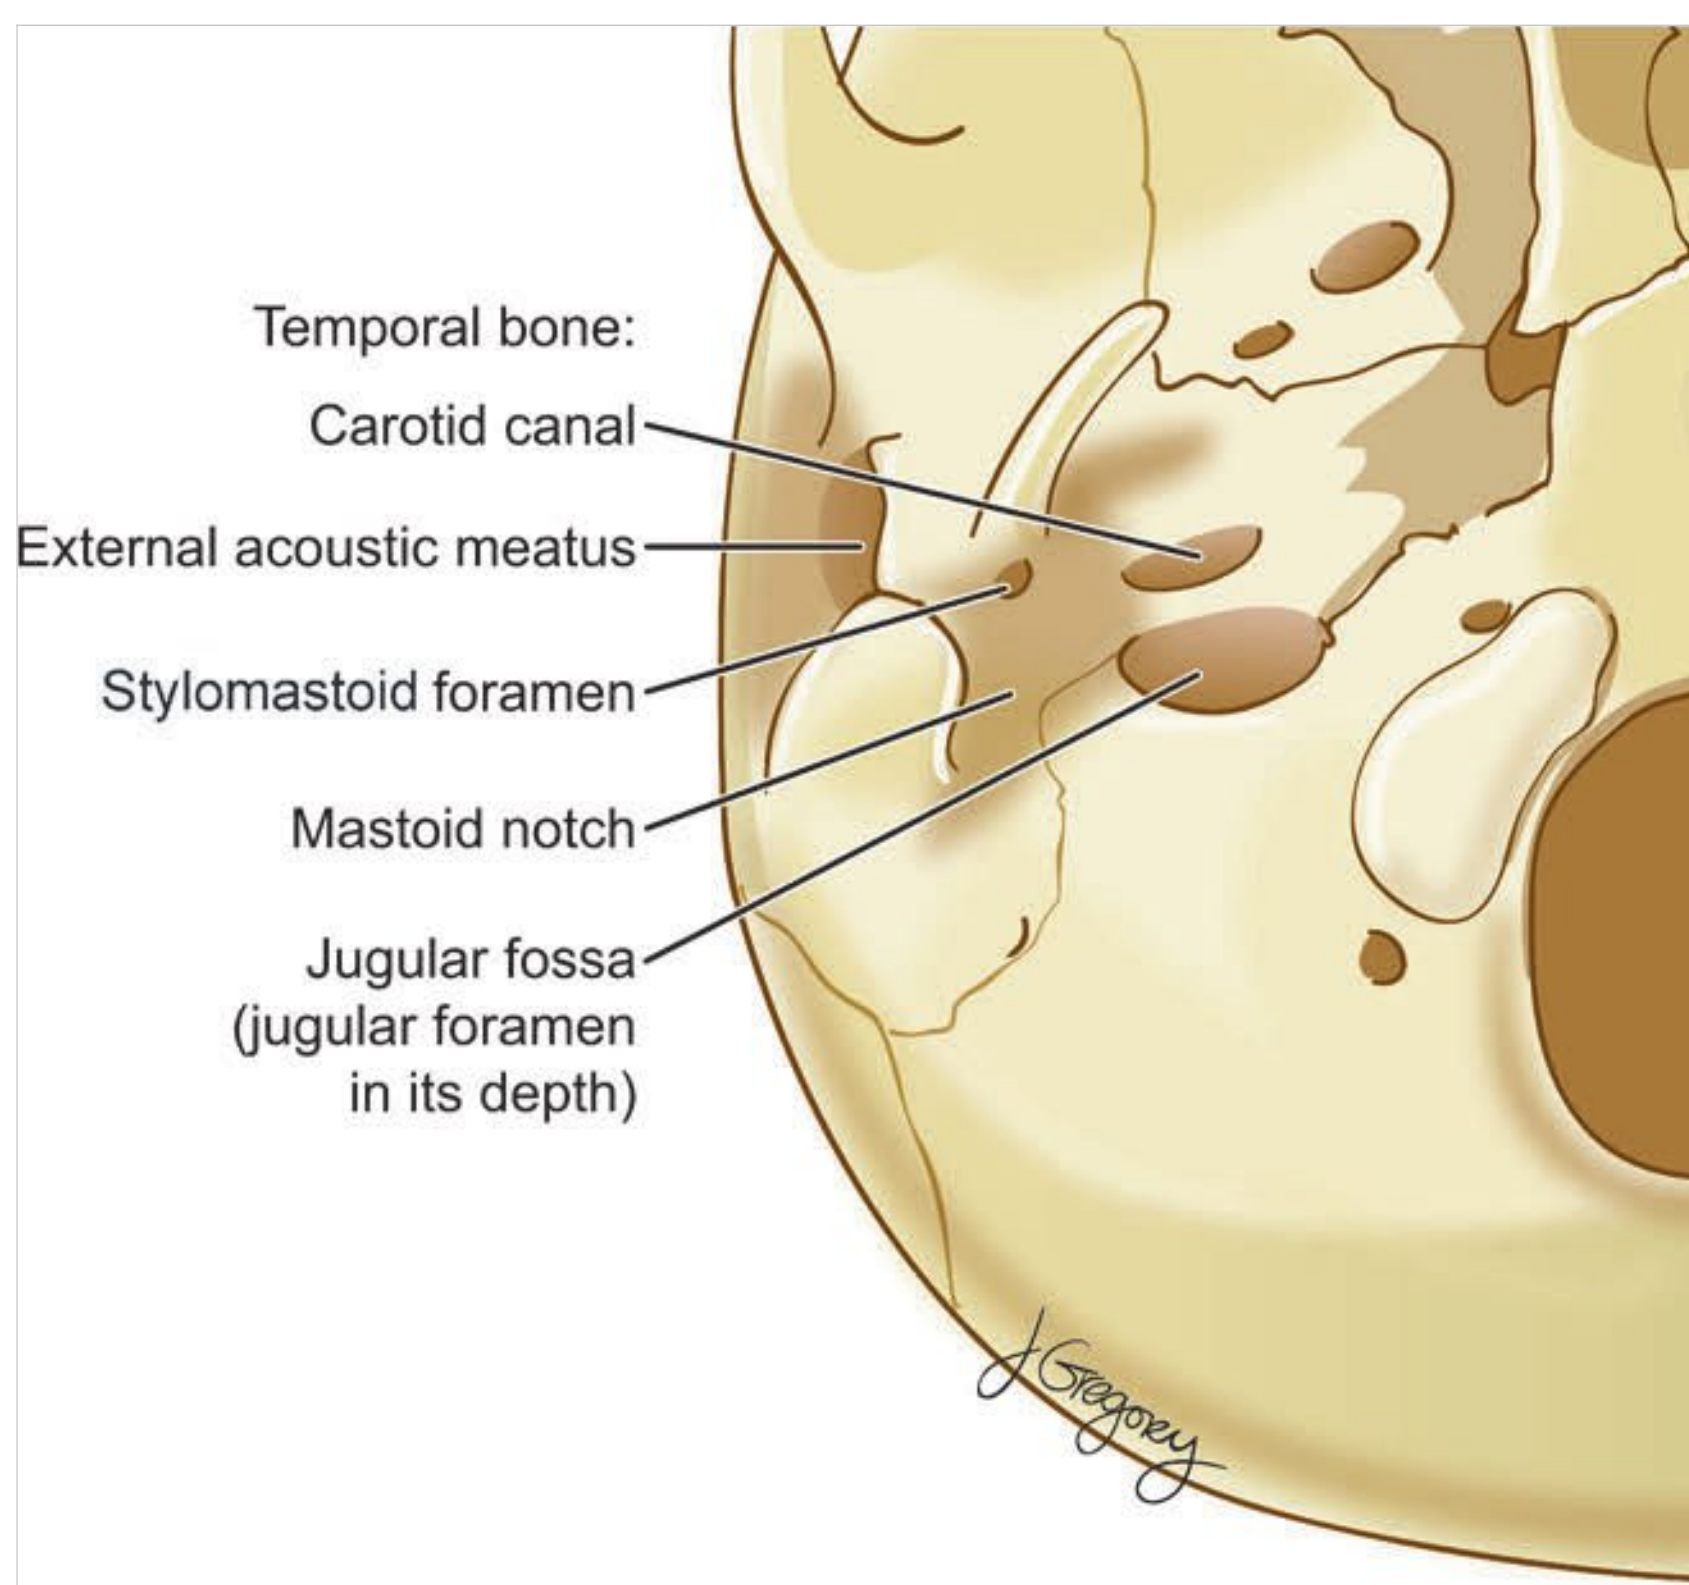

Fig. 136.3 Cranial base anatomy: inferior view. Source:

ting the jugular bulb, posterior meningeal artery, and cranial nerves (CNs) X and XI. The smaller anteromedial compartment (pars nervosa) receives the inferior petrosal sinus and CN IX (see □ Fig. 136.2, □ Fig. 136.4, □ Fig. 136.5, □ Fig. 136.6).

The inferior petrosal sinus and the sigmoid sinus join to form the internal jugular vein in the posterior compartment of the jugular foramen. At its origin, the internal jugular vein is somewhat dilated, and this dilatation is called the superior bulb. The lower cranial nerves are situated medial to the superior jugular bulb and posterior to the entry of the inferior petrosal sinus. The jugular canal then courses in an anterior, inferior, and lateral direction to exit the skull. The internal jugular vein runs down the side of the neck in a vertical direction, maintaining a lateral position first to the internal carotid artery and then to the common carotid. At the root of the neck, the jugular vein

unites with the subclavian vein to form the brachiocephalic vein (innominate vein); just before its termination is a second dilatation, the inferior bulb.

Many important structures lie in close proximity to the jugular foramen at the base of the skull, including the internal auditory canal, the middle ear, the medial external auditory canal (superiorly), the facial nerve (posterolaterally), and the internal carotid artery (anteriorly) within the carotid canal (see □ Fig. 136.1 and □ Fig. 136.2). At the exiting end of the jugular foramen, the internal carotid artery, internal jugular vein, and CNs VII, X, XI, and XII are all within a 2-cm area (see □ Fig. 136.3 and □ Fig. 136.4).

Both the glossopharyngeal nerve and the vagus nerve have parasympathetic branches arising from ganglia within the jugular foramen. The tympanic branch of the glossopharyngeal

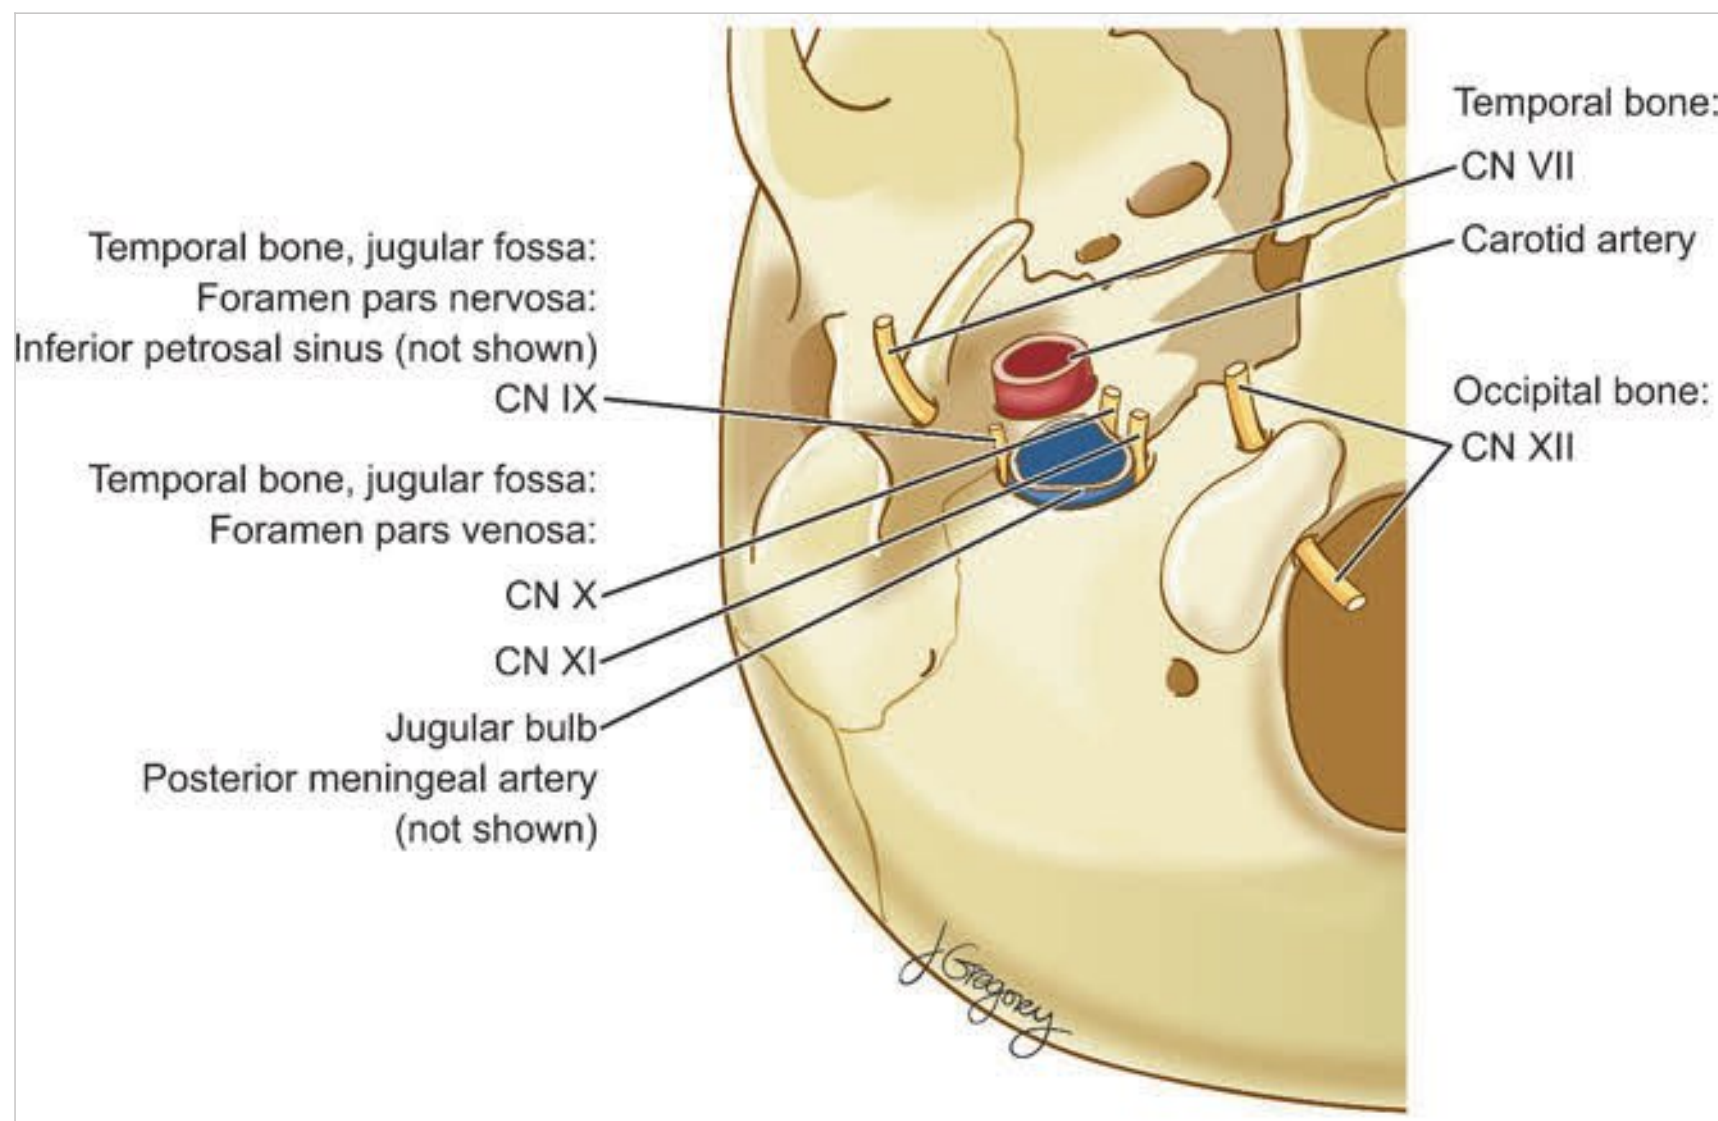

Fig. 136.4 Cranial base anatomy: inferior view including selected vascular and nerve structures. CN, cranial nerve.

nerve and the auricular branch of the vagus nerve are the largest of these, and they form a complex plexus within the jugular foramen and the adjoining tympanic cavity. Glomus tumors are thought to originate in these autonomic ganglia.

Because a great deal of anatomical variation occurs in this area, careful study with computed tomography (CT) and magnetic resonance (MR) imaging is essential for calculating the precise locations of these structures in the skull base of an individual patient. For example, the jugular bulb in some patients may be very high-riding, almost as high as the internal auditory meatus itself. In such a case, the jugular bulb can be accidentally entered while the internal auditory meatus is being drilled, resulting in troublesome bleeding. Thin-cut CT studies of the temporal bone with axial, coronal, and sagittal reconstructions will delineate the anatomy of this region in detail. It is also essential for students to perform cadaver dissections of the temporal bone under the microscope to understand the three-dimensional anatomy of these structures.

136.1.3 The Disease Process: Etiology and Pathogenesis

Glomus jugulare tumors are examples of chemodectomas, or nonchromaffin paragangliomas. They originate from chromaffin-negative glomus cells derived from the embryonic neural crest, functioning as part of the sympathetic nervous system. Accordingly, they are categorized as originating from a neural cell line in the World Health Organization classification of neuroendocrine tumors. Chemodectomas also occur at other sites in the body, such as the carotid sheath, where they are referred to as carotid body tumors.

Glomus jugulare tumors are thought to originate from chemoreceptor cells located within the adventitia of the jugular bulb. They can be associated with either the tympanic branch of the glossopharyngeal nerve (Jacobson nerve) or the auricular branch of the vagus nerve (Arnold nerve), both of which are in close proximity to the jugular bulb. Many of these tumors secrete neuropeptides and catecholamines, occasionally in clinically symptomatic amounts that cause hypertension, excessive perspiring, tachycardia, and headaches.

The tumors are often well encapsulated and appear purplish to the naked eye. They tend to grow slowly, expanding into and destroying the surrounding bone of the jugular foramen. Within the temporal bone, they expand through the pathways of least resistance, such as air cells, vascular lumina, skull base foramina, and the eustachian tube. They invade and erode bone in a lobular fashion, often sparing the ossicular chain. As the tumor grows, it can compress the surrounding nerves in the jugular foramen and occlude the jugular bulb itself.

Glomus jugulare tumors are hypervascular, with a great tendency to recruit numerous blood vessels from the surrounding areas, and are often supplied by branches of the external carotid artery, especially the ascending pharyngeal and occipital arteries. Vascular growth factors may play an important role in this excessive vascularity. Large tumors may also invade the carotid artery wall and directly derive their blood supply from this vessel, or they may grow within the lumen of the jugular bulb.

Histologically, glomus tumors are made up of round to polygonal cells that congregate in small nests, known as zellballen.

These cells are dispersed between vascular channels. The principal cell, also known as the chief cell, is positive for chromogranin and neuron-specific enolase. The surrounding cellular matrix of the zellballen, made up of sustentacular cells, stains positive for S-100 protein and sometimes also for gliofibrillary acidic protein (GFAP).

Metastases from glomus tumors occur in approximately 4% of cases. A reduction in the proportion of chief cells and a poorer staining of sustentacular cells for S-100 and GFAP are reported to be correlated with a higher tumor grade. Metastatic lesions are distinguished from multicentric lesions on the basis of location and have been found in the lungs, lymph nodes, liver, vertebrae, ribs, and spleen. Malignancy of the tumor is likely related to TP53 and p16INK4A mutations but is also characterized by the immunohistologic presence of MIB-1, Bcl-2, and CD3.

136.1.4 Medical Evaluation

Presenting Complaints

Symptoms due to glomus tumors often have an insidious onset and as a result go unnoticed, often with a delay in diagnosis. The signs and symptoms can be classified as those related to the ear, to the cranial nerves, or to other structures, and they can often be correlated with the anatomical compressive/erosive characteristics of the lesion.

The most common symptoms are hearing loss and pulsatile tinnitus. The hearing loss is usually conductive in nature, resulting from a secondary effusion or mass effect in the middle ear. Often, a characteristically pulsatile, reddish blue tumor can be seen behind the tympanic membrane on otoscopic examination. Other aural signs include dizziness, vertigo, a sensation of fullness in the ear, ear pain, and discharge from the ear.

Symptoms of cranial nerve compression can include hearing loss due to involvement of cranial nerve VIII and/or hoarseness of voice or difficulty swallowing due to involvement of CNs IX and X. The presence of jugular foramen (Vernet) syndrome, characterized by the simultaneous paresis of cranial nerves IX through XI (referred to as Collet-Sicard syndrome when CN XII is concomitantly involved), is pathognomonic for this tumor. The onset of the syndrome is usually delayed by almost a year after the initial symptoms of hearing loss and pulsatile tinnitus. The affected patient may exhibit dysphonia/hoarseness, soft palate dropping, deviation of the uvula toward the normal side, dysphagia, loss of sensory function in the posterior one-third of the tongue, decreased parotid gland secretion, loss of the gag reflex, and sternocleidomastoid and trapezius muscles paresis. In larger tumors, the facial nerve may be involved, and patients can present with a peripheral facial palsy. Very large tumors and recurrent tumors with a large intracranial extension can compress the brainstem, resulting in contralateral hemiparesis, ataxia, hydrocephalus, and increased intracranial pressure. Dural sinus involvement can lead to presentations similar to that of sinus thrombosis. Petrous carotid extension may herald Horner syndrome.

A few glomus tumors are hormonally active (2 to 4%) to the extent of causing symptoms and resulting in systemic hypertension and tachycardia (pheochromocytoma-like). Other related symptoms may include headache, perspiration, pallor, and nausea.

Fig. 136.7 MR images demonstrating a large, lobulated, intensely enhancing heterogeneous destructive tumor centered at the left jugular foramen and extending intracranially to the cerebellopontine angle and inferiorly below the base to the C2 level.

Fig. 136.8 Computed tomographic scans of the temporal bone and soft tissue demonstrating an invasive destructive tumor, consistent with glomus jugulare, at the left skull base. The tumor is destroying the left jugular foramen and left hypoglossal canal and is invading the medial left temporal bone, as well as the left occipital condyle.

Fig. 136.9 Internal carotid arteriogram, lateral view, demonstrating the vascular blush of a glomus tumor (short arrows). The main feeding artery is the ascending pharyngeal artery (long arrows).

Testing

Glomus jugulare tumors are diagnosed through clinical examination and imaging rather than biopsy. Diagnostic biopsy is generally contraindicated because of the vascular nature of the tumors and poor accessibility. Identification and operative

planning can be aided by thin-cut CT of the temporal bone with bone and soft-tissue windows, with and without contrast. MR imaging with and without contrast is also useful, especially for larger tumors with intracranial extension (□ Fig. 136.7). Cranial nerve and audiometric examinations are important for baseline investigation, along with urinary assay for catecholamines or their breakdown products.

Imaging studies are particularly helpful in identifying patients in whom the bone between the jugular foramen and the carotid canal is destroyed (□ Fig. 136.8). This finding indicates that the tumor is encroaching upon the carotid artery and is important to recognize before surgery.

Almost all patients with glomus jugulare tumor should undergo vascular studies before surgery. Although CT angiography, MR angiography, and MR venography are useful, the gold standard remains cerebral angiography. Both the internal carotid and external carotid circulation and the vertebral circulation should be studied, with the venous phases included to show the sigmoid sinus and jugular vein on both sides. The classic finding on cerebral angiography is a tumor with a blush in the region of the jugular foramen, with arterial supply from the ascending pharyngeal and occipital arteries (□ Fig. 136.9). The jugular bulb may be completely occluded by the tumor. In these cases, the venous drainage may be entirely contralateral. Cerebral angiography will also reveal the extent of collateral venous drainage, especially from the inferior petrosal sinus. Sometimes, the tumor may be seen as a filling defect within the jugular bulb.

Although formal cerebral angiography is not necessary, its advantage is that it allows the external carotid branches supplying the tumor to be embolized. Such embolization is extremely useful in limiting blood loss during surgical removal of this

Table 136.1 Glasscock-Jackson classification of glomus tumors

Tumor type	Description
I	Small tumor involving jugular bulb, middle ear, and mastoid
II	Tumor extending under internal auditory canal; may have intracranial extension
III	Tumor extending into petrous apex; may have intracranial extension
IV	Tumor extending beyond petrous apex into clivus or infratemporal fossa; may have intracranial extension

Table 136.2 Fisch classification of glomus tumors

Tumor type	Description
A	Tumor limited to middle ear
B	Tumor limited to middle ear or mastoid without involvement of infralabyrinthine space of temporal bone
C	Tumor involving infralabyrinthine and apical spaces of temporal bone, with extension into apex
C1	Tumor with limited involvement of vertical portion of carotid canal
C2	Tumor invading vertical portion of carotid canal
C3	Tumor invading horizontal portion of carotid canal
D1	Tumor with intracranial extension <2 cm in diameter
D2	Tumor with intracranial extension >2 cm in diameter

tumor and is usually performed as a preoperative maneuver 1 or 2 days before surgery. Cross-compression or trial balloon occlusion allows circle of Willis completeness to be evaluated in cases in which the carotid may be heavily involved in the tumor.

Classification of Glomus Jugulare Tumors

Many classification systems exist for these tumors. For example, they can be classified as functional or nonfunctional depending on whether they produce clinically symptomatic levels of catecholamines. They also can be classified on the basis of their location; tumors located primarily in the middle ear are referred to as glomus tympanicum tumors, and those whose main bulk is in the jugular foramen or middle ear are referred to as jugulotympanic tumors. Most commonly, the Glasscock-Jackson and Fisch-Mattox methods are used, which relate to morbidity and mortality. These classifications are based on extension of the tumor to surrounding anatomical structures (□ Table 136.1 and □ Table 136.2).

136.1.5 Treatment

Medical Treatment

Because these tumors commonly present in the sixth and seventh decades of life, many are followed with imaging only and may not require surgical intervention. Patients who have symptomatic catecholamine-secreting tumors may be treated medically with α -blockers and β -blockers. These therapies are also instituted before any interventional procedures to prevent lethal hypertensive crises and arrhythmias. Octreotide has reportedly been used with success to control the growth of somatostatin receptor–positive tumors.

Gross total resection of some extensive tumors may be extremely difficult and carry unwarranted risk. In such cases, radiation therapy is often used for tumor control. It is certainly an option for patients with small tumors, residual tumors, or recurrent tumors, as well as for patients who refuse surgical treatment. Because of its long-term effects on bone and brain, radiation that is not stereotactically targeted is outdated.

Occasionally, glomus jugulare tumors are associated with metastatic disease. Radiation therapy is an option in these circumstances, and the successful treatment of pulmonary metastases with etoposide and cisplatin has been described.

Surgical Treatment

Complete surgical resection is the treatment modality of choice whenever possible but depends on the localization and extent of the tumor. Intraoperative monitoring with electroencephalography and somatosensory evoked potentials is routinely used. Type A and type B glomus tumors are best removed through standard middle ear or mastoid approaches. Type C and type D tumors require skull base techniques, and management is usually shared by a neurotologist and a neurosurgeon. These tumors are typically approached infratemporally. During surgery, the sigmoid sinus, jugular bulb, and presigmoid dura are completely exposed. The jugular vein, internal carotid artery, and lower cranial nerves are all isolated in the neck and traced up to the jugular foramen. The sigmoid sinus is occluded, and the jugular vein is tied off in the neck. The isolated jugular bulb is then excised with the tumor. Tumor may be present within the lumen of the jugular bulb itself. Many of the branches of the inferior petrosal sinus entering the jugular bulb will have to be coagulated and divided. The exact location of the internal carotid artery in large tumors can be detected with intraoperative ultrasound. The tumor can usually be removed

from the adventitia of the internal carotid artery without damaging it.

The integrity of the lower cranial nerves can be preserved, but they have to be manipulated during surgery, which can cause temporary lower cranial nerve palsies. Postoperative cranial nerve deficits must be carefully diagnosed, and when they are present, early rehabilitation must be instituted. The facial nerve may require rerouting, especially in patients with larger tumors. Such rerouting is avoided if possible because it invariably causes at least a temporary facial palsy.

The surgical procedure is long and tedious, and a thorough knowledge of the regional anatomy gained by cadaver dissections is required. Complications include cranial nerve palsies, hearing loss, cerebrospinal fluid leakage, and blood loss. For patients who have very large tumors with significant intradural extension, it is often necessary to use a staged surgical approach.

136.1.6 Outcome and Prognosis

Glomus jugulare tumors are relatively slow-growing tumors that produce cranial nerve palsies, and many of these palsies are benign and cosmetically acceptable. However, long-term quality of life is reduced in patients with glomus tumors. Mortality ranges from 6.2% in those treated with radiation to 2.5% among those treated surgically. The overall mortality rate is 8.7%. Surgical treatment offers the best prognosis, with a 94% survival rate at 20 years and a 77% rate of symptom-free progression.

136.2 Other Vascular Tumors of the Skull Base

Although outside the scope of this chapter, it is necessary to mention some other important vascular tumors of the skull base. These tumors on the whole are relatively rare, and surgical resection remains the mainstay of treatment. Like all skull base lesions, they commonly present with symptoms of compression of important skull base structures.

Juvenile angiofibromas are found exclusively in adolescent boys and originate in the mucosa around the sphenopalatine foramen. The tumor consists of a dense fibrous mass interlaced with variable amounts of thinly walled, endothelium-lined vascular spaces. These tumors of the anterior skull base enlarge to present as nasopharyngeal masses with extension into the paranasal sinuses, orbit, pterygomaxillary space, and cavernous sinus. Epistaxis is a common presentation, along with other sino-nasal symptoms. As for most skull base lesions, the treatment is

primarily surgical resection, although anti-androgenic hormonal treatment and radiation therapy have been described for selected patients.

Hemangiomas are true neoplasms; they can be capillary, cavernous, or mixed, depending on the type of blood vessels present in the lesion. Skull hemangiomas vary from small to very large and may be solitary or multiple. They proliferate rapidly after birth, then gradually shrink during childhood. Involvement of bone is uncommon. Hemangiomas of the skull base most commonly involve the orbital apex, where they affect vision by compressing the optic nerve or structures that pass through the superior fissure.

The term angioablasic meningioma was used in the early literature for a broad group of highly vascularized tumors of the meninges comprising both angiomatous meningiomas and hemangiopericytomas. These extremely rare vascular tumors of the skull base arise from the meningeal lining of the skull base. There is a high rate of recurrence after surgical resection.

136.3 Petrous Apex Lesions

The petrous apex forms part of the middle cranial fossa and lies at the anterior–superior border of the temporal bone (see □ Fig. 136.1). Petrous apex lesions are diagnosed primarily as complications of chronic otitis media. Improved imaging has made it possible to diagnose these lesions accurately and plan surgery in an area with complex anatomy. Lesions of the petrous apex are classified as infectious, inflammatory, neoplastic, or vascular abnormalities (□ Table 136.3), with neoplastic and inflammatory lesions the most common pathologic processes. Generally, the presentation results from compression or other effects of these lesions on surrounding structures.

136.3.1 Incidence

Lesions of the petrous apex remain relatively rare. Once, infectious lesions resulting from middle ear complications were common, but their incidence is decreasing because of improved antibiotic therapy, improved techniques in surgery for chronic ear disease, and the earlier and more frequent placement of tympanostomy tubes. However, incidental lesions are becoming more common because of the routine use of imaging modalities.

136.3.2 Applied Anatomy

The temporal bone is made up of four portions: petrous, squamous, tympanic, and mastoid. The petrous portion is a pyramid with its apex directed anteromedially and its base directed

Table 136.3 Common lesions of the petrous apex

Type	Lesions
Inflammatory or congenital	Cholesterol granuloma, cholesteatoma, mucocele, epidermoid cysts
Infectious	Petrous apicitis, skull base osteomyelitis
Neoplastic	Meningioma; schwannoma (trigeminal, acoustic, jugular foramen); chordoma; chondroma; chondrosarcoma; glomus tumors; metastatic tumors
Vascular	Intrapetrous carotid artery aneurysm, dural arteriovenous fistula, hemangioma, hemangiopericytoma

posterolaterally (see □ Fig. 136.1). The base of the pyramid is the inner ear, the internal carotid artery, and the eustachian tube. The medial, pointed end of the petrous apex connects with the clivus. The anterosuperior or cerebral portion of the petrous apex forms the floor of the middle cranial fossa. The posterosuperior surface or cerebellar aspect of the petrous bone is vertical and marks the anterior limit of the posterior cranial fossa. The junction of the anterior and posterior surfaces is known as the petrous ridge. The inferior surface faces outward as the floor of the lateral skull base.

A number of neural and vascular structures are intimately related to the petrous apex. The trigeminal nerve and ganglion occupy the Meckel cave on the sloping anterosuperior surface of the petrous apex. CN VI traverses the Dorello canal in the petroclinoid ligament before entering the cavernous sinus. CNs VII and VIII enter the petrous bone through the internal auditory canal. The jugular foramen at the posterior and inferior surfaces is traversed by the jugular bulb and the lower cranial nerves. The internal carotid artery courses through the carotid canal in the anterolateral part of the petrous apex. The superior petrosal sinus is located along the petrous ridge. The tentorium is also attached in this location. The petrous apex is variably pneumatized.

136.3.3 Presenting Complaints

It is clear that lesions of the petrous apex can cause signs and symptoms referable to any of the structures mentioned in the preceding anatomical description. Hearing loss may be secondary to an effusion resulting from eustachian tube dysfunction or ossicular erosion resulting from chronic otitis media; sensorineural hearing loss may be secondary to invasion of the otic capsule or the cochleovestibular nerve. Tinnitus and vertigo can occur along with or independently of hearing loss. Facial paralysis occurs as a result of pressure on the facial nerve anywhere throughout its course in the temporal bone, especially near the geniculate ganglion. Headaches result from distortion of the dura near the lesion and are primarily retro-orbital or located at the vertex. Syncope, stroke, or amaurosis fugax can occur as a consequence of carotid artery occlusion. Other cranial neuropathies are associated with posterior lesions that affect CNs VIII through XII or with anterior lesions that affect CNs II through VI.

136.3.4 Inflammatory Lesions of the Petrous Apex

Cholesterol granuloma is the most common cystic lesion involving the petrous apex. The exact mechanism responsible for the formation of cholesterol granulomas in the petrous apex is not known. One theory is that they result from poor ventilation with a relative vacuum, resorption of air, mucosal hemorrhage, and hemoglobin breakdown leading to cholesterol formation. Hemorrhage seems to be a very important predisposing factor for the formation of cholesterol granulomas. Cholesterol crystals are produced during the anaerobic metabolism of free hemoglobin, and this process incites a giant cell foreign body reaction. The cycle of events is repeated and ultimately results in the formation of an expanding cholesterol granuloma. The

Fig. 136.10 Computed tomographic scan of the temporal bone demonstrating an expansile right petrous apex mass with thinned-out bony walls.

lesions contain a dark brown fluid with shining cholesterol crystals. The cysts occur either with or without an accompanying ear infection. Most of the cysts are unilateral and occur in adults. Symptoms include headache, diplopia from CN VI palsy, ear pain, dizziness, hearing loss, vertigo, and headaches. Sometimes, the cysts are an incidental finding on routine imaging studies. CT of the temporal bone (□ Fig. 136.10) and MR imaging reveal the presence of an expansile petrous apex mass with thinned-out bony walls. On T1-weighted MR imaging, the lesion appears homogeneously hyperintense, whereas on T2-weighted MR imaging, a markedly hyperintense mass is revealed with a peripheral ring of low signal due to hemosiderin-laden macrophages (□ Fig. 136.11). These MR imaging characteristics permit the differentiation of a cholesterol granuloma from an epidermoid cyst or arachnoid cyst. Small asymptomatic or incidental cholesterol granulomas can be managed with observation and periodic imaging studies alone. Large cholesterol granulomas can be drained through a transmastoid infralabyrinthine approach, and once the cystic cavity is ventilated, the lesion is unlikely to recur.

Infection of the petrous apex is also known as petrous apicitis. The triad of diplopia due to cranial nerve VI palsy, retro-orbital pain due to involvement of CN V, and otorrhea due to ear infection is known as Gradenigo syndrome. The infection is usually bacterial and is caused by pyogenic organisms.

Petrous apex infections can also be due to skull base osteomyelitis. Malignant otitis externa is a type of skull base osteomyelitis usually seen in diabetic or otherwise immunocompromised patients. The most common organism is *Pseudomonas*. In this

Fig. 136.11 T1-weighted (left) and T2-weighted (middle) magnetic resonance images and T1-weighted FIESTA (fast imaging employing steady-state acquisition) image (right) demonstrating a cholesteatoma of the right petrous apex.

setting, a relentless type of progressive osteomyelitis of the petrous bone occurs. The symptoms include chronic ear infection, drainage, ear pain, and cranial neuropathies as the disease advances. Treatment consists of prolonged and appropriate intravenous antibiotics accompanied by surgical drainage as indicated.

136.3.5 Neoplasms of the Petrous Apex

Benign tumors in the region of the petrous apex include meningiomas and schwannomas, usually of the trigeminal nerve. They often present as a cranial neuropathy, and the symptoms include dysfunction of CNs V, VI, VII, and VIII in this region. The tumors can also present with generalized headaches. Trigeminal schwannomas typically present with numbness in one or more distributions of the trigeminal nerve. The management of these tumors is surgical through a skull base approach. Petrous apex meningiomas, also known as petroclival meningiomas, require a lateral temporal approach with exposure both above and below the tentorium. The superior petrosal sinus and the tentorium are then divided to provide a wide access to the meningioma. These procedures are carried out with a team including both a neurotologist and a neurosurgeon.

Chordomas occur rarely and arise from notochord cells, primarily in the sphenoid and clivus. Tumors originating within the apex are rare, and spread is usually from the clivus. Surgery with postoperative radiation is the treatment plan of choice. Chordomas are difficult to excise completely and are only moderately radiosensitive. Average survival with aggressive treatment is only 4 years. Chondrosarcomas account for 0.15% of all intracranial neoplasms. Hearing loss, pulsatile tinnitus, vertigo/unsteadiness, CN VI palsy, and headaches are the presenting symptoms.

Breast and prostate carcinomas metastasize to the temporal bone, especially to the petrous apex and clivus. Kidney, lung, gastric, and thyroid carcinomas metastasize to the apex less commonly. When these lesions are discovered in the temporal bone, studies suggest that the lesion has already metastasized elsewhere. CT and MR imaging findings are specific to the primary tumor and depend on whether the tumor causes an osteogenic or osteoblastic reaction. The prognosis in patients with distant metastases remains poor.

An extensive three-dimensional understanding of the anatomy of the temporal bone is absolutely necessary to address disorders of the petrous apex surgically. This region is filled with critical structures that are unforgiving of subtle mistakes in surgical technique and of surgeons not intimately acquainted with the anatomy.

136.4 Roundsmanship

- A variety of vascular tumors can affect the skull base. These lesions include hemangiomas, hemangiopericytomas, lymphangiomas, juvenile nasopharyngeal angiofibromas, angiomatous meningiomas, and paragangliomas (glomus tumors).
- Although glomus jugulare tumors are rare, they remain the most common tumor of the middle ear and the second most common tumor of the temporal bone.
- Tumors of the skull base commonly affect multiple cranial nerves, particularly CNs VII through XII, which accounts for the significant morbidity associated with these lesions.
- Close proximity to vital cranial structures, including the carotid artery and jugular vein, makes the management of these tumors surgically challenging, and multidisciplinary teams are required.

137 Stereotactic Radiation Treatment for Benign Tumors of the Posterior Cranial Fossa

Seilesh C. Babu and Sean R. Wise

137.1 Introduction

Over the past decade, stereotactic radiation has become an increasingly used treatment option for patients with acoustic neuromas, as well as those with other benign intracranial and skull base neoplasms. Advancements in imaging techniques, radiation delivery systems, and dose-planning software have contributed to improved patient outcomes.

The term stereotactic radiation therapy is used to define treatment modalities that deliver high-dose radiation in a highly conformal manner to a three-dimensional intracranial target through the use of multiple, precisely collimated beams of ionizing radiation. The goal of stereotactic radiation is tumor control with minimal toxicity to adjacent normal tissues. Such techniques have found particular application in the treatment of tumors within the posterior cranial fossa, where critical neurovascular structures, such as the brainstem, cerebellum, cochlea, vestibule, and multiple cranial nerves, lie in close anatomical proximity.

Stereotactic radiation techniques involve one of several types of ionizing radiation, and treatment may be delivered in a single dose (most commonly referred to as stereotactic radiosurgery) or in multiple fractions (generally referred to as fractionated stereotactic radiotherapy).

Advantages of radiation treatment include its ability to provide high rates of tumor control with minimal side effects. Additionally, such therapy is noninvasive and can be delivered as an outpatient procedure. The primary disadvantage of radiation therapy for such lesions is that the tumor generally persists following treatment. As a consequence, the potential for future tumor growth remains. The long-term outcomes and potential complications of various stereotactic radiation techniques remain a subject of continued investigation.

137.2 Types of Radiation

The most commonly used ionizing radiation sources for stereotactic radiosurgery or stereotactic radiotherapy are gamma photons and X-ray photons. Gamma photons are emitted through the decay of radioactive nuclei, typically cobalt 60. X-ray photons are generated from a linear accelerator (LINAC) through the collision of accelerated electrons and a target metal. Beams of heavier charged particles (e.g., protons) are also occasionally used consequent to their unique physical properties. The availability of particle beam therapy is generally limited, however, and it is found in only a few specialized facilities. The biological effectiveness of each of these sources is roughly equivalent.

137.3 Radiation Biology

Radiation delivered in the therapeutic range results in the production of free radicals within target cells through Compton

scattering. The primary effect of radiosurgery is vascular fibrosis resulting in a diminished blood supply to the tumor. Evidence of more direct cellular injury has been demonstrated centrally where the radiation dose is greatest.

137.4 Stereotactic Radiation Delivery Systems

137.4.1 Gamma Knife

The gamma knife unit, developed by Leksell in 1968, contains a hemispheric array of 201 intersecting beams of cobalt 60 gamma radiation. Various sized helmet collimators are used to further focus the individual sources of radiation to the unit's isocenter. The isocenter is the point in space where the radiation beams intersect, and essentially where the targeted tissue is positioned.

Before treatment, a stereotactic titanium frame with fiducial markers is rigidly fixed to the patient's skull. Magnetic resonance (MR) imaging or computed tomography (CT) is then acquired, with or without additional image merging. The frame ensures precise immobilization and provides the reference for defining the target in space relative to a Cartesian coordinate system. The treatment team then stereotactically localizes the tumor, and dosing software is employed to assist in developing a plan for treating the tumor effectively with high-dose radiation while sparing surrounding structures from the effects of radiation.

Treatment planning consists of placing one or more isocenters, or "shots," to fill the target of interest. Conformity to tumor is further refined through adjustments made in the collimators to vary the size and relative weight of each isocenter.

The amount of radiation delivered is the prescribed isodose, measured in units called grays (Gy). A steep falloff of radiation occurs at the periphery of the targeted volume. During treatment planning, this gradient is represented by isodose lines, which are the boundaries at which the radiation dose has fallen to a percentage of the prescribed dose. Gamma knife treatment plans commonly prescribe the 50% isodose line to the margin of the tumor (□ Fig. 137.1).

When treatment planning is complete, the patient is positioned with the head frame fixed to the treatment couch and prescribed collimator helmet, and then advanced into the unit in a manner ensuring that the target volume resides at the unit's isocenter (□ Fig. 137.2).

137.4.2 Linear Accelerator (LINAC)

An alternative radiosurgery technique involves the use of a LINAC. These systems employ accelerated photons and rely on a particle accelerator mounted on a gantry that rotates around the patient's head. Multiple beam positions or arcs are used to create a conformal radiation dose to the target. Tumor margin

Fig. 137.1 Treatment plan for a left-sided acoustic neuroma depicting the tumor volume as well as the 50% and 20% isodose lines. Also note the contour lines of the cochlea and labyrinth; the dose distribution is tailored to minimize irradiation to these critical structures.

doses are similar to those employed with gamma knife, and traditional single-fraction stereotactic treatment still requires the use of a fixed head frame for patient immobilization.

Some LINAC systems have been modified so that stereotactic frames can be more readily removed and replaced. The primary advantage of such devices is that fractionated radiotherapy can be delivered while the targeting accuracy that is enabled through immobilization is preserved. Fractionated therapy enables efficient tumor control by making it possible to administer a higher total dose to the tumor while the surrounding normal tissues are spared from long-term radiation-induced injury because the total radiation dose is delivered over multiple sessions. This becomes particularly relevant in the treatment of larger tumors and those immediately adjacent to critical structures such as the brainstem, cranial nerves, and cochlea. A relative disadvantage of these systems is the potential for small tumor volume frameshifts between radiation fractions as the stereotactic frame is repeatedly removed and replaced.

137.4.3 Cyberknife

Cyberknife is an innovative, frameless, LINAC-based, stereotactic radiotherapy system in which a lightweight linear accelerator is mounted on a mobile robotic arm. It differs from other

Fig. 137.2 Cross-sectional schematic of gamma knife unit.

systems in that image guidance technology is used that depends on real-time acquisition of the patient's bony anatomy to maintain orientation. The arm rotates the LINAC through a series of predetermined locations. This system also employs a non-isocentric treatment planning technique that improves the conformality and homogeneity of the delivered radiation. Additional advantages include greater patient comfort relative to rigid fixation systems, as well as the ability to provide stereotactic fractionated treatments (□ Table 137.1).

137.5 Outcomes and Indications

Stereotactic radiation therapy is commonly used for a variety of intracranial neoplasms, both benign and malignant. Of primary interest to the otolaryngologist is the application of these techniques to several commonly encountered benign neoplasms involving the posterior cranial fossa, including acoustic neuromas, meningiomas, and glomus tumors. The indications for and outcomes of the treatment of such tumors are briefly reviewed.

137.5.1 Acoustic Neuroma

Acoustic neuromas are benign, slow-growing neoplasms originating from Schwann cells of the eighth cranial nerve. They account for approximately 15% of newly diagnosed intracranial neoplasms. Historically, the management of these tumors primarily involved observation or microsurgical resection. Stereotactic radiosurgery was reserved for patients deemed to be poor microsurgical candidates, and for those requiring adjuvant therapy for recurrent or residual disease following surgery. Over the last 20 years, the safety and efficacy of this treatment modality have been firmly established, and acoustic neuroma remains one of the most frequent targets for stereotactic radiosurgery.

Before 1992, treatment protocols for stereotactic radiosurgery involved relatively high doses of radiation, with prescribed isodoses typically of 16 Gy or more. Excellent rates of tumor control were achieved, but such protocols also resulted in significant morbidity in the form of facial weakness (21%) and facial numbness (27%). Since that time, reductions in doses to 12 to 13 Gy, as well as advancements in imaging technology and dose-planning software, have significantly improved treatment outcomes.

Table 137.1 Comparison of stereotactic radiation delivery systems

	Gamma knife	LINAC	Cyberknife
Type of radiation	Gamma photons	X-ray photons	X-ray photons
Radiation source	Cobalt 60	Linear accelerator	Linear accelerator on mobile robotic arm
Radiation delivery	Hemispheric array of 201 intersecting radiation beams	Multiple converging radiation arcs from rotating gantry	Fixed beam delivered through multiple points to converge on target
Means to ensure localization accuracy	Fixed stereotactic head frame	Fixed frame or removable frame	Frameless, image-based guidance system
Treatment	Single session	Single or multiple sessions	Single or multiple sessions

Abbreviation: LINAC, linear accelerator.

Recent studies evaluating gamma knife stereotactic radiosurgery have reported tumor control rates ranging from 91 to 98%. Tumor control is generally defined as tumor stability or regression. Hearing preservation rates in these series vary widely (50 to 78%), and some data suggest that rates of preserved hearing may continue to decline with longer-term follow-up. When the current marginal doses of less than 13 Gy are used, the new onset of facial paralysis following treatment is rare. However, temporary facial paralysis is seen in approximately 1%. Similarly, the new onset of facial numbness or pain is uncommon but is occasionally encountered in 1 to 4% of cases. Less common complications after treatment that are rarely encountered include hydrocephalus (with the possible need for ventriculoperitoneal shunt placement), seizure, and rarely radiation-induced malignant transformation. The risks for such complications appear to be increased when larger tumors (>2.5 cm) are treated.

In attempts to preserve hearing and decrease the rate of cranial neuropathies, a broad range of fractionated stereotactic radiotherapy protocols have been developed in the treatment of acoustic neuroma, ranging from hypofractionated regimens involving only three to six sessions to conventional regimens involving up to 30 fractions. Despite the theoretical advantages of stereotactic radiotherapy, rates for tumor control, hearing preservation, and cranial neuropathy appear similar whether patients are treated with conventionally fractionated, hypofractionated, or nonfractionated stereotactic techniques.

Despite initial data supporting the safety and efficacy of stereotactic radiation therapies, follow-up times in most studies to date have been relatively short. Late tumor growth, continued hearing decline, and delayed-onset cranial neuropathies have been encountered many years following initial treatment. Long-term follow-up will remain critical as we continue to evaluate outcomes.

The optimal strategy for the management of growing, small to medium-size acoustic neuromas remains controversial. For tumors 3 cm or smaller, similar outcomes are reported when microsurgery is compared with radiation. The ideal treatment plan for such patients depends on surgeon experience and institutional resources, as well individual medical factors and patient preferences. Stereotactic radiation is not generally recommended as primary treatment for tumors that are larger than 3.0 cm or that compress the brainstem because of the increased risks for associated brainstem injury. Radiation remains a safe and effective treatment option for the elderly, for patients medically unable or unwilling to undergo surgery, and

for those with recurrent or residual disease following microsurgical resection.

137.5.2 Meningioma

Meningiomas account for approximately 25% of all intracranial tumors, and approximately 7 to 12% of them occur in the posterior cranial fossa. Meningiomas are usually benign, slow-growing neoplasms that arise from arachnoid cap cells. They can often reach substantial size before becoming symptomatic. Complete microsurgical resection remains the treatment of choice. However, when meningiomas occur within the regions of the posterior cranial fossa, total excision has been notoriously limited because of their intimate relationships with critical neural and vascular structures. Reported rates of gross total resection vary widely in different series (40 to 96%), and resection is frequently associated with significant morbidity (13 to 40%), mortality (0 to 13%), and recurrence (9 to 40%).

Over the last decade, stereotactic radiosurgery and stereotactic radiotherapy have become increasingly important in the treatment of meningiomas of the posterior fossa and skull base, not just as adjunctive therapy following incomplete resection or recurrent disease, but also as a viable treatment alternative to open surgery. In reviews of published studies, reported tumor control rates range from 82 to 100%. Adverse neurologic outcomes after treatment are generally encountered in fewer than 10% of cases. The overall results compare favorably with those after complete microsurgical resection. However, the follow-up intervals in most studies to date have been relatively short. Given the indolent nature of benign meningiomas, prolonged follow-up of these patients will be necessary to fully assess long-term outcomes.

When treatment for meningiomas within the posterior fossa becomes necessary, surgery is preferred if the tumor appears completely resectable with minimal risk, or if neurologic decompression is required because of progressive neurologic symptoms or significant mass effect. Radiation plays a limited role in the treatment of tumors larger than 3.0 cm, although staged radiosurgical treatment following initial surgical debulking may be considered for such patients. Radiation is most frequently indicated for patients with posterior fossa meningiomas who are of advanced age or have high operative risks, and for patients who refuse surgery or have residual or recurrent tumors.

137.5.3 Glomus Jugulare Tumor

Paragangliomas (glomus tumors) are slow-growing, usually benign, hypervascular tumors of neuroendocrine origin. Glomus jugulare tumors arise from rests of paraganglionic tissue in the adventitia of the jugular bulb. As such, they are intimately associated with cranial nerves IX, X, and XI. Spreading along pathways of least resistance, glomus tumors will commonly extend through the hypotympanic air cell tracts surrounding the jugular bulb and carotid artery to involve the jugular foramen and posterior cranial fossa. The standard treatment is microsurgical resection or radiation therapy. Because of the challenging location of glomus tumors at the skull base, their hypervascular nature, and their tendency to present at advanced stages, the optimal management is controversial. Microsurgical resection for these neoplasms is highly effective, with rates of tumor control of approximately 90%. However, surgery in this region risks significant morbidity and mortality.

Conventional fractionated radiation therapy has historically provided successful tumor control in those patients deemed unsuitable for surgery. When typical doses of 45 to 55 Gy are given in 20 to 25 fractions, tumor control rates of approximately 86 to 100% are reported. However, such results do not come without a risk for significant morbidity, including osteoradionecrosis, cranial neuropathy, and brain parenchymal necrosis.

In recent years, stereotactic radiosurgery techniques based on the gamma knife, modified LINAC, and cyberknife have been used in the treatment of glomus jugulare tumors in attempts to achieve satisfactory tumor control while minimizing treatment-related toxicity. In pooled analyses of published studies, gamma knife stereotactic radiosurgery with a mean marginal dose of 15.3 Gy yielded a tumor control rate of approximately 91% with minimal morbidity. The mean duration of follow-up in these various series was approximately 40 months. Recent short-term data have revealed excellent results when a combined, staged approach to radiosurgery was used following planned subtotal resection. With all of these approaches, longer-term follow-up will be required to better delineate overall risks and benefits.

The optimal management for glomus jugulare tumors remains a matter of controversy. However, in patients at an advanced age or with poor medical status, and in those with bilateral disease, radiosurgery offers a viable alternative to surgery as primary or adjunctive therapy. Microsurgical resection is generally indicated for patients who present with progressive neurologic deterioration, including those with hydrocephalus or increased intracranial pressure consequent to mass effect. Uncertainty regarding the radiologic diagnosis, a tumor diameter larger than 3 cm, and tumor extension below the skull base are additional relative contraindications to radiosurgery as primary therapy.

137.6 Roundsmanship

- The term stereotactic radiosurgery is applied when stereotactic radiation is delivered as a single dose, whereas the term stereotactic radiotherapy is used when multiple fractions are administered.

- The risk for complications following stereotactic radiosurgery for acoustic neuromas is significantly diminished by using a marginal dose of 12 to 13 Gy.
- Current evidence supports stereotactic radiation treatment for both primary and recurrent small to medium-size acoustic neuromas.
- Radiation treatment for posterior fossa tumors is limited to lesions smaller than 3 cm but may be used in combination with microsurgery.
- The long-term effects of stereotactic radiation therapy with respect to tumor control, hearing preservation, risks for cranial nerve dysfunction, malignant degeneration, and other potential complications warrant continued investigation in large studies.

138 Lesions of the Petrous Apex

Christopher J. Linstrom

138.1 Introduction

Lesions of the petrous apex are uncommon in general otolaryngologic practice but will most likely be encountered in a practice limited to otology and neurotology. Certainly a lesion of the petrous apex must be considered as part of the differential diagnosis in a patient presenting with hearing loss, tinnitus, vertigo, disequilibrium, otalgia, or headache. The combination of any unilateral otologic complaint with weakness or paralysis of the sixth cranial nerve points to a lesion of the petrous apex. This chapter will focus on the clinical presentation, investigation, and treatment of the common lesions of the petrous apex.

138.2 Anatomy

The petrous (from the Greek *πέτρα*, “stone”) apex has the shape of a pyramid, with the point about 45 degrees medial and the base lateral, along the axis of the temporal bone. The medial surface of the pyramid corresponds to the medial surface of the temporal bone, with the other surfaces named in turn. The term apex is used to refer to that portion of the temporal bone medial to the otic labyrinth, the carotid artery, and the eustachian tube. These structures form the base of the petrous apex. The petrous apex abuts the internal auditory canal (IAC) and the canal for the petrous portion of the internal carotid artery. A small notch in the most superior and medial edge of the petrous pyramid identifies the Dorello canal. A small dural reflection creates the canal itself, through which passes cranial nerve VI. A small depression of the anterosuperior surface of the petrous apex identifies the position of the Meckel cave and the trigeminal ganglion; the arcuate eminence, seen more laterally, gives an approximation, but not a precise location, of the superior semicircular canal. The petrous apex is normally pneumatized by air cells that invaginate the apex from the middle ear along named tracts that may pass above or below the cochlea, although the degree and extent of pneumatization from left to right in an individual may vary considerably. The apex is dense in nonpneumatized bone. Variable amounts of fatty marrow may be present within the cancellous bone of the petrous apex.

138.3 Pathophysiology

The pathophysiology of a lesion in the petrous apex is determined by the lesion itself: arising from within the apex (e.g., cholesterol granuloma or epidermoid) or a vascular abnormality within the apex (e.g., aneurysm); coming from above (e.g., cerebrospinal [CSF] fluid cyst or cephalocele); growing into the area of the petrous apex from a nearby structure (e.g., meningioma arising from the dural lining adjacent to the petrous apex); or from metastatic spread of cancer to the petrous apex (e.g., metastatic breast, renal cell, lung, or prostate carcinoma and malignant melanoma). Several of these lesions will be considered in greater detail in the section on the differential diagnosis of lesions of the petrous apex.

138.4 Clinical Presentation and Physical Examination

The clinical history of lesions found within the petrous apex is often disproportionately mild compared with the actual findings on radiologic investigation. It is remarkable that until a lesion within the petrous apex reaches a size large enough to impinge upon the otic capsule, the IAC, or the eustachian tube, the patient may have only vague otologic complaints, such as aural fullness without definite hearing loss or tinnitus, often accompanied by facial pressure or pain, a lack of sensation in an area of the face, or headache.

It is vital that the examining physician attend to the nature, duration, and location of the complaints. Knowledge of the anatomy of the petrous apex and its surrounding structures will point to the petrous apex if the history suggests pathology in this location. The history is probably the most important step in the investigative process, often outweighing the physical findings, which may be absent or mild.

Attention should be paid to those complaints that could stem from a lesion in the petrous apex: hearing loss, aural fullness, tinnitus, dizziness, facial hypesthesia or pain, weakness of the facial nerve, or headache. A complete otologic and head and neck examination should be done, with a focus on cranial nerves II through XII. A microscopic examination of the tympanic membrane is usually included, with care taken to examine each and every part of the drum. Crusting on the drum, especially near the pars flaccida, may hide disease. If at all possible, this should be softened and removed.

A minimal clinical examination of hearing includes a tuning fork examination at 512 Hz and possibly more frequencies, as necessary. The tuning fork examination must agree with the audiometric findings. If the patient describes pulsatile tinnitus, it is helpful to listen to the neck, ear, retromastoid area, and orbit in a quiet room, preferably in an audiometric booth. Clinical tests of balance should be performed if indicated. These may include tests of postural control, such as the Romberg, Quix, and Fukuda tests, as well as tests of the otolith system, such as the Dix-Hallpike maneuver. The test for head shake–induced nystagmus may help to point to the side and/or site of the putative problem.

138.5 Testing

138.5.1 Audiometry

All patients who have otologic complaints, regardless of the suspected lesion, should have an audiogram with a minimum battery of tests of pure tones, bone conduction (masked appropriately), word discrimination, and immittance with reflex decay, if obtainable. Each ear should be tested separately.

In rare cases, an auditory brainstem response test may demonstrate either a lack of wave I or, more commonly, increased I through III interwave latency on the side with hearing loss or known pathology. The abnormality on the auditory brainstem

response test may revert toward normal after the lesion has been treated.

138.5.2 Radiology

Patients who have unilateral otologic complaints such as hearing loss, tinnitus, and fullness/pressure should be evaluated for a retrocochlear lesion with an appropriate study.

Although not every single dizzy patient will need a retrocochlear radiologic evaluation, many treating physicians feel that the patient is better served by testing more rather than less frequently. The decision pathway is relatively easy if the hearing is asymmetric. For most patients, the study of choice will be magnetic resonance (MR) imaging without and with gadolinium enhancement. MR imaging is highly sensitive and specific for the detection of soft-tissue lesions in the skull base, cerebellopontine angle, IAC, and brain. It is the test of choice for the detection of retrocochlear pathology, and many lesions of the petrous apex will be incidentally discovered by screening MR imaging.

A word of caution is indicated at this point. The degree of pneumatization of each petrous apex in an individual may normally vary from left to right. The petrous apex is pneumatized in approximately 30% of temporal bones. Signal from bone marrow in a nonpneumatized bone will be distinctly different from signal from a pneumatized petrous apex. If there are no corresponding clinical complaints (e.g., facial pain, hypesthesia, hearing loss, tinnitus, dizziness) and no objective signs of disease (e.g., unilateral sensorineural hearing loss, cranial nerve VI involvement), it is a safe bet that the increased signal on the T1-weighted image is from bone marrow. A quick look at the other petrous apex or a review of other marrow-containing areas of the skull may yield the answer. A T1-weighted image with fat suppression may already be part of the study and will demonstrate that the suspected lesion is marrow fat.

Once a lesion in or near the petrous apex has been discovered, additional imaging studies will most likely be planned. In an excellent review of radiographic imaging of the petrous apex, Curtin and Som postulated five questions that should be asked and answered with an appropriate study to properly identify a lesion of the petrous apex:

1. Is the abnormality arising in the petrous apex or from contiguous areas? (Is the lesion expansile from within the petrous apex itself, or infiltrative and destructive, either from within or without?)
2. Are the bony walls of the apex and the septa in the air cells smoothly remodeled? (Are the bony air cell walls of the petrous apex expanded (e.g., cholesterol granuloma, cholesteatoma, mucocele, aneurysm, meningocele, histiocytosis, giant petrous air cell) or destroyed (metastases to the petrous apex)?)
3. What are the MR imaging signal characteristics of the lesion?
4. Is there enhancement of the internal “matrix” of the lesion? (Does the central part of the lesion have a blood supply?)
5. What is the relationship of the lesion to the carotid artery? (Is it bowed to the side, is the canal effaced, is it an aneurysm of the petrous carotid artery?)

These questions may usually be answered by complementary studies of the petrous apex. If the patient has undergone MR

imaging, computed tomography (CT) would be the next test of choice. CT with a bone algorithm yields excellent information about bone and the interface of soft tissue, bone, and air, but it is far less sensitive and specific than MR imaging in detecting soft-tissue neoplasia. In patients who cannot otherwise undergo MR imaging with enhancement, CT with contrast may allow definition of the great vessels within the skull and neck and may give information about infectious or inflammatory processes and neoplasia. MR imaging, as previously discussed, will yield the most precise information about soft-tissue structures.

If additional sequences, such as MR angiography (MRA) and MR venography (MRV) are desired, it is important for the ordering physician to speak to the radiologist before planning the study. These sequences cannot be imported or added to MR data after they have been obtained and must be set up in advance. MRA and MRV yield information about first- and second-order named vessels. If one is concerned about a vascular lesion (e.g., aneurysm, arteriovenous malformation) or about the interface between a solid or cystic structure within the petrous apex and a named vessel, such as the petrous carotid artery, it may save the patient additional testing to obtain MRA and/or MRV at the same time as MR imaging. If the lesion is known to be vascular in nature (e.g., paraganglioma) and will need to be embolized, MRA and MRV yield little information that four-vessel angiography will not and for these lesions should not be ordered. Above all, it is vital that the otologist/neurotologist establish a comfortable working relationship with an experienced neuro-radiologist and/or interventionalist who will take the time and effort to listen to the patient’s history and attend to the radiologic requirements of the proposed imaging study.

138.6 Differential Diagnosis

The differential diagnosis of lesions of the petrous apex is large. They may be classified as benign or malignant, as expansile or erosive, or as arising from within, from above, from a nearby structure, or from metastatic spread.

Although a wide differential diagnosis should be kept in mind, the lesions most commonly encountered in an otologic/neurotologic practice will be cholesterol granuloma, cholesteatoma, and mucocele, with encephalocele/meningocele and aneurysm less commonly seen. It is important always to keep the patient’s history in mind when developing the differential diagnosis.

Many sources differ in the classification and nomenclature of lesions of the petrous apex. A distillation of lesions described by many authors will be presented, as well as a brief description of the more common lesions.

138.6.1 Inflammatory/Infectious/Cystic Lesions

Cholesterol Granuloma

Manasse reported a case of “granulation tumor with foreign body cells” of the petrous apex in 1894. The term “cholesterin or cholesterol granuloma” has been used since this report.

The most common clinical entity an otologist will encounter within the petrous apex is cholesterol granuloma. There are

several proposed mechanisms of formation. The second most common lesion will be cholesteatoma. The pathophysiology of these two lesions will be considered here.

Cholesterol granulomas have been produced in animal studies by two mechanisms: by introducing irritants into the middle ear cleft and by isolating a bony air-filled cavity that normally communicates with the atmosphere.

Beaumont produced cholesterol granuloma in a chick humerus by obstructing the foramen pneumaticum (the connection with the respiratory system) with a muscle pedicle. Histologic examination revealed no associated loss of blood or infection. Surgical trauma as a causative factor was excluded because an identical procedure performed on the contralateral humerus without complete occlusion of the foramen pneumaticum did not result in cholesterol granuloma formation. These findings support the “obstruction–vacuum” hypothesis of cholesterol granuloma formation.

Friedman was able to develop cholesterol granuloma by injecting sterile suspensions of cholesterol into the middle ear of a guinea pig. He proposed that the blood breakdown product cholesterol incited a foreign body reaction, thus leading to cholesterol granuloma formation. Sadé and Teitz disputed the necessity for hemorrhage as a predisposing factor for cholesterol granuloma formation.

A second major theory of the pathogenesis of cholesterol granuloma is that of “exposed marrow.” The marrow-filled cavities of the petrous apex are eroded as air cells develop. This erosion may cause hemorrhage into the air cells; subsequent degradation into blood products such as cholesterol results in an inflammatory reaction and cyst development. The expansion of the cyst results from continued bleeding within the marrow cavities. These authors reported a small retrospective series of four patients with aggressive cholesterol granulomas in the mastoid. In all cases, there was a nearby blood source. The authors noted that an “obstruction–vacuum” postulate alone would not have explained the source of the hemorrhage, and that a blood source must have supplied these aggressive lesions.

A cholesterol granuloma may appear as granulation tissue or as a brown, green, or glistening yellow cystic mass; it is not a precursor of cholesteatoma.

It would appear that major factors predisposing to the formation of cholesterol granuloma are the following: (1) obstruction of the ventilation of an air-filled bony cavity that normally equilibrates with the atmosphere; (2) obstruction of drainage; (3) reaction to a foreign body, such as cholesterol; (4) the presence of bone marrow products, including blood, which lead to the development of cholesterol cysts; and (5) hemorrhage, although there is not unanimous agreement that this is a causative factor.

Epidermoid/Cholesteatoma

Cholesteatoma (more properly, keratoma) is not a true neoplasm but rather the accumulation of a living matrix of keratinizing squamous epithelium and its cellular debris in an enclosed space. It may be classified as congenital (arising *de novo* within the anatomical location) or acquired. Acquired cholesteatomas may be primary (arising from a retraction of a squamous epithelium-lined surface into the target) or secondary

(arising from a break in the integrity of the target location, caused by either perforation or seeding from trauma). In patients with cholesteatoma of the petrous apex, the clinical and radiologic examination must look for a source outside the petrous apex, such as the pars flaccida (e.g., an attic retraction cholesteatoma). This is uncommonly found. If a “source” lesion is found, it is usually disproportionately small relative to the disease within the petrous apex. Cholesteatomas of the petrous apex are most commonly congenital.

Congenital cholesteatomas of the petrous apex may arise from epithelial cells trapped during embryogenesis by overclosure of the neural tube. Epithelial migration in the absence of other clinically obvious foci of cholesteatoma is another, although unlikely, possibility. Congenital cholesteatomas of the petrous apex may be clinically silent. If they expand to a volume sufficient to impinge upon structures within or adjacent to the petrous apex, the clinical manifestation will depend upon the size and location of the mass and may include hearing loss, aural fullness, facial pain or hypesthesia, headache, or blurred vision/diplopia. The clinical examination *per se* does not yield a pathologic diagnosis but rather points to the likely site of the lesion (e.g., in pathologies involving the fifth or sixth cranial nerve).

Effusion

Effusion of the middle ear and mastoid may cause a blocked feeling in the ear and a conductive hearing loss. This process may extend to the petrous apex. In some cases, the effusion is due to chronic mastoiditis in which the respiratory mucosa of the middle ear and mastoid has become hypertrophic. In these cases, the mucosa of the middle ear and mastoid will often remain hypertrophic and not revert to normal, thus becoming the source of an effusion rather than the result of an active infection. CT will usually reveal a nearly complete middle ear and mastoid but without erosion of bony septa or expansion of the apex. T1-weighted MR images will often be hypointense and T2 weighted images hyperintense. In rare cases, all of the hypertrophic mucosa must be removed during a mastoidectomy and/or a middle ear exploration to allow a new mucosa to develop for these spaces. Because the air cell system is contiguous, the mastoidectomy will usually provide drainage for the petrous apex.

Mucocele

Simple obstruction of the regular draining pathways of the petrous apex may rarely cause a mucocele. The apex expands as mucus continues to collect within it. The CT and MR imaging characteristics of a mucocele are similar to those of a cholesteatoma: a smooth, expansile appearance on CT that is isointense to CSF. On MR imaging, mucoceles are hypointense on T1- and hyperintense on T2-weighted images. However, the signal can vary depending upon the protein content of the fluid. Fluid with a low protein content is dark on T1-weighted images and bright on T2-weighted images. As the mucocele becomes chronic, the water fraction decreases and the protein content increases. This may alter the enhancing characteristics so that both T1- and T2-weighted images become bright.

Cerebrospinal Fluid Cysts and Cephaloceles

CSF cephaloceles are meningeal diverticula that may include only CSF (meningocele) or both CSF and brain (encephaloceles). If they arise from the dura of the Meckel cave, they are called petrous apex cephaloceles and typically contain only CSF. Encephaloceles typically arise from the middle fossa near the mastoid and tegmen tympani, and they are often associated with chronic ear disease or surgical trauma. CSF cephaloceles may be an incidental finding or may present with a variety of findings, including CSF otorrhoea, vertigo, hearing loss, diplopia, facial numbness, and meningitis.

Petrous Apicitis/Abscess

Gradenigo in 1904 described an infection of the ear with concomitant paralysis of the abducens nerve (cranial nerve VI). Profant first used the term petrositis to describe infection of the petrous apex combined with mastoiditis. Inflammation of the leptomeninges around the Dorello canal produces palsy of the sixth cranial nerve. Involvement of the adjacent trigeminal ganglion (cranial nerve V) may lead to periorbital and facial pain. The combination of otorrhoea, lateral rectus palsy, and pain in the trigeminal distribution represents classic Gradenigo syndrome.

Cases of petrous apicitis are almost always found in a setting of acute or subacute otitis media. On both CT and MR imaging, the air cells are opacified, with enhancement of the dura over the petrous apex. Complications may arise in neighboring structures, such as intracranial abscess and venous thrombosis. The cavernous sinus, sigmoid sinus, and jugular vein are at risk because of their proximity to the apex. A variety of organisms may cause petrous apicitis, including *Mycobacterium tuberculosis*.

Skull Base Osteomyelitis/Necrotizing (Malignant) Otitis Externa

Malignant otitis externa, more properly called osteomyelitis of the skull base or necrotizing otitis externa, is a skull base osteomyelitis. *Pseudomonas* species are generally the predominant organisms. Toulmouche described a case of progressive osteomyelitis of the temporal bone in 1838 that was most likely the first reported case of necrotizing otitis externa. Risk factors for this disease include old age, diabetes, and immunosuppression for any reason. The typical complaint is deep-seated, boring pain in the ear that radiates toward the middle of the head. Granulations in the inferior margin of the external canal near the tympanic bone may be seen, but aural discharge is rare. A conductive hearing loss due to fluid or granulations within the middle ear may be diagnosed. Involvement of the facial nerve indicates more advanced disease. The treatment is medical, with dual antibiotic therapy and control of underlying medical conditions, such as diabetes. In extremely rare cases, surgical decompression of a phlegmon or abscess of the skull base may be necessary, as well. For further discussion, see Chapter 116.

Petrous Carotid Aneurysm

A smooth-bordered mass seen within the petrous apex may in fact be an aneurysmal dilatation of the petrous carotid and

must always be included in the differential diagnosis. Violation of an aneurysm in this location would lead to catastrophic sequelae. An easy way to distinguish the lesion from the artery is to include MRA sequences along with the MR imaging to detail the soft tissues of the mass. MRA delineates first- and second-order vessels, will be formatted in many different planes, and will clearly show the mass to be separate from the lesion within the petrous apex. This is demonstrated in Case 3. If doubt remains after MRA, four-vessel angiography, with its attendant risks, can be performed.

Paget Disease and Fibrous Dysplasia

Paget disease of bone affects the skull base in sclerotic, lytic, and mixed forms. The skull base is rarely involved without simultaneous calvarial disease. In the base of the skull and petrous apex, the lesions are primarily lytic and may have an appearance similar to that of metastatic disease. Paget disease may cause demineralization or erosion of the otic capsule. It often involves the petrous temporal bones symmetrically.

Fibrous dysplasia has a typical appearance on CT of areas of bony thickening with a “ground glass” appearance. In the medullary region of the lesion, areas of dense ossification may be mixed with areas of fibrous tissue. Both T1- and T2-weighted MR images are of low signal intensity unless there are cystic areas, which are bright on both sequences. It is rare to find fibrous dysplasia isolated to the petrous apex.

138.6.2 Primary Neoplasms

Primary neoplasms of the petrous apex are rare, but a variety have been reported. These include giant cell tumor, xanthoma, endolymphatic sac tumor, hemangioma, hemangiopericytoma, chondroma/chondrosarcoma, aneurysmal bone cyst, plasmacytoma, undifferentiated carcinoma, various sarcomas, and by extension nasopharyngeal carcinoma. With the exception of aneurysmal bone cyst, these tumors tend to be cellular. The origin of aneurysmal bone cyst is controversial. Various pathologists believe that this expansile lesion is more properly classified as a giant cell tumor or that it may develop from a benign bone lesion. The appearance on CT and MR imaging is characteristic, with expanded bone and multiple cysts, most of which have air–fluid levels.

The endolymphatic sac tumor is a papillary adenoma arising from the endolymphatic sac or its adnexa. It tends to be more aggressive than similar lesions arising elsewhere in the temporal bone.

Chondroma/chondrosarcoma is thought to arise from embryonic rests of cartilage in the region of the foramen lacerum. Malignant chondrosarcoma is more common than its benign counterpart, chondroma. Chondrosarcomas appear as bulky, enhancing, irregular, destructive lesions with “popcorn” calcifications that arise from the midline. They are homogeneous on T1-weighted imaging and heterogeneous on T2-weighted imaging, with intense contrast enhancement.

Nager described sarcomas affecting the temporal bone under general categories of rhabdomyosarcoma, extraskeletal Ewing sarcoma, myxoma and fibromyxoma, and osteosarcoma. These malignancies have in common at least one primordial element from mesenchymal tissue. Although all of these cancers are

uncommonly seen solely in the petrous apex, they may secondarily spread to this site as a consequence of their aggressive behavior.

Rhabdomyosarcoma is a highly malignant tumor of rhabdomyoblasts in varying stages of differentiation, with or without intracellular myofibrils or cross-striations. Three subtypes are distinguished: embryonal (including the botryoid type), alveolar, and pleomorphic. The first two are more common in children; the third is an adult neoplasm.

Extraskelatal Ewing sarcoma is a malignant tumor believed to arise from primitive mesenchymal tissue without obvious differentiation. It is often mistaken clinically and histologically for juvenile rhabdomyosarcoma. Approximately 70% of these tumors have been reported in patients younger than 20 years of age. It is rare in the temporal bone and is included for completeness.

Other sarcomatous lesions to be considered in the differential include myxoma, fibromyxoma, and osteosarcoma.

Eosinophilic Granuloma: Langerhans Cell Histiocytosis X

Langerhans cell histiocytosis may involve the skull base. Any bone can be involved, but the temporal bone is a common site. The clinical history often is that of an ear infection that will not heal despite appropriate aural toilet and antibiotic therapy. The temporal bone may be expanded or destroyed. The bone–lesion interface may be sharp on CT. The internal density of the lesion and the imaging characteristics on MR imaging may be variable. The patient tends to be young, further raising the index of suspicion. Other entities to be considered are teratoma, neuroma, and giant cell tumor.

Chordoma

Chordomas, derived from primitive notochord remnants, are midline masses arising from the clivus that may secondarily spread to the petrous apex. It is possible for notochord remnants to extend laterally toward the petrous apex, causing a primary tumor. Chordomas are bulky, lobulated, midline lesions on CT that enhance with contrast, are destructive of bone, and contain calcifications. They appear similar to chondrosarcomas on MR imaging, but they tend to arise more in the midline and are less brightly enhancing with gadolinium.

Meningioma

This benign tumor, arising from the meninges, comprises approximately 14% of all intracranial tumors and is the most common solid tumor involving the petrous apex. It appears rarely as a primary tumor, more commonly invading the apex secondarily. Meningiomas commonly present as broad-based tumors along the posterior petrous wall. They may exhibit calcification within and enhance with contrast, and they often have a characteristic dural “tail.” Meningiomas tend to follow sites of dural penetration by cranial nerves VII through XII.

Paraganglioma

Paragangliomas (glomus tumors) usually do not arise from within but may grow into the petrous apex. It would extremely

rare to find a glomus tumor primarily within the petrous apex in the absence of this lesion elsewhere.

138.6.3 Metastatic Neoplasms

Extratemporal primary cancers may metastasize via hematogenous routes to the temporal bone, specifically to the rich marrow spaces of the petrous apex. These include breast, prostate, lung, and renal cell carcinoma and malignant melanoma. The appearance is variable, depending upon the site of the primary. Metastatic cancer to the temporal bone may erode and remodel bone or be less invasive in appearance. A history of known cancer at any of these sites or the presence of additional metastatic disease anywhere raises the index of suspicion.

138.7 Treatment Paradigms

Few lesions of the petrous apex will be solely observed in otherwise healthy patients. Some, such as necrotizing otitis externa and petrous apicitis, will be treated medically, with very rare surgical intervention. However, the majority of lesions of the petrous apex will eventually require surgery for either drainage or resection. Many surgical approaches to the petrous apex exist, each tailored to the lesion and the extent of disease. The surgeon must carefully review the nature and extent of the lesion and its relationship to the important adjacent structures, such as the otic capsule, the petrous carotid artery, the jugular bulb, the facial nerve, and the eustachian tube. The surgeon must have several surgical approaches to lesions of the petrous apex available in the event that the selected approach fails to reach the pathology or adequately address the surgical requirements of treatment. If the lesion involves highly critical areas either adjacent to or within the petrous apex, such as the petrous carotid artery, the middle fossa dura, or the clivus, the patient’s care is facilitated by a combined neurotologic and neurosurgical team approach.

Surgical approaches to the petrous apex may be classified according to the neighboring anatomy, the ability to preserve hearing, or the direction of the approach. Because the temporal bone is pneumatized by named air cell tracts invaginating the mastoid complex around the vestibular and cochlear labyrinths and the facial nerve, an easily understood classification scheme is based upon hearing conservation/hearing ablation and the named pathways of pneumatization around the otic capsule. It is understood that all approaches attempt to preserve and protect the facial nerve.

Flood and Kemink listed six requirements that must be fulfilled in approaching tumors of the petrous apex: (1) provide adequate exposure for complete excision or allow easy access to an exteriorized cavity; (2) preserve useful residual hearing if possible; (3) preserve facial nerve and other cranial nerve function when possible; (4) preserve the internal carotid artery; (5) avoid hazard to the brainstem; and (6) provide wound closure without CSF leak.

138.7.1 Hearing Conservation Approaches

These surgical approaches aim to reach the petrous apex while preserving the otic capsule in an attempt to preserve hearing.

The approaches follow established air cell tracts above, below, or anterior to the otic capsule. Many were first described in the preantibiotic era and were used to exteriorize abscesses of the petrous apex. None involves transposition of the facial nerve or of the petrous carotid artery. The jugular bulb is the third anatomical boundary.

Above the Labyrinth

Middle cranial fossa approach: This is an extension of the standard middle cranial fossa approach for decompression of the labyrinthine facial nerve and resection of lesions within the IAC, as described by William House in 1959 and thereafter. It may be a preferred approach for lesions, such as cholesteatomas, in which surgical removal and subsequent exenteration are the goals. It is difficult to drain lesions to other dependent areas of the temporal bone, although this has been described. The major landmarks to be preserved are the petrous carotid artery, the cochlea, and the facial nerve. This approach affords a “keyhole” window from above, through which a lesion may be more thoroughly exenterated. The middle fossa approach is further discussed in Chapter 135.

Through the superior semicircular canal, along the path of the subarcuate artery: In patients with a well-developed perilyabyrinthine air cell tract and a more posterior lesion, this approach may be contemplated. However, the diameter of the superior semicircular canal is no more than a few millimeters, and thus the vestibular and cochlear labyrinths are both placed at risk with this approach, which was developed to drain abscesses of the petrous apex and is mentioned here for historical interest.

Through the attic: This approach is rarely indicated for lesions of the petrous apex with extension above and posterior to the vestibular labyrinth. It may be of value for obtaining a biopsy but today would not in itself be considered a definitive approach. It is often combined with other approaches to the petrous apex, especially when the goal is to provide drainage or exteriorization and not definitive resection.

Through the root of the zygomatic arch: This is mentioned for historical completeness only and today would most likely be replaced by or combined with another technique, such as a middle cranial fossa approach.

Below the Labyrinth

Infracochlear (subcochlear) approach: This approach uses the triangular space bordered by the basal turn of the cochlea, the ascending petrous carotid artery, and the jugular bulb. In an anatomical study of 20 preserved temporal bones, Haberkamp found the average window created via this approach to be 9.41 x 7.33 mm; in none of his specimens was this approach impossible. In the living, well-defined axial and coronal CT scans with a bone algorithm are needed to estimate the space between the basal turn of the cochlea and the petrous carotid. If the space is more than approximately 3 to 4 mm, surgical drainage of the petrous apex will likely be possible. This approach is limited by a short distance between these two structures or by a high-riding jugular bulb. It is the most common otologic approach in current use and has been described by many authors.

Infralabyrinthine (retrofacial) approach: This approach is bordered by the posterior semicircular canal, the vertical (descending) facial nerve, and the jugular bulb. It is a straightforward approach, an anterior extension of a complete mastoidectomy. Preoperative axial CT with edge enhancement will help in the surgical planning. Haberkamp found the average window created via this approach to be 4.99 x 7.23 mm. The major limitation to this approach is a high-riding jugular bulb. In rare cases, the posterior semicircular canal may be blue-lined to allow a few extra millimeters of the operculum of the superior semicircular canal to be dissected. As in other approaches, the petrous apex is drained to a well-ventilated area, in this case the mastoid and subsequently to the eustachian tube. In the literature reviewed for this chapter, it is the second most commonly used approach.

Retrosigmoid (suboccipital) approach: This is the standard approach toward the posterior cranial fossa for the excision of lesions of the cerebellopontine angle and IAC. It is rarely used alone to approach the petrous apex, but it may be combined with another approach when intracranial extension of a petrous apex tumor produces signs of brainstem compression. The surgeon works at a great distance from the petrous apex, and the morbidity associated with this technique limits its usefulness as a primary approach to the petrous apex.

Infratemporal approach: The infratemporal approach to the skull base, with anterior transposition of the facial nerve, as is typically used in the resection of paragangliomas, allows the combined infracochlear and infralabyrinthine drainage of lesions of the petrous apex with preservation of hearing. Transposition of the facial nerve with attendant facial weakness is the major limiting factor with this approach.

Anterior to the Labyrinth

These approaches use the triangle formed by the cochlea, the petrous carotid artery, and the middle fossa dura. They were developed in the preantibiotic era and are rarely if ever indicated today.

Transsphenoidal approach: The history of this approach to the pituitary is a veritable history of modern advances in neuro-otology and neurosurgery. It was first popularized in North America by Harvey Cushing, although he claimed no credit for its discovery. It fell into disfavor because of poor anesthesia and limited visibility in an era devoid of the operating microscope. It was revived by Guiot and Jules Hardy after the advent of intraoperative radiofluoroscopy in 1958. Although this approach is aimed precisely at lesions of the sella turcica, it may be modified for lesions of the petrous apex. Gray et al have described the transnasal, transsphenoidal marsupialization of a cholesterol granuloma of the petrous apex and sphenoid sinus. This approach may be favored in patients who have lesions that expand the far anterior aspect of the petrous apex and in whom the petrous carotid artery has been laterally displaced. Preoperative planning may include edge-enhanced CT of the temporal bone and MR imaging with MRA to detail both the nature of the lesion and the exact location of the horizontal portion of the petrous carotid artery. An intraoperative navigational system or intraoperative fluoroscopic system is often used to confirm anatomical landmarks. The sphenoid sinus is approached

in a transnasal fashion. The posterior wall of the sphenoid sinus is thinned with a diamond bur, and the anterior face of the petrous apex is opened. Removal of the intrasphenoid septum may facilitate exposure. A drain may be left in place, or a posteriorly based flap of septal mucosa may be rotated into the neo-osteum of the petrous apex, as described by Montgomery.

138.7.2 Hearing Ablation Approaches

These approaches are intended to reach the petrous apex via the cochlear and/or the vestibular labyrinth, the most direct pathway, at the expense of the vestibular or cochlear labyrinth. None of these approaches intentionally involves transposition of the facial nerve or of the petrous carotid artery. The jugular bulb is the third major boundary of these approaches.

Translabyrinthine Approach

In lesions of the petrous apex in which useful hearing is no longer present, the approach is through the labyrinth but not through the IAC. Combined with a canal wall down mastoidectomy and a sufficient meatoplasty, it yields a cavity that can be easily visualized and cleaned. The posterior and middle fossa dura may have been thinned by expansion of the lesion. It is important that toilet of the cavity be performed under microscopic vision, in an extremely gentle fashion and without the use of sharp instruments, in order to avoid a CSF leak. This is described later in Case 2.

Transcochlear Approach

This approach has been described by William House and is indicated in the patient with a lesion of the petrous apex in whom useful hearing is no longer present. It is important to follow the usual landmarks of the basal turn of the cochlea, the tympanic facial nerve, the eustachian tube orifice, and the petrous carotid artery carefully in order to prevent injury to vital structures. This approach, combined with a canal wall down mastoidectomy and a sufficient meatoplasty, will yield a cavity that is open and that can be cleaned.

Subtotal Petrosectomy

This is a “workhorse” approach, familiar to all skull base surgeons who have studied the work of Professor Ugo Fisch.

This technique leaves the otic capsule, the facial nerve, the carotid artery, and the jugular bulb as the only remaining anatomical landmarks within the temporal bone. The surgical goal is to exenterate all remaining disease from the external and middle ear clefts and all air cells of the mastoid. All squamous epithelium from the external auditory canal up to and including the tympanic membrane is removed, and the canal is over-closed. The ossicular chain, except for the mobile stapes footplate, is removed. Depending upon the pathology, the facial nerve may be decompressed, transposed, or grafted. The petrous carotid may be decompressed, according to need. There are many variations of this approach, including leaving the canal open for surveillance.

138.8 Clinical and Radiographic Follow-up

The lesion itself and the ability to preserve the function of the otic capsule in large measure determine the mode of surveillance for patients with lesions involving the petrous apex. If the lesion is being observed, clinical examination and serial audiograms at 6-month intervals or whenever the patient may experience a decrease in hearing are indicated. If the hearing remains unchanged, CT or MR imaging initially at 6 months and thereafter at longer intervals is commonly performed. The patient is instructed to attend to his or her symptoms. If these worsen at any time, new investigations will be ordered.

If the lesion has been medically treated (e.g., 6 to 12 weeks of intravenous antibiotics for necrotizing otitis externa involving the petrous apex), the patient should be examined and the hearing tested at shorter and then longer intervals. Many patients will require a full course of treatment only once. A gallium scan at 3 to 4 months after treatment should show significant improvement. However, it may never become completely clear and must be interpreted according to the clinical state of the patient. In an elderly patient or a patient of any age immunocompromised for any reason, the index of suspicion must be raised, especially if deep-seated otitic pain or pain at the base of the skull returns. In this case, in addition to the clinical examination and the audiometric and radiographic studies, radionuclide studies may need to be repeated.

If the patient has been treated surgically, the nature of the disease and the surgical approach will dictate the follow-up. If the disease has been exteriorized and can be visualized under the microscope, surveillance radiography may rarely be indicated. If, however, the disease has been drained to an area that is ordinarily not clinically accessible, such as to the mastoid in a canal wall up technique or to the hypotympanum, serial CT at the 6- and then the 12-month mark is indicated. Patients who have had subtotal excision of disease processes within the petrous apex with overclosure of the ear must know that lifelong surveillance at appropriate intervals is mandatory. Because there will always be a chance that a residuum of disease may continue to grow, appropriate imaging (CT, MR imaging, or other) at appropriate intervals must be organized along with the clinical examination. As long as the patient remains clinically and radiologically stable, the disease may be observed. Radiographic progression of disease, with or without progression of clinical symptoms, must be carefully assessed and a treatment plan outlined. The overall clinical state of the patient with any comorbidities will help determine what is to be done.

138.9 Case Illustrations

138.9.1 Case 1

A 56-year-old man with a 4-month history of tinnitus and decreased hearing in the right ear was referred for evaluation. He had no complaints of otitic pain or dizziness/vertigo and did not have facial pain. His ear, nose, and throat examination, which included cranial nerves II through XII, was unremarkable. His clinical tests of balance were normal. With a 512-Hz tuning

Fig. 138.1 Case 1. Preoperative audiogram, demonstrating asymmetric sensorineural hearing loss in the right ear.

fork, the Rinne tests were both positive, and the Weber test was midline.

A pretreatment audiogram demonstrated a significant asymmetry of hearing in the right ear at and above 2,000 Hz (□ Fig. 138.1).

MR imaging of the brain demonstrated a 1.7 x 3.1 x 2.5-cm expansile lesion within the right petrous apex, high in signal on both T1- and T2-weighted images, with remodeling of bone and expansion into the cerebellopontine angle, consistent with cholesterol granuloma (□ Fig. 138.2).

CT of the petrous temporal bone further detailed the bony architecture of this lesion. The scan demonstrated thinning and displacement of the posterior horizontal portions of the petrous carotid artery, as well as medial bowing and thinning of the petrous apex. Erosive changes were noted along the lateral margin of the porus acusticus, the clivus, and the basisphenoid. A careful review of the coronal images did not favor an infracochlear approach to the petrous apex but did show that a retrofacial (retrolabyrinthine) approach would be possible (□ Fig. 138.3).

The patient elected to have the lesion surgically treated. He underwent a right retrofacial (infralabyrinthine) approach to the petrous apex, in which the standard landmarks of the posterior semicircular canal, the descending facial nerve, and the jugular bulb were used. The bone over the cystic space was thinned, and a 25-gauge needle was used to aspirate dark brown fluid, confirming the cholesterol granuloma. The posterior face of the

Fig. 138.3 Case 1. Preoperative (a) axial and (b) coronal computed tomographic scans, showing the ascending carotid artery abutting the cochlea.

Fig. 138.4 Case 1. Postoperative (a) axial and (b) coronal computed tomographic scans, showing the Silastic (Dow Corning, Midland, MI) drain passing beneath the posterior semicircular canal and into the petrous apex.

Fig. 138.5 Case 1. Postoperative audiogram, demonstrating modest improvement in hearing.

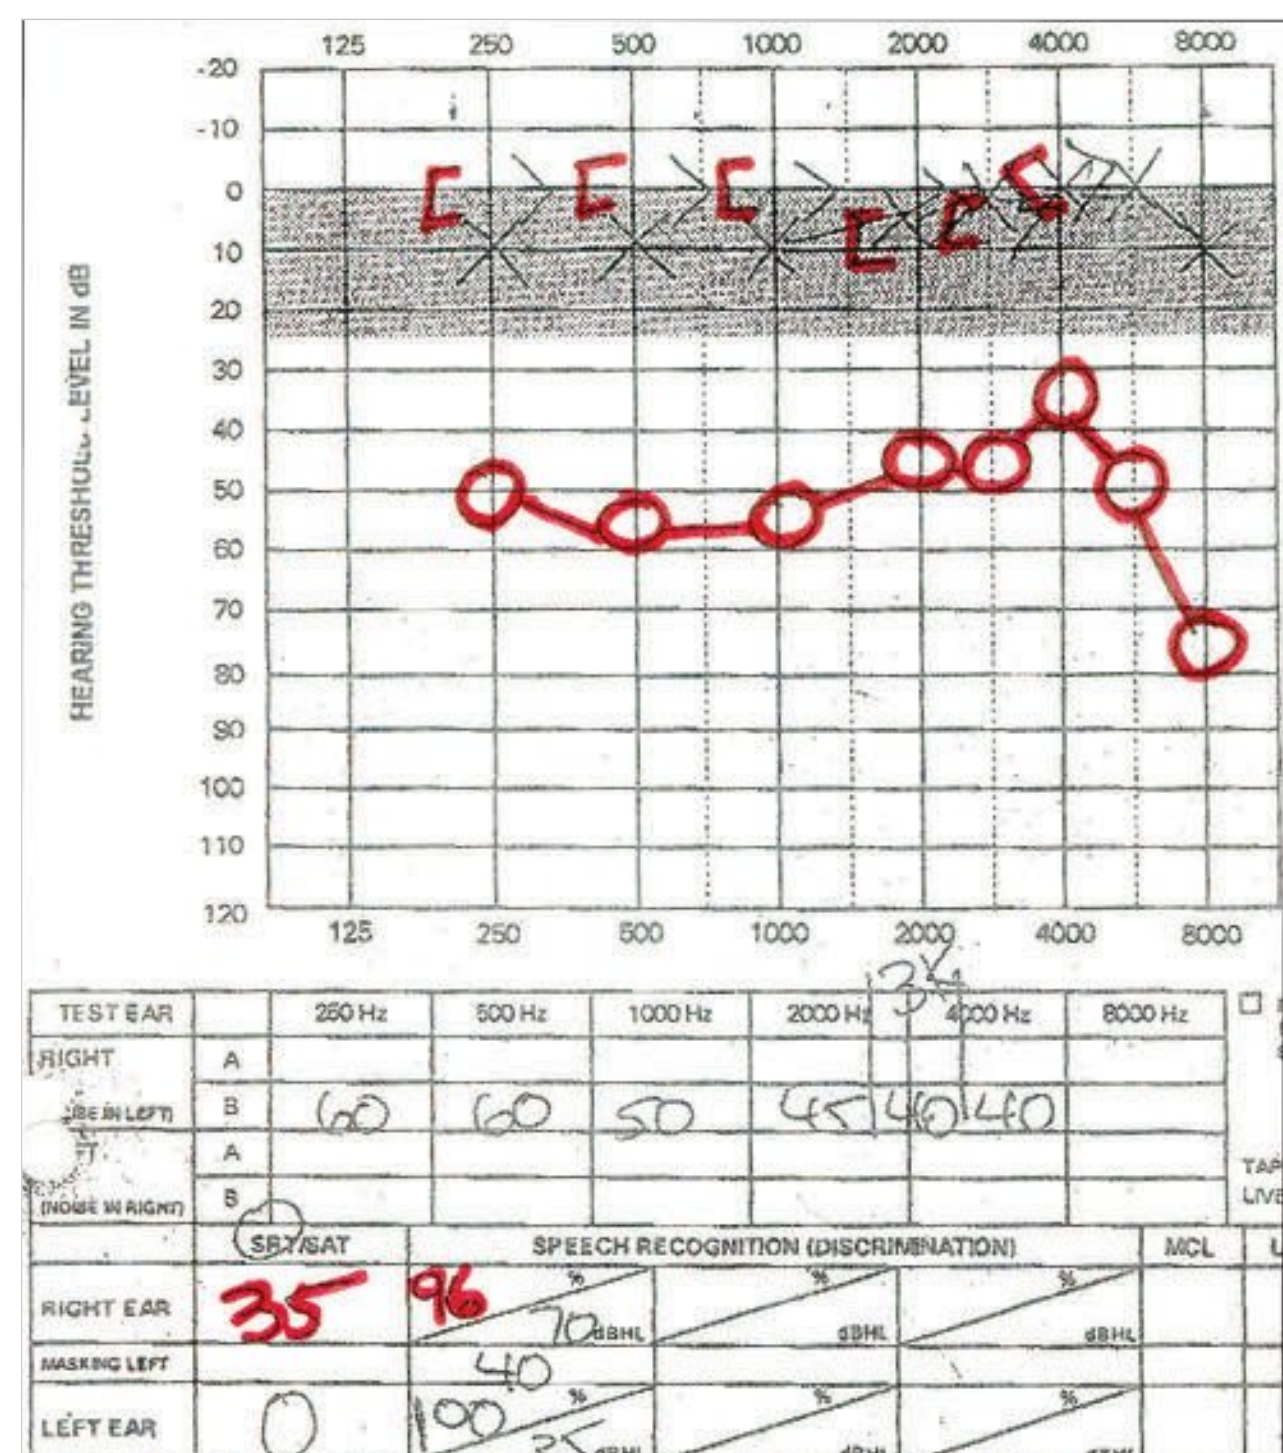

Fig. 138.6 Case 2. Preoperative audiogram, demonstrating right conductive hearing loss.

petrous apex was then opened with graduated diamond burs to a diameter of about 7 mm. This allowed gentle curettage with ringed forceps. Because of the known effacement and displacement of the petrous carotid artery, no attempt was made to strip the lining of the cystic space. A No. 5 Jackson-Pratt drain was placed within the petrous apex and brought out to the mastoid (□ Fig. 138.4). An audiogram performed 1 month after surgery revealed a slight improvement in hearing at 2,000, 3,000, and 4,000 Hz, with 100% speech discrimination (□ Fig. 138.5).

138.9.2 Case 2

A 19-year-old woman presented with right facial weakness, hearing loss and fullness in the right ear, dizziness, and right facial pressure/pain of approximately 6 months' duration. Examination revealed a right III/VI facial paresis and bulging in the right epitympanum. No discrete mass was seen. The 512-Hz fork lateralized to the right ear with bone conduction better

than with air conduction on the right side. The remainder of the examination was unremarkable.

An audiogram revealed a conductive hearing loss of 50 dB in the right ear with good word discrimination. The nerve line on the right ear was well preserved. Hearing in the left ear was normal (□ Fig. 138.6).

CT of the temporal bone revealed an expansile lesion in the right petrous apex with extension toward the IAC and labyrinthine portion of the seventh cranial nerve, with significant bony erosion (□ Fig. 138.7). MR imaging showed a lesion of the right petrous apex less bright on T1-weighted images and brighter on T2-weighted sequences, supporting the diagnosis of cholesteatoma of the petrous apex (□ Fig. 138.8).

The patient subsequently moved to South America, and when she returned to New York a year later, she complained of worse hearing and worse facial function. On examination, she had complete (VI/VI) right facial paralysis. A repeat audiogram showed a conductive hearing loss of 60 dB on the right with

Fig. 138.8 Case 2. Preoperative (a) T1-weighted and (b) T2-weighted axial magnetic resonance images, showing a lesion of the petrous apex brighter on T2 than on T1 sequences, consistent with cholesteatoma.

Caloric Weakness: 100% in the right ear
 Directional Preponderance: 15% to the right

Fig. 138.9 Case 2. Preoperative bithermal calorics, showing absent responses in the right ear. SPV, slow-phase velocity.

92% speech discrimination. Electroneurography showed 100% right-sided weakness to bithermal caloric irrigation (□ Fig. 138.9). Preoperative electroneurography showed 100% degeneration of the right facial nerve. The patient underwent a right infratemporal fossa and transmastoid dissection of the mass, as well as placement of gold weight in the right upper lid. In an effort to preserve hearing, the labyrinth was kept intact. The cholesteatoma was unroofed above the superior semi-circular canal and removed with suction and curettage. The postoperative audiogram showed that little useful hearing remained on the right (□ Fig. 138.10). The patient was followed conservatively with serial débridement, and the facial nerve

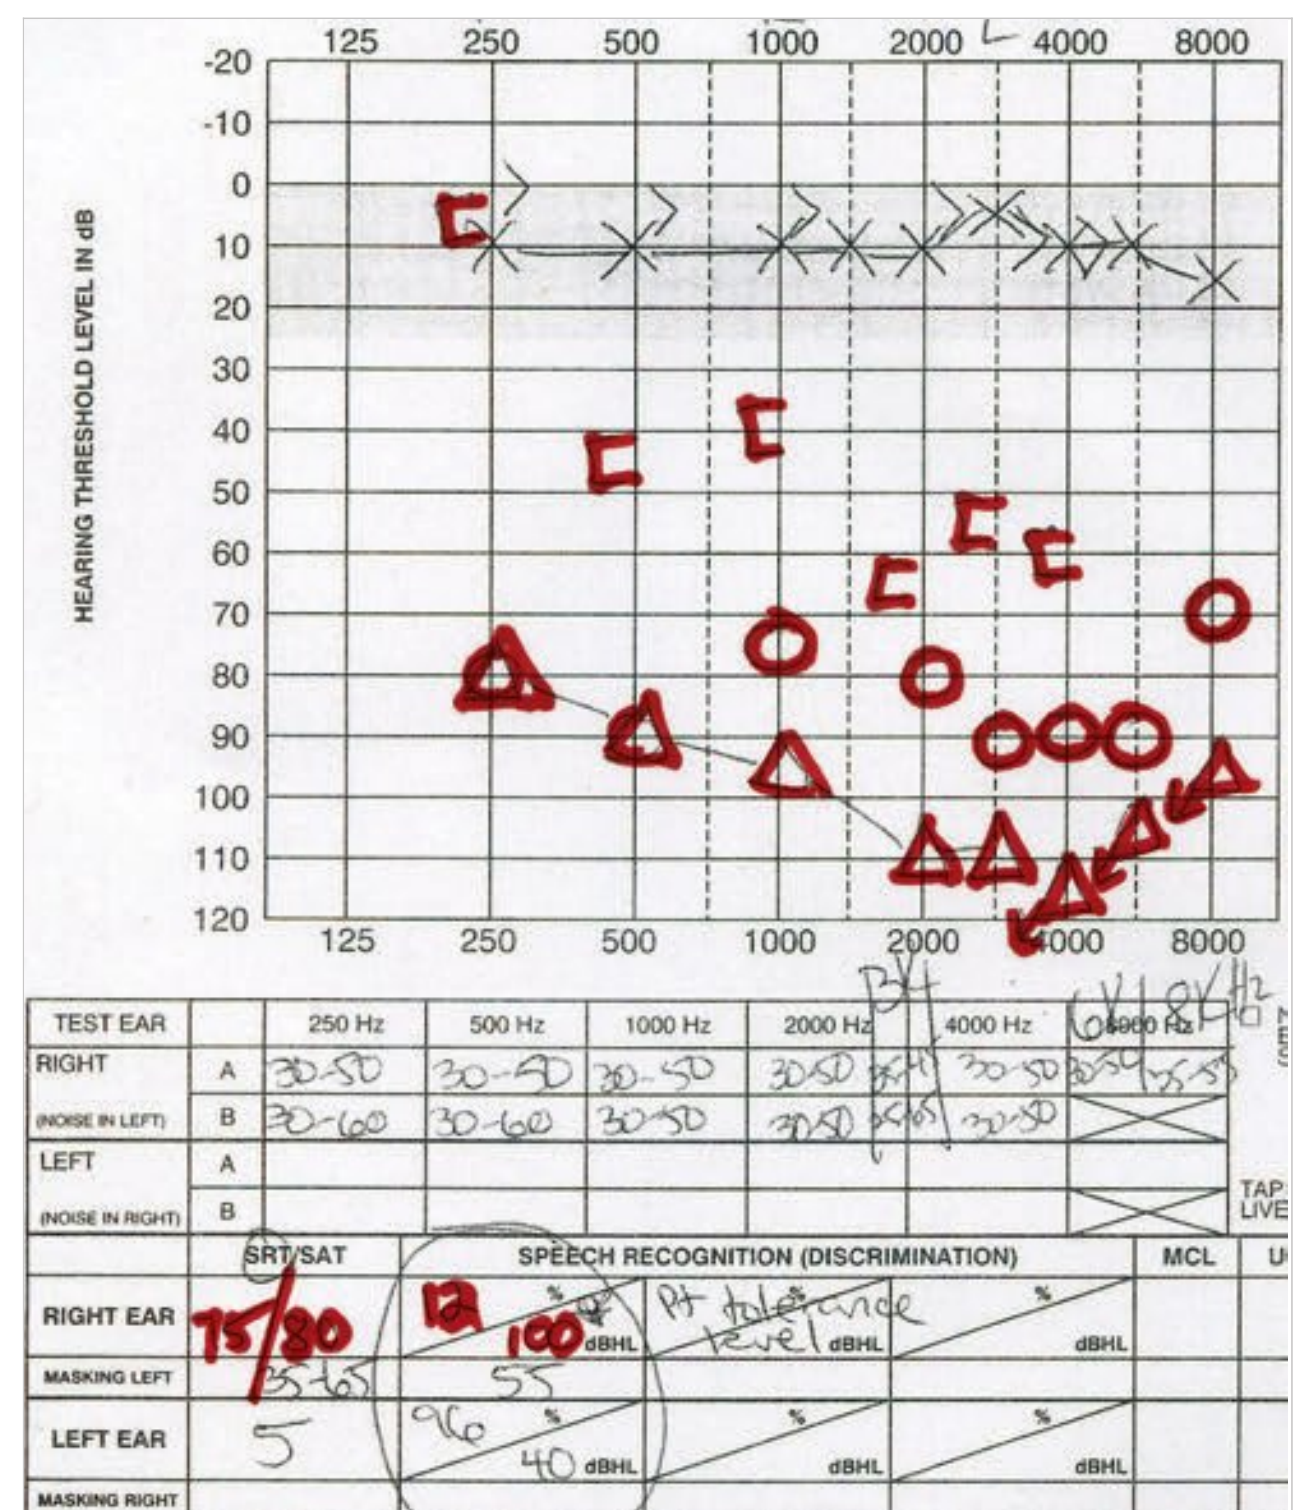

Fig. 138.10 Case 2. Postoperative audiogram, with no serviceable hearing in the right ear.

slowly improved over a 1-year period, but follow-up MR imaging revealed little change in the overall size of the lesion. Because the hearing was no longer useful, the patient underwent a right labyrinthectomy, dissection of the cholesteatoma, and meatoplasty. Postoperatively, the patient's right facial nerve function recovered to a House-Brackmann grade III/VI.

138.9.3 Case 3

A 46-year-old woman was referred for evaluation of a "suspicious finding" on her CT scan by a general otolaryngologist. This patient had a lifelong history of left ear infections and had undergone two otologic procedures on the left ear in 2005 and 2006, resulting in a canal wall down mastoidectomy defect. She described tinnitus in the left ear as well as infrequent episodes of dizziness, but not vertigo. There were no other significant otologic complaints.

Microscopic examination revealed mild retraction of the right pars flaccida. There was a canal wall down mastoid cavity

Fig. 138.11 Case 3. Postoperative audiogram (following left canal wall down mastoidectomy).

on the left with a grafted, blunted drum. No ossicles were visualized on the left, but there was no obvious residual cholesteatoma either. Tuning fork testing at 512 Hz lateralized toward the left, with air conduction greater than bone conduction on the right side but reversed on the left. The facial nerve was normal bilaterally, as were clinical tests of balance.

An audiogram performed on June 5, 2008, revealed a mixed hearing loss in the left ear with good bone reserve and a conductive component of 45 dB, 96% word recognition score (WRS). The hearing on the right was normal at 5 dB, 96% WRS (□ Fig. 138.11).

Noncontrast CT of the petrous temporal bone done on June 16, 2008 revealed postoperative changes consistent with a canal wall down tympanoplasty and mastoidectomy on the left, as well as an expansile mass in the inferior left petrous apex with osseous remodeling that measured 13 mm in greatest dimension (□ Fig. 138.12), suggestive of an aneurysm of the petrous carotid artery.

MR imaging and MRA without and with gadolinium enhancement was performed and interpreted with the findings of the previous CT scan. The lesion in the left petrous apex was seen to be distinct from the petrous carotid artery (□ Fig. 138.13). It

was hyperintense on T1-weighted images (□ Fig. 138.14) and heterogeneous on T2-weighted images (□ Fig. 138.15), suggesting a cholesterol granuloma. Given the lack of symptoms, the patient is being observed.

138.9.4 Case 4

A 14-year-old girl was evaluated for hearing loss in both ears. The child had a history of recurrent otitis media and prior myringotomy and tube placement at the time of a tonsillectomy and adenoidectomy. The otoscopic examination revealed retracted tympanic membranes, with a whitish mass seen in the posterior–superior quadrants bilaterally. Tuning fork testing at 512 Hz was heard midline, with bone conduction greater than air conduction bilaterally. An audiogram showed bilateral conductive hearing loss, worse on the left side. The speech recognition threshold (SRT) and WRS were 30 dB, 92% on the right and 40 dB, 88% on the left (□ Fig. 138.16). The child's mother was advised that investigation of the problem was urgently required

Fig. 138.15 Case 3. T2-weighted (a) coronal and (b) axial magnetic resonance images, showing a heterogeneous mass in the left petrous apex.

with CT of the temporal bones and most likely otologic surgery. Despite frequent phone calls and a telegram, the patient was lost to follow-up for approximately 8 months. At that time, CT of the petrous temporal bones was obtained that demonstrated significant scalloping of the petrous apex and otic capsule, worse on the left. Despite thorough discussion with the child's parent regarding the need for treatment, the patient did not return for care for almost 2 years; at that time, repeat CT revealed worsening of the erosion of both petrous apices with significant scalloping of the otic capsule (□ Fig. 138.17). The mother finally consented to surgery, and a left tympanoplasty with a canal wall down mastoidectomy approach was performed. Cholesteatoma was found underneath osteitic bone and was exteriorized as much as possible, with no attempt made to remove the matrix. Facial nerve monitoring demonstrated an intact facial nerve, and facial nerve function was normal postoperatively. A follow-up audiogram demonstrated an intact left bone line (□ Fig. 138.18). Although the patient's mother was advised of the need for right ear surgery, the child has again been lost to follow-up.

138.10 Summary

Although rare in general otolaryngologic practice, lesions of the petrous apex will likely be encountered by the otologist/neurotologist. Most cases are referred, the patient having been seen by one or several other physicians before lesion imaging. Of the large body of possible lesions presented in the preceding text, several are by far more common than all of the others

Fig. 138.16 Case 4. Preoperative audiogram, demonstrating bilateral conductive hearing loss.

combined, especially cholesterol granuloma and cholesteatoma. Other lesions include mucocele and discrete metastatic disease from several primary tumors.

The history, physical examination, and audiometric and radiologic evaluation of the patient presenting with a lesion of the petrous apex have been reviewed. Above all, the cooperation of a skilled neuroradiologist is essential to help clinch the diagnosis before surgery.

The rare medical and more commonly performed surgical treatments of lesions of the petrous apex have been described. The surgical approach to lesions of the petrous apex is determined by the nature of the complaint, the age and underlying health of the patient, the amount of residual hearing, and the

Fig. 138.18 Case 4. Postoperative audiogram, showing intact sensorineural hearing in the left ear.

Fig. 138.17 Case 4. Preoperative (a) axial and (b) coronal computed tomographic scans of the right temporal bone, and (c) axial and (d) coronal computed tomographic scans of the left temporal bone, showing erosion of both petrous apices and scalloping of both otic capsules.

anatomical extent of the lesion. Cystic lesions should be drained to a nearby aerated structure. Solid lesions may be excised or rarely treated with stereotactic radiation. The common surgical approaches to lesions of the petrous apex have been reviewed.

Surveillance for lesions of the petrous apex must be planned according to the age of the patient and the nature of the lesion. It is the rare patient who will be “cured” and in whom follow-up will eventually cease. For the majority of patients, the disease process will be rendered less potentially aggressive, whether by medical care, excision, or drainage, so that clinical and radiographic follow-up at regular intervals will determine the future course of treatment.

138.11 Roundsmanship

- Lesions of the petrous apex may be classified as primary or secondary.
- Describe the anatomical boundaries of the petrous apex.
- Cholesterol granuloma is the most common primary lesion of the petrous apex.
- Breast, prostate, lung, and renal cell carcinoma and malignant melanoma are the most common metastatic lesions of the petrous apex.
